Preface

Sustainable agriculture involves designing a farm system employing nature as a model. In most natural ecosystems, the greater the diversity, the more resistant an ecosystem is to change and better able to recover from disturbances. In an agricultural ecosystem or the so-called agroecosystems (AESs), disturbance is much more frequent, regular, and intense. The ecological concepts of disturbance and their recovery through succession play an important role in AES management. AESs are undergoing disturbances in the form of cultivation, soil preparation, sowing, planting, irrigation, fertilizer application, pest management, pruning, harvesting, and burning. The diversity and intensity of AESs in developing and developed countries have been changing over time in response to a number of interacting biophysical and social factors at the local, regional, and global levels. The impact of increased spatiotemporal climate variability on AESs is likely to be intensified by climate change, which will disrupt many ecosystem functions, altering their capacity to provide goods and services and rendering them more susceptible to degradation. In addition, the security of food supply to an increasing world population has turned into a pressing issue worldwide. Sustainable food production can be achieved by avoiding excessive disturbance and allowing successional processes to generate greater AES stability. One can enhance the ability of AESs to maintain both fertility and productivity through appropriate management of disturbance and recovery.

Plant productivity is often limited by soil nutrient availability and the interface between living roots and soils, i.e., rhizosphere, which is a central commodity of exchange where organic C flux from root fuels and microbial decomposers can provide nutrients available to roots. It is virtually impossible to investigate the intricacies of potential rhizosphere interaction in every environmental condition by virtue of tremendous diversity of soil microbes, soil fauna, and plants. In addition, the physicochemical and structural properties of soils including development have been strongly affected by the action of rhizosphere over consecutive evolutionary time frame, and the evolution of true plant roots along with their extension deep into substrate is considerably hypothesized to have led to a revolution in planetary C and water cycling that reflects on the biogeochemical functions of the rhizosphere on Earth today. Understanding the complex microbial community in the rhizosphere environment has proven to be a challenging task because of the vast diversity and the enormity of the population inhabiting this unique habitat. Extensive studies have investigated perturbation of microbial community equilibrium population by

changes in environmental conditions and soil management practices. It has long been recognized that the activity of soil microorganisms plays an intrinsic role in residue decomposition, nutrient cycling, and crop production. Any shift in microbial community structure can be reflected in the implementation of various land use and management systems that lead to development of best management practices for an AES.

In subsistence AESs, crop yields are directly dependent on the inherent soil fertility and on microbial processes that govern the mineralization and mobilization of nutrients required for plant growth. In addition, the impact of different crop species that are used in various combinations is likely to be an important factor in determining the structure of plant-beneficial microbial communities that function in nutrient cycling, the production of plant growth hormones, and the suppression of root diseases. Microorganisms represent a substantial portion of the standing biomass in terrestrial ecosystem and contribute in regulation of C sequestration, N availability and losses, and P dynamics. The size and physiological state of the standing microbial biomass are influenced by management practices including rotational diversity, tillage, and the quality and quantity of C inputs to the soils. In AES, sustainability is dependent on the biological balance in the soils that is governed by the activity of microbial communities. Soil microbial populations are immersed in a framework of interactions known to affect plant fitness and soil quality; thereby, the stability and productivity of both AES and natural ecosystem are enhanced. The global necessity to increase agricultural productivity from steadily decreasing and degrading land resource base has placed significant strain on the fragile agroecosystems. Therefore, it is necessary to adopt strategies to maintain and improve agricultural productivity employing high-input practices. Improvement in agricultural sustainability requires the optimal use and management of soil fertility and soil physical properties and relies on soil biological processes and soil biodiversity. It is necessary to understand the perspectives of microbial diversity in agricultural context that is important and useful to arrive at measures that can act as indicators of soil quality and plant productivity.

Sustainable agriculture has currently to cope with serious threats that compromise the food security for a human population under continuous growth, all these exacerbated by climate change. Some of these include the loss of usable land through overuse, deforestation, and poor irrigation practices, which have led to desertification and salinization of soils, especially in dry lands. Approaches currently being taken to face this situation come from the development of stress-tolerant crops, e.g., by genetic modification or breeding traits from wild plants. Genetic engineering has been proposed as the solution to these problems through a rapid improvement of crops. Crop genetic modification has generated a great public concern regarding their potential threats to the environmental and public health. As a consequence, legislation of several countries has restricted their use in agriculture. On the other hand, exotic libraries from wild plants for clever plant breeding could overcome the problem of narrowed genetic variability of today's high-yield crops. Plant breeding driven by selection marker has also been a major breakthrough. However, these approaches have met limited success, probably because stress

tolerance involves genetically complex processes and the ecological and evolutionary mechanisms responsible for stress tolerance in plants are poorly defined.

Heavy metal contamination in soils is one of the world's major environmental problems, posing significant risks to public health and ecosystems. Therefore, the development of a remediation strategy for metal-contaminated soils is urgent for environmental conservation and human health. Phytoremediation offers significantly more benefits than conventional technology to accumulate heavy metals from the soil due to it being less expensive and safer for humans and the environment. But slow growth and low biomass of plants in heavy metal-contaminated soil may limit the efficiency of phytoremediation. This has prompted us to explore the possibilities of enhancing the biomass of metal accumulators using bacteria as plant growth-promoting bioinoculants. Bacteria that can produce IAA, siderophores, and ACC-deaminase are capable of stimulating plant growth; lowering the level of ethylene by consuming ACC, the immediate precursor of ethylene in plants growing in the presence of heavy metals; and helping plants acquire sufficient iron for optimal growth. Most of the heavy metals have low mobility in soil and are not easily absorbed by plant roots. Plant roots and soil microbes and their interaction can improve metal bioavailability in rhizosphere and lead to host adaptation to a changing environment.

Pathogen suppression by antagonistic microorganisms can result from one or more mechanisms depending on the antagonist involved. Direct effects on the pathogen include competition for colonization or infection sites, competition for carbon and nitrogen sources as nutrients and signals, competition for iron through the production of iron-chelating compounds or siderophores, inhibition of the pathogen by antimicrobial compounds such as antibiotics and HCN, degradation of pathogen germination factors or pathogenicity factors, and parasitism. These effects can be accompanied by indirect mechanisms, including improvement of plant nutrition and damage compensation, changes in root system anatomy, microbial changes in the rhizosphere, and activation of plant defense mechanisms, leading to enhanced plant resistance. Nowadays, it is well known that some soils are naturally suppressive to some soilborne plant pathogens including *Fusarium*, *Gaeumannomyces*, *Rhizoctonia*, *Pythium*, and *Phytophthora*. Although this suppression relates to both physicochemical and microbiological features of the soil, in most systems, the biological elements are the primary factors in disease suppression, and the topic of "biological control of plant pathogens" gained feasibility in the context of sustainable issues. The groups of microorganisms with antagonistic properties toward plant pathogens are diverse, including plant-associated prokaryotes and eukaryotes. Among the prokaryotes, a wide range of bacteria such as *Agrobacterium*, *Bacillus* spp. (e.g., *B. cereus*, *B. pumilus*, and *B. subtilis*), *Streptomyces*, and *Burkholderia* have been shown to be effective antagonists of soilborne pathogens. The most widely studied bacteria by far in relation to biocontrol are *Bacillus* spp. and *Pseudomonas* spp., viz., *P. aeruginosa* and *P. fluorescens*, which are probably among the most effective root-colonizing bacteria.

Sustainable agriculture has a long history of research targeted at understanding how to improve the effectiveness of root symbionts, viz., rhizobia and mycorrhiza.

A promising approach has been employed to understand how natural selection regulates changes in mutualistic interactions. A descriptive knowledge of basic evolutionary processes can be employed to develop agricultural management practices that favor the most effective symbionts. Mutually beneficial interactions between plant and associated rhizospheric microorganisms are ubiquitous which is important for ecosystem functioning. Symbiotic nitrogen fixation by bacteria, e.g., *Rhizobium*, *Bradyrhizobium*, *Mesorhizobium*, *Sinorhizobium*, and *Azorhizobium* spp., that are collectively known as rhizobia or by *Frankia* spp. is the major N input to many natural and agricultural ecosystems in the root nodules of legumes or actinorhizal plants, respectively. In addition, mycorrhizal fungi supply their host plants with mineral nutrients, viz., P, and other benefits. Several rhizospheric microorganisms cause severe infection to roots, and these so-called root pathogens can be suppressed by *Pseudomonas fluorescens* after colonization of the roots thereby improving plant health.

The exploitation of plant–fungal symbiosis appears as a smart alternative for plant adaptation due to their great quantity, ubiquity, diversity, and broad range of ecological functions they play in the natural ecosystem. Recent studies have shown that symbiotic microbes are of crucial importance in the distribution of plant communities worldwide and are responsible of their adaptation to environments under highly selective pressure. These indicate that some microbes confer tolerance to specific stresses and are responsible of the survival of plants to environments submitted to these particular conditions. The stress tolerance conferred by the symbiosis is a habitat-specific phenomenon, which has been defined as habitat-adapted symbiosis that confers tolerance to heat but not salt and coastal symbiotic microbes conferring tolerance to salt but not to heat. The same fungal species isolated from plants in habitats devoid of salt or heat stress did not appear to confer tolerance to these stresses. It is currently thought that each plant in natural ecosystems comprises a community of organisms, including mycorrhizae and bacteria. The ability of the symbiotic fungi to confer tolerance to stress may provide a new strategy to mitigate the impacts of global climate change on agriculture and natural plant communities. Such symbiotic lifestyles suppose a potential source for the improvement of food crops through adapting them to situations of increasing desertification and drought on global crop lands. It appears therefore as a sustainable alternative to the use of genetically modified organisms, which on the other hand did not yield the expected results.

Finally, plant-associated microorganisms can play an important role in conferring resistance to abiotic stresses. These organisms could include rhizoplane and symbiotic bacteria and fungi that operate through a variety of mechanisms like triggering osmotic response and induction of novel genes in plants. The development of stress-tolerant crop varieties through genetic engineering and plant breeding is an essential but a long-drawn process, whereas microbial inoculation to alleviate stresses in plants could be a more cost-effective environmental friendly option which could be available in a shorter time frame. Taking the current leads available, concerted future research is needed in this area, particularly on field evaluation and application of potential organisms. It is our contention that native plants survive and

flourish in stressed ecosystems because of endosymbiotic organisms that have coevolved and were essential for their adaptation to changing environments. Plant growth and development cannot be adequately described without acknowledging microbial interactions. We need to determine the extent of microbial associations in the plant kingdom. This question will only be answered as technology is developed to detect their presence in plant tissues. What we have learned is that there is a need to understand how plant and microbes communicate in these endosymbiotic relationships and how they regulate basic genetic and physiological functions.

Hence, in the present book, editors compiled researches carried out by researchers in three sections with elaborate description related to "plant–microbe interaction for sustainable agriculture."

Part I: An Introduction to Plant-Microbe Interaction

Chapter 1 summarizes an exposition of plant–microbe and microbe–plant interactions describing the interplay of chemicals and signals that participate in the complex domain of the rhizosphere. The information derived from the current studies and the utilization of current technological platforms will enable researchers to explore and garner more information at the plant–microbe and plant–microbiome levels.

Chapter 2 briefly describes the various physical and chemical processes occurring in the rhizosphere, how the change in environment hampers these factors, and how that affects the rhizospheric diversity in modifying the microbial ecology and root architecture.

Chapter 3 emphasizes the insight of the rhizosphere and plant growth-promoting rhizobacteria under the current viewpoints. Conclusively, the applicability of these favorable rhizobacteria in different agroecosystems has been offered systematically under both normal and stress circumstances to focus the recent trends with the objective to improve upcoming visions.

Chapter 4 describes a holistic perception of rhizosphere functioning with a highlight on the ecological drivers that promote colonization of coherent functional groups of microorganisms influencing plant life through several direct and indirect mechanisms.

Chapter 5 describes the concept of rhizosphere, hyphosphere, and mycorrhizosphere and the various activities involved in understanding the functional diversity of microorganisms inhabiting the mycorrhizosphere necessary to optimize soil microbial technology for the benefit of plant growth and health.

Chapter 6 highlights the importance of mycorrhizae with beneficial microbes in plant growth promotion, nutrient uptake, and stress tolerance either biotic or abiotic. The presence of bacteria in the rhizosphere synchronizes with mycorrhizae termed as "mycorrhizae helper bacteria" that increase plant growth by focusing on N and P in particular while micronutrients in general.

Part II: Plant-Microbe Interaction Under Abiotic and Biotic Stress

Chapter 7 describes deployment of microbe–plant interactions that results in the promotion of plant health in arid and semiarid regions with reference to India under abiotic stress.

Chapter 8 briefly describes an attempt to explore current knowledge of bacterial ACC-deaminase-mediated physiological and molecular changes in the plants under diverse environmental conditions (drought and high salinity), mode of ACC-deaminase enzyme action, and drastic effects of salinity and drought on plant growth with a special reference to ethylene evolution.

Chapter 9 highlights the success and efficiency of phytoremediation with association of heavy metal-resistant plant growth-promoting rhizobacteria.

Chapter 10 briefly describes the importance of microbe–plant interaction under salt stress. It describes strategies that plants adapt to deal with salinity, and current biotechnological efforts toward producing salt-tolerant crops are summarized.

Chapter 11 summarizes the comprehensive understanding that required learning the mechanisms and critical factors influencing the plant–microbe–toxicant interaction in soils for success of phytoremediation.

Chapter 12 elaborately describes priming of benign microbes especially bacteria for plant growth promotion under biotic stresses to unravel the mystification of mechanisms involved in plant defense including ISR and SAR using sustainable development of plants.

Chapter 13 discusses on the susceptibility of most important bacterial and fungal plant pathogens toward different essential oils and their constituents responsible for biological activities such as antibacterial and antifungal. In addition, the potential effectiveness of herb essential oils against different plant pathogenic fungi and bacteria has been verified.

Chapter 14 elaborately describes the use of halophilic bacteria in agriculture system toward producing salt stress-tolerant crops and understanding the mechanisms of plant and halophilic bacterial interaction.

Chapter 15 describes that PGPR has the ability to mitigate most effectively the impact of abiotic stresses on plants through degradation of the ethylene precursor ACC by bacterial ACC-deaminase and through biofilm and exopolysaccharide production.

Part III: Plant-Microbe Interaction and Plant Productivity

Chapter 16 presents an overview of the importance of the microbiome to the plant growth promotion, focusing on the diversity, functional and taxonomic, of the microbiota associated to maize, and the desirable characteristics of microorganism's candidates to the use in PGP formulations.

Chapter 17 describes the role of biofertilizers that not only exhibit plant growth promotion but also are effective in bioremediation by detoxifying detrimental pollutants such as pesticides and heavy metal pollutants. Besides, PGPR-mediated organic farming would pave the way to prosperous, healthy, and sustainable nation. Thus, this trend of least possible input of chemicals in sustainable agricultural systems may help to achieve the goal of holistic well-being of planet Earth.

Chapter 18 describes the mechanisms underlying beneficial impacts of fungi on growth promotion of the host plant. It involves benign fungi that are potentially useful in agriculture sector to avail several services to crop plants such as water status, nutrient enrichment, stress tolerance, protection, weed control, and biocontrol.

Chapter 19 summarizes various microbial interactions between mycorrhizal fungi and other soil microbial communities. This chapter discusses on the following: (1) microbial communities in the soil, (2) arbuscular mycorrhiza fungi interaction with plants, (3) interaction with rhizosphere microorganisms, (4) interaction with soilborne pathogens, (5) potential benefits of arbuscular mycorrhizal fungi in plant growth and disease control, and (6) effect of soil microorganisms on mycorrhizal symbiosis. The main conclusion is that the microbial population interactions with arbuscular mycorrhizal fungi in the rhizosphere majorly influence plant health, crop productivity, and soil fertility.

Chapter 20 addresses general characterization of phyllospheric environment, microbial association process, microbial population structure, quorum sensing, and cross talk between plant and microbes. This chapter provides information on the microbial diversity of the phyllosphere bioenergy crop *Jatropha curcas*. Major bacterial groups prevalent on the *J. curcas* phyllosphere and plant growth-promoting activities are addressed.

Chapter 21 ascribes more complex physiological and ecological role to tree roots with soil profile. This is more particularly so in many tree species where roots have a characteristic dimorphic spread having (i) the surface roots that have a subterranean horizontal spread a few meters around the trunk and (ii) sinker roots that go vertically downward to 10 m and beyond. The sinker root system, therefore, enables hydraulic redistribution sustaining dry-season transpiration and photosynthetic rates of the parent tree and surrounding shallow-rooted vegetation, prolonging the life span of fine roots and maintaining root–soil contact in dry soils, and storing rainwater down into deeper soil layers for dry-season utilization.

Chapter 22 summarizes the information related to biosynthesis, metabolism, regulation, physiological role, and agronomical impact of phytohormone produced by the plant growth-promoting rhizobacteria.

Chapter 23 describes an overview of diversity of endophytes associated with sugarcane with special reference to *Gluconacetobacter diazotrophicus*. It also describes the role of different bacterial traits that are necessary for successful colonization of the plant interior part.

Finally, we'd like to express our gratitude to the contributors upon their consent to be a part of this book.

About the Editors

Devendra K. Choudhary Dr. Choudhary has 15 years of experience in microbial ecology and is currently working as an assistant professor in Grade III at Amity University, Noida. Before joining Amity University, Dr. Choudhary spent several years at Mody University, Lakshmangarh, as an assistant professor, preceded by work at People's and Barkatullah University, Bhopal, as a lecturer cum scientist. Dr. Choudhary received his Ph.D. in microbiology in the year 2005 from GB Pant University of Agriculture and Technology, Pantnagar, after having received his M.Sc. in microbiology from MDS University, Ajmer, and qualifying CSIR-UGC-NET in 2002.

Dr. Choudhary has worked on GOI-sponsored major projects as principal investigator (PI) wherein recently he worked on two major projects sponsored by DBT and SERB, New Delhi, at Amity University until the year 2015 preceded by Mody University and DST Fast Track project at the Department of Biotechnology, Barkatullah University, Bhopal.

As an active researcher, Dr. Choudhary has published research and review articles along with several book chapters for reputed journals and edited books. In addition, he has served as Ph.D. supervisor/co-supervisor for several research scholars. Under the supervision of Dr. Choudhary, his scientific team has assigned three accession numbers for bacterial cultures wherein two from MTCC (12057 and 12058), IMTECH, and one with MCC no. 2607. Most recently, his team has filed three patents with the India Patent Office, New Delhi. Recently, in association with senior colleagues, Dr. Choudhary has edited the book *Microbial-Mediated Induced Systemic Resistance in Plants* with emphasis on global food security.

Dr. Choudhary has been recognized as a member of the National Academy of Sciences (MNASc) in 2016. Besides, he has been selected for Indian National Science Academy (INSA) visiting and summer research fellowship in 2014. Further, he received the Dr. RS Rana Memorial best research award in the year 2013, sponsored by the Association of Microbiologists of India. Besides, several other achievements have been credited in his account.

Ajit Varma Dr. Varma completed his M.Sc. (1959) and Ph.D. (1964) degrees at Allahabad University, Allahabad, India. In the course of his professional career, he has also served as a microbiologist (assistant professor) of IARI, New Delhi

(1963–1971); senior microbiologist (associate professor) of IARI, New Delhi (1971–1974); associate professor of JNU, New Delhi (1975–1984); and professor of JNU, New Delhi (1985–2004). He has been a visiting professor and visiting research scientist at the Graz University of Technology, Graz (Austria); University of Tübingen, Tübingen (Germany); Friedrich Schiller University, Jena (Germany); Philipps-Universität Marburg, Marburg (Germany); Technical University of Munich, Munich (Germany); Kingston (Jamaica); Max Planck Visiting Professorship (Germany); Helmholtz Zentrum, München (Germany); Gutenberg University, Mainz (Germany); CSIC, Madrid (Spain); University of Dundee (Scotland); University of Ljubljana (Slovenia); and ICGEB (Italy). His international awards/fellowships include the Commonwealth fellowship (Australia), National Research Council (Canada), Alexander von Humboldt Foundation (Germany), National Science Foundation (USA), Indo-Czechoslovakia Exchange Programme (Prague), DAAD fellowship (Germany), and the Deutsches BMFT Programme, Georg-August-Universität Göttingen, Gottingen (Germany), RAISA. He was awarded a fellowship for Innovative Research in Biotechnology (Italy), Swiss federal research fellowship (Switzerland), the BP Koirala award (Nepal), and DFG-INSA fellowship (Indo-Germany), as well as the FAMI Award-Association of Microbiologists of India and honorary diploma of the UMF, Cluj-Napoca, Romania. Dr. Varma has successfully completed major projects as PI sponsored by DBT, DST, DRDO, and ICAR. Besides, he has supervised more than 60 Ph.D. students and published over 300 research articles for national and international journals of repute, as well as several major review articles and chapters in books. He has published 50 books in the area of microbial technology. Dr. Varma has been the series editor and has edited 50 volumes on *Soil Biology*. He was also nominated as editor in chief by IK International to make a series of books on microbial and biotechnological research. Dr. Varma has been a member of the National Academy of Agricultural Sciences (FNAAS); International Society of Symbiosis, Boston, USA; Indian Science Congress Association; Executive Council, Amity University Uttar Pradesh; University Research Council, Amity University Uttar Pradesh; Academic Council, Amity University Rajasthan; ASSOCHAM Knowledge Millennium Council; ASSOCHAM Expert Committee on Agriculture and Food Processing; and ASSOCHAM Expert Committee on S&T and Innovation. He has vast experience in organizing national and international training workshops/symposia and congresses.

Narendra Tuteja Dr. Narendra Tuteja is presently acting as director of Amity Institute of Microbial Technology (AIMT), Amity University Uttar Pradesh (AUUP), Noida. Before joining AIMT, he spent years as group leader and senior scientist in the International Centre for Genetic Engineering and Biotechnology (ICGEB), New Delhi. Academically, Dr. Tuteja completed his M.Sc. (1977), Ph.D. (1982), and D.Sc. (2008) in the subject biochemistry from the University of Lucknow. Professionally, he served as group leader and senior scientist (2012–2015) of the Plant Molecular Biology (PMB) group, International Centre for Genetic Engineering and Biotechnology (ICGEB), New Delhi; senior scientist (2008–2011)

of the PMB group, ICGEB, New Delhi; associate scientist (1997–2007) of the PMB group, ICGEB, New Delhi; group leader and associate scientist (1995–1997) of the PMB group, ICGEB, New Delhi; assistant research scientist (1988–1995) of the Molecular Biology group, ICGEB, Trieste, Italy; postdoctoral fellow (1986–1988) of the UCLA, Los Angeles, California, USA; visiting scientist (1983–1986) of the NIH (NCI and NICHHD), Bethesda, Maryland, USA; and research assistant (1977–1983) of K.G. Medical College, Lucknow, UP, India. Based on his contribution to science and society, he has been elected as fellow for various science academies in India/abroad such as fellow of "Third World Academy of Sciences" (FTWAS), Trieste, Italy; fellow of "National Academy of Agricultural Sciences" (FNAAS), New Delhi; fellow of "National Environmental Science Academy" (FNESA), New Delhi; fellow of "Indian Academy of Sciences" (FASc.), Bangalore; fellow of "Indian National Science Academy"; and fellow of "National Academy of Sciences" (FNASc.), Allahabad. Besides, he has served as an expert member for various advisory committees and task force constituted by GOI, advisory committee of "Bejo Sheetal Bioscience Foundation," Jalna, MR, India; task force expert member of the Plant Sciences Research Committee of the Council of Scientific and Industrial Research (CSIR), New Delhi; expert member of the academic committee meeting of the Central Institute of Medicinal and Aromatic Plants (CIMAP), CSIR, Lucknow; task force expert member of the Department of Information Technology (DIT), Ministry of Communication and Information Technology, New Delhi; and expert member of the Advisory Board, Agricultural Scientists Recruitment Board, New Delhi. Dr. Tuteja has become associate editor for *Plant Signaling and Behavior* (PSB) and editor in chief for *Plant Signaling and Behavior* (PSB) Vol. 6, Issue 2, Feb. 2011, special issue on *Plant Abiotic Stress*. In addition, his name was included in the list of members of the Editorial Advisory Board for *The Open Plant Science Journal*, *Archives of Biochemistry and Biophysics* (ABB), and *Plant Physiology and Biochemistry* (PPB).

Part I

An Introduction to Plant-Microbe Interaction

Rhizosphere Interactions: Life Below Ground

1

Kalaivani K. Nadarajah

Abstract

The interface between roots and soil is a region with high interaction among a myriad of organisms that affect biogeochemical cycles, plant growth, and stress tolerance. Similarly chemical compounds secreted within the rhizosphere act as attractants to microorganisms. Due to its dynamic nature and complexity, understanding rhizospheric biology and activity is essential in ensuring improved plant function and productivity within an ecosystem. Sustainable agricultural practices are dependent on studies conducted with regards to plant–microbe interactions in the rhizosphere. This chapter is an exposition of rhizospheric interactions spanning the chemistry of exudates and signals that contribute towards the complexity of the rhizosphere. The information derived from recent studies and the utilization of current technological platforms will enable us to explore and gather more information at the plant and microbiome level.

1.1 Introduction

The rhizosphere was described by Lorenz Hiltner a century ago as a microbial hotspot that is dependent on plant roots (Hartmann et al. 2008). The interactions and activities within have been researched extensively due to the dynamic nature of this region (Bakker et al. 2013). Studies have shown that the microbial communities within the rhizosphere can affect the well-being of plants (Mendes et al. 2011) by either directly or indirectly affecting the biomass and composition within the plant's natural ecosystem (Schnitzer et al. 2011). The microbiota contributing towards

D.K. Choudhary et al. (eds.), *Plant-Microbe Interaction: An Approach to Sustainable Agriculture*, DOI 10.1007/978-981-10-2854-0_1

these processes in the rhizosphere involve antagonists, mutualists, symbionts, and the rich plant root system (Kardol et al. 2007). The microbial activity is essential as they contribute towards physiological processes such as nutrient uptake and plant defense responses (Berendsen et al. 2012). Although much has been done to unravel the mysteries of these underground plant–microbe interactions, the complexity of these interactions leaves gaps in knowledge that requires further investigation (Urich et al. 2008; Jansson et al. 2011).

The variety of low molecular weight (LMW) exudates secreted into the plant's surrounding soil environment influences the complex interaction between the root and plant. These exudates when secreted into the environment contributed towards the highly interactive nature of this region. Though enormous strides have been made in understanding the interactions down under, much still remains elusive in our understanding with regard to the root–microbe–insect–nematode interactions within the rhizosphere (Weir et al. 2004; Walker et al. 2003). As plant roots remain hidden below ground, most of these interactions remain unnoticed especially the chemical components facilitating these belowground interactions (Bais et al. 2006).

Root chemicals result in varying consequences and responses in different plant systems. However to date, the mechanism underlying the chemical signal perception and response between the soil, roots, and invertebrates remains largely obscure. Ultimately the positive or negative way in which these chemicals are perceived will determine the plant and soil community's dynamics. We anticipate that deciphering the processes that direct the variety of activities within the rhizospheric microbiome will provide new avenues of crop manipulation for plant fitness and yield. Initial reports into these insights have been obtained through studies of *Arabidopsis thaliana* and *Medicago truncatula* plant systems. These studies have shown us how microbial ecosystems in the rhizosphere influence allocation, diversity, and belowground interactions (Berendsen et al. 2012; Bakker et al. 2012).

Here we have outlined current advances in deciphering the rhizospheric interactions, paying special emphasis on how these exudates mediate the various interactions below ground. In addition this chapter addresses how these beneficial interactions will influence plant growth, yield, and therefore contribute towards sustainable agriculture.

1.2 Rhizosphere and Root Exudates

The adaptability and survival of plants in any given environment is dependent on acquisition of resources from the soil environment (Badri et al. 2009b, 2013a; Chaparro et al. 2013a; Nihorimbere et al. 2011). The variation in amount of root exudates within the soil will determine the nutrient dynamics and hence affect the microbial population and diversity (Paterson et al. 2006). It has been reported that plants exude their photosynthetic components (5–21 %) such as sugars, proteins, and secondary metabolite into the root environment (Badri et al. 2013b; Badri and Vivanco 2009; Chaparro et al. 2013b). There are two groups of root exudates: (i) LMW exudates, e.g., amino acids, sugars, phenolics, secondary metabolites, and

organic acids, and (ii) the HMW exudates, e.g., proteins and complex carbohydrates (Bais et al. 2006; Narasimhan et al. 2003). LMW and HMW compounds that are exuded into the soil environment are largely dependent on the plant cultivar and species, the developmental stages of the plant, soil chemistry, and microbial diversity (Badri and Vivanco 2009; Huang et al. 2015; Uren 2000). Recent reports have implicated root cells in the cap and root hairs as secretors of compounds from roots into the soil (Czarnota et al. 2003; Pineros et al. 2002; Nguyen 2003). In addition to secretion, root hairs are involved in anchoring and nutrient-water intake (Fan et al. 2001). The relationship between root exudates and microorganisms are chemotactically disposed, i.e., where plant roots secrete glucose, sugars, organic, and amino acids into the soil; microbes migrate chemotactically toward these exudates (Kumar et al. 2007).

1.3 System of Root Emission

Despite the huge strides made by scientists in investigating exudates within the rhizospheric domain, the mechanisms involved in root secretions are poorly understood. The synthesis and release of root-derived components are generally constitutive, while the secretion mechanisms of these exudates are thought to be passive involving three separate pathways such as dissemination, vesicle transport, and particle channels (Dennis et al. 2010).

1.3.1 Diffusion

Membrane permeability and the cytosolic pH largely influences the passive diffusion of small polar and uncharged molecules produced by plants across the cell's lipid membranes (Marschner 1995; Sanders and Bethke 2000). This is the simplest form of mobilizing molecules across the membrane.

1.3.2 Vesicular Transport

High molecular weight root exudates are secreted through different mechanisms such as vesicular transport (Battey and Blackbourn 1993). Field et al. (2006) reviewed vesicle-mediated trafficking of proteins, but this review however did not involve the mechanism of transport for phytochemicals (Grotewold 2004). While there are extensive reports on the phytochemical exudates in leaf tissue, little has been reported with regards to phytochemical exudates from roots. Vesicular secretion has been implicated in the transportation of antimicrobial products at the location of bacterial or fungal infections. One such example is the pigmented 3-deoxyanthocyanidins, an antimicrobial flavonoid observed in fungal infection sites of sorghum leaves (Snyder et al. 1991). Roots of knapweed plants have been reported to secrete cytotoxic and antimicrobial catechin flavonoids (Bais et al. 2002).

Although certain researchers have implicated the cytoplasmic surface of the endoplasmic reticulum (ER) as the site of synthesis for certain root exudates from the phenylpropanoids and flavonoids families (Winkel-Shirley 2001), the mechanism of transport from the ER to the membrane is unknown. However there is a possibility that these compounds are transported through ER-originating vesicles that secrete their contents once bound to the cell's membrane.

1.3.3 Transporter Proteins

Transporter proteins are responsible for the transportation or passage of amino acids, sugars, and carboxylate anions from root cell cytoplasm to soil (Colangelo and Guerinot 2006; Hirner et al. 2006; Lee et al. 2007; Svennerstam et al. 2007). ABC transporter proteins are implicated in various cellular processes, spanning the discharge of harmful compounds, translocation of lipids, disease resistance, salt stress, nutrient transport, and substantial metal resilience (Stein et al. 2006; Kobae et al. 2006). The utilization of *Arabidopsis* ABC transporter knockout mutants proved that these transporters were involved in root secretions. What's more, the ABC transporters are confined to the plasma membrane (Sidler et al. 1998) and are involved in auxin pumping and secretion of resistance metabolites (Badri et al. 2009a).

Another transporting system, MATE, is involved in the discharge of phytochemicals. MATEs, through electrochemical gradient of other ions, are effectively able to transport substrates across cell membranes. Numerous MATE genes involved in transporting compounds such as toxic materials, plant-inferred alkaloids, antimicrobials, phenolics, and anions have been identified and characterized in the root cells of sorghum, *Arabidopsis*, rice, and grain (Furukawa et al. 2007; Ishimaru et al. 2011; Liu et al. 2009; Magalhaes et al. 2007; Weston et al. 2012).

Further, MFS transporter proteins assist with the release of secondary metabolites such as phytosiderophores from root cells (Kim and Guerinot 2007). These proteins can work as uniporters, co-transporters, or antiporters. In rice for instance, deoxymugineic and avenic acids are aided by *TOM1* (transporter of mugineic corrosive family phytosiderophores1) (Nozoye et al. 2011) in translocation of proteins. Through transgenic studies it was proven that the expression of *TOM1* is induced in the state of limited iron supply where overexpressing *TOM1* showed improved deoxymugineic acid release and enhanced resilience to a limited iron supply. ALMT transporter proteins belongs to the *ALMT* gene family that enables malate efflux from plants. *ALMT* genes encode the pore-forming anion channels within the membranes that facilitate the passive transport of substances across the membranes (down their electrochemical slopes) (Ryan et al. 2011; Weston et al. 2012). Other than the above transporters, monosaccharide transporters have been associated with hexose, pentose, ribose, and polyols transport (Klepek et al. 2005; Buttner 2007), while silicon efflux transporters have been associated with the excretion of silicon from rice root cells to soil (Ma and Yamaji 2008).

1.4 Rhizospheric Plant–Microbe Interactions

Root-secreted phytochemicals can result in beneficial, deleterious, or neutral interactions (Raaijmakers et al. 2009; Mercado-Blanco and Bakker 2007). Likewise, microbes are also able to transition from pathogenic to symbiotic in response to differing environments (Newton et al. 2010). Hence we can anticipate that the chemical diversity exhibited by root exudates will be an excellent source to look for novel, biologically active compounds, including antimicrobials (Huang et al. 2014). Previous reports have highlighted that the association of plants and the microbial community in the soil is important for plant health. These communities are dependent on the root exudates that positively or negatively affect the microorganisms within the soil. In the following sections, the integral role played by the exudates in plant–microbe and microbe–plant interactions will be expounded. Figure 1.1 presents the various underground processes that occur within the rhizosphere (Huang et al. 2014; Zhuang et al. 2013).

1.4.1 Positive Plant–Microbe Interactions

(a) *Nitrogen fixation*

The nitrogen levels within the rhizosphere will determine the diversity of nitrogen (N)-fixing bacteria within the soil (Zahran 1999). In nitrogen-limiting conditions, the nodule containing nitrogen-fixing bacteria produces flavonols and flavones that attract and initiate legume–rhizobia symbiosis (Zhang et al. 2009; Coronado et al. 1995). The flavones and flavonols induced bacterial nod gene expression, which lead to the initiation of root nodulation. The aerobic N_2-fixing bacterium also exhibited N_2ase activity when inoculated into the rhizosphere of rice, wheat, and oat seedlings. Further, microscopic observations of this N_2-fixing bacterium in barley roots suggest that this organism is an endophyte that associates with root tissue to form vesicle-like structures (Santi et al. 2013). The aggregation of rhizobia to legume root tissues is dependent on the association to specific sugar-binding sites. During nitrogen fixation, lectins (functions as binding protein) bind polysaccharides to stimulate aggregation. Lectins sustain increased nod factor concentrations and mitotic activity necessary for nodulation (Mathesius and Watt 2010). In general mixed cultures have been shown to increase nitrogen-fixing capacity as observed in the association between *Staphylococcus* sp. and diazotrophic bacteria that increased the nitrogen-fixing capacity of *L. anguillarum* by 17 %. Another example is the production of nodulating compounds such as exopolysaccharides (EPS and EPS II) by a mixed culture of *Rhizobium* sp. and *Sinorhizobium* sp. Exopolysaccharide-deficient mutants were incapable of invading legumes and establishing symbiotic relations (Jones et al. 2008). Legume-secreted isoflavonoids such as daidzein and genistein have been reported to effectively induce *Bradyrhizobium japonicum* nod genes, while nod genes in *Sinorhizobium meliloti* were induced by luteolin (Juan et al. 2007). The level of specificity exhibited enables the rhizobial community to identify their specific host accurately (Bais et al. 2006) (Table 1.1).

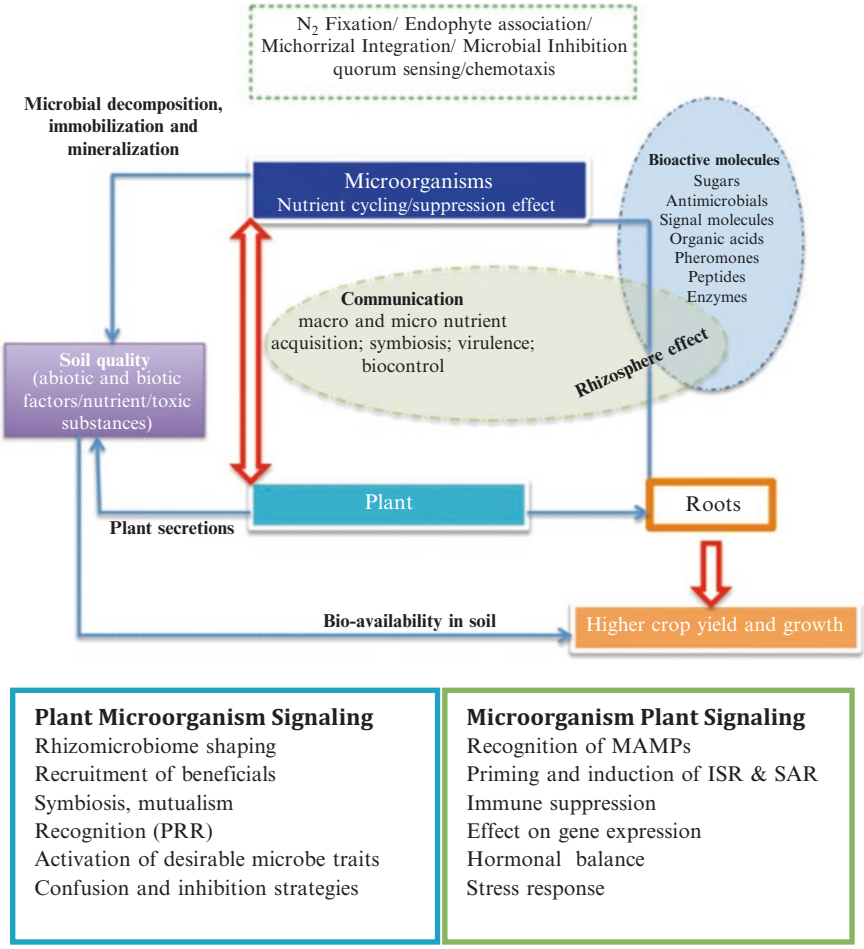

Fig. 1.1 Plant-microbe interactions and their role in belowground ecosystem and sustainable agriculture (Modified from Zhuang et al. 2013)

A mixed inoculation of *Rhizobium* sp. and *Azotobacter* sp. resulted in *Azotobacter* sp. significantly increasing *Rhizobium* nodulation. Both microorganisms enhanced growth and yield in various soil and mineral compositions. These findings suggest that there exist a mutualistic relationship between *Azotobacter*, *Azospirillum*, and *Rhizobium*, which results in improved yields in crops (Parmar 1995; Parmar and Dadarwal 1997). Researchers have reported that *Azotobacter* and *Azospirillum* contribute towards a plethora of positive responses in plants that include good root development, increase in nutrient and water uptake, inhibition of pathogenic and non-beneficial interactions, and a small contribution towards nitrogen fixation (Okon and Itzigsohn 1995; Steenhoudt and Vanderleyden 2000).

Table 1.1 Biomolecules involved in direct and indirect microbe and root-based activity

Activity	Biomolecules	Function
Direct microorganism-based activity		
Nitrogen fixation	EPS, EPS II, lipochitooligosaccharides, flavanols, flavanones, nodulating factors	Division of root cortical cells and nodule morphogenesis
Mycorrhizal association	Sesquiterpene, Myc factor	Fungal factors that trigger mycorrhization
Metal uptake	Glutathione, metallothioneins, and acid such as ferulic, chorismic, mugineic, caffeic, p-coumaric, oxalic	Metallic bioavailability
Virulence factors	Extracellular polysaccharide, phytotoxins, effector proteins	Crucial for virulence and suppression of resistance reactions
PGPR	LPS, EPS, antimicrobials, siderophores, lipopeptides, cell wall-degrading enzyme (CWDE)	Protection of plants against pathogens
		Improved nutrient uptake and growth
Direct root-based activity		
Bacterial and fungal symbionts	Flavonoids (glyceollin, coumestrol, daidzein, glyceollin, coumestrol, genistein), strigolactones, jasmonates, auxins, abscisic acid, ethylene, gibberellin	Stimulating pre-symbiotic processes and enhanced Arbuscular mycorrhiza fungi (AMF) colonization of roots
Carbon uptake	Arabinose, fructose, ribose, hexose	Carbon utilization and metabolism
Pathogenicity factors and defense response	Phytoalexins, naphthoquinones, indole, saponins, benzoxazinone, flavonoid, terpenoid, rosmarinic acid, glucosinolates	Protection against pathogenic microorganisms
Indirect microorganism-based activity		
Quorum sensing	Peptide molecules, N-acyl homoserine lactones (AHLs), quinolone, p-coumarate	Cellular communication, swarming, biofilm, and antibiotic production
Indirect root-based activity		
Defense	Phospholipases, phosphatases, MAP kinases: Lipoxygenase, linolenic acid, jasmonate, methyl jasmonate	Activation of other defense reactions

(b) *Mycorrhizal interactions*

The "fair-trade" between plant and mycorrhiza involves the provision of N by mycorrhiza and carbon by the plant (Fellbaum et al. 2012). A quantitative and qualitative change in the chemical content of soil and plant observed during AMF establishment includes the transient rise in phytoalexin levels during colonization (Leyval and Berthelin 1993). The beneficial fungal isolates or plant cultivars involved in AMF symbiosis can influence the concentration and types of flavonoids produced. The type of flavonoids produced influences the mycorrhizal spore germination, hyphal growth and root colonization. For example, strigolactone, a sesquiterpene

lactone, is essential in inducing AMF hyphal branching (Akiyama et al. 2005; Siegrid et al. 2007). Morandi et al. (1984) reported that flavonoids such as glyceollin, coumestrol, and daidzein stimulates AMF colonization in soybean and thus implicates flavonoids as signaling compounds involved in AMF root colonization. In contrast there are chemicals that inhibit hyphal growth of mycorrhiza such as observed within a non-nodule-forming legumes (Oba et al. 2002). Further, it has also been reported that sugars, carbohydrates, and strigolactone 5-deoxygol facilitate the symbiotic associations between the mycorrhiza and non-legume crops (Yoneyama et al. 2008; Fang and St. Leger 2010; Kiers et al. 2011).

Vesicular-arbuscular mycorrhizae (VAM) on the other hand are a group of fungi that are involved in the mobilization of phosphorus from soil with low levels of available phosphorous. The associative relationship of these fungi with legumes influences the root and shoot development as well as the phosphorous uptake that eventually results in enhanced nodulation and nitrogen fixation. Combinatorial inoculation of soil systems with *Rhizobium* and VAM has unequivocally contributed towards plant growth enhancement, nodulation, and N_2 fixation. The effectiveness of *Rhizobacterium* sp. as nodulating and N_2-fixing fungi in the mycotrophic legume, *Anthyllis cytisoides*, further substantiates AM's function in supplying P to root nodules (Requena et al. 2001). Research shows that other root–microbe symbionts share the same symbiotic genetic pathway as the N_2-fixing rhizobia. "Myc" triggers gene activation in roots through a diffusible signaling factor that is required for mycorrhization. This signaling factor results in elevated calcium levels which inevitably caused calcium fluctuations required for epidermal root cell priming for fungal colonization (Meier et al. 2013; Zhuang et al. 2013). These specific interactions have provided insights into functional compatibility between AMF and PGPR as plant growth promoters.

(c) *Endophytic associations*

Plants have supported endophytes that are either nonpathogenic bacterial or fungal species with no detrimental effects to the host. Although this is a long-standing interaction, but it has not been well studied and documented. Hosts that harbor these endophytes have shown increased resistance to plant stresses. The presence of these endophytes can result in the alteration of root exudates causing a change in the secretion of phenolics and hence altering the pH within the rhizosphere and elevating tolerance toward mineral deficiencies. While endophytic relationships are largely beneficial, there are however some opportunistic associations. The altered exudates from endophytic plants may affect the microbial community within the soil and influence the biology and ecology of the system (Malinowski and Belesky 2000). Plants involved in symbiotic relations with endophytes have also been reported to enhance AMF interactions through root exudates (Novas et al. 2011).

(d) *PGPR*

PGPRs have been characterized as organisms that colonize and suppress plant pathogens. This group of organisms has been exploited extensively for economic

gains due to its inhibitory potential (Parmar 1995). Through a plethora of direct and indirect mechanisms, the PGPR is found to positively influence plants. It is believed that soil microorganisms involved in this interaction are recruited by cues exuded by the host roots hence establishing the PGPRs population and activities. PGPRs on the other hand are reported to produce chemicals that affect plant growth and resistance indicating a two-way relationship between plants and PGPR for improved plant health (Ryu et al. 2004). The involvement of rhizospheric PGPRs in triggering the host immune response through various pathways such as jasmonate and salicylic acid has been previously reported and associated with plant fitness (Compant et al. 2010; Saharan and Nehra 2011). Chemical agents such as amino acids and carbohydrates were reported to be the signals involved in the mobilization of PGPRs to specific roots (de Weert et al. 2002).

Plant growth has been enhanced by bacterial communities that include *Azotobacter*, *Bacillus*, *Azospirillum*, *Enterobacter*, *Serratia*, *Klebsiella*, and *Pseudomonas.* Compared to single inoculums, dual inoculations significantly improved plant weight, dry mass, protein content, and grain yield. Yadegari et al. (2008) reported that combined inoculation of PGPRs increased growth, development, nodulation, and nitrogenase activity. The cumulative effects of growth-promoting substances exuded by organisms such as *Pseudomonas* sp. CRP55b, *Rhizobium* Ca181, *Pseudomonas* sp. CRP55b, *Azospirillum* spp., and *Pseudomonas fluorescens* P21 resulted in an increase of apical and root growth, plant biomass, and crop yield (Rokhzadi et al. 2008). The mechanisms contributing toward the increase in yield and growth are multitudinous, where substances or processes such as phytohormones, plant growth-regulating substances (PGRs), mineralization, cyanogens, siderophores, and phytoalexins/flavonoids collectively resulted in enhanced agricultural output (Mukerji et al. 2006; Nadarajah 2016).

Rhizobacteria produce phytostimulators in the absence of pathogens. These compounds include hormone analogues such as gibberellic acid, indole acetic acid (IAA), ethylene, and cytokinins (Lambrecht et al. 2000). The production of IAA is a plant growth-promoting trait among PGPRs. Tryptophan-dependent and tryptophan-independent pathways have been identified as contributing toward IAA biosynthesis in rhizobacteria (Steenhoudt and Vanderleyden 2000). Shoot development is stimulated in response to the action by cytokinins and gibberellins. Additionally cytokinins are also involved in cell division, primary root development, nodulation, and branching (Murray et al. 2007; Tirichine et al. 2007; Ortiz-Castro et al. 2009). N-Acyl-L-homoserine lactones, another class of phytostimulants, are associated with cellular communication and modulation of gene expression in plants (Choi et al. 2008; Ortiz-Castro et al. 2009).

A multitude of plant responses including stress is regulated by ethylene. Various factors such as temperature, nutrition, gravity, and plant hormone levels influence ethylene production (Glick 2005). In incidences of high ethylene levels, the plant undergoes stress and exhibits impaired root growth (Argueso et al. 2007). However the modulation of ethylene via ACC-deaminase is crucial in the degradation of 1-aminocyclopropane-1-carboxylic acid (ACC ethylene precursor). Various microbes have been reported to cleave ACC to ketobutyrate and ammonia as a

means of improving plant stress response to ethylene production (Glick 2005; Stearns et al. 2012). Further, ACC-deaminase activity in *Achromobacter piechaudii* ARV8 improved seedling biomass in tomato and pepper (Mayak et al. 2004). Similarly a study of ACC-deaminase in *Brassica napus* revealed a downregulation of ethylene stress response while recording upregulated gene expression of auxin production genes (Stearns et al. 2012). Arshad et al. (2008) and Mayak et al. (2004) in their reports indicated a role for ACC-deaminase in reducing ethylene levels and thus contributing toward management of drought, salinity, and generally various other abiotic stresses. This therefore clearly indicates that microorganisms with ACC-deaminase activity benefits the overall well-being of plants. Understanding the overall contribution of microbial communities in reducing and mediating ethylene stress in plants may be utilized to generate technologies for plant abiotic stress management.

(e) *Enzymes and proteins*

While it has been reported that plants secrete enzymes and proteins in addition to primary and secondary metabolites into the rhizosphere (Charmont et al. 2005), information is lacking on how these substances influence the rhizosphere (De Hoff et al. 2009; De-la-Peña et al. 2008). A proteomic analysis on *A. thaliana* root exudates indicates that there is a difference in the secreted proteins according to developmental stages. During the flowering stage, defense-related proteins such as glucanases, chitinases, and myrosinases were produced (De-la-Peña et al. 2010). Higher levels of defense-related proteins such as peroxidases, hydrolase, and chitinase have been reported as secretomes into the plant root systems of *A. thaliana* in response to an infection by pathogenic *Pseudomonas syringae* pv. tomato DC3000. However when inoculated with a nonpathogenic isolate, *S. meliloti* Rm1021, no defense response proteins were secreted into the rhizosphere.

Arabinogalactan protein (AGP) is a hydroxyproline-rich glycoprotein superfamily that is found in plant cell wall proteins. AGPs play a vital role in root and rhizospheric microbe interaction (Nguema-Ona et al. 2013). Cannesan et al. (2012) and Vicré et al. (2005) reported that root tip cells and AGP containing mucilage was observed in the rhizosphere. This glycoprotein acts as an attractant to root pathogen inhibiting microbes and is implicated in the colonization by *Rhizobium* sp. through recognition and attachment to root surfaces (Vicré et al. 2005; Cannesan et al. 2012; Xie et al. 2012). Xie et al. (2012) reported on a similar glycoprotein, which promotes surface attachment of *Rhizobium leguminosarum* to roots of legumes and non-legumes. *P. fluorescens* strain WCS365 colonization of tomato roots involves a plethora of amino acids which includes aspartic acid, glutamic acid, leucine, lysine, and isoleucine (Simons et al. 1997). In another study, the exposure of plants to *Rhizobium* sp. (Sb16) and *Cyanobacterium* sp. (Sb26) (Naher et al. 2008) resulted in higher levels of amino acid exudates in rice. This may perhaps be a consequence to secretion of microbial products that result in amino acid exudates (Chaparro et al. 2013a, b; Phillips et al. 2004). However, the influence of these enzymes and proteins in the establishment, colonization, and configuration of microbial communities remains elusive.

(f) *Sugars*

Chaparro et al. (2013a) reported that the rate of sugars exuded decreased with the plant's development. This could possibly be the consequence of pathways and cycles utilizing sugars being synergistically regulated by sugars and amino acids (Poysti et al. 2007). Considering the large number of genes (27) identified and correlated to carbohydrate metabolism in microbes, sugars are probably actively utilized by these organisms. Metabolic priming of soil microbes enhanced degradation and mineralization of soil organic matter in the presence of fructose and alanine (Hamer and Marschner 2005). The observed priming effect is due to the ability of these substrates to trigger metabolism and enzyme production (Kuzyakov 2002). The priming of enzyme activities results in increased metabolic capabilities of the soil microbiome, which improves the plant acquisition of various limiting nutrients.

1.4.2 Antagonistic Plant–Microbe Interactions

(a) *Quorum sensing (QS)*

QS involves cell-to-cell communication between microorganisms in an environment. It has been implied that the plant's root systems have developed the mechanism to exude chemical signals (mimics, blockers, and or degrading enzymes) that have the ability to affect microbial QS (Gao et al. 2003). Diffusion of these small signal molecules (autoinducers), which are present in both Gram-negative and Gram-positive bacteria, is known to mediate QS. QS is essential in the development of plant–microbe interactions regardless if it's beneficial or non-beneficial. These QS-mimicking or quenching signals are potential targets for the discovery and development of new antimicrobial molecules.

Molecules that imitate acylated homo-Ser lactones (AHLs) with specific effects on QS-controlled behavior have been reported in *Oryza sativa* L. (rice), *Pisum sativum* L. (pea), and *Glycine max* (L.) Merr. (soybean). The lasIR system of QS sensing in *P. aeruginosa* regulates virulence factors such as toxins and extracellular enzymes. A second system, rhlIR, also modulates expression of virulence factors. In PUPa3, both systems form useful associations with plants. AHL signaling in *Chromobacterium violaceum* was inhibited by an arginine analog, L-canavanine, that did not interfere with its growth in alfalfa or other legumes. L-Canavanine also regulates QS ability in *S. meliloti* and is also responsible for the control of EPS II biosynthesis in this organism (Daniels et al. 2002; Teplitski et al. 2000; 2004; Zhuang et al. 2013).

The pcoIR system in *P. fluorescens* is connected to the biosynthesis of antimicrobial compounds, e.g., pyrrolnitrin, phenazines, hydrogen cyanide, and pyoluteorin. Similarly the pcoIR system in *P. fluorescens* 2P24 indirectly regulates the production of metabolites, including siderophores, 2,4-diacetylphloroglucinol, and hydrogen cyanide. Tyrosol, farnesol, trisporic acid, and dimethoxycinnamate are some of the signal molecules produced by *Uromyces phaseoli*, *Candida albicans*, and

zygomycetes in their host–microbe interactions. 3-oxo-C12-HSL from *P. aeruginosa* inhibits structural changes from yeast-like to filamentous in *C. albicans* (required for virulence). In turn, AHL synthesis in *P. aeruginosa* is strongly suppressed by farnesol. However, the pathways and specific mechanisms involved in fungal QS remain obscure (Hogan 2006; Sanchez-Contreras et al. 2007; Wu et al. 2010; Zhuang et al. 2013).

GABA is another component involved in cellular communication. GABA quenches QS and reduces the virulence of *A. tumefaciens* (Chevrot et al. 2006) while utilizing GABA as sole nutrient source in *P. putida* (Ramos-González et al. 2005). Proline however reverses GABA's ability to quench QS (Haudecoeur et al. 2009). These opposing signals require further investigation to understand the interplay involved in the complex rhizospheric interaction.

(b) *Antimicrobial*

Plant secondary metabolites are compounds that attract beneficial microbes and defend plants against negative interactions. Plants synthesize secondary metabolites such as phenols or their oxygen-substituted derivatives in a limitless manner (Badri et al. 2008; Neal et al. 2012). One such example is rosmarinic acid (RA) (Bais et al. 2002). Basil roots, for instance, have been reported to exude RA when induced or challenged by fungi. RA demonstrates powerful antimicrobial activity against a vast selection of soil microbes, including *P. aeruginosa* (Bais et al. 2002). Fungal (*Phytophthora cinnamomi* and *Pythium ultimum*) elicitation of basil roots produced naphthoquinones and RA that are strong inhibitors of pathogenic and opportunistic microorganisms in the soil including the opportunist plant pathogen *P. aeruginosa*. In addition, grafted watermelon roots with high levels of chlorogenic and caffeic acid exudates and low levels of cinnamic acid (Ling et al. 2013) were resistant towards *Fusarium oxysporum* f.sp. *niveum* infections. Cai et al. (2009) reported that the antimicrobial agent canavanine obtained from leguminous plants inhibits rhizospheric bacteria excluding rhizobia. This suggests canavanine's involvement in the selection of beneficial microbes.

Most antimicrobial products are broad spectrum, and their specificity is determined by the existence of enzymatic machinery to detoxify any of the host products. Antimicrobial compounds are induced through the activation of linked signal transduction pathways as a consequence of pathogen perception by host resistance gene-encoded receptors. However, most studies have not looked into the mechanism of accumulation of these secondary metabolites within the plants and its excretion into the soil environment. In a study conducted on root exudates from *Gladiolus* spp. L., the resistant varieties produced root exudates that had antimicrobial effects against *Fusarium oxysporum* sp. *gladioli*, while the susceptible lines showed no reduction on conidial germination (Taddei et al. 2002). The inhibition of conidial germination of *F. oxysporum gladioli* by resistant cultivars is mainly regulated by the presence of aromatic-phenolic compounds.

Fungal communities in the rhizosphere produced abundant antimicrobial substances (Hoffmeister and Keller 2007; Brakhage and Schroeckh 2011). For example, *Trichoderma* species have been reported to produce a large array of antimicrobials (Elad et al. 2008) among other bioactive compounds. Fungal and bacterial biocontrol strains produced several antimicrobial compounds with similar or varying degree of activity. Bacteriocin such as agrocin 84 (Kim et al. 2006) exhibits narrow-spectrum antimicrobial activity against closely related genera, while polyketides and peptides exhibit broad-spectrum activity (Raaijmakers et al. 2010). The effectiveness of these compounds varies from microbe to microbe. The antimicrobial compounds found within the root cells differ in composition to the antimicrobials found in root exudates (Bednarek and Osbourn 2009).

1.5 Multitrophic Interactions in the Rhizosphere

From the one-to-one interactions observed in the rhizosphere, here we look into the multipartite interactions that present the complexity within the rhizosphere. In the root soil environment of plants such as switch grass, endophytic associations of microbe–insect–plant enhanced N availability for the plant (Behie et al. 2012). The presence of raffinose and sucrose in root exudates of switch grass attracted *Metarhizium robertsii* and enabled the tripartite interaction. In addition, plant volatiles from the legume *M. truncatula* attracted *Caenorhabditis elegans*, a nematode that transported *S. meliloti* to the plant's roots to initiate symbiosis (Fang and St. Leger 2010; Horiuchi et al. 2005). Similarly the tripartite relations between PGPR–mycorrhizae and PGPR–rhizobia resulted in the efficient colonization of mycorrhizae and nodulation of rhizobia, respectively (Guiñazú et al. 2010). Due to the complexity of the multipartite interactions, very little is known of the mechanisms involved, and hence more studies are needed to elucidate these mechanisms, colonization, establishment, and benefits of the interaction.

1.6 Concluding Remarks

The above segments have dealt with the various ways in which the plant–microbe interaction in the rhizosphere affects both the plant and the soil microbial community. These interactions have been known to effect soil fertility, thus affecting plant health, overall yield, and growth. Hence, it is evident that microorganisms are key players in plant productivity and should be given due attention in the interest of advancing our knowledge in rhizosphere biology. As we transition from conventional agriculture to sustainable agriculture, it is important to understand the differences and the benefits of this transition.

Conventional agriculture practices selection of high yielding genotypes coupled with high fertilizers inputs and pesticides to reduce losses from biotic infestations while enhancing growth and yield. Rhizospheric microorganisms play a minor role

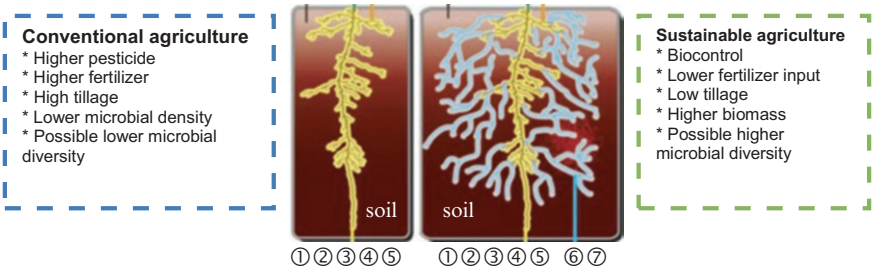

Fig. 1.2 Conventional vs. sustainable agriculture. The above diagram differentiates between conventional and sustainable agriculture, highlighting the contribution of microbes in sustainable agriculture (① rhizosphere ② N_2 fixation ③ root pathogens ④ endophytes ⑤ arbuscular mycorrhiza ⑥ hydrosphere ⑦ mycorrhizosphere)

in conventional agriculture unless they are pathogens. By excluding the microorganisms from the equation, agriculture has been dependent on plant genotypes which may not be as well adapted to adverse conditions. However, in sustainable agriculture, the microorganisms within the rhizosphere are important in crop production (Fig. 1.2). Hence through sustainable agriculture, one could select for plant genotypes that are able to mobilize nutrients from their environments directly or indirectly through interactions with rhizospheric organisms. The results from sustainable agriculture can be further enhanced through the application of good management practices, inclusive of crop rotation, mulching, and utilization of PGPRs.

In this chapter we have provided a comprehensive outline of the major interactions within the rhizosphere and how these interactions affect the plant and the microbial population. Understanding the microbial community and the potential that it carries in enhancing plant processes that leads to enhanced yield and growth would be beneficial to end users, i.e., the farmers. Enhanced yield may be attained through exploiting soil biological fertility, where lesser pesticides and fertilizers are required for improved yield and growth. Therefore through the utilization of existing knowledge and modern technologies, it is expected that valuable insight may be garnered to fill in the gaps in knowledge and information required to provide new opportunities and practices that increase crop production.

Shaping the Other Sides: Exploring the Physical Architecture of Rhizosphere

2

Madhurima Chatterjee, Raktim Bhattacharya, and Rabindranath Bhattacharyya

Abstract

The root system is immediately surrounded by a narrow zone of soil called the rhizosphere. A major proportion of biodiversity of the soil resides in the rhizosphere, hence accounting for the various activities found in that area. There are various abiotic and biotic factors which help in modifying the physical structure of the rhizosphere. The main abiotic factors are light, temperature, humidity, carbon dioxide, water uptake, pH change, etc. The physical architecture determines the richness of the microbial community which in turn affects the plant growth. In this chapter, the various physical and chemical processes occurring in the rhizosphere and how the change in environment hampers these factors and how that affects the rhizospheric diversity in modifying the microbial ecology and root architecture will be discussed.

2.1 Introduction

Soil is considered the habitat of most of the organisms on earth, ranging from prokaryotes to eukaryotes. It consists of the important organisms, like various soil microflora and fungi including invertebrates (like protozoa, mites, nematodes, earthworms and insects) (Hinsinger et al. 2009). It is estimated that the number of prokaryotes inhabiting the soil ecosystem is three times more than the combination of all the other environmental counterparts of the earth's ecosystem (Curtis et al. 2002; Crawford et al. 2005; Curtis and Sloan 2005). Soil is the platform where the

D.K. Choudhary et al. (eds.), *Plant-Microbe Interaction: An Approach to Sustainable Agriculture*, DOI 10.1007/978-981-10-2854-0_2

plant grows; it is from the soil that most of the members of plant community acquired the required amount of nutrition and water in the form of sap.

The rhizosphere is defined to be the volume of soil around the living roots, influenced by certain activity of the root (Darrah 1993; Hinsinger 1998a). The rhizosphere is considered to be the hot spot of activity in soils, constituting its unique environment. It is believed that most of the diversity of soils resides in the rhizosphere (Jones and Hinsinger 2008). Different physical, chemical and biochemical processes occur in the rhizosphere as a result of root growth, water and mineral uptake, rhizodeposition and respiration. These factors distinguish it from the bulk soil. Microbial ecology and plant physiology are also affected owing to these processes.

The term rhizosphere was first coined by German plant physiologist and agronomist Lorenz Hiltner. The word rhizosphere originated from the Greek word rhiza (meaning root) (Hiltner 1904; Hartmann et al. 2008). From that time the definition and explanation of the term rhizosphere has undergone a thorough modification. And nowadays it has been considered that rhizosphere actually consists of three basic parts, and they are:

1. Endorhizosphere, the region which includes the cortex and endodermis, where microbes along with the cations can occupy the apoplastic space
2. The rhizoplane, which is the middle portion of the root situated just beside the root, consisting of the epidermis (epiblema) and mucilage
3. The ectorhizosphere, which is the outermost region, which spans from the rhizoplane to the outer bulk soil

Now it has been understandably clear that by the term rhizosphere, we cannot define a specific area, but it defines a zone of gradient spanning across the root along with the soil microflora as well as some physical and chemical factors.

The Physical Properties and Processes of the Rhizosphere The physical processes occurring in the rhizosphere are responsible for the movement of water and minerals inside and outside of the root.

The factors which alter the physical properties of the rhizosphere are primarily the root activities necessary for the root's growth and uptake of water. The bulk density, porosity and soil strength are some of the notable physical factors which are affected by the forces exerted by the growth of the root (Dexter 1987; Czarnes et al. 1999). Changes in soil structure are found due to changes in the physical properties of the rhizosphere. This is caused mainly by polysaccharides which constitute a major proportion of rhizodeposits (Czarnes et al. 2000). Rhizodeposits are basically certain organic compounds (mostly C-rich substrates) which are released by the plant roots, to be fed by heterotrophic bacteria (Lynch and Whipps 1990; Jones et al. 2004, 2009). Rhizodeposition alters the nutrient abundance in the rhizosphere. Rhizosheaths, which are certain unique structural features restricted to rhizosphere, are formed by the mucilage produced from the roots and also root hairs (McCully

1999). Rhizosheaths are mainly found in the grasses. Aggregation of soil around roots can be attributed to the mycorrhizal hyphae and also the exopolysaccharides secreted by the microorganisms residing in the rhizosphere (Amellal et al. 1998). These processes facilitate or retard the transport of water, solutes and toxic compounds and also affect plant nutrition and health.

Water uptake can also have dramatic effect on the rhizosphere architecture (Doussan et al. 2003). This alters the water potential around the roots by affecting the microbial activities happening in the rhizosphere as well as the radial movement of water particles.

Water captured in the rhizospheric region will be supplied throughout the whole plant, so change in water potential can greatly affect the rhizosphere. A very recent study on cavitation and its effect on cohesion-tension theory depicted that the small roots are more vulnerable to cavitation, so these small roots may be the weakest link in the soil-plant-atmosphere continuum (Hacke and Sauter 1996). It has also been found that, in *Acer grandidentatum*, if the negative water potential (ψ) remains constant, then the safety margin of cavitation of the roots is smaller than that of the shoots (Alder et al. 1996). As a result of this, at the time of drought, extensive cavitation in the roots inhibits the gas exchange in the shoots.

Moreover, the soil-water relationships, viscosity and surface tension properties of the soil are affected by the mucilage secreted by the roots.

The soil associated with roots confers a resistance to the external, mechanical stress in comparison to the bulk soil, thus exhibiting increased stability. The enhanced soil stability within and outside the rhizosphere can also be due to certain biological activity.

2.1.1 Chemical Processes and Properties of the Rhizosphere

Plant roots perform various functions like absorption, respiration and exudation. These functions are responsible for changes in nutrient and toxic elements' concentrations, pH, redox potential, partial pressure of oxygen and partial pressure of carbon dioxide in the rhizosphere (Hinsinger 1998a).

Due to rhizodeposition, there occurs a carbon flow in the rhizosphere, triggering the growth of bacteria. So, it seems that the rhizosphere gets enriched by C, but it lacks nitrogen. Nutrient uptake by roots often results in nutrient depletion in the rhizosphere. Nutrients such as calcium, magnesium and potassium occurring as solutes in the soil solution get transferred and are accumulated near the root surface by mass flow, when the flow of the nutrient transferred is more than the plant's demand (Lorenz et al. 1994; Barber 1995; Hinsinger 2004). Similarly, the nutrient concentration decreases in the rhizosphere when the flow is less than that required by the plant. This type of decrease is mainly found for phosphorus, nitrogen and potassium (Hendriks et al. 1981; Kuchenbuch and Jungk 1982; Gahoonia et al. 1992; Hinsinger et al. 2005). Hence, based on the two conditions, the rhizosphere may become nutrient-enriched or nutrient-depleted zone.

The pH of the rhizosphere generally increases when the plants absorb nitrogen as NO_3^-. Hence the rhizosphere becomes alkaline in this condition. But when the plants absorb nitrogen as N_2 or NH_4^+, the pH decreases (Nye 1981). The pH change can be calculated from efflux of H^+ efflux and radius of the root, initial pH, pH buffering capacity, partial pressure of CO_2 in the soil and also moisture content (Nye 1981). pH changes also affect nutrient availability. Protons in the rhizosphere compete for metal cations (e.g. Cu and Zn) (Loosemore et al. 2004; Michaud et al. 2007) on cation binding sites, thus altering nutrient composition. pH change sometimes has a dramatic effect on phosphorus acquisition.

Again, it is found that roots and rhizosphere microorganisms often exude certain organic ligands which help in increment of nutrient availability by desorption of anions in exchange of the ligands (Hinsinger 2001a; Ryan et al. 2001; Read et al. 2003; Dunbabin et al. 2006).

Usually in the rhizosphere, increased activity of certain enzymes like phosphatases, proteases and arylsulfatases, released by ectomycorrhizal fungi and microorganisms, is found, in comparison to bulk soil. These help in cycling of P, N and S.

2.1.2 Rhizosphere Architecture

Rhizosphere architecture can vary between species or between genotypes of a given species (Ge et al. 2000). It also changes in response to environmental cues; e.g. roots proliferate in nutrient-rich patches or roots form cluster in phosphorus deficiency.

It is found that root hairs by extending up to a few millimetres away from the root surface can increase the rhizosphere volume (Bhat et al. 1976). Similarly, the mycorrhizal hyphae in phosphate-deficient soil can extend several centimetres above the soil surface, thus enhancing the volume of the rhizosphere of the plants having symbiotic relationships with mycorrhizae (Li et al. 1991; Jakobsen et al. 1992; Read and Perez-Moreno 2003).

Following are the factors which affect the rhizosphere architecture:

2.1.2.1 Effects of Elevated Atmospheric CO_2 on the Microbial Structure and Rhizosphere Architecture

When concentration of atmospheric CO_2 increases, then it alters the plant C allocation. Several biochemical and physiological reactions start occurring in the fine roots, ultimately affecting the rhizosphere food webs, also the rates at which the C and N cycle take place. Mycorrhiza and the fine roots are mainly responsible for the mineral nutrition, input of soil C as well as microbial activity inside the soil. With increased CO_2 concentrations, fine root growth is enhanced (Curtis 1996; Curtis and Wang 1998; Pendall et al. 2004; Rillig et al. 1997). Increased rate of nutrient uptake and mycorrhizal activities are also found which sometimes can alter the dynamic equilibrium existing between the rhizosphere microbial community and plant roots (Hu et al. 1999; Klironomos et al. 1996). Mycorrhizal biomass increases due to limited C and nutrient availability. So, mycorrhizae are indirectly affected due to

changes in C allocation from their host plants (Allen et al. 2005; Gamper et al. 2004, 2005; Parrent et al. 2006; Sanders et al. 1998; Staddon et al. 2002; Treseder and Allen 2000).

With increase in CO_2 concentration, the existing C dynamics in the rhizosphere is altered resulting in an elevated C/N ratio of rhizodeposition, despite no increase in the total plant biomass (Hu et al. 1999; Paterson et al. 1997).

It is found that the soil respiration consisting of root and microbial respiration increased when the plants were exposed to higher CO_2 concentrations.

Microbial growth and activity are usually stimulated in response to elevated CO_2 levels (Cotrufo and Gorissen 1997; Diaz et al. 1993; Paterson et al. 1997; Sadowsky and Schortemeyer 1997; Zak et al. 1993, 2000). This results in an increase in grazing which again results in a quicker nutrient recycling from the bacterial biomass, thus increasing nutrient flux to the plant.

2.1.2.2 Effect of Light on Rhizosphere Architecture

It is often found that the light intensity is directly proportional to the production of roots. It means that the plants which are subjected to low light intensity show slower growth rate of roots in comparison to the plants which are treated with high light intensity (Biswell 1935; Haig 1936). Hence plants receiving sunlight show a good response to root development than plants remaining under shade. An increment in the ratio of dry weights of roots to tops was observed in several species (Shirley 1936).

Infection by the vesicular-arbuscular mycorrhizae (VAM) is influenced by the photon flux density and photoperiod. When the plants, especially at higher altitudes, are subjected to higher light intensity, in sunlit areas and during springtime or summer, greater mycorrhizal infection was observed (Winter and Meloh 1958). Light intensity not only affects the shaping of the root, but also it helps in the rhizosphere microflora maintenance. In one study it has been found that increasing light intensity is actually helping *Glomus fasciculatum*, vesicular-arbuscular mycorrhizal (VAM) fungi, to increase colonization in the roots of Sudan grass (Ferguson and Menge 1982). All these are the evidences, which clearly indicate that root growth is actually directly proportional to the photosynthetic carbon production by the shoot and which ultimately depends on the light. So, the more a plant will get light, the more there will be photosynthesis, hence more carbon, thus more root growth. Similarly, it is found that photoperiods of longer duration cause increased infection of mycorrhiza in comparison to photoperiods of shorter duration (Hayman 1974).

2.1.2.3 Effect of Temperature on Rhizosphere Architecture

Soil temperature has a positive correlation with the root growth. The higher the temperature, the higher the root growth, and reduced growth of the root is observed during lower temperature prevailing in the soil. An experiment performed on young loblolly pine seedlings shows that with increasing temperature, initially there was a uniform rise in root growth rate at 5 till 25 °C, after which the root growth declined (Barney 1951). The length of the individual root is expressed as a function of time. This root growth can be calculated by the following formula:

$$Y = \bar{y} + b\left(x - \bar{x}\right),$$

where

Y = length of any individual root
x = average response of root growth to a given temperature
$\bar{y}$ = average of y values
$\bar{x}$ = average of x values
b = coefficient of the regression equation (Barney 1951).

Increase in soil temperature influences heterotrophic respiration, thus affecting atmospheric CO_2. Enzyme activity and chemical kinetics get increased, thus increasing decomposition rates in the soil. This ultimately leads to decreased net ecosystem production (NEP). Elevated soil temperatures again trigger microbial activity and increase availability of N and also the net primary productivity (NPP). It also results in an increased activity of the roots and soil heterotrophic organisms, and these are thus responsible for the loss of carbon dioxide and methane from the soil. The soils often dry up owing to an increase in the soil temperature; thus various soil nutrients get immobilized. Higher temperature often results in an increase in the number of fine roots. This has been seen in *Pinus taeda* but not *Pinus ponderosa* (King et al. 1996). Root N concentration is found to increase in response to higher temperature (King et al. 1997; Kandeler et al. 2002; Wan et al; 2004), owing to diffusion and mineralization of N, which are elevated at increased temperature (BassiriRad et al. 1993; BassiriRad 2000). This higher N concentration sometimes results in mortality of the fine roots, thus affecting the soil N cycling (Zak et al. 2000).

2.1.2.4 Effect of pH Change on Rhizosphere Architecture

Whenever there is an imbalance of cation-anion uptake at the root-soil interface, the roots try to adjust the pH of the rhizosphere by releasing H^+ or OH^- ions. When a surplus of cations enter in comparison to anions, then to compensate for the extra positive charges entering the cell, H^+ ions are released into the apoplasm, thus increasing the pH of the cytosol. This type of pH adjustment occurs when the plant is treated with K_2SO_4 solution and an excess amount of K^+ ions enters the cell than the SO_4^{2-} ions (Haynes 1990; Hiatt 1967; Marschner 1995). Similarly, when an excess of anions enter the cell in comparison to cations, to compensate for the surplus negative charges entering, OH^- ions are released into the apoplasm, thereby decreasing the pH. This type of pH adjustment occurs when the plant is treated with $CaCl_2$ solution and an excess amount of Cl^- ions enters the cell than the Ca^{2+-} ions (Hiatt 1967; Haynes 1990; Marschner 1995). Plants like legumes, showing a dependence on atmospheric N_2, release excess positive charges in the form of H^+ since they are able to take up more cations than anions and thus increase the acidity by decreasing the pH.

Again, it is found that some portions of the root just behind the root apex may release H^+, while basal parts release OH^- ions into the rhizosphere, thus constructing a spatial variation along the root axes (Jaillard et al. 2002).

Organic acids, e.g. citric acid, malic acid and oxalic acid, play a major role in soil acidification (Jones and Brassington 1998; Jones et al. 2002). These acids are present in increased concentrations in the root cells. In few plant species, these acids are found to be present inside the vacuoles of root cells, while in others these acids are exuded into the rhizosphere.

It has been found that under various conditions of stresses, localized exudation of H^+ ions occurs to tackle the ion imbalance in the rhizosphere. Among these the most noted are shortage of iron (Fe) or phosphorus (P) or aluminium (Al)-induced toxicity in the form of Al^{3+} (Haynes 1990; Hinsinger 2001b). Al^{3+} toxicity decreases NO_3^- uptake, thus causing increased acidification of the rhizosphere. Hence nowadays, Al-resistant genotypes are being made by the scientists. These genotypes will be better suited to take up anions, thus decreasing acidity in the soil and alkalinizing the environment.

2.2 Conclusion

Thus it can be said that rhizosphere is one of richest biodiversity regions in the soil containing a variety of organisms. The very essence of rhizosphere lies at the basics of community and mutual interaction. Apart from that, there are many physical and chemical factors that play a vital role in shaping the rhizosphere into its complete structure. Most of the time, the biotic factors controlling the architecture of the rhizosphere are taken into account. But these physicochemical factors like bulk density, porosity and soil strength, light, temperature and pH also play a major role in modifying the rhizosphere architecture. Water uptake can change the water potential around the roots by affecting the microbial activities taking place in the rhizosphere as well as the radial movement of water particles. Usually soil temperature shows a positive correlation with the growth of roots. Change in pH in the rhizosphere affects the nutrient availability of the plant. Generally more roots are produced in response to increasing light intensity. With increase in CO_2 concentration, the existing C dynamics in the rhizosphere is altered resulting in an elevated C/N ratio of rhizodeposition. The random fluctuation of these factors is giving rise to loss of rhizospheric microflora, which in turn affects the plant which is in symbiotic relationship with the affected bacteria and fungi. If we want to save our planet, we need to save the trees, and for that we need to keep this rhizosphere intact. Especially with the event of global warming looming over us, the optimum values of each and every physical factor and how change of one factor can affect another are very much important. Presently it is our need to determine the range of change of these optimum values up to which a plant can tolerate, and above all it is also needed to determine how these physical factors cross-talk with each other; only then can one understand the language of rhizosphere. Still, lots of investigations need to be done to understand the proper architecture of the rhizosphere. Various short-term and

long-term experiments need to be performed at the molecular level in the future to better understand the effects of the physical factors on the structure of the rhizosphere.

Applications and Mechanisms of Plant Growth-Stimulating Rhizobacteria

3

Prem Chandra and Enespa Singh

Abstract

Plant growth-stimulating rhizobacteria (PGPR) are the symbiotic soil-dwelling bacteria existed at the outer part of the plant root and participate for growth and improvement of the crops. Various regulatory substances are secreted by these bacteria in the circumstances of rhizospheric regions. Normally, PGPR mechanisms simplify the growth of a plant by fixing the nitrogen from atmospheric regions, dissolved the phosphorus and other raw materials, siderophores assembly which liquefy the appropriated iron, or controlling the phytohormones levels at numerous phases of growth. When unplanned development of plant growth takes place, the activities of PGPR diminish or avoid the disastrous effect of one or more plant pathogens microbes in the form of biocontrol agents. Various researchers have been recognized to improve the fitness and proficiency of aquanaut's species of plants by using the growth-supporting rhizospheric bacteria under systematic and harassed circumstances. The advantageous rhizobacteria of the plant may reduce the comprehensive dependency on hazardous agronomic compounds which disrupt the agro-biota. This chapter emphasizes on the insight of the rhizospheric microbe which supports the growth of plant under the existing viewpoints. Conclusively, these favorable rhizospheric bacteria in various agro-biotas have been offered scientifically under normal and stress circumstances to focus on current developments with the objectives to improve forthcoming visions.

3.1 Introduction

The soil has one of the utmost essential raw materials for the existence of microbes directly or indirectly. Microbes elaborate the numerous biotic activities in the soil biota to make it energetic for nutrient turnover and biological for crop production (Chandler et al. 2008; Paul and Lade 2014). They stimulate the growth of plants through biological cycles of micro- and macronutrients in soils, producing plentiful plant growth substances, and protect the plants from plant pathogens by regulating or preventing them. They detoxify the polluted soil by sequestering contaminated heavy metals, biodegrading the xenobiotic components such as pesticides, as well as reducing the biotic or abiotic stress of plants, without deliberating the pathogenicity (Braud et al. 2009). Certainly, sufficient microbial colony is found surrounding the root of plants (rhizobacteria), which are responsible for the more adaptability in assembling, altering, and solubilizing the nutrients compared to those from bulk soils (Hayat et al. 2010). The integrated plant nutrient management system is more successful for cultivating the crop production between ecologists and agronomists using biological approaches. In this perspective, those types of rhizospheric bacteria which have original traits like heavy metal-detoxifying capabilities, salinity tolerance, pesticide removal, and biocontrol of plant pathogens and insects (Tank and Saraf 2010; Paul and Lade 2014; Mayak et al. 2004; Hynes et al. 2008; Berg et al. 2013), along with the natural plant improvement-promoting resources like plant hormones, nitrogenase activity, ammonia production, phosphate solubilization (Jahanian et al. 2012) and also essential for soil fertility, etc., should be discovered continuously at universe level by the superior assistance (Glick 2012; Bhardwaj et al. 2014). Therefore, the bio-inoculants of symbiotic and nonsymbiotic microbes are now being used globally to promote the plant growth and improvement under various stresses like heavy metals, insecticides herbicides, etc. (Berg et al. 2013; Chang et al. 2014; Oves et al. 2016). The present study in this chapter is an effort to define the mechanism and their theory of rhizospheric bacteria for plant growth improvement with recent updates. The newly updated examples of globally applicable rhizospheric bacteria in various agro-biotas have been offered to harvest the wide range of perspectives about their applicability.

3.2 Rhizosphere

The rhizospheric regions are a very modest setting where roots of connecting species and microbes compete for existence. The plant roots perform specific characters in the rhizospheric area providing mechanical supports to plant and uptake micro- and macronutrients with water content which depends on the production and releasing of metabolites (Brzostek and Finzi 2012; Feike et al. 2013). These metabolites are released by plant roots (such as oligosaccharides, α-aminoadipic acid, valeric acid, invertase, cytidine, pantothenate, etc.) and act as chemical attractants for dynamically metabolizing soil microbial populations.

Table 3.1 Various biochemical compounds secreted by plant roots of different plant species

Amino acids	Asparagines, cysteine, cystine, glycine, leucine, methionine, serine, valine, tryptophan, ornithine, histidine, arginine, α-aminoadipic acid, phenylalanine, β-alanine, α-Alanine, proline, homoserine, aspartate, glutamate, isoleucine, lysine, threonine
Organic acids	Acetic acid, pyruvic acid, malonic acid, citric acid, oxalic acid, succinic acid, butyric acid, aldonic acid, glycolic acid, malic acid, fumaric acid, aconitic acid, lactic acid, valeric acid, formic acid, glutaric acid, and tetronic acid
Sugars	Desoxyribose, raffinose, fructose, rhamnose, xylose, ribose, galactose, oligosaccharides, maltose, arabinose, and glucose
Enzymes	Invertase, amylase, protease, and acid/alkaline phosphatase
Vitamins	Riboflavin, niacin, pantothenate, thiamine, biotin
Nucleosides or purines	Cytidine, uridine, adenine, guanine
Gaseous molecules and inorganic ions	CO_2, H_2, HCO^{-3}, OH^-, H^+

Adapted from Dakora and Phillips (2002)

The biochemical released in the rhizospheric regions by plant roots known as root exudates. The chemical compounds of root change the physicochemical properties of the soil (Table 3.1) and also control the structure of microbial populations at the surface of plant root in the soil (Jung et al. 2003). These chemical compositions of the exudates are dependent upon the physiological status and the microbial and plant species (Kang et al. 2010). They also promote the plant growth by improving symbiotic interactions between plant and microbial community and inhibit the growth of antagonistic plant species (Ahemad and Kibret 2014). These microbial activities in the rhizospheric zone disturb the structure of root and the resources of available nutrients to plant species. The atmospheric carbon content is sequestered to the rhizospheric zone through root exudation by the photosynthesis (Hinsinger et al. 2009; Marschner et al. 2011). The rhizospheric zone of the soil is influenced by the biochemical components secreted by the plant roots and distress the activities of microorganisms. The soil particle strongly adheres to the root surface of rhizoplane. The root is the part of the system because various endophytic microbes have the capability to colonize in the internal part of root tissues (Barea et al. 2005). The root colonization is the zone of rhizoplane or root tissues of symbiotic microbes (Barea et al. 2005; Barros et al. 2014).

3.3 Plant Growth-Stimulating Rhizobacteria

The rhizospheric bacteria are soil-dwelling bacteria and have the capability of inhabiting at the vicinity of root environment (Kloepper 1994). Valuable root-inhabiting plant growth rhizospheric bacteria are defined on the basis of important characteristics; they have the capability to colonize the surface of the plant root, and they have the capability of proliferation and existence in microhabitats related with

the superficial part of the root in comparisons with other microbes (Cleyet-Marcel et al. 2001). After sowing the seeds or propagation of plants in soils, then these bacteria promote the growth of the plants/crops directly by providing nutrients to plants or indirectly by decreasing the loss from soil-borne phytopathogens (Vessey 2003).

On the basis of biochemical compounds, rhizospheric activities classified as biofertilizers to provide the micro- and macronutrient promote the plant growth by using the plant hormones, biocontrol agents for monitoring the plant infections by production of antibiotics and antimicrobial metabolites, and rhizoremediators for degradation of organic pollutants and heavy metals (Somers et al. 2004). These substrates are capable of the production of plant hormones like gibberellic acid, indole acetic acid, ethylene, cytokinins, and symbiotic N_2 fixation (Haas and Defago 2005; Pérez-Miranda et al. 2007; Lugtenberg and Kamilova 2009; Kang et al. 2010; Laslo et al. 2012).

The rhizospheric zone has more nutrients compared to the loose soil because the root secretes various biochemical substances, like various organic acids, amino acids, sugars, and enzymes (Table 3.1), which provides the energy and micronutrient for the growth and development of microorganisms (Gray and Smith 2005). There are two types of rhizospheric bacteria that are found in this zone which is symbiotic and free-living (Khan 2005). On the basis of survival, these bacteria are divided into two groups, i.e., intracellular symbiotic bacteria (iPGPR) and extracellular free-living rhizobacteria (ePGPR). Symbiotic bacterial species like *Allorhizobium*, *Azorhizobium*, *Bradyrhizobium*, *Mesorhizobium*, and *Rhizobium* sp. reside inside root cells in specialized nodular forms (Viveros-Martinez et al. 2010; Figueiredo et al. 2011), and free-living rhizobacteria reside in the rhizospheric zone of the plant cells. The *Azotobacter*, *Arthrobacter*, *Azospirillum*, *Agrobacterium*, *Bacillus*, *Chromobacterium*, *Burkholderia*, *Caulobacter*, *Erwinia*, *Flavobacterium*, *Pseudomonas*, *Serratia*, and *Micrococcus* species of rhizobacteria are found in the rhizoplane regions or in the space between cells of the root cortex. These bacteria do not produce the nodules but still quicken the growth of plants (Gray and Smith 2005; Bhattacharyya and Jha 2012). The microbial population of rhizospheric regions shows the marvelous growth of plants in the presence of various actinomycetes (Merzaeva and Shirokikh 2006; Bhattacharyya and Jha 2012). These actinomycetes stimulate the growth of plants by constructing growth stimulators and are known as plant growth-promoting rhizobacteria. The various species of the actinomycetes, i.e., *Thermobifida*, *Streptomyces*, *Micromonospora*, and *Streptosporangium*, exhibited the potential against fungal pathogens of various roots as biocontrol agents (Franco-Correa et al. 2010; Bhattacharyya and Jha 2012).

3.4 Mechanisms of Plant Growth Promotion

Plant growth promotion increased in rhizospheric niche through the production of various biochemical substances by the entire population of microbes (Table 3.2) (Kloepper et al. 1980). Mostly, rhizospheric bacteria promote the growth of plants

in a direct way by solubilizing phosphate minerals, releasing siderophores that dissolve the sequester irons, fixing the nitrogen of the atmosphere, and controlling the levels of phytohormones at various growth phases of the plant. The indirect mechanism of plant growth promotion arises when the rhizospheric bacteria reduce the injurious effect of microbial plant pathogens (Persello-Cartieaux et al. 2003; Glick 2012) (Fig. 3.1).

(**c**) Penetration of root hair by bacteria which forms the contaminated filament and enters the cortical regions of the cells and forms bacteroid state, thereby nodules are molded (Adapted from Ahemad and Kibret (2014))

3.4.1 Direct Mechanisms

3.4.1.1 Nitrogen Fixation

Nitrogen is the essential macronutrient of plants and all vital components. These atmospheric N_2 are converted into utilizable forms to plants by biological nitrogen fixation (BNF). This amends nitrogen to ammonia by nitrogen-fixing bacteria using a nitrogenase enzyme (Kim and Rees 1994). Biological nitrogen fixation arises usually at insignificant temperatures by nitrogen-fixing bacteria, which are extensively circulated in nature (Raymond et al. 2004). Nitrogen can supply sufficient nutrients to increase production; it also leads to a global concern about environmental pollution resulting from extreme nitrate leaching (Dong et al. 2005). Its accessibility in soils may alter significantly at relatively short time intervals. Nitrogenase (*nif*) genes convoluted in the initiation of the iron–protein, Fe-Mo cofactor biosynthesis, electron transfer, and controlling genes required for the synthesis of enzymes. In both the process of symbiotic and nonsymbiotic classifications, nif genes are found (Kim and Rees 1994). Approximately two-thirds nitrogen is fixed worldwide by the BNF accounts. The remaining percent of nitrogen is synthesized industrially bases by the Haber–Bosch process (Rubio and Ludden 2008).

The nitrogen-fixing microbe generally characterized as symbiotic N_2-fixing bacteria forms a symbiotic relationship with the leguminous plants and includes the members of family Rhizobiaceae (Ahemad and Kibret 2014). And the nonleguminous plants are associated with the wider range of plants from eight families (e.g., *Frankia*) (Huss-Danell 1997; Vessey et al. 2004). The gram-negative soil-dwelling bacteria contain the unique capability to infect and establish a biological nitrogen-fixing symbiotic relationship with the roots of leguminous family. This type of symbiotic relationship forms a complex interaction between host and symbiont (Giordano and Hirsch 2004; Elmerich and Newton 2007). Finally, the nodulation takes place and the bacteria colonize as intercellular symbionts (Fig. 3.2). In the nonsymbiotic relationship, the nitrogen fixing takes place between the free-living

bacteria and endophytes by *Azospirillum*, *Azotobacter*, *Azocarus*, *Gluconoacetobacter diazotrophicus*, and the cyanobacteria like *Nostoc*, *Anabaena*, etc. (Franche et al. 2009; Bhattacharyya and Jha 2012). In the nonleguminous plants, the diazotrophs fixed nitrogen and have the capability of establishing a non-obligate interaction with the host plants (Glick et al. 1999). However, diazotrophs provide only a little quantity of the fixed nitrogen that the bacterially associated host plant requires (Glick 2012). The nitrogenase enzyme which is coded by the nif gene involved in the nitrogen fixation process (Kim and Rees 1994).

The structure of nitrogenase enzyme was explained by two components, metalloenzyme which consists of dinitrogenase reductase is the iron–protein and dinitrogenase has a metallic cofactor.

The electrons transferred with high reducing influence by dinitrogenase reductase activity, while N_2 converted to NH_3 due to the production of these electrons by dinitrogenase. On the basis of the metallic cofactor, there are three different types of N-fixing systems that have been recognized which are iron-nitrogenase, vanadium nitrogenase, and Mo-nitrogenase. The existence of N_2-fixing system varies between different bacterial genera, which is carried out by the movement of the Mo-nitrogenase and found in all diazotrophs (Bishop and Jorerger 1990; Rubio and Ludden 2005; Newton 2007). The nitrogenase enzyme consisted of two metalloproteins and is purified from various sources. The first component is designated as MoFe protein and the second two known are as iron–protein (Hu et al. 2007; Newton 2007; Rubio and Ludden 2008). Mostly the compact association of *nif* genes is always defined. There are three structural genes *nifD*, *nifK*, and *nifH* that code for the Mo-nitrogenase polypeptides, for the Mo-protein subunits, and for the Fe protein, respectively. It is recognized that a core of nif genes (nifH, nifD, nifK, nifY, nifB, nifQ, nifE, nifN, nifX, nifU, nifS, nifV, nifW, nifZ) is compulsory for the synthesis of nitrogenase activity, and catalysis is preserved in all the diazotrophs. Various genes are responsible for the in vivo nitrogenase action based on the system; these code for the mechanisms of biological electron transport chains (the rnfABCDGEF cluster codes the ferredoxin, flavodoxin, and the NADH-ubiquinone oxidoreductase (NQR)) to nitrogenase, molybdenum endorsement, and homeostasis, including respiratory chains modified to oxygen situations at which the biological nitrogen fixation process can operate (Dixon and Kahn 2004; Pedrosa and Elmerich 2007; Glick 2012). Nitrogenase assemblage requires products of additional *nif* genes which are involved in the synthesis of FeMoCo (*nifB*, *nifQ*, *nifE*, *nifN*, *nifX*, *nifU*, *nifS*, *nifV*, *nifY*, also *nifH*) and also in association of iron–sulfur clusters (*nifS* and *nifU*) and the development of the nitrogenase mechanisms (*nifW and nifZ*) (Hu et al. 2007; Rubio and Ludden 2008).

3.4.1.2 Phosphate Solubilization

Phosphorus (P) is another vital macronutrient for growth and development of plant after nitrogen. It is plentifully accessible in soils in both inorganic and organic forms (Fig. 3.3) (Fernandez et al. 2007; Ahemad 2015). But the rate of absorption by plants is very slow. The less accessibility of phosphorus to plants is because,

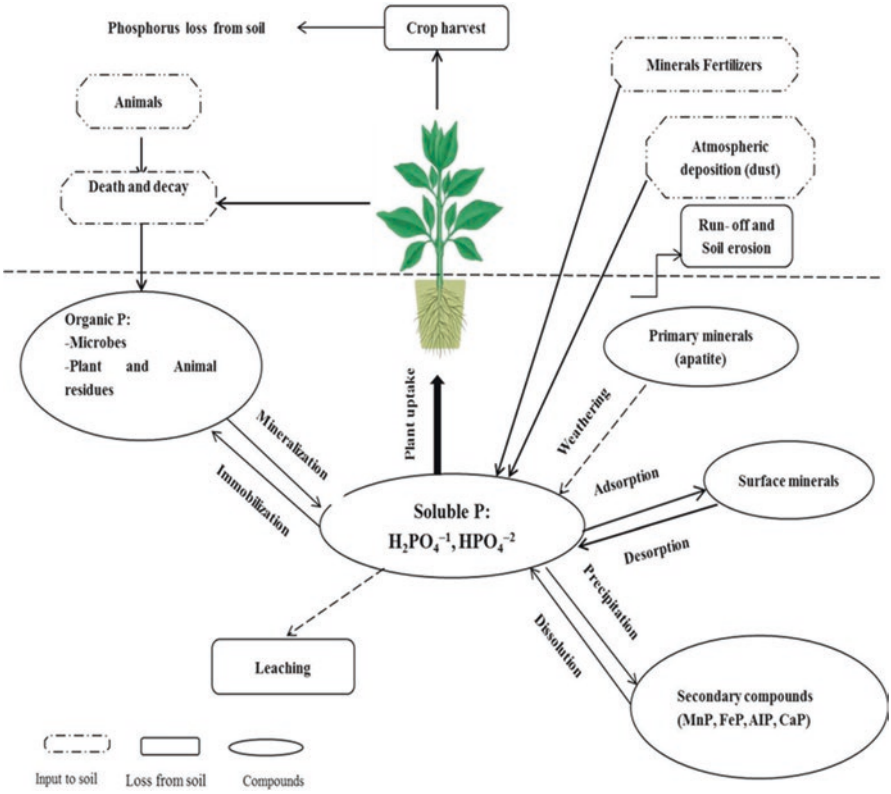

Fig. 3.3 Movement of phosphorus in soils

generally, the soil phosphorus is available in insoluble forms, while the plants uptake it in the forms of monobasic ($H_2PO_4^-$) and dibasic (HPO_4^{2-}) ions which are a soluble form of phosphorus (Bhattacharyya and Jha 2012).

The insoluble form of phosphorus is present in apatite which is an inorganic mineral or in the form of organic components such as inositol phosphate (soil phytate), phosphotriesterase, and phosphomonoesters (Glick 2012). Phosphatic fertilizers are applied for avoiding this type of shortage in soils. But a small amount of phosphorus is absorbed by the plants because most of the phosphatic fertilizers became precipitated (Mckenzie and Roberts 1990). Therefore, the regular application of phosphate fertilizer is objectionable for the ecological activity. In this context, the microbes have the capability of phosphate solubilization known as phosphate-solubilizing microorganisms. They may transfer the available forms of phosphorus to plants, therefore a sustainable substitute to chemical phosphatic fertilizers (Khan et al. 2006). The numerous phosphate-solubilizing microorganisms (PSMs) dwelling in the rhizospheric zone, considered as promising biofertilizers; subsequently they can supply the P to plants from various sources (Fig. 3.4) (Khan et al. 2006; Zaidi et al. 2009). Most substantial phosphate-solubilizing bacteria are

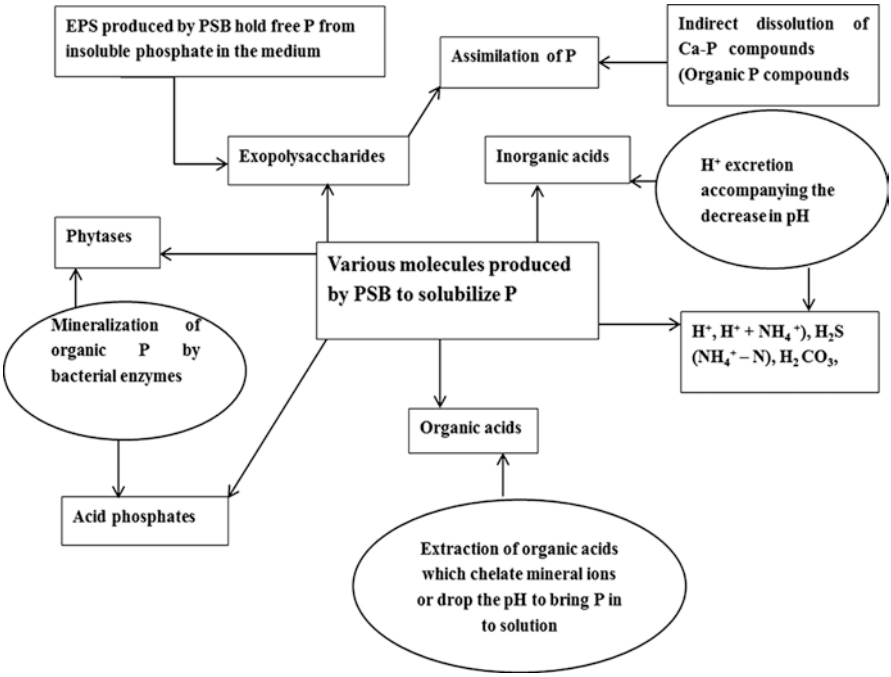

Fig. 3.4 PSB accountable for phosphate solubilization in the form of organic/inorganic substances in soils

reported such as *Azotobacter*, *Beijerinckia*, *Burkholderia*, *Bacillus*, *Enterobacter*, *Erwinia*, *Flavobacterium*, *Pseudomonas*, *Microbacterium*, *Serratia*, and *Rhizobium* (Bhattacharyya and Jha 2012). Usually, various soil-dwelling bacteria synthesized the low molecular weight organic acids which dissolved the inorganic phosphorus in soluble forms (Zaidi et al. 2009). On the other hand, the mineralization of organic phosphorus takes place by the production of various phosphatases, catalyzing the hydrolysis of phosphoric esters (Glick 2012). Significantly, the phosphate solubilization and mineralization can harmonize in the same strain of bacteria (Tao et al. 2008).

Under stress environment, the formation and performances of phosphate-solubilizing bacteria are harshly affected in soils (Ahemad and Khan 2013), but the advantageous effects of the inoculation with PSB used alone (Poonguzhali et al. 2008) or in amalgamation with other rhizospheric microbes have been reported (Zaidi and Khan 2005; Vikram and Hamzehzarghani 2008). Moreover providing the phosphorus to the plants, the phosphate-solubilizing bacteria enhance the plant growth by stimulating the efficiency of biological nitrogen fixation and augmenting the accessibility of other trace elements (Fe, Zn) and by producing essential plant growth-promoting substances (Ponmurugan and Gopi 2006; Mittal et al. 2008; Zaidi et al. 2009) (Table 3.2).

3.4.1.3 Siderophore Production

Iron is a dynamic micronutrient to plant growth, and it works as a cofactor of various enzymatic activities. It is also essential for major physiological procedures like N_2 fixation, photosynthesis, respiration, etc. (Sharma and Johri 2003). Iron is found mainly as Fe^{3+} in aerobic conditions and is prospectively to form insoluble hydroxides and oxyhydroxides. Thus it is normally inaccessible to both plants and microorganisms (Rajkumar et al. 2010). Siderophore complex iron (Fe^{3+}) is reduced to Fe^{2+} on the bacterial membrane which is further released *via* a gating mechanism into the cell from the siderophore (Ahemad and Kibret 2014). These are secreted to solubilize the iron from their circumstances, producing a complex of ferric siderophore that can transfer by diffusion and be returned to the cell surface (Beneduzi et al. 2012). These siderophores may be hydroxamates, phenol-catecholates, and carboxylates (Podile and Kishore 2006). The siderophores can be lesser peptidic particles containing various functional groups and side chains, which can deliver a high-affinity set of ligands to coordinate ferric ions (Crosa and Walsh 2002). Therefore, the siderophores work as solubilizing agents for Fe from minerals or organic compounds in limited conditions of iron (Indiragandhi et al. 2008). In the presence of heavy metals like Cr, Al, Cd, Cu, Ga, Pb, Zn, and radionuclides including U and Np, the siderophores form stable complexes that are of ecological concern (Neubauer et al. 2000; Ahemad and Kibret 2014). The bacterial siderophore sustenance to develop the strains is imposed on plants by rich soil levels of metals (Gamalero and Glick 2012). Plants absorb iron from bacterial siderophore using various mechanisms, for example, iron binding and discharge and absorption of siderophore-iron complexes directly or by a ligand interchange reaction (Ahemad and Kibret 2014).

Fluorescent *Pseudomonas* secreted yellow-green pigments and is characterized as pyoverdines which incandesce under UV light and utilized as siderophores (Agrawal et al. 2014). Additionally, the iron-pyoverdine complex production that has been detected in *P. fluorescens* C7 was taken up by *Arabidopsis thaliana* plant, inside the plant materials the iron content enhance the growth of plant (Vansuyt et al. 2007). The soil composition and various crop plants are also affected by siderophores activities which are effective pathogen-suppressive agents. Long-lasting specific suppression of *Fusarium oxysporum*-mediated wilt in flax and other susceptible crops by soil microbes (Janvier et al. 2007) and intercropping cultivation of corn and black-eyed pea against *Fusarium solani* CFF109 (Barros et al. 2014) are also examples of soil recollection. In both cases, suppression was recognized to a more diverse microbiome disturbed and sustained by diversified host disposal (Lapsansky et al. 2016). Furthermore, in the rhizosphere, the bacterial siderophores are commonly linked with biocontrol activities and not with the nutrition of plants (Vessey 2003). Latest researches confirmed the dominancy of soil-dwelling fungal pathogens through the discharge of iron-chelating siderophores by *Fluorescent pseudomonads*; adaptation is inaccessible to other microbes (Beneduzi et al. 2012).

3.4.1.4 Phytohormone Production

Plant growth-stimulating rhizobacteria (PGPR) produced plant hormones like indole acetic acid, gibberellins, cytokinins, auxins, and ethylene that can distress the cell propagation in the root way by excessive production of cross roots and hairs on root with a successive upturn of nutrients and uptake of water (Arora et al. 2013). Rhizospheric bacteria have the capability in the production of phytohormones which regulate the growth, improvement, and resistance responses of plants. Microbial production of the plant hormones such as auxin (indole-3-acetic acid/ indole acetic acid/IAA) recognized for a long time (e.g., cell division and differentiation), as well as rapid stimulation (e.g., increase in cell elongation) responses in plants (Egamberdiyeva 2007; Kaur et al 2016). It is described that eighty percent of microbes sequestered from rhizospheric regions from numerous crops have the capability to produce and discharge auxins as secondary metabolites (Patten and Glick 1996). Plant hormones such as ABA, IAA, and cytokinins were diligently linked to nitrogen signaling and provided insight that nitrogen and phytohormones signals were assimilated in order to change the morphological and physiological characters of plants (Kiba et al. 2011).

Mostly, the IAA which is secreted by rhizospheric bacteria interferes with the many plant innovative developments because the endogenous group of plant IAA may be improved by the attainment of IAA that has been secreted by soil bacteria (Spaepen et al. 2007a; Glick 2012) (Fig. 3.5). Indole acetic acid (IAA) promotes the seed and tuber propagation, with the increasing rate of xylem and root expansion; also affects the photosynthesis, pigment foundation, and biosynthesis of numerous metabolites; starts lateral and adventitious root formation; facilitates responses to light; and controls the procedures of vegetative growth, gravity, and fluorescence and resistance to hectic conditions (Spaepen and Vanderleyden 2007; Gupta et al. 2015). IAA has the capability of gene manifestation in numerous bacteria and acts as a mutual signaling molecule. The rhizobacterial IAA probably hampers the above biological processes of plants by modifying the plant's auxin pool. Similarly, the growth of root surface area and length increased by bacterial IAA, and thus it provides the plant greater access to soil nutrients (Glick 2012). Accordingly, the rhizobacterial IAA is recognized as an effective molecule in plant–microbe interactions, both in pathogenicity and plant growth promotion (Spaepen and Vanderleyden 2011; Glick 2014). Indole-3-acetamide that forms IAA through biosynthesis is stated for plant pathogenic bacteria *Pseudomonas syringae*, *Agrobacterium tumefaciens*, and *Erwinia herbicola* and saprophytic pseudomonads like *Pseudomonas putida* and *P. fluorescens*. Another amino acid like tryptophan is generally originated in root exudates and works as a precursor molecule for the biosynthesis of IAA in bacteria (Etesami et al. 2014). The independent pathway of tryptophan is more common in plants and also found in azospirilla and cyanobacteria. The biosynthesis of indole acetic acid by plant growth promoting rhizobacteria includes the production via indole-3- pyruvic acid and indole-3-acetic aldehyde, is the common apparatus in PGPRs like *Pseudomonas, Rhizobium, Bradyrhizobium, Agrobacterium, Enterobacter* and *Klebsiella* (Shilev 2013).

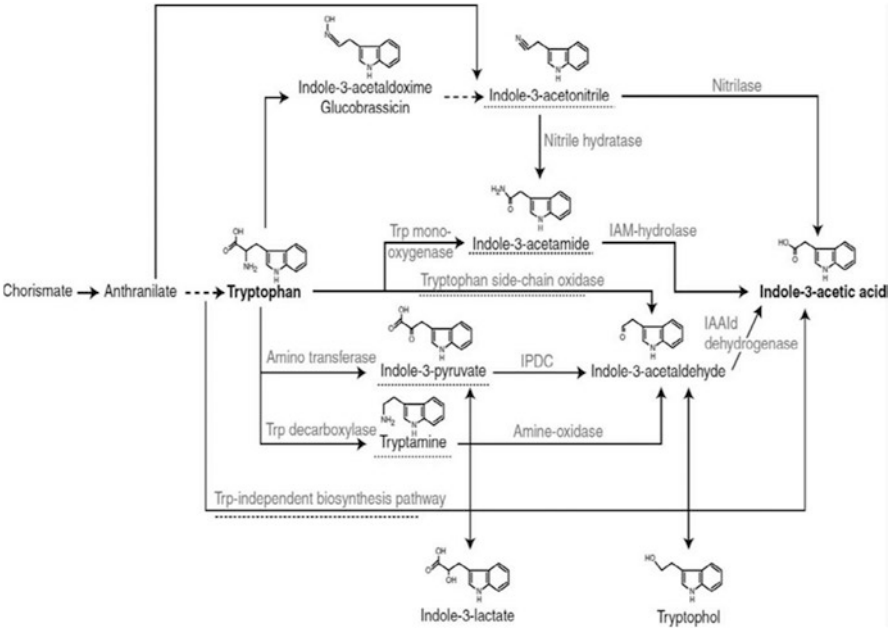

Fig. 3.5 Outline of several trails to the creation of IAA in bacteria. The intermediate mentioning to the name of the trail or the trail itself is highlighted with a dashed line. IAAld, indole-3-acetaldehyde; IAM, indole-3-acetamide; IPDC, indole-3-pyruvate decarboxylase; Trp, tryptophan (Adapted from Spaepen et al. (2007a)

3.4.1.5 1-Aminocyclopropane-1-Carboxylate (ACC) Deaminase

Ethylene has an extensive variety of biological activities that can distress the growth and improvement of plants; it is a key plant hormone (Khalid et al. 2006) and displays active role in root initiation, prevents root elongation, promotes lower wilting, motivates the seed germination, helps leaf abscission, stimulates fruit ripening, and activates the synthesis of other plant hormones (Kaur et al. 2016). It improves the growth of plants in various species such as *Arabidopsis thaliana* at a lower concentration, and generally it is known as senescence hormone because it inhibits the growth of the plant (Kaur et al. 2016). While, at higher concentrations, it encourages defoliation processes, it may reduce the production of the crop (Bhattacharyya and Jha 2012). An enzyme, 1-aminocyclopropane-1-carboxylate (ACC) deaminase, is reported in *Pseudomonas putida* bacterium and hydrolyzes ACC (precursor of ethylene) into ammonia and α- ketobutyrate (Zahir et al. 2003; Kang et al. 2010). The ACC is an essential enzyme for the production of ethylene and catalyzed by ACC oxidase. The several biochemical studies of ACC-deaminase designate that the substrate ACC is found essentially within plant tissues; the enzyme is not secreted by bacteria but is typically found in the cytoplasm (Glick 2014).

Pyridoxal 5-phosphate (vitamin B6) is an essential cofactor that is utilized by ACC-deaminase for enzymatic activity (Christen and Metzler 1985).

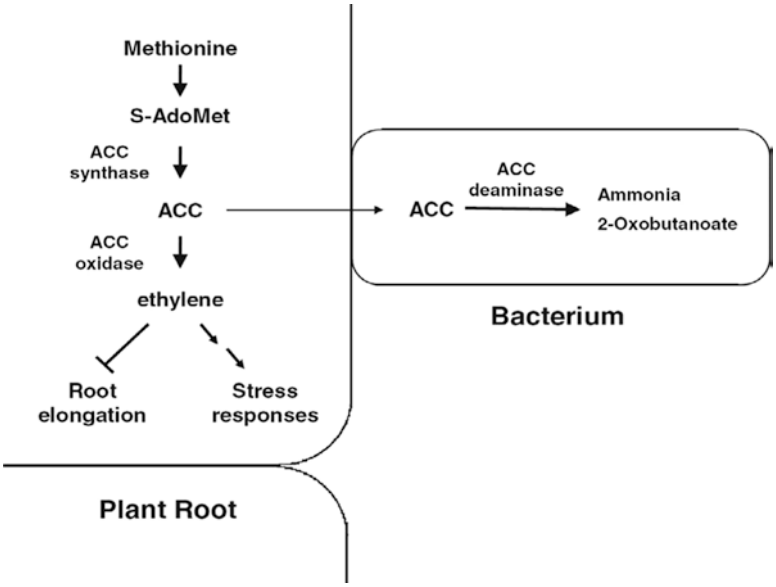

Fig. 3.6 A potential machinery of how stress controller bacteria diminish ethylene stages in the plant root by bacterial ACC-deaminase. ACC produced in plant tissues by ACC synthase is supposed to be transported from plant roots and be taken up by adjacent bacteria. After, the bacteria hydrolyze ACC to ammonia and 2-oxobutanoate. This ACC hydrolysis sustains ACC concentrations low in bacteria and permits continuous ACC relocation from plant roots to bacteria. Then, ethylene can be produced from ACC and then cause stress responses including growth inhibition. S-AdoMet: S-adenosyl-L-methionine; ACC: 1- aminocyclopropane-1-carboxylate (Adapted from Kang et al. (2010)

ACC-deaminase producers released various types of stress such as effects of plant pathogenic microbes like bacteria, viruses, and fungi and resistance to stress from salinity stress, oxidative stress, high temperature, hydrocarbons, heavy metals, radiation, wounding, insect predation, and water logging (Lugtenberg and Kamilova 2009). Consequently, ACC-deaminase-producing rhizospheric bacteria enhanced the growth of plants, rhizobial nodulation, mycorrhizal colonization, and N, P, and K uptake in various crops (Glick 2014). Several rhizospheric bacteria, for instance, *Achromobacter* sp., *Acinetobacter* sp., *Alcaligenes* sp., *Agrobacterium* sp., *Azospirillum* sp., *Burkholderia* sp., *Bacillus* sp., *Enterobacter* sp., *Ralstonia* sp., *Pseudomonas* sp., *Serratia* and *Rhizobium* sp., etc., have the capability for the production of ethylene (Zahir et al. 2010; Kang et al. 2010). These rhizospheric bacteria absorb the ethylene precursor ACC and convert it into 2-oxobutanoate and NH_3 (Arshad et al. 2007) (Fig. 3.6). The rhizospheric bacteria such as *Azotobacter* sp., *Rhizobium* sp., *Pantoea agglomerans*, *Rhodospirillum rubrum*, *Bacillus subtilis*, and *Pseudomonas fluorescens* also have the capability for the production cytokinins or gibberellins and enhanced the growth plants (Kang et al. 2010; Gupta et al. 2015).

3.4.2 Indirect Mechanisms

Biocontrol agents control the plant pathogens by microbial activity and have the eco-friendly approach (Lugtenberg and Kamilova 2009). The rhizospheric bacteria promote the plant growth by biocontrol agents through the indirect mechanisms (Glick 2012). Normally, the competition for nutrients, niche elimination, induced systemic resistance, and antifungal metabolites production are the main kinds of biocontrol activity in PGPR (Lugtenberg and Kamilova 2009). Various rhizospheric bacteria produced the antifungal metabolites such as HCN, 2,4-diacetylphloroglucinol, pyrrolnitrin, pyoluteorin, phenazines, viscosinamide, and tensin (Bhattacharyya and Jha 2012). Plant roots interaction of some rhizospheric bacteria can result in plant resistance against some pathogenic microbes such as bacteria, fungi, and viruses. It is known as induced systemic resistance (ISR) (Lugtenberg and Kamilova 2009). Moreover, the ISR mechanisms involve for ethylene signaling within the plant, and these hormones encourage the host plant's defense responses against several phytopathogens (Glick 2012). A lot of specific microbial mechanisms encourage ISR, like lipopolysaccharides (LPS), siderophores, flagella, homoserine lactones, 2, 4-diacetylphloroglucinol, cyclic lipopeptides, and volatiles like acetoin and 2,3-butanediol (Lugtenberg and Kamilova 2009).

3.4.2.1 Antibiosis

The biocontrol capabilities of *Pseudomonas* strains principally depend on antagonistic root settlement, initiation of collective conflict in plants, and manufacturing of antimicrobial antibiotics (Beneduzi et al. 2012). The antibiotic production machinery commonly linked with the rhizospheric bacteria to performance as hostile representatives against plant pathogens. There are six classes of antibiotic compounds, are better connected to the biocontrol of root diseases (Hass and Defago 2005), which are cyclic lipopeptides, pyrrolnitrin, phenazines, phloroglucinols, and pyoluteorin; all are found in the diffusible form and hydrogen cyanide (HCN) in volatile form (Beneduzi 2012; Nielsen and Sorensen 2003). Pyrrolnitrin antibiotic which is produced by *Pseudomonas fluorescens* BL915 strain has the capability to control the damage of *Rhizoctonia solani* throughout damping-off of cotton plants (Hill et al. 1994). Lipopeptide biosurfactants produced by some *Pseudomonas* and *Bacillus* species, which is used as biocontrol agent due to their possible progressive impact on functional associations with microorganisms like fungi, oomycetes, protozoa, nematodes, bacteria, and some plant species (Raaijmakers et al. 1999; de Bruijn et al. 2007). Pseudomonads also produced an effective and extensively studied antibiotic known as 2, 4-diacetylphloroglucinol (DAPG), which damages membrane to *Pythium* sp., produces the hindrance for zoospores formation in the oomycete (Bhattacharyya and Jha 2012), and acts as a biocontrol of bacterial canker of tomato (Lanteigne et al. 2012). Some *Pseudomonas* sp. also produced the phenazine, which possesses the redox activity, and it destroys the pathogenicity of plants, for instance, *F. oxysporum* and *Gaeumannomyces graminis* (Chin-A-Woeng et al. 2003). Phenazine −1-carboxamide is synthesized by *P. chlororaphis* PCL1391 bacterium isolated from roots of tomato plants, which has the capability to discharge the

solvable form of iron from ferric oxides at neutral pH and contributes to iron utilization in soils (Hernandez et al. 2004; Haas and Defago 2005). Circulin, colistin, and polymyxin antibiotics are vibrant against phytopathogens formed by the popular *Bacillus* sp. (Maksimov et al. 2011). Excessively, use of antibiotic-producing rhizobacteria as biocontrol agents for plant growth promotion, various plant pathogens produced the induced systemic resistance (ISR) mechanism for particular antibiotics due to the augmented habit of these isolates. For the avoidance of this type of popularity, various researchers exploited those biocontrol isolates that produce more than one antibiotics (Lugtenberg and Kamilova 2009; Glick et al. 1999).

3.5 Applications of PGPR as Multifunctional Agents

Commercial application of PGPRs (inoculants) in crops to enhance the growth of plant and increase productivity or induce systemic resistance against pathogens or bring about mitigation of stress tolerance in any environments as prospective plans used for ecological farming. The PGPR affects the farming which differs from the laboratory, glasshouse, and field trials, because the soil has a volatile background and an envisioned product is sometimes difficult to attain. PGPR activity is very much affected when the climate fluctuations take place. But occasionally poor growth conditions in the field are to be predicted as the usual functioning of farming (Zaidi et al. 2009). Plant growth-supporting characters do not work freely from each other. But additionally, as it was recommended in the "additive hypothesis," that various tools, for instance, nitrogen fixation, siderophore biosynthesis, phosphate solubilization, IAA, ACC-deaminase, and antifungal activity are accountable for the promotion plant growth and improve the productivity. It is observed that after using the rhizospheric bacteria, the productivity of various crops increased in both organized forms of soil as well as the natural environment (Table 3.3). Due to the prevailing lack of enthusiasm worldwide to hold foods produced by genetically modified plants, advantageous as a means of promoting plant growth globally, it reduces the requirement of agrochemicals products. Moreover, PGPR machinery is freely available to planters globally (Gamalero et al. 2009).

3.6 Conclusion

A perfect ecological farming system as PGPR is one which protects the environment, increases the productivity of cereals, provides food to the whole inhabitants universally, and maintains and improves the health problem of human being. These microorganisms are found in rhizospheric regions, which includes rhizobacteria, and symbiotic fungus species; having the capability to bioremediation potentials of heavy metal, biodegradation of xenobiotic compounds regulates the wide range of plant pathogens as biocontrol and provides the phytohormones as well as nutrients. After this, they can be used as biofertilizers, biocontrol agents without any harmful effect to the environment and sustainable forming.

Table 3.3 The examples of several plant growth-stimulating rhizobacteria tested for crop types

Plant growth-promoting bacterial species	Crop plant	Conditions	Results of addition of bacteria to plants	References
Pseudomonas aeruginosa, Bacillus sp., *E. faecalis*	Cucumber, chickpea	In vitro and field experiments	Have the capability to control the bacterial and fungal root pathogens and improve the growth of plants significantly	Oves et al. (2016)
Bacillus sp., *Pseudomonas* sp., *Azotobacter* sp., *Mesorhizobium* sp.	Wheat, rice, maize, pea, green gram, peanut, potato,	In vitro conditions, pot experiments, field study,	The quantity of N, P, Fe, and Mn is increased by the bacterial inoculum in wheat shoots grown in normal and saline soil and enhanced the growth of pepper, canola, bean, tomato, and lettuce under salinity stress	Shrivastava and Kumar (2015) and Singh (2015)
Streptomyces sp. strain PGPA39	"Micro-Tom" tomato	Pot experiments	Improves the salinity and stimulates growth of "Micro-Tom" tomato plants	Palaniyandi et al. (2014)
Bacillus pumilis, Pseudomonas sp., and *Acinetobacter* sp.	Barley and oats	Field experiments	Assist the growth of barley and oats in salt affected soil	Chang et al. (2014)
Pseudomonas pseudoalcaligenes	Salt-sensitive rice GJ-17	Field experiments	Decrease superoxide dismutase activity and lipid peroxidation	Jha and Subramanian (2014)
Pseudomonas fluorescens, Pseudomonas putida, Enterobacter cloacae, Serratia ficaria	Wheat	Pot experiments, field experiments, and in vitro experiments	Increase the growth rate, growth percentage, index and status of nutrient in wheat crops	Nadeem et al. (2014)
Pseudomonas and *Rhizobium*	Mung bean (*Vigna radiata* L.)	In saline condition	Increase the osmotic stress tolerance	Ahmad et al. (2013)
Rhizobium phaseoli	*Vigna radiata* L.	Pots experiments	*Rhizobium* alleviated the adverse effects of salinity in the presence of tryptophan and improved the growth, biomass and grain yield, quantity of nodules, and grain concentration of nitrogen per plant significantly	Zahir et al. (2010)

(continued)

Table 3.3 (continued)

Plant growth-promoting bacterial species	Crop plant	Conditions	Results of addition of bacteria to plants	References
Paenibacillus polymyxa	Pepper	Gnotobiotic conditions	Improved the plant biomass considerably and stimulated induced systemic resistance against bacterial spot pathogen like *Xanthomonas axonopodis* pv. Vesicatoria untreated plants	Phi et al. (2010)
Pseudomonas putida strain R-168, *Pseudomonas fluorescens* DSM 50090, *Azospirillum brasilense* DSM 1690	Maize (*Zea mays* L.)	Fields experiments	Improved the growth of leaf area, dry weight of shoot, height, and seed weight and seed quantity per year	Gholami et al. (2009)
Ralstonia metallidurans and *Pseudomonas aeruginosa*	Maize	Pots experiments	Encouraged the plant growth, assisted soil metal utilization, and enhanced Cr and Pb uptake	Braud et al. (2009)
Pseudomonas sp.	Chickpea	Pots experiments	Upgraded the dry and fresh biomass of crops at 2 mM concentration of Ni	Tank and Saraf (2010)
Azospirillum amazonense	Rice (*Oryza sativa* L.)	Greenhouse	Grain dry matter accumulation (7–11.6 %), number of panicles (3–18.6 %), and nitrogen accumulation at grain maturation (3.5–18.5 %) increased	Rodrigues et al. (2008)
Pseudomonas sp.	Rice (*Oryza sativa*), maize (*Zea mays* L.)	In vitro experiments	Have the proficiency to control the phytopathogens which are obtained from maize crops	Lawongsa et al. (2008)
Pseudomonas aeruginosa strain MKRh3	Black gram	Pots experiments	Reduction of cadmium accumulation observed in plants, extensive rooting, and improved growth of plants	Ganesan (2008)
Azospirillum brasilense Sp245	Common bean (*Phaseolus vulgaris* L.)	Greenhouse experiment	Root development increased	Remans et al. (2008)

Bacillus sp. *Paenibacillus* sp.	Rice	Pots experiments	Shoot and root growth significantly induced	Beneduzi et al. (2008)
Pseudomonas tolaasii ACC23, *Alcaligenes* sp. ZN4, *Mycobacterium* sp. ACC14	*Brassica napus*	Pots experiments	Protected canola plant against the inhibitory effects of cadmium	Dell'Amico et al. (2008)
Bacillus sp.	Barley (*Hordeum vulgare*)	Greenhouse experiments	Shoot and root weight increased up to 34.7 % and 16.7 %, respectively	Canbolat et al. (2006)
Sinorhizobium sp. Pb002	*Brassica juncea*	Microcosms	Phytoextraction of lead efficiency increased by *Brassica juncea*	Di Gregorio et al. (2006)
Xanthomonas sp. RJ3, *Pseudomonas* sp. RJ10, *Bacillus* sp. RJ31	*Brassica napus*	Pots experiments	Increased cadmium accumulation with plant growth	Sheng and Xia (2006)
Pseudomonas jessenii PS06, *Mesorhizobium ciceri* C-2/2	*Cicer arietinum* (chickpea)	Greenhouse, fields	The co-inoculation treatment increased the seed yield (52 % greater than the uninoculated control treatment) and nodule fresh weight	Valverde et al. (2006)
Azotobacter chroococcum HKN-5, *Bacillus megaterium* HKP-1	*Brassica Juncea*	Greenhouse experiments	Plant protected from metal toxicity, enhanced plant growth	Wu et al. (2006)
Variovox paradoxus, *Rhodococcus* sp.,	*Brassica juncea*	In vitro experiments	Root elongation increased	Belimov et al. (2005)
Pseudomonas fluorescens PGPR1, PGPR2, PGPR4	Peanut (*Arachis hypogaea* L.)	Pots and fields experiments	Pod yield increased significantly, nodule dry weight and halum yield over the control	Dey et al. (2004)
Pseudomonas fluorescens Avm, Rhizobium leguminosarum bv *phaseoli* CPMex46	Alfalfa	Growth chamber	Cu and Fe translocation improved from root to shoot	Carrillo-Castaneda et al. (2003)
Enterobacter sakazakii 8MR5, *Pseudomonas* sp. 4MKS8, *Klebsiella oxytoca* 10MKR7	*Zea mays* L. (maize)	Pot experiments	Growth parameters increased by the inoculation	Babalola et al. (2003)

Microbial Ecology at Rhizosphere: Bioengineering and Future Prospective

4

Shyamalina Haldar and Sanghamitra Sengupta

Abstract

Rhizosphere, the interface between soil and plant roots, is a chemically complex environment which supports the development and growth of diverse microbial communities. Studies in rhizosphere science have undoubtedly improved our ability to steer the knowledge into technological applications in agricultural industry, ecological engineering, and nature restoration. In this chapter we provide a holistic perception of rhizosphere functioning with a highlight on the ecological drivers that promote colonization of coherent functional groups of microorganisms influencing plant life through several direct and indirect mechanisms. We also discuss how the activities of the indigenous microbes from rhizosphere may be exploited toward developing profitable techniques or methods in sustainable agriculture, biotechnology, and environmental management. In this context, we emphasize on the need for high degree of innovation and active collaboration between basic research and technology development wings for the best use of the knowledge in order to meet the increasing global demand for food, fiber, and bioenergy.

4.1 Introduction

Rhizosphere represents one of the most diverse habitats on our planet (Trabelsi and Mhamdi 2013). It is technically defined as the soil adhering to the root which is chemically enriched with the substances released from the plants and stimulate microbial growth and activities. Over the past two decades, a growing body of empirical research has shown that ecological and biochemical processes in the rhizosphere are mediated by intricate arrays of direct and indirect interactions occurring between the plants and residing microorganisms which cumulatively make the microenvironment unique, physically, chemically, and biologically (Fig. 4.1). Rhizosphere processes, at a global scale, utilize approximately half of the total energy fixed by photosynthesis in terrestrial ecosystems, contribute roughly 50 % of the total carbon dioxide emitted from terrestrial ecosystems, and mediate virtually all aspects of biogeochemical transformation, biomass turnover, and nutrient cycling (Hopkins et al. 2013). Plants and the rhizobiome together contribute to a significant extent, for the preservation of biodiversity and ecological sustainability of urban green infrastructures (Weyens et al. 2015). Consequently, there is a worldwide effort to comprehend and model rhizosphere functioning using multiscale information generated through genetics, genomics, metabolomics, and system biological approaches for effective translation of this knowledge for the upliftment of human health and living (Weyens et al. 2015). Fortunately for us, due to recent technological advances, the paradigm of microbiology has shifted toward understanding and

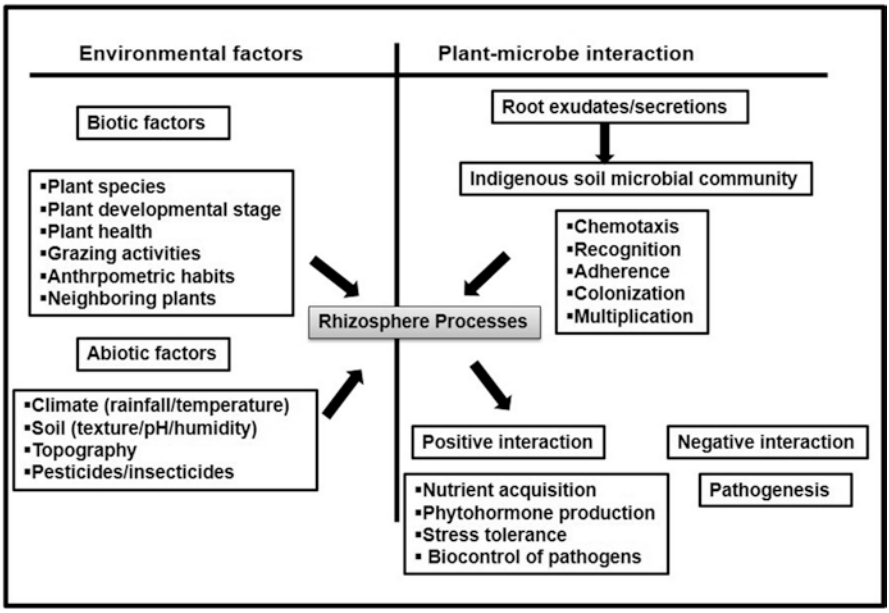

Fig. 4.1 Physical, chemical & biologial interactions affecting plant's rhizosphere

predicting the function of rhizo-consortia instead of a single dominant species. We are beginning to understand how plant systems interact with their environment, monitor biotic or abiotic stresses, and battle diseases in the field by modulating the associated microbial forum (Hill et al. 2013). Efforts have been initiated to engineer the knowledge into practical application such as production of sustainable food, fiber, and energy, maintenance of forest ecology and biodiversity, management of water resources, and alleviation of climate change (Mark et al. 2006; Jones 2008; Dessaux et al. 2016). In this book chapter, we summarize this worldwide endeavor by throwing light on the mechanistic and the ecological knowledge of the rhizosphere accumulated so far with a focus on agro-economy, biotechnology, and environmental management.

4.2 Microbial Ecology in the Rhizosphere

Following the colonization in the terrestrial ecosystem, "plants" as sessile organisms communicate with innumerable microorganisms residing in its ecosystem. The most significant part of this operates belowground, in general, and in the rhizosphere, in particular. Studies on rhizosphere date back to 1904, when Lorenz Hiltner (1904) observed that microbes are more abundant in rhizosphere than they are in distant soil environment. Since then a huge body of literature has accumulated and unequivocally demonstrated that this narrow zone of soil is a highly favorable site for microbial activities. It may contain up to 10^{11} microbial cells per gram root and more than 30,000 prokaryotic species (Egamberdieva et al. 2008; Mendes et al. 2011). Rhizosphere may be imagined as a cloud of microbes, vital for plant growth and survival, surrounding the plant root. Microbial proliferation at the plant roots and root–soil interface is supported by diverse varieties of root exudates (Badri et al. 2009). It is estimated that the collective genome of the rhizosphere microbial community is much larger than that of the plant itself and hence affectionately referred to as the plant's second genome (Berendsen et al. 2012). At present, the entire consortium of plants and associated microorganisms is perceived as a holobiont and is no longer recognized as "individual entities" (Dessaux et al. 2016).

4.2.1 Rhizosphere: A Platform for Microbial Growth

4.2.1.1 Rhizosphere as a Chemical Hotspot

Microbial colonization in rhizosphere is rooted to the phenomenon of "rhizosphere processes" which is collectively composed of various physicochemical and biological turnovers defined by the host plant through the uptake of minerals and water and subsequent release of nutrients and carbon dioxide, exudation, and secretion of an array of chemical compounds (Philippot et al. 2013). Significant advances in our knowledge about plant exudate chemistry and the impact of "rhizodeposition" on microbial growth at the root–soil interface have been made in the last few years (Smalla et al. 2001; Dunfield and Germida 2003; Nunan et al. 2005; Mougel et al.

2006). It may be surmised from these studies that many soil microorganisms remain dormant in the absence of organic input due to general carbon (C) limitation in normal soil (Owen et al. 2007). Growth of plants triggers an increase in the rate of turnover of soil organic matter (SOM) in the order of 20- to 30-folds around areas of exudation, and this pulse of organic input often fosters microbial activity and associated soil organic matter (SOM) turnover (Xiao et al. 2007). In contrast to bulk soil, rhizosphere is thus extremely nutrient rich due to the abundance of low molecular weight (LMW) compounds released during normal root cell metabolism (root exudates): both low and high molecular weight compounds that are synthesized for secretions (root secretions) and compounds released by plant cell lysis (Marschner 1995). Microorganisms thrive on these resources and form a plant-specific assemblage in the rhizosphere.

Mucilage secreted from the growing roots contains hydrated polysaccharides, organic acids, vitamins, and amino acids and can also bind to water molecules. This creates a well-hydrated environment supportive of microbial growth. Developing roots generally support fast-growing microorganisms like bacteria, whereas matured roots support slower-growing organisms such as fungi and actinomycetes; the latter produce less mucilage and fewer cell lysates due to the absence of border cells and emerging lateral roots and also leak less water due to the deposition of a water-impermeable layer around epidermal cells. Outward diffusion of nutrients and inward movement of salts and minerals during transpiration develop complex chemical gradients around the root and create a range of distinct microbial habitats. LMW carbon compounds such as sugar, organic acids, amino acids, and flavonoids are readily assimilated by microorganisms and play a primary role in regulating microbial community dynamics in the rhizosphere (Bais et al. 2006). Flavonoids, a diverse class of polyphenolic compounds, often serve as important chemical cues in mediating plant–microorganism interactions (reviewed by Shaw et al. 2006). Surfactant-active compounds such as carboxylic compounds in the root exudates have been found to increase the solubility of the heavy metals/toxic substances and make them bioavailable to root-colonizing microorganisms (Balseiro-Romero et al. 2014). Root volatiles include sulfur-containing compounds or the terpene (E)-b-caryophyllene which serve as foraging cues for parasitic entomopathogenic nematodes [EPNs] (Hiltpold and Turlings 2012; van Dam and Bouwmeester 2016). Organic phosphorus which is, in general, poorly available is solubilized through grazing by nematodes (Wenke et al. 2010). Phenolic compounds such as salicylic acid and gamma-aminobutyric acid (GABA) in the root exudates are suggested to send specific signals for soil bacteria, namely, *Sphingomonas*, *Methylobacterium*, *Frankineae*, *Variovorax*, *Micromonosporineae*, and *Skermanella* (Badri et al. 2013).

4.2.1.2 Factors Affecting Rhizo-Atmosphere

Much of our current understanding about rhizosphere incidences has emerged from studies on agricultural or horticultural crop plants: model species such as *Arabidopsis thaliana* (Bulgarelli et al. 2012) and *Medicago truncatula* (Kisiel and Kepczynska 2016) and a few noncultivated plant species such as arbuscular mycorrhizal associations (Bennett and Bever 2007). The excerpt from these findings points that plant

genetic makeup unequivocally plays a dominant role in the selection of rhizobacterial community. This is not surprising because the variety and amount of the compounds synthesized and released by roots are mostly under the plant's physiological and genetic control (Costa et al. 2006; Berg and Smalla 2009; Badri et al. 2009). Corroboratively root microbiome of plants grown in the same soil has been found to differ between plant species (Curlango-Rivera et al. 2013; Bonito et al. 2014) and between ecotypes, chemotypes, and genotypes within species (Micallef et al. 2009; Hill et al. 2013; Bulgarelli et al. 2013). To be more specific, plant-specific variation in root exudation is regulated both quantitatively and qualitatively by the root system architecture (RSA) which is determined by the inherent genetic factors and varies across plant species (Badri and Vivanco 2009). Secretion of phytochemicals and proteins from roots is an important way for plants to respond to various environmental factors and stresses (Walker et al. 2004; Bais et al. 2004). Root structure additionally affects oxygen pressure and carbon and nitrogen availability which in turn influences nitrogen transformation by soil microorganisms (Blossfeld et al. 2011). Furthermore, root growth changes the physical and chemical properties of the soil, including the mineral and organic content, the water potential, the pH, and the salinity.

The type and condition of soil also influence the nature of rhizodeposits. Nutrient deficiency is a major factor enhancing the secretion of metabolites by plant roots (Rengel and Marschner 2005). Besides, the presence or absence of particular minerals or toxic metals affects the composition of root exudation. For example, citric, malic, and oxalic acids are secreted to detoxify aluminum (Wang et al. 2006). Secretion of phenolic compounds is increased in phosphorus-deficient soils (Khorassani et al. 2011), while secretion of flavanones and flavones is enhanced in nitrogen-limiting conditions (Schultze and Kondorosi 1998). Mineral deficiency enhances the production of elicitors that influence root exudation. For example, potassium deficiency increases jasmonic acid-mediated defense responses (Schachtman and Shin 2007). Hypoxia due to high soil moisture causes an increased anaerobic respiration rate resulting in accumulation of ethanol, lactic acid, and alanine in the rhizosphere (Rivoal and Hanson 1994). Low temperature and light reduce secretion of root exudates. For example, the exudation of tannins and phenolic compounds in *Vicia faba* was greatly reduced at 4 °C compared to the amounts secreted at 30 °C (Bekkara et al. 1998). The root exudation process follows diurnal rhythms with exudation increasing during light periods (Watt and Evans 1999). In the root exudates from *Alnus glutinosa* (L.), the flavonoid content has been found to be increased under light conditions (Hughes et al. 1999). Root exudation is even affected by neighboring plant species. Quantity of glucosinolates in the root exudates is increased when *Arabidopsis* plants are grown at a higher density causing a shift of the rhizobiota toward the glucosinolate-utilizing microorganisms (Wentzell and Kliebenstein 2008). Root-induced pH changes in the rhizosphere influence bioavailability of phosphate and copper by modulating adsorption and precipitation of ions and soil minerals, respectively, and thereby shape the microbial ecology in the root environment (Bravin et al. 2009).

4.2.2 Microbial Community Structure

In general, the microbes take the advantage of the nutrients that the plant provides as discussed above, and in effect, they assist their host plant in making more essential nutrients (reviewed in Mendes et al. 2013). Therefore, microorganisms typically represent the largest fraction of belowground biomass. One gram of soil is thought to constitute tens of thousands of microbial "species" (reviewed in Kent and Triplett 2002). Microbes in rhizosphere can be broadly classified as bacteria, fungi, nematodes, protozoa, and actinomycetes. Of these, bacteria and fungi are most well documented.

4.2.2.1 Bacteria

The ratio of the microbial population in the rhizosphere (R) to that in the bulk soil (S), i.e., R/S value, is >=20 for the bacteria, while that for fungi and actinomycetes are 10 and 2–3, respectively (Bagyaraj and Rangaswami 2005). The overall proportion of aerobic bacteria is relatively less in the rhizosphere because of low level of oxygen due to root respiration. Rhizosphere is programmed to recruit wide range of bacterial genera, beneficial to the plants by using the signals from the host. The beneficial bacteria are collectively termed as plant growth-promoting rhizobacteria (PGPRs). The most common genera of bacteria observed in the rhizosphere include *Acinetobacter, Agrobacterium, Alcaligenes, Arthrobacter, Azospirillum, Azotobacter, Bacillus, Cellulomonas, Flavobacterium, Micrococcus*, *Mycobacterium, Pseudomonas*, and *Rhizobium*. PGPRs may be categorized depending on their modes of beneficial action into biofertilizers, phytostimulators, biopesticides, and elicitors of tolerance to abiotic and biotic stresses (Bhattacharyya and Jha 2012; Bhardwaj et al. 2014; Perez-Montano et al. 2014; Yang et al. 2009). A list of common beneficial bacteria is given in Table 4.1.

Biofertilizers directly promote plant growth by endowing plants with nutrients such as nitrogen, phosphorus, and trace elements (iron) which otherwise would have remained inaccessible to the plants. They are composed of *Rhizobium* sp., *Pseudomonas fluorescens*, *Trichoderma* sp. (e.g., *Trichoderma asperellum* and *Trichoderma hamatum*), and *Allorhizobium* sp. Of these, root nodule symbiosis established by *Rhizobium* sp. with legumes for nitrogen fixation has been vividly investigated (reviewed in Wang et al. 2012). Besides nitrogen, iron is another important element required for the growth of plants. However, it is essentially unavailable in aerobic environments, as it tends to form insoluble hydroxides at biological pH (Guerinot 1994). Rhizobia (*Bradyrhizobium japonicum*, *Sinorhizobium meliloti*, *Rhizobium leguminosarum bv. Viciae*, *Rhizobium ciceri*), fluorescent pseudomonads, *Enterobacter*, *Burkholderia*, and streptomycetes are capable of producing LMW compounds called siderophores that complex with ferric iron and several membrane-bound/periplasmic proteins (Neilands 1995; Crosa and Walsh 2002). This iron sequestration helps these bacteria to establish themselves in the rhizosphere and also to provide plants with soluble iron. *Bradyrhizobium japonicum* and *Sinorhizobium meliloti*, on the other hand, also help the plants to take up the natural siderophores (ferrichromes) present in the soil directly by forming heterologous

Table 4.1 Mechanism of action of plant growth-promoting rhizobacteria (PGPR) and biocontrol agents (BCAs)

Microbial species	Mechanism of action	References
PGPR (biofertilizers and phytostimulators)		
Rhizobia	Nitrogen fixation; inorganic and organic nutrient solubilization; plant growth regulator (IAA, gibberellins, cytokinines) synthesis	Ferguson and Mathesius (2014)
Pseudomonads	IAA production; siderophore production and phosphate solubilization	Ajilogba and Babalola (2013)
Firmicutes		
Burkholderia		Farag et al. (2013) and Ghosh et al. (2016)
Azotobacter sp.	Cytokinine production; nitrogen fixation	Leaungvutiviroj et al. 2010
BCA (biopesticides)		
Rhizobium sp.	Disease suppression (antibiosis, competition for iron, enhancing plant defense mechanism)	Dutta et al. (2014)
Pseudomonads	Systemic resistance induction; antifungal volatile production; induced systemic tolerance to high temperature and salinity; stabilization of soil aggregates; quorum quenching (QQ)	Ajilogba and Babalola (2013) and Farag et al. (2013)
Firmicutes (*Bacillus* sp.)		
	Induced systemic resistance (ISR); antifungal volatile production; quorum quenching (QQ); induced systemic tolerance (IST) to high temperature and salinity	Shrivastava and Kumar (2015)
Burkholderia	Induced systemic tolerance for drought by producing ACC-deaminase	Onofre-Lemus et al. (2009)
Azotobacter sp.	Oxidative stress tolerance through production of abscisic acid (ABA) and degradation of reactive oxygen species (ROS)	Marsalek and Simek (1992)

PGPRs are also endowed with biocontrol properties, while BCA can also stimulate direct plant growth

siderophores (Powell et al. 1983). Likewise, a large proportion of phosphorus exists in insoluble forms in the soil. Phosphate-solubilizing bacteria like *Enterobacter*, *Pantoea*, *Pseudomonas*, *Klebsiella*, *Cedecea*, *Cronobacter*, *Bacillus*, *Rhodococcus*, *Arthrobacter*, *Chryseobacterium*, *Delftia*, *Gordonia*, *Phyllobacterium*, and *Serratia* identified from the rhizosphere of various plants have shown the ability to solubilize inorganic soil phosphates, such as $Ca_3(PO_4)_2$, $FePO_4$, and $AlPO_4$, by synthesizing organic acids (citric, gluconic, lactic, succinic, and propionic acids), siderophores, and hydroxyl ions (Chen et al. 2006; Sharma et al. 2013).

Rhizobium, *Pseudomonas*, *Bacillus*, *Azospirillum*, *Enterobacter*, *Azotobacter, Pantoea*, and *Streptomyces* are grouped as *phytostimulators* by the virtue of their ability to produce phytohormones like indole-3-acetic-acid (IAA), gibberellic acid (GA3), and cytokines which directly enhance plant growth by modulating root

system architecture (Spaepen et al. 2007; Apine and Jadhav 2011; Duca et al. 2014). Coordination among the hormonal pathways is associated with overall development in plants. In addition, this is important for the maintenance of plasticity of plant morphogenesis essential for plants to respond to environmental cues (Hardtke et al. 2007). Gibberellins regulate cell elongation, cytokinins control cell proliferation, and auxin modulates both (Hardtke et al. 2007; Nakaya et al. 2002). Gibberellins act in collaboration with auxins to regulate the transition of root meristem cells from division to elongation (Hardtke et al. 2007). IAA and cytokinins regulate the root development by acting as a "control switch" between cell division and differentiation, thereby controlling the size of the organs (Barrada et al. 2015). Root morphogenesis and growth are basically controlled through a cross talk between these phytohormones where IAA increases the length and cytokinins maintain the length by inhibiting extra growth (De Vos et al. 2014).

Pseudomonas sp. (e.g., *P. fluorescens, P. cepacia, P. aeruginosa, and P. aureofaciens*) and *Bacillus* sp. (e.g., *Bacillus subtilis*) along with *Streptomyces* sp. are termed as *biopesticides* or *biocontrol agents* (BCAs) due to their role in inhibition of plant pathogens by producing hydrogen cyanide, 2,4-diacetylphloroglucinol, pyrrolnitrin, phenazine, oomycetes, and other compounds and thereby conferring protection against diseases (Kwak and Weller 2013; Haas and Keel 2003). BCA also inhibits the growth of pathogenic bacteria directly by quorum quenching. N-Acyl-homoserine lactone (AHL), an important molecule for cell to cell communication and used by several plant pathogens to establish virulence, is degraded by N-acyl-homoserine lactonase (AHL-lactonase), produced by *Bacillus* sp. Fluorescent pseudomonads can suppress the growth of pathogens by efficiently competing with them for the siderophores. Pyoverdines, produced by pseudomonads have a very high affinity toward iron in comparison to other microbes and thereby can limit the availability of iron for the pathogens in the rhizosphere (Cezard et al. 2015).

The other groups of rhizobacteria (*Burkholderia* sp., *Enterobacter* sp., *Rhizobium* sp.) assist plants to tolerate stress due to accumulation of reactive oxygen species and 1-aminocyclopropane-1-carboxylate (ACC). The latter molecule is an intermediate in ethylene biosynthesis. Ethylene is activated under nutrient stress and is harmful for the plants during post-harvest phases (Khan et al. 2015). *Bacillus subtilis* and *Achromobacter piechaudii* enhance salinity tolerance in plants growing in coastal regions, while *Paenibacillus polymyxa* and *Rhizobium tropici* have been reported to provide tolerance to drought stress in *Arabidopsis*, tomato and common bean (Mayak et al. 2004; Zhang et al. 2008; Timmusk and Wagner 1999; Yang et al. 2009).

4.2.2.2 Fungi

Both symbiotic and pathogenic fungi reside in the rhizosphere. One gram of rhizosphere soil harbors 10^5–10^6 organisms. Arbuscular mycorrhizal fungi (AMF), belonging to *Glomerales*, are one of the oldest groups of fungi that have been hypothesized to form the most primitive interaction with plant roots. This multitrophic symbiosis is present ubiquitously in the terrestrial plants, both from natural

and agricultural ecosystems, including gymnosperms, ferns, angiosperms, halophytes, hydrophytes, and xerophytes. Therefore, the beneficial role of AMF in biofertilization and bioremediation has been widely explored (reviewed in Lee et al. 2013). The beneficial outcome of the root–AMF association is mutually determined by the microbial consortia and soil chemistry (Khan 2006). The positive effect of AMF on plant physiology is modulated in the presence of specific microbe–microbe interaction. For example, co-inoculation with mycorrhization helper bacteria (MHB) such as *Bacillus* sp. in nutrient-poor soils has been found to improve the mycorrhizal effects (Vivas et al. 2003). AMF improve the productivity, biomass and diversity of plants by mineral sequestration (phosphorus scavenging and nitrogen acquisition), nutrient acquisition, and increased tolerance of the plants to abiotic stresses [drought/salinity resistance] (Lenoir et al. 2016; Porras-Soriano et al. 2009). In addition, AMF alter the overall microbial activity in the soil by modulating the rhizodeposits and improving the soil quality through immobilization of heavy metals (Yang et al. 2015). The wide surface area of the extra-radical mycelium and the synthesized iron-containing protein, "glomalin," by AMF, cooperatively determine the beneficial activities of AMF. Glomalin also contributes to the sequestration of toxic elements to enhance survival rate of the plants in polluted soils (Khan 2006). Glomalin has a role in the stabilization of soil aggregates leading to an improved penetration of the soil by water and air and also rendering an enhanced resistance to soil toward erosion (Rillig and Mummey 2006). AMF may act as a biocontrol agent by protecting the host plant against biotic stresses such as plant-parasitic nematode (PPN) infection by induced systemic resistance (ISR) and direct competing with the nematodes for space and nutrients (Schouteden et al. 2015). Increased rate of root respiration and respiratory acclimation due to AMF colonization in tropical plants is also reported. This indicates a role of AMF in terrestrial organic carbon influx as well (Fahey et al. 2016).

A common mycorrhizal network (CMN) is sometimes shared among the plants. AMF in this instance contribute to the transfer, distribution, and partitioning of carbon, nitrogen, phosphorus, and water from source (resource-rich plants) to sink (resource-poor plants) (Walder et al. 2016). This net translocation offers multiple benefits to the plants under environmental stresses not only by providing an access to resources from other plants but aiding to a speedy revival from the periods of rigorous water stress and protecting against pathogens (Babikova et al. 2013). AMF can also act as a support system for seedling establishment and can influence plant invasion success (Klironomos 2002). Recent observations have shown that the co-occurrence of complementary diverse AMF species among the plants in a single region helps in increased plant to plant facilitation, an important ecological process practiced by the woody plants to establish themselves in semiarid areas (Montesinos-Navarro et al. 2012). However, species richness and genetic variation among AMF is the major factor influencing plant species diversity and ecosystem functioning (van der Heijden et al. 2006). Conversely, response to AMF inoculation is also dependent on the genotype of plants. But this plant genotype-dependent AMF colonization has been explored inadequately to date (Montes-Borrego et al. 2014). In natural systems, among the AMF, *Glomus* sp. has been most comprehensively

studied for their pertinent role in plant productivity as biofertilizers and BCA (Labidi et al. 2015). Another widely studied AMF species in pot cultures is *Rhizophagus irregularis* (Tisserant et al. 2013). Nevertheless, recent advancements in "omics" techniques have helped to assess a huge number of both active and spore-forming AMF taxa from the soil, indicating that molecular diversity of soil AMF is enormous and thus might be manipulated toward sustainable agriculture and phytoremediation (Davison et al. 2012).

Trichoderma sp. is another important fungal BCA that combats with plant pathogens via multifarious mechanisms including competition, antibiosis, induced resistance, and parasitism and thereby offer an indirect beneficial effect on plant health (Zhang et al. 2015a, 2016). Many species of *Trichoderma* have been reported to exert direct effects on plant growth through solubilization of plant nutrients and/or better uptake of macro- and micronutrients and through production of plant growth factors (Li et al. 2015). However, our knowledge about *Trichoderma* sp.-mediated plant growth promotion is still limited.

4.2.2.3 Others

Although bacteria and fungi form the most significant members of the microbial consortia in rhizosphere, the other micro-/macroorganisms such as nematodes, protozoa, and oomycetes are also present. This latter group of species is mainly marked for their pathogenic invasion with the plants. Nevertheless, they too exert few microbial control properties to inhibit the growth of other pathogens like insects in the rhizosphere (Lacey et al. 2015).

The nematodes are complex eukaryotic invertebrate worms and mostly free-living which parasitize plants as well (reviewed in Kenney and Eleftherianos 2016). Among the nematodes, the genera *Steinernema* and *Heterorhabditis* have been identified as potent microbial control agents (MCA) that resist the growth of a number of pathogenic insects and pests in the rhizosphere. Beneficial EPNs are obligate parasites that destroy the insect very rapidly and hence are considered as one of the potent BCAs in several cropping systems (Ehlers 2003). Considerable progress toward the application of these EPNs in agriculture and pest management has been made in the past decade (Lacey et al. 2015). Secondary metabolites exuded from root tips play a dual role in attracting the nematodes so that the EPNs are selected over the pathogenic nematodes (Hiltpold et al. 2015). Studies have shown that insect herbivory at the roots could induce the secretion of volatile substances that attract EPN like *Heterorhabditis megidis* in many wild and cultivated plants, and thus this was adopted as an important plant defense mechanism against insects (Rasmann et al. 2005; Ali et al. 2010).

Protozoa, the unicellular animals, feed on microorganisms and form a ubiquitous group of rhizo-fauna. Protozoa by virtue of their grazing activities stimulate microbial decomposition and stimulate the release of organic matter and supplies plants with adequate nitrogen which otherwise would have remained limitedly accessible. Increased availability of nitrogen benefits AMF which transport it via the hyphae to the internal roots. The grazing also fosters rapid transportation of photosynthates from aboveground to belowground roots. In this process, the protozoa subsequently

interact with AMF and strengthen the interaction by controlling the nutrient supply (Koller et al. 2013a, b).

Frankia, nitrogen-fixing *Actinobacteria* that form symbiotic association with actinorhizal plants, has a potential role in increasing soil fertility and thereby enhancing the plant productivity in degrading and nitrogen-limiting soils (Diagne et al. 2013). This actinorhizal association is very productive toward maintenance of soil stability and henceforth facilitates the establishment and development of subsequent plant communities in disturbed landforms (Gtari et al. 2012). *Frankia* indirectly influences the plant productivity mitigating the adverse effects of salinity, drought, and contamination of heavy metals in degraded lands. As a whole, this association considerably enhances the plant growth, nitrogen content in roots and shoots, overall biomass, and survival rate of the plants (Diagne et al. 2013).

4.3 Bioengineering: Turning New Knowledge into Useful Societal Benefit

Demand for food, fiber, fuel, and other amenities will continue to grow as a result of population growth and rising incomes. To meet up these mounting demands, the stress on the natural resources and environment is leading to the resource depletion and environment destruction. Sustainable intensification is proclaimed to be only alternative to overcome this problem (Gregory et al. 2013). The goal of sustainable intensification is to maximize agricultural output from existing farmland while minimizing pressure on the environment. To accomplish this, an integrative approach coalescing biological science with community ecology is needed (Reynolds et al. 2014). In this "omics" era of new molecular tools and biotechnological advances, the knowledge accrued from basic research is expected to contribute more meaningfully to the development of more sustainable systems of intensive production (Ryan et al. 2009).

4.3.1 Rhizosphere Engineering

"Rhizosphere engineering" refers to the manipulation of a plant's root and surrounding milieu with a view to create a "biased" environment that will specifically enhance the crop productivity and plant survival (Ryan et al. 2009). In nature, plants themselves can adapt to any unfavorable environment by developing a variety of strategies; one of them being the modulation of rhizosphere chemistry. The knowledge of plant's inherent mechanisms is basically applied for any kind of "rhizosphere engineering/management." The selection of appropriate crop species, soil amendments, introduction of beneficial microorganisms, and genetic modification of plant and microbial activities are the fundamental components of rhizosphere engineering (Ryan et al. 2009). The benefit of managing rhizosphere is multifold. It not only paves the way to increased production of food/fiber/fuel but also results in diminished dependence on agrochemicals through replacement of their functions with

beneficial microbes, biodegradable biostimulants, or transgenic plants. As a consequence, the environmental and ecosystem integrities are preserved. Bioremediation is another aspect of rhizosphere engineering, which uses natural/genetically modified organisms/plants to degrade environmental pollutants and soil contaminants to restore the environmental and the ecological balance (Bisht et al. 2015). Rhizosphere engineering has emerged as an important tool to provide a cost-effective and environmentally sustainable "green technology" to address several global problems due to population growth. Research has confirmed a considerable progress in this field to date but still holds promise for further development (Ryan et al. 2009).

4.3.2 Rhizosphere Engineering and Agriculture

The goal of plant–microbiome engineering is to stimulate the wide spectrum of interaction among the phytomicrobiome toward overall enhanced beneficial outcome for the plant (Quiza et al. 2015). The two major aspects that are primarily taken care of are irrigation and application of fertilizers. The latter usually shifts the soil microbiome in and around the roots by altering soil pH. The acidic fertilizers (ammonium based) decrease the pH of the rhizosphere, while the basic fertilizers (nitrate based) enhance the alkalinity of the soil (Ryan et al. 2009). The practice of organic agriculture through input of organic fertilizers such as animal manure, biosolids, and composts is well established worldwide (Savka et al. 2002; Lim et al. 2015; Mazzola 2007). However, the lack of knowledge about the population of desired microorganisms in composts results in lack of reproducibility of the methods. Besides, this method adversely affects the soil acidity, salinity, and root colonization of certain species such as AMF. Moreover, biohazards due to toxic materials from biowaste and heavy metals used in compost composition cannot be overlooked (Quiza et al. 2015). To facilitate long-lasting modification in the rhizosphere, plant breeding and establishment of genetically modified (GM) organisms are alternative approaches for organic farming (Ryan et al. 2009). Genetic engineering has much to offer to bring about "new green revolution" in agriculture (Araus et al. 2014). Engineering of rhizosphere is mainly established through three potential means such as *plant-based methods*, *microbiome-based approach*, and *meta-organism-based techniques* (Quiza et al. 2015).

4.3.2.1 Plant-Based Methods

Plant-based strategies of rhizosphere engineering are achieved by either plant breeding (cultivar selection) or specific genetic modification of plant species. The basis for plant breeding is to develop and select cultivar lines that have the ability for (1) enhanced root exudation, (2) systemic resistance to disease and environmental stresses, and (3) increased rate of mutual symbiosis (Magalhaes et al. 2007; Campbell et al. 2002; Farrar et al. 2014). Genetically engineered plants are bestowed with a capacity of producing higher quantity of exudates that are highly specific for beneficial microorganisms (1) synthesizing quorum sensing/quorum quenching signal molecules, (2) altering soil organic anion efflux and transportation of the same

through the roots, (3) modifying soil properties (pH, salinity), and (4) promoting disease suppressiveness in soils (Koyama et al. 2000; Gevaudant et al. 2007; Yang et al. 2007; Mazzola 2007; Savka et al. 2002). These are achieved by introduction of genes of interest in selective plants from either the same species [cisgenic] or different species [transgenic] or deleting the genes that might repress different physiological processes [subgenic] (Wang et al. 2014).

The first genetically modified crop plant was an antibiotic-resistant tobacco plant (Fraley et al. 1999). Introduction of foreign germplasm into crops has been achieved by traditional crop breeders by overcoming species barriers. Farmers have widely adopted this technology to produce GM crops (GMC)/biotech (Bt) crops. Breeding lines of GM cultivars have been well established for the food crops including rice, wheat, potato, egg plants, tomatoes, soybeans, apples, beans, melons, papaya, and plums and for fiber and fuel crops such as cotton and grass and commercially important plants like tobacco (GM Approval Databse-ISAAA.org; *www.isaaa.org, 2016* accessed). These crops have been modified for the traits including improved shelf life, stress resistance, herbicide resistance, pest resistance, disease suppression, production of useful goods such as biofuel or drugs, and ability to absorb toxins and for use in bioremediation of pollution. The recent aim of research is to develop locally important crop breeds for developing countries such as production of rice rich in vitamins and iron that may mitigate chronic malnutrition in Asian countries, virus-resistant sweet potato, insect-resistant cowpea, and brinjal in Africa (Bawa and Anilakumar 2013).

To date, most genetic modifications target the properties of aboveground parts of plants. However, recently root-specific modifications have been attempted in the plants like *Arabidopsis* (30 %), tobacco (14 %), rice (11 %), maize (8 %), *Medicago* (5 %), and potato and tomato (both 4 %) (Kabouw et al. 2012). This is possible due to accumulating knowledge on plant root properties and rhizosphere processes (Perez-Alfocea et al. 2011). Drought-resistant transgenic rice lines have been developed by introducing auxin-transporting genes with a root-specific promoter (Jeong et al. 2010), while in another study salt stress-resistant rice has been developed through introduction of *Arabidopsis* gene (AtHKT1) that is accountable for sequestering Na+ in roots (Plett et al. 2010). A decrease in nematode abundance in rhizosphere was recorded in GM rice and potato that constitutively expressed a proteinase inhibitor for nematode control (Kohli et al. 1998; Cowgill et al. 2002). Transgenic lines of potato and tobacco have been established with the property of "quorum quenching" by transforming with quorum sensing signal (NAHL) degrading/synthesizing genes from *Bacillus* sp. and *Yersinia enterocolitica* (Dong et al. 2001; Fray et al. 1999). The transgenic variety of potato could directly inactivate quorum sensing molecules and is tolerant to the pathogen *Pectobacterium*. The transgenic tobacco could synthesize bacterial quorum sensing signal molecules and complemented biocontrol ability of *Pseudomonas aureofaciens*, defective in NAHL synthesis. The genetic transformation of crops to produce insecticidal proteins from the soilborne beneficial bacterium, *Bacillus thuringiensis* (Bt), is now one of the most important elements of pest control management system. Insect-resistant Bt rice (*Oryza sativa*) lines, maize (sweet corn), and cotton have been developed leading to increase in the production of these crops with reduced pesticide application

worldwide (Yang et al. 2011; Abbas et al. 2013; Blanco 2012). Transgenic lines of *Arabidopsis* (AVP1) and *Nicotiana tabacum* (PMA4) with modified H+−ATPase coding gene have been established with enhanced H+ efflux capabilities from roots, salinity resistance, phosphate mineralization, drought resistance, and auxin uptake (Yang et al. 2007; Gevaudant et al. 2007). Transgenic lines of *Medicago sativa, Brassica napus, Hordeum vulgare* (barley), sorghum, carrot, rice, tomato, and tobacco plants have also been established by transformation with genes encoding proteins for synthesis of citrate (citrate synthetase), extrusion of multidrug and toxic compound (MATE), and transport of malate (i.e., Al^3+-activated malate transporter gene or ALMT). The latter enhances the efflux of these anions from the roots and subsequently confers aluminum resistance and efficient phosphorus uptake (Koyama et al. 2000; Tesfaye et al. 2001; Delhaize et al. 2007). In recent times, the manipulation of regulatory genes (transcription factors or TFs) to establish stress-tolerant stable crops has emerged as an effective strategy. Transgenic rice, wheat, potato, apple, tobacco, sugarcane, alfalfa, and *Arabidopsis* with enhanced tolerance for drought, salinity, and cold have been developed with the capability of overexpressing TFs involved in regulating stress-responsive genes for abscisic acid (ABA)-dependent pathway or ABA-independent pathway (Wang et al. 2016a, b).

4.3.2.2 Microbiome-Based Approach

Microbiome-based approach involves either direct inoculation of individual microorganism or co-inoculation of mixed cultures of PGPR, AMF, ectomycorrhizal fungi (EMF), and endophytes to modulate crop productivity (Ping and Boland 2004; Ryan et al. 2009). PGPR with BCA promotes plant growth collaboratively through their abilities of biofertilization and phytostimulation through phosphate solubilization, siderophore production, nutrient and mineral uptake, and symbiosis for nitrogen assimilation: plant hormone production on one hand and disease suppression by inducing ISR in plants or through production of antifungal compounds (phenazines, pyoluteorin, and phloroglucinols), antibiotics (hydrogen cyanide, oligomycin, phenazine), and bacteriocins, on the other (Ping and Boland 2004; Paulin et al. 2009). Microbiome can also alter the plant metabolic profile toward producing better yield. However, this method of application of microbial inoculants into the soil requires the availability of cultured isolates and maintenance of their cultivability in soil (Quiza et al. 2015). An alternative strategy is to enhance plant performance through inoculation of recombinant microbial strains into the soil. The GM microorganisms (GMO) not only have an enhanced capability to specifically stimulate plant growth and kill pathogens, but they also stimulate the growth of members from indigenous soil community through transmission of genetic information by horizontal gene transfer [HGT] (Quiza et al. 2015). PGPR/BCA activities are also enhanced in GMO. The first report for GMO was *chiA*-introduced heterologous bacteria. This engineered species degrade chitin from fungal cell membrane to impart suppression of fungal infection. Engineered strains of *Escherichia coli* and *P. fluorescens* containing *chiA* could effectively control the infections caused by *Sclerotium rolfsii* in bean and *Fusarium oxysporum* f. sp. *redolens* and *Gaeumannomyces graminis* (*G. graminis*) var. *tritici* in wheat, respectively (Shapira

et al. 1989). Transformation of ACC-deaminase gene, *acdS*, from *P. putida* into *P. fluorescens* CHA0 strains improved phytostimulation in canola seedlings and disease resistance in cucumber against *Pythium* sp. (Wang et al. 2000). A number of studies have shown that constitutive production or overproduction of antibiotics/antifungal compounds by engineered bacterial strains (*P. fluorescens* Q2–87; *P. fluorescens* BL915) and their subsequent application in field crops reduced the occurrence of diseases in plants (take-all disease and root rot) even more effectively than the wild types (Alsanius et al. 2002). The first study on the effect of inoculated microbes to inhibit pathogenesis in soil was performed by introducing diacetylphloroglucinol (DAPG) producing *P. fluorescens* strains to suppress the growth of *G. graminis* var. *tritici* (Ggt), the causative agent of take-all disease in wheat (Kwak and Weller 2013). Even pretreatment of soil with recombinant strains effectively decontaminated it, reducing the rate of disease outbreak (Timms-Wilson et al. 2000). In addition to application of wild-type and/or recombinant strains, disruption of indigenous microbial population through imposition of mechanical (tillage) or chemical (fungicides, antibiotics) disturbances and thereby introducing beneficial microorganisms in the rhizosphere are another method to establish exogenous communities and modulate the rhizosphere milieu (Bulluck and Ristaino 2002).

4.3.2.3 Meta-Organism-Based Techniques

Interdependence of plants and the microbes in the rhizosphere redefines plant and the rhizobiome collectively as a metabiome or holobiont (Lakshmanan et al. 2014). Therefore, a school of thought in rhizosphere engineering is in the favor of addressing both the partners together, instead of accounting on them separately. This approach is addressed in two ways: (1) crop rotation and (2) inoculation of GMC with GMO.

Crop rotation is a decade-old method that has been applied extensively worldwide. This approach basically involves culturing of plants in turns, so that the residual microorganisms and phytochemicals in the soil from one plant might be beneficial to the next, and thereby an associative rhizo-microbiome can be established (Quiza et al. 2015). Various reports have been documented for utilities of crop rotation. A study from North America showed the association of higher diversity of AMF and the antagonist species *Penicillium canescens* with two cultivars of chickpea (CDC Anna and CDC Amit, respectively). This in turn influenced the productivity of the soil that subsequently helped in the establishment of durum wheat in that same soil (Ellouze et al. 2013). Similarly, the alternate cropping of potato with alfalfa, white lupin, and oats promoted potato yield (Honeycutt 1998). This approach induces the formation of disease-suppressive soils. In addition, this improves organic carbon content, nutrient cycling, and physicochemical characteristics of soil, thereby promoting a diverse microbial community (Honeycutt 1998; Mazzola 2002, 2007).

Inoculation of genetically engineered plants with genetically engineered organisms basically stimulates the plant to exudate specific chemicals which can be degraded by the selected GMO, thereby causing a proliferation of a specific group of organisms. An example is “opine concept” where it has been observed that the transgenic plants (*Lotus corniculatus*) modified to produce opine which is a

xenotopic compound produced from the *Agrobacterium tumefaciens*-induced tumor. Opine, in turn, selects opine-degrading bacteria over others that could maintain themselves at high concentrations, even after removal of the transgenic plants (Oger et al. 1997; Savka et al. 2002). A similar approach was adopted to study the interaction between rhizopine-synthesizing transgenic *Arabidopsis* and rhizopine-degrading transgenic bacteria, and rhizopine-degrading strains were favored in a rhizopine-rich environment (Gordon et al. 1996).

4.3.3 Rhizosphere Engineering in Bioremediation

The hindsight of urbanization, advancement, and development of technologies is increased accumulation of chemical/industrial/agricultural remnants which are often biohazardous. Therefore, there is also a need for "environment cleaning" to save our earth. Most of these pollutants are accumulated in soil and cannot be removed easily until the soil is excavated and treated at a particular site. However, this is arduous and expensive. Therefore, "bioremediation," i.e., the use of plants and their associated microbes to assimilate and degrade/stabilize/volatilize the pollutants, has become an attractive substitute (Eapen and D'Souza 2005; Pilon-Smits 2005). A huge body of literature suggests that bioremediation has been globally accepted as a cost-effective and environment-friendly alternative or complementary technology for conventional remediation (Clemens et al. 2002; Gisbert et al. 2003; Eapen and D'Souza 2005).

Microbial activity and plant intervention are both required for biodegradation of pollutants (Yergeau et al. 2014). Plants can directly take up the pollutants from the soil and degrade them to less bioavailable forms via precipitation in the rhizosphere or via phytase activity, a process known as phytodegradation (Newman and Reynolds 2004). In some cases, a part of the pollutants are lost into the atmosphere during transpiration through leaves. This is termed as phytovolatilization (Zhu and Rosen 2009). However, hydrophobic organic compounds which cannot be taken up by the plants are degraded by the rhizosphere microorganisms. Herbicides, trinitrotoluene (TNT), methyl tertiary butyl ether (MTBE), and trichloroethylene (TCE), which are mobile within plant tissues, are usually degraded by the plants directly, while polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), and other petroleum hydrocarbons are degraded by rhizosphere microorganisms (Harvey et al. 2002).

The process in which the plants stimulate soil microbes to degrade the pollutants is called phytostimulation or rhizodegradation. Besides participating in biodegradation, the microbes also stimulate the plants to take up contaminants from soil and to combat stresses developed due to accumulation of pollutants (Taghavi et al. 2005; Bell et al. 2015). It has been demonstrated that wild-type/genetically engineered microbial strains/microbial consortia accelerate the degradation of pollutants more effectively in the presence of plants (rhizoremediation) to bioaugmentation, the latter indicating the application of microbes in the soil without the plants. This is presumably because rhizosphere processes mediated cooperatively by plants and rhizobiota supplement the activity required for remediation, which cannot take place in bulk soil (Zhuang et al. 2007). Furthermore, plant roots provide greater

surface area, transport the microbes to that proper depth of the soil where the contaminants are present, and induce soil aeration, which enhance oxidative degradation of recalcitrant compounds (Chaudhry et al. 2005). Rhizoremediation is thus better over bioaugmentation (Zhuang et al. 2007).

The process of rhizoremediation which occurs naturally may be manipulated by engineering suitable plant–microbe pairs, such as plant–PGPR or plant-contaminant degrading microbes (Bisht et al. 2015). Beneficial plant–microbe symbioses have been exploited for rhizoremediation of hazardous and xenobiotic compounds like PAHs, PCBs, and TCE by choosing the right type of plant cultivar with appropriate rhizobacteria or by mechanically injecting efficient rhizobacterial strains on plant seeds/roots (Narasimhan et al. 2003; Walton and Anderson 1990). A wide variety of plants including alfalfa, barley, grass, lupin, oat, pepper, pine, poplar, radish, rape, sugarbeat, wheat, willow, and corresponding rhizobacterial strains such as *Pseudomonas fluorescens*, *Burkholderia cepacia*, *Pseudomonas putida*, *Bacillus* sp., *Deinococcus* sp., *Kurthia* sp., *Micrococcus* sp., *Arthrobacter* sp., and *Actinomycetes* have been identified (Kuiper et al. 2001; Bisht et al. 2014).

However, it is to be remembered that rhizoremediation is the outcome of activities of an entire microbial consortium, rather than a particular species (Kuiper et al. 2004). Although there is no dearth of studies involving isolation and characterization of pollutant-degrading rhizobacterial strains, studies on specific plant–microbe pair selection for rhizoremediation system are still limited (Bisht et al. 2015). Nevertheless, attempts of rhizoengineering by modifying plants to increase their size/number and augmenting their competence for biodegradation have been widely undertaken (Kabouw et al. 2012; Zhang et al. 2015b). The process relies on the following elements: (i) enhancement of root biomass to foster accumulation of high quantity of contaminants so that stress tolerance toward accumulated substances develops, (ii) stimulation of secretion of enzymes that will mobilize and degrade the noxious waste, and (iii) modulation of root exudation to attract microbes which are capable of degrading specific pollutants (Bhargava et al. 2012; Abhilash et al. 2009; Lojkova et al. 2014).

For competent biodegradation, plants require the presence of membrane transporter proteins (MTPs) that will export inorganic metal ions from the soil to the root xylem. Transgenic *Arabidopsis* and tobacco plants with overexpressing genes encoding membrane transport proteins result in increased uptake and accumulation of inorganic pollutants and heavy metals like cadmium, calcium, nickel, lead, manganese, and zinc in the plant tissues (Arazi et al. 1999; Hirschi et al. 2000; Van der Zaal et al. 1999). Recombinant DNA technology has mainly been applied to existing hyperaccumulator plant species (*Thlaspi caerulescens*, a natural zinc–cadmium hyperaccumulator) and high biomass species (Pence et al. 2000). Protein engineering has been applied to model plant, *Arabidopsis*, to increase specificity of transport proteins for heavy metals (Rogers et al. 2000). Transformation of *Arabidopsis* with pea metallothionein-like gene *PsMTA* enhanced their capacity to chelate metal ions (Evans et al. 1992). Overexpression of glutathione synthetase and γ-glutamylcysteine synthetase in *Brassica juncea* (Indian mustard) enhanced cadmium tolerance and accumulation (Zhu et al. 1999). Iron fortification of rice seed by the soybean ferritin gene was also established (Goto et al. 1999). In another study, transfer of the yeast metallothionein

gene (CUP1) caused remarkable improvement of heavy metal tolerance in GM plants (Thomas et al. 2003). Transgenic plants with bacterial pentaerythritol tetranitrate reductase and nitroreductase genes were reported to be more efficient in reductive transformation of TNT (French et al. 1999; Hannink et al. 2007). Even enhanced metabolism of halogenated hydrocarbons in transgenic plants containing mammalian cytochrome P450 2E1 was reported (Doty et al. 2000). Volatilization of heavy metals like mercury and arsenic in wild plants occurs in a very limited manner. However, introduction of a modified bacterial *merA* gene enhanced resistance and rate of reduction for mercury ions in *Arabidopsis* plants (Rugh et al. 1996).

Following AMF inoculation (either single or in combination with PGPR), stress tolerance for heavy metals like cadmium, cesium, iron, lead, trace elements (arsenic), PAHs, PCBs (petroleum), and their accumulation was enhanced in various plants including medicinal plants (*Cassia italica Mill*), food crops (sorghum, barley, oats, legumes, rice), flowering plants (sunflower), switch grass, rye grass, *Miscanthus* sp. via a variety of mechanisms including increasing chlorophyll content, endogenous hormone level, and protein content in the host plant and subsequently decreasing lipid oxidation, accumulation of ROS, and synthesis of ABA, peroxidase (PO), and superoxide dismutase (SOD) (Hashem et al. 2016; Huang et al. 2015; Arora et al. 2015; Mishra et al. 2015; de Melo et al. 2014; Xun et al. 2015; Chan et al. 2013; Arias et al. 2015; Cabral et al. 2015; Lu et al. 2014; Firmin et al. 2015).

However, to date, most studies have been performed under laboratory conditions. Due to various confounding factors, field trials appear to be more complex than anticipated. One field trial for selenium-resistant transgenic *Brassica juncea* (Indian mustard) was undertaken that showed enhanced Se accumulation in the field (Pilon-Smits et al. 1999; Zhu et al. 1999). The availability of genomic sequences of *Arabidopsis* and rice has led to the identification and manipulation of novel key genes and regulatory elements (transcription factors/tissue-specific transporters) for establishment of high biomass species for pollutant remediation and accelerated the pace of translational research and development of technology. Transgenic plants with modified hairy roots to enhance their capacity of absorbing inorganic chemicals have emerged as an attractive model system in the field of phytoremediation (Ibanez et al. 2015). Tailored transgenics is also emerging as a tool to study plant-site-specific or environment-specific gene expression and manipulation toward ecosystem management and environmental cleaning. Hyper-accumulation and increased tolerance for arsenic were established in plants by combining arsenate reductase and gamma-glutamylcysteine synthetase expression to combat arsenic toxicity (Dhankher et al. 2002).

4.3.4 Rhizoengineering for Industrial Application

Knowledge on plant–microbe interactions in the rhizosphere has unfolded diverse functionality of soil microorganisms in medicine and chemical industries in addition to agriculture. In this regard, isolation and purification of "enzymes" from various microbial strains suggest the potential use of microbes in biotechnological and/

or industrial processes. Presently, genetic engineering and protein engineering techniques have been applied to improve the production of enzymes both qualitatively and quantitatively (Gurung et al. 2013). Proteases and carbohydrases such as amylase and cellulase are the dominant enzyme groups isolated from the rhizosphere microorganisms because of their extensive use in dairy, detergent, textile, baking, and starch industries (Underkofler et al. 1958). Presently, hydrolases, which catalyze breakdown of molecules in the presence of water, find an extensive application in industries manufacturing food and beverages, cleaning supplies, clothing, paper products, transportation fuels, pharmaceuticals, and monitoring devices (Gurung et al. 2013).

The species under *Bacillus* genera (*Bacillus subtilis, Bacillus licheniformis*, *Bacillus stearothermophilus*, and *Bacillus amyloliquefaciens*) serve as the richest source of industrial amylases (Konsoula and Liakopoulou-Kyriakides 2007; Sokarda Slavić et al. 2016). Thermostable amylases isolated from *Bacillus subtilis*, *Bacillus licheniformis*, *Bacillus stearothermophilus*, and *Bacillus amyloliquefaciens* are widely used for starch degradation and production of crystalline sugar, dextrose syrup, and maltodextrins (Hua et al. 2014; Hwang et al. 1997). Amylases that can particularly function at halophilic environments have been isolated from halophilic bacteria such as *Chromohalobacter* sp., *Halobacillus* sp., *Haloarcula hispanica*, *Halomonas meridiana*, and *Bacillus dipsosauri* (Gupta et al. 2016; Kumar et al. 2012). Lipase derived from *Bacillus*, *Burkholderia* (*Achromobacter* sp.), *Pseudomonas*, *Enterococcus*, and *Arthrobacter* species are used in food, textile, detergent, cosmetic, biosensor, and medicine industries (Gurung et al. 2013). These enzymes have also found their use in therapeutics at a limited scale. Notable examples include streptokinase from *Streptomycetes*, urokinase from *Bacillus subtilis*, and glutaminase from *E. coli*, and these are used to treat thrombosis and leukemia, respectively (Banerjee et al. 2004; Zaitsev et al. 2010; Spiers and Wade 1976).

In addition, the microbes are genetically modified using genes/transcription factors from metabolic pathways or stress regulatory network to produce high quantities of metabolites like ethanol, N-butanol, glycerol, and mannitol which have wide applications as solvent, extractants, antifreeze, dye base, lubricants, detergents, pesticides, resins, explosives, plasticizers, synthetic fibers, brake fluids, and petroleum derivatives and also in medicine and food industry (reviewed in Jia et al. 2014).

The production of "biofuels" using plants forms another important application of rhizosphere biology. One of the important sources of biofuel is "biomass," i.e., deposition of free energy from photosynthesis. Usually, nonfood crops or residues are used as feedstock for biofuel production. Vegetative parts from sugarcane (*Saccharum* sp.), poplar, switch grass (*Panicum virgatum*), *Miscanthus* species (*Miscanthus x giganteus*), and *Erianthus* species (*Erianthus arundinaceus* Retz.) are utilized for this purpose (Furtado et al. 2014). Thus, any engineering event in plants that accelerate vegetative meristematic activity is advantageous for biofuel production. Genetic diversity among *Saccharum* sp., *Erianthus* sp., and *Miscanthus* sp. has been exploited in breeding programs targeting different genetic markers, growth factors (GFs), enzymes, and transcription factors to introduce disease resistance, adaptability feature, and biofuel traits (Zhu et al. 2014; De Souza et al. 2015).

Genetically modified sugarcane with high biomass and cellulose-degrading microbes has been used for biofuel production (reviewed in Arruda 2012). In another study, tobacco plants transformed with NAC family genes from *Lepidium latifolium* gave rise to increased production of a number of transcription factors that resulted in marked improvement of plant biomass indicating the future potential of NAC gene transgenesis in biofuel production (Singh et al. 2016). Attempts to manipulate cellulase and laccase production in *Arabidopsis*, maize, and rice have also been successful in providing a new direction toward production of lignocellulose-based biofuel (reviewed in Wang et al. 2015). Syngas, produced from lignocellulose, can be fermented to biofuels using acetogenic bacteria such as *Eubacterium limosum*, *Clostridium autoethanogenum*, or *Acetobacterium woodii* (Bertsch and Muller 2015). GM microorganisms with abilities to use hemicellulose-derived C5 sugars (pentoses) may also aid production of biofuel as pentose constitutes one-third of the lignocellulose component of biomass (Silva et al. 2010). In this respect, genetically engineered *Cyanobacteria* are worthy of mentioning as they are being largely used to convert CO_2 into various chemicals directly (Lai and Lan 2015).

4.4 Conclusion and Future Perspectives

Of the countless problems and challenges our globe is facing today, perhaps the most overwhelming is how to shape the "Fourth Industrial Revolution" that has been initiated in this century. New concept, information, and technologies from physical, digital, and biological worlds are propelling toward bringing about an altruistic societal change. Perhaps "biological science" has to offer the most important contribution in today's industrial revolution. Armed with genetic and protein engineering, the new era of synthetic biology integrates engineering to biological principles toward establishment of more systematic, efficient, robust, predictable, and scalable biological systems. The time is just ripe to harness the knowledge of rhizosphere biology with technology to yield fascinating results with beneficial impacts on mankind. Although there is monumental progress in understanding the existing plant–microbe coordination, in-depth knowledge is still missing in many parts. This lacuna needs to be bridged for maintenance of progress rate. Advances have been made utilizing "system approaches" to identify key molecular players (such as genes, RNAs, proteins, etc.) in plant–microbe cross talk associated with plant health and productivity. However, exigent issues still exist and need to be tackled with urgent priority. Last, but not the least, the plant performance needs to be investigated at a population scale. Therefore, multiscale mechanistic models that will link plant, microbes, and field ought to be developed taking care of influential environmental factors (Hill et al. 2013). Developing mixed genetic-ecophysiological models to amend the gap between genetic and environmental parameters is an important goal that may help in overcoming the constraints still prevailing while manipulating genes in recombinant species (Roose and Schnepf 2008). For example, implementation of "synthetic biology" for successful biotransformation has often proven cumbersome due to vulnerability of host organisms to intermittent and

unpredictable environmental parameters (Jia et al. 2014). A robust knowledge of metabolic network and the mechanisms of systemic resistance operating in microorganisms at both cellular and community levels will provide solution to this problem. Besides, there is also a necessity of increasing public awareness and acceptance of genetically modified products (Adenle 2011; Kikulwe et al. 2011). This of course calls for coordinated participation of scientists and other professionals to spread the true information to the community.

Mycorrhizosphere: The Extended Rhizosphere and Its Significance

5

P. Priyadharsini, K. Rojamala, R. Koshila Ravi, R. Muthuraja, K. Nagaraj, and T. Muthukumar

Abstract

Plant roots influence soil through the release of carbon-rich exudates and rhizodeposits. The soil region influenced by plant roots is termed as rhizosphere. A unique community of microorganisms thrives in the rhizosphere whose activities enable plants to acquire various resources from soil for their growth and survival. Most plants in natural and agricultural ecosystems are associated with mycorrhizal fungi, which act as interlink between two different environments, the root and the soil. Mycorrhizal fungi play an important role in plant uptake of nutrients and protecting plants against various abiotic and biotic stresses. Like roots, mycorrhizal fungal hyphae also release exudates containing carbon into the surrounding soil, the hyphosphere that contributes to the formation of microbial communities and aggregation of soil particles. The soil region influenced by the mycorrhizal roots is the mycorrhizosphere. A wide range of microorganisms like bacteria, fungi, protozoa, nematodes, arthropods, etc., inhabit the mycorrhizosphere. These microorganisms interact with each other and with the plant system either directly or indirectly. The activities in the mycorrhizosphere include stimulation in the activities and populations of microorganisms, changes in pH, nutrient release from organic matter and nutrient cycling, suppression of plant pathogens, mycorrhizal formation, and changes in soil structure. An understanding of the functional diversity of microorganisms inhabiting the mycorrhizosphere is necessary to optimize soil microbial technology for the benefit of plant growth and health. This chapter describes the concept of rhizosphere, hyphosphere, and mycorrhizosphere and the various activities in these regions.

5.1 Introduction

Roots, the hidden half of plants, form a linkage between the plant and the soil environment. The soil surrounding roots is inhabited by several fungi, bacteria, and other microflora and fauna (Linderman 1992). An intense effort is being carried out to understand and exploit the root system of plants in an endeavor to expand the yield probability of stable food crops to face the dual increase of population and global demand for food within the next 50 years (Zhang et al. 2010). The root system of the higher plants is interlinked with a diverse metabolically active microbial community together with the soil environment which has organic and inorganic matter (Fulekar and Pathak 2015). A unique habitat exists around the roots of the living plants. Hence, the population of microbes in soil surrounding the roots is greater than that of root-free soil. Further, these two regions of the soil have several qualitative and quantitative dissimilarities (Fulekar and Pathak 2015).

Mycorrhizal symbioses are associations formed between the roots of terrestrial plant species and soil fungi belonging to *Glomeromycota*, *Ascomycota*, and *Basidiomycota* (Smith and Read 2008). This is the most widespread type of symbiosis in the plant kingdom occurring in more than 80 % of the terrestrial vascular plant species and is believed to have facilitated colonization of terrestrial habitats by plants (Parniske 2008). During mycorrhization, the mycorrhizal fungi develop intimate relation with root cells on one side and soil on the other. The fungi grow on the root surface as runner hyphae or cover the roots in the form of mantle. It is fairly well established that mycorrhizal fungi extend the influence of roots into the non-root zones through their extraradical mycelium. The intraradical structures of mycorrhizal fungi within roots depending on the type of mycorrhizae include arbuscules, vesicles, Hartig net, hyphal coils/pelotons, and linear hyphae that may be inter- or intracellular (Smith and Read 2008).

Mycorrhizal association imparts a wide range of benefits to the plant species. These include plant growth promotion, nutrient uptake and translocation to the roots, and resistance to stresses induced by soilborne pathogens (Whipps 2004; Pozo and Azcon-Aguilar 2007), heavy metals (Vogel-Mikus et al. 2006; Dong et al. 2008), drought, and salinity (Feng et al. 2002; Miransari 2010). The prime benefit of mycorrhiza on plant growth is by providing large amounts of phosphorus (P) and nitrogen (N) to the host plant in nutrient-stressed soils. They also supply other mineral nutrients and help in dissolving and absorbing insoluble organic substances (non-glomeromycotean fungi) which in turn enhance plant growth. The extraradical mycelium of the mycorrhizal fungi facilitates the uptake of water and nutrients by plants as it extends its range into areas of the soil profile that is beyond the reach of the roots. Further, the smaller diameter of the fungal hyphae compared to roots enables their entry into soil pores that cannot be reached by roots (Kaiser et al. 2015). The extraradical mycelium of mycorrhizal fungi also acts as a pathway in the translocation and release of energy-rich molecules from the plant to the soil (Johnson et al. 2002). In addition, mycorrhizal symbiosis also enhances the efficiency of other plant-microbe symbiosis like nodulation and N_2-fixation in leguminous and actinorhizal plants.

The mycorrhizal fungi interact with other microorganisms both in the root and in the soil (Barea et al. 2002). The synergistic effect of mycorrhizal fungal association with plant growth-promoting rhizobacteria (PGPR), asymbiotic N_2-fixing bacteria, non-mycorrhizal fungi, and microfauna renders positive effects to plant growth and development (Sturz and Nowak 2000). Moreover, the microbial activity in the soil not only interferes with the plant root system, but it also stimulates the germination of mycorrhizal fungal propagules, mycelial growth, and mycorrhization of roots (Barea 2000). Though the mycorrhizal fungi could alter the plant root morphology, it also influences the activity and favors some organisms like bacteria to establish and flourish in the soil environment (Parniske 2008; Deveau et al. 2010).

In this chapter, we present an overview on the rhizosphere, hyposphere, and mycorrhizosphere. The changes in biological and soil properties in response to the development of mycorrhizosphere are also discussed.

5.2 The Rhizosphere Concept

Soil is one of the important frontiers of science, and the rhizosphere is the most dynamic part of that frontier where a multitude of biogeochemical activities occur, which influence many environmental and worldwide processes (McNear 2013; Haldar and Sengupta 2015). Rhizosphere is the narrow region of soil that is directly influenced by root secretions and rhizodeposits as well as the soil microorganisms associated with it (Fig. 5.1). This region can be differentiated from the bulk soil by the availability of the carbon compounds, water potential, and redox state, and it demarcates the distribution and activity of the widely diverse rhizosphere biota (Cardon and Whitbeck 2007). Being a resource-rich region, it is one of the most complex ecosystems on the earth (Pierret et al. 2007; Jones and Hinsinger 2008; Hinsinger et al. 2009). The rhizosphere constitutes about 10^{11} microbial cells per gram of root (Egamberdieva et al. 2008) and prokaryotic species that number around 30,000 which influence the productivity of plants (Mendes et al. 2011; 2013). The rhizosphere resembles a trade zone where symbionts or neighbor roots interact with the plant. Moreover, it acts as a preventive microbial buffer zone against pathogens (Baetz and Martinoia 2014).

The term rhizosphere includes three zones which are based on their relative proximity and influence from the plant root (Morgan et al. 2005). The endorhizosphere includes portions of the cortex and the endodermis, where the microbes and the cations occupy the apoplastic space, viz., the free space between the cells (Balandreau and Knowles 1978; Reinhold-Hurek et al. 2015). The rhizoplane or the root surface is the medial zone, which includes the root epidermis and mucilage (Nihorembere et al. 2011; Bulgarelli et al. 2012). The outermost zone is the ectorhizosphere which extends from the rhizoplane out into the region of bulk soil (Lynch and Whipps 1990; Badri and Vivanco 2009).

The plants are not only influenced by soil but also active microbial populations in the rhizosphere (Hiltner 1904). Recently, York et al. (2016) proposed the concept of a holistic rhizosphere that encompasses constituents like mucigel; modifications of soil

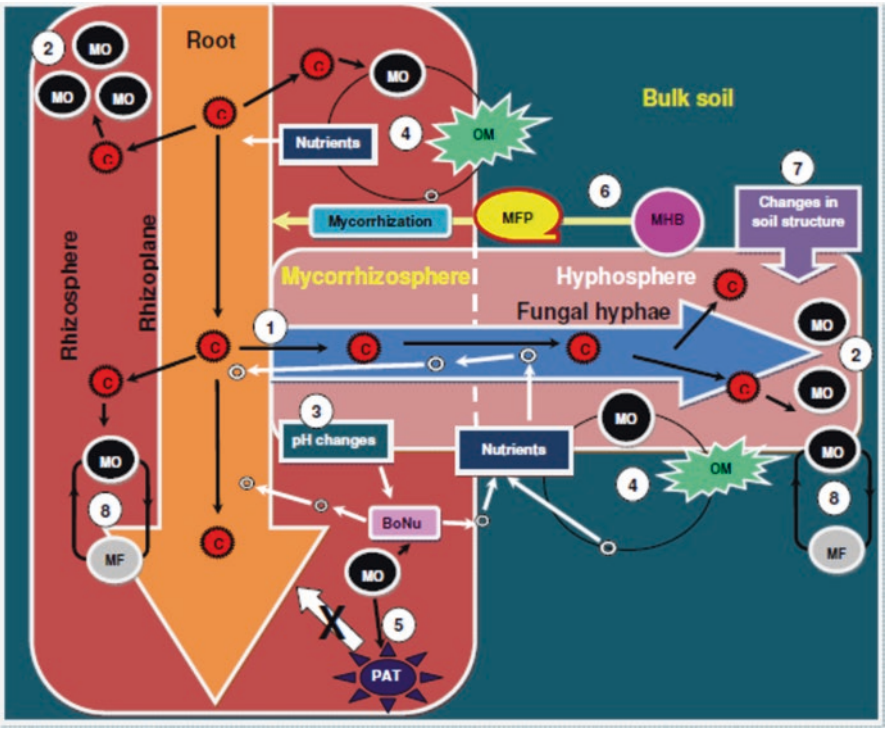

Fig. 5.1 Schematic representation of different types of activities occurring in the mycorrhizosphere. *1* Carbon transfer from root to rhizosphere, mycorrhizal fungal hyphae, and hyphosphere. *2* Increase in the activities and populations of microorganism. *3* Changes in pH resulting in the release of bound nutrients and their uptake. *4* Release of nutrients from organic matter by microorganisms and their uptake. *5* Control of plant pathogens. *6* Mycorrhizal fungal propagule germination and mycorrhization. *7* Changes in soil structure. *8* Interactions among microorganisms. *C* carbon, *MO* microorganisms, *OM* organic matter, *MHB* mycorrhiza helper bacteria, *MFP* mycorrhizal fungal propagule, *PAT* pathogens, *BoNu* bound nutrients, *MF* microfauna

structure; gradients of microbial communities, microorganisms; or a loss or gain of substances like water, root exudates, nutrients, gases, and other volatile products. However, the ingredients of the rhizosphere have been formed due to effectual processes. Hence, it is necessary to understand these processes for future considerations.

5.2.1 The Rhizosphere Effect

As the seeds germinate, they exude carbon compounds into soil which activates the microbial populations. This phenomenon is termed the rhizosphere effect (Morgan and Whipps 2001). Alternatively, it describes the development of soil microorganism communities as a result of the physical and chemical alterations of the soil by the products of excretions and organic debris of roots within a rhizosphere (McNear 2013).

Starkey (1938) defined the rhizosphere effect in terms of processes which occur at the root-soil interface of a plant inclusive of root exudation, microbial activity, genetic exchange, nutrient transformation, and gradient diffusion. In living plants, the organic carbon released by plant roots decomposes to carbon dioxide by a mechanism of rhizosphere priming effect (Kuzyakov 2002). Almost one-third to more than half of the total carbon assimilated by plants is allocated to belowground roots, of which 15–25 % is exuded into the soil resulting in a fast carbon turnover (Kuzyakov 2002). The intense microbial activity in response to carbon availability leads to intense competition for other nutrients in the rhizosphere (Hartmann et al. 2009; Haldar and Sengupta 2015). On the other hand, in a root-free bulk soil, all the nutrients except carbon are unlimited (Wardle 1992). Thus, the rhizosphere zone strongly differs from the root-free zones in physical, chemical, and biological properties (Hartmann et al. 2009).

5.2.2 Rhizodeposits

The substances secreted by the roots and its associated microorganisms into the rhizosphere are called rhizodeposits. Rhizodeposits have been classified depending on their chemical composition and mode of release or function (Rovira 1969). These compounds include: (1) Low-molecular mass compounds like monosaccharides, amino acids, organic acids, and water-soluble ions that are lost passively along a concentration gradient, (2) High-molecular mass compounds such as carbohydrates and proteins that act as signal molecules and lipids that are actively transported along an electrochemical gradient, (3) Insoluble mucilage composed of polygalacturonic acid and polysaccharides, (4) Secondary metabolites like antimicrobial compounds, flavonoids, and nematicides and (5) Remnants of the dead and lysed root cap and border cells (Marschner 1995; De-la-Peña et al. 2012; Weston et al. 2013; Zhang et al. 2014). The process of communication and interaction begins once the recipient organisms recognize the signaling phenomenon of the rhizodeposits. The nature and composition of root exudate can alter the microbial vitality and diversity of the soil, favoring growth of microorganisms that can benefit plant health and productivity, whereas, in others, root-exuded compounds prevent the growth of harmful microorganisms (Bais et al. 2006; Chaparro et al. 2012; Dutta et al. 2013; Li et al. 2013).

5.2.3 Effect of Rhizosphere Microbiome on Plant Growth and Health

The rhizosphere biome influences the composition and productivity, viz., biomass, of the natural plant communities (van der Heijden et al. 2006, 2008; Schnitzer et al. 2011). As a result, the species richness of the underground microbial communities can be considered as a factor to predict the aboveground plant diversity and productivity (Hooper et al. 2005; van der Heijden et al. 2008; Lau and Lennon 2011; Wagg et al. 2011).

5.2.4 Microbial Interactions in the Rhizosphere

5.2.4.1 Bacteria

The bacterial community in the rhizosphere promotes the production and germination of spores and hyphal growth of arbuscular mycorrhizal (AM) fungi. In addition to plant roots, spores (Bharadwaj et al. 2008; Cruz and Ishii 2012) and extraradical mycelium (Mansfeld-Giese et al. 2002) of AM fungi also associate predominantly with bacteria in the mycosphere. A bacterial community in the rhizosphere not only associates with the extraradical mycelium but also with spores of AM fungi. The association of bacteria with AM fungal spores is related to the size and surface roughness of the outer spore wall (Bharadwaj et al. 2008). Some bacterial taxa are exclusively restricted to a few mycorrhizal isolates, whereas others are extensively found in the mycosphere of several AM fungal taxa (Rillig et al. 2005). Bacterial association with AM fungal spores induces germination and establishment of mycorrhizal association under unfavorable conditions (Xavier and Germida 2003; Hildebrandt et al. 2006). This is often due to the bacterial secretion of volatile compounds, rupturing of the spore wall, and nutrient acquisition (Ruiz-Lozano and Bonfante 2000). Studies on AM fungal interactions with rhizosphere bacteria suggests that it may be either positive (Abdel-Fattah and Mohamedin 2000) or negative (Amora-Lazcano et al. 1998). Though AM fungal processes are enhanced by bacteria, some studies showed prohibitory activity of bacteria on AM fungal growth (Azcón 1989). This might be due to specificity in bacterial species and AM fungi. The AM fungi form a bridge between the root and soil (Bethlenfalvay and Schüepp 1994); in turn, the AM fungi affect the composition of bacterial communities in the rhizosphere (Linderman 1988; Paulitz and Lindennan 1991).

The fungi and bacteria in the rhizosphere are also involved in plant resistance to various types of stresses (Linderman 2000; Han and Lee 2005). The bacterial population in the rhizosphere mainly includes the beneficial associative N_2-fixing bacteria (Subba Rao et al. 1985), PGPR (Meyer and Linderman 1986), and phosphate-solubilizing bacteria (PSB) (Toro et al. 1997; Bonfante and Anca 2005). However, bacterial populations also vary under the influence of different plant and AM fungal species. The size and the composition of bacterial populations in the rhizosphere depend on the quantity of the root exudates (Azaizeh et al. 1995) and the competition for carbon source (Christensen and Jakobsen 1993). The carbon source is the major energy provider for various microbial communities, and its beneficial effect on plants has been well established. Mycorrhiza-associated bacteria also succeed to establish from AM fungal exudates (Toljander et al. 2007), which facilitate nutrition for both plant and fungal partners as well as protection from root pathogens (Larsen et al. 2015).

5.2.4.2 Fungi and Phytopathogens

In defense mechanism, mycorrhizal species directly or indirectly protect the host plant in the ecosystem. Such direct mechanisms include the production of physical structures (e.g., mantle by ectomycorrhizal fungi), secretion of toxic compounds against the pathogens, providing mechanical strength to the root system, and

activating the host plant production of compounds like salicylic and jasmonic acids (Artursson et al. 2006; Finlay 2008). Indirect mechanisms include protection of the host plant by changing the microbial community, root exudates, and stimulation of suitable antagonistic microorganisms (Zarnea 1994; Zamfirache and Toma 2000; Miransari 2011). For example, the architecture of AM fungi-colonized roots is greatly modified. The mycorrhizal roots are highly branched, short and thick with reduced specific root length, resulting in conditions that are unfavorable for pathogenic microorganisms (Berta et al. 1993).

Studies have shown that rhizosphere bacteria could suppress plant pathogens (Berg and Hallmann 2006; Shehata et al. 2016). The rhizosphere fluorescent *Pseudomonas* strains produce the antibiotic 2,4-diacetylphloroglucinol (DAPG) that protects the plants against *Gaeumannomyces graminis* var. *tritici*. The bacterium produced significantly large amounts of DAPG in the presence of soluble carbon exuded by *Rhizophagus intraradices* and offered a sustainable strategy for plant protection (Siasou et al. 2009). The AM fungi and pathogen share common resources in the root system (Whipps 2004). But, competition in the endorhizosphere would arise when the carbon source from the host plant becomes scarce, resulting in the reduction in the colonization by AM fungi (Wehner et al. 2009). The intensity of the pathogenic effect on the host plant is reduced when multiple AM fungi species colonize the root system compared to colonization by an individual AM fungus (Jaiti et al. 2007). Bacteria associated with AM fungi enhance the plant resistance against pathogens through their antagonistic activity. For example, bacteria isolated from the spores of AM fungi inhibited the growth of *Ganoderma boninense*, which causes basal stem rot disease in oil palm (*Elaeis guineensis*) (Bakhtiar et al. 2010).

5.2.4.3 Microfauna

The rhizosphere contains microfauna like nematodes, protozoa, and arthropods. Most of these organisms are involved in the complex system of the food web that shares the plant resources (Pierret et al. 2007; Raaijmakers et al. 2009). Among these organisms, nematodes are free-living, eukaryotic invertebrates that feed on bacteria and fungi and some existing as plant parasites (Tiberius and Cătălin 2011). Nematodes cause diseases in plants by entering the root and establishing a stable feeding location within the root system (Badri et al. 2009). The interactions between mycophagous nematodes and mycorrhizal fungi result in the reduction of the extraradical hyphal production that can indirectly affect plant growth and yield (Giannakis and Sanders 1990; Khan 1993). However, to reduce the negative effect of nematode infestation, plants generally adapt various strategies like the association with mycorrhizal fungi, increased nutrient uptake, and structural and physiological changes in the root system (Schouteden et al. 2015). Even though AM fungi induce tolerance against adverse effects on host plants, several factors like host plant and AM fungal and nematode species determine the nature of interactions between AM fungi and nematodes (Hol and Cook 2005). Recently, Banuelos et al. (2014) found that roots of *Impatiens balsamina* inoculated with a consortium of AM fungi (11 species) reduced the root-knot disease caused by the nematode *Meloidogyne incognita* than the plant inoculated with *Glomus coronatum* alone.

However, the concentrations of antioxidant in shoots and phenolic compounds in roots were higher for AM fungal consortium inoculated plants and showed defense activity against the root-knot nematodes (Banuelos et al. 2014).

In addition to fungi, bacteria are also involved in the control of plant parasitic nematodes in soil. The nematophagous bacteria are differentiated based on their mode of activity and mostly belong to the genera *Bacillus*, *Pseudomonas*, and *Pasteuria* (Li et al. 2015). These bacteria have been isolated from soil, host tissues, and nematodes (Kerry 2000; Meyer 2003). The nematophagous bacteria affect nematodes through various mechanisms like producing toxins and antibiotics/enzymes, competing for nutrients, and inducing systemic resistance in plants (Tian et al. 2007). Some of the major rhizobacteria like *Azotobacter* and *Gluconacetobacter* also affect the plant parasitic nematodes. The antagonistic effect of bacteria against nematodes in the soil is due to the secretion of volatile compounds like ammonia and fatty acids which inhibit the juveniles of nematodes (Bansal and Bajaj 2003). A study by Bansal et al. (2005) in cotton showed that the antagonistic effect of *Gluconacetobacter diazotrophicus* (=*Acetobacter diazotrophicus*) on the root-knot nematode, *M. incognita*, was through suppression of egg hatching.

Abundance of bacterial grazers like the nematodes and protozoa significantly alters the bacterial community composition and their activities in the rhizosphere (Bonkowski 2004). Such changes in bacterial activities and populations are shown to significantly affect plant growth (Kreuzer et al. 2006; Mao et al. 2007). In a boreal forest, ectomycorrhizal fungus was shown to affect bacterial community composition, subsequently altering food resources for protozoa (Timonen et al. 2004). Both ectomycorrhizal fungi and protozoa can complement each other in rendering benefit for plants. For example, Bonkowski et al. (2001) showed that the protozoa increased the N availability to Norway spruce (*Picea abies*) seedlings, whereas the ectomycorrhizal fungus *Paxillus involutus* increased the availability of P. The excretion of N after the consumption of bacterial biomass by protozoans increases the N availability for direct or mycorrhizal mediated uptake by plants (Bonkowski 2004). In a microcosm study, Koller et al. (2013) showed that protozoa mobilized N by stimulating microbial activity in degradation of organic matter. The N released was transferred to the roots of *Plantago lanceolata* via hyphae of *R. intraradices*. Though different microorganisms in the rhizosphere complement each other from the plant's perspective, a competition for plant carbohydrates does exist between these microorganisms. A substantial reduction in the numbers of protozoa has been reported by Rønn et al. (2002) in AM-colonized pea plants. The presence of protozoa also affects root architecture and biomass in rice plants (Herdler et al. 2008). The influence of AM fungi on changes in the microbial community of the rhizosphere tends to vary with the growth phase of the plant. For example, in pea plants the presence of the AM fungus *R. intraradices* decreased the number of protozoa during late vegetative phase prior to flowering, but the negative effect on protozoa decreased during flowering and pod formation (Wamberg et al. 2003).

5.3 The Hyphosphere Concept

Generally, the amount of fungal hyphae in any given volume of the soil is enormous. There can be up to 20,000 km of fungal hyphae per cubic meter of soil (Moore et al. 2011). Ectomycorrhizal fungi can produce up to 800 m of hyphae per gram of soil and about 700–900 kg of mycelium per hectare in a humus-rich layer of the soil (van Elsas et al. 2007). Similarly, AM fungi can produce up to 100 m of hyphae per gram of soil (Miller et al. 1995). The extraradical mycelia of mycorrhizal fungi constitute around 20–30 % of total soil microbial biomass and have a powerful influence upon the biogeochemical cycling of nutrients and the composition and functioning of plant communities (Leake et al. 2004). Mycorrhizal mycelial networks in the soil are the most dynamic and functionally diverse components of the symbiosis, and they receive as much as 10 % or more of the net photosynthate from their host plant; part of which is exuded into the soil (Leake et al. 2004) (Fig. 5.1).

Like roots, the mycorrhizal hyphae also release compounds into the soil and play an important role in the microbial activity and nutrient dynamics of the soil (Jones et al. 2004). This holds well, especially for the ecto-, ericoid, and orchid mycorrhizal fungal mycelium which can release hydrolytic enzymes to acquire nutrients from organic sources (Chalot and Brun 1998) and other compounds (Sun et al. 1999). The highest concentration of glucose and trehalose and the lowest concentration of fructose, galactose, sucrose, raffinose, and mannitol were detected in hyposphere soil of olive trees (*Olea europaea*) colonized by *R. intraradices* (Mechri et al. 2014). The term hyphosphere was thus introduced to denote the soil region influenced by extraradical mycelium of the mycorrhizal fungus (Jones et al. 2004). In some cases, the activity and composition of microorganisms in the hyphosphere have been shown to affect the activities of AM fungi (Andrade et al. 1997; Filion et al. 1999).

The hyphosphere may be rich in carbon, but deficient in available nutrients like P for many microbes, which in turn may influence their activity of mineralizing the phytate-P of the soil and later adding the available P into microbial biomass P that is potentially available to AM fungal hyphae (Zhang et al. 2014). Plant genotype, development of the root system, quality and quantity of the root exudates, and plant's carbohydrate metabolism can influence microbial biomass and activity in the mycorrhizal hyphosphere (Marschner et al. 2001; Sood 2003; Hooker et al. 2007; Toljander et al. 2007). These have resulted in studies where colonization of plant roots by AM fungi has been shown to decrease (Wamberg et al. 2003; Cavagnaro et al. 2003), increase (Van Aarle et al. 2002; Albertsen et al. 2006), or have no effect (Olsson et al. 1996; Andrade et al. 1997) on the microbial biomass.

As per the reciprocal reward mechanism suggested for stabilizing the cooperation of mycorrhizal-plant symbiosis (Kiers et al. 2003; Hammer et al. 2011), the amount of carbon supplied to the soil by different fungi could vary significantly. For instance, when there is a one-to-one situation like an individual fungus colonizing the plant root system, the quantity of carbon that is provided by the plant to the fungus depends on the P contribution of its fungal partner and vice versa (Hammer et al. 2011). But, when situation involves many-to-many like different mycorrhizal

fungi colonizing roots of different plant species in a community, the plants can detect and discriminate fungal partners with either excess or limited supply of carbohydrates. The fungal partners can also reciprocate by increasing the transfer of nutrients only to the roots that provide more carbohydrates (Kiers et al. 2011; Fellbaum et al. 2014). It can be seen that in mycorrhizal symbiosis, the plants and fungi have a choice to select between multiple potential partners. However, in the hyphosphere, AM fungi may receive P from different phosphate-solubilizing microorganisms (PSMs) including bacteria and fungi. It is possible that the choice of AM fungi is more limited for the PSMs because of scale and nonfilamentous growth issues, and thus each bacterium is probably dependent upon only a single AM fungal hypha for its carbon support. Thus, this may be expected to make the PSM more open to cooperative behavior (Zhang et al. 2016).

The mycorrhizal fungi aid plants in their forage for nutrients and water by extending its range into areas of soil that are not accessible by roots and to nutrient-rich soil hotspots through a large network of extraradical mycelium (Kaiser et al. 2015). Mycorrhizal hyphae also stimulate the surrounding soil microbes by release of carbon which is labile. This increases the availability of local nutrients in the hyphosphere (Hodge et al. 2010; Cheng et al. 2012; Jansa et al. 2013). Nevertheless, when the AM fungi pass on the plant photosynthates to the hyphosphere, it results in an increase in the availability of nutrients by stimulating the depolymerization of organic matter by soil microorganisms (Hodge et al. 2010; Jansa et al. 2013). This strategy is useful for AM fungi which do not have the ability to secrete extracellular enzymes to degrade complex organic compounds (Kaiser et al. 2015; Smith and Smith 2011).

5.3.1 Microbial Interactions in the Hyphosphere

Like rhizosphere, some bacteria are associated with the mycelium of both ectomycorrhizal and AM fungi in hyphosphere (Poole et al. 2001; Mansfeld-Giese et al. 2002; Naumann et al. 2010). The mycorrhizal fungal hyphae influence bacterial populations and their activity (Andrade et al. 1997). Although numerous studies exist on the rhizosphere colonization by bacterial populations, studies are limited to the distribution of bacterial populations in the hyphosphere (Ravnskov et al. 1999; Zhang et al. 2014). The AM fungal mycelium plays a crucial role in the transfer of carbon sources to the associated bacteria (Leake et al. 2006; Drigo et al. 2010). The AM fungi in the soil decompose the organic matter indirectly through the production of exudates, which stimulate the microbial communities in the hyphosphere that are involved in the decomposition of organic matter. The hyphal exudates not only promote microorganisms but also inhibit others (Toljander et al. 2007). The ectomycorrhizae harbor bacteria, which use the type III secretion system (T3SS) encoding for the attachment of infection needle (Warmink and van Elsas 2008). However, recently, sulfonate desulfurizing bacteria, *Gammaproteobacteria* and *Actinobacteria* with T3SS, were detected in the hyphosphere of AM fungi (Gahan

and Schmalenberger 2015). But unlike the previous study where the system was used for encoding bacterial attachment, it helped plants to take up sulfur from unavailable forms.

Over the past decade, several attempts have been made to unravel the physical interactions that take place between AM fungi and bacteria in the hyphosphere (e.g., Bianciotto et al. 2001; Johansson et al. 2004). Ravnskov et al. (1999) studied the influence of *R. intraradices* on *Pseudomonas fluorescens* DF57 bacteria in the hyphosphere and rhizosphere soil. It was clear that the presence of AM did not induce P starvation response and it did not affect the metabolic activity of the bacterium. The authors also found that it could not use the hyphae as a carbon substrate. Proposals were made to conclude that *R. intraradices* can negatively affect the growth and survival of *P. fluorescens* DF57 both in the presence of roots, where the fungus can change the quality and quantity of root exudates and in the hyphosphere, where the microbes can interact directly.

Bacteria that were associated with the hyphosphere of the AM fungal species, namely, *Claroideoglomus etunicatum*, *R. intraradices*, and *Funneliformis mosseae*, were investigated by Andrade et al. (1997). The changes observed in the bacterial community in the hyphosphere were not related to the quantity of AM mycelium, but were due to qualitative effects like the composition of exudates of the fungal species which is very important for the composition and the proliferation of rhizobacteria (Johansson et al. 2004). The synergistic film surrounding the fungal hyphae acts as a highway for dispersal of bacteria in water-unsaturated media (Kohlmeier et al. 2005). Although this phenomenon is well demonstrated for non-mycorrhizal fungi like *Fusarium* and *Chaetomium* (Simon et al. 2015), it is yet to be demonstrated for mycorrhizal fungi.

5.4 The Mycorrhizosphere Concept

The concept of rhizosphere has been broadened to include the fungal component of the symbiosis, which has resulted in the term mycorrhizosphere (Rambelli 1973). The mycorrhizosphere is influenced both by the root and the mycelium of the mycorrhizal fungus (Fig. 5.1). Therefore, the term mycorrhizosphere is inclusive of the specific term hyphosphere that denotes exclusively the soil zone surrounding individual fungal hyphae that extends beyond the rhizosphere into the bulk soil (Johansson et al. 2004).

Mycorrhizosphere is the soil zone influenced by mycorrhizal roots, and it consists of two components: (1) the rhizosphere, a layer of soil surrounding the root system which is directly influenced by root and root hairs, and (2) the hyphosphere, a region where mycorrhizal fungal hyphae and soil interaction takes place (Marschner 1995). Both rhizosphere and hyphosphere influence several organisms, including saprotrophic fungi and bacteria (Meier et al. 2015). These microorganisms interact in the mycorrhizosphere and affect the abiotic and biotic factors (Rillig and Mummey 2006).

5.4.1 Significance of Mycorrhizosphere

Mycorrhizosphere communities play a significant role in sustainable agriculture (Johansson et al. 2004), plant fitness, soil quality (Barea et al. 2002), and nutrient cycling (Azcon-Aguilar and Barea 2015). The management of mycorrhizosphere with the focus on restoration of ecosystems, biological control of pathogenic roots, enhancing the quality of soil, phytoremediation of heavy metals in contaminated soil, and osmotic stress reduction was recently reviewed by Barea et al. (2013). The importance of mycorrhizosphere was also revealed in the sustainable, low-cost phytoremediation methods (Trotta et al. 2006), development of bioenergy crops (Philippot et al. 2013), carbon sequestration (Rees et al. 2005), mineral weathering (Frey-Klett et al. 2009; Koele et al. 2014), and pyrene degradation in soil (Li et al. 2008).

5.4.1.1 Role of Plant Growth-Promoting Rhizobacteria (PGPR)

PGPR are the rhizosphere bacteria involved in the plant growth and development through various direct and indirect processes (Gupta et al. 2000; Glick et al. 2007). They also act as biocontrol agents. PGPR facilitate plant growth by enhancing the uptake of nutrients (Adesemoye et al. 2009), solubilization of phosphate and other essential minerals (Ramachandran et al. 2007; Vyas and Gulati 2009), synthesizing plant growth regulators (Kannan and Surrendar 2009), production of siderophores (Idris et al. 2007; Ahmad et al. 2008), and suppression of disease-causing pathogens (Kloepper et al. 2004; Salimpour et al. 2010). PGPR are potential antagonists and are capable of producing hydrolytic enzymes which lyse the pathogenic fungal cells (Maksimov et al. 2011).

A significant increase in growth and yield has been reported in many important crops (Gray and Smith 2005; Peng et al. 2013). Some of the PGPR belong to the genera, *Azotobacter*, *Pseudomonas*, *Bacillus*, *Klebsiella*, *Arthrobacter*, *Azospirillum*, *Enterobacter*, *Azoarcus*, *Serratia*, and *Rhizobium* (Burdman et al. 2000). *Pseudomonas fluorescens* is present in the rhizosphere of many crop plants and is well known for its biocontrol activity (Costa et al. 2006; Ahmad et al. 2008). The suppression of root pathogens by symbiotic root-colonizing microorganisms is well documented (Rezzonico et al. 2007; Abbas-Zadeh et al. 2010). Okubara et al. (2010) demonstrated the biocontrol activity of *Pseudomonas fluorescens* against soilborne fungal pathogens of *Triticum aestivum* during the infection process. An isolate of *P. fluorescens* B16 isolated from the graminaceous plant roots colonized the roots of different plants and increased the height, flower and fruit number, and total weight of tomato plants (Minorsky 2008). PGPR have the ability to secrete metabolites such as antibiotics, fungal cell wall-degrading enzymes, some gaseous products, and siderophores (Idris et al. 2007). Further, they also produce plant growth regulators such as auxins, gibberellins, and cytokinins that facilitate nutrient release (Idrise et al. 2002) and provide resistance against environmental stresses (Ashraf et al. 2004). The IAA (indole-3-acetic acid) produced by bacteria enhances plant growth (Khare and Arora 2010). The production of siderophores, by *Pseudomonas*

fluorescens and *Pseudomonas putida*, helps plants in their uptake of iron and deters the growth of plant pathogens (Santoyo et al. 2012).

Rhizosphere colonization by *Azospirillum* species enhances the plant growth due to its ability to fix N (Helman et al. 2011). They are also involved in the production of siderophores (Massenia Reis et al. 2011) and plant hormones like IAA and gibberellins (Martinez-Morales et al. 2003). Dual inoculation of PGPR (*Pseudomonas*, *Azotobacter*, *Azospirillum*) and AM fungi stimulates lycopene production and antioxidant activity in tomato (Kourosh et al. 2010). *Pseudomonas* sp. and *Azospirillum* sp. isolated from root cuttings of *Piper nigrum* resulted in significant phosphate solubilization (Ramachandran et al. 2007). Phosphate-solubilizing *Bacillus megaterium* isolated from the rhizosphere of tea was known to promote plant growth. Some PGPR contain ACC-deaminase enzyme which has the ability to scale down the ethylene levels, thereby promoting plant growth and development (Zahir et al. 2008). The role of PGPR with ACC-deaminase activity in phytoremediation (Cavalca et al. 2010) and biocontrol of the plant pathogens has also been demonstrated (Belimov et al. 2007).

5.4.1.2 Mycorrhization Helper Bacteria (MHB)

Bacteria which are beneficial to both arbuscular and ectomycorrhizal fungi are often called mycorrhiza or mycorrhization helper bacteria (Duponnois 2006; Frey-Klett et al. 2007). Some of the MHB strains include the Gram-positive bacteria (*Agrobacterium*, *Azospirillum*, *Azotobacter*, *Bradyrhizobium*, *Pseudomonas*, *Klebsiella*), Gram-negative bacteria (*Bacillus*, *Paenibacillus*, *Variovorax*), and Gram-positive actinomycetes (*Streptomycetes*, *Arthrobacter*, *Rhodococcus*) (Frey-Klett et al. 2007). Mycorrhization helper bacterium enhances the mycorrhiza formation mostly, ectomycorrhizal fungi by producing growth metabolites thus allowing fungal hyphae to colonize plant roots with large surface area (Bending et al. 2006).

Pseudomonas is one of the important groups of MHB that facilitate rapid colonization of the root by mycorrhizal fungi and stimulate the formation of lateral roots (Poole et al. 2001). MHB and the plant roots come in direct contact to promote mycorrhizal symbiosis (Aspray et al. 2006).

Actinomycetes are often free colonizers of plant roots, mycorrhizosphere and rhizospheres (Tarkka et al. 2008). Some actinomycetes are involved in the suppression of AM fungi due to its inhibitory effect in the rhizosphere. Root rot of apple caused by *Pythium*, *Dematophora*, and *Fusarium* is suppressed by MHB obtained from spores of AM fungi (Dohroo and Sharma 2012). MHB also induces AM fungal spore germination and mycelial growth due to the production of growth factors and by detoxifying the antagonistic compounds (Frey-Klett et al. 2007). *Streptomyces* sp. AcH505 produces metabolite auxofuran that suppresses the growth of pathogenic fungi and induces pre-symbiotic growth of *Amanita muscaria* and *Suillus bovinus* (Keller et al. 2006; Frey-Klett et al. 2007). One of the MHB isolates *Burkholderia* sp. EJP67 isolated from the ectomycorrhizal roots of *Pinus sylvestris* promoted the formation of long and short roots in the same host plant (Poole et al. (2001). On the whole, MHB has the ability to promote mycorrhization by different ectomycorrhizal fungi (Bending 2007).

5.4.1.3 Fungi

Other than PGPR and MHB, soil fungi also play a vital role in the mycorrhizosphere. The AM fungi also contribute to its role as biofertilizer, resistance against plant diseases, heavy metals, and various stress conditions (Hildebrandt et al. 2007). *Trichoderma* sp. secretes metabolites which act as a biological fungicide against the disease-causing fungi (Vinale et al. 2009). Other potential fungi known for biocontrol of soilborne diseases are *Trichothecium*, *Epicoccum*, and *Aspergillus*. Application of both *Trichoderma* sp., and mycorrhizal fungi improves plant growth by reducing the negative effect of pathogens (Ene and Alexandru 2008). The AM fungal association with plants decreases both the incidence and severity of disease caused by phytopathogens (Chakraborty et al. 2011).

5.4.1.4 Soil Aggregation

Soil aggregates that favours growth of plants and microbes consist of minerals, roots, fungal mycelium, bacteria, organic matter, and AM fungal derived glomalin (Rillig et al. 2007). These aggregates are formed by the adhesive action of oligosaccharides in glomalin with the help of iron or polyvalent cations (Rillig 2004). Glomalin is a fungal glycoprotein, insoluble in water, resistant to heat degradation, and found in almost all soils (Nichols and Wright 2004; Bai et al. 2009). The AM fungal mediated formation of aggregates in the soil enhances hyphal length, plant roots, and microbial communities in the mycorrhizosphere (Nichols 2008). The AM fungal hyphae may affect the soil aggregation directly by providing a skeletal structure to physically hold the mineral particles of the soil. The entangled hyphae also serve as a source for the organic and inorganic binding agents, and the soil microaggregates are transformed into macroaggregates (Miller and Jastrow 1992). The AM fungi are also capable of secreting considerable quantities of glomalin into the soil environment (Wright and Upadhyaya 1998; Wright 2000; Rillig et al. 2002, 2003), and in due course of time, a portion of these compounds may be reabsorbed by the mycorrhizal hyphae (Sun et al. 1999) similar to the reabsorption of exuded compounds by the roots (Jones and Darrah 1993). The soil aggregates are more stable in the hyphosphere when compared to the soils that are free from mycorrhizal hyphae. This clearly shows that the extraradical mycelium of mycorrhizal fungi can stabilize soil aggregates without any contributions from plant roots (Andrade et al. 1998). In addition, the fungi also play an important role in the improvement of soil structure as they provide reduced amount of carbon to the extrarhizosphere microflora of the hyphosphere (Tisdall and Oades 1982; Bagyaraj 1984). When the microbial biomass increases, the aggregate stability also increases (Lynch 1981). Moreover, the AM hyphal growth that is outside the rhizosphere helps the movement of organic nutrients from the plant to microorganisms (Jakobsen and Rosendahl 1990). Therefore, the hyphosphere is marked by severe bacterial colonization than the bulk soil without AM hyphae as revealed by the positive relationship between the length of hyphae and stability of the soil aggregates (Foster et al. 1983).

5.4.2 Molecular Mechanisms of Mycorrhizosphere

The molecular mechanisms could provide a better knowledge about the interactions occurring between plants and microbes in the mycorrhizosphere. Different types of biochemical and molecular mechanisms occur in the mycorrhizosphere. The mechanism involved in the uptake of nutrients and how mycorrhizosphere microbes defend plants against phytopathogens at the molecular level is discussed below.

5.4.2.1 Mechanism Involved in Biocontrol of Soilborne Diseases

The AM fungi have the ability to induce the establishment of rhizobacteria that deter the growth of pathogens in the mycorrhizosphere before they infect the plant roots (Lioussanne 2010). Plant diseases can be controlled by manipulation of indigenous or through introduction of antagonistic microbes or by management of resident soil microbes that can decrease the pathogen propagules responsible for causing diseases (Linderman 1992). Mycorrhizal plants are more resistant to infestation by soilborne pathogens, nematodes, and also root insects (Whipps 2004). A number of hypotheses have been put forward to explain the role AM fungi in controlling soilborne plant pathogens. Induced systematic resistance (ISR) is one of the mechanisms through jasmonic acid and ethylene production, in which rhizobacteria suppress diseases in plants. Systemic acquired resistance (SAR) is an induced defense mechanism through salicylic acid (SA) production, which protects the plants from pathogenic microbes (Van Loon et al. 1998). These ISR and SAR play an important role in plant defense mechanism through different signaling pathways that are interlinked with each other (Pozo et al. 2008). The plant defenses are preconditioned by an infection that results in tolerance to pathogens (Van Hulten et al. 2006; Beckers et al. 2009). Certain defense-related genes are activated by SA, known as pathogenesis-related proteins (Van Loon 2007). Another mechanism known as mycorrhiza-induced resistance (MIR) is also a well-known plant defense mechanism which has been demonstrated in rice against the blast fungus *Magnaporthe grisea* (Pozo et al. 2008; Campos-Soriano et al. 2012).

In the ISR, the AM colonization regulates the stimulated pathogenic symptoms in a systematic manner (Pozo and Azcon-Aguilar 2007). Many components have been isolated from AM-colonized plants which could control pathogenic activities. For example, high concentration of phenolic acids (Singh et al. 2004), few isoforms, superoxide dismutases, and peroxidases was also found (Garmendia et al. 2006). Isoforms of few enzymes such as chitosanases, β-1,3-glucanases, chitinases, and peroxidases have been identified in mycorrhizal roots (Pozo et al. 1996). In another mechanism, two strains of fluorescent pseudomonads proved to be an excellent biocontrol agent. They suppress other microbes by secretion of secondary metabolites (Srivastava et al. 2001; Kang et al. 2008).

5.4.2.2 Mechanism of Nutrient Exchange and Nutrient Cycling

Root-associated microbes involved in the nutrient cycling in plants are N_2-fixers, P mobilizers, and AM fungi. AM fungal interactions are responsible for the nutrient exchange between the plant and fungi. Moreover, saprophytic rhizobacteria also

have the ability for N and P mobilization (Azcon-Aguilar and Barea 2015). Mostly the nutrient exchange takes place within root cortical cells having arbuscules. The extracellular hyphal network spreads into the surrounding soil and reaches the nutrient depletion zone and enhances the supply of inorganic nutrients mostly phosphate and nitrate (Smith et al. 2011). In return, the heterotrophic fungal partner receives photosynthates from the host plant (Smith and Smith 2011). This causes important changes in primary and secondary metabolism of plants (Harrison 1999). The N and P transport from the soil to plants occurs both via mycorrhizal pathway and direct pathway. AM roots absorb nutrients through root epidermis, root hairs, and AM fungal hyphae and transport them to root cortical cells. The N and P from the soil are transported to roots mostly by the mycorrhizal pathway (Smith and Smith 2011).

In N transport process, inorganic N is taken up by the extraradical mycelium of the mycorrhizal fungi and incorporated into arginine in the fungal cytoplasm. Next, it is transferred to the intraradical mycelium where it can associate with polyphosphate. The arginine is broken down in the intraradical mycelium prior to its translocation to the plant root. As a result, the fungal N reaches root as ammonium (Govindarajulu et al. 2005). Most of the fungal N that is transferred to the plants in the form of ammonia is acquired by the mycorrhizal fungi through the involvement of ammonium transporter gene like *GintAMT1* (Lopez-Pedrosa et al. 2006). In phosphate acquisition, the uptake of inorganic phosphate by AM fungi from soil requires high-affinity transporters which are present in the fungal extraradical mycelium (Benedetto et al. 2005). After the fungal uptake of inorganic phosphate, it is transported into the vacuoles and gets deposited in the form of polyphosphate chains. Further, polyphosphate chains are released by the fungus after moving into arbuscules and finally it reaches the cells of the root cortex. A number of AM fungi and plant phosphate transporters involved in P transport of mycorrhizal plants have been identified. For example, P transporter genes *GiPT* from *R. intraradices* (Maldonado-Mendoza et al. 2001); *ORYsa*, *Pht1*, *Pht11*, and *MtPT4* from rice (Paszkowski et al. 2002), and *Medicago truncatula* have been isolated and characterized (Harrison et al. 2002).

5.5 Conclusion

Non-mycorrhizal plants possess only rhizosphere, while the mycorrhizal plants have mycorrhizal mycelium that may contribute to around 75 % of the plant's absorptive surface. Mycorrhizospheres are unique and intricate systems whose composition and function determine the existence and sustainability of most terrestrial plant communities. The study of mycorrhizosphere is inherently difficult because of the intimacy of the plant roots and the fungal hyphae with the soil. This is further complicated by the mycorrhizal mycelial networks that interlink plant roots and stretch the conventional rhizosphere. Limited studies on the complicities of the mycorrhizosphere suggest that the microbial communities in the mycorrhizosphere have multilevel interactions among themselves and with the environment. Further studies using molecular tools as suggested by Timonen and Marschner (2006) would be of immense value in unrevealing the composition and physiological functions of the mycorrhizosphere.

Arbuscular Mycorrhizae: Effect of Rhizosphere and Relation with Carbon Nutrition

6

Ibrahim Ortaş, Somayyeh Razzaghi, and Mazhar Rafique

Abstract

More than 90 % of terrestrial plants form symbiotic association with mycorrhizae which develop and promote cooperation belowground in rhizosphere. Mycorrhizal fungi produces spores in the soil and vegetative propagules in root fragments which respond to stimulation of root exudates in the rhizosphere. As a result, symbiotic relationship takes place where physiology and morphology of both participants rely on each other. Mycorrhizae are present in a range of horticultural, agricultural, forestry and other plant species. Along with mycorrhizae, other beneficial microbes also add in plant growth promotion, nutrient and uptake and stress tolerance either biotic or abiotic. The presence of bacteria in rhizosphere synchronizes with mycorrhizae termed as 'mycorrhizae helper bacteria' and increases plant growth by focusing on N and P in particular while micronutrients in general. Besides that, carbon has important structural and functional role in symbiotic association, because of mycorrhizal reliance on plants for food. Additionally, movement of C to the roots is an interesting area for exploration due to recent global focus on addressing climate change and carbon mitigation approaches particularly for sustainable agriculture. AM symbiosis can influence soil CO_2 emissions and soil in ecosystems dominated by mycorrhizal plants that

contain 70 % more carbon per unit nitrogen than soil in ecosystems dominated by non-AM-associated plants. Absorption of CO_2 by mycorrhizae is contributing in climate change mitigation and translated as plant biomass production.

6.1 Introduction

The most widespread symbiotic association between microorganisms and plants is arbuscular mycorrhizal fungi (AMF), which is present in a range of horticultural, agricultural and forestry plants Marschner (2012). Different plant species are infected with indigenous AMF in their natural habitat (Ortas and Coskan 2016a). Mutualistic mycorrhizal fungi-root association has been known and being studied since 1885, when Frank for the first time gave the name *mycorrhiza* (*myco*, fungus; *rhiza*, root) to readily observable morphological complexes between fungi and tree roots. Mycorrhizal infection occurs in 83 % of dicotyledonous and 79 % of monocotyledonous plants (Trappe 1987).

According to Azcon-Aguilar and Barea (2015), beneficial microbes contribute in plant growth and increase nutrient uptake such as nitrogen and/or soluble phosphate. Understanding the mechanism of high N use efficiency by mycorrhizal/rhizobial plants and carbon allocation in a context of mutualistic system is critical for managing agricultural system for the ecosystem sustainability by microbial symbionts. Since there is significant effect of carbon on climate change and sustainability of agriculture, it is sound to explore the influence of beneficial organisms on carbon sequestration (Ortas et al. 2013). It has been suggested that soil microflora may have significant influence on the formation of mycorrhizal association. The results of Sutton and Sheppard (1976) showed that adding non-sterile soil leachate to a sterile soil increases biomass of AM hyphae.

Recently research groups on mycorrhiza have concentrated on the effect of mycorrhizal inoculum on nodulation, when both mycorrhizae and bacteria are inoculated together. It is an indication of additive and positive cooperation in between fungi and bacteria. Dual inoculation (of AMF and *Azotobacter*) had a synergetic effect on growth increase of the host plant. In rhizosphere, it is possible that some beneficial bacteria, such as symbiotic or free-living nitrogen fixer (Hamdia and Shaddad 2010), phosphate solubilizers and hormone producer organisms (Ratti et al. 2001), could develop cooperation with mycorrhizae. Besides that, very recently the role of mycorrhizae on CO_2 absorption is getting more attention because of continuously piling up of the atmospheric CO_2 concentration to affect climate. Since climate change is related with atmospheric CO_2, the role of mycorrhizae for plant growth promotion and biomass production through carbon absorption is significantly important.

6.2 Mycorrhizal Formation and Functions

Mycorrhizal fungi's characteristic structures are vesicles, arbuscules, hyphae (external and internal hyphae) and resting spores in the host root (Smith and Read 2008). One of the important structural features of mycorrhizae is hyphae which grow longitudinally between the cells of the root cortex. When fungal hyphae contact the root surface, penetration occurs through an aspersorium. After its development, fungus produces hyphae which penetrate between inner cortical cells (Berruti et al. 2013; Sieverding 1991; Smith and Read 2008). The AM root infection usually begins after hyphae extending from propagules (spores, hyphae and root fragments) penetrate into the host root from an entry point on root surface. The mycorrhizal fungi survive in the soil as resting spores, and when environmental conditions become favourable, they start to germinate. The spore formation is generally on the coarse external hyphae. These spores usually range from 50 to 600 μm (Sieverding 1991). Once infection is established, the developing fungi can produce inter- or intracellular vesicles (Rodriguez-Moran et al. 2015). Usually, vesicles are oval, round or lobe shaped and occur within or between cortical cells. They may contain lipid droplets which act as storage structures of fungus. Vesicle shape, wall structure content and their number can differ according to the fungal species forming mycorrhizae (Sieverding 1991; Smith and Read 2008). Arbuscules are intracellular, branched or tree-shaped structures of the symbiont and are formed by repeated branching. They are considered to function for the transfer of nutrients (Marschner 2012; Smith and Gianinazzipearson 1988).

The internal morphology of AMF can be easily observed on cleared and stained root samples under the microscope (Seok-Cho et al. 2007). The mycorrhizal fungus lives with host (plant partner) in a balanced close association. Mycorrhizal fungi can be seen in the soil as spores or as vegetative propagules in root fragments. Propagules of mycorrhizal fungi apparently respond to the stimulation of root exudate, and their hyphae and germ tubes grow and penetrate root epidermal cells. The colonization of the host tissue progresses, both internally and externally along the root surface. The formation depends on the association between host and fungi, the latter resulting in morphological and physiological changes which lead to the formation of different types of mycorrhizae. When mycorrhiza forms, symbiosis significantly changes the physiology and morphology of roots particularly and the whole plant generally (Bray et al. 2003; Wulf et al. 2003). In some plants such as onion and maize, there is a yellow pigmentation which accompanies root colonization. The physiological change is explained as the change has great impact on rhizospheric microorganisms, which alter permeability of the membranes. It is well understood that membrane permeability can alter the quantity and quality of root exudates and results in changed plant nutrient composition. The microbes in microsphere of mycorrhizal fungi may profoundly affect mycorrhizal functions, such as nutrient and water uptake. Moreover, mycorrhizospheric organisms and root exudates have significant influence on soil development as well. Mycorrhizal hyphae are normally supported by the host plants, but their biomass may be influenced by soil biotic and abiotic factors such as soil microorganisms.

6.3 Factors Affecting Mycorrhizal Association

Soil physical, chemical and biological factors affect mycorrhizal development. Water contents (Krishna et al. 2005), temperature (Zhang et al. 2016), light (Clark and St Clair 2011; Moratelli et al. 2007) soil type and their characteristics (Ortas and Coskan 2016b; Thougnon Islas et al. 2016) are illustrations of physical factors. Fitter et al. (2004) indicated that AM fungi respond directly to elevated soil temperature. Furthermore, examples of chemical factors are soil pH (Moon et al. 2016), phosphorus availability (da Silva et al. 2016), nitrogen forms (Smith and Read 2008), micronutrient levels (Hoffmann et al. 2009), salinity stress (Labidi et al. 2011; Ruiz-Lozano and Azcon 2000), organic matter content (Wang et al. 2015), excessive use of pesticides (Zocco et al. 2008), etc. Biological factors are based on host plant (Ocampo et al. 1980) interactions with other soil microorganisms such as pathogenic and competitive with other mycorrhizal fungi (Azcon-Aguilar and Barea 2015). These environmental conditions affect root colonization and fungal growth development in the cortex (Smith and Read 2008). It has been indicated that mean spore abundance was significantly different in cropped systems and soil management (Säle et al. 2015). Barea et al. (2011) and Burkle and Belote (2015) reported that disturbance of target semiarid ecosystem decreases density and diversity of mycorrhizal fungi population. In general, the sporulation of AMF is dependent on soil/plant nutrition, the ecophysiological status of hosts, climate, that is, previous precipitation and also sampling time.

Soil pH reflects the nutrient availability in soil through ion exchange process (Helgason and Fitter 2009). Varying soil pH can change species richness and community composition. For different mycorrhizal species, effect of soil pH on germination of mycorrhizal spores, hyphal growth from spores and hyphal growth from mycorrhizal roots may be different. Guo et al. (2012) have shown that soil medium with liming effect from pH 5.5 to 5.9 increased *G. mosseae* germination by 43–60 % with no further increase observed with addition of lime. The results of (Sivakumar 2013) showed positive correlation between the mycorrhizal spore abundance and soil pH moreover with root colonization. In general, soil with pH range 5.5–6.6, AMF is abundant (Sharma et al. 2009). Martensson et al. (2012) reported that the amount of AMF is very low in poor nutrient and drought-stressed habitat, and they also found that a high pH in the topsoil does not lead to higher AMF biomass.

The results of Alloush and Clark (2001) showed that mycorrhizal infection was strongly inhibited by Al and Mn. Similarly Lambais and Cardoso (1993) recorded that soil may have toxic concentration of Al and Mn to fungal growth, but it supported plant growth. It is believed that soil acidity is not an independent factor as pH itself may have little significant effect on spore germination and root colonization. Resting spores are thick-walled structures formed in the soil. Spore numbers are affected by several factors such as nutritional status of the host plant and soil moisture contents (Ortas and Coskan 2016a; Smith and Smith 2011; Smith and Read 2008).

The frequency of mycorrhizal infection is affected by nitrate (NO_3^-) and ammonium (NH_4^+) ions. According to Asghari and Cavagnaro (2012) and Valentine et al. (2002), the application of NO_3^- or NH_4^+ resulted in higher level of mycorrhizal

infection. Mycorrhizae formation was decreased at high level of NH_4^+-N (Wallenda et al. 1996). The application of increasing amount of NO_3^- reduced the level of AM infection in lettuce roots when the root was inoculated with *G. mosseae* (Kohler et al. 2008). Wallenda et al. (1996) found that high NO_3^- levels can result in the low mycorrhizal formation of conifer seedlings, but with NH_4^+ supply, fungi formed abundant mycorrhizae (Correa et al. 2006). The results of Irshad et al. (2002) showed NO_3^- fertilizer is more inhibitory to AMF development than NH_4^+ fertilizer. Addition of NO_3^--N to the soil decreases AMF infection (van Diepen et al. 2013) and infectivity of mycorrhizal propagules (Cornejo et al. 2007). NH_4^+-N application magnified considerable morphological changes and showed plasticity of *G. intraradices* (Bago et al. 2004). The mechanism responsible for nitrogen inhibition of AM formation is not fully understood.

6.4 Carbon Relation with Mycorrhizae

Soil microorganisms are dependent upon plants for supply of energy mainly carbon. By this way, population of organisms is indirectly dependent on plant photosynthesis. A figure of soil-fungi-plant and their relationship with plant carbon nutrition is presented in Figs. 6.1 and 6.2. The relationship between mycorrhizal fungus and the host plant is bidirectional (Fig. 6.1) where both sides derive benefits. The fungi obtain its required carbon directly from the roots, and at the same time fungi supply inorganic minerals, especially phosphorus (P) from the surrounding soil (Smith and

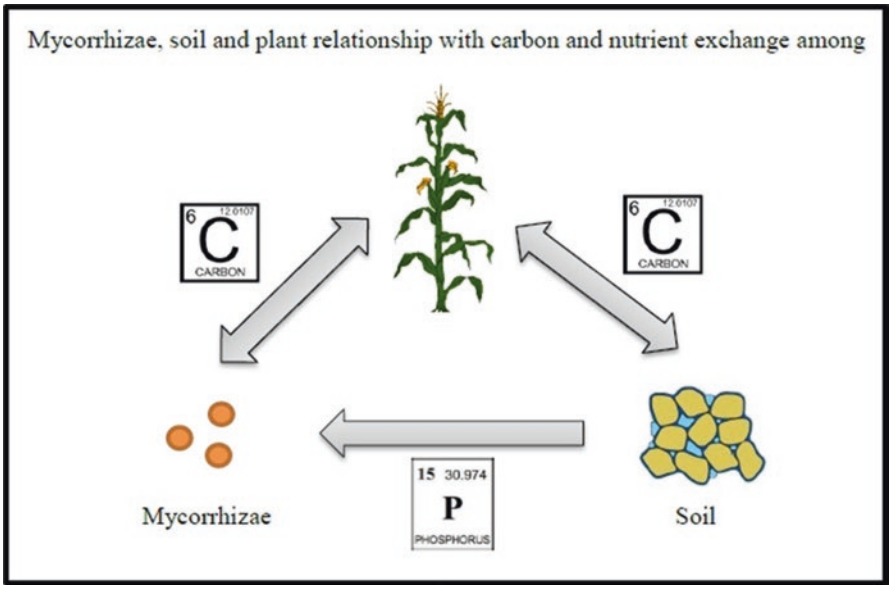

Fig. 6.1 Relationship between mycorrhizae-soil and plant-carbon-nutrient exchange (Ortas 1994)

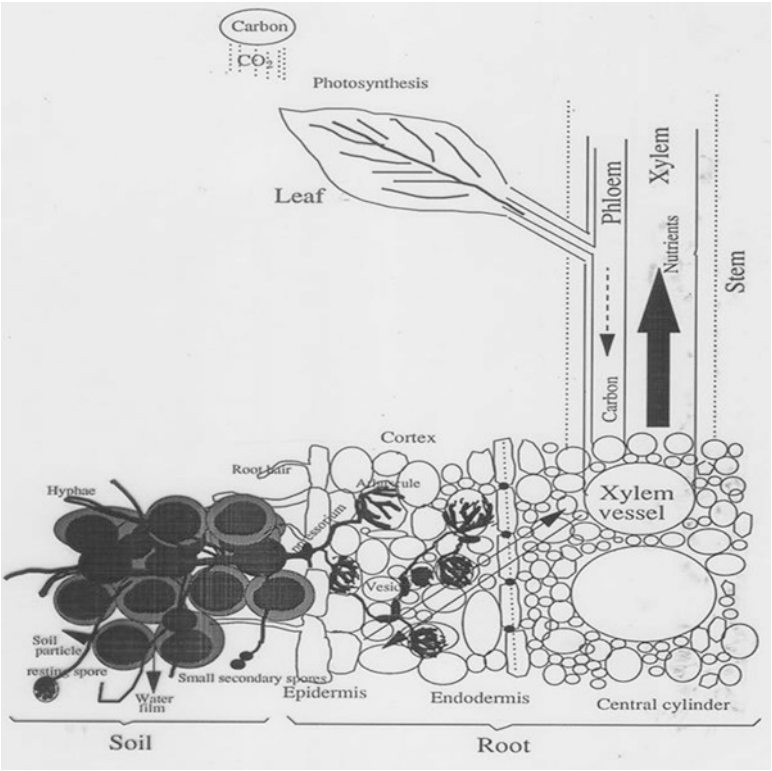

Fig. 6.2 Nutrient transportation from soil to plant tissue and phloem transportation from leaves to mycorrhizal hyphae (Ortas 1994)

Read 2008). Carbon (C) and P are the key nutrients required for mycorrhizal development and functions. It is well understood that AMF are completely dependent on soluble carbohydrates produced by the host plant for carbon. This carbon demand can inhibit plant growth in stress conditions of low light intensity, high level of root colonization (Asensio et al. 2012) and low soil temperature. Mycorrhizal fungi, because of their unique carbon system, can efficiently combine soil mineralization and nutrient uptake by plant roots (Mellado-Vazquez et al. 2016).

In rhizosphere, soil bacteria and fungi generally immobilize mineral nutrients, as carbon is consumed, and thereby compete with plant for nutrients. A useful indicator of plant material supply to soil is net primary production. Living plant roots supply a tremendous amount of C to the soil which can potentially be used by microorganisms. The C utilization by mycorrhizae becomes important when competing with other soil microorganisms.

It is generally accepted that root exudes sufficient quantity of organic compounds to support microorganism population in rhizosphere and support growth of certain microorganisms derived by root exudate quality. In rhizosphere, C losses by plant roots in complex associations of root and soil microorganisms contribute both

positively and negatively which determine plant efficiency. Roots in non-sterile media support a large population of microorganisms on external surface (the rhizoplane) and in rhizospheric soil. The population density of bacteria and partly fungi in the rhizosphere depends on the amount of exudate, mucilage and sloughed-off cells which are carbon based. In soil-grown wheat plants under non-sterile conditions during a period of 3 to 8 weeks, 20–40 % of traslocated C from shoot to root was lost as organic carbon (OC) into the rhizosphere.

It has been suggested that enhanced plant growth and C flow below ground could increase C storage in soils, and it could be the missing sink (Ford et al. 2012). Increased C flow to the soil can be directly via plant roots or indirectly via soil organisms, of which mycorrhizae could potentially be a very important element. Indeed, C allocation to mycorrhizal fungi is often around 10 % of total fixed C (C allocated to belowground fractions such as roots and mycorrhizal hyphae accounted for an average of 10 %, with 4.3 % allocated to mycorrhizal hyphae) (Tome et al. 2015) and has been estimated to be high as 20 %. Cheng et al. (1996) showed that carbon availability index (CAI) and water soluble organic carbon (WSOC) were inversely related to the relative distance from root surface, with several times higher concentration in the rhizoplane soils. It is widely known that carbon availability in the rhizosphere is much higher than bulk soil where AMF could be responsible for carbon sequestration (Ortas et al. 2013).

Most of the carbon is utilized fairly and rapidly by rhizospheric microorganisms. A large turnover of OC by microorganism's activity in the rhizosphere has an important implication for both the carbon balance of plant and mineral nutrient relationships in the rhizosphere. At maturity, only a small fraction of the root-derived OC is retained in the root system.

Willis et al. (2013) indicated that the mechanisms involved in C transfer from plant to fungus are still not well understood. It has been estimated that mycorrhizal plants direct up to 20 % more photosynthate towards root system than non-mycorrhizal plants.

6.5 Mycorrhizae Affect Atmospheric CO_2 Absorption

Interaction between root and soil microorganisms controls nutrient availability and uptake by plants and influences soil greenhouse gas (GHG) emissions such as CO_2 and N_2O (Jackson et al. 2008). This symbiosis increases the uptake of soil nutrients in exchange of photoassimilated carbon compounds (Fellbaum et al. 2012). Mycorrhizal fungi of chlorophyllous plants absorb C compounds from their host. The role of AM symbiosis for plant and soil GHG emissions might be particularly important in ecologically managed systems. Several studies have reported higher CO_2 emissions in mycorrhizal plants than non-mycorrhizal. The results of Heinemeyer et al. (2006) showed that concentration of CO_2 flux is highest in the mycorrhizal treatments. It has been previously suggested that AM symbiosis can influence soil CO_2 emission either due to direct respiration of the fungi or indirect impacts on heterotrophic microorganisms (Cavagnaro et al. 2008). On the other

hand, Tome et al. (2016) reported that mycorrhizal contribution to soil respiration (11 ± 6 %) was of similar magnitude to the roots (12 ± 4 %). However, respiration of SOM and mycorrhizae significantly increased in late summer and autumn terms; this is related with priming effect of roots on SOM degradation or to a stimulation of mycorrhizal respiration. The organic matter has key role in soil ecosystems (Lejon et al. 2007), while limited information is available for SOM effects on AMF, though it is well acknowledged that growth of AMF can be both increase and decrease (Cavagnaro 2014; Ravnskov et al. 2006) by soil organic amendments.

Fitter et al. (2004) indicated that under field studies, variation in vegetation due to environmental changes may play enormous role in determining AMF community structure. Elevated CO_2 could stimulate mycorrhizal colonization, since plants are fixing more C, and its availability to the fungus is increased. According to hypothesis, more C could flow in the soil via mycorrhizal hyphae. The amount of C translocated below ground by AM fungal structures varies between 4 and 20 % of the total C fixed by the plant (Smith and Read 2008). Several researchers have examined mycorrhizal colonization in conditions of elevated CO_2, which might stimulate ectomycorrhizal colonization in various species (Langley et al. 2003), but the evidence for arbuscular mycorrhizae is less clear. The effect of mycorrhizal type on soil carbon is dependent on the effects of net primary production, temperature, precipitation and soil clay content. Hence, the effect of mycorrhizal type on soil carbon content holds at the global scale.

The impact of ectomycorrhizal fungi (EMF) on C turnover in forest soils has been considered limited. Rineau et al. (2012) indicated, using global data sets, that soil in ecosystems dominated by mycorrhizae-associated plants contains 70 % more C per unit nitrogen. Although some climatic models estimated that increased C storage in temperate forest soils is because of increased photosynthetic C allocation to roots and symbiotic fungi (Clemmensen et al. 2013; Drigo et al. 2010), there is still a room for exact degree of C storage estimation. Mycorrhizosphere activity may also stimulate decomposition of previously recalcitrant SOM (Cheng et al. 2012). The saprotrophic and EMF species produce a range of hydrolytic and oxidative enzymes with a potential effect to break down C-containing compounds such as OM and mobilize nutrients from SOM (Norby et al. 2010) Although photosynthates are likely the primary source of C used by EMF in ideal condition (Wolfe et al. 2012), many studies suggest that fungi may directly (Vaario et al. 2012) or indirectly (Rineau et al. 2012) access SOM-C pools.

6.6 Mycorrhizal Development Influenced by Rhizospheric Organisms and Nitrogen

It has been previously reported that effect of AMF on P uptake and plant growth was more in sterilized soil in comparison to non-sterilized soil. It has been hypothesized that more plant growth and P uptake may result from more N mineralization especially the mineral NH_4^+-N flush after soil irradiation. According to Ortas et al. (1996), (Ortas and Rowell (2000) and Ortas et al. (2004), the amount of NH_4^+-N

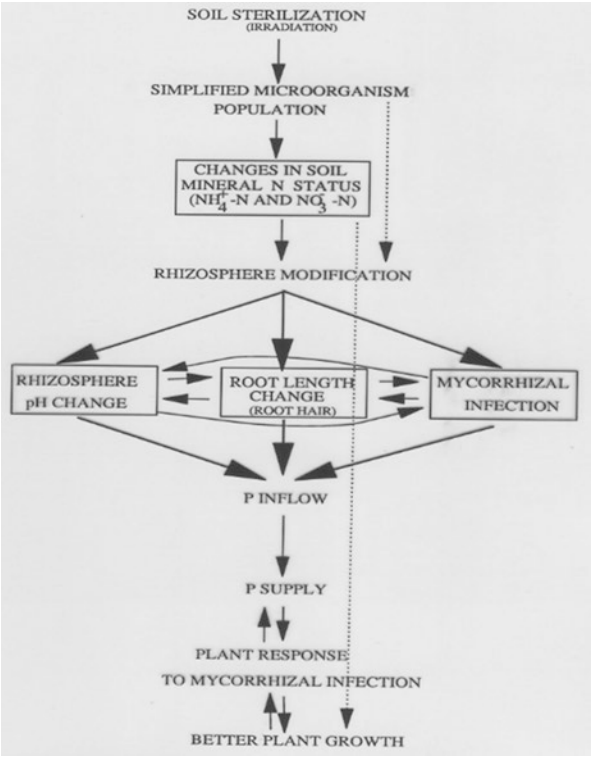

Fig. 6.3 The effect of soil sterilization on nutrient dynamics and P uptake

should be taken into account for plant growth and P uptake (Fig. 6.3). Phosphorus uptake mechanisms are related with nitrogen effect on rhizosphere pH (Hinsinger 2001; Isaac et al. 2012; Rubio et al. 2012). Under partial sterile soil conditions, N mainly comes after dead organisms and organic matter degradation.

So far numerous pot experiments have been carried out in partially sterilized soil to eliminate the effects of indigenous mycorrhizae on self-introduced mycorrhizal inoculum. The results of inoculation experiments are generally positive, because unwanted growth response in sterilized soil is related to increased level of available N and in particular N mineralized from the soil microbial biomass (Ortaş and Harris 1996) along with elimination of nutrient competition with other microorganisms. The effect of sterilization on soil properties (Gebremikael et al. 2015) and nutrient dynamics has been widely studied (Ortas and Rowell 2004; Ortas et al. 2004; Ortaş and Harris 1996).

The main aim of partial soil sterilization in mycorrhizal studies is to eliminate indigenous mycorrhizal spores and pathogenic microbial activity in the soil, but this procedure often alters the chemical and biological properties of the soil (Hassan et al. 2012). Under the greenhouse with sterile conditions, pathogen activities have been largely restricted, and plant growth especially root development was

Fig. 6.4 The effect of mycorrhizal inoculation on the maize growth under fumigated and unfumigated field conditions (Ortas unpublished photo)

maximized. AMF have been shown to affect root growth, root exudate, nutrient absorption and host physiological response to environmental stresses (Folli-Pereira et al. 2012; Liu et al. 2015; ZhongQun et al. 2007). Increasing the AMF in soil, P nutrition for root growth also enhances and expands the absorptive capacity of the root system for water and nutrients which influence cellular processes in root (Smith and Read 2008; Tischer et al. 2015).

The main procedure so far adopted is elimination of indigenous fungi from soil than reinoculated under controlled conditions before their effects on plant growth can be assessed by comparing mycorrhizal and non-mycorrhizal plants. As expressed by Hetrick et al. (1988) and Miransari et al. (2009)), the effect of other soil microorganisms eliminated during soil sterilization on plant growth or mycorrhizal growth response is generally not considered. The contribution of AMF to plant growth in non-sterile soil may be different from sterile one. Nevertheless, it is extremely difficult to evaluate the contribution of AMF on plant growth in non-sterile soil. Under the fumigated soil conditions, reinoculation of mycorrhizae increased maize growth (Fig. 6.4).

With soil sterilization, soil organisms are killed and organic matter mineralization releases sufficient nutrients such as NH_4^+-N and NO_3^--N. Partial soil sterilization can result in four–tenfold increase in NH_4^+-N level (Ortaş and Harris 1996; Tanaka et al. 2003). The contribution of soil partial sterilization to nutrient release may be explained as follows:

Table 6.1 Literature on the effect of partial sterilization on mineral nitrogen release from organic compounds and soil microorganisms

NH_4^+–N	NO_3^--N	References

↑ = Increase, ↓ = Decrease, ND = No Data

1. Some extractable nutrients come from decomposition or breakdown of organic matter present in soil as a direct result of irradiation treatment.
2. Several enzymes, including the urease (which produces ammonia as a decomposition product), are released after irradiation.
3. Some nitrogen is released from dead organisms (Ortaş and Harris 1996), and other nutrients are possibly released after the death of soil microorganisms (such as bacteria, fungi and actinomycetes).

Partial soil sterilization generally stimulates subsequent plant growth which is associated with an increased net mineralization of NH_4^+-N (Tanaka et al. 2003). The effects of partial soil sterilization on N-release reported in the literature are shown in Table 6.1.

The fertility of sterilized soil may be different than non-sterilized soil (Ortas 2003). According to Malkomes and Dietze (1998), partial soil sterilization drastically reduces the microbial population of soil with total eradication of certain microorganism groups. It is well known that N is one of the essential macronutrients and is required by plants in considerably large amount than P. According to Clemmensen et al. (2008) and (Tahovska et al. (2013) in different climates and neutral to slightly acid soils, the primary form of N available to plants is NH_4^+-N. The supply of nitrogen can influence rate of plant growth. Plant species differ in the form and amount of inorganic N uptake and its metabolism in roots (Azcon-Aguilar and Barea 2015). N supply to the host plant root influences, either directly or indirectly,

susceptibility of the roots to infection, which can be influenced by rhizosphere pH change (Turnbull et al. 1995). Since N forms alter rhizospheric soil pH, two different N forms NH_4^+ and NO_3^- may affect mycorrhizal development in different ways as well (Ortas et al. 1996; Ortas et al. 2004).

It is widely accepted that plants can increase P uptake by chemically modifying the rhizosphere (Conversa et al. 2013; Marschner 2012; Ortas 1997). The main mechanism that has been suggested is pH alteration through excretion of H^+ and OH^-/HCO_3^-. pH is a major factor influencing the soil solution concentration of many plant nutrients, and plant-induced variation in pH affects the availability of many nutrients (Gao et al. 2012; Nietfeld and Prenzel 2015; Ortas and Rowell 2000; Valentinuzzi et al. 2015). The pH changes surrounding environment and infected roots, thereby affecting P availability. The intensity of AM root colonization, host plant P uptake and growth response to AM has been reported to be pH dependent (Baar et al. 2011; Zhu et al. 2007).

The local acidification around mycorrhizal-infected roots may be very important for P uptake. It was suggested that application of N and possibly P resulted in mycorrhizae making a significant contribution to the plant's P status. As mentioned above, because of utilization of NH_4^+-N by hyphae of mycorrhizal plants, this may have further consequences in the rhizosphere pH. Recent studies of Cely et al. (2016), Feitosa de Souza et al. (2016), Hall and Bell (2015), Zhou et al. (2016) and Zong et al. 2015) showed better understanding to the effect of mycorrhizal infection on P uptake. However, additional study, especially the effect of NH_4^+-N supply on P uptake with and without AMF, is required. It is also necessary to understand the relationship between P uptake and rhizosphere pH change (caused by NH_4^+-N) with VA inoculation an area which has received little attention in the past (Ortas 2012a). Gahoonia and Nielsen (2004) indicated that manipulation of rhizosphere pH through agronomic measures such as application of NH_4^+ or NO_3^- fertilizers may be more practical than breeding approaches.

6.7 Mycorrhizal Importance in Rhizospheric Soil

AMF are the largest symbiotic associations between plants and fungi which make significant contribution on physical, chemical and biological aspects of soil quality through AM fungal hyphae extending into the rhizosphere and thereby improving the absorption of nutrients especially P and micronutrients (Karandashov and Bucher 2005; Ortas 2003; Smith and Read 2008). Burkle and Belote (2015) results showed that the relationship between productivity and diversity varied among pioneer treatments and mycorrhizal amendments. This means that soil and crop management is related to the existence of mycorrhizae (Almaca and Ortas 2010; Ortas and Coskan 2016a). The establishment of mycorrhizae causes changes in the physiology of host plants. Like other soil microorganisms, AMF act as ecosystem engineers on roots and surface of the plants.

Fig. 6.5 Aggregate formation by the plant roots and AM mycelium (Ortaş 2008)

6.8 Mycorrhizae Effect on Soil Development Related with C Fixation

In an ecosystem, mycorrhizae actually play an important role across the rhizosphere and provide an organic link between the root and bulk soil. Moreover, mycorrhizae have significant effect on soil development. Aggregates encapsulate SOC and reduce rate of decomposition. Similarly, plant roots and AMF hyphae provide physical protection to soil C against microbial decomposers through aggregation (Leifheit et al. 2015; Ortas et al. 2013). AMF play a contributory effect on soil aggregate formation (Fig. 6.5) because of the symbiosis which significantly changes the root functioning (Espeland et al. 2013). The AMF symbiosis may also influence soil biogeochemical processes and GHG emissions through change in soil physical properties such as soil water holding capacity (Cavagnaro et al. 2006). Organic compounds and AMF hyphae are important in binding soil into macroaggregates and microaggregates (Singh et al. 2009). Thus, depletion of SOM and the degradation of soil structure can adversely affect soil fertility and crop productivity. Soil aggregation is one of the important soil characteristics that mediates many soil chemical, physical and biological properties and improves soil quality and sustainability (Ortas et al. 2013).

Graf and Frei (2013) reported that EMF increase water stable aggregates (WSA) along with promotion of plant growth. Therefore, mycorrhiza has a significant impact on soil resilience which is also an important component of soil quality. Several studies have reported that soil biology, especially mycorrhizal fungi, significantly influences soil fertility and soil quality.

6.9 Mycorrhizal Application for Plant Growth and Nutrient Acquisition

AMF influence soil functions such as C, N and P cycling to support plant growth and nutrition in the agro-ecosystem. Colonization by AMF ameliorates abiotic plant stress by enhancing plant nutrient uptake and delivering drought tolerance (Lehmann

et al. 2014). The symbiosis influences plant water relation and drought resistance (Augé et al. 2015). AMF play a significant role in the establishment of plants in different environments by assisting in nutrient uptake enhancement along with stress tolerance such as drought and salt stress and even protecting them against soil pathogens (Azcon-Aguilar and Barea 2015).

There are good studies which explain that mycorrhizal plant has enhanced capability of plant root in acquiring nutrients from soil, particularly when the nutrient is poorly soluble and present in low concentration (Abrahao et al. 2014; Teste et al. 2014). For a given dry weight, mycorrhizal plants usually have higher P concentration in plant tissue than non-mycorrhizal plants (Zhang et al. 2014). Several crop plants absorb more P from low P soils when infected with AM fungi (Ortas 2003; Ortas et al. 2001). It has been found that mycorrhizal-infected roots can utilize rock P, whereas non-mycorrhizal roots cannot (Chinnusamy et al. 2006). How mycorrhizal plants obtain more P from soil than non-mycorrhizal plants is not yet fully understood. Several mechanisms have been proposed to define the AM effect on improving the absorption of available phosphate. Miranda et al. (2016) evaluated the effect of mycorrhizae and phosphorus (P) on forage peanut and reported that the seedlings grown in pots and fertilized with P, the extent of the response was higher for those inoculated with AMF. Moreover, Ortas et al. (2013) showed different mycorrhizal species significantly inoculated different plant roots and observed root colonization and P uptake. The species *G. clarum* was more efficient under conditions of low P availability for citrus seedlings (Ortas 2015).

Mycorrhizae may induce both quantitative and qualitative changes in plant P utilization (Smith and Read 2008). The amount of acid phosphatase present in AM hyphae (Cavagnaro 2014) and increased phosphatase activity of root surface as a result of infection (Guo et al. 2016) may liberate inorganic P from organic P sources, making P available for uptake. Alford et al. (2010) suggested that the roots of mycorrhizal plants may alter the rhizosphere chemistry by changing soil pH and produce exudates such as organic acids which may increase the availability of phosphorus by liberating phosphate ions in the soil (Rajkumar et al. 2012). There is still a wide research gap in understanding mechanism involved for increased P availability in the soil by mycorrhizal-infected roots. The low dry weight increment of experimentally inoculated plants in same conditions may be mycorrhizal, and all make greater demands on their host for carbon than the naturally released into the soil.

6.10 Soil P Influenced by Mycorrhizal Association

In agricultural and horticultural ecosystems, mycorrhizal colonization has been frequently observed less associated with high rates of P application (Elbon and Whalen 2015). The symbiosis of plant with AMF increases its efficiency in absorbing nutrients from the soil solution, especially the nutrients of low mobility such as phosphorus (Brito et al. 2013), which makes it possible to use phosphate fertilizers of low solubility in seedling production (Silva et al. 2016). Khade et al. (2010)

hypothesized that the infection is affected by P status of the plant rather than soil P levels. Graham et al. (1981) provided evidence that the roots of sorghum produce less root exudates in high P soils and hypothesized that colonization was affected by high soil P levels. It has been concluded that a large amount of P uptake can be explained by the increased surface area of hyphae alone (Sharif and Claassen 2011). In such case, plants have several mechanisms to employ for more P uptake, such as acidification of rhizosphere (Zahra et al. 2015) and excretion of organic acids (Palomo et al. 2006). Mobilization and solubilization of P are the principal chemical (soil pH change) and biological causes of increased nitrogen availability (Isaac et al. 2012). The soil organisms are also involved in mobilization of phosphate. Plant roots infected with AMF are known to have a higher phosphorus (P) absorption ability compared to non-mycorrhizal plants in P-deficient soils (Conversa et al. 2013; Smith and Smith 2011). Large inputs of soluble P, associated, for example, with application of superphosphate, can decrease mycorrhizal advantages by inhibiting the growth and activity of the vegetative mycelium (Greenhalgh et al. 1994). According to Feitosa de Souza et al. (2016), infection is affected by soil P as well as plant P concentration. As plants vary in their ability to absorb P and mycorrhizal fungi vary in their response to soil P, each plant-soil-AM symbiont system must be evaluated separately.

The soil P concentration is usually critical in mycorrhizal infection. Soil P must be sufficient for host plant growth and colonization of mycorrhizae. Very high and very low phosphorus levels may reduce mycorrhizal infection/colonization (Goncalves de Oliveira et al. 2015; Lirio Rondina et al. 2014). It is well established that infection by mycorrhizal fungi is significantly reduced at high soil P levels (Balzergue et al. 2013). The level of P in the plant has also been shown to influence the establishment of mycorrhizae with high levels inhibiting colonization; moreover it depends upon the root system (Yang et al. 2015). Ortas (2012a) showed that addition of P decreased AM infection in wheat under field conditions. The high concentration of soluble phosphate decreases AMF percentage (Table 6.2). Ortas (2012a) reported that with increasing P levels, mycorrhizal colonization significantly reduces. In *G. mosseae*-inoculated plants, when plant received no P fertilizer, root colonization was 90.8 % and with P treatment root colonization was 57.1 % (Table 6.2). Controlled plant roots had 3–10 % of colonization, but *G. etunicatum*-inoculated plants had 41–72 % and *G. mosseae*-inoculated plants had 30–75 % root colonization. Therefore, mycorrhizae formation, response to added P, host nutrient requirement and mycorrhizae responsiveness are all interrelated.

The results of mycorrhizal research have strongly suggested that infection does not change the size of labile pool, but the hyphae extend beyond P depletion zone and provide a well-distributed surface for absorbing phosphorus (Sharif and Claassen 2011). Rubio et al. (2012) demonstrated a field and greenhouse experiments and showed that different plant species have different effects on rhizosphere P depletion which is related with plant P demand. Plants uptake P from the soil solution at a much faster rate than they can diffuse to the root surface. Consequently, a P depletion zone develops around the absorbing organs (mycorrhizal hyphae or roots) of the plants (Marschner 2012).

Table 6.2 Effect of P, Zn and mycorrhizal inoculation on maize plant root infection (Ortas 2012a)

Mycorrhizal species	Treatments		Root infection (%)	
Control	P0		2.0	±1.00
	P1	**Zn0**	2.3	±2.50

Since the diffusion of P in soil is very slow, P absorption capacity of roots does not have great effect on rate of uptake. When plant roots are not able to absorb sufficient P for adequate growth, then plants employ other physiological variables of root on P absorption by increasing the amount of P available to diffuse the root surface interpreted (Isaac et al. 2012). The direct effect of soluble P on fungi metabolism, mainly by regulating enzymatic activities, is related to phosphate transfer to the host and has been recently discussed. Carrasco et al. (2011) showed higher levels of acid phosphate activity in the root and rhizosphere infected by *G. mosseae* and *G. geosporum* compared with control. Although increased phosphatase activity has been demonstrated in several mycorrhizal symbioses, plant roots and other microorganisms can also produce acid phosphatase. In this case, it is difficult to interpret contribution of mycorrhizae.

6.11 Effect of Mycorrhizal Infection on Nitrogen Uptake

The effect of N form and P rate application on total dry matter production on harvesting varied with mycorrhizal inoculation. Hoeksema et al. (2010) reported in a meta-analysis work that N-fertilization is an important predictor of plant response to mycorrhizal inoculation. AMF inoculation enhanced differences between N sources (Ortas and Rowell 2004). Sorghum plants infected with mycorrhizae had nearly three times more shoot dry matter yield than non-inoculated control plants

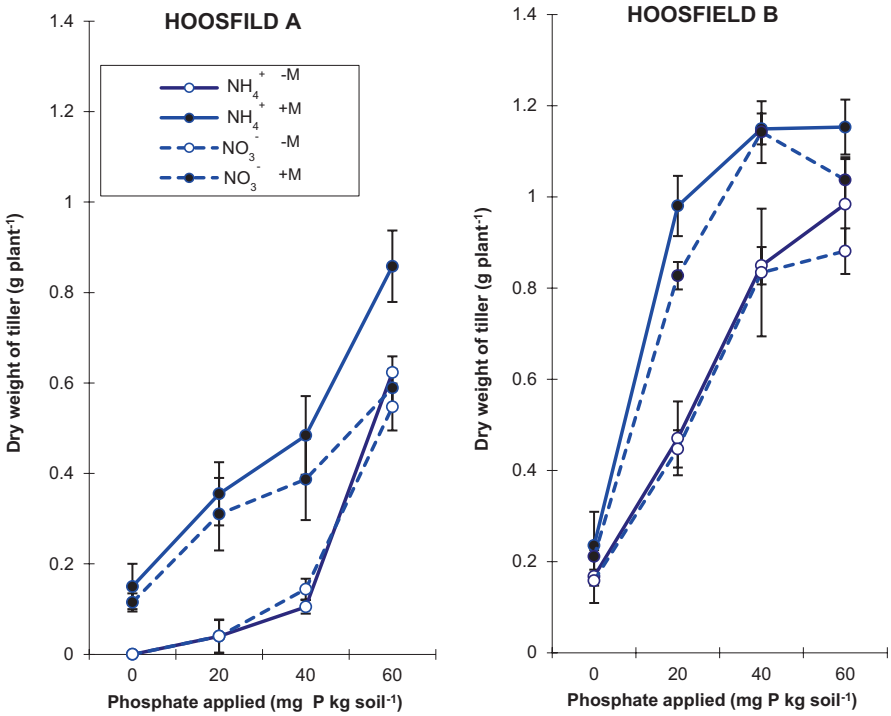

Fig. 6.6 Effect of nitrogen form, phosphate rate and AMF inoculum on dry weight of sorghum shoot at 40 days (+M AMF inoculum used, −M no inoculum) (Ortas et al. 1996)

(Fig. 6.6). Mycorrhizal inoculation with increased P application significantly enhanced tiller dry weight production (Ortas et al. 1996).

When the N source was $(NH_4)_2SO_4$, the specific absorption rate of N by mycorrhizal roots (nitrogen absorbed per g of root) was higher than that of non-mycorrhizal roots (Smith 1980). Similar results have been reported by Ortas et al. (1996) when soil was sterilized, as a result of more mineral NH_4^+-N, and the specific absorption rate of N was higher. Moreover, ectomycorrhizal and ericoid mycorrhizal fungi generally appear to prefer NH_4^+-N to NO_3^--N (Kosola et al. 2007; Kranabetter and MacKenzie 2010). Lundeberg (1970) has shown that most of the 27 ectotrophic mycorrhizal fungi grew better with NH_4^+-N than NO_3-N.

According to Azcon-Aguilar and Barea (2015), mycorrhizal infection stimulated growth of NH_4^+-N-fed plants more than that of NO_3^--N. Increasing availability of P by the rate of N fixation was related to AM fungus infection with dual application of mycorrhizal fungi and rhizobium. Barea et al. (1987) by using ^{15}N technique showed that both NH_4^+-N and NO_3^--N forms of N can be absorbed by AM hyphae and that growth enhancement of legumes by AM can be attributed to both enhanced N fixation as well as improved N uptake from the soil, especially with the NH_4^+-N forms (Tome et al. 2015). The release of NH_4^+ from nodules to the soil was

immediately absorbed by the surrounding AM hyphae. N uptake by AMF has been reported to take place in the following situations:

1. Mycorrhizal fungi increase plant-absorbed NO_3^--N and NH_4^+-N from the growing substrate (Ortas et al. 1996).
2. Mycorrhizal fungi assimilate NH_4^+-N via glutamine syntheses, and this would have a significant influence on the function of external hyphae (Johansen et al. 1996).
3. Fungi directly uptake NH_4^+-N through the hyphae (Marschner and Dell 1994; Perez-Tienda et al. 2014). According to Javaid (2009) NH_4^+-N can be taken up by plant roots because it is relatively immobile compared to NO_3^--N in soil.
4. Mycorrhizal fungi increase N inflow of plant roots. N inflow was considerably increased when supplied as $(NH_4)_2SO_4$ (Ortas 1994).

6.12 Micronutrient Uptake Significantly Affected by Mycorrhizae

Since mycorrhizal hyphae can exploit more efficiently large volumes of soil, in the presence of AM symbiosis, more nutrients are taken up and transported specifically. In addition to P, AMF enhance the acquisition of other nutrients such as sulphur and potassium (K) (Ortas 2003) and immobile micronutrients, particularly Zn and Cu (Li and Christie 2001; Ortas 2012a). When P and Zn contents of leaves were compared with the recommended levels, entire P status of mycorrhizal plants was observed above the normal level, regardless of AM fungi. Watts-Williams et al. (2015) reported that up to 24 % of Zn in shoots of the AM plants was delivered via the AM pathway in soil with Zn concentration. In addition, non-mycorrhizal plants apparently suffered from Zn deficiency according to leaf analysis, whereas Zn status of inoculated plants was around an acceptable level. *G. intraradices* appeared to be more effective than *G. mosseae* in terms of Zn concentration of leaves. Wu and Zou (2009) and Ortas (2012b) showed that sole AMF inoculation significantly increased total dry weight, leaf P, K, Ca, Mg, Fe, Cu and Mn contents and root P, K, Ca, Fe, Cu and Zn contents of the seedlings, compared to the non-AMF control. The result of Balliu et al. (2015) indicates that AM fungi may increase the uptake of Fe to host plant.

Plant-Microbe Interaction Under Abiotic and Biotic Stress

Microbial-Mediated Amelioration of Plants Under Abiotic Stress: An Emphasis on Arid and Semiarid Climate

7

Amrita Kasotia, Ajit Varma, Narendra Tuteja, and Devendra Kumar Choudhary

Abstract

It is consensus that plant growth-promoting bacteria (PGPB) be studied extensively in the last two decades, but several of them are not fully investigated/explored especially in arid and semiarid regions worldwide. They have been deployed as potent source of bioactive compounds useful in prospecting of sustainable agricultural. In the present scenario to meet food security, a number of different approaches have been employed to cultivate crops in salt- and drought-prone area. Hence, nowadays, the use of microbial inoculation to alleviate abiotic stress and amelioration of crops could be considered a more cost-effective eco-friendly approach. By keeping current approaches available for plant-microbe interaction, it is needed to pursue prospective research in this area. In the present chapter, authors will emphasize the role of benign PGPB in crop cultivation under stress through produced elicitors/determinants. It is very urgent need to explore this approach for sustainable agriculture grown under stress and

also to understand the mutual interactive activities belowground. Therefore, an exploitation of PGPB-plant interactions may be opted in the amelioration of plant health in arid and semiarid area.

7.1 Introduction

Among the total agricultural production around world, legumes encompass 25 % which include mainly pulses and oil seeds, namely, soybean and peanut. Based on the report generated by FAOSTAT (2012), India ranks first in worldwide pulse production and soybean ranks fourth. Abiotic and biotic stresses are major constraints for agriculture production worldwide. Therefore, an immediate and imperative integrated approach is required to avoid stresses and dissemination of the low-cost technologies in legume production (Reddy et al. 2013). In food web life does not exist without producers and, in natural resources wherein plants represent huge diversity in agroecosystems (AES), provides benign to detrimental metabolites. Among the benign are foods rich in proteins, feeds, and organic manures, and fix dinitrogen (N_2) improves soil structural characteristics and encourages beneficial microorganisms and the reclamation and revegetation of barren/degraded lands (Chaer et al. 2011). Based on these attributes, legumes are one of the most promising components of the Climate Smart Agriculture concept (FAO 2013). It finds major application as livestock forage and silage, grain, blooms, pharmaceutical/industrial, fallow/green manure, and human consumption as these are the good source of protein and rich in iron and vitamin B complex.

In India top legume producers constitute of Madhya Pradesh, Uttar Pradesh, Maharashtra, Rajasthan, Andhra Pradesh, Karnataka, Chhattisgarh, Gujarat, Jharkhand, and Bihar. Rajasthan ranks good enough in this list (Fig. 7.1a, b). The Thar Desert (Great Indian Desert) is a part of Rajasthan (constitutes 60 % of its area

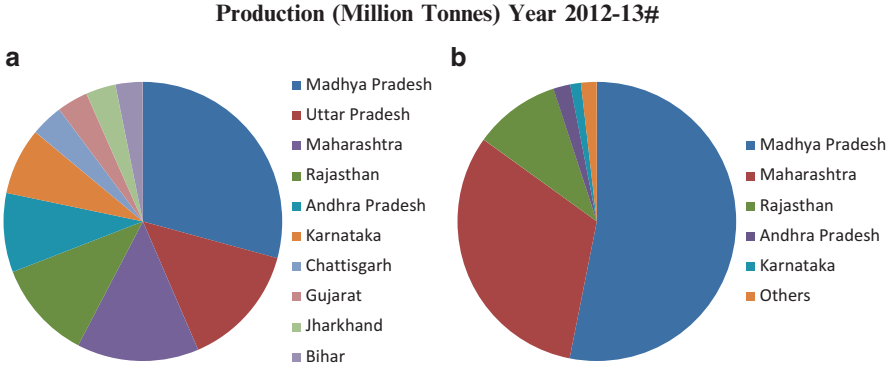

Fig. 7.1 (**a**) Top ten states in pulse production of India. (**b**) Major soybean-producing states of India. Fourth advance estimate (Source: DES, DAC, India)

Fig 7.2 Different climatic zones of Rajasthan state (Source: http://www.nicra-icar.in/nicrarevised/index.php/component/content/article?layout=edit&id=195)

in Thar Desert). Geographically, Rajasthan lies between 23° 3′ to 30° 12′ longitude and 69° 30′ to 78° 17′ latitude. It occupies 342,239 km^2 land area which solely implies 10.41 % of the total land area of India. The Thar Desert lies between 24° to 28° N latitude and 68° to 71° E longitude, occupying an area of about 200,000 km^2. Its vegetation describes 911 wild species belonging to 780 genera and 154 families. Rajasthan consist of three climatic zones, namely, arid zone, semiarid temperate zone, and semiarid tropical zone (Fig. 7.2). Enduring flora of the Thar Desert (arid zone) involves tree and shrubs including cultivated leguminous plants, e.g., *Vigna* (*V. aconitifolia*, *V. mungo*, *V. radiata*, *V. unguiculata*, etc.), *Pisum sativum*, *Cicer arietinum*, *Trigonella foenumgraecum*, *Cajanus cajan*, *Cyamopsis tetragonoloba*, *Lens culinaris*, *Vicia faba*, *Phaseolus lunatus*, *Lablab purpureus*, *Canavalia ensiformis*, *Arachis hypogea*, etc. (http://dst.rajasthan.gov.in/), whereas semiarid zone is rich in *Glycine max*, *Arachis hypogaea*, *Cajanus cajan*, *Cicer arietinum*, *V. unguiculata*, etc. Legumes grown in these regions posses problem of abiotic stresses like salinity, alkalinity, high temperature, and drought, which lead to dehydration and osmotic stress in soil and thereby reduction in crop yields worldwide. Around 70 % of yield losses in major crops occur due to abiotic stress (da Silva et al. 2014).

The major limiting factors affecting the agricultural productivity worldwide are environmental stresses. Ecosystem of Rajasthan's Thar Desert is mainly affected with high temperature, salinity/alkalinity, low pH and several other abiotic factors. Apart from decreasing yield these introduces devastating impact on plant growth (Suzuki et al. 2014). High salinity and severe drought are the major constraints affecting the agricultural practices in Rajasthan. Out of this, soil degradation through salinization accounts the most wherein the main cause of salinization is irrigation. However, annual precipitation of rainfall (APRF) is poorly disseminated to make certain harvestable crops in arid and semiarid regions, resulting in gradual degradation (Singh et al. 2012). It has been reported that APRF affects approx. 50 % of irrigated areas worldwide and causes very stern threat to AES and leads to decline of natural resources (Gabrijel et al. 2009). In India, 8.4 Mha land is affected by soil salinity and alkalinity per se, of which about 5.5 Mha are waterlogged (Singh et al. 2012). And hence, over recent decades, soil salinization threatening environment

health and sustainable development induced by human activities had developed sound land-use policies and planning actions for integrated land management to come in scenario (Zhang et al. 2011).

Soil salinization is considered as the occurrence of suspended inorganic ions that include Cl^-, SO_2^4, Mg^{++}, Ca^{++}, K^+, Na^+, HCO_3^-, and CO_3^{2-} in the aqueous phase of soil milieu. The change in soil salinity affects the survival of salt-sensitive plants so-called glycophytes, e.g., soybean. Soil with EC_e greater than 40 mM NaCl (4 dS/m) is considered saline (USDA Salinity Laboratory). Hence, increase in these limits leads to two major stresses for the plant osmotic and ionic stress. The occurrence of osmotic stress outside the plant root is the result of a rise in salt over threshold level which reflects hassles in H_2O uptake, cell growth, and expansion of lateral bud (Munns and Tester 2008). The ionic stress rose upon increase in toxic level of Na^+ that accumulates in leaf tissues over threshold level and causes leaf mortality with chlorosis/necrosis, whereby hindering cellular metabolic and enzyme activities (Chaves et al. 2009; Nawaz et al. 2013). To reduce salt-led phytotoxicity, the halophytes develop strategies to limit Na^+ uptake; further accumulation in shoot tissues is significant for survival (Zhang et al. 2008a, b).

According to crisis management plan (national) 2014, arid region of Rajasthan has shown drought efficiency of 2 in 5 years and semiarid region has 1 in 3 years. Drought has been considered as subtle peril of natural ecosystem and so-called creeping phenomenon and varied from one place to another. Land becomes dry when it gets light rain and sleet and leads to deep drought that cause noteworthy harm to the confined economy. Drought may also affect cropping system and threatens lasting erosion of AES enterprises (Kasotia and Choudhary 2014a, b). Water deficit caused by drought results in reduced turgor pressure of plant cells which thereby affects worth and measure of crop yield worldwide. It affects phenetic and genetic parameters of the plant and reflects reduction in cell division, enlargement, and differentiation including overall plant growth (Huang et al. 2012).

There is a cross talk between drought and salt stress as they eventually result in osmotic imbalance and lead to dehydration of the cell (Nakashima et al. 2014). This comprises three parameters: (1) restoration of ionic and osmotic equilibrium of the cell to develop homeostasis, (2) production of detoxification mechanisms to restore stress damage, and (3) induction of cell signaling to control cell division and metabolic pathways. Soil drying and salinization alter optimal supply of water, mineral nutrients, small organic molecules, proteins, and hormones in xylem (Pérez-Alfocea et al. 2011). Under stress condition plant cell implies signal transduction pathway that leads to production of secondary messengers, e.g., Ca^{+2}, ROS, and IMP. When plant possesses abiotic and biotic stresses, cytosolic level of calcium increases in the plant cell. Thereafter several simultaneous pathways are activated by calcium-interacting proteins (Kim et al. 2009). Mainly two stress responses are revealed by salinity stress, i.e., osmotic stress and ionic stress, whereas drought stress shows only osmotic stress (Huang et al. 2012). Osmotic stress produced by drought stress and salinity stress leads to ABA-dependant and ABA-independent signaling (Saibo et al. 2009), while ionic stress is alleviated by salt overly sensitive pathway (SOS pathway). Upon occurrence of salt stress, ion homeostasis of plant gets distressed

that results in the rise of Na^+ and lack of K^+ in the cytoplasm. To mitigate such imbalance, ion transporters (plasma membrane Na^+/H^+ antiporter SOS1 and the high-affinity K^+ transporter 1 (HKT1)), located in the cell membrane, reflect exclusion of Na^+ entry into and exit out of cells and regulate Na^+/K^+ ration (Huang et al. 2012; Brini and Masmoudi 2012).

To alleviate such stressful conditions in plant, plant growth-promoting bacteria (PGPB) have been reported to implicate in the metabolism and growth of plants (Kang et al. 2014; Kasotia and Choudhary 2014b). In addition, PGPB that resides in the spermosphere (sphere that surround the seed) and rhizosphere (area around roots with 1–10 mm) enhance plant growth, after attaching to root surface. To alleviate abiotic stress, PGPB strains have been reported and include *Bacillus*, *Burkholderia*, *Acinetobacter*, *Enterobacter*, *Azospirillum*, *Beijerinckia*, *Rhizobium*, *Serratia*, *Erwinia*, *Flavobacterium*, *Alcaligenes*, etc. (Bharti et al. 2013). These microbes secrete bacterial AAC-deaminase, volatiles, antioxidants, cytokinin, IAA, and unknown metabolites in response to plant's ethylene, HKT1, ROS, and ABA under salt and drought stress (Yang et al. 2009). These microbial determinants result in "induced systemic tolerance (IST)" in plants, and further IST has been utilized to overcome the harmful effects of abiotic stress (Yang et al. 2009).

In higher plants, ethylene is produced under various abiotic stresses. It is a simple gaseous hydrocarbon that regulates many physiological processes, including root and shoot growth, seed germination, flower development, ripening of fruits, and senescence of plant organs. Under various abiotic stress conditions (salinity, chilling, drought, wounding, temperature, and heat), the level of C_2H_4 increases in plants (Li et al. 2013). Synthesis of ethylene mediated through L-methionine via the intermediates, S-adenosyl-L-methionine (SAM) and 1-aminocyclopropane-1-carboxylic acid (ACC) following Yang cycle (Yang and Hoffman 1984). The instant originator of C_2H_4 is ACC (Chen et al. 2013). It has been described that ACC-deaminase secreted by PGPB reduces the deleterious levels of ethylene. Bacteria use ACC as nitrogen source and degrade it to ammonia and α-ketobutyrate that are readily assimilated.[5] Salinity results in elevated levels of Na^+:K^+ which can be reduced by HKT1. HKT1 plays main physiological role in Na^+ homeostasis and thereby protects both mono- and dicotyledonous plants upon toxic level of Na^+ (Almeida et al. 2013). Among transporters, tt is one of Na^+ transporters that allows to transport Na^+ back to the soil by coupling to H^+ (Shi et al. 2002), transporters that avoid toxic level of Na^+ in the leaf tissues (Byrt et al. 2007), and antiporters that seize Na^+ in the vacuoles along with H^+-ATPase/H^+-PPase (Apse et al. 1999). Bacterial volatiles help the plant to regulate expression of HKT1 gene in maintaining low Na^+:K^+ ratio in plant (Zhang et al. 2008a, b).

Upon induction of salinity and drought, there is a rise in variety of ROS species which include radical (O_2^-, OH, HO_2, and RO) and non-radical forms (H_2O_2, and $^1O_2$) synthesized in plant cells (Gill and Tuteja 2010). To alleviate toxic level of ROS species, plant tissues per se contain several enzymatic (superoxide dismutase, catalase, glutathione reductase, peroxidase, etc.) and nonenzymatic (phenolic compounds, ascorbate, glutathione, carotenoid, and α-tocopherol) scavenging mechanisms (Jaleel et al. 2009; Gill and Tuteja 2010). The balance between the

generation of ROSs and further the sequestration of antioxidants for ROSs gets disturbed under environmental stress conditions and leads to oxidative damage (Miller et al. 2010).

The induced activities resulted by PGPB detoxify plant cell by elevating antioxidant enzyme levels in plant cells (Kohler et al. 2008). The rise in ABA in plants showed a developmental process and allows an adaption to environmental stimuli in plants (Figueiredo et al. 2008; Fujita et al. 2011). Characteristically, it gets increased in roots, xylem sap, and shoots under osmotic stress (Albacete et al. 2008). For this cytokinin-producing bacteria are known to confer resistance (Nishiyama et al. 2011; Liu et al. 2013). Above all, PGPB secretes some more hormones such as IAA and GA that helps in the promotion of amplified root growth which leads to nutrient uptake in plants under stress (Kochar et al. 2011; Duca et al. 2014; Kang et al. 2014). They also act as signaling molecule in bacteria (Bashan and de-Bashan 2010). Nitrogen fixation via rhizobia-legume symbiosis is a well-known mechanism employed by PGPB to fix atmospheric nitrogen. PGPB convert atmospheric nitrogen to ammonia, a form that can be used up by plants (Franche et al. 2009). These bacteria contain enzyme complex nitrogenase that fixes atmospheric nitrogen to ammonia (Santi et al. 2013). Moreover PGPB influence soil fertility by solubilizing organic and precipitated phosphates in soil (Khan et al. 2009). PGPB excretes organic acids, namely, gluconic/citric acid, that dissolve calcium phosphates in the form of Pi and PO_4^{3-} (orthophosphate) and solubilize inorganic phosphate available largely in soil to bioavailable phosphorous. Besides, many phosphatase and cellulolytic enzymes are released for enzyme-labile soil organic phosphorous in favor of plant availability (Richardson and Simpson 2011).

To chelate iron in soil, PGPB also produce siderophore (Fe-III chelating agent) which can solubilize and sequester iron, whereby alleviating stress and allowing plant growth. Kintu et al. (2001) reported that microbially produced siderophores are of size <10,000 Da and showed the ability to chelate ferric ion as scavenging agent to fight against low iron stress (Kintu et al. 2001). Proteases secreted by PGPB break down complex proteins available in soil into plant-usable amino acids. They catalyze total hydrolysis of proteins to peptides and thereby function as degradative enzymes (Zhang et al. 2008a). In response to osmotic stress in soil, PGPB secretes compatible solutes which help them to adapt in external osmolarity (Paul and Nair 2008). Compatible solutes are low molecular weight hydrophilic molecular osmolytes including carbohydrates, amino acids, and their modified forms (Wood 2011). PGPB colonizes plant roots and alleviates the debilitating effects of salt stress (Paul 2013). Production of microbial EPS in soil under stress helps in removal of drought stress and whereby develops water retention capacity of soil (Sandhya et al. 2009). It is reported that EPS also binds to positively charged ions including Na^+ and therefore reduces the toxic level of Na^+ in soil and ameliorates plant growth (Nunkaew et al. 2014).

PGPB have been proven to be best eco-friendly remedy to accelerate the growth of plant in nutrient-deficient soil with respect to chemical fertilizers which are least available to plant. PGPB solubilizes nutrient and makes them available for uptake by plants (Choudhary 2011). There are some legumes like mung bean and soybean

which are incapable of growing in drought and salt stresses as they may be devoid of mechanisms to survive in stressed conditions or due to unavailability of nutrient or increased secretion of ethylene hormone or decreased secretion of plant growth-promoting hormones.

Bacterial ACC-deaminase: An Eco-friendly Strategy to Cope Abiotic Stresses for Sustainable Agriculture

8

Sarita Kumari, Ajit Varma, Narendra Tuteja, and Devendra Kumar Choudhary

Abstract

Ethylene is the simplest unsaturated two-carbon gaseous plant hormone which regulates many physiological and developmental processes during plant growth at molecular level. High ethylene concentration, produced by virtually all higher plants under abiotic stresses such as drought, salinity, etc., acts as stress hormone which detrimentally affects the plant root growth, seed germination, and the whole plant growth. Under abiotic stresses like salinity and drought, the endogenous level of ethylene is enhanced substantially due to increased production of its immediate biochemical precursor, 1-aminocyclopropane-1-carboxylic acid (ACC), and it shows major contribution in stress ethylene production under such type of stress conditions. Plant growth-promoting bacteria (PGPB) around the plant root surface or in the roots having a potent enzyme ACC-deaminase maintain ethylene level in plants under adverse environmental conditions (severe drought and high salinity) by the enzymatic degradation of ACC into α-ketobutyrate and ammonia as a carbon and nitrogen source. The use of PGPB containing ACC-deaminase as a bio-inoculant is a most powerful technique in agricultural biotechnology for sustainable crop production in terms of decreasing the detrimental effect of high ethylene concentration and improving growth and development of plants under extreme environmental conditions. In this chapter we endeavor to explore current research on maintaining the physiological and molecular changes in the plants under diverse environmental conditions (drought and high salinity) by the use of PGPB having ACC-deaminase, mode of ACC-deaminase enzyme action, and severe effects of salinity and drought on growth of plant special due to ethylene evolution.

8.1 Environmental Challenges

Several physiological and environmental factors that include availability of essential nutrients, physical and chemical nature of surrounding soil, and abiotic stresses (i.e., temperature, drought, salinity, flooding, etc.) reduce the plant growth. Apart from these physiological stresses, abiotic stresses negatively affect the productivity of agricultural crops mainly legume plants (*Glycine max* L., *Vigna radiata* L., *Cicer arietinum* L., etc.), and the population of beneficial microorganisms in rhizospheric soil is also adversely affected, which is a serious problem for the whole world. As an effect of increases in environmental destruction and population growth, the sufficient crop production to provide essential food for the world's people is a crucial challenge. To feed these entire populations, it is very necessary to improve the production of agricultural crops within the next few years. However, it is not an easy task to supply sufficient food to the growing worldwide population of people by using existing techniques; it will require some advanced and eco-friendly strategies and approaches. Many approaches have been applied such as the use of different chemicals including herbicides, insecticides, etc., and genetic engineering to solve this problem, but still these are not viable and will be effective only for a short period. To mitigate the deleterious effect of different abiotic stresses mainly drought and salinity, it is necessary to reevaluate these approaches to enhance the agricultural productivity and also improve soil fertility; that includes the interaction of plant roots with drought and salt-tolerant beneficial bacteria, which is an alternative eco-friendly and cost-effective approach to address this problem (Glick et al. 2013). When crops are exposed to environmental stress conditions, these beneficial soil microbes enhance the growth and yield of plants through direct and indirect mechanisms including inductions of expression of stress-responsive genes; accumulation of osmoprotectors such as proline, glycinebetaine, total soluble sugars, heat shock proteins, antioxidant enzymes, etc.; and suppression of disease caused by pathogenic microorganisms such as bacteria, fungi, viruses, and nematodes (Porcel and Ruiz-Lozano 2004; Nautiyal et al. 2008; Dimkpa et al. 2009; Mutava et al. 2015). In this present chapter, we focus on induced systemic tolerance (IST) in legume crops in response to drought and salt stress by the enzymatic mechanism of bacterial 1-aminocyclopropane-1-carboxylic acid (ACC)-deaminase, which cleaves ACC, the direct precursor of plant ethylene hormone into α-ketobutyrate and ammonia, and thereby lowers the accelerated level of ethylene in the plant tissue.

8.2 Ethylene Plant Stress Hormone

The detection of ethylene was recognized as a plant phytohormone which regulates the whole plant growth and development. The plant hormone ethylene which is found in the higher plants is an important regulator for several phases of plant growth and developmental process; this is also important for its role in plant responses under different abiotic and biotic stresses (Abeles and others 1992). Ethylene, which plays multiple roles in the regulation of plant biological

processes, such as growth of plant roots, shoots, leaves, fruits, and flowers as well as plant development (Bleecker and Kende 2000; Binder 2008). The production of ethylene is highly regulated by the developmental process in plants, and normally it is required at low level (10–25 μg/L) for normal growth and functions of the plants. Ethylene is an inhibitor for plant growth but at very low concentration; it may promote plant growth in a wide range such as promoting lateral root formation in many plant species including *Arabidopsis* (Pierik et al. 2006). In the presence of a wide range of environmental stresses, like salinity (Mayak et al. 2004a; Nadeem et al. 2009), drought (Mayak et al. 2004b), temperature stress (Ghosh et al. 2003), metal stress (Belimov et al. 2009), etc., ethylene production may increase; this stress level of ethylene inhibits the root and shoot elongation, inhibiting root nodule formation, decreasing plant-microbe interaction, and inhibiting seed germination (Abeles et al. 1992). Hirsch and Fang (1994) have reported that in leguminous plants, more ethylene production adversely affects the nodule formation. At the molecular level, stress ethylene induces the gene expression of those responsible for fruit ripening (Lincoln and Fischer 1988). Many researchers experimentally provide evidence that the induced level of ethylene has been reduced by using ACC-deaminase-containing bacteria (Glick 2004; Mayak et al. 2004a, b; Cheng et al. 2007; Siddikee et al. 2011).

8.2.1 Ethylene Biosynthesis

Drought and salinity stress cause an imbalance in the production of endogenous ethylene and increased level of ethylene in the higher plants which is responsible for growth inhibition. The major discovery that made the ethylene biosynthesis through Yang cycle was the production of 1-aminocyclopropane-1-carboxylicacid (ACC) as the intermediate product by the conversion of methionine to S-adenosyl-L-methionine (SAM) and finally ethylene production in the higher plants (Adams and Yang 1979). In plants ACC acts as a precursor of plant ethylene biosynthesis pathway, which affects the eventual level of the plant hormone ethylene (Yang and Hoffman 1984). Ethylene biosynthetic pathway involved three enzymatic steps in higher plants (Fig. 8.1): (1) the conversion of methionine (Met) to SAM by SAM synthetase, (2) the conversion of SAM into ACC by ACC synthase (ACS), and (3) then the conversion of ACC into ethylene by ACC oxidase (ACO). For Met recycling, SAM is converted into 5-methylthioadenosine (MTA), and finally MTA is converted into 2-keto-4-methylthiobutyrate (KMTB), the immediate precursor of Met through many enzymatic steps of Yang cycle (Sauter et al. 2013; Li 1999). Adams and Yang (1979) reported that the discovery of SAM as an intermediate between methionine and ethylene was a tremendous progress in understanding the biosynthesis pathway of ethylene in the plant tissues. Murr and Yang (1975) also reported that the ethylene biosynthesis was started with the MTA, an intermediate product in the reaction of ACC production from SAM, and that MTA could be recycled back into methionine and maintained the methionine level in the plants. The steps of different enzymatic reactions in methionine cycle of plants, referred to

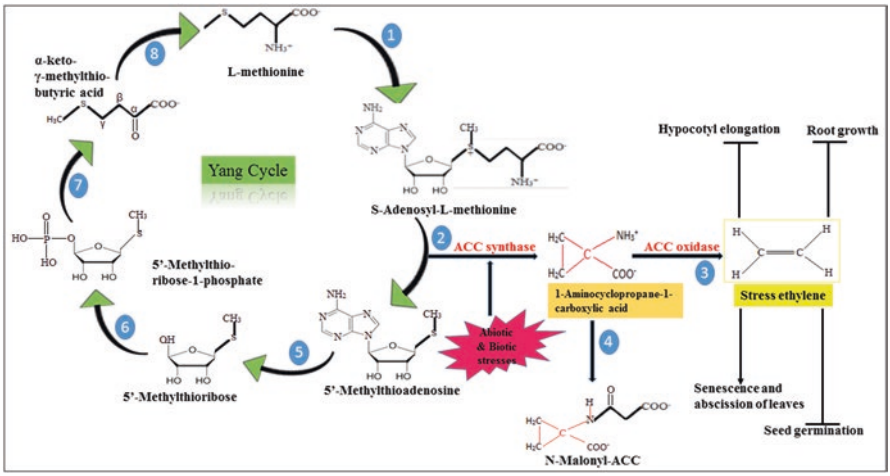

Fig. 8.1 A schematic presentation of ethylene biosynthetic pathway through L-methionine (an immediate precursor of ethylene synthesis) in plants and recycling of L-methionine (Source: Li 1999 with some changes)

as the Yang cycle, mainly showed the similarities between the plant pathway and the methionine salvage pathway in the prokaryotes, yeast, and mammalians (Fig. 8.1). Sauter et al. (2013) proposed a complete overview of the methionine and SAM metabolism in the biosynthesis of plant hormone ethylene in plants. Recently, Van de and Van der (2014) also documented that the ACC is an intermediate precursor between SAM and ethylene synthesis pathway.

In the whole process of ethylene biosynthesis, ACC is an immediate precursor of ethylene synthesis in higher plants. It is postulated that the higher plants release the large portion of ACC from roots in the surrounding environment, which is then taken up by PGPB, and ACC is hydrolyzed into α-ketobutyrate and ammonia by the help of bacterial ACC-deaminase enzyme (Glick et al. 1998; Penrose and Glick 2001).

8.3 Plant Growth-Promoting Bacteria

Soil is the largest favorable ecological niche for the microbes and their metabolic activities. Root zone area of plants contains huge microbial population and high metabolic activities. Instead of the high microbial population and metabolic activities in the rhizospheric area, these microbes occupy only 5 % area of the total space (Chakraborty et al. 2015). However, microbial activity or population is not uniform throughout the soil, but is highly concentrated in the region of the root surface area, known as the rhizosphere (Pinton et al. 2001; Chakraborty et al. 2015). Increased populations of microbes colonize the root zone of plants. Microbes present around

the plant roots in higher concentration are the main reason of dense microbial population in the rhizosphere, making it a favorable habitat than bulk soil due to the presence of the higher level of nutrient availability including amino acid, sugars, organic acids, and flavonoids which are excreted from the roots of plants and are then used by the microbes in the soil (Dimkpa et al. 2009; Ashraf et al. 2013). More than 85 % of the total organic carbon in the rhizospheric soil can originate by excretion of root cells and tissues in the form of root exudates (Barber & Martin 1976). Gray and Smith (2005) also reported the soil conditions and the composition of different root exudates which play important roles in the specificity of plant-microbe interactions and microbial activities. Many literatures are repleted with reports describing the plant growth promotion under abiotic stresses in the occurrence of rhizospheric bacteria. Several approaches have been adopted in order to minimize the adverse effect of abiotic stresses including genetically modified crop, but the use of diverse species of rhizospheric microorganisms containing ACC-deaminase belonging to various taxonomic groups, including *Pseudomonas*, *Azospirillum*, *Azotobacter*, *Bacillus*, *Klebsiella*, *Enterobacter*, *Xanthomonas*, and *Serratia*, degrades the ACC into α-ketobutyrate and ammonia for use as carbon and nitrogen sources, which is shown to promote plant growth and is a well-known and sustainable approach for enhancing plant tolerance to abiotic stresses including drought and salinity (Duan et al. 2009; Yang et al. 2009; Egamberdieva 2009; Tilak et al. 2005). These microorganisms are generally termed as plant growth-promoting bacteria (PGPB) attached to plant tissue which provides a sink for ACC from the plant tissue and, thereby, reduces ethylene synthesis, promotes root elongation, and reduces the adverse effects of stress. ACC-deaminase-containing bacteria significantly decrease a lot of physiological damage in plants due to exposure to adverse environmental stresses including extreme high and low temperature, high soil salinity, water stresses (flooding and drought), metal stresses, and organic contaminants. PGPB are involved in the decomposition of organic matter as well as solubilization of nutrients and ions in the surrounding soil, which become easily available to the plant roots. PGPB, which live in association with the plant roots, elicit the largest influence on the plants, increasing their productivity and immune response and reducing disease caused by pathogens such as fungi, bacteria, and viruses (Kloepper et al. 2004). The exact mechanisms rf plant growth stimulation either of direct or indirect mechanism applying PGPB remain largely tentative, because of the difference between bacterial strains and most certainly its dependence on the various compounds such as auxin, ACC-deaminase, siderophore, osmolytes, and many others released by the different microorganisms. PGPB accelerate plant growth through either of direct or indirect mechanisms (Fig. 8.2).

The direct mechanism of plant growth promotion (PGP) by PGPB includes production of metabolites such as proline, betaine, total soluble sugars, etc. and volatile production, modulating plant hormone level such as IAA (indole-3-acetic acid), cytokinin, ABA (abscisic acid), salicylic acid (SA), and ethylene (Glick 2012; Vaishnav et al. 2015; Mutava et al. 2015) and facilitating the acquisition of nutrient

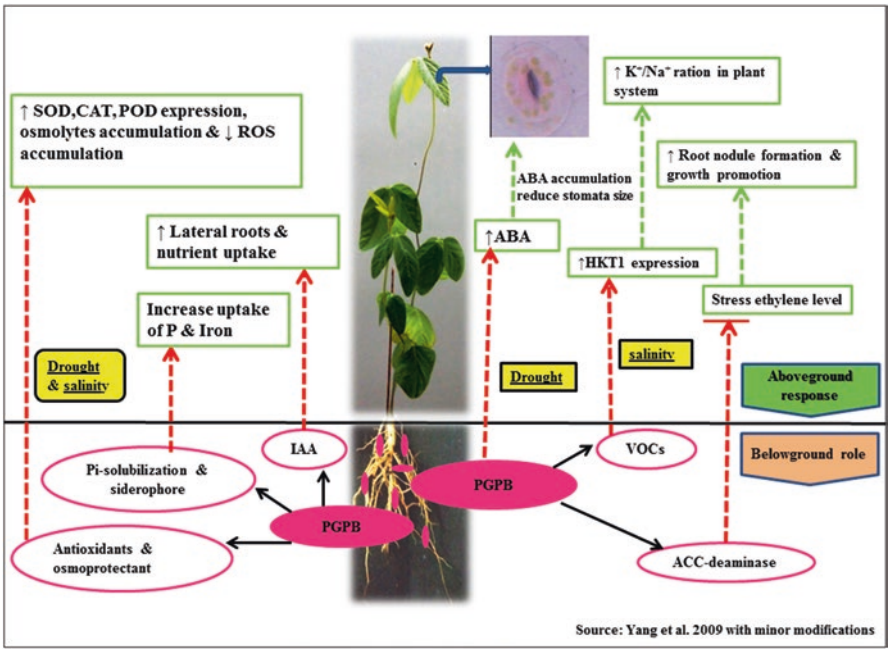

Fig. 8.2 PGPB-induced systemic tolerance against drought and salt stresses belowground (root) and aboveground (shoot and leaves). Solid black arrows indicate PGP traits; broken arrows indicate effects of PGPB on plants. PGPB strains, indicated in pin on the plant roots, having ACC-deaminase activity, suppressed the stress ethylene level by degradation of the ethylene precursor ACC and rescue normal plant growth under drought and salt stresses. Here, abscisic acid (ABA), 1-aminocyclopropane-1-carboxylate (ACC), high-affinity K^+ transporter 1 (HKT1), indole acetic acid (IAA), volatile organic compounds (VOCs), plant growth-promoting bacteria (PGPB), reactive oxygen species (ROS)

uptake from the surrounding environment including nitrogen, iron, auxin, and phosphate through nitrogen fixation, siderophore production, IAA synthesis, ACC-deaminase activity, and phosphate solubilization, respectively, through roots under environmental stress conditions (Yang et al. 2009; Kumari et al. 2015). In contrast, indirect mechanism of PGP by PGPR includes induced systemic resistance, antibiotic protection against pathogens, reduction of iron availability by sequestration of nutrients with siderophores, and synthesis of antifungal enzymes such as chitinase enzyme (Lucy et al. 2004; Dobbelaere and Okon 2007; Jain and Choudhary 2014). Hontzeas et al. (2004) have reported the ACC-deaminase-containing PGPB upregulate genes involved in plant growth and defense protein production while downregulating plant genes involved in ethylene synthesis pathway. PGPB strains containing this enzyme may have a competitive advantage over other microorganisms in the rhizosphere because they can degrade the ACC into α-ketobutyrate and ammonia as carbon and nitrogen source and they help plants to overcome many of the harmful effects of abiotic stresses (Glick et al. 2007).

8.4 Bacterial Enzyme ACC-Deaminase

ACC-deaminase has been found only in microorganisms, they reduce the stress ethylene level in the plants by the use of ACC, and there are no microorganisms that produce ethylene through ACC. Glick (2012) described a scheme of the mechanism of action of ACC-deaminase to reduce the stress ethylene level by catalytic conversion of ethylene precursor ACC that includes cyclopropane ring fragmentation and deamination of ACC to form α-ketobutyrate and ammonia.

8.4.1 Biochemistry

The bacterial ACC-deaminase is a pyridoxal 5-phosphate (PLP)-dependent polymeric enzyme with a subunit molecular mass of approximately 35–42 kDa and was first studied in a soil bacterium *Pseudomonas* sp. strain ACP that degrades the ACC (Honma and shimomura 1978), and subsequently it was purified from *P. chlororaphis* 6G5, *P. putida* GR12-2, and *P. putida* UW4 (Klee et al. 1991; Jacobson et al. 1994; Hontzeas et al. 2004). Apart from above all these, the biochemical and physical characteristics of ACC-deaminase have been reported by numerous other researchers in different PGPB (Honma 1985; Hontzeas et al. 2004; Jia et al. 1999; Ose et al. 2003; Minami et al. 1998). The various biochemical studies of ACC-deaminase indicated that the substrate ACC is found largely within plant tissues; the enzyme ACC-deaminase is not secreted by bacteria but is typically found within the cytoplasm that did not have a particularly high affinity for ACC, ranging from 1.5 to 15 mM approximately (Glick et al. 2007). In this case the substrate ACC is exuded by the plants through roots and is then taken up by the PGPB containing ACC-deaminase. Glick (2005) reported the large differences in the level of ACC-deaminase activity in the different types of bacteria. ACC-deaminase activity is assayed by monitoring the concentration of α-ketobutyrate, the product of ACC hydrolysis. Organisms with high expression of ACC-deaminase activity typically bind nonspecifically to the variety of plant species, and those organisms express low level of ACC-deaminase activity and bind only to specific plant species, or they do not lower the overall stress ethylene level in plants (Glick 2005).

8.4.2 Prevalence of ACC-Deaminase Genes and Its Regulation

The ACC-deaminase activity has been reported in all three domains (Bacteria, Eukarya, and Archaea), but it is known to be present in the majority of different species of bacteria and fungi (Minami et al. 1998; Shah et al. 1998; Ma et al. 2003; Singh and Kashyap 2012; Nascimento et al. 2012). Recently many research studies reported that ACC-deaminase structural (*acdS*) gene has been found in a wide range of gram-negative bacteria such as *Achromobacter xylosoxidans*, *Rhizobium leguminosarum*, *Pseudomonas putida*, *Burkholderia phytofirmans*, etc. (Wand et al. 2001; Belimov et al. 2001; Hontzeas et al. 2004; Babalola et al. 2013; Duan et al. 2013);

gram-positive bacteria such as *Brevibacterium iodinum*, *Bacillus licheniformis*, *Zhihengliuela alba*, *Micrococcus* sp., *Brachybacterium saurashtrense*, *Brevibacterium casei*, etc. (Belimov et al. 2001; Siddikee et al. 2011; Timmusk et al. 2011; Jha et al. 2012); some fungi like *Penicillium citrinum*, *Trichoderma asperellum*, *Phytophthora sojae*, and *Issatchenkia occidentalis* (Jia et al. 1999; Palmer et al. 2007; Viterbo et al. 2010; Singh and Kashyap 2012); and different species of rhizobia such as *Mesorhizobium loti*, *Rhizobium leguminosarum*, *R. phaseoli*, etc. (Uchiumi et al. 2004; Duan et al. 2009; Ahmad et al. 2011). On the basis of existing literature, *acdS* genes from bacteria are being extensively used for the development of transgenic plants for tolerance toward abiotic stresses. Bacterial gene *acdS* is highly regulated and expressed differentially on the basis of many factors like the presence or absence of oxygen, concentration of ACC, and accumulation of product. Based on current literature, precise mechanisms of regulation of *acdS* are understood in few bacteria. Many of the *acdS* genes have been mainly regulated by the leucine-responsive regulatory protein (LrP) gene located approximately 50–100 base pairs upstream to the *acdS* gene and AcdB protein encoding glycerophosphoryl diester phosphodiesterase (for the binding with ACC) (Cheng et al. 2008; Duan et al. 2009). Glick et al. (2007) proposed a well-described model for the transcriptional regulation of *acdS* gene through LrP in bacteria; this protein has been encoded by the ACC-deaminase regulatory (*acdR*) gene. According to this model, in the presence of ACC, *acdR* gene encodes active octamer of LrP that interacts with AcdB protein and ACC; this complex further initiates transcription of *acdS* gene. Upon this interaction, *acdS* produced ACC-deaminase, and it hydrolyzes the ACC into ammonia and α-ketobutyrate (precursor of branched-chain amino acids such as leucine). When the concentration of leucine increases in the bacterial cell, it interacts with the active LrP octamer and forms inactive LrP dimer, which leads to shutting down the further transcription of *acdS* gene (Fig. 8.3).

In addition to above regulatory mechanism of *acdS* gene expression, it is also regulated by different regulatory proteins in different bacterial species such as *Burkholderia* sp. CCGE 1002 and *Burkholderia phymatum* STM 815, LrP, and σ70 promoter which are involved in the transcriptional regulation of *acdS* gene (Kaneko et al. 2002). In *Mesorhizobium loti* ACC-deaminase expression is regulated by *nifA2*, *nifA1*, and σ^{54} polymerase sigma recognition factor located upstream to *acdS* gene. The NifA2 protein (encoded by *nifA2)* interacts with σ^{54} polymerase sigma recognition factor favoring *acdS* gene transcription (Nukui et al. 2006), and *nifA1* also increases the *acdS* transcription; however the mechanism of regulation of *acdS* transcription through *nifA1* is not well understood.

8.4.3 Approach of ACC-Deaminase Action

The mode of action of PGPB containing ACC-deaminase was described by the originally proposed model (Glick et al. 1998); this model explains how ACC-deaminase-containing PGPB can lower plant ethylene level and in turn stimulate plant growth, especially under harsh conditions. ACC-deaminase-containing PGPB

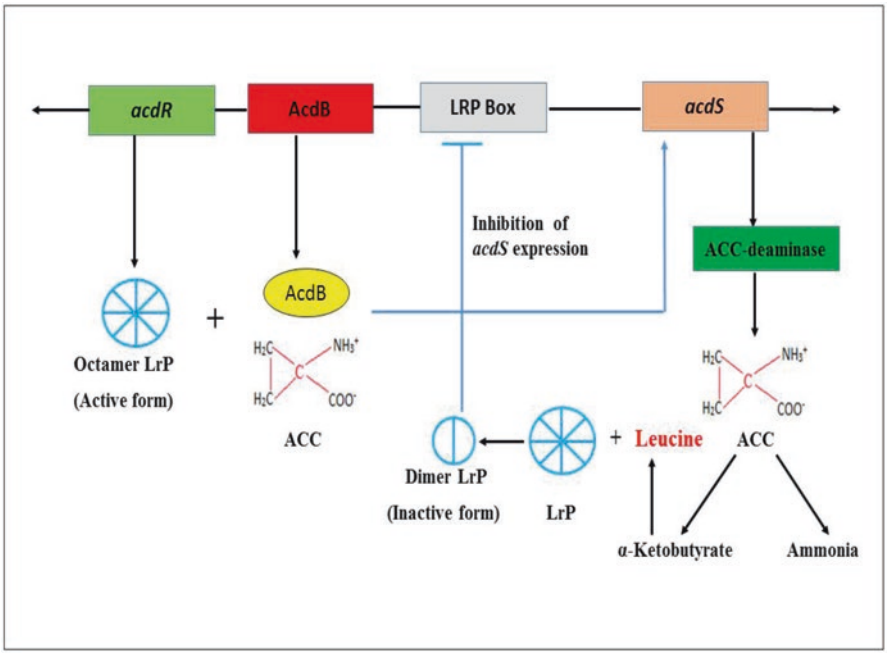

Fig. 8.3 A schematic presentation represents common mechanism of regulation of *acdS* gene transcription in bacteria (mainly *Pseudomonas putida* UW4). Abbreviations: *acdR* ACC-deaminase regulatory gene, *AcdB* encoding for glycerophosphoryl diester phosphodiesterase, *LrP* leucine-responsive protein, *acdS* deaminase structural gene (*acdS*) (Source: Glick et al. 2007)

first bind to the surface of either seed or plant roots in response to root exudates, although these bacteria may also be found on aerial parts of plants (leaves and flowers) or within a plant's internal tissues (Fig. 8.4).

Plants typically exude a huge fraction of their metabolically fixed different amino acids, sugars, and organic acids through their roots in the surrounding soil. Root exudates act as a bacterial food source which is the main reason that the numbers of bacteria present around the roots of plants (i.e., the rhizosphere) are 1000 times higher than in the bulk soil. In response to the presence of tryptophan and other photosynthetically fixed small molecules in the plant root exudates, the associated bacteria synthesize and secrete the phytohormone indole-3-acetic acid (IAA), some of IAA is taken up by the plant roots. IAA level in the plant trusses affects plant growth in different ways such as stimulation of the plant cell proliferation and cell elongation, and IAA can also induce the transcription of the plant enzyme ACC synthase that catalyzes the formation of ACC and stimulate the synthesis of ethylene in the plant. It can also act to loosen plant cell walls, thereby facilitating cell elongation and increasing the number of lateral roots and level of root exudation. Along with the IAA level in the plants also enhanced the plant ACC exuded from seeds or roots (Penrose et al. 2001), and this ACC may be taken up by the PGPB associated with these tissues and subsequently cleaved by ACC-deaminase (Stearns

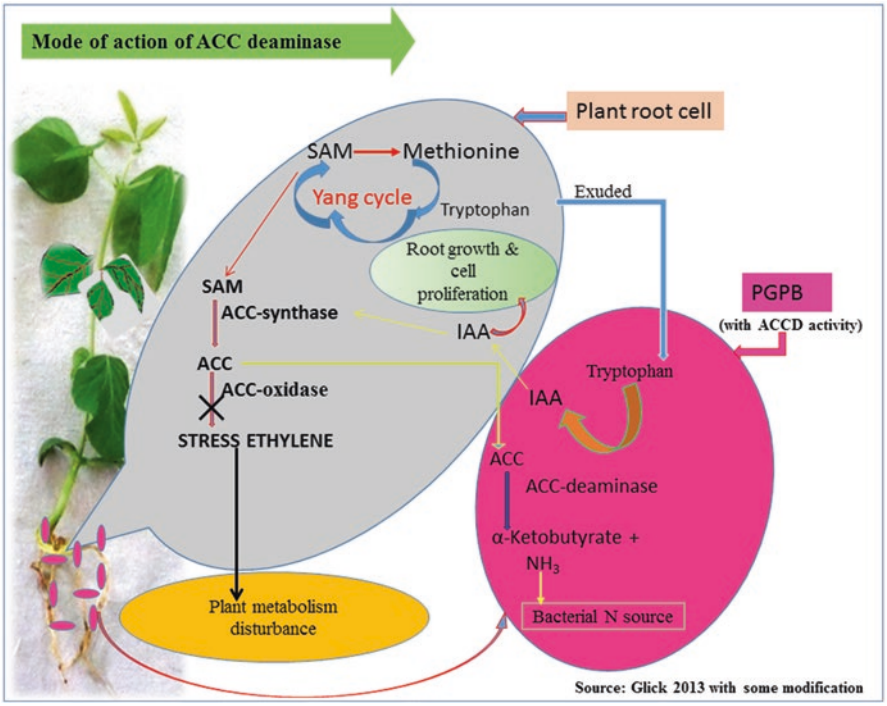

Fig. 8.4 Schematic presentation of how stress controller PGPB containing ACC-deaminase activity bound to plant root lower the stress ethylene concentration and prevent ethylene inhibition in plant's metabolism disturbance. Abbreviations: *SAM* S-adenosyl-L-methionine, *ACC* 1-aminocycl opropane-1-carboxylate, *IAA* indole acetic acid

et al. 2012; Penrose and Glick 2003). The net result of the cleavage of exuded ACC by bacterial ACC-deaminase is that lowering either the endogenous or the bacterial IAA-stimulated ACC level, the amount of ethylene in the plants is reduced. Subsequently, as a consequence of lowering plant ethylene levels, ACC-deaminase-containing PGPB can reduce a portion of the ethylene inhibition of plant growth and mitigate the adverse effect of a wide range of abiotic stresses. Plants which grow in association with ACC-deaminase-containing PGPB generally have longer roots and shoots and are more resistant to growth inhibition by a variety of ethylene-inducing stresses (Saleem et al. 2007).

8.5 ACC-Deaminase in Salinity and Drought Stress Amelioration

Glick et al. (2007) and Saleem et al. (2007) have reviewed that inoculation of plants with PGPB containing ACC-deaminase may lead to various subsequent physiological changes in plants. Belimov et al. (2001) and Penrose et al. (2001) also studied

the ability of ACC-utilizing PGPB to improve plant growth inhibition caused by stress ethylene through decreased ACC content in plant tissue. Similarly many researchers also demonstrated the stimulation of root elongation and biomass production of different plant species by inoculations of PGPB containing ACC-deaminase activity, particularly when the plants were subjected to stressful growth conditions (Glick et al. 1998; Belimov et al. 2001; Safronova et al. 2006). Li et al. (2000) have documented that the ACC-deaminase-deficient mutated strain of *P. putida* UW4 simultaneously lost the ability to degrade the ACC and elongate roots in infected canola plants. Environmental stresses such as drought, salt, flooding, etc. cause overproduction of ethylene in the plant tissues which hamper plant growth by different ways like inhibition of root elongation, leaf senescence and abscission, early fruit ripping, and inhibition of legume root nodule formation (Gamalero and Glick 2012). Bacterial hydrolysis of ACC through ACC-deaminase leads to a decrease in plant stress ethylene level, which results in increased plant growth (Belimov et al. 2009; Glick et al. 2013). This property of bacterial ACC-deaminase activity and several other mechanisms of PGPB to alleviate abiotic stresses in plants are referred as "induced systemic tolerance" (IST) (Yang et al. 2009). Thus, the use of PGPB having ACC-deaminase activity is the most important and sustainable mechanism in agricultural sector to reduce the deleterious effect of adverse environmental stresses on the crop productivity (Table 8.1).

8.5.1 Salinity Stress

Soil salinity is a major abiotic environmental factor that adversely inhibits the growth of crops and reduced the yield. In these crops, legumes are mainly affected by a low level of salinity. Legumes also represent a very significant group of crops in agriculture ecosystem. Legume crops are the most important grains because they are rich sources of protein and oil in both human and animal diets. Furthermore, it plays a significant role in the maintenance of soil fertility, through its symbiotic association with rhizobia. Like other legumes, chickpea is very sensitive to salinity, which affects its growth and development. The excess salinity in the soil, due to the high concentration of Cl^- and Na^+ ions, affects the plant system and decreased the yield and quality of the crops (Shukla et al. 2012). Soil salinity induces production of reactive oxygen species (ROS) such as superoxide anion (O_2^-), singlet oxygen ($^1O_2$), and hydrogen peroxide (H_2O_2) and causes cellular damage in the plant system. To contract the adverse effect of these ROS, plant accumulates osmolytes (proline, glycinebetaine, sugars, etc.) resulting in the decrease of the adverse effect of oxidative damage (Qureshi et al. 2013a, b). To mitigate the deleterious effect of salinity, plant roots interact with PGPB containing ACC-deaminase (Table 8.1) which can decrease the high level of ethylene concentration, thereby alleviating the negative impact of salinity exerted on the plant growth and yield. PGPB promote plant growth by enhancing efficiency of water and nutrient uptake and maintain K^+/Na^+ ratio under salt stress (Mayak et al. 2004a). Many mechanisms of stress alleviation, such as lowering the ethylene concentration, production of phytohormones,

and regulation of nutrient uptake, are used by the PGPB containing ACC-deaminase activity to facilitate plant growth under salinity stress. PGPB-inoculated plants enhanced lateral root development due to higher indole-3-acetic acid (IAA) production and reduced the stress ethylene level in plants by the production of 1-aminocyclopropane-1-carboxylic acid (ACC)-deaminase enzyme activity (Senthil et al. 2009; Glick et al. 2007). Bacterial-inoculated plant root accumulated higher proline content compared to controlled plant root under salt stress, which may be due to higher uptake of nutrients, resulting in high biosynthesis rate (Vardharajula et al. 2011). The accumulation of proline in roots suggests an osmotic mechanism to keep a positive water potential for water entrance into the roots, leading to a lower stress damage in the plant (Porcel and Ruiz-Lozano 2004). In response to environmental stress such as salinity, reactive oxygen species (ROS) may generate in excess, which are extremely harmful to living organisms. The excess production of ROS can cause cell destruction by various pathways like peroxidation of lipids, oxidation of proteins, and nucleic acid damage finally leading to programmed cell death. The efficient removal of ROS requires the action of several antioxidant enzymatic reactions including catalase (CAT), peroxidase (POD), polyphenol oxidase (PPO), and superoxide dismutase (SOD) which can be considered as one mechanism of salt tolerance in plants (Sharma et al. 2012). Bacterial-inoculated plants showed less antioxidant enzyme activity under salinity stress suggesting that these plants are submitted to a lower oxidative stress under saline conditions (Porcel and Ruiz-Lozano 2004; Kohler et al. 2008; Kohler et al. 2009; Kumari et al. 2015). Recent studied related to the hydrolysis of ACC-deaminase by PGPB carrying ACC-deaminase activity diluted the detrimental effects of salinity by decreasing the ethylene level, thus improving the growth of plants (Glick et al. 1998; Cheng et al. 2007; Nadeem et al. 2009). Similarly, bacterial strain carrying ACC-deaminase has also been studied to decrease the adverse effects of soil salinity on the plants by the hydrolysis of salt stress-induced ACC concentration, regulating accelerated level of ethylene in response to stress in plants, and promote plant growth under saline condition (Belimov et al. 2009). Inoculation with PGPB containing ACC-deaminase has been reported to reduce the stress-induced ethylene-mediated negative effects on plants and boost plant growth particularly under stressed conditions (Glick 2005; Safronova et al. 2006).

8.5.2 Drought Stress

Water is a fundamental constituent of all life, about 90 % of the fresh weight in physiologically active plants. In most plants, if the water content goes down much below this level, many physiological processes are impaired. Water deficiency occurs when there is more water loss by evaporation than the amount taken up by roots; this is often referred to as "drought stress." Drought stress is common in many parts of the world, and more than 50 % of the globe is arid and semiarid. Soil water deficiency affects the water relations at whole plant level and finally makes plants more susceptible to other environmental stresses by decreasing the adequacy of

defense mechanisms (Vardharajula et al. 2010) and can also adversely affect plant growth and yield, causing the most fatal economic losses in agricultural sector. The effects of drought stress can be counted as reduction in growth and simultaneous reduced dry weight, stomatal conductance decreases, and thus water loss from leaves and photosynthetic rate are reduced due to decreased intercellular CO_2 concentration (Mahajan and Tuteja 2005). Drought stress has been extensively associated with elevated release of endogenous ethylene in the plants which is responsible for growth inhibition (Mayak et al. 2004b; Arshad et al. 2008). Ethylene is a plant hormone that is involved in the regulation of many physiological responses (Arshad and Frankenberger 2002), and it was also regarded as a "stress hormone" because ethylene synthesis in plants is increased under a number of biotic and abiotic stresses. Stress ethylene production has been often coupled with reduced growth and premature senescence; therefore it may act as an indicator of plant susceptibility to stresses such as drought and heat (Wang et al. 2003; Belimov et al. 2009). PGPB containing ACC-deaminase might have decreased the drought stress-induced ethylene concentration in inoculated plants, which resulted in better plant growth under water stress conditions. Therefore, inoculation with PGPB containing ACC-deaminase could be helpful in eliminating the inhibitory effects of stress ethylene on the growth of plants under severe drought stress. Inoculation of plants with beneficial PGPB containing ACC-deaminase induced plant growth by root colonization and mitigates adverse effect of drought in arid or semiarid areas (Marulanda et al. 2007, 2009; Zahir et al. 2009; Vardharajula et al. 2011). Under adverse condition such as drought stress, bacterial cells accumulate various computable solutes such as proline and sugars that protect bacterial cells from degenerative process and improve survival under adverse environment. Drought stress can also create physicochemical and biological properties of soil unfavorable for soil microbial activities. *Pseudomonas* spp. can survive under stress conditions due to the production of EPS, which protects bacterial cells from drought stress by enhancing water preservation and regulating the diffusion of organic carbon sources (Vardharajula et al. 2009).Similarly other workers also reported that EPS-producing bacteria increased resistance to water stress and significant increase in root-adhering soil per root tissue (RAS/RT) ratio in plants (Alami et al. 2000). *Paenibacillus polymyxa* confers drought tolerance through the induction of drought-responsive gene, *early response to dehydration 15* (*ERD15*), in *Arabidopsis thaliana* (Timmusk and Wagner 1999). Researchers found the inoculation of *Pseudomonas*, *Bacillus*, and *Mycobacterium* strains significantly promotes the plant growth by increasing plant growth parameters in maize plants (Egamberdiyeva 2007) and alleviated the adverse effect of water deficiency on wheat (Kasim et al. 2013). Many other studies have reported on the ability of microbes under determined conditions in protecting plants from the deleterious effects of drought stress (Belimov et al. 2009; Arzanesh et al. 2011). Cohen et al. have reported the inoculation with *Azospirillum brasilense* increases the relative water content in the leaves due to the production of ABA hormone by the bacterial strain containing ACC-deaminase, thus reducing the ACC level in the plants. Inoculation with PGPB containing ACC-deaminase enhances root growth, which might be helpful in the uptake of relatively more water and nutrient uptake from

deep soil under drought stress conditions (Dodd et al. 2005). The inoculation with PGPB containing ACC-deaminase was helpful in increasing water-use efficiency in peas under drought stress and confers resistance against drought stress in tomatoes and peppers (Zahir et al. 2008).

8.6 Conclusion and Future Prospects

In the present day, agricultural productivity is challenged by adverse environmental stresses. From the above discussion, it is clear that plants are exposed to numerous abiotic stresses such as drought and salinity in the environment which cause ethylene-induced inhibition of plant growth. Plants under both types of stresses are likely to face many conditions such as toxic level of ethylene, ionic imbalance, and more ROS production. There is now a consensus that PGPB with ACC-deaminase are able to mediate the enhanced tolerance to abiotic stresses in their host plants. Therefore, these PGPB have the potential to promote plant growth and productivity and reduce the detrimental effects of stress ethylene level in response to adverse environmental conditions. Therefore, it requires consideration of efficient PGPB with robust ACC-deaminase activity which can interact with plants and increase plant productivity under stress conditions. Moreover, this technique is also beneficial for the soil fertility and decreases the environmental hazards due to the use of chemical fertilizers which are harmful for the soil fertility as well as for animal health. Therefore, inoculation of plants with PGPB having ACC-deaminase gene could be very effective in facilitating plant growth both under normal and stressed environments. PGPB containing ACC-deaminase gene could have a positive benefit for tolerance to stresses in crops, where the environment and degree of stresses such as salinity, drought, high temperature, etc. are not always predictable, and development of *acdS* gene overexpressing transgenic plants to prevent these harsh environmental stresses. However, the expression of *acdS* gene has been reported in only few transgenic plants such as *Arabidopsis*, tomato, poplar, etc. Therefore, future research studies need to ascertain the mechanisms of regulation of *acdS* gene in bacteria and the development of other *acdS* transgenic plants to overcome the detrimental effects of stress-induced ethylene.

Increasing Phytoremediation Efficiency of Heavy Metal-Contaminated Soil Using PGPR for Sustainable Agriculture

9

Payman Abbaszadeh-Dahaji, Mahtab Omidvari, and Mansour Ghorbanpour

Abstract

Raising industrial activities and agricultural practices as well as other human anthropogenic actions adds a significant amount of heavy metals in soil and water, resulting in degradation of the environment. Some examples of the environmental concern metals are nickel, copper, arsenic, lead, cadmium, cobalt, and zinc. Due to their nonbiodegradable nature, toxic heavy metals accumulate in the environment and therefore contaminate the food chain. The presence of these hazardous metals further than the threshold limit exhibits a critical threat to the human health and total environment. Different physical, chemical, and biological procedures have been applied for the remediation of contaminants from the environment. Bioremediation is the application of biological remedy for cleanup and or mitigation of contaminants from the environment. This process is a cost-effective and worthwhile method for removal of heavy metal-contaminated soil compared to physicochemical remediation techniques which are expensive and deleterious for soil properties. Phytoremediation is defined as the direct use of appropriate living plants for removal, degradation, or sequester of contaminants from environments (atmosphere, hydrosphere, and lithosphere). The efficiency of phytoremediation depends on many factors like plant biomass yield, plant tolerance to metal toxicity, and heavy metal solubility or mobilization in the soil.

The success of the phytoremediation process can be attained through developing the association of hyperaccumularor plant species with microorganisms like heavy metal-resistant plant growth-promoting rhizobacteria.

9.1 Introduction

Developing industrialization and anthropogenic activities are the most common factors releasing toxic wastes into the soil, water, and air. This toxic chemical waste is classified as pollution. The consequent pollutants are dangerous to the environment and living things such as human beings, animals, plants, and microorganisms (Rajkumar et al. 2009). Inorganic chemical contaminants occur as natural elements in the biosphere, and result from man-made toxins, and several human activities such as industry, mining, agriculture, traffic, and military activities enhance their release into the environment, causing toxicity. Inorganic pollutants cannot be destroyed; however, they may be remediated through sequestration or stabilization inside the plant tissues. According to Pilon-Smits (2005), inorganic contaminants that can be phytoremediated comprised of plant macronutrients (e.g., nitrate and phosphate), plant trace elements (e.g., Fe, Cu, Cr, Mo, Mn, and Zn), and nonessential elements (e.g., Co, F, Cd, Hg, Pb, Se, and V), as well as radioactive isotopes (e.g., ^{238}U, ^{137}Cs, and ^{90}Sr). Heavy metals are one of the most important contaminants, which have a density >5 g cm^{-3} (Abdelatey et al. 2011). These toxic metals are the most important inorganic contaminants, which are very stable and progressively accumulate in the environment (Chaudhary and Khan 2015).

Soil contamination with heavy metals may take place by mining practices, discharge of industrial effluents, extensive use of synthetic fertilizers, pesticides, etc. and is of great environmental concern because of its harmful impacts on biological systems (Ma et al. 2013). High concentrations of heavy metals not only reduce activity of soil microorganisms and crop production but also intimidate human health because they may enter the food chain, enhancing the risk of toxicant transfer to food products (Boyd 2010). Several biological and physicochemical methods have been chosen for the removal of heavy metals, which is considered as a challenging work with regard to cost and technical intricacy (Sheoran et al. 2011; Wuana and Okieimen 2011). Physicochemical approaches comprise excavation, landfill, thermal treatment, leaching, as well as electro-reclamation. These procedures are quick but incompetent and expensive and cause negative impacts on different soil chemical, physical, and biological characteristics, resulting in secondary pollution (Glick 2010; Ali et al. 2013).

It has been suggested that the physicochemical approaches only alter the problem from one form to another, and can't entirely remediate the contaminants (Lambert et al. 2000). Bioremediation of contaminated sites has taken much attention globally as a procedure for enhancing soil quality through elimination of metals from soils (Marques et al. 2009). Phytoremediation is among these methods presenting significantly more advantageous than conventional technology of cleanup (Pilon-Smits 2005).

However, slow growth with low plant biomass in metal-polluted soils may restrict the efficiency of phytoremediation process (Li and Ramakrishna 2011; Ma et al. 2011). Furthermore, bioavailability of the metal in soil rhizosphere is believed to be another important factor that affects the successes of metal translocation and phytostabilization (Ma et al. 2011). In recent years, many chemical amendments, such as ethylenediaminetetraacetic acid (EDTA), have been applied to improve phytoextraction and/or phytostabilization process (Barrutia et al. 2010). However, chelators are known to be toxic to plants and to the most soil microorganisms (Evangelou et al. 2007). A promising option is the application of plant-microorganism interactions to enhance the effectiveness of phytoremediation, changing the bioavailability and mobilization of metals in soil environment (Glick 2010; Ma et al. 2011; Rajkumar et al. 2010). The efficiency of phytoremediation mainly depends on plant growth and a high content of heavy metal in the shoot parts of the plant (Petriccione et al. 2013). It has been acknowledged that plant growth-promoting rhizobacteria (PGPR) may improve the effectiveness of phytoremediation through increasing plant growth under harsh conditions and increasing heavy metal solubility by different mechanisms (Gadd 2004; DeBashan et al. 2012).

9.2 Phytoremediation

Phytoremediation may suggest a cost profitable, noninvasive, and secure alternative to standard soil-cleaning techniques through using specific shrubs, trees, and grass species to remove, immobilize, or even degrade hazardous materials from soil (Rajkumar et al. 2012).

Most recently, Arora et al. (2016) reported that in phytoremediation process, generally, two types of plants are utilized: (1) hyperaccumulators with a very high heavy metal accumulation potential and low biomass productivity and (2) non-hyperaccumulators, which have lower extraction capacity than hyperaccumulators, but whose total biomass yield is significantly higher and are fast-growing species.

Moreover, the type of plant species for phytoremediation is usually selected according to regional climate, root system, and the nature of the pollutants. It has been estimated that the approximate remediation depths for grasses, shrubs, and deep-rooting trees are 3, 10, and 20 ft, respectively (Chirakkara and Reddy 2015). Generally, there are six different processes for phytoremediation (Fig. 9.1) (Pilon-Smits 2005), but for heavy metal-polluted soils, four processes such as phytostabilization, phytoextraction, phytovolatilization, and rhizofiltration are more consequential (Laghlimi et al. 2015).

Phytoextraction, a subprocess of phytoremediation, can be defined as uptake of dangerous elements by roots from the soil and its translocation into harvestable biomass of plant (Ali et al. 2013). Phytostabilization can be defined as metal trapping from the rhizospheric soil through decreasing its availability or mobility in the environment (Arora et al. 2016). However, phytovolatilization is transpiration of certain contaminants from plant (Pilon-Smits 2005). Phytodegradation, also known as phytotransformation, is direct degradation of organic pollutants through plant

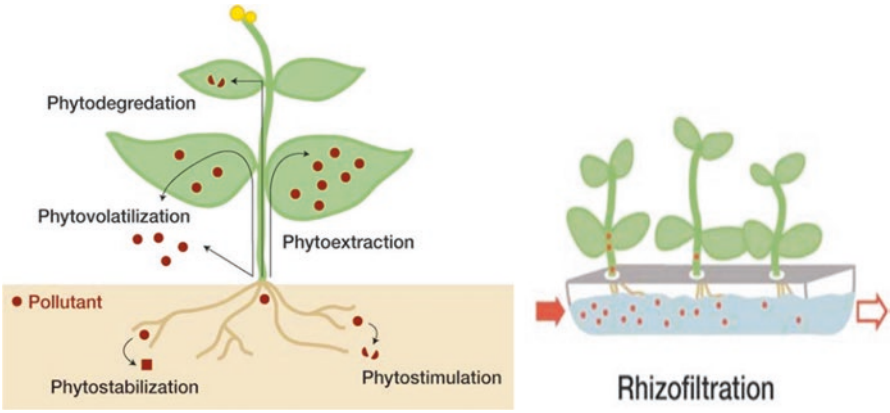

Fig. 9.1 Different processes of phytoremediation (Pilon-Smits 2005)

enzymatic activities (McCutcheon and Schnoor 2003). Phytostimulation, or rhizodegradation, is the process in which root-released materials increase microbial activity near the plant roots (Hutchinson et al. 2003). Rhizofiltration, however, involves filtering toxic pollutants by a mass of plant roots (Raskin et al. 1997). Phytoremediation, the same as other remediation procedures, contains many benefits and limitations.

The most important phytoremediation benefits include cost-effectiveness, potentially environmental friendly and long-term applicability to a variety of hazardous metals, as well as aesthetically pleasing. However, there are some limitations for phytoremediation. Duration of the process is too long, i.e., it is a slow process; therefore, it may take several years or even decades to clean up a polluted site, and it is only feasible to surface soils (Laghlimi et al. 2015). Phytoremediation process may also be limited through the bioavailability of toxic materials.

Multiprocess phytoremediation system (MPPS) has been proposed for an effective phytoremediation process. The process is based on combination of microbial, mechanical, and plant growth stages to improve biomass accumulation, especially plant below ground parts in the soil, and therefore increase the remediation kinetics. The processes utilized are land farming and inoculation with PGPR (Huang et al., 2005). Generally, plants with excellently high capacity for accumulating toxic metals often grow slowly and produce low biomass, especially when the metal content in the soil is high. However, there is a way to increase the efficiency of phytoremediation using PGPR, which are soil-living microorganisms that inhabit the rhizosphere. When PGPR are presented to a polluted site, they enhance the potential for plants that grow there to degrade toxic metals and to remobilize nutrients, preserve soil structure, detoxify synthetic chemicals, and suppress pathogens and pests; also, PGPR reduce the toxicity of heavy metals through altering their bioavailability in plants.

The plants subsequently supply the microorganisms with plant root secretions including proteins, carbohydrates, free amino acids, sugars, vitamins, hormones,

mucilage, and alcohols, which are essential sources of their nutrition. The rhizosphere has high levels of easily degradable root-exuded compounds, attracting greater microbes than does bulk soil (Babalola 2010). According to Babalola (2010), efficiency of phytoremediation depends on the extent of soil pollution, bioavailability of metals in soil, and plants' ability to take up and accumulate metals as biomass (Babalola 2010). Several researchers have reported the positive effect of PGPR on bioavailability of heavy metals (Braud et al. 2006; Abou-Shanab et al. 2006). Generally, PGPR may improve phytoremediation efficiency of heavy metals by two mechanisms such as enhanced plant growth (abbaszadeh et al. 2010) and increased bioavailability of metals in soil (Whiting et al. 2001).

9.3 Plant Growth-Promoting Rhizobacteria (PGPR)

Among the rhizospheric microorganisms, PGPR believed to be worthy of special attention for heavy metal phytoremediation. PGPR are heterogeneous group of soil bacteria, categorized into two main parts, extracellular and intracellular, which are able to colonize plant root systems and enhance the plant growth (Pereira et al. 2015; Dimkpa et al. 2009a). The intracellular group bacteria are able to enter the plant as endophytic bacteria that create nodules, whereas extracellular PGPR exist in the rhizosphere, on the rhizoplane, or in the spaces between cells (apoplast) of the root cortex (Dimkpa et al. 2009a; Rajkumar et al. 2009). Since endophytic bacteria exist inside the plant, they could be more protected from different types of environmental stresses than rhizospheric bacteria (Rajkumar et al., 2009). PGPR may stimulate plant growth through various direct or indirect mechanisms such as production of growth substances (phytohormones), solubilization of insoluble elements, biocontrol of host plant pathogens, or enhancement of plant nutritional status (Abbaszadeh-dahaji et al. 2012; Glick et al. 1999).

These mechanisms comprise the synthesis of plant growth hormones such as auxin (Khakipour et al. 2008) and 1-aminocyclopropane-1-carboxyilic acid (ACC) deaminase, improved solubility of insoluble nutrients such as phosphorous and iron, fixation of atmospheric nitrogen, and control of the adverse impacts of pathogens on plant growth (Jalili et al. 2009). The major type of PGPR contains the strains of *Azospirillum*, *Azotobacter*, *Acetobacter*, *Burkholderia*, *Bacillus*, and *Pseudomonas* (Abbaszadeh et al. 2010).

9.4 Heavy Metal-Resistant PGPR

PGPR tolerance to the concentration of heavy metal is the most important limiting factor for using phytoremediation process. Metal-tolerant microorganisms have been often reported in the rhizosphere of hyperaccumulator plants growing in metal-contaminated soils exhibiting that these microorganisms have evolved a heavy metal tolerance and that they may play important roles in mobilization and/or immobilization of heavy metals through releasing different compounds such as

organic acids or extracellular polymeric materials (Sessitsch et al. 2013). It has been suggested that plant inoculation with metal-resistant PGPR plays significant role in enhancing the efficiency of phytoremediation process (Ma et al. 2011; Rajkumar et al. 2012). Specific heavy metal-resistant PGPR may positively impact plants through improving plant tolerance to different environmental stresses, increasing root development and improving plant health and productivity (Glick 2010).

Plant growth-promoting and heavy metal-resistant activities are key attributes for bacteria used in metal phytoremediation; therefore, screening of effective PGPR and heavy metal-resistant bacteria should be taken into account as the primary work for cleaning up the heavy metal-polluted soil (Yu et al. 2014). Heavy metal-resistant PGPR may increase efficiency of phytoremediation by several mechanisms as follows:

A. Increasing the bioavailability of heavy metals for plant absorption.
B. Polluted soils are often poor in nutrient status; hence, PGPR enhance plants' nutrition and their growth and consequently phytoremediation efficiency.
C. Enhancement of plant growth through reducing plant stress generated by metal-polluted sites.

9.4.1 Enhanced Efficiency of Phytoremediation by Increasing the Bioavailability of Heavy Metals

Many factors such as soil nutrients, plant species type, pH, plant-associated microbial flora, and so on influence plant-microorganism interactions and thereby affect uptake of heavy metal by plants. However, as mentioned above heavy metal bioavailability in rhizosphere is considered to be a prominent factor determining the efficiency of phytoextraction and phytoremediation (Sessitsch et al. 2013). The content of bioavailable metals in the soil extremely affects the amount of metal accumulation in plants, because most parts of heavy metals are usually bound to different organic and inorganic compounds in contaminated soils and their phytoavailability are closely related to their chemical speciation (Ma et al. 2011). Rhizosphere plays an important role in phytoremediation process of heavy metal-polluted soils, in which microbial populations are believed to impact heavy metal mobility and availability to the plant by several pathways including release of chelating agents, solubilization activity, acidifcation, and redox changes (Bharti et al. 2014). According to the uptake by plants, heavy metals in soil may be categorized into three main classes, which comprise absorbable forms (e.g., free ions and chelating ions), exchangeable forms (bound to carbonates, organic matter, and iron-manganese oxides), and unavailable/or residual forms (Wei et al. 2008).

PGPR are among the soil microorganisms which are drawn in the plant interactions with metal-contaminated soil environments and require certain attention due to the fact that these may directly facilitate the phytoremediation process through changing bioavailability of metals by changes in synthesis of phytohormones

(e.g., auxins), siderophores, and increased release of chelators (Ma et al. 2011). The use of heavy metal-solubilizing microorganisms is a promising procedure for improving bioavailability of heavy metals in contaminated soils. Plant-associated bacteria may be utilized to enhance phytoextraction activities through changing the solubility, availability, and translocation of toxic metals as well as nutrients, by decreasing soil pH and releasing chelating agents (Ma et al. 2011).

Production of metal chelating agents like siderophores by PGPR plays an important role in mobilization and accumulation of metals through a complexation reaction (Rajkumar et al. 2010; Gadd 2010). Braud et al. (2009) observed that Cr and Pb can be released into the soil solution after soil inoculation with *P. aeruginosa.* However, siderophores can constitute stable complexes with other environmental concern metals including Al, Cd, Cu, Ga, In, Pb, and Zn. The plant growth-promoting siderophore-producing rhizobacteria may enhance the phytoextraction rate that usually restricts the application of phytoremediation procedures (Braud et al. 2009). The importance of PGPR on Ni solubilization in soils was previously reported by Abou-Shanab et al. (2003).

According to Carrillo-Castaneda et al. (2003), siderophores secreted by PGPR play a key role in mobilization of soil metals. Some results emphasized the potential of plant inoculation with siderophore-producing bacteria to better enhance their phytoextraction efficiency (Pereira et al. 2015). It has been reported by Dimkpa et al. (2009b) that bacterial culture filtrates having hydroxamate siderophores produced via *S. tendae* F4 significantly improved uptake of Cd through the plant, when compared to the un-inoculated control. This study revealed that siderophores may help to mitigate toxicity of metals in bacteria while concurrently accelerating the uptake of such metals through plants. Soil beneficial rhizobacteria produce certain organic acids including gluconic, oxalic, and citric acids, which play essential roles in the solubility and mobilization of heavy metals. Ullah et al. (2015) reported that aforesaid organic acids play significant role in the adsorption reaction of heavy metals and improve their mobility for plants.

Moreover, Saravanan et al. (2007) displayed the production of gluconic acid derivative by *Gluconacetobacter diazotrophicus*, which contributes in the solubilization of Zn compounds.

Biosurfactants are believed to be integral significant metabolites produced by growth promoting that have the potential to increase mobilization and phytoremediation of toxic metals. The released biosurfactants by soil microorganisms create complexes with heavy metals at the soil interface, removing metals from the soil matrix and therefore accelerating solubility and bioavailability of metals and assisting phytoremediation process (Rajkumar et al. 2012). For example, biosurfactants produced through Pseudomonas aeruginosa BS2 would result in solubilization of Pb and Cd (Juwarkar et al. 2007). Furthermore, redox reactions are involved in mobilization of metals (Bolan et al. 2014).

According to (Gadd 2004), *Thiobacillus thiooxidans* (a promising sulfur-oxidizing bacteria) may acidify their surroundings through oxidation from ferrous iron to ferric iron and production of H_2SO_4 (Gadd 2004).

9.4.2 Improvement of Plant Nutrition, Root System, Metal Detoxification, and Biocontrol of Phytopathogens and Consequently Plant Growth and Phytoremediation Efficiency

PGPR in hosted plants not only trigger physiological changes but also alter the root architecture which may be monitored through variation in total root length and root tip (Bhattacharyya and Jha 2012). Phytohormones are very efficient on plant growth and development, and among them, IAA (indole-3-acetic acid) is one of the most important groups of growth regulators (Stepanova et al. 2008; Friml et al. 2003), often produced by PGPR (Mayak et al. 2004). PGPR generating IAA have been widely applied to enhance phytoremediation efficiency of metalliferous soil (Khan et al. 2009; Ma et al. 2011). Production of IAA is proposed as a key property of PGPR (Ahmad et al. 2008). IAA supplementation to soil may increase the uptake of metals in plant root surfaces. The presence and richness of strains producing high dose of IAA isolated from heavy metal-polluted soil in comparison to other soils implied that this PGP ability of the strains might aid in phytoremediating the soil (Yu et al. 2014). Marques et al. (2010) suggested that the correlation between IAA-producing rhizobacteria and corn (*Zea mays*) root biomass promotion was positive. Also, Khalid et al. (2004) reported that bacterial strains with ability to produce the highest amount of IAA increased the growth of wheat plant.

Enhancement of root growth is one of the main indicators by which the positive influence of PGPR is determined. Rapid establishment of plant root systems is useful for juvenile seedlings as it enhances their ability to attach themselves to the soil and to acquire water and different nutrients from their environment, increasing their chances of survival (Patten and Glick 2002).

The low level of iron uptake into plants cultivated in the presence of heavy metals may cause chlorosis because iron deficiency reduces both biosynthesis of chlorophyll and development of chloroplast (Ismande 1998). According to these ideas, the siderophore-overproducing bacteria could serve as potential source of iron for plants that grow under heavy metal stress conditions and hinder plants from chlorosis (yellowing of leaf tissue) through providing an adequate value of soluble iron to the plants (Suthersan 1999). PGPR's presence in heavy metal-polluted soil increases the uptake of iron in plants, which subsequently improve the chlorophyll contents and plant growth in the PGPR-treated plants (Kamran et al. 2015). Moreover, excessive value of accumulated heavy metals in plant tissues may cause changes in different critical processes of growth and have adverse effects on iron nutrition status. Under such conditions, the beneficial siderophore-producing rhizobacteria might offer an alternative biological rescue approach that is able to chelate Fe^{3+} and make it soluble to plants. The plant roots then could take up iron from siderophore-iron chelates possibly through various mechanisms including chelate degradation and release of iron, the direct uptake of siderophore-iron complexes, and/or a ligand exchange substitution (Rajkumar et al. 2010). Siderophores also stimulate

biosynthesis of bacterial IAA through decreasing the deleterious impacts of heavy metals by chelation reaction (Ma et al. 2011). Rhizobacteria ability to convert insoluble forms from phosphorous to soluble forms is an important feature in PGPR for increasing plant productivity (Chen et al. 2006). However, under metal stress conditions, most heavy metal-tolerant PGPR strains can either change the insoluble phosphates into the soluble forms by the processes of acidification, chelation, exchange reactions, and production of organic acids (Chung et al. 2005).

Nitrogen-fixing rhizobacteria can beneficially influence on host plant growth through accelerating nitrogen availability. Therefore, they can act as an efficient biofertilizer which enhances plant growth and development (Kang et al. 2010). The PGPR can also contribute in decreasing phytotoxicity of metals through biosorption and bioaccumulation procedures. Because the bacterial cells (~1.0–1.5 mm^3) have very high-surface-area-to-volume ratio, they could take up more heavy metals than inorganic soil fractions (e.g., kaolinite and vermiculite) either through metabolism-independent or by a metabolism-dependent process, i.e., through passive or active pathways (Khan et al. 2007).

The ability of soil microorganisms to take up and accumulate toxic metals including Ag, Co, Cd, Cu, Zn, Mn, Pb, Ni, Hg, etc. has been previously reported. Various PGPR such as *Pseudomonas*, *Azospirillum*, *Azotobacter*, etc. and fungi including *Glomus* sp., *Gigaspora* sp., certain alga, and diatoms have such capability and are being investigated for their high biotechnological potential as effluent detoxification agents (Rajkumar et al. 2012). PGPR can also synthesize extracellular enzymes including cellulases, pectinases, proteases, and lipases. These bacterial characteristics will confer important benefits in the presence of phytopathogens, because their cell membrane and cell wall will be degraded through the exoenzymes and their negative impacts inhibited, resulting in enhancement of plant growth (Pereira et al. 2015).

9.4.3 Improvement of Plant Growth by Decreasing Plant Stress Generated by Metal-Contaminated Soils

Proline is a well-known α-amino acid, which is present in plants and microorganism (e.g., bacteria and fungi) experiencing abiotic stress conditions (John et al. 2009). Accumulation of proline also assists to maintain the structure of cell organelles and plays a key role in adjusting osmotic potential in plants under stress conditions (Kamran et al. 2015). Ahmad et al. (2006) reported that proline plays an essential role in the folding of proteins and molecular membrane, improving buffer cellular redox potential and protecting cell by scavenging reactive oxygen species (ROS) (Ahmad et al. 2006). Heavy metal stress induces accumulation of free proline in some plant species. Free proline enhances plant resistance to stress through osmoregulation process, which subsequently stabilizes protein synthesis, and protects enzymes against proteolytic degradation and denaturation (Modirroosta et al. 2014).

It has been reported that an increase in proline concentration was found in PGPR-inoculated wheat plants under heavy metal stress conditions (Janmohammadi et al. 2013). This process is regulated by PGPR-assisted tolerant plant species, which reduce the phytotoxic influence for several contaminates and are assumed to improve the metal absorption. According to Kamran et al. (2015), *Eruca sativa*-treated plants at higher Cd levels produce more proline contents, which verify the metal tolerance characteristics of this plant and role of PGPR to survive under heavy metal stress conditions.

The classical phytohormone, ethylene, has a prominent role in modulating the growth and metabolism of plants (Ping and Boland 2004) and seem to be involved in stress tolerance, disease resistance, plant-microorganism association, as well as plant nutrient cycle. Among its central role in triggering different physiological and biochemical variations in plants, the overproduction of ethylene may cause the reduction of primary root growth, lateral root initiation, and root hair formation (Ma et al. 2011); however, PGPR are potentially able to ameliorate the stress-mediated effect on plants via enzymatic hydrolysis of ACC (Glick et al. 2007). Bacterial ACC-deaminase enzyme is an inducible enzyme that plays a significant role in the regulation of ethylene, modifying growth and development of plants. It is acknowledged that inoculation with the ACC-deaminase-producing bacterial strains may ameliorate the stress-induced ethylene-mediated negative effect on plants (Glick 2005). Bacterial ACC-deaminase metabolizes the root's ACC into a-ketobutyrate and ammonia and inhibits ethylene production, which otherwise reduce plant growth by several mechanisms (Fig. 9.2).

The plant inoculation with bacteria possessing ACC-deaminase may have relatively extensive root system and therefore more growth and development because of less ethylene level and can better tolerate different biotic/abiotic stresses (Jalili et al. 2009). ACC-deaminase enzyme has been greatly reported in multiple PGPR such as *Agrobacterium genomovars*, *Alcaligenes*, *Azospirillum lipoferum*, *Bacillus*, *Burkholderia*, *Enterobacter*, *Methylobacterium fujisawaense*, *Pseudomonas*, *Ralstonia solanacearum*, *Rhizobium*, *Rhodococcus*, *Sinorhizobium meliloti*, and *Variovorax paradoxus* (Ghorbanpour and Hatami 2014; Ghorbanpour et al. 2013, 2016; Saleem et al. 2007).

Burd et al. (1998) reported that canola (*Brassica napus*) seedlings grown in the media supplemented with high concentrations of nickel produced lower quantities of ethylene when the canola seeds were treated with an ACC-deaminase-containing nickel-resistant bacteria. A positive correlation has been found between in vitro bacterial ACC-deaminase activity and their promoting effect on root elongation, suggesting that utilization of ACC is a prominent feature determining root growth enhancement. Soil bacteria offer promise as inoculants to enhance growth of *Brassica juncea* (a metal-accumulating plant) in the presence of toxic levels of Cd and are believed to be a useful approach for developing a successful phytoremediation strategy in contaminated soils (Belimov et al. 2005). It has been reported that

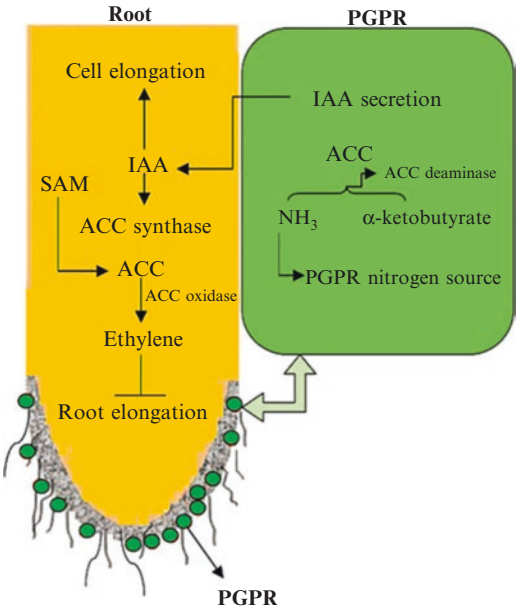

Fig. 9.2 Schematic diagram of the role of plant growth-promoting rhizobacteria (PGPR) on ethylene production and root growth inhibition. Abbreviations: *IAA* indoleacetic acid, *ACC* 1-aminocyclopropane-1-carboxylic acid, *SAM* S-adenosylmethionine (Ghorbanpour and Hatami 2014)

tobacco plants inoculated with *Pseudomonas putida* UW4 (containing ACC-deaminase enzyme activity) revealed better growth and accumulated a considerable value of metal from nickel-polluted site (Arshad et al. 2007). Furthermore, Sun et al. (2009) found that ACC-deaminase played influential for PGPR ability to enhance plant growth under heavy metal stress conditions. In a study, *S. plumbizincicola* inoculated with RC6b performed better in terms of growth in metal-polluted soils. The strain RC6b increased the root length, shoot length, fresh weight, and dry weight by 176 %, 27 %, 27 %, and 22 %, respectively, compared to non-inoculated plants. The increase in plant growth caused by *P. myrsinacearum* RC6b in metal-contaminated soils may be attributed to its ability to produce IAA, ACC-deaminase, and siderophores and solubilize P (Ma et al. 2013). Some researches in relation to the use of PGPR for increasing phytoremediation efficiency were listed in Table 9.1. Generally, the result of different researches and publications indicated that the use of PGPR could be effective and enhanced phytoremediation proficiency in heavy metal-contaminated sites.

Table 9.1 Some recent studies regarding the effects of PGPR on phytoremediation enhancement in heavy metal-contaminated soils

PGPR strains	Plant	Heavy metal	Role of PGPR	References
Azospirillum	*Panicum virgatum*	Pb and Cd	Bacteria increased the root length, branches, surface area, and root and shoot biomass	Arora et al. (2016)
Pseudomonas brassicacearum, *Rhizobium leguminosarum*	*Brassica juncea*	Zn	Plant growth increased	Adediran et al. (2016)
Streptomyces, *Azotobacter*, *Pseudomonas*, and *Paenibacillus*	*Pennisetum glaucum* and *Sorghum bicolor*	Fe	PGPR increased the extent of iron absorption	Mishra et al. (2016)
Pseudomonas putida	*Eruca sativa*	Cd	Inoculation with *P. putida* enhanced the Cd uptake potential of *E. sativa* and favors the healthy growth under Cd stress	Kamran et al. (2015)
Rhodococcus erythropolis EC34, *Achromobacter* sp. *1AP2*, and *Microbacterium* sp. *3ZP2*	*Trifolium repens*	Zn and Cd	Enhanced plant growth and the available and exchangeable metal concentrations in rhizosphere	Pereira et al. (2015)
Pseudomonas aeruginosa	*Amorpha fruticosa*	Cd, Cu, Ni, and Zn	Promoting plant growth and improving tolerance of the plant to heavy metals	Yu et al. (2015)
Bacillus licheniformis NCCP-59	*Oryza sativa*	Ni	Improved seed germination and plant growth	Jamil et al. (2014)
Pseudomonas fluorescence and *Pseudomonas aeruginosa*	*Prosopis juliflora*	F (fluoride)	Significantly increased the biomass and bioaccumulation factor	Vidyapith and Rajasthan, (2014)
Pseudomonas fluorescens	*Mirabilis jalapa*	Cd, Cr, Cu, Ni, and Zn	Significantly increased the biomass and heavy metal concentration	Petriccione et al. (2013)
Phyllobacterium myrsinacearum RC6b	*Sedum plumbizincicola*	Cd, Zn, and Pb	Increased growth, organ metal concentrations, and metal mobility in soil	Ma et al. (2013)

Bacillus safensis FO.036b and *Micrococcus roseus M2*	*Helianthus annuus*, *Amaranthus retroflexus*, *Medicago sativa*	Ni	Absorption of nickel increased	Motesharezadeh and Savaghebi-Firoozabadi (2011)
Psychrobacter sp. SRS8	*Helianthus annuus*, *Ricinus communis*	Ni	Enhanced plant growth and Ni accretion in both plant species	Ma et al. (2011)
Agrobacterium radiobacter	*Populus deltoides*	As	Arsenic concentrations in roots, stems, and leaves were significantly increased	Wang et al. (2011)
Bradyrhizobium sp., *Pseudomonas* sp., *Ochrobactrum cytisi*	*Lupinus luteus*	Pb, Cu, and Cd	Increasing plant biomass	Dary et al. (2010)
Bacillus subtilis, *Bacillus cereus*, *Flavobacterium* sp., *Pseudomonas aeruginosa*	*Orychophragmus violaceus*	Zn	Increased shoot biomass and Zn accumulation.	He et al. (2010)
Bacillus subtilis, *B. cereus*, *Flavobacterium* sp., *Pseudomonas aeruginosa* (RS)	*Orychophragmus violaceus*	Zn	Increasing availability of water-soluble Zn in soil and Zn accumulation by plants	He et al. (2010)
Streptomyces tendae F4	*Sunflower* (*Helianthus annuus*)	Cd	Increasing cadmium availability and uptake	Dimkpa et al. (2009b)
Ralstonia metallidurans Pseudomonas aeruginosa	Maize	Cr and Pb	Increased metal uptake	Braud et al. (2009)
Pseudomonas fluorescens G10, *Microbacterium* sp. G16	Rape	Pb	Shoot Pb accumulation increased	Sheng et al. (2008)
Burkholderia cepacia	*Sedum alfredii*	Cd and Zn	Plant growth increased	Li et al. (2007)
Bacillus subtilis SJ-101	*Brassica juncea*	Ni	Approximately increased the accumulation of Ni; increased plant biomass	Zaidi et al. (2006)

PGPR-Mediated Amelioration of Crops Under Salt Stress

10

Anukool Vaishnav, Ajit Varma, Narendra Tuteja, and Devendra Kumar Choudhary

Abstract

Soil salinity is a major abiotic factor which adversely affects the crop growth and productivity worldwide. Higher salt concentration caused ion imbalance and hyperosmotic stress which often lead to oxidative stress in plants. Soil salinization is mainly due to the poor irrigation management practices and natural causes. A total 20 % of the world's cultivated lands and almost half of all irrigated lands are affected by high salinity. This chapter begins by stressing the importance of research into plant salt tolerance. After a brief outline of salinity-induced damage to both agricultural yield and growth of plants, strategies which plants adopt to deal with salinity are discussed, and current biotechnological efforts towards producing salt-tolerant crops are summarized. Particular attention is paid towards the application of plant growth-promoting bacteria in agriculture system for producing salt stress-tolerant crops and a fundamental understanding towards the mechanisms of beneficial plant–microbe interaction in the presence of salt.

The global need for food production has never greater than it is today. This issue is a major concern for developing countries, where the population is expected to rise by 90 % and where food insecurity is a major subject. Hence, increasing human population and decreasing cultivable land are two threats for agricultural sustainability (Shahbaz and Ashraf 2013). The increasing demand of food may be meet either by bringing more area under cultivation or increasing the productivity from the land already under cultivation. The former one seems unlikely to happen because of increasing pollution, urbanization, industrialization, soil degradation and limited

water availability. Thus, to increase the agriculture productivity, the only possible environment-friendly approach is to improve the agricultural land already in use. However, it is a big challenge to increase the efficiency and sustainability of existing global agriculture system, because this system is regularly marked by several biotic and abiotic factors.

10.1 Stresses

Once a seed germinates, plants being immobile are destined to stay where they are. Thus, they experience heavy selection pressure in their environments. Plants have developed many traits that help them to evolve and succeed across the globe under different environmental regimes. This selective pressure can be divided into abiotic and biotic stresses. Biotic stresses occur when a plant is attacked by an unwanted organism that causes damage to them, may it be the attack by virus, bacteria and fungi or grazing by an insect or higher animal. Abiotic stresses include the effect of winds, extreme temperatures, soil salinity, drought and flood. Among these stresses soil salinity is one of the most serious abiotic stresses which majorly reduce cultivated land area, productivity and quality.

10.1.1 Soil Salinity

A soil is defined as saline when its electrical conductivity (EC) exceeds 4 dSm^{-1} (approximately 40 mM NaCl). This salinity level is critical to reduce yield of many crop plants (Jamil et al. 2011). Different types of salts, e.g. sodium chloride (NaCl), sodium sulphate (Na_2SO_4), sodium nitrate ($NaNO_3$), magnesium sulphate ($MgSO_4$), magnesium chloride ($MgCl_2$), potassium sulphate (K_2SO_4), calcium carbonate ($CaCO_3$), etc., are present in saline soil in which NaCl causes serious problems for higher plants. Increase in these salt limits leads to two major stresses for the plants: osmotic stress and ionic stress. The osmotic stress firstly comes in plants when salt concentrations increase outside the roots, which leads to reduction in water uptake and subsequently plant development. The ionic stress develops when Na^+ accumulation increases in plants particularly in leaves over threshold level which caused chlorosis in leaves and reduced photosynthesis and other metabolic activities (Munns and Tester 2008).

10.1.2 Reason for Soil Salinity

A saline soil possesses high concentration of Na^+, K^+, Ca^{2+}, Mg^{2+} and Cl^- salts, which comes from weathering of minerals, irrigation water or evaporation of shallow groundwater. Due to insufficient precipitation, ions could not leach from the soil profile resulting salts to accumulate in the soil. Rainfall contains seawater salts, mainly sodium chloride (10 mg/kg) that would affect the land by deposition of

10 kg/ha of salt during each 100 mm of rainfall per year. In arid and semiarid regions of the world, soils are becoming saline due to poor irrigation management. Soil salinity is regularly increasing, and it has been estimated that 20 % of total cultivated and 33 % of irrigated agricultural lands worldwide are salt affected. If it happens continuously, the cultivable land would be 50 % salinized by the year 2050.

10.2 Plant Physiology Under Salt Stress

In saline soil, water potential decreased in surrounding the root, and plants suffer from the osmotic stress and ionic effect of Na^+ and Cl^-. Accumulation of Na^+ plays a central role in reduction of plant growth and senescence during salinity. Therefore, cytoplasmic Na^+ concentration is regulated by the plants to tolerate salt stress. In general, the salt stress response of plants consists of ion homeostasis, osmotic adjustment and detoxification (Fig. 10.1).

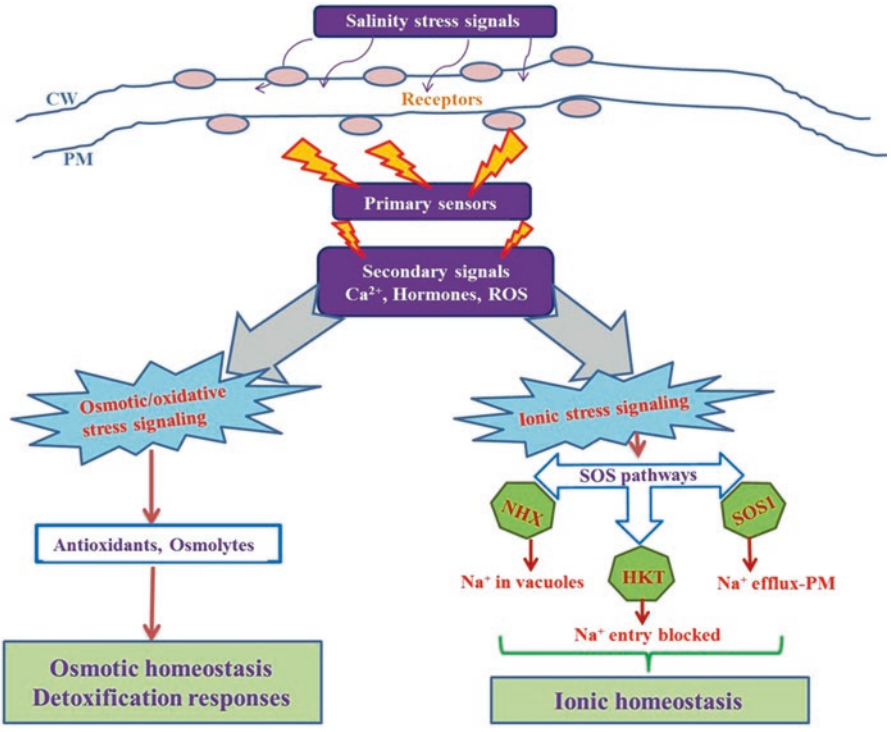

Fig. 10.1 Schematic pathway for the transduction of osmotic and ionic stress in plants

10.2.1 Ion Homeostasis

From an energetic viewpoint, it is preferable to control ion uptake initially rather than spending energy on detoxification and damage repair. Plant cells have mechanisms to buffer excess ions temporarily through the large, membrane-bound vacuoles. During salinity stress ion homeostasis of plant gets disturbed, resulting in excess toxic Na^+ in cytoplasm and deficiency into K^+. To regulate this, several ion transporters function to regulate Na^+ transport and its accumulation in plant tissues (Huang et al. 2012). The Na^+/H^+ antiporters catalyse the exchange of Na^+ for H^+ across the membranes. Plant Na^+/H^+ antiporters have been isolated from *Arabidopsis* (AtNHX1, SOS1; Gaxiola et al. 1999; Shi et al. 2002) and rice plants (Fukuda et al. 2004). *A. thaliana* plasma membrane Na^+/H^+ antiporter (*AtNHX1*), salt overly sensitive (*SOS1*) and the high-affinity K^+ transporter 1 (*HKT1*) genes were suggested to be essential for salt tolerance (Brini and Masmoudi 2012).

10.2.2 Osmotic Adjustment

Osmotic shock induced by a rapid increase of salinity triggers a fast and transient decrease in rates of leaf expansion and root elongation. Increased salt concentrations cause the water potential of the soil more negative than the root symplast, arising in tissue dehydration. The plant root must establish a water potential gradient so that water abounds into the plant from the soil. Plants can regulate their osmotic potentials within a certain range to indemnify for the low exterior water potential, and this is assembling osmotic adjustment. During salt stress, plants accumulate organic solutes together with primarily organic acids, nitrogen compounds and carbohydrates, e.g. malate, aspartate, glutamate, glycinebetaine, proline and sucrose, in the cytoplasm to take care of a low water potential within the cell. These solutes are involved in osmotic/oxidative stress management and protect macromolecules from damaging effects of increasing ionic strength of surrounding media of these stresses (Sharma et al. 2012). Polyols such as sorbitol, pinitol and mannitol also play a role as osmoprotectant. In addition, free amino acids have been reported to accumulate in plants subjected to salt stress. Proline accumulation occurs in larger amount in comparison to other amino acids and thus regulates N availability and osmotic adjustment. Proline being osmotically active contributes to stability of membrane and thus reduces the damaging effects of salt on membrane (Iqbal et al. 2014).

10.2.3 Detoxification

During salinity, the level of reactive oxygen species (ROS) is increased which creates oxidative stress in plants. Reactive oxygen species are consistently for metabolic pathways localized in altered cellular compartments. These are hydroxyl radicals ($OH^{\cdot}$), singlet oxygen ($^1O_2$), hydrogen peroxide (H_2O_2) and superoxide

radical (O^{2-}) (Sharma et al. 2012). These radicals catalyse self-propagating autoxidation reactions that lead to the formation of other organic peroxides, which cause major damage to biological system. Higher ROS concentrations are responsible for plant cell death by causing lipid peroxidation, protein oxidation and harm to nucleic acid. To fight against the deleterious effects of reactive oxygen species, plants are endowed with several antioxidants and metabolites in different plant cell compartments. The enzymatic antioxidants include superoxide dismutase (SOD), catalase (CAT), guaiacol peroxidase (GPX) and enzymes of ascorbate glutathione (AsA-GSH) cycle such as ascorbate peroxidase (APX), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR) and glutathione reductase (GR). The nonenzymatic antioxidants inside the cell are ascorbate (AsA), glutathione (GSH), carotenoids, tocopherols and phenolics (Gill and Tuteja 2010).

10.3 Approaches for Producing Salt-Tolerant Crops

Strategies for making tolerant plants to salinity and produce economically valuable species have been extensively studied for decades. A variety of strategies are used for improvement of crop tolerance, including traditionally (breeding), chemically (priming agents), molecular method (genetic engineering) and biologically (biofertilizers). Through traditional approaches, crops resistant/tolerant to salt stress have been bred, and the work is continuing. Direct selection based on higher yields on different location trials has been traditionally used for the development of tolerant/resistant varieties. This approach is time-consuming and labour intensive. In addition, strategic marker-assisted breeding is used in the development of tolerant cultivars that is further accelerated by development of molecular techniques such as molecular markers, gene mapping, QTL analysis and transgenics (Agarwal et al. 2013).

Genetic engineering (gene transfer) is the most progressive molecular approach which is used for the enhancement of tolerance level in plants. The variation between salt-tolerant (halophytes) and salt-sensitive (glycophytes) genotypes provides a genetic basis for engineering salt-tolerant crops. Several genes associated with salt response have been transferred into different plants to improve their tolerance against salt stress. These genes are involved in various types of activities during salt stress like compartmentalization of toxic ions in the vacuole, induction of antioxidant enzymes, synthesis of new proteins and accumulation of compatible solutes (Ashraf and Akram 2009). However, genetic engineering technique is not so successive due to its related ethical issues.

Salt-tolerant plants are also achieved via priming treatment with exogenous chemicals. These chemicals are natural products produced in plants at very low concentration, and when they are synthesized chemically and applied on plants, they start controlling downstream process. These chemicals include nitric oxide (NO), hydrogen peroxide (H_2O_2), sugars, hydrogen sulphide (H_2S), proline (Pro), glycinebetaine (GB), β-aminobutyric acid (BABA), jasmonates (JA), salicylic acid (SA), etc. (Ben Rejeb et al. 2013). However, these chemicals are

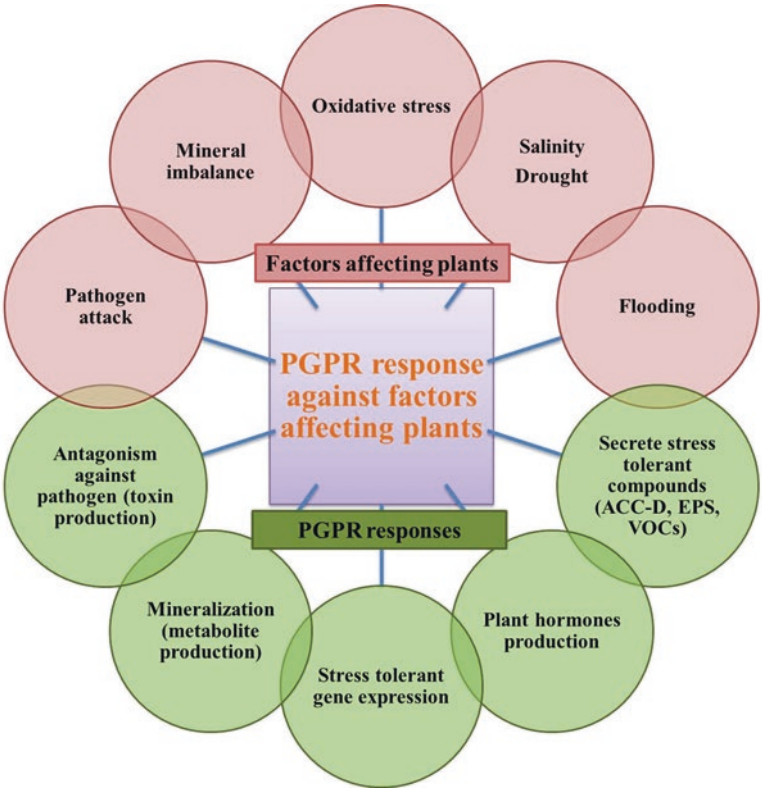

Fig. 10.2 Various types of PGPR responses against different factors affecting plant growth

cost-effective and also caused a number of long-term environmental problems. Hence, these chemicals are not suggested for easy and economical approaches for sustainable agriculture.

Alternatively, the use of plant growth-promoting rhizobacteria (PGPR) is the most promising approach to enhance crop production in saline regions. The beneficial relationship between PGPR and plants is an earlier theory, but the current concern is the application of these bacteria as inoculums in agriculture to mitigate stress conditions (Shrivastava and Kumar 2015). PGPR are bacteria which colonize in the rhizosphere/endorhizosphere of plants and promote growth of the plants through various direct and indirect mechanisms. Indirect mechanisms are related with plant pathogen inhibition. In this mechanism, bacteria secrete antibiotics and lytic enzymes that provide resistance against pathogen attack. In direct mechanisms, bacteria directly effect on plant itself and enhance growth by facilitating the nutrient uptake through mineral solubilization and phytohormone production (Fig. 10.2). Various salt-tolerant PGPR genera including *Rhizobium*, *Pseudomonas*, *Acetobacter*, *Bacillus*, *Serratia* and *Azospirillum* are being used and tested for plant growth promotion under salinity (Choudhary et al. 2015).

10.4 Induced Systemic Tolerance

Plants are sessile in nature; that's why they have evolved many adaptive strategies against a broad range of external factors. Adaptation to stresses has been suggested to be mediated by pre-existing or "memory" defences which lead to rapid and strong induction of first-line defence mechanisms upon subsequent exposure to stress (Pastor et al. 2013). The induction of "memory" defences in plants has been reported through priming with microbes and certain chemicals. Plant's perception for exogenous chemicals and microbe-associated molecular patterns (MAMPs) is able to induce response against abiotic stresses, providing tolerance in stress conditions. Such type of mechanism is known as "induced systemic tolerance (IST)".

10.5 PGPR-Mediated Induced Systemic Tolerance

Upon deployment of various mechanisms, it has been reported that IST reflects amelioration of plants under abiotic stress. Various traits of PGPR have been reported on amelioration of salinity stress, e.g. ACC-deaminase, exopolysaccharide, volatile production, Pi solubilization, indole-3-acetic acid (IAA) production, etc. (Fig. 10.3). Rhizosphere microbes are involved in altering hormonal root–shoot signalling in plants. Indole-3-acetic acid (IAA)-producing PGPR stimulate exudation of flavonoids by bean plants; regulate nodulation, nitrogen fixation and nutrient uptake; and relieved the negative effects of salt stress (Dodd and Pérez-Alfocea 2012). PGPR contain the enzyme 1-aminocyclopropane-1-carboxylic acid deaminase (ACC-D), which hydrolyzes the ethylene precursor ACC and reduces the level of ethylene during salt condition (Glick 2014; Choudhary et al. 2015). Microbial secreted exopolysaccharides (EPS) are reported to chelate excessive Na^+ and reduce their availability to plants during saline condition (Choudhary et al. 2015). PGPR are reported to enhance the nutrient uptake efficiency of plants by secreting enzymes in the soil and solubilizing bound nutrients such as phosphorus, potassium, zinc and iron. In recent years, volatile organic compounds (VOCs) were found as a novel way of signalling between PGPR and plants, in which VOCs from specific strains of bacteria enhanced plant growth by regulating different biological processes including hormone distribution, nutrient uptake, sodium homeostasis and biosynthesis of osmoprotectant (Liu and Zhang 2015). The ability of soil microbes to improve plant growth and alleviate negative effects of salinity is evaluated below.

10.5.1 Osmolyte Accumulation and Maintaining Water Homeostasis

Plant growth is firstly affected by osmotic stress and then recovers a little bit by accumulation of osmolytes during salt stress. Salinity creates water stress around the root due to accumulation of salt ions which decrease osmotic balance in plants. Water homeostasis and photosynthesis structures are critical to salt stress; hence,

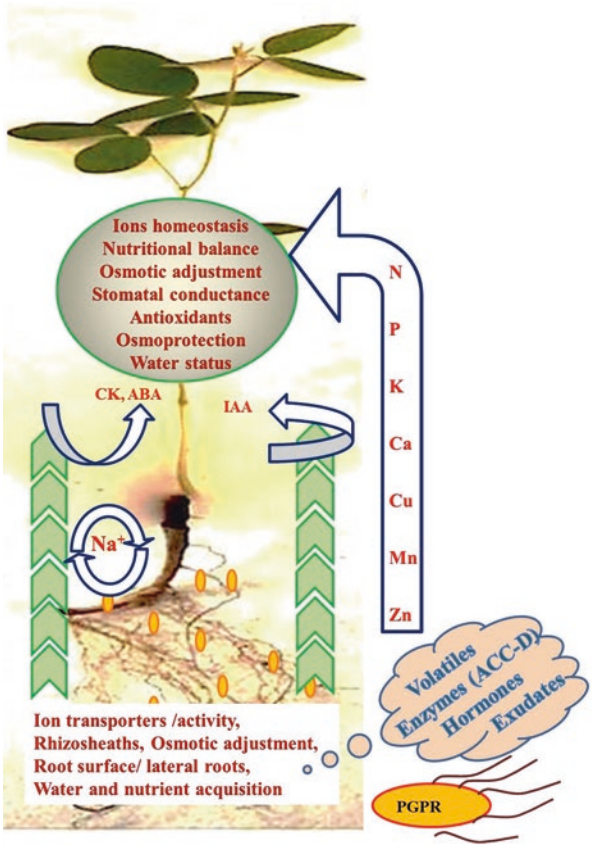

Fig. 10.3 Plant and PGPR interaction in response to salt stress

their maintenance is essential for alleviating the impact of salinity on plant growth (Iqbal et al. 2014). PGPR have the ability to improve plant–water relations by enhancing the accumulation of osmolytes in plants. Different bacterial genera such as *Burkholderia*, *Arthrobacter*, *Bacillus* and *Pseudomonas* are reported to enhance proline synthesis in abiotically stressed plants (Choudhary 2012). *Bacillus* sp.-inoculated plant root accumulated higher proline content in salt stress compared to non-inoculated plant root (Vardharajula et al. 2011). Kumari et al. (2015) suggested that higher proline content in roots maintain osmotic balance, leading to water entrance into the roots. Inoculation of *Rhizobium* and *Pseudomonas* bacterial strains in *Zea mays* was found to increase proline content along with relative water content (Bano and Fatima 2009). In addition, several reports determined the relation between proline accumulation and pyrroline-5-carboxylate synthase *(P5CS)* gene expression level in the presence of PGPR inoculation and suggested that bacterial treatment upregulated the *P5CS* gene expression in plant roots leading to accumulation of free proline content (Kim et al. 2007; Kumari et al. 2015). Similar

to proline, the soluble sugars have been reported to increase in PGPR-inoculated plants during salt stress (Kumar et al. 2010; Shukla et al. 2012). Rhizobacteria are reported to maintain root hydraulic conductance which is suggested to assist the maintenance of plant–water status under saline environment (Marulanda et al. 2007). Relative water content is the best indicator of water stress which reduced during salt stress. Plants inoculated with PGPR have been reported to hydrate more than non-inoculated plants and enhanced photosynthesis activity and biomass content (Shukla et al. 2012; Kumari et al. 2015). Furthermore, Vardharajula et al. (2009) explored the role of bacterial exopolysaccharide in protection of plants from water stress. Authors examined that inoculation of *Pseudomonas putida* sp. GAP-P45 enhanced the survival rate of sunflower seedlings along with plant biomass and root-adhering soil under drought stress. The biofilm formation increased the percentage of stable soil aggregates which protect plants from water stress and improve soil health (Choudhary et al. 2015).

Plants keep protecting their photosynthesis activity and apparatus to ROS via the upregulation of antioxidative enzyme expression. Different *Rhizobium* strains (*Mesorhizobium ciceri*, *Mesorhizobium mediterraneum* and *Sinorhizobium medicae)* were studied on chickpea plant, in which *M. ciceri* strain was found potent to enhance plant tolerance by increasing POD enzyme activity under salt stress (Mhadhbi et al. 2004). *L. sativa* seedlings were inoculated with *P. mendocina* and affected by different levels of water stress. POD and CAT activities were increased in *P. mendocina*-inoculated seedlings in response to drought stress. *P. mendocina*-inoculated seedlings exhibited higher shoot and root biomass and relative water content compared with non-inoculated seedlings (Kohler et al. 2008). In another study, the effect of salt-tolerant *Bacillus amyloliquefaciens* NBRISN13 (SN13) inoculation was evaluated on rice plants exposed to salinity. SN13 increased plant growth as exposed by higher plant length, biomass and chlorophyll content and also enhanced salt tolerance by increasing proline content and upregulation of defence-related gene including *CAT* expression also (Nautiyal et al. 2013).

10.5.2 Ion Homeostasis

Na^+ and Cl^- accumulation in plant tissue is a crucial factor responsible for plant senescence and limiting growth. It is generally accepted that the exclusion of these ions is mostly related to salt tolerance mechanisms in glycophyte species. Rhizobacteria are reported to contribute in toxic ion homeostasis which improves plant growth and tolerance during salinity. These microbes can reduce the uptake of toxic ions by regulating ion transporter expression in plants and formation of rhizosheaths by producing exopolysaccharides (EPS) which work as a physical barrier around the roots. Rhizobacteria are also contributed in the macro-/micronutrient status in plants. These nutrients become more accessible to the plants due to some microbial activities in rhizosphere like Pi solubilization, organic acid excretion and siderophore production. These nutrients have been reported to reduce toxic ion accumulation, and the specific importance has been given to microbial-mediated

enhancement of K^+/Na^+ ratios in plants (Shukla et al. 2012; Shkolnik-Inbar et al. 2013; Vaishnav et al. 2015). Ashraf et al. (2004) explained that *Aeromonas hydrophila/caviae* and *Bacillus* sp. decreased Na^+ accumulation in wheat plants by the excretion of EPS, which bind Na^+ in roots and prevent their transfer to leaves. In the same way, EPS producing *B. circulans* and *B. polymyxa* were found to enhance dry matter yield of root and shoot of wheat plants, K^+/Na^+ and Ca^{2+}/Na^+ ratio during salt stress. The effect may be attributed to the cation chelating capacity of EPS (Khodair et al. 2008). In another study, wheat rhizospheric bacteria were found to produce EPS which significantly decreased Na^+ uptake in plants under both nonsaline and saline conditions (Upadhyay et al. 2011). Moreover, Kumari et al. (2015) suggested that EPS producing bacterial strains enhanced K^+/Na^+ which maintained photosynthesis machinery in soybean plants under salt stress.

Another mechanism of PGPR-mediated ion homeostasis could be explained by the exposure of bacterial volatile organic compounds (VOCs) which are reported to modulate Na^+ homeostasis pathway in plants. These compounds have low molecular weight and are found as a novel way of signalling between two organisms. *Arabidopsis* plants exposed to *B. subtilis* GB03 VOCs were exhibited to tolerate salt stress than control plants. This exposure was found to decrease root *AtHKT1* expression in roots but upregulated it in the shoots which facilitate root-to-root Na^+ recirculation (Shkolnik-Inbar et al. 2013). In a study, Vaishnav et al. (2015) examined that *P. simiae* AU-mediated putative VOC blend enhanced the expression of vegetative storage protein (VSP) in soybean leaves, correlated with lower uptake of Na^+ ions by regulating sodium transporter activity under 100 mM NaCl stress.

10.5.3 Nutrient Acquisition

Plant growth and productivity is severely affected by inadequate supply and limitation of nutrients in the soil system. Availability and uptake of nutrients depend on several parameters of soil such as composition, pH, moisture, soil texture and microflora composition. Most of the nutrients are available in the range of 5–7 pH of soil. Salinity changes the pH of soil by which most of compounds bound to cations and anions to form a stable compound which further makes them less available in soil. PGPR solubilize these nutrients and make available to plants.

Phosphorus is a crucial macronutrient for plant growth and development. It is present in organic form (30–65 %) in the soil which is not assimilated by plants. The organic P in soils is present in the form of inositol phosphatases, phosphoesters, phosphodiesters and phosphotriesters (Sindhu et al. 2010). It is well-known facts that P chemical fertilizers which are added to soil have sparingly soluble nature which is completely not available to the plants leading to add large amount of fertilizers by farmers into the fields which later cause environmental problems. Phosphate-solubilizing bacteria (PSB) that belong to genera *Bacillus*, *Pseudomonas*, *Achromobacter*, *Alcaligenes*, *Brevibacterium*, *Corynebacterium*, *Serratia* and *Xanthomonas* are capable of hydrolyzing unavailable form of phosphorus in available form (Sindhu et al. 2010). In a study, a large number of fluorescent

pseudomonad strains were screened for the solubilization of tricalcium phosphate on the basis of visible dissolution halos on Pikovskaya agar medium (Naik et al. 2008). These bacteria excrete low molecular weight organic acids such as gluconic acid, citric acid, succinic acid, propionic acid and lactic acids that mineralize and dissolve organic phosphate compounds and make available to plants in the form of inorganic phosphate (Choudhary 2012). Phosphatases are enzyme that can hydrolyze different form of phosphate, originating from the organic soil sources. Additionally, the production of hydrogen ions in rhizosphere environments alters the pH sufficiently to mobilize soil minerals (Khan et al. 2013). Salinity causes the depletion and precipitation of available phosphorus, and PSB have tendency to solubilize precipitated forms of phosphorus in hydroponic MS medium and enhanced the phosphorus content in plant system under NaCl stress (Shukla et al. 2012; Vaishnav et al. 2015). A PGPR *P. mendocina* has been observed to protect *Lactuca sativa* L. cv. Tafalla against different levels of salt stress. Kohler et al. (2008) reported that bacterial-inoculated plants exhibited higher phosphatase activity which released soluble phosphate from its insoluble compounds inside the plant cells and helped plants to tolerate salt stress.

Nitrogen is an essential component required for protein and nucleic acid synthesis and other nitrogen compounds, those that are considered as vital components of the living system. Soil microorganisms have the capacity to fix atmospheric and provide it to plants in the form of ammonia via nitrogen fixation process. PGPR can fix nitrogen by symbiotic or non-symbiotic mechanism. In symbiotic N_2 fixation, bacteria associated with host plant root by nodule formation and fixed nitrogen inside the cell that accounts nearly 65 % of the total biologically fixed nitrogen (Rajwar et al. 2013). Symbiotic N_2 fixation occurs in *Azotobacter* spp., *Bacillus* spp., *Beijerinckia* spp., etc., whereas non-symbiotic nitrogen fixation occurs through free living diazotrophs, *Azospirillum*, *Pseudomonas* and *Burkholderia*, those fixed nitrogen in the rhizosphere (Mia et al. 2013). Nitrogen fixation in legume plants is mediated mainly by associative bacteria *Rhizobium*. Salinity has a major effect on legume biology as it affects the diversity of rhizobia in soil and their interaction with legume plants. Salt stress mostly reduces number of nodules that result in reduction amount of nitrogen fixed. In the past few years, salt-tolerant PGPR which can tolerate higher levels of salts, up to 1.5–2.0 M NaCl, were co-inoculated with *Rhizobium* in legumes for growth enhancement and successful N_2 fixation (Divito and Sadras 2014). The co-inoculation of PGPR is a good strategy when *Rhizobium* is not so effective in saline environment. ACC-deaminase-containing PGPR have been observed to reduce the ethylene concentration which decreases nodulation efficiency in legumes under stress environment (Ahmad et al. 2011). *Pseudomonas* and *Rhizobium phaseoli* co-inoculation was observed very effective for enhancing nodulation process in mung bean plants under laboratory as well as field conditions affected by salinity stress (Ahmad et al. 2013). Similarly, co-inoculation of *Mesorhizobium* sp. with IAA-producing *Pseudomonas* has been found to increase nodulation in chickpea (Malik and Sindhu 2011). In another study, co-inoculation of *Pseudomonas* and *Rhizobium* was found to increase nodulation and nutrient uptake (Mishra et al. 2011). Furthermore, *Azospirillum* and *Rhizobium* consortia

were found to enhance nodulation which increased tolerance in plants against unfavourable conditions (Bashan and de-Bashan 2010).

Iron is the fourth most abundant element required by most of the living organisms for growth. It plays a key role as cofactor for nearly 140 enzymes catalysing specific biochemical reactions and processes. Iron exists in the form of ferric state (Fe^{3+}) and produces insoluble hydroxides and oxyhydroxides which are not readily available to plants and microorganisms (Ma et al. 2011). In saline soil, the availability of ferric is further reduced due to decreased solubility from lower pH to higher pH (Thomine and Lanquar 2011). Organisms have employed various mechanisms to get available form of iron; among them siderophores have been best studied. Siderophores are iron-chelating agents and proved in different PGPR strains as an important attribute for plant growth promotion and phytopathogen protection (Scavino and Pedraza 2013). PGPR secrete siderophore in the rhizosphere, and then plant roots uptake iron from siderophore by either chelate degradation or direct uptake (Rajkumar et al. 2010). A great variability has been found in microbial siderophores such as peptidic siderophores, aminoalkane siderophore and citric acid-based siderophore (Budzikiewicz 2010). Siderophores have been concerned for both direct and indirect mechanism of plant growth by PGPR. Sharma and Johri (2003) reported that siderophore-producing *Pseudomonas* spp. strains GRP3A and PRS significantly increased maize seed germination and plant growth under iron-stressed condition and suggested application of these bacterial strains for crop productivity in calcareous soil system. Pandey et al. (2005) characterized *P. aeruginosa* GRC1-secreted siderophores. The purified siderophore was pyoverdine type with amino acid composition, when this bacterium applied in field trials, found to enhance the growth of *Brassica campestris*.

Potassium (K) is the third major essential nutrient for plant growth which involved in various metabolic processes in plants (Sindhu et al. 2010). Potassium is present in soil in the form of available (water soluble) and unavailable (micas, illite and orthoclase). The common components of potassium in the soil are feldspar and mica in 90–98 % (Sindhu et al. 2010). Potassium-solubilizing bacteria (KSB) are able to release K from its unavailable form. Meena et al. (2014) described the importance of KSB in K uptake efficiency by plants and reduction in the use of costly chemical fertilizers. Two KSB strains, KNP413 and KNP414, that possessed higher dissolution capacities of mineral K are widely used as potassium fertilizer in China (Hu et al. 2006). Three PGPR strains *B. mucilaginosus*, *Azotobacter chroococcum* and *Rhizobium* sp. were found to solubilize K from waste mica and enhanced its uptake in maize and wheat plants (Singh et al. 2010).

Sulphur (S) is the secondary essential macronutrient which has a crucial role in sulphur-containing amino acids, methionine and cysteine. Only 5 % of total soil S is available for plants in the form of sulphate (SO_4^{-2}), and the remaining 95 % is organically bound include pyrite (FeS_2), gypsum ($CaSO_4.2H_2O$) and epsonite ($MgSO_4.7H_2O$), which are unavailable for plants. Sulphur turnovers are reported by both biochemical and biological mineralization (Gharmakher et al. 2009). In biochemical mineralization, sulphate pools are hydrolyzed through enzymatic reactions, while the biological mineralization is driven by the soil microflora.

Sulphur-oxidizing bacteria are chemoautotrophic and photosynthetic bacteria which include *Beggiatoa*, *Chromatium*, *Chlorobium*, *Thiobacillus*, *Sulfolobus*, *Thiospira* and *Thiomicrospira*, *Bacillus*, *Pseudomonas*, *Arthrobacter* and *Flavobacterium*. Common PGPR species such as *Bacillus* and *Pseudomonas* have been reported to reduce sulphate to H_2S (Sindhu et al. 2010).

Zinc (Zn) is an essential micronutrient for plants, which plays several functions throughout the life of plants. It plays crucial roles in more than 100 enzymes which are involved in many types of functions in plants such as auxin synthesis, photochemical reactions of chlorophyll, stability of biological membranes and SOD and carbonic anhydrase enzymatic activity (Broadley et al. 2007). Plant growth, maturity, seed quality and yield are very much dependent upon Zn. Zinc is present in the soil as ZnS (sphalerite), and mineral ores include smithsonite ($ZnCO_3$), zincite (ZnO), zinkosite ($ZnSO_4$), franklinite ($ZnFe2O_4$) and hopeite [Zn_3 $(PO_4)^2$ $4H_2O$]. Zinc-solubilizing bacteria have been tested on different insoluble Zn ores (Abaid-Ullah et al. 2015). Tariq et al. (2007) have found that Zn-mobilizing bacteria enhanced Zn uptake in rice seedlings which had positive impact on plant growth and grain yield. In another study, *Serratia* sp. has been noted to more solubilize ZnO as compared to other insoluble ores and was able to significantly increased wheat yield under various climatic conditions (Abaid-Ullah et al. 2015).

10.5.4 Plant Hormones

The ability to produce plant hormones is a major property of many PGPR which directly influence plant growth. Among these hormones, IAA, gibberellic acid (GA), cytokinin (CK) and abscisic acid (ABA) may play a significant role in salt stress. These phytohormones alter metabolism and morphology, nutrient and water uptake efficiency and consequently larger and healthier plants.

10.5.4.1 Indole-3-Acetic Acid

Indole-3-acetic acid (IAA) is the best-studied compound involved in numerous plant mechanisms like cell division, differentiation, extension, apical dominance, gravitropism and phototropism (Korasick et al. 2013). Salinity was found to accumulate IAA in root which affects cell elongation and growth. It is also supposed to act as an inhibitor of cytokinin synthesis and their transport from root to shoot during stress condition leading to increased root elongation (Dodd et al. 2005). Most of PGPR adapted tryptophan-based pathway for IAA production either via indole-3-pyruvic acid (IPyA) or indole-3-acetamide formation (IAM) (Spaepen et al. 2007). Tryptophan is synthesized from chorismate in plant and secreted out from loosely bound root cells, then taken up by soil microbes. Phytohormone production in PGPR especially IAA was extensively studied in *Azospirillum* spp. during the last decade (Cassán et al. 2014). *Azospirillum brasilense* strain Cd was found to relieve the negative effects of 50 mM NaCl on *Phaseolus vulgaris* as exposed by higher branching of roots and flavonoid production in hydroponical condition (Dardanelli et al. 2008). An IAA-producing *Azospirillum brasilense*

Az39 strain was co-inoculated with *Bradyrhizobium japonicum* E109 and found to enhance germination and growth of corn and soybean (Cassán et al. 2009). Albacete et al. (2008) reported that plants inoculated with IAA-producing bacterial strains exhibited higher root and leaf growth which is considered as adaptive response of salinity. IAA-producing PGPR strains were also reported for enhancement of nutrient uptake efficiency under hydroponic conditions (Shukla et al. 2012). In another study, *B. subtilis* GB03-mediated VOCs were found to trigger *Arabidopsis* seedling growth by regulation of different RNA transcript involved in different metabolic processes. Further analysis confirmed that GB03 triggered growth promotion by regulating auxin homeostasis and cell wall loosening enzymes (Zhang et al. 2007). Similarly, bacterial VOCs were also reported to enhance expansin gene (*EXP2, EXP6* and *EXPA5*) expressions in *Nicotiana tabacum* and *Lactuca sativa* (Minerdi et al. 2011).

10.5.4.2 Abscisic Acid

Abscisic acid (ABA) is primarily known for abscission of leaves and shoot growth, but recent studies suggested that increased concentration of ABA is required for inhibiting excess ethylene production in plants during stress conditions. It is associated with phytohormone response to environmental stresses. Typically, stress condition increases ABA level triggering adaptive responses essential for survival (Pliego et al. 2011). During low water potential condition, ABA is produced in roots and then translocated in leaves, where it directly involves in stomatal closing to reduce transpiration activity and maintain water potential. It is also responsible for stimulation of root growth and emergence of lateral roots leading to enhancement of water uptake during drought condition. Furthermore, ABA is also involved in regulation of ion transport across the membrane and synthesis of specific proteins (Bashan and De-Bashan 2010). It was proposed that many PGPR produce ABA in vitro, and its production increases under osmotic stress (Dodd et al. 2010). The role of rhizobacteria on plant ABA status is conflicting; some reports explored that bacterial colonization prevented salinity-induced accumulation of ABA, while others were found that PGPR enhance accumulation of ABA, which may be responsible for survival in stress conditions. *P. putida* Rs-198-inoculated cotton seeds exhibited higher biomass accumulation and prevented ABA production in 10 % salinity, while uninoculated seedlings showed higher accumulation in foliar ABA concentration (Yao et al. 2010). In another report, Zhang et al. (2008b) proposed that *B. subtilis*-mediated VOCs were observed to promote photosynthesis capacity by decreasing transcription levels of ABA synthesis in aerial parts of *Arabidopsis* plants. Furthermore, *P. chlororaphis* O6 colonization was reported to decrease stomatal apertures in both wild-type and ABA-insensitive *Arabidopsis* mutant plants which suggested ABA-independent stomatal closure mechanism responsible for bacterial-mediated IST against drought and salt stress (Cho et al. 2012). In a recent study, ABA metabolizing rhizobacteria were observed to decrease ABA concentration *in planta* and alters plant growth during stress condition (Belimov et al. 2014).

10.5.4.3 Ethylene

Ethylene is known as stress hormone which synthesized in plants under stress conditions. Ethylene is also an inhibitor of rhizobial nodulation of legumes. However, during normal condition, ethylene production is minimal which regulate some physiological responses such as breaking of seed dormancy (Dodd et al. 2005). Ethylene is produced by Yang cycle in plants in which ACC is the precursor of ethylene biosynthesis that is converted into ethylene by ACC oxidase enzyme. ACC can be transported to particular stressed organ resulting in synthesis of ethylene in the affected tissue (Yoon and Kieber 2013). In salinity stress, increased foliar ethylene is correlated with Na^+ accumulation responsible for decreased growth of tomato (Mayak et al. 2004). In another study, 100 mM NaCl concentration enhanced ACC and Na^+ accumulation in the root, xylem sap and leaf correlated with onset of oxidative stress and decreased photosynthesis capacity suggesting ethylene role in foliar senescence (Albacete et al. 2008; Ghanem et al. 2008). Many soil bacteria contain ACC-deaminase (ACC-D) enzyme, which cleaves ACC to α-ketobutyrate and ammonia and thereby lowers the ethylene level in stressed plants. According to Glick et al.'s (1998) described model, ACC-D-producing bacteria attached to the root surface and take up ACC exuded from plant roots and then hydrolyze it through ACC-D mechanism. Hence, more ACC is exuded from roots to maintain equilibrium and finally ACC level reduced inside the cell. There are several reports that showed ACC-D containing PGPR can decrease salinity-induced growth inhibition (Ahmed and Farag 2011; Wu et al. 2012). *Achromobacter piechaudii* ARV8 which produced ACC-D was found to significantly increase plant weights and nutrient uptake efficiency in tomato seedlings under NaCl stress (Mayak et al. 2004). Shaharoona et al. (2006) reported that co-inoculation of ACC-D possessing PGPR with a *Rhizobium* strain *Bradyrhizobium* enhanced nodulation in mung bean by lowering ethylene production compared with *Bradyrhizobium* alone. ACC-deaminase-producing halotolerant bacterial strains *B. licheniformis* RS656, *Z. alba* RS111 and *Br. iodinum* RS16 have been reported to reduce ethylene production in red pepper plants at 150 mM NaCl stress. Bacterial-inoculated plants exhibited higher salt tolerance index and increased nutrient uptake as compared to non-inoculated plants which suggested amelioration of salt stress effect (Siddikee et al. 2011). Furthermore, plants treated with ACC-deaminase-producing PGPR strains exhibited higher root nodules, plant growth and yield under oxidative stress conditions (Roopa et al. 2012; Zafar-ul-Hye et al. 2013).

10.5.4.4 Cytokinin

Cytokinins are a group of purine-type phytohormone that regulate cell division, differentiation processes in meristematic tissues, chloroplast maturation, cell expansion and stomatal conductance of higher plants (Cassán et al. 2014). It is necessary for inducing root nodule organogenesis for nitrogen fixation (Kisiala et al. 2013). Auxin and CK ratio plays an important role in cell division and differentiation. Cytokinin production is a common PGP trait of rhizobacteria (Dodd et al. 2010). A PGPR strain *B. subtilis*, which produced CK, was found to enhance biomass content in the shoot of lettuce plants during drought stress considered root-to-shoot CK

signalling (Arkhipova et al. 2007). Cytokinin-producing bacterium *B. megaterium* increased the level of CK in *A. thaliana* roots which predicted the role of CK signalling pathway in the plant growth promotion (Ortíz-Castro et al. 2008). Giraud et al. (2007) investigated that PGPR strain *Bradyrhizobium* has taken part in nodulation process with the help of CKs in the absence of nod factor in soybean plants.

10.5.4.5 Gibberellin

Gibberellins are diterpenoid acids synthesized by terpenoid pathway and involved in several developmental processes such as cell division and elongation, breaking seed dormancy. This is widely reported for starch hydrolysis mechanism during germination. Gibberellic acid stimulated the transcription level of α-amylase gene in seed embryo that is responsible in hydrolysis of starch into glucose (Richards et al. 2001). Inoculation of GA-producing *A. brasilense* enhanced germination of wheat and soybean and rapid plant growth at least partial to GA production under salt stress (Cassán et al. 2014). In another study, GA-producing *Promicromonospora* sp. SE188 was observed to improve tomato plant growth as exposed to higher shoot length and biomass (Kang et al. 2012). Kang et al. (2014) have reported that a GA-producing *P. putida* H-2-3 was found to significantly enhance plant length, weight and chlorophyll content in GA-deficient mutant soybean plants.

10.6 Selection, Characterization and Commercialization of PGPR Strains

For successful application of PGPR under saline regions, inoculants should be isolated from indigenous salt-affected soils. Certain PGPR lost their ability and failed to colonize with root system under salinity (Paul and Nair 2008). Under such condition, halotolerant bacteria as inoculums would be the most appropriate approach. In a study, five plant growth-promoting halotolerant bacteria were found to ameliorate salt stress (80, 160 and 320 mM NaCl) in wheat plants and increased root length up to 71.7 % (Ramadoss et al. 2013).

To commercialize any PGPR strain, different stages have been followed step by step which include isolation, screening, pot tests and field efficacy, formulation development, formulation viability, industrial linkages and quality control (Bhattacharyya and Jha, 2012). A potent PGPR strain is selected from diverse rhizospheric bacteria by screening on the basis of their ability to produce PGP activity and inhibit the growth of various phytopathogens and a positive interaction with the host plant. Pure cultures of PGPR strains are applied on seeds in in vitro glasshouse trials. Seeds are treated with pure and fresh bacterial suspension and then planted in soil for test. During the experiment, PGPR which are found potent for plant growth promotion and alleviate negative symptoms of stresses are selected for further field trials (Compant et al. 2005). Once isolates have been selected, then their characterization is done based on biochemical and molecular characteristics. Biochemical characterization is done according to Bergey's Manual of Determinative Bacteriology. In molecular characterization, DNA- and RNA-based homology

testing, ribosomal protein profiling through MALDI and fatty acid profiling through GC-MS analysis are considered for identification (Bashan et al. 1993; Maiti et al. 2009; Bhattacharyya and Jha 2012). 16S ribosomal RNA is a component of the 30S small subunit of prokaryotic ribosome. Through evolution this region of the gene remained conserved and hence widely used to define molecular phylogeny and taxonomy of bacteria since the last decade (Sun et al. 2008).

The mass production of bacterial formulation is performed under liquid, semi-solid and solid state (Bhattacharyya and Jha 2012). The success and commercialization of PGPR formulations require a strong linkage between the research organizations and private industries, although it also depends on economical and viable market demand, longer shelf life, low capital costs and easy availability of career materials.

10.7 Conclusion

In saline conditions PGPR can induce tolerance mechanism in crop plants and promote plant growth and development. On the other hand, PGPR also improve soil fertility. In recent years a number of researchers have explained that plant–microbe interactions help to develop tolerance mechanisms in saline soil, but still need to understand details of their molecular and biochemical mechanism. Nevertheless, the microorganisms present in saline area or in the rhizosphere of halophytic plants may provide a valuable resource for improving the crop tolerance to salinity.

Plant–Microbe Interaction for the Removal of Heavy Metal from Contaminated Site

11

Asit Mandal, J.K. Thakur, Asha Sahu,
Sudeshna Bhattacharjya, M.C. Manna, and Ashok K. Patra

Abstract

The diversity of microbes present in the rhizosphere plays a significant role in nutrient cycling and soil sustainability. Plant–microbe-modulated phytoremediation is a viable technology for the cleanup of contaminated environments. Several plants that were identified have various degrees of capacity to eliminate, degrade or detoxify, metabolize, or immobilize a wide range of soil contaminants. Plant-based remediation technologies are not yet commercialized because of its major limitation of slow process and restricted bioavailability of the contaminants, and it is greatly influenced by the climatic factors. The extensive use of plants can overcome most of the limitations by exploring the potential of microbe–plant–metal interaction. The biogeochemical process occurring in the root zone can influence on several rhizobacteria and mycorrhizae directly linked with microbial metabolite synthesis. Thus, a holistic approach of novel remediation technologies and understanding of plant–microbe–contaminant interaction would help for customizing phytoremediation process in relation to site-specific contamination. There is a huge challenge to remediation of contaminated sites by long-term accumulation of heavy metal. Unlike organic contaminants, metals are very much resistant to degradation, and in the long run, continuous accumulation may cause food chain contamination. It is very important to decontaminate the polluted sites in order to reach safe level of metal concentration below the threshold limit of toxicity. Recent studies revealed that phytoextraction, mainly the use of hyperaccumulator plants to extract toxic metals from the contaminated sites, has emerged as a cost-effective, eco-friendly cleanup technology. Novel, efficient microbes and their potential use in the plant rhizosphere could further enhance the phytoremediation for wider range of soil contaminants.

11.1 Introduction

The era of industrial revolution and rapid urbanization caused various degree of soil contamination. The elevated levels of heavy metal at a long time in the soil are excessively absorbed by plant roots and translocated to aboveground parts, leading to impaired metabolism and reduced plant growth (Bingham et al. 1986). The severe soil contamination with various heavy metals tremendously hampered the soil biological function and soil fertility (McGrath et al. 1995) as well as food chain contamination (Richards et al. 2000). The contamination of the soil environment in the long run is considered as a potential threat to the soil ecosystem services. The soil contaminant bioavailability is highly influenced by various factors such as nature of pollutants, clay content, pH, moisture content, hydrogeology, microbial community dynamics, temperature, and redox potential (Dua et al. 2002). Thus, understanding the plant–microbe–heavy metal has received a great attention for the remediation of contaminated site. Biological means of remediation for the contaminated environment are a promising technique that offers the possibility to degrade or detoxify various contaminants by employing plants and microbes. The approaches of bioremediation are more economically viable, environment-friendly, and an aesthetically pleasing approach which is most widely used for the purpose of remediation of contaminated site. Developing sustainable remediation technologies by employing plant and microbes is a promising solution to reestablish the natural state of soil health (Jansen et al. 1994). However, introduction of numerous waste including toxic heavy metals into the soil leads to considerable loss of the microbial diversity, despite their vital role for the growth and survival of microbes at very low concentrations. The plants employing for cleanup of contaminated environments is quite old concept. More than 300 years ago, plants were used for the treatment of contaminated wastewater. During the nineteenth century, *Thlaspi caerulescens* and *Viola calaminaria* were reported as the first plant species to accumulate higher levels of metals in shoots (Baumann 1885). Several reports were available for the heavy metal accumulation plants like genus *Astragalus* which have a high potential to accumulate selenium up to 0.6 % in dry shoot biomass; some plants were indentified for Ni accumulator (1 %) in shoots (Minguzzi and Vergnano 1948), and *Thlaspi caerulescens* for high Zn accumulation (Rascio 1977). The plants used for phytoextraction of metals from the contaminated soil were developed and reintroduced by Utsunamyia (1980) and Chaney (1983). The first field trial for phytoextraction was conducted for Zn and Cd (Baker et al. 1991). Many plants that are classified as hyperaccumulator depend on type of metal and accumulation behavior from the soil. The diversity of plant rhizosphere microbes and mycorrhiza also play key role for the remediation of contaminated site with heavy metals. The key for successful bioremediation depends on the nature and bioavailability of pollutants. The comprehensive understanding is still required to learn the mechanisms and crucial factors influencing the plant–microbe–toxicant interaction in soils for the success of phytoremediation.

11.2 Rhizosphere Microbe-Assisted Phytoremediation

Phytoremediation involves the use of green plants to extract, sequester, degrade, and/or detoxify pollutants by means of biological processes (Wenzel et al. 1999) and has been reported to be an in situ, nonintrusive, cost-effective, ecologically benign, aesthetically pleasing, socially acceptable technology to remediate contaminated soils (Garbisu et al. 2002). It also helps to prevent landscape deterioration and enhances the diversity of soil microorganisms to maintain healthy ecosystems; hence, it is considered to be a more attractive technique than traditional approaches that are currently in use for heavy metal decontamination.

Phytoremediation process can be classified according to the method and nature of the soil pollutants (Salt et al. 1995). Various aspects of phytoremediation process in relation to organic and inorganic contaminants are depicted in the Fig. 11.1.

Phytoremediation techniques can be studied under different strategies such as: (a) Phytoextraction: It is the process by which plants absorb metal from the contaminated site and transfer it to aboveground parts of the plants. These plants have a high degree of potential to absorb and accumulate or translocate metals or metalloids to the aboveground biomass. (b) Phytostabilization: It involves restriction of the mobility of metals in the soil. The reduced mobility of the contaminants may be achieved by accumulation and absorption onto roots, or precipitation within the rhizosphere. (c) Phytostimulation: It is also called plant-assisted biodegradation. Phytostimulation is the process where root-induced microbial activity is capable of degrading the organic contaminants. (d) Phytovolatilization/rhizovolatilization: In this approach, plants take up contaminants from the soil and transformed it into volatile compounds into the atmosphere through transpiration. These methods are highly used for the metal(loid)s in the soil such as mercury (Hg), selenium (Se), and arsenic (As). (e) Phytodegradation: It is the process of enzymatic degradation of

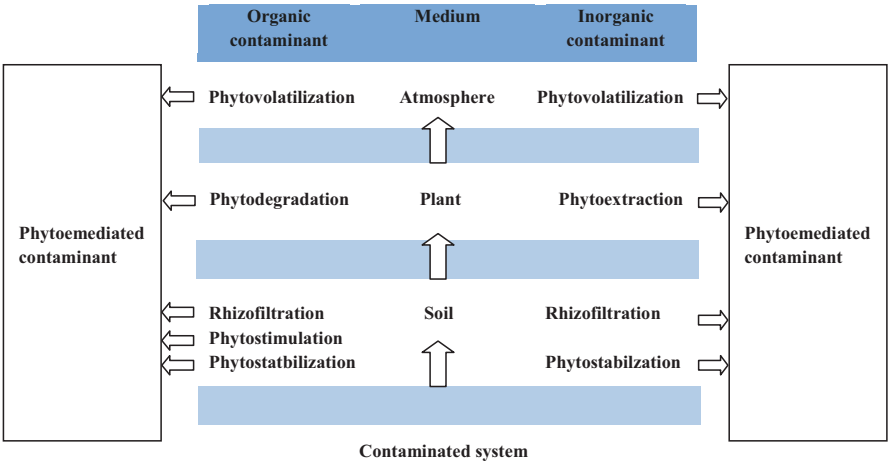

Fig. 11.1 Phytoremediation processes for organic and inorganic contaminants

complex organic molecules to simpler ones by means of enzymatic action or the incorporation of these molecules into plant tissues or into new plant material. (f) Rhizofiltration: It is primarily used to remediate aquatic systems with low levels of contaminant. It can be used for heavy metals such as lead (Pb), cadmium (Cd), copper (Cu), nickel (Ni), zinc (Zn), and chromium (Cr) which are generally retained within the roots and do not translocate to the shoots. This method can be explored in both terrestrial and aquatic plants for in situ or ex situ purposes.

11.2.1 Interactions in the Rhizosphere

Efficient phytoremediation techniques rely on the complex interactions among soil, contaminants, microbes, and plants.

11.2.1.1 Plant–Microbe Interactions

The interaction between plant roots and wide range of soil microbes, especially rhizospheric one, is the major determinants of the phytoremediation potential (Glick et al. 1995). Both the micropartner, i.e., plant-associated microbes and the host plant, control the functioning of associative plant–microbe symbioses in the contaminated soil. In plant bacterial symbiosis, plant provides specific carbon source to the bacteria inducing the bacteria to reduce the heavy metal phytotoxicity. Alternatively, in nonspecific association between plants and bacteria, plant metabolic processes stimulate the microbial community through root exudates, which in turn enable the microbes to degrade the contaminants in soil. Moreover, the adaptation capabilities of both the partners of associative symbiosis and the bioremediation potential of the microsymbiont play a vital role in minimizing the heavy metal toxicity.

11.2.1.2 Heavy Metal–Microbe Interactions

Rhizosphere microbes are empowered with different traits that can modify the solubility and bioavailability of the heavy metals in soil (Lasat 2002; McGrath et al. 2001; Whiting et al. 2001). Rhizobacteria may release different chelating substances by which acidification of the environment takes place through production of organic acid and changes the redox potential (Smith and Read 1997). Soil pH reduction mediated through *Sphingomonas macrogoltabidus*, *Microbacterium liquefaciens*, and *M. arabinogalactanolyticum* has been reported to enhance the Ni uptake in *Alyssum murale* grown in a serpentine soil (Abou-Shanab et al. 2003). An earlier study reported that the metal-polluted sites have negative impact on soil microbial diversity and microbial activities (Giller et al. 1998).

11.2.1.3 Plant–Bacteria–Soil Interactions

The soil condition also dictates the specificity of the plant–bacteria association. Different soil conditions regulate the bioavailability of soil contaminant such as composition of root exudate and levels of nutrient, influencing the bacterial metabolic activity as well as phytoremediation potential. Moreover, the requirements for

heavy metals for bacterial metabolism may also govern whether the plant–bacteria interaction would be specific or nonspecific. Along with metal toxicity, there are several other factors that limit plant growth in the contaminated soils including harsh climatic conditions, poor soil structure, low water retention, and nutrient deficiency.

11.2.2 Rhizoremediation: Microorganism-Assisted Phytoremedation

Rhizoremediation is a subprocess of phytoremediation where plants along with their rhizospheric microorganisms are being used to enhance the efficiency of contaminant extraction (Jing et al. 2007). It is a beneficial association where the microorganisms enhance the bioavailability of the metals and the plants help in the extraction and removal of such compounds from soil (Chaudhry et al. 2005). It has positive role for both sides, where the plants supply nutrients to microorganisms, which, in turn, grow and proliferate, increasing the potential of degradation by the plant. However, there is a lack of studies about this synergism between plants and microorganisms facilitating phytoremediation (Kavamura and Esposito 2008). Some beneficial associations among plant and rhizospheric microbes that participated in the rhizoremediation are as follows:

11.2.2.1 Plant Growth-Promoting Rhizobacteria and Rhizoremediation

Plant growth-promoting rhizobacteria are generally known to promote the growth of the plants in the following manner:

1. Fix nitrogen from the atmosphere and deliver it to the plants.
2. Produce siderophores that can make complex with iron present in the soil and make available for assimilation to plant cells. Plants can easily take up the bacterial siderophore–iron complex and also through production of plant hormones like auxins, cytokinins, gibberellins, etc. which may stimulate the growth of the plant.
3. Solubilize mineral nutrients such as phosphorus through production of various organic acids, making them more easily available for plant growth.
4. Act as biocontrol agent.

Several experiments were conducted to examine the ability of a wide range of plants for heavy metal extraction and then to translocate those metals from roots to leaves and shoots. However, the potential of heavy metal removal is limited by slow plant growth and low biomass production by hyperaccumulator plants (Raskin and Ensley 2000). In this context, the use of plant growth-promoting rhizobacteria as adjuncts has been found to stimulate significant growth of plants even in the presence of higher concentration of heavy metals in soil (Zhuang et al. 2007; Glick 2010).

11.2.2.2 Endophytic Microorganisms and Rhizoremediation

Endophytic microorganisms can be defined as microbial colonizations in the internal tissues (root cortex or xylem) of plants without causing any symptoms of infection or negative impacts on their host (Schulz and Boyle 2006). Among the most predominant genera of culturable endophytes are *Pseudomonadaceae*, *Burkholderiaceae*, and *Enterobacteriaceae.* Endophytes play a very important role in phytoremediation especially in rhizoremediation. Idris et al. (2004) studied the endophytes and rhizobacteria with *Thlaspi goesingense*, a hyperaccumulator of Ni using both cultivation and cultivation-independent techniques. Results revealed that endophytes are generally culture independent and are more tolerant to higher concentration of Ni as compared to rhizobacteria. Though endophytes hold great promise for heavy metal remediation, the mechanisms by which endophytes enhanced metal accumulation are yet to be well understood. Furthermore, the application of culture-independent endophytes is quite a challenging task (Weyens et al. 2009).

11.2.2.3 Mycorrhizoremediation

Mycorrhizoremediation is an advanced phytoremediation strategy involving contribution from tripartite association among plant, mycorrhiza, and rhizobacteria. Mycorrhizae can be efficiently explored in the soil microsites that are not accessible for plant roots. They can further change the heavy metal bioavailability through competition with roots and other microorganisms for water and metal uptake, protection of roots from direct contact with the heavy metal via development of the ectomycorrhizal sheath, and restricted metal transport by increasing soil hydrophobicity (Lazcano et al. 2010). Ectomycorrhizal associations are reported to enable the host plant to withstand higher heavy metal toxicity. The structure of the fungal sheath, density, and surface area of the mycelium are key factors to determine the efficiency of an ectomycorrhizal association to resist/tolerate metal toxicity and to protect the host plant from pollutant contact (Hartley et al. 1997). Studies also reported increased uptake of metal(loid)s in the presence of arbuscular mycorrhizal fungi; however, there are some contradictory reports indicating negligible effect or decreased accumulation in plant tissues (Lazcano et al. 2010). The controversial results are difficult to interpret and could be attributed to the differential response under greenhouse experiment and field study.

11.2.3 Phytoextraction

Phytoextraction is a subprocess of phytoremediation where the pollutant-accumulating plants are being utilized for removal of heavy metals from contaminated soils by concentrating them in the aboveground biomass (Salt et al. 1998). The selection of plants for heavy metal phytoextraction should possess features like (a) potential tolerance to high levels of heavy metal concentration, (b) fast-growing plants for effective accumulation of heavy metal, (c) ready translocation of heavy metal in the aboveground biomass of plants, and (d) ease of harvest (Vangronsveld et al. 2009).

However, the success of phytoextraction depends upon factors such as bioavailability of heavy metal and the potential of the plant to intercept, take up, and accumulate the metals in shoots (Ernst 2000).

11.2.3.1 Role of Plant-Associated Rhizobacteria in Phytoextraction

To enhance the efficiency and rate of phytoextraction, the role of plant-associated rhizobacteria is highly beneficial. Microorganisms can increase plant uptake of heavy metal in the following way: (1) may increase the root surface area and root hair architecture, (2) enhance the metal bioavailability, and/or (3) increase the metal translocation from the rhizosphere to the plant shoot (Weyens et al. 2009). Further, improving the plant biomass production can influence the efficiency of trace element phytoextraction.

The plant-associated rhizobacteria metabolic performance may help develop new improved phytoremediation strategies. However, the dynamic and variable metabolic capacities of plant-associated rhizobacteria are still poorly highlighted. Plants stimulate the growth of rhizosphere microorganisms due to secretion of different organic molecules by their roots, which in turn improved the bacterial densities in the rhizosphere (Anderson and Coats 1995).

11.2.4 Bacterial Heavy Metal Resistance

The plant-associated rhizospheric bacteria have several benefits conferred to their hosts; the major qualification for protecting plants from heavy metals stress is resistance of the bacteria to heavy metals. Along with dynamic metabolic capacity of the bacteria, metal resistance operon is also important to empower the bacteria against heavy metal toxicity. Among the heterotrophic bacteria, members of the β-proteobacteria have the maximum levels of heavy metal resistance. *Alcaligenes eutrophus* is a potential member of this group. *A. eutrophus* CH34 species is the extensively reported that harbors two endogenous megaplasmids encoding genes for multiple heavy metal resistance. Plasmid pMOL28 is 180 kb and codes for resistance to various heavy metals such as cobalt, nickel, chromate, mercury, and thallium. Resistance genes are organized with the *chr*, *mer*, *and cnr* operons, coding for resistances to chromate, mercury, and both cobalt and nickel, respectively, (Mergeay et al. 1985; Taghavi et al. 1997). The plasmid from strain CH34 is pMOL30 (240 kb) responsible for resistance against some heavy metals. This plasmid also consists of organized operon out of which the *mer*, *cop*, and *pbr* operons encode resistance to heavy metal mercury, copper, and lead, respectively. The *czc* operon encodes for heavy metal cadmium, zinc, and cobalt resistance.

11.3 Plant–Microbe Association for Heavy Metal Transformation in Soil–Plant System

Rhizospheric microbes play an important role in improving phytoremediation process by changing the metal bioavailability through altering redox reactions, soil pH, or release of some chelators like siderophores, organic acids, biosurfactants, etc. (Zarei et al. 2010; Miransari 2011; Rajkumar et al. 2012) (Fig. 11.2).

Metabolites or reactions produced by plant-associated microbes have been reviewed and summarized in Table 11.1

11.3.1 Siderophores

Most plant-associated microorganisms can produce iron chelator siderophores at low levels of iron concentration in soil; however, siderophore can also form stable complex with other heavy metals such as Al, Cd, Cu, Ga, In, Pb, and Zn (Glick and Bashan 1997; Schalk et al. 2011) and cause solubilization of unavailable form of heavy metal to available form, thus improving efficacy of phytoextraction (Braud et al. 2009b; Rajkumar et al. 2010). Pyoverdine and pyochelin produced by *Pseudomonas aeruginosa* are responsible for enhancing the bioavailability of Cr and Pb in the rhizosphere of maize (Braud et al. 2009b). Similarly, siderophores produced by *Streptomyces tendae* F4 significantly enhanced uptake of Cd by sunflower plant (Dimkpa et al. 2009). Nevertheless, there are also contradictory reports

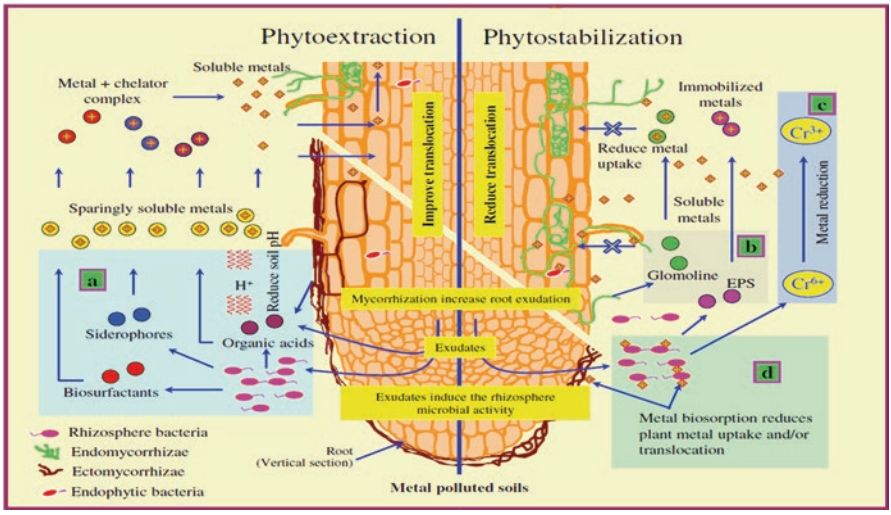

Fig. 11.2 Schematic representation of role of rhizospheric microbes for phytoremediation (**a**) by producing metal-mobilizing chelators, (**b**) by excreting metal-immobilizing metabolites, (**c**) by reducing metal reduction, and (**d**) by metal biosorption. EPS, extracellular polymeric substances (Source: Rajkumar et al. 2012)

Table 11.1 Potential of microbial metabolites/actions to mobilize/immobilize metals by plants

Metabolites or reactions	Microorganisms	Microbial potential	References
Siderophores			
Azoto chelin and azotobactin	*Azotobacter vinelandii*	Helps in Mo and V acquisition	Wichard et al. (2009)
Pyochelin	*Pseudomonas aeruginosa*	Chelates many metals like Cd^{2+}, Cr^{2+}, Al^{3+}, Mn^{2+}, Zn^{2+}	Braud et al. (2009a)
Desferrioxamine and coelichelin	*Streptomyces tendae*	Enhanced uptake of Cd and Fe by plants	Dimkpa et al. (2009)
Organic acids			
Oxalic acid, tartaric acid, formic acid, acetic acid, malic acid	*A. niger*, *Burkholderia cepacia*, *Beauveria caledonica*, *Oidiodendron maius*, *Pseudomonas fluorescens*, *Penicillium bilaiae*	Solubilized Zn, Ni, Fe, Pb, and Cd	Arwidsson et al. (2010), Li et al. (2010), and Hoberg et al. (2005)
Gluconic acid, 5-ketogluconic acid	*Gluconacetobacter diazotrophicus*, *Pseudomonas aeruginosa*	Solubilized ZnO, $ZnCO_3$, and $Zn_3(PO_4)_2$	Saravanan et al. (2007), and Fasim et al. (2002)
Biosurfactants			
Rhamnolipids, dirhamnolipid	*Pseudomonas aeruginosa*	Mobilized Cu, Cd, and Pb	Venkatesh and Vedaraman (2012), and Juwarkar et al. (2007)
Polymeric substances			
Polymeric substances (extracellular)	*Azotobacter* spp.	Immobilized Cd and Cr	Joshi and Juwarkar (2009)
Glomalin	*Glomus mosseae*	Immobilized Cu, Pb, and Cd	Gonzalez-Chavez et al. (2004)
Redox reaction			
Oxidation and reduction	*Streptomyces lividans* sp., *Rhodococcus* sp., *Acidithiobacillus thiooxidans*, *Leptospirillum ferrooxidans*	Increased the mobility of As, Cu, Cd, Hg, and Zn	Yang et al. (2012), Beolchini et al. (2009)

(Sinha and Mukherjee 2008; Tank and Saraf 2009; Kuffner et al. 2010) which generated the need to study the interaction of plant–siderophore-producing microorganisms–metals in the contaminated soils. Siderophore production by microbes is controlled by various factors, viz., iron availability, pH, nutrient status of soils, type, concentration of heavy metals, etc. Therefore, higher heavy metal concentration acts as stimuli to produce more siderophore by microbes. Findings of Braud et al. (2009a) revealed the fact that addition of heavy metals, Al, Cu, Ga, Mn, and Ni, in iron-limited succinate medium induced pyoverdine synthesis by P. *aeruginosa*.

Moreover, the presence of heavy metals such as Cu, Ni, and Cr stimulated pyoverdine synthesis even in the case of iron (Braud et al. 2010).

11.3.2 Organic Acids

Low molecular weight organic acids, synthesized by plant–microbe interaction, play an instrumental role in enhancing the bioavailability of the trace elements and metals in the soil mainly through formation of metal complex. Organic acids work as a ligand which form stable complex with the heavy metals. However, the stability of the complex is regulated by several factors, viz., number and the position of carboxyl groups in organic acids, form of heavy metals, and most importantly pH of the soil solution (Ryan et al. 2001). Different studies have reported that 5-ketogluconic acids and 2-gluconic acids are prime responsible for solubilizing and mobilizing of insoluble ZnO, $Zn_3(PO_4)_2$, and $ZnCO_3$. The bacterial strain involved in gluconic acid productions and Zn solubilization are reported to be *Gluconobacter diazotrophicus* and *Pseudomonas aeruginosa* (Fasim et al. 2002; Saravanan et al. 2007). Similarly, formic acid, succinic acid, oxalic acid, acetic acid, and tartaric acid produced by rhizospheric bacteria have been reported to solubilize Cd and Zn in the rhizosphere of *Sedum alfredii*, a hyperaccumulating plant (Li et al. 2010). Furthermore, organic acids secreted by plant-associated microbes expedite the absorption of Cu (Chen et al. 2005), Pb (Sheng et al. 2008), and Cd and Zn (Li et al. 2010) by plant root. Mycorrhizal fungi, especially ericoid mycorrhizal fungi (*Oidiodendron maius*) and other soil fungi (*Beauveria caledonica*), can also increase solubility of Zn from insoluble sources by releasing citric and malic acids. These organic acids either by chelation or by acidolysis process can increase the solubility and availability of Zn from insoluble ZnO, $Zn_3(PO_4)_2$, and pyromorphite (Martino et al. 2003; Fomina et al. 2005).

Although the role of organic acids seem promising, however, the factors governing the fate and the performance of the organic acids need to be considered for better understanding of their mechanisms. Moreover, the other root-mediated process such as contribution of root exudates and other metabolites in metal mobilization (Wenzel 2009) also need to be taken into account before describing the role of organic acids produced by plant–microbe interaction in heavy metal transformation and solubilization. In this respect, precise quantification of organic acids in rhizosphere and the genetic sequencing of responsible microbes could shed light in understanding organic acid dynamics between soil, plant, and microbe continuum.

11.3.3 Biosurfactants

Biosurfactants are amphiphilic molecules comprising of a nonpolar (hydrophobic) tail and a polar/ionic (hydrophilic) head. Biosurfactant produced by microbes can increase metal solubility and bioavailability through complex formation with heavy

metals at the soil interface leading to desorption of metals from soil matrix. The potential of biosurfactant dirhamnolipid produced by *P. aeruginosa* in solubilizing and mobilizing Cd, Pb, and Cu has already been documented in earlier studies (Juwarkar et al. 2007; Venkatesh and Vedaraman 2012). In addition, biosurfactants produced by plant–microorganism association also show high promise for improving the metal (Cd) uptake by rape, maize, Sudan grass, and tomato plants, a desirable trait for plants to be used for phytoextraction. The biosurfactant released from *Bacillus* sp. J119 was capable of enhancing Cd uptake from soil artificially contaminated with different levels of Cd (0 and 50 mg kg^{-1} Sheng et al. (2008)). Hence, the knowledge regarding interactive effect of biosurfactant-producing microbes on plants will enrich our perception about the role of biosurfactant-producing microbes in heavy metal phytoremediation.

11.3.4 Polymeric Substances and Glycoprotein

Extracellular polymeric substance (EPS), mucopolysaccharides, and proteins produced by plant-associated microbes can form complex with heavy metals and reduce their mobility in soil. Joshi and Juwarkar (2009) reported that EPS produced by *Azotobacter* spp. could immobilize Cd and Cr through complex formation (15.2 mg g^{-1} of Cd and 21.9 mg g^{-1} of Cr) and reduce the uptake of Cd (−0.5) and Cr (−0.4) by *Triticum aestivum*. Arbuscular mycorrhizal fungi are also reported to produce glomalin which form complex with Cu, Pb, and Cd and extract approximately 4.3 mg Cu, 1.1 mg Pb, and 0.1 mg Cd per gram of glomalin from metal-polluted soils (Gonzalez-Chavez et al. 2004). Therefore, AMF with higher amount of glomalin secretion capacity could play an instrumental role in phytoextraction and phytostabilization effort.

11.3.5 Redox Transformation of Metal in Rhizosphere

Plant-associated microbes can change the mobility of heavy metals through redox transformation reactions. Oxidation of metals by rhizospheric microbes is particularly interesting from a phytoextraction point of view. For instance, Cu mobilization in contaminated soils and its uptake in plant tissue were enhanced in the presence of sulfur-oxidizing bacteria in the rhizosphere (Shi et al. 2011). This enhanced uptake of copper in the presence of sulfur-oxidizing bacteria was due to lowering of the soil pH as a result of conversion of reduced sulfur to sulfates. Potential of Fe-/S--oxidizing bacteria to enhance metal bioavailability in the soils through acidification reaction was also reported by Chen and Lin (2001).

Microbial reduction of heavy metals also sometime immobilizes the heavy metals in the rhizosphere. For example, decreased uptake of Cr by of 37 % in shoot and 56 % in root of green chili grown in Cr(VI)-contaminated soils upon inoculation with *Cellulosimicrobium cellulans* was reported by Chatterjee et al. (2009). This

effect was brought about by microbial reduction of mobile and toxic Cr(VI) to non-toxic and immobile Cr(III) in the soil. Abou-Shanab et al. (2007) reported lower Cr translocation from root to shoots of water hyacinth as indicative of the Cr-reducing potential of rhizosphere microbes. Similarly, Di Gregorio et al. (2005) demonstrated the Se-reducing potential of *Stenotrophomonas maltophilia* isolated from the rhizosphere of *Astragalus bisulcatus*. This bacterium significantly reduced soluble and harmful Se(IV) to insoluble and unavailable Se(0), thereby reducing the uptake of Se by plant. These examples demonstrate mechanisms, by which metal-reducing microbes lock the metals within the rhizosphere soil and reflect the suitability of these microbes for phytostabilization applications.

Besides, the synergistic interaction of metal-oxidizing and metal-reducing microbes on heavy metal mobilization in contaminated soils has also been studied. Inoculation of Fe-reducing bacteria and the Fe-/S-oxidizing bacteria together significantly increased the mobility of Cu, Cd, Hg, and Zn by 90 %. This effect was attributed to the coupled and synergistic metabolism of oxidizing and reducing microbes Beolchini et al. (2009). Though these results open new perspectives for the bioremediation technology for metal mobilization, further investigations are needed to utilize such bacteria in phytoextraction process.

11.3.6 Biosorption

Through biosorption mechanism, the plant-associated microbes may also contribute in plant–metal uptake. Biosorption can be defined as the microbial adsorption of soluble/insoluble organic/inorganic contaminant by a metabolism-independent, passive or by a metabolism-dependent, active process (Ma et al. 2011). The biosorption process involves a solid phase (sorbent or biosorbent; biological material) and a liquid phase (solvent, normally water) containing a dissolved species to be sorbed (sorbate, metal ions). Higher affinity of the sorbent for the sorbate species (metals) is responsible for binding of metals on sorbent by different interactions. The process continues till equilibrium is established between the amount of solid-bound sorbate species and its portion remaining in the solution (Das et al. 2008). The efficiency of biosorption depends upon factors like initial metal concentration, pH, temperature, and biomass weight in solution. Several researchers have pointed out the restricted entry, reduced bioavailability, and lower metal uptake by plant due to biosorption. For instance, Madhaiyan et al. (2007) reported inoculation of metal-binding fungi *Magnaporthe oryzae* and bacteria *Burkholderia* sp. reduced Ni and Cd accumulation in roots and shoots of tomato. These effects of inoculation of *Trifolium repens* with *Brevibacillus* sp. B-I decreased the concentration of Zn in shoot tissues compared to respective uninoculated control due to the increased Zn biosorption by *Brevibacillus* sp. B-I Vivas et al. (2006).

The mycorrhizal fungi have also been reported to act as a filtration barrier against the translocation of heavy metals from plant roots to shoots. Experiments revealed that the inoculation of pine seedlings with *Scleroderma citrinum*, *Amanita muscaria*, and *Lactarius rufus* reduced translocation of Zn, Cd, or Pb from roots to

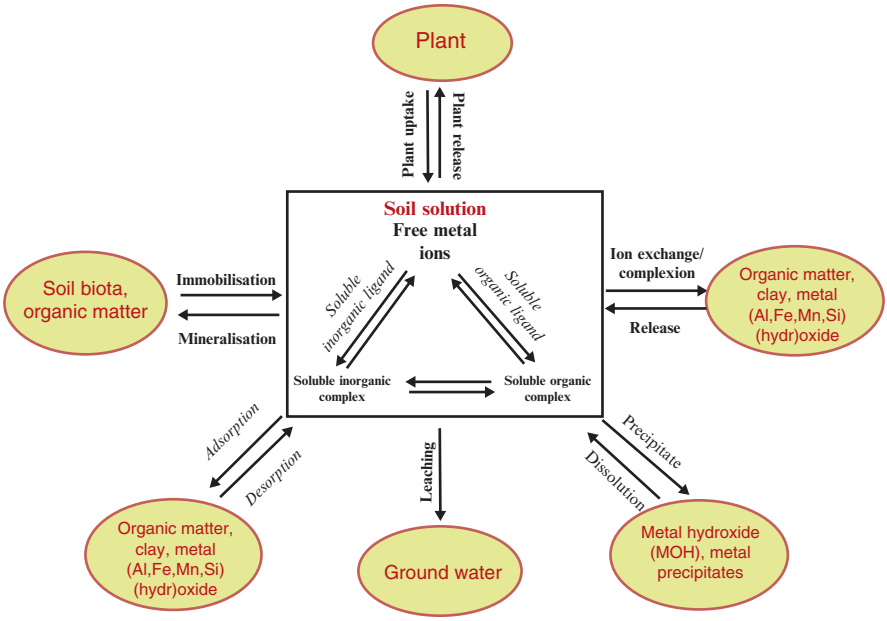

Fig. 11.3 Possible reactions involved in physical, chemical, and biological transformation of metal(loid)s in soil (Source: Seshadri et al. 2015)

shoots by increased metal biosorption in outer and inner components of the mycelium (Krupa and Kozdrój 2007). Large surface area of mycorrhizal fungi endows mycorrhizal fungi with a strong capacity for adsorbing heavy metals from soil. The fungal cell wall components (e.g., chitin, extracellular slime, etc.) and intracellular compounds (e.g., metallothioneins, P-rich amorphic material) may also immobilize/arrest the metals in the interior of plant roots (Meharg 2003). An exhaustive compilation of microbes for biosorption of heavy metals was made by Volesky and Holan (1995). Although inoculation of plants with metal-binding microbes could be a suitable approach for plant protection against heavy metals and phytostabilization of metal-polluted soils, many authors believe that the reduction in accumulation and translocation of metal in plants is not due to biosorption/bioaccumulation alone (Babu and Reddy 2011).

Plant-associated microorganisms differ in their ability to alter heavy metal bioavailability and its uptake by plants through metal-mobilizing/metal-immobilizing metabolites/processes. Colonization and survival of these microbes also greatly influence the quantity of metal accumulation in plants growing in metal-contaminated soils which in turn is governed by soil physicochemical–biological properties such as metal toxicity, indigenous microbial communities, adverse pH, nutrient deficiency, etc.

The general mechanisms involved in the transformation of metal(loid) ions in the soil lead to retention (mediated by sorption, precipitation, and complexation reactions) or loss (plant uptake, leaching, and volatilization) of heavy metal(loid)s (Fig. 11.3). Although most metal(loid)s do not undergo volatilization-related losses,

some metal(loid)s such as As, Hg, and Se tend to form gaseous compounds (Bolan et al. 2013). A greater understanding of the microbiological (activity) and chemical (exudates) changes occurring in the rhizosphere would identify the mechanisms involved in the transformation of heavy metals in the contaminated soil.

11.4 Role of Mycorrhiza and PGPR for Heavy Metal Removal from Metal-Contaminated Site

Rhizosphere microbes have played a key role for nutrient cycling and soil sustainability. Arbuscular mycorrhizal fungi (AMF) are a group of endophytic fungi infecting the roots of majority of the terrestrial plants. This symbiosis association between mycorrhiza and host plants has very important role on the plant's growth and development through the acquisition of phosphorous and other essential mineral nutrients from the soil. Plant growth-promoting rhizobacteria (PGPR) is a group of bacteria that colonize plant roots and promote growth and yield (Wu et al. 2005). However, PGPR are known to increase root system uptake properties of colonized plants, thus facilitating better supply of plant nutrient such as N, P, and Fe. The potential application of mycorrhizal plants for land decontamination has several benefits such as increased plant biomass, plant phosphorus nutrition, and tolerance to heavy metal stress. Mycorrhizal species influences metal toxicity to plants through decreasing translocation of heavy metals and its concentration.

11.4.1 Role of Mycorrhiza for the Remediation of Contaminated Site

Remediators choose the applicable and suitable microbial species that are used as inoculants to plant growth promotion and bioremediation process. The arbuscular mycorrhizal (AM) fungi have several critical roles for improving the plant's resistance to various biotic and abiotic stresses (Harrier 2001). AM fungi also have great advantage to alleviate heavy metal toxicity of plants (Hildebrandt et al. 1999). AM fungi has significant role for improving the uptake of nutrient and water by host plants through their mycelial networks and protecting the host plants from heavy metal toxicity. Besides AM fungi, there are several other beneficial microorganisms in the rhizosphere that may also help for heavy metal tolerance to the plants. According to Khan et al. (2000), mycorrhizal species enhance the bioavailability of toxic metals by altering the microenvironment of the rhizosphere through decontamination. This AM fungi may improve the plant nutrient uptake in alkaline and calcareous soils of arid and semiarid regions in which the bioavailability of P and several cationic micronutrients is limited. The presence of carbonates in calcareous soils is also limiting water holding capacity. Furthermore, plant transpiration is significantly reduced with an increase in soil heavy metal concentration (Davari et al. 2010). It has been reported that heavy metals like Cd can affect the hydraulic conductivity of root by multiple mechanisms occurring on the apoplastic and/or the symplastic pathway (Shah et al. 2010). The ability of beneficial microorganisms to

promote the growth of canola and tomato seedlings treated with toxic concentrations of various metal(loid)s such as As, Cd, Ni, Pb, Se, and Zn has been demonstrated. There have been few analytical studies available on AM fungi in the contaminated soils. While some workers highlighted that the external mycelium of the arbuscular mycorrhizae was the primary site for various heavy metal localization (Kaldorf et al. 1999; Turnau 1998), other reports emphasized the selective exclusion of toxic and nontoxic metals by adsorption onto chitinous cell wall structure (Zhou 1999), or onto extracellular glycoprotein called glomalin (Wright and Upadhyaya 1998), or intracellular crystallization. These mechanisms have great significance in reducing a plant's exposure to potentially toxic metals, which is called mycorrhizoremediation. Localization of Cu accumulation in the extraradical mycelium (ERM) of different AM fungi differed in their capacity for sorption of Cu which was directly related to the cation exchange capacity of ERM of AM fungi (Gonzalez-Chavez et al. 2002). Difference exists in accumulation and tolerance for different heavy metals among the species of AM fungi. Hence, mechanism involved in tolerance and accumulation of heavy metals require future research in order to explore the contribution of AM fungi in plant tolerance and its ecological significance in polluted soils.

11.4.2 Role of PGPR for the Remediation of Contaminated Site

Plant growth-promoting rhizobacteria (PGPR) colonize in the rhizosphere and improve plant growth through various mechanisms, such as plant nutrient uptake, suppressing harmful phytopathogens by producing antibiotics and siderophores or other bioactive compounds, phytohormone production, and fixation or solubilization of plant nutrient and making it available to the plants. Better colonization of rhizospheric microorganism increases stress endurance of a plant and improves the metal bioavailability. Many isolated strains of PGPR used to enhance crop yield and improve agriculture sustainability (Begonia et al. 2005). PGPR are known to increase root system uptake properties of colonized crops by facilitating ion nitrate adsorption, phosphate solubilization, and iron chelation (Islam et al. 2009). Maize seed inoculation with rhizobacteria such as *Pseudomonas cepacia*, *P. fluorescens*, and *Streptomyces aurantiacus* in combination with nitrogen increased 25 % more crop yield than the non-rhizobacterium-colonized control.

When Indian mustard (*Brassica juncea*) and canola (*Brassica campestris*) seeds grow in the presence of PGPR strain, the plants produce siderophores, and this plays an important role in the remediation of Ni-, Pb-, and Zn-contaminated site (Burd et al. 1998). According to Belimov et al. (2001), growth of *Brassica napus* plant is improved by inoculating recalcitrant PGPR through ACC-deaminase activity, and growth of barley plants is improved by biological nitrogen fixation and auxin production with PGPR inoculation in Cd-contaminated soil (Belimov and Dietz 2000). The rhizosphere is a type of microenvironment where microorganisms form a special type of communities with plant growth-promoting capabilities present to remove the toxic contaminants (Ma et al. 2009). Findings of Idris et al. 2004 confirmed that metal mobility and bioavailability to the plants are enhanced by rhizospheric bacteria by releasing chelating agents, acidification, phosphate solubilization, and redox changes.

Thus, interactions between plants and useful rhizosphere microbes can improve biomass production and accumulation of heavy metals. Growth of crop plant is promoted by PGPR which help in decreasing the plant stress related with phytoremediation methods (Reed and Glick 2005). Selection of highly potential microbial combination is a big challenge for developing phytoremediation strategies.

11.5 Conclusion

As an economic and green approach for decontamination of polluted soil and water, phytoremediation is an optimistic technology. Association of microbes has shown improved efficiency of phytoremediation in many cases. The capability of soil function is mostly regulated by the soil biological component. Plant–microbe interaction plays a critical role to remediate extensive contaminated sites and recover to health state of soil. Though the mechanism involved in reducing the load of contaminating metal through plant assisted by microbes is complex and involves several processes occurring simultaneously in a habitat, thorough understanding of processes will further improve the efficiency of phytoremediation by manipulating the interaction depending upon nature of pollutant, condition of microhabitat, concentration of contaminant, type of associated microbial community, etc. Further, identification of specific biomarker associated with the promising microbes for efficient microbe-assisted phytoremediation will further improve the remediation efficiency. Although promising response of inoculation of beneficial microbes particularly plant growth-promoting bacteria and/or mycorrhizae has been reported under laboratory conditions, the result under field condition showed limited effectiveness because of complexity of soil environment and competing microbes. Characterizing the physicochemical and biological features of target contaminated soils may be important for making successful microbe-assisted phytoremediation technology. The colonization and survival of inoculums in metal-contaminated soil is necessary to exhibit beneficial traits for improving the plant growth and overall phytoremediation process in metal-contaminated soils. Advancing the knowledge on identification of favorable soil condition, efficient microbes with multiple metal resistance/tolerance potential, survival, and compatibility with other microbes may be important to utilize the potential of inoculants for phytoremediation purpose. Identification of efficient microbes for bioaccumulation of heavy metal and understanding biochemical and molecular mechanisms of interaction of plant–microbe toxicant play a major role in the processes involved in phytoremediation.

Bacteria-Mediated Elicitation of Induced Resistance in Plants upon Fungal Phytopathogen

12

Shekhar Jain, Ajit Varma, Narendra Tuteja, and Devendra Kumar Choudhary

Abstract

Plants are sessile organism and primary producer of the ecosystem and communicate with above- and belowground communities that consist of benign/pathogenic microbes. Among these interactions, phytopathogenic fungi and oomycetes are the major causative agents of infectious crop plant diseases. To control these pathogens is extremely difficult, and a very small percentage of applied fungicides used for crop protection reach the target pathogen. To combat with such pathogen, higher level of resistance in addition to indigenous immune system is required which is elicited by plant growth-promoting bacteria (PGPB) in the form of induced systemic resistance in plants. Induced systemic resistance is prior activation of resistance in plants through PGPB via root priming that leads to defense-related protein activation which is independent of salicylic acid and dependent on jasmonic acid and ethylene. In case of it, nonexpressor of pathogenesis-related protein 1 (NPR1) plays the most important role by regulating hormonal defense signaling pathway leading to activation of pathogenesis-related and defense-related protein depending on the preceding signals. PGPB-elicited induced resistance showed that some of the bacterial determinants are responsible for the elicitation of induced systemic resistance (ISR). Although PGPB seem to actively suppress local host defense responses in the roots, it also produces elicitors that are responsible for the onset of systemic immunity. This chapter focuses on recent research study concerning the interaction between PGPB and plants under biotic stress condition.

12.1 Introduction

Plants are a source of nutrition for a vast biota in terrestrial environments and being sessile organisms continuously challenged by biotic and abiotic stresses. Fungal diseases caused by different phytopathogenic fungi and oomycetes are responsible for the major economic and social problems in the affected countries by severely decreasing the crop production (Vaishnav et al. 2014). To control these pathogens is extremely difficult, and a very small percentage of applied fungicides used for crop protection reach to the target pathogen. On the other hand, chemical control of diseases has negative effects on the environment such as a decrease in the biodiversity of soil microbiota, development of fungicide-resistant pathogens, and contamination of fruits and vegetables with chemicals that endanger the health of consumers (Bernard et al. 2012; Ludueña et al. 2012). In plant rhizosphere, the interactions of microorganisms with each other may be associative, competitive, mutualistic, or antagonistic. Some bacteria known as plant growth-promoting bacteria (PGPB) promote plant growth and increase the availability of essential nutrients through nutrient cycling activities, and some of them also induce resistance in the plants against plant pathogens (Wahyudi et al. 2011).

The extracellular products present in the rhizosphere and root-associated bacteria play an important role in inhibiting plant pathogens (Lugtenberg and Kamilova 2009). PGPB may colonize the rhizosphere and root surface and protect plants from various stresses. Biological control of plant disease by PGPB involves several mechanisms such as production of antifungal metabolites, cell wall-degrading enzymes, induced host resistance, and competition for nutrition and niches (Li et al. 2011). It is well documented that biological control agents based on PGPB are able to control plant diseases, increase plant growth, and improve resistance to environmental stresses, including drought and salt (Dodd and Perez-Alfocea 2012; Egamberdieva et al. 2013).

Plant growth-promoting bacteria have the ability to elicit changes in the physiology and induction of defenses in the host plant that leads to protection from the above- and belowground pathogenic communities involving organisms at different trophic levels (Pineda et al. 2010, 2013), and this defense elicitation mechanism is termed as induced systemic resistance (ISR) which expressed not only locally but also systemically (in the distal parts from the site of primary infection) against subsequent attack. A complex networking signaling pathway that involves salicylic acid (SA), jasmonic acid (JA), and ethylene (ET) as key signaling molecules regulates the induced resistance in plants (Glazebrook 2001; Thomma et al. 2001).

Upon getting affected by any pathogen infection or herbivore damage/PGPB, plants respond by activating defense machinery via activation of distinct sets of pathogenesis-related and defense-related genes preceded by accumulation of SA and JA. Defense reaction, mediated by the SA- and JA-dependent defense pathways, totally depends on the type of attacker encountered and can cross communicate with respect to plant protection (Pieterse et al. 2001; Choudhary et al. 2007; Jain et al. 2016). By keeping views of plant growth promotion under biotic stresses, the present chapter will unravel the mystification of mechanisms involved in plant

defense including ISR and system acquired resistance (SAR) using sustainable development of plants.

12.2 Plant Immune System and Induced Resistance

Due to the nonhost resistance, majority of the phytopathogens cannot infect plants. The primary defense system of the plant contains layer-by-layer protection in the form of physical and chemical barriers such as the cell wall, waxes, hairs, antimicrobial enzymes, phytoanticipins, and secondary metabolites. Apart from these, plants also have heightened-level defense system that gets activated by signaling molecules, if primary defense is found deficient to overcome pathogens (Jain et al. 2016). Malinovsky et al. (2015) have described plant immune system in two broad types, namely, PAMP-triggered immunity (PTI) and effector-triggered immunity (ETI), based on the type of molecules recognized by the plant as indicator of pathogen attack (Fig. 12.1).

Microbe/pathogen-associated molecular patterns (MAMPs/ PAMPs), such as flagellin from bacterial flagella or chitin or different glucans present in fungal/ oomycete cell walls, are referred to as small molecular motifs/structures conserved within a class of microbes, hence characteristic of microbes, and required for the overall fitness of microbes, and these patterns act as "nonself" signals for the plants to activate basal/PAMP-triggered immunity (Newman et al. 2013). Apart from these, basal immunity can get activated by plants' ability to sense a compromised

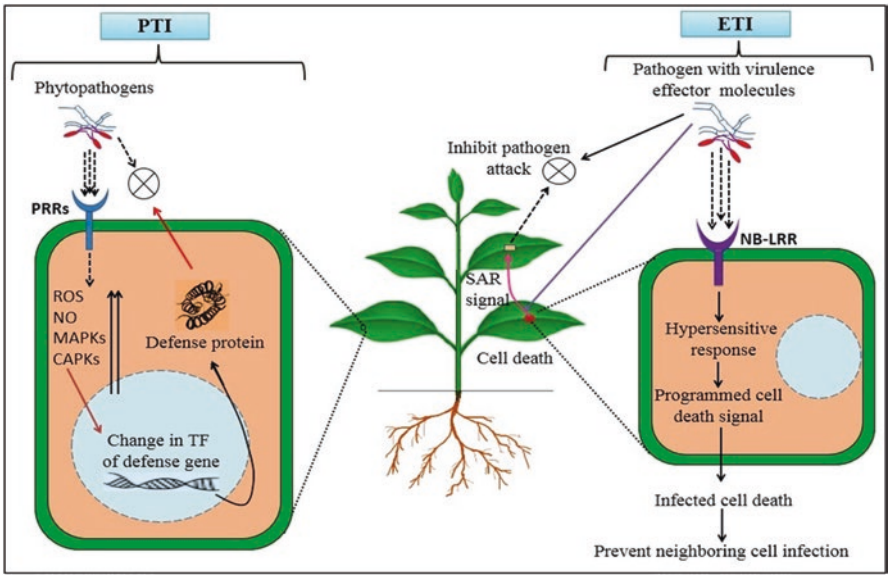

Fig. 12.1 Schematic representation of PAMP-triggered immunity (PTI) and effector-triggered immunity (ETI) in plants

"self" by detecting damage-associated molecular patterns (DAMPs) which are plant degradation products resulting from the action of invading pathogens or endogenous peptides, constitutively present or newly synthesized, that are released by the plants following pathogen attacks (Boller and Felix 2009). Recognition of DAMPs also triggers immune responses similar to the PTI response. Plasma membrane-localized pattern recognition receptors (PRRs), present on the plant cells, recognized these signature motifs (MAMP/PAMP) present on the invading pathogen leading to induction of a broad variety of defense responses through activation of a complex cascade of signaling events, including ion fluxes leading to plasma membrane depolarization, production of reactive oxygen species (ROS) and nitric oxide (NO), and activation of mitogen-activated protein kinases (MAPKs) and calcium-dependent protein kinases (CDPKs). All these signaling event activities lead to change in transcription factor (TF) activities to activate defense genes resulting in accumulation of different enzymes and stress-specific metabolites which kept most of the potential invader in check (Burketová et al. 2015). Apart from these, plants also possess a second line of defense in which it produces resistance (R) NB-LRR (nucleotide-binding–leucine-rich repeat) receptor proteins that recognize virulence effector molecules released by some of the powerful pathogen which can overcome the first line of defense either by suppressing PTI signaling or preventing detection by the host (Borges and Sandalio 2015). This second line of defense, induced due to effector molecule known as effector-triggered immunity (ETI) (Dodds and Rathjen 2010), is a manifestation of gene-for-gene resistance, which is often accompanied by a programmed cell death at the site of infection that prevents further access of biotrophic pathogens that flourish on living host tissue. Basically, ETI is coupled with hypersensitive response (HR), a strong local defense leading to programmed cell death at the site of infection (Dodds and Rathjen 2010). The onset of PTI and ETI often triggers an induced resistance in tissues distal from the site of infection and involves one or more long-distance signals that proliferate an enhanced defensive capacity in still undamaged plant parts (Shah and Zeier 2013). This well-characterized form of pathogen-induced resistance is commonly known as systemic acquired resistance (SAR) (Spoel and Dong 2012) and confers enhanced resistance against a broad spectrum of pathogens.

Likewise pathogen recognition system, plants also recognize herbivorous insects, most likely through a similar signaling concept (Howe and Jander 2008). Generally, induced resistance is an induced state of resistance in plants, triggered by biological/chemical inducers to protect plant parts against future attack by pathogenic microbes and herbivorous insects. Induced resistance takes place not even locally but also systemically (in distal plant parts that are spatially separated from the inducer) and confers an enhanced level of protection against a broad spectrum of attackers through a regulated network of interconnected signaling pathways in which plant hormones play a major regulatory role (Pieterse et al. 2012; Walters et al. 2013).

12.3 Signaling Events upon Fungal Pathogen

In the signaling cascade of plant defense system, the commencement of pathogen-induced SAR is triggered upon local activation of a PTI or ETI response due to limited primary infection with a pathogen and leads to long-lasting and broad-spectrum disease resistance to uninfected plant tissue against subsequent pathogen attack (Wendehenne et al. 2014; Gao et al. 2015). The establishment of SAR is coupled with increased levels of salicylic acid (SA) followed by regulated activation of a specific set of pathogenesis-related (PR) genes that encode PR proteins with antimicrobial activity (Van Loon et al. 2006). According to Conrath (2011), primary infection with pathogen is a vital step of SAR, and infected tissues are in an alert state that enables them to more rapidly and efficiently deal with both biotic and abiotic stresses. The defense alert expressed upon pathogen attack in the plant cell amplified and transferred from the site of infection by a system of mobile signals into distal (systemic) plant parts (Jain et al. 2016).

The use of SA transgenic and mutant plants for the research studies has revealed an essential role for this phytohormone in SAR (Loake and Grant 2007; Vlot et al. 2008a). The accumulation of SA in SAR had been proven by using *Arabidopsis* SA-non-accumulating mutant plant NahG which expressed the bacterial salicylate hydroxylase (*nahG*) gene responsible for conversion of SA into catechol. This type of plants cannot express SAR. SAR pathway is activated by SA, primary molecule for SAR, which further activates further signaling cascade to activate pathogenesis-related (PR) genes responsible for resistance against pathogen, which encode different pathogenesis-related proteins of families PR-2, PR-5, and PR-1, such as chitinases, β-1,3-glucanases, lipoxygenases, thaumatin-like proteins, antimicrobial peptides, etc. (Jain and Choudhary 2014). Upon elicitation of signal from SA accumulation, nonexpressor of PR genes-1 (*npr-1*) gets activated and encodes NPR1 which acts as a transcriptional coactivator of PR gene expression. Hence, as shown in Fig. 12.2, the overall sequence of the signaling event in SAR is in such a way that after recognition of pathogen, SA accumulation takes place which activates *npr-1* gene followed by activation of PR genes (Choudhary et al. 2016).

Methyl salicylate (MeSA), the volatile form of SA, is itself biologically inactive but in the systemic tissue gets hydrolyzed to SA by the MeSA esterase activity of SA-binding protein 2, and that's how it can act as long-distance mobile signal for SAR (Park et al. 2007; Vlot et al. 2008a, b). Being a volatile compound, MeSA can pass through by both air and vascular transport to intercede long-distance induction of resistance in distal leaves that lack a direct vascular connection to the attacked leaf and in neighboring plants (Heil and Ton 2008). In tobacco plant upon getting infection by tobacco mosaic virus, along with SA, ethylene (ET) perception is also required for the onset of SA-dependent SAR (Verberne et al. 2003). In addition, Truman et al. (2007) showed that the JA-signaling mutants *sgt1b* (suppressor of g2 allele of SKP1 1b), *opr3* (12-oxo-phytodienoate reductase 3), and *jin1* (jasmonate insensitive 1) failed to develop SAR upon leaf infiltration with an avirulent strain of

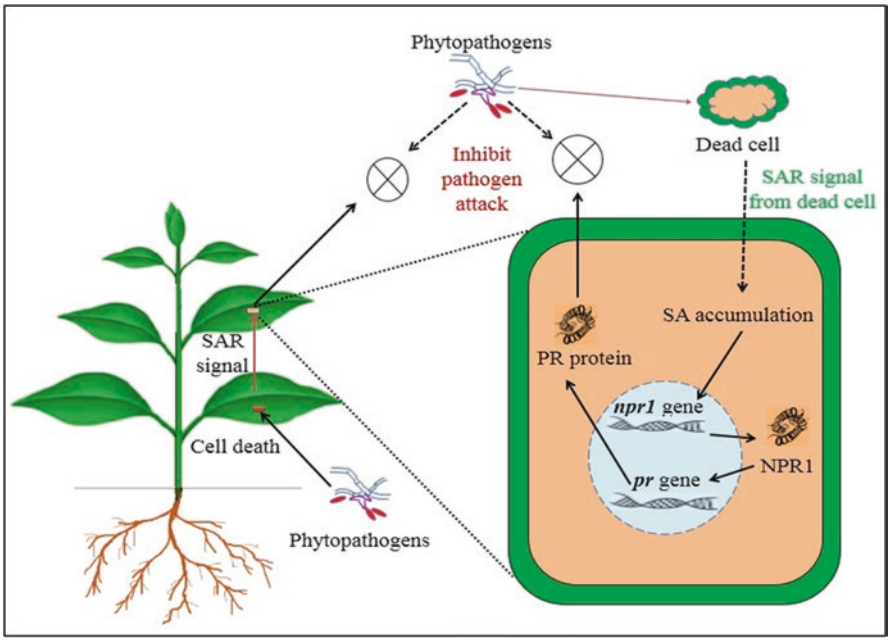

Fig. 12.2 Signal transduction pathway of pathogen-induced systemic acquired resistance (SAR) in plants

the pathogen *Pseudomonas syringae* pv. *tomato*, suggesting that JAs play a role in SAR as well. However, other JA-signaling mutants such as *jar1* (jasmonate resistant 1), *eds8* (enhanced disease susceptibility 8), and *coi1* (coronatine insensitive 1) were shown to develop normal levels of SAR (Attaran et al. 2009).

12.4 Defense Molecular Mechanisms

In comparison to SAR, ISR have a more assorted and composite route to establish a higher degree of prior resistance. In place of PR gene, defense-related gene activation takes place in ISR. Besides SA, the plant growth regulators JA and ET have been implicated in plant defense responses. ISR signal transduction pathway is independent of SA accumulation and totally dependent on JA and ET.

12.4.1 ISR: SA Independent but JA and ET Dependent

In contrast to plant defense system, two of the main signaling pathways, namely, ISR and SAR, confer a broad-spectrum disease resistance in systemic plant parts and look like similar, but actually they are regulated by different signal transduction pathways. The first facts in support of the differential regulation of SAR and

ISR came from studies on the plant growth-promoting rhizobacteria (PGPR) WCS417r. Pieterse et al. (1998) have used *Arabidopsis* SA mutant NahG plants that lack SA accumulation activity. NahG plants contain bacterial salicylate hydroxylase (*nahG*) gene responsible for conversion of SA into catechol. In research it was shown that this mutant plant also develops normal level of ISR after treatment of the root with ISR-inducing rhizobacterial strain *P. fluorescens* WCS417r against the challenge inoculation that confirms ISR independency over SA. After that, many research studies have been done in support of SA-independent ISR in *Arabidopsis* (Stein et al. 2008; Segarra et al. 2009) and other plant species, such as tobacco (Zhang et al. 2002), tomato (Hase et al. 2008), and rice (De Vleesschauwer et al. 2008). JA and ET are the central players in the regulation of ISR, and similar to SA mutant NahG plants, their role was also confirmed by using JA mutants such as *jar1*, *jin1*, *eds8*, and *coi1* and ET mutants such as *etr1* (ethylene response1) and *ein2* (ethylene insensitive 2). These plants were found unable to confer ISR upon against challenge inoculation that clears the dependency of ISR on JA and ET. Jasmonic acid and its different derivatives induce the expression of genes encoding defense-related proteins, such as thionins (Pieterse et al. 1998) and proteinase inhibitors, while ethylene is involved in the expression of the pathogen-inducible genes (van Wees et al. 1999).

The signaling cascade of the ISR is elicited by nonpathogenic rhizobacteria/PGPR and there is no need of initial infection as required in SAR. Upon receiving elicitation from PGPR, transient synthesis of JA and ET takes place, and the formation of phloem-mobile signal moves this signal in the direction of distal part of the plant, and after challenge inoculation, JA and ET responses activate *npr-1* gene expression, which encodes NPR1 followed by activation of defense-related gene. NPR1 is known as the master regulator of both defense pathways, as upon getting preceding signal, it activates the expression of either PR gene or defense-related gene for the establishment of SAR and ISR, respectively. Likewise MeSA, methyl jasmonate (MeJA) also works as a volatile signal for the distal part of the plant. Król et al. (2015) studied that tomato seed priming with MeJA is found to induce resistance to hemi-biotroph *Fusarium oxysporum* f.sp. *lycopersici*. Based on the preceding signal NPR1 get from either JA or ET or from both in concert expression of different defense-related genes will get express.

Saskia et al. (1999) have categorized different defense-related genes activated by JA and ET. Pathogen-inducible genes *Hel* (encoding a hevein-like protein) (Potter et al. 1993), *ChiB* (encoding a basic chitinase) (Samac et al. 1990), and *Pdf1.2* (encoding a plant defensin) (Penninckx et al. 1996) that code for the antifungal protein get induced by ET and JA (Thomma et al. 1998). Among the three, plant defensin proteins possess a wide range of activity that includes antifungal activity, antibacterial activity, proteinase inhibitory activity, and insect amylase inhibitory activity, and for its full expression, both ethylene and jasmonate are required, indicating that these hormonal signals act in concert (Penninckx et al. 1998). *Pal1* gene encodes for the phenylalanine ammonia-lyase, which plays an important regulatory role in the synthesis of phenylpropanoid such as lignin and of SA in *Arabidopsis* (Mauch-Mani and Slusarenko 1996), which has been also found to be induced by JA

(McConn et al. 1997). Along with these JA also protects plant from insect and herbivory. *Pin* gene which encoded for the proteinase inhibitor proteins was induced by JA in the tomato plant in case plant tissues get wounded by any intruder. This protein protects the plant against herbivory (Heitz et al. 1999). On another hand to combat against insect, it activates expression of the *Atvsp* gene (encoding vegetative storage protein) in *Arabidopsis* that possesses acid phosphate activity, and that's how it retards the development of insect and increases mortality rate. That's how, by triggering the activation of such a wide range of different defense-related genes, PGPR-elicited ISR help protect plant against a broad range of pathogens, insects, and herbivores (Berger et al. 1995).

12.4.2 NPR1: The Master Regulator of SAR and ISR

Even though both signal transduction pathways, ISR and SAR, vary from each other with respect to elicitor and signaling molecule, the defense regulatory protein NPR1 plays a key role in the regulation of both SA-dependent SAR and JA-/ET-dependent ISR (Dong 2004; Pieterse and Van Loon 2004), and that's why these signaling pathways are independent but overlapped due to requirement of NPR1 (van Wees et al. 2000). Research studies on the mutant *Arabidopsis npr1* plants were shown to be blocked in their ability to express ISR upon colonization of the roots by the PGPR WCS417r (Pieterse et al. 1998*)*, *P. fluorescens* CHAO (Iavicoli et al. 2003), *P. fluorescens* 89B61 (Ryu et al. 2003), *P. putida* LSW17S (Ahn et al. 2007), *Serratia marcescens* 90–166, and *B. pumilus* SE34 (Ryu et al. 2003) upon challenge inoculation.

Based on the varied initiation site, that is, root in case of ISR, whereas leaves in SAR, it was recommended that these two responses may not compete for NPR1, but these are not independent, however, and may compete for NPR1 in leaves. In case of SAR, NPR1 works as transcriptional coactivator of SA-responsive PR gene expression (Kuai et al. 2015) while not in case of SA-independent ISR (Pieterse et al. 1996) that indicates a different role of NPR1 in ISR signaling pathway. Additive enhanced capacity in case of simultaneous activation of SAR and ISR suggests the roles of NPR1 are not mutually exclusive and it regulates and connects different hormone-dependent induced defense pathways by playing a junctional key role (Van Wees et al. 2000; Pieterse et al. 2009; Yang et al. 2015). SA signaling is clearly connected to a function of this regulatory protein in the nucleus; evidence is accumulating that the role of NPR1 in JA/ET signaling is connected to a cytosolic function of NPR1 (Dong 2004; Leon-Reyes et al. 2009).

12.5 Root Priming and Systemic Resistance

Root colonization, i.e., priming, is a critical step to establish ISR in plants. Although nonsymbiotic but mutualistic association between plant roots and PGPB is less well characterized, researchers have done well to resolve it (Zamioudis and Pieterse

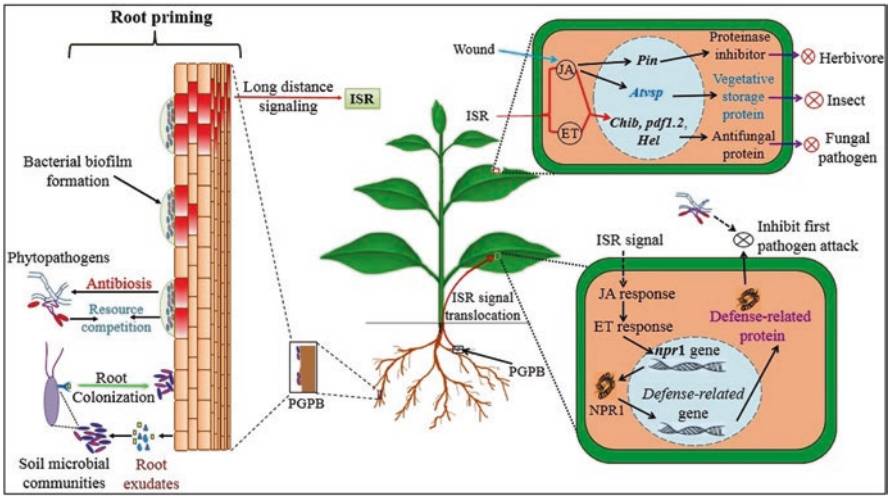

Fig. 12.3 Mechanism of root priming and induced systemic resistance signaling pathway in plants

2012). It was first confirmed by Van Loon et al. (1998) that colonization of plant roots by plant growth-promoting rhizobacteria (PGPR) protects aboveground plant tissues against different types of pathogens.

During the root priming phenomenon, different free-living PGPR get attracted toward root exudates secreted by plant roots. Then changes in the transcriptional program of the PGPR take place toward the traits involved in chemotaxis, root colonization, and energy metabolism (Fan et al. 2012; Mark et al. 2005). After root attachments, PGPB get enclosed within an extracellular matrix of self-produced polymeric substances, mainly exopolysaccharides (EPS) and mucilage, and form biofilm on the root surface. It is necessary for the colonization of roots by *B. subtilis* and was recently revealed to be stimulated by polysaccharides derived from host cell walls that function as signaling molecules for the expression of bacterial genes involved in matrix production (Beauregard et al. 2013).

In this matrix, the coordinated interpretation of the host and self-derived signals was done by bacterial cells to coordinate the production and release of compounds related to plant growth promotion, nutrition, and ISR. That's why this matrix can be considered as the mutualistic interface between the plant and bacteria through which they can exchange solutes and chemical information (Fig. 12.3). Due to the cell wall-degrading exoenzymes, such as cellulase and pectinase, PGPR endophytes commonly enter the root interior through cracks in the newly emerged lateral roots or utilize root hairs and the apical zone as entry points (Reinhold-Hurek and Hurek 2011).

Similar to pathogen-induced SAR, this PGPR-mediated ISR has been demonstrated in many plant species and has a wide range of effectiveness (Chen et al. 2014). Nonpathogenic *Pseudomonas* spp. and *Bacillus* spp. were found to be the

most effective PGPR with respect to ISR (Van Loon and Bakker 2006). Maize plants treated with *P. putida* KT2440 are found to protect plant against fungal pathogen *Colletotrichum graminicola* (Planchamp et al. 2014). Even though both SAR and ISR work for the plant protection against different types of pathogens, their range of effectiveness is partly divergent.

Ton et al. (2002) have worked on *Arabidopsis thaliana*, and it was shown that SAR triggered by an avirulent strain of the bacterial leaf pathogen *P. syringae* pv. *tomato* and ISR elicited by the PGPR *P. fluorescens* WCS417r are equally effective against diseases caused by the fungal root pathogen *F. oxysporum* and the downy mildew pathogen *Hyaloperonospora arabidopsidis*. Over the last decade, it has become clear that many bacterial genera such as *Acinetobacter*, *Agrobacterium*, *Arthrobacter*, *Azospirillum*, *Bacillus*, *Bradyrhizobium*, *Frankia*, *Pseudomonas*, *Rhizobium*, *Serratia*, *Thiobacillus*, and many others can elicit induced systemic resistance to provide prior resistance to plants against fungal pathogens.

Along with these, the properties of PGPB to elicit a range of defense-responsive activities in plants such as activation of antioxidant status by reprogramming defense-related enzymes, modulation of quorum sensing phenomenon, and activation of phenylpropanoid pathway leading to phenolic production, lignin deposition, and transgenerational defense response in order to combat the pathogen challenge make it a powerful substitute of synthetic chemicals for the improvement of agroecosystem (Mishra et al. 2015).

12.6 Role of Bacterial Determinants

Research studies on the bacterial-elicited ISR have shown that some of the bacterial determinants are responsible for the elicitation of ISR. Although PGPB appear to actively repress local host defense responses in the roots, it also produces elicitors that are responsible for the onset of systemic immunity. Early reports on MAMPs and other elicitors of ISR-inducing PGPB pay attention on the contribution of lipopolysaccharides (LPS) and the iron-regulated metabolites pyoverdine and SA (De Vleesschauwer and Höfte 2009), but in the past years, many other bacterial determinants have been identified that elicit ISR, including antibiotics, flagella, *N*-acyl homoserine lactones, N-alkylated benzylamine, volatiles, exopolysaccharides, iron-regulated siderophores, and biosurfactants (De Vleesschauwer and Höfte 2009).

LPS is the major structural component of the outer membrane of gram-negative bacteria with highly conserved structure that consist of three components: a lipid A, a core oligosaccharide, and an O-antigen. Among the three, O-antigen of the LPS seems to be the moiety that triggers ISR in plants. Leeman et al. (1995) have shown the ISR-triggering capacity of two strains, *P. fluorescens* WCS374 and *P. fluorescens* WCS417, against *F. oxysporum* f.sp. *raphani* in the radish plant. The role of O-antigen in triggering ISR has been also proven by showing the inability to trigger ISR by the mutant of *P. fluorescens* strain WCS 417 that lacks the O-antigen side chain of the LPS. LPS of *P. fluorescens* strain WCS 417 have also found to be

induced systemic resistance in carnation against *Fusarium* wilt caused by *F. oxysporum* f.sp. *dianthi* (Van Peer and Schippers 1992).

Biosurfactants are varied group of surface-active molecules/chemical compounds synthesized by microorganisms. These amphiphilic compounds more importantly cyclic lipopeptides in case of bacteria are produced on living surfaces or excreted extracellularly. Several plant-associated bacteria such as pathogenic and antagonistic *Pseudomonas* bacteria (Raaijmakers et al. 2006) and antagonistic *Bacillus* strains (Ongena and Jacques 2008) are reported to produce cyclic lipopeptides. Cyclic lipopeptides produced by *B. subtilis* include surfactin, iturin, and fengycin families and reported for ISR-mediated protective effect on bean plants against *Botrytis cinerea*, similar to the one induced by living cells of the strain *B. subtilis* S499 (Ongena et al. 2007). Raaijmakers et al. (2006) have classified *Pseudomonas* spp. that produced cyclic lipopeptides into four major groups, namely, the viscosin, amphisin, tolaasin, and syringomycin groups. The massitolide-producing *P. fluorescens* strain SS101 was effective in avoiding infection of tomato leaves by *Phytophthora infestans* and considerably reduced the extension of presented late blight lesions. A massitolide-negative mutant of *P. fluorescens* SS101 entirely lost the ability to induce systemic resistance. These results show that massitolide A is a bacterial determinant of ISR in tomato (Tran et al. 2007). Cell suspensions of *P. fluorescens* SS101 or massitolide A are also found to cause lysis of zoospores of oomycete pathogens (De Souza et al. 2003).

Another determinant, N-acyl-L-homoserine lactone (AHL) present in gram-negative bacteria, acts as signal molecules to control the expression of various functions in a cell density-dependent manner, and this phenomenon is termed as quorum sensing (Miller and Bassler 2001). *Serratia liquefaciens* MG1 produces two types of AHL molecules, namely, N-butanoyl and N-hexanoyl homoserine lactones. It can induce systemic resistance in the tomato plant against the fungal pathogen *Alternaria alternata*, while an AHL-negative mutant of *S. liquefaciens* MG1 slowed down the development of *A. alternata*-induced cell death, but infected plants showed no significant alterations in response to the fungal pathogen when compared with the non-inoculated control.

Inoculation with the *P. putida* strains IsoF having AHL-producing activity can also induce resistance against *A. alternata. S. liquefaciens* MG1 and pure N-hexanoyl homoserine lactone significantly increased free and conjugated SA levels in tomato leaves, while this increase was not observed for the AHL-negative mutant (De Vleesschauwer and Höfte 2009). Ongena et al. (2008) reported that *P. putida* BTP1 induces resistance in bean and tomato against *B. cinerea* and in cucumber against *P. aphanidermatum* and *Colletotrichum lagenarium*. They also showed that N, N-dimethyl, N-tetradecyl-N-benzylammonium (NABD) appears to be the bacterial determinant responsible for ISR. Besides this, pure benzylamine is also found to be effectual in triggering induced resistance in bean and cucumber that shows importance of the aromatic amino part for the biological activity of the entire molecule. According to Ahn et al. (2007), the aromatic phenol group present in thiamine is another inducer of systemic resistance in plants.

Siderophores are low molecular weight organic compounds and possess a very high and specific affinity to chelate iron (Boukhalfa and Crumbliss 2002). Different microorganisms produce a wide range of siderophore, but out of them, pseudobactines, also known as pyoverdine or fluorescein, is the most important.

It exhibited distinctive phenotypic trait of the rRNA homology group I species of the genus *Pseudomonas* (Visca et al. 2007). According to Compant et al. (2005), siderophores produced by different PGPB reduce the growth of pathogenic fungi through Fe^{3+} ion sequestering and showed heterologous siderophores produced by coinhabitant. Siderophores produced by fungi have lower affinity for ferric ion. Other than Fe^{3+} ion sequestering mediated protection, it also triggers immune response in plants (Höfte and Bakker 2007). A lot of research has been done on pseudobactines in the past decade which demonstrate its role in triggering resistance in plants. For example, pseudobactines produced by *P. putida* WCS358 were reported for its role in the suppression of *Ralstonia solanacearum* in *Eucalyptus urophylla* (Ran et al. 2005), *Erwinia carotovora* in tobacco (Van Loon et al. 2006), and *Botrytis cinerea* in tomato (Meziane et al. 2005). Earlier two strains of PGPB *Rhizobium meliloti*, RMP_3 and RMP_5, have been isolated by Arora et al. (2001) from *Mucuna pruriens* which produce siderophore and showed strong antagonism against pathogen *Macrophomina phaseolina*.

Antibiotics produced by PGPB also play a principal ISR elicitor task in plant defense. Finding of the characteristic of PGPB to produce antibiotics has made a significant increase in our knowledge about the biocontrol of disease. There is a wide range of antibiotics produced by gram-negative and gram-positive bacteria. Antibiotics produced by fluorescent *pseudomonads* comprise of 2,4-diacetylphloroglucinol (DAPG), pyoluteorin (PLT), pyrrolnitrin (PRN), phenazine-1-carboxyclic acid (PCA), 2-hydroxy phenazines, and phenazine-1-carboxamide (PCN) which have different structural configurations. Other than *Pseudomonas* a wide range of bacteria produces different types of antibiotic which target different pathogens and protect plant from respective diseases (Raaijmakers and Weller 1998; Weller et al. 2002; Fernando et al. 2005).

Diacetylphloroglucinol produced by *Pseudomonas* sp. is the most studied antibiotic among the listed one and most frequently reported in PGPB-mediated disease control. DAPG produced by *P. fluorescens* CHA0 is reported to induce resistance against oomycete *H. arabidopsidis* (Iavicoli et al. 2003) and the root-knot nematode *Meloidogyne javanica* (Siddiqui and Shaukat 2003). A wide range of bacterial strains have the ability to produce a broad range of antibiotics and help in suppression of diverse microbial competitors, e.g., *B. cereus* strain UW85 produced zwittermicin (Pal and Gardener 2006; Silo-Suh et al. 1994) and kanosamine (Milner et al. 1996). Upon study on *Arabidopsis* mutants and transgenic lines which implicated defense signaling pathways, it was find out that DAPG-induced resistance does not follow standard ISR pathway nor depend on the master regulator NPR1 or functional JAR1 protein but is regulated by *eir1* (ethylene-insensitive root-1) gene, which is ET insensitive in the roots only (De Vleesschauwer and Höfte 2009). Lack of ISR expression after exogenous exposure of DAPG on the *eir1* mutant recommended that an intact ET signaling pathway is required for the establishment of

DAPG-inducible resistance (De Vleesschauwer and Höfte 2009; Iavicoli et al. 2003). PCA is the another potent antibiotic with respect to plant protection having antagonistic activity coupled with the accumulation of toxic superoxide radicals in the target cells (Fernando et al. 2005). PCA produced by *P. fluorescens* 2–79 and *P. aureofaciens* 30–84 exhibited antagonism against *Gaeumannomyces graminis* var. *tritici* (Thomashow et al. 1990). *S*tem rot disease of canola caused by *Sclerotinia* is suppressed by activity of *P. chlororaphis* strain PA-23 (Zhang and Fernando 2004).

In the context of the plant defense, volatile organic compounds (VOCs) produced by PGPB-elicited plant growth promotion and induced systemic resistance provide a new insight in PGPB–plant interaction. Out of the different types of VOCs produced by bacteria with respect to plant defense, some of the most notable includes dodecane, 2-undecanone, 2-tridecanone, 2-tridecanol, tetramethylpyrazine, 2,3-butanediol and 3-hydroxy-2-butanone (acetoin), etc. Ryu et al. (2003) have done a lot of research on VOCs and reported that 2,3-butanediol and 3-hydroxy-2-butanone are the most important one with respect to their role in elicitation of ISR. Two bacterial strains, namely, *B. subtilis* GB03 and *B. amyloliquefaciens* IN937a, were found to consistently release 2,3-butanediol and 3-hydroxy-2-butanone. Priming of *A. thaliana* plants with these strains has shown significant resistance against the challenge inoculation of *Erwinia carotovora* subsp. *carotovora* SCC1. Priming activity of such VOCs to induce resistance against diseases is confirmed with genetically modified *Bacillus* strain which is unable to produce VOCs and found to be unable to elicit ISR (Ryu et al. 2003). Besides *Bacillus*, a number of strains of *P. fluorescens* were also reported for the production of VOCs and have shown more effectiveness in controlling root and seedling diseases (Landa et al. 2002).

12.7 Role of Defense Enzymes

By using the property of defense gene to get induced upon an appropriate stimulus/signal, through prior induction of plant's own defense mechanisms by application of a biological inducer, plants can be protected against invading pathogens. Different defense enzymes, namely, lipoxygenase (LOX), phenylalanine ammonia-lyase (PAL), peroxidase (POD), polyphenol oxidase (PPO), chitinase, and β-glucanase, get activated through prior treatment of plants with plant growth-promoting microbes and lead to plant protection against the biotic stress.

Peroxidases are expressed to restrain cell spreading of disease through generation of highly toxic environments by enormously producing ROS and reactive nitrogen species (RNS) or foundation of basic obstructions, for example, lignin and suberin deposition (Passardi et al. 2005; Cavalcanti et al. 2004), while PPO also plays an important role in defense against plant pathogens due to its reaction products and wound inducibility property (Mayer and Harel 1979; Chunhua et al. 2001). Sundaramoorthy et al. (2012) found the increased level of POD, PPO, and β-glucanase in the *Capsicum annum* L. treated with co-inoculation of two

endophytic bacteria *B. subtilis*, namely, EPCO16 and EPC5, and rhizobacterium strain *P. fluorescence* PF1 after challenge inoculation with *F. solani*.

An elevated level of enzymatic activity of cell wall-bound PODs has been reported in different plants such as cucumber (Chen et al. 2000), soybean (Jain et al. 2013; Jain and Choudhary 2014), rice (Reimers et al. 1992), tomato (Mohan et al. 1993), and tobacco (Ahl Goy et al. 1992) against challenge inoculation. Research studies on different plants such as cucumber (Chen et al. 2000), banana (Thakker et al. 2007), tomato (Thipyapong and Steffens 1997), and poplar plant have been found with higher level of PPO upon pathogen infection. β-1,3-Glucan and chitin, polymer of N-acetylglucosamine (NAG), are the main components of fungal phytopathogen cell wall, and β-1,3-glucanase and chitinase play a straight role in plant protection by degrading these cell wall compounds, respectively. PAL and LOX are the other defense enzymes elicited by bacteria in plants against challenge inoculation. PAL regulates the critical steps in phenylpropanoid metabolism and plays an important role in lignin production which is an inducible defense mechanism used for protection against pathogen attack (Liang et al. 1989), while LOX is requisite for the synthesis of antifungal oxylipins, such as jasmonic acid (JA) that may act as signal factor for eliciting ISR in the plant (Creelman and Mullet 1997; Pieterse et al. 1998).

Numerous former studies on the plant–microbe interaction in the course of plant defense have found a significant role of PAL. Recently Ramamoorthy et al. (2002) found higher level of PAL and LOX in the roots of tomato plant treated with *P. fluorescens* Pf1 challenged inoculated with *F. oxysporum* f.sp. *lycopersici.* Daayf et al. (1997) have shown the role of PAL in the production of phenolics and phytoalexins in cucumber. PAL activity could be induced in plant–pathogen interactions and fungal elicitor treatment (Ramanathan et al. 2000). Chen et al. (2000) reported prominent level of PAL enzyme in the cucumber roots inoculated with *Pythium aphanidermatum* and treated with *P. corrugata*, but in later treatment, levels were deceased after challenge inoculation with *P. aphanidermatum*. De Meyer et al. (1999)) reported stimulation of PAL in bean roots and increased level of salicylic acid (SA) in leaves upon colonization of rhizosphere by *P. aeruginosa* 7NSK2.

12.8 Conclusion

Plants comprise an outstanding ecosystem for microorganisms that interact with plant tissues and cells with differing degrees of dependence. To attain practical agricultural applications, studies on the relationship between roots and microbiota are important. Among the bacterial strains that play important roles in the prevention of plant infectious diseases, many can promote plant growth by suppressing pathogenic microorganisms, synthesizing growth-stimulating plant hormones, and promoting increased plant disease resistance. New biotechnological products are currently being developed based on stimulation of the plant defense response and on the use of plant-beneficial bacteria for biological control of plant diseases and for plant growth promotion.

Essential Oils as Antimicrobial Agents Against Some Important Plant Pathogenic Bacteria and Fungi

13

Bachir Raho Ghalem

Abstract

Plant diseases impact negatively on human well-being through agricultural and economic loss and also have consequences for biodiversity conservation. They are caused by some pathogens like bacteria, fungi, nematodes and viruses. Bacteria and fungi are the most common cause of many diseases of plants. The use of antibiotics for the control of plant diseases is limited due to the possibility to the production of some pathogen populations resistant to fungicides and pathogen populations resistant to antimicrobial agents and the ability to the transfer of responsible resistant genes to human and animal pathogenic microbes. In addition, these chemical compounds can cause undesirable effects on environment due to their slow biodegradation and several serious side effects on mammalian health associated to toxic residues in agricultural products. There is, therefore, a need to develop alternative control agents to pathogenic bacterial and fungal diseases in plants. Essential oils are a concentrated hydrophobic liquid containing volatile aroma compounds derived from the different parts of the plants. They were previously known to possess many biological activities such as antifungal and antibacterial properties. In addition, the potential effectiveness of essential oils against many plant pathogenic bacteria and fungi has been verified by many authors. This review discusses the susceptibility of most important ten bacterial and fungal plant pathogens towards different essential oils and their constituents, which have been reported in scientific references.

13.1 Introduction

Plants are continuously confronted in their environment with a wide range of potential pests and pathogens that include insects, nematodes, viruses, bacteria, fungi and oomycetes. While many pathogens evolved to infect aerial parts of the plant (leaves, stems, flowers and fruits), others target belowground organs (roots and tubers) (Hajek 2004; Yadeta and Thomma 2013). From plant diseases, fungal and bacterial plant pathogens cause major production and economic losses in agriculture by reducing quality and yield of particular crops or limiting their production in areas with environmental conditions conducive for disease development (Obradovic et al. 2008; Sankaran et al. 2010; Tajane and Janwe. 2014). In addition to fungal diseases which account for many of disease problems due to their prevalence and the amount of loss caused in plant production, there are an important number of bacterial diseases that are extremely destructive, and they are a threat to crops (Obradovic et al. 2008). Despite that chemical control reduces the effects of most fungal and bacterial disease effectively and extensively, these are not always desirable and present a danger to the health of humans, animals and the environment if they are used in excessive and improper manner (Shabana et al. 2008; El-Mohamedy and Aboelfetoh 2014). In addition, many farmers particularly in developing countries cannot use them for their high costs and lack of knowledge about its application (Dhlamini et al. 2005). Therefore, extensive studies for biopesticides that are easily biodegradable and safe to the environment to control fungal – and bacterial – diseases of crops have been carried out during the last two decades (Al-Askar 2012). Hence, aromatic plants that have been used in traditional medicine for their antimicrobial activities since ancient times could represent a promising solution and wise tool (Ismail et al. 2012; Pawar 2013). Studies done previously have confirmed that many plant essential oils exhibited antimicrobial effect on Gram-positive and Gram-negative bacteria, fungi and phytopathogens. The aim of this paper is to provide an overview of the published data on essential oils that have been reported to be effective against the most important bacteria, fungi and phytopathogens.

13.2 Brief History of Plant Essential Oils as Antimicrobial Agents

Since ancient times, herbs and spices have enjoyed a rich tradition of use both for their flavour-enhancement characteristics and for their medicinal properties (Kaefer and Milner 2008). The earliest records of the valuable properties of medicinal plants were by the Sumerians (6000 BC), followed by Chinese and Greek. A Chinese (4000 BC) wrote the first book about herbal plants (Kaliora and Kountouri 2012). Around 1550 BC, the ancient Egyptians used these substances as preservative agents for food conservation and as embalming agent to preserve their deceased pharaohs (Davidson et al. 1983). EO production appeared in the East (India and Persia) more than 2000 years ago and was improved in the ninth century by Arabs (Tajkarimi et al. 2010). Essential oils started to be manufactured by chemists after

the thirteenth century AD, and their pharmacological effects are described in pharmacopoeias. After their use only in London, they disseminated consequently to the rest of Europe in the fourteenth century (Burt 2004). In the sixteenth century, Paracelsus von Hohenheim used the term of "essential oil" for the first time to the component of a drug as "quinta essential" (Guenther 1950). Many researches in the nineteenth century on plant products have been focused on the antimicrobial properties of herbs, spices and their constituents; the interest in the properties of these compounds continues to grow (Zaika 1988). In 1881, la Croix carried out the first bactericidal experiment of EOs (Boyle 1955), followed by Chamberland in 1887 who tested over 100 essential oils against spores of *Bacillus anthracis* and found that the vapour of the cinnamon oil was lethal to the spores. Hoffman and Evans were among the first researchers to describe the preservative effect of some spices such as cinnamon, cloves, mustard, allspice, nutmeg, ginger, black pepper and cayenne pepper. They demonstrated that cinnamon, cloves and mustard were most effective, while ginger, black pepper and cayenne pepper were least effective (Arora 2003). The utilization of essential oil pharmaceutical preparations had been declined by the middle of the twentieth century, and its role had been limited almost totally to be used in food flavourings, cosmetics and perfumes (Edris 2007).

In the last two decades, many studies have been conducted with a large number of essential oils from different plants in order to investigate their antimicrobial properties on plant pathogenic microorganisms (Vasinauskiene et al. 2006; Tabanca et al. 2007; Ozturk and Ercisli 2007; Kowalska and Smolinska 2008; Kotan et al. 2010; Dadasoglu et al. 2011; Kokoskova et al. 2011; Silva et al. 2012; Adebayo et al. 2013; Islam et al. 2013; Kotan et al 2014; Alamshahi and Nezhad 2015).

13.3 Chemical Composition of Essential Oils

Essential oils are volatile, natural, complex mixtures of compounds characterized by a strong odour and are formed by aromatic plants as secondary metabolites (Bakkali et al. 2008). There are many different methods of essential oil extraction from plants: water or steam distillation, solvent extraction, expression under pressure and supercritical fluid and subcritical water extraction (Edris 2007). They have a complex composition, containing from a few dozen to several hundred constituents (Miguel 2010). These compounds are mainly terpenes and terpenoids, aromatic (phenolic) components and in a lower extent aliphatic (alkanes and alkenes) compounds (Bayala et al. 2014).

Terpenes are known as the large group of hydrocarbons made up of isoprene units (C_5H_8). They are synthesized in the cytoplasm of plant cells via the mevalonic acid pathway starting from acetyl CoA. They have a hydrocarbon backbone which can be rearranged into cyclic structures (monocyclic or bicyclic structures) by cycles. Monoterpenes ($C_{10}H_{16}$) and sesquiterpenes ($C_{15}H_{24}$) are usually the main terpenes, but longer chains such as diterpenes ($C_{20}H_{32}$), triterpenes ($C_{30}H_{40}$), etc., also exist. Examples of terpenes include ρ-cymene, limonene, terpinene, sabinene and pinene (Hyldgaard et al. 2012).

The monoterpenes are formed from the coupling of two isoprene units. They are the most representative molecules constituting 90 % of the essential oils and allow a great variety of structures. The following chemical classes are included as monoterpenes such as carbures, alcohols, aldehydes, ketones, esters, ethers, peroxides and phenols. The sesquiterpenes are formed from the assembly of three isoprene units. The extension of the chain increases the number of cyclizations which allows a great variety of structures. The structure and function of sesquiterpenes are similar to those of the monoterpenes which also include carbures, alcohols, ketones and epoxide (Bajpai et al. 2011).

Most terpenes do not possess high inherent antimicrobial activity of ρ-cymene, one of the most important components of thyme essential oil, and do not show antimicrobial activity against many Gram-negative pathogens (Bagamboula et al. 2004). Other terpenes, such as limonene, α-pinene, β-pinene, γ-terpinene, δ-3-carene, (+)-sabinene and α-terpinene, showed a very low or no antimicrobial activity against 25 genera of bacteria (Dorman and Deans 2000). These in vitro tests indicate that terpenes show ineffective antimicrobial activity when used as singular compounds (Nazzaro et al. 2013).

Terpenoids are terpenes that undergo biochemical modifications via enzymes that add oxygen molecules and move or remove methyl groups. Terpenoids can be subdivided into alcohols, esters, aldehydes, ketones, ethers, phenols and epoxides.

Examples of terpenoids are thymol, carvacrol, linalool, linalyl acetate, citronellal, piperitone, menthol and geraniol (Hyldgaard et al. 2012). The antimicrobial or antifungal mode of action of essential oil may be due to terpenoids. These compounds are highly lipophilic and are of low molecular weight which disrupt the cell membrane, cause the cell death and are also effective in the inhibition of sporulation and germination of food spoilage fungi (Tian et al. 2011). For example, the ethanol-soluble fraction of purple prairie clover yields a terpenoid called petalostemumol, which produces significant activity against *Bacillus subtilis* and *Staphylococcus aureus* while lesser activity against Gram-negative bacteria as well as *Candida albicans* (Cowan 1999; Ciocan and Bra 2007).

The other chemical classes of typical constituents in the essential oils are some aromatic compounds which are derived from phenylpropane and occur less frequently than all the terpenes mentioned above. The most common aromatic compounds are aldehydes such as cinnamaldehyde, alcohols (e.g., cinnamic alcohol), various phenols and methoxy and methylenedioxy derivatives. Nitrogenous or sulphur components such as glucosinolates or isothiocyanate derivatives can occur in some specific essential oils. However, these last classes of compounds are really less frequent in comparison with mono- and sesquiterpenes and their derivatives (Bertoli et al. 2011).

13.4 Mechanism of Action of Essential Oils

The mechanisms by which essential oils inhibit bacteria involve different modes of action; one of the well documented is membrane disruption by the lipophilic components (Dreger and Wielgus 2013). They cause lipid partitioning of bacterial cell

membranes and mitochondria, disturbing the cell structures and rendering them more permeable. Extensive leakage from bacterial cells or the exit of critical molecules and ions will lead to death (Božović et al. 2015). Another possibility of action is inhibition of production of amylase and protease which stops the toxin production and electron flow and results in coagulation of the cell content (Djilani and Dicko 2012). Antifungal actions are quite similar to those described for bacteria (Djilani and Dicko 2012). According to Freiesleben and Jäger (2014), the antifungal agent can destroy the fungus by one of these six mechanisms:

Inhibition of cell wall formation: The fungal cell wall primarily consists of β-glucans. If the synthesis of these compounds is inhibited, the cell wall integrity will disrupt.

Cell membrane disruption: The ergosterols are essential for the cell membrane. If these sterols are bound by antifungal drugs, or the synthesis of them is inhibited by ergosterol biosynthesis inhibitors, the cell membrane integrity will disrupt. Thereby the membrane becomes leaky.

Dysfunction of the fungal mitochondria: Inhibition of the mitochondrial electron transport will result in reduction in mitochondrial membrane potential. The inhibition can occur via inhibition of the proton pumps in the respiratory chain, leading to reduction in ATP production and subsequent cell death.

Inhibition of cell division: Inhibition of cell division can happen via inhibition of microtubule polymerization, thereby inhibiting the formation of the mitotic spindle.

Inhibition of RNA/DNA synthesis or protein synthesis: If the antifungal agent enters the cell, for instance, via active transport on ATPases, and interferes with the RNA, it can cause faulty RNA synthesis and inhibition of DNA transcription. Inhibition of protein synthesis is also a known antifungal target.

Inhibition of efflux pumps: Efflux pumps are present in all living cells, and their function is to transport toxic substances out of the cell. This transport often includes transport of accumulated drug out of the fungal cell. Overexpression of efflux pumps can lead to drug resistance. By inhibiting the efflux pumps, it is believed that drug resistance can be reduced.

The antimicrobial activity of several essential oils has been attributed to the presence of specific terpenoid and phenolic compounds (Villa and Veiga-Crespo 2013; Zengin and Baysal 2014), as well as the chemical constituents and functional groups contained in the essential oil, the proportions in which they are present and the interactions between them (Dorman and Deans 2000). Interactions between these components may lead to antagonistic, additive or synergistic effects. Some studies have showed that whole essential oils usually have a greater antibacterial activity than the major components mixed, suggesting that the minor components are critical to the synergistic activity, though antagonistic and additive effects have also been observed (Davidson and Parish 1989; Gill et al. 2002; Mourey and Canillac 2002).

13.5 Review of the Susceptibility of Ten Fungal Plant Pathogens to Different EOs

Dean et al. (2012) published the top ten fungal plant pathogen list, based on scientific/economic importance. The top ten list includes, in rank order, (1) *Magnaporthe oryzae*, (2) *Botrytis cinerea*, (3) *Puccinia* spp., (4) *Fusarium graminearum*, (5) *Fusarium oxysporum*, (6) *Blumeria graminis*, (7) *Mycosphaerella graminicola*, (8) *Colletotrichum* spp., (9) *Ustilago maydis* and (10) *Melampsora lini*.

13.5.1 *Magnaporthe oryzae*

Magnaporthe oryzae was inhibited by essential oils of *Gliomastix murorum* and *Pichia guilliermondii* at 0.84 mg/mL and 1.56 mg/mL, respectively (Zhao et al. 2009); methanol extract of *Myristica fragrans* Houttyn (nutmeg) seeds (Cho et al. 2007); hydro-distilled roots and rhizomes of two valerianaceous species, *Nardostachys chinensis* and *Valeriana officinalis* (Wang et al. 2010a); EOs of the leaves of *Ocimum gratissimum*, *Chromolaena odorata* and *Cymbopogon citratus*; seeds of *Eugenia aromatica* and *Piper guineense*; nuts of *Garcinia kola* (Olufolaji et al. 2015); *Corymbia citriodora* and *Cymbopogon nardus* essential oils (Aguiar et al. 2014); the essential oil of star anise (*Illicium verum* Hook. f.) fruit (Huang et al. 2010); EOs of *Callistemon lanceolatus* DC leaves at 3000 ppm (Misra et al. 1997); EOs from *Piper nigrum* at 500 ppm and *Coriandrum sativum* oils at 1000 ppm concentration (Sukanya et al. 2011); liquid extract of *Ruta graveolens* (Reis et al. 2015); the root bark essential oil of *Periploca sepium* Bunge (Asclepiadaceae/Apocynaceae) (Wang et al. 2010b); hydro-distilled essential oil from flowering shoots of *Tanacetum annuum* (Greche et al. 2000); and the aqueous extracts of processed *Coffee arabica*, *Nicotiana tabacum*, *Aloe vera* and *Chrysanthemum coccineum* (Hubert et al. 2015). Extracts of three different plants, evaluated by food poisoning method, had the following relative inhibitory effects on *Magnaporthe oryzae*: garlic (*Allium sativum* L.) > neem (*Azadirachta indica* L.) > *Calotropis* (*Calotropis procera* L.) (Jamal-U-Ddin et al. 2012).

13.5.2 *Botrytis cinerea*

Antifungal activity of essential oils or extracts on *Botrytis cinerea* has been reported by several researchers. In this regard, vapours of thyme, oregano and lemongrass and their respective major components showed complete growth inhibition of *Botrytis cinerea* as reported by Plotto et al. (2003). Also, Arrebola et al. (2010) indicated that thyme and lemongrass oils caused over 50 % and 25 % inhibition of radial mycelium growth in the presence of lemon and oregano essential oils at concentration of 17 µl/ml and 0.02 µl/ml, respectively (Vitoratos et al. 2013). Jaspers et al. (2001) reported that thyme oil at concentration of 0.33 % reduced significantly *B. cinerea* sporulation on artificially induced necrotic leaf lesion. In this respect,

Tzortzakis and Economakis (2007) reported that lemongrass oil at 25 ppm could inhibit *B. cinerea* spore production, and at 500 ppm, the highest oil concentration employed, fungal sporulation was completely inhibited. However, complete inhibition of *B. cinerea* to the black caraway and fennel oils at concentrations of 400 and 600 μLL^{-1}, respectively, in vivo and black caraway, fennel and peppermint oils at all applied concentrations in vivo on plum fruits has been shown (Aminifard and Mohammadi 2013). Daferera et al. (2003) observed that the growth of *B. cinerea* was completely inhibited by oregano, thyme, dictamnus and marjoram essential oils at relatively low concentrations (85–300 μg/ml). Moreover, Hammam et al. (2011) reported that *Viola odorata* L. essential oils exhibited strong antifungal activity against *B. cinerea* based on the inhibition zone and minimal inhibitory concentration values. Doğu and Zobar (2014) tested the antifungal effect of seven different plant essential oils and observed that thyme, mint and rosemary oils were found more effective to *B. cinerea*, but sage, grapeseed, ozone and basil oils showed varying effects. The effect of several essential oils on the growth of *B. cinerea* was investigated by Mohammadi et al. (2014) where this fungi was completely inhibited by the essential oil of black caraway at 400 μg l^{-1}. Recently, Şesan et al (2015) tested nine different plant extracts on *Botrytis cinerea* and found high inhibition of *Hyssopus officinalis* (at 20, 10 and 5 %), *Satureja hortensis*, *Allium sativum*, *Tagetes patula* (at 20 and 10 %) and *Mentha* (at 20 %), and a moderate anti-*Botrytis* activity (efficiency between 35.7 and 65.7 %) has been noticed for *Mentha* (at 10 and 5 %), *Satureja hortensis*, *Allium sativum* and *Tagetes patula* (at 5 %) extracts.

13.5.3 *Puccinia* spp.

To date very few researches have been conducted on the antifungal activities of the plant essential oils or extracts on the three *Puccinia* spp. which rust diseases occur on wheat (*Puccinia graminis* Pers. f. sp. *tritici* (*Pgt*), *Puccinia striiformis* f. sp. *tritici* (*Pst*) and *Puccinia triticina* Eriks (*Pt*)). Somaya and El-Sharkawy (2014) assayed the effect of chamomile, thyme, cumin, basil, eucalyptus and garlic essential oil on wheat rust disease at seeding and adult stage of two susceptible wheat cultivars (Morocco and Sids-1) under greenhouse and field conditions in 2013/2014 growing season and found that the addition of these essential oils decreased leaf rust severity (%), significantly, increased both spike weight (g), grains weight/spike (g) and 1000 kernel weight (g).

13.5.4 *Fusarium graminearum*

A variety of antifungal activities on *Fusarium graminearum* has been shown by *Eucalyptus camaldulensis* essential oils (Mehani et al. 2014); cinnamon, clary sage and marjoram essential oils (Gömöri et al. 2013); water-distilled EOs of mint (*Mentha spicata* var. *crispa* L.) and the commercially essential oil of cinnamon (*Cinnamomum verum*) (Aromax Ltd., Hungary) (Horváth et al. 2013); *Ocimum*

sanctum L. essential oil at 1250 µg/mL (minimum inhibitory concentration) and 1800 µg/mL (minimum fungicidal concentration) (Kalagatur et al. 2015); *Zataria multiflora*, *Satureja hortensis* essential oils, thymol and carvacrol at 16, 31.5, 70 and 15 µl/100 ml, respectively, in PDA media and at 16, 30, 70 and 20 µl/100 ml, respectively, in PDB media (Lahooji et al. 2010); oregano, cinnamon, lemongrass, clove and palmarosa essential oils at two concentrations (500 and 1000 mg kg^{-1}), at different water activity (aw) (0.95 and 0.995) and temperature (20 and 30 ° C) levels (Velluti et al. 2004); EOs from seed of asafoetida at 0.15 and 0.3 % (Mostafa et al. 2013); hydro-distilled aerial parts of *Echinophora platyloba* (Hashemi et al. 2016); *O. vulgare* essential oil (Marín et al. 2004); *Allium fistulosum* L., *Allium sativum* L. and *Allium cepa* L. oils (Benmeddour et al. 2015); rice, oat and wheat crude protein extracts (Pagnussatt et al. 2013); hydro-distilled *Artemisia afra*, *Conyza scabrida*, *Helichrysum foetidum*, *Leucosidea sericea*, *Mentha piperita* and *Pelargonium graveolens oils* (Samie and Nefefe 2012); *Mentha piperita* (peppermint) and *Salvia officinalis* L. (sage) oils (Tomescu et al. 2015); essential oil of *Artemisia sieberi* Besser (Amir et al. 2013); hydro-distilled of *Zataria multiflora*, *Thymus vulgaris* and *Thymus kotschyanus* (Amini et al. 2012); *Thymus vulgaris*, *Satureja hortensis*, *Anethum graveolens*, *Mentha sativa* and *Capsicum annuum* essential oils (Hoseiniyeh et al. 2012); and pure eugenol and carvacrol and clove EO (Cardiet et al. 2012).

13.5.5 *Fusarium oxysporum*

A significant antifungal effect was observed with *Cinnamomum zeylanicum*, *Thymus vulgaris* and *Syzygium aromaticum* oils which had a total inhibition at 100, 150, 200, 250 and 300 ppm. *Teloxys ambrosioides*, *Mentha piperita* and *Citrus aurantifolia* oils exhibited a dose-dependent inhibition on mycelial growth of *Fusarium oxysporum* to increase the dose of 100 at 300 ppm (Barrera-Necha et al. 2009). In another study, the volatile essential oils of *Cinnamomum zeylanicum* and *Syzygium aromaticum* showed good effects in controlling the Panama disease caused by *Fusarium oxysporum* f. sp. *cubense* in both 1000 and 2000 ppm (Monteiro et al. 2013).

Istianto and Emilda (2011) studied the inhibitory effect of *Cymbopogon nardus*, *Eugenia aromatica*, *Pogostemon cablin* and *Vitiveria zizanoides* essential oils on the mycelial growth of *Fusarium oxysporum* f. sp. *cubense* (*Foc*), and the results showed that *E. aromatica* oil provided the strongest suppression of *Foc* mycelial growth, mainly when used at a volume of 9 and 18 µl. Lima et al (2010) studied the growth and survival of *Fusarium oxysporum* S. and *Thanatephorus cucumeris* F. in the presence of essential oil from leaves of *Hedychium coronarium*, which showed inhibitory effect on the in vitro growth of *F. oxysporum.* Arango et al. (2011) reported the fungicide effect of *Eucalyptus tereticornis* essential oil on the pathogenic fungus *Fusarium oxysporum.* Guzmán-Guzmán et al. (2003) analysed the inhibitory effect of various concentrations of mint, eucalyptus, laurel, clove, sweet marjoram, rosemary, origanum, thyme, cinnamon, pepper and grapefruit essential

oils (1,250, 2,500 and 3,750 ppm) on the growth of *Fusarium oxysporum* f. sp. *phaseoli* and reported that it is possible to control *Fusarium oxysporum* f. sp. *phaseoli* with essential oils. Manganyi (2013) and Manganyi et al. (2015) also noticed that clove and thyme essential oils inhibited the mycelial growth of *Fusarium oxysporum.* Recently, a study carried out by La Torre et al.(2016) analysed the action of clove oil, thyme oil, rosemary oil and their major components in controlling *Fusarium* wilt in tomato, which showed that the clove oil and its major component eugenol were the most effective, while rosemary oil gives the lowest inhibitory activity on *Fusarium oxysporum* f. sp. *lycopersici*.

13.5.6 *Blumeria graminis*

The effects of plant extracts on *Blumeria graminis* have been studied by a very large number of researchers in different parts of the world. Haugaard et al. (2002) reported that the whole-plant bioassays for testing possible effects of mycelial extract from *Bipolaris oryzae*, *Pythium ultimum* and *Rhizopus stolonifer* showed that the mycelial extracts strongly reduced the numbers of *Blumeria graminis* colonies formed on the leaves and that the few colonies that developed appeared small and with reduced conidial production. Terzi et al. (2007) observed the inhibitory action of *Melaleuca alternifolia* essential oil and its principal components (terpinen-4-ol, γ-terpinen and 1,8-cineole). Terpinen-4-ol was the most effective. Hafez (2008) tested the antifungal effect of black seed (*Nigella sativa*) oil, rapeseed (*Brassica napus*) oil and paraffin oil and observed great reduction of the disease severity of barley powdery mildew (*Blumeria graminis* f. sp. *hordei*) from 63.4 % (control) to 9.4 % (black seed oil), 16 % (rapeseed oil) and 16.4 % (paraffin oil). The results obtained after the treatment of infected barley (*Blumeria graminis*) leaves with different concentrations of *Artemisia herba-alba* essential oil (0.25 and 0.5 % of oil) showed that this essential oil had a strong toxic effect against the hyphal growth and spore germination (Morcia et al. 2015). Recently, Věchet and Šerá (2015) analysed the antifungal activity of extracts from plants (oak, giant knotweed, curcuma and ginger) on powdery mildew (*Blumeria graminis* f. sp. *tritici*) attack on winter wheat and found that the two plant extracts, giant knotweed (*Polygonum sachalinense*) and turmeric spice (curcuma, *C. longa*), showed the best results.

13.5.7 *Mycosphaerella graminicola*

Recently, in a study by Matusinsky et al.(2015), the antifungal activity of essential oils extracted from *Pimpinella anisum*, *Thymus vulgaris*, *Pelargonium odoratissimum*, *Rosmarinus officinalis* and *Foeniculum vulgare* against five fungi, including *M. graminicola*, was studied using agar dilution method. All essential oils used in this experiment affected the growth of these fungi. Ultimately, the best antifungal activity (on the basis of inhibitory effect) was demonstrated by *Thymus vulgaris*. A screening of the level of inhibitory activity of essential oils from aerial parts of

Acantholippia deserticola, *Artemisia proceriformis*, *Achillea micrantha* and *Libanotis buchtormensis* tested by Sampietro et al. (2015) on *M. graminicola* showed a moderate antimicrobial activity of *A. deserticola*, *A. micrantha* and *L. buchtormensis* oils on these phytopathogenic fungi with MIC_{100} ranged between 0.5 and 1.5 mg/ml. Scher et al. (2004) showed also antifungal activity of the dichloromethane and a methanol extract of liverwort *Bazzania trilobata* against *M. graminicola*. Deweer et al.(2013) reported that dill seed essential oils used crude or with DMSO are more efficient on S6 – sensitive strain of *Zymoseptoria tritici* (teleomorph: *M. graminicola*) – at 350 mg/L than on R1187, resistant strain, at 1000 mg/L but with Tween 80; the essential oil effectiveness is the same on both strains (300 mg/L).

13.5.8 *Colletotrichum* spp.

Colletotrichum is one of the most common and important genera of plant pathogenic fungi. Virtually every crop grown throughout the world is susceptible to one or more species of *Colletotrichum.* Many essential oils have been reported as effective compounds against *Colletotrichum* sp.: the oil isolated by hydrodistillation of basil, rosemary and cinnamon on *C. musae* isolated from banana (Idris et al. 2015); hydro-distilled essential oils of *Zanthoxylum monophyllum Z. rhoifolium* and *Z. fagara* oils on *Colletotrichum acutatum* (Prieto et al. 2011); oregano and thyme essential oils, among 56 EOs investigated on *C. acutatum* and *C. gloeosporioides* (Grahovac et al. 2012); crude extracts of *Acorus calamus* L., *Stemona curtisii* HK.f., *Stemona tuberose* L., *Memmea siamensis* Kost, *Eugenia caryophyllus* and an eugenol essential oil (Thobunluepop et al. 2009); and *Amomum cardamomum*, *Asarum sieboldii*, *Illicium verum*, *Juniperus chinensis*, *Myristica fragrans* and *Schizonepeta tenuifolia* oils on *C. gloeosporioides* (Sun et al. 2007).

13.5.9 *Ustilago maydis*

Steam distillate from leaves of *Cymbopogon citratus* completely inhibited the growth of *U. maydis*, and hot water extracts from fresh leaves of *Ocimum gratissimum* and *Chromolaena odorata* and dry fruits of *Xylopia aethiopica* reduced radial growth by 37–57 %. A hot water extract from dry fruits of *Monodora myristica* was ineffective as a fungi toxicant (Awuah 1989). Maize oil was more effective against *Ustilago maydis* followed by soybean and sunflower oils in controlling the disease (Moursy et al. 2001). The plant oils of eucalyptus, clove, cinnamon, peppermint and anise at 750 and 1000 ppm and clove and anise oils only at 500 ppm caused 100 % inhibition of the in vitro *Ustilago maydis* growth (El-Fiki et al. 2003).

13.5.10 *Melampsora lini*

Melampsora lini (Ehrenb.) Desm., the fungal pathogen responsible for rust disease on flax and linseed (*Linum usitatissimum* L.), is of interest for both economic and scientific reasons. It can cause severe losses in seed yield as well as reducing fibre quality in flax plants grown for linen production (Lawrence et al. 2007).

In my research in literature, I have not found any work on the antifungal activity of essential oils on this fungus, which constitutes a very important field of research to discover natural antifungal components against this species.

13.6 Review of the Susceptibility of Ten Bacterial Plant Pathogens to Different EOs

The top bacterial species have been listed based on their scientific and economic importance in plant disease: (1) *Pseudomonas syringae* pathovars, (2) *Ralstonia solanacearum*, (3) *Agrobacterium tumefaciens*, (4) *Xanthomonas oryzae* pv. *oryzae*, (5) *X. campestris* pathovars, (6) *X. axonopodis* pathovars, (7) *Erwinia amylovora*, (8) *Xylella fastidiosa*, (9) *Dickeya* (former *Erwinia*) (*dadantii* and *solani*) and (10) *Pectobacterium* (former *Erwinia*) carotovorum (and *Pectobacterium atrosepticum*) (Mansfield et al. 2012).

13.6.1 *Pseudomonas syringae*

A large number of investigations have been performed on the antifungal activities of essential oils against *Pseudomonas syringae* pv. Kokoskova et al. (2011) examined the antimicrobial effects of five aromatic herb species of the family Lamiaceae against plant pathogenic (*Erwinia amylovora* and *Pseudomonas syringae* pv. *syringae*) and saprophytic (*Pseudomonas fluorescens*, *Pantoea dispersa* and *P. agglomerans*). Plant essential oils from *M. officinalis* and *M. arvensis* were significantly more effective against *P. syringae* pv. *syringae.* The steam-distilled essential oils from oregano, sweet flag, caraway, peppermint, common, fern leaf and willow-leaved yarrow field accessions were investigated against the growth of phytopathogenic bacteria, *Erwinia carotovora* subsp. *carotovora*, *Xanthomonas vesicatoria*, *Pseudomonas marginalis* pv. *marginalis*, *P. syringae* pv. *syringae*, *P. syringae* pv. *tomato* and *Bacillus* sp. by Vasinauskienė et al. (2006). *P. syringae* pv. *syringae* was sensitive to oregano and willow-leaved yarrow essential oils. Poswal and Witbooi (2012) evaluated essential oils of *Artemisia afra*, *Eriocephalus punctulatus*, *Mentha piperita*, *Lavandula angustifolia* and *Lippia javanica* on the growth of *Pseudomonas syringae* pv. *syringae*. Essential oils from *L. angustifolia* and *A. afra* (indigenous to South Africa) were the most effective in inhibiting the growth of *P. syringae* pv. *syringae.* Antifungal properties (IŞcan et al. 2002) of the *Mentha piperita* oils were also investigated against 21 human and plant pathogenic microorganisms. Peppermint oils showed stronger inhibition (MIC 0.07–2.5 mg mL^{-1}) against

Pseudomonas syringae pv. *phaseolicola*, *P. syringae* pv. *tomato* and *Pseudomonas syringae* pv. *syringae*. Essential oils extracted by hydrodistillation from fruits of *Cuminum cyminum* L. and *Carum carvi* L. were also investigated on Gram-positive and Gram-negative bacteria. Among them, *P. syringae* pv. *phaseolicola*, *P. syringae* pv. *pisi*, *P. syringae* pv. *syringae*, *P. syringae* pv. *aptata*, *P. syringae* pv. *apii*, *P. syringae* pv. *atrofaciens*, *P. syringae* pv. *lachrymans*, *P. syringae* pv. *maculicola*, *P. syringae* pv. *tomato* and *P. syringae* pv. *glycinea* were sensitive (MIQ 910–7360 (μg)) (Iacobellis et al. 2005). Similar activity was also verified on the same organisms for essential oils that were extracted from fruits of *Coriandrum sativum* L. and *Foeniculum vulgare* Miller. *C. sativum* oil inhibits *P. syringae* pv. *phaseolicola*, *P. syringae* pv. *pisi*, *P. syringae* pv. *syringae*, *P. syringae* pv. *aptata*, *P. syringae* pv. *atrofaciens*, *P. syringae* pv. *maculicola*, *P. syringae* pv. *tomato* and *P. syringae* pv. *glycinea*, but *F. vulgare* oil inhibits only *P. syringae* pv. *atrofaciens* and *P. syringae* pv. *glycinea* (Cantore et al. 2004). Karaman et al. (2003) reported low inhibition of *Juniperus oxycedrus* extracts *Pseudomonas syringae* pvs. (8–10 mm). In recent screening study, Gormez et al. (2015) evaluated antibacterial activities of *Satureja hortensis* and *Calamintha nepeta* oils against 20 phytopathogenic bacteria causing serious crop loss. *C. nepeta* oil was most active on *P. syringae* pv. *syringae*, *P. syringae* pv. *phaseolicola*, *P. syringae* pv. *pisi*, *P. syringae* pv. *tabaci* and *P. syringae* pv. tomato.

13.6.2 *Ralstonia solanacearum*

Many plant EOs have demonstrated antibacterial activity against *Ralstonia solanacearum*. The efficacy of thymol, palmarosa oil and lemongrass oil against *R. solanacearum* was investigated by Pradhanang et al. (2003). The results showed that the tomato seedlings transplanted in soil treated with 700 mg/l of thymol, palmarosa oil and lemongrass oil were free from bacterial wilt, and 100 % of plants in thymol treatments were free of *R. solanacearum.* Huang and Laksman (2010) observed antibacterial activity of clove oil against seven different species of plant pathogenic bacteria. Both Gram-positive and Gram-negative bacteria tested were sensitive to clove essential oil (0.1 and 0.5 %), *R. solanacearum* being the most sensitive one. In another investigation performed by Paret et al. (2010), palmarosa (*Cymbopogon martini*), lemongrass (*C. citratus*) and eucalyptus (*Eucalyptus globulus*) oils evaluated for their efficacy against *R. solanacearum.* The experiments revealed that 0.04 % of palmarosa and lemongrass oils reduced the growth of the bacterium compared with control, and at 0.07 and 0.14 %, they showed complete inhibition of bacterial growth. However, eucalyptus oil treatments at 0.04 and 0.07 % had bacteriostatic effects on the cells. Wagura et al. (2011) reported that extract and essential oils derived from leaves of *Ocimum gratissimum* at concentration of 0.4, 0.2, 0.1, 0.05 and 0.025 mg ml^{-1} exhibited highly significant ($p < 0.0001$) differences on their effects against the growth of *R. solanacearum*, the causal agent of bacterial wilt of potato. Nezhad et al. (2012) reported on the antibacterial potential

of essential oils of *Coriandrum sativum*, *Thymus vulgaris*, *Cumimum cymimum*, *Rosmarinus officinalis* and *Eucalyptus globulus* against *Pectobacterium carotovorum*, *Ralstonia solanacearum* and *Escherichia coli*. Results showed that the most active essential oils against tested bacteria were thyme oil with the inhibition zone of 34.8 mm against *R. solanacearum* and the MIC of 1 µl/ml. In another experiment reported by Hosseinzadeh et al. (2013), antibacterial activity of essential oil from *Cinnamomum zeylanicum*, *Thymus vulgaris*, *Lavandula angustifolia* and *Eucalyptus camaldulensis* was also tested against *R. solanacearum*. The results of in vitro assay indicated that the sub-bactericidal concentrations of essential oils applied in this study suppressed *R. solanacearum* pathogenicity and virulence factors. Oboo et al. (2014a) investigated the antibacterial activity of *Rosmarinus officinalis*, *Ocimum suave*, *Tarchonanthus camphorates*, *Lantana trifolia*, *Lippia javanica* and *Lippia ukambensis* oil against *R. solanacearum*. Results demonstrated that essential oils extracted from *O. suave*, *L. javanica* and *T. camphorates* possess antibacterial activity that is effective in the control of *R. solanacearum* at 24 °C, 28 °C and 32 °C. The inhibitory effect of essential oil from *Lippia javanica*, *Ocimum suave* and *Tarchonanthus camphoratus* against *R. solanacearum* was investigated by the same team (Oboo et al. 2014b). Treatment with the three plants, *T. camphorates*, *L. javanica* and *O. suave*, reduced the bacterial wilt disease caused by *R. solanacearum* by 38, 21 % and more than 90 %, respectively. Alamshahi and Nezhad (2015) evaluated the antibacterial effects of the essential oils extracted from *Coriandrum sativum*, *Cuminum cyminum*, *Rosmarinus officinalis* and *Eucalyptus globulus* against *R. solanacearum.* Of all the essential oils tested, the treatment by thyme essential oil caused significant reduction in bacterial wilt incidence on potato by 44 %. The antibacterial activity of essential oil from the leaves of *Macleaya cordata* was evaluated for the effect on the growth of several pathogens (Li and Yu 2015). The results showed that bacteria had different sensitivities to essential oil of *M. cordata* with diameters of inhibition zones ranging from 8.5± 0.6 to 18.6± 1.9 mm and MIC values from 125 to 500 µg/ml. Among these bacteria, *R. solanacearum* was the most sensitive to essential oil. Screening for antibacterial oils was done on nine essential plant oils, *viz.* spearmint (*Spearmint viridis*), neem (*Azadirachta indica*), marigold (*Tagetes erecta*), castor (*Ricinus communis*), calamus (*Acorus calamus*), olive (*Olea europaea*), turpentine (*Syncarpia glomulifera*), eucalyptus (*Eucalyptus macrorhyncha*) and garlic (*Allium sativum*), against growth of tomato, brinjal and capsicum isolates of *Ralstonia solanacearum* (Sood and Pardeep 2015). Neem oil was found most effective to all the three isolates of *R. solanacearum* followed by eucalyptus oil and spearmint oil.

13.6.3 *Agrobacterium tumefaciens*

Agrobacterium tumefaciens was inhibited by *Thymbra spicata* essential oil with MBC of 328 mg/ml (Basim et al. 2000); cinnamon, clove, chenopodium, caraway, rosemary and thyme oils and their constituents thymol, chlorothymol and carvacrol

(El-Zemity et al. 2008); *Heracleum persicum* oils and extracts and essential oils of *Cinnamomum zeylanicum* with MIC ranged between 0.2 and 50 mg/mL (Noudeh et al. 2010); and leaves essential oils of *Syzygium cumini* L. (12 mm, MIC< 250 µg/mL) and *Cupressus sempervirens* L. (8 mm, MIC 500 µg/mL) (Elansary et al. 2012).

13.6.4 *Xanthomonas oryzae*

A variety of antimicrobial effects on *Xanthomonas oryzae* has been shown by leaf extract of *Datura metel* (Kagade et al. 2004); *Cymbopogon citratus*, *Monodora myristica*, *Ocimum gratissimum*, *Thymus vulgaris* and *Zingiber officinale* oils (Nguefack et al. 2005); essential oil of *Metasequoia glyptostroboides* at 125 µg/ml concentration (Bajpai et al. 2010a) and *Cleistocalyx operculatus* at 62.5 µg/ml at 62.5 µg/ml concentration (Bajpai et al. 2010b); essential oil and compounds of limonin and imperatorin or *Poncirus trifoliata* (Rahman et al. 2014); essential oil of *Ocimum ciliatum* Hornem (Moghaddam et al. 2014); essential oil of neem and lemon (Singh et al. 2015); garlic bulb (*Allium sativum*), tamarind fruit (*Tamarindus indica*), gooseberry fruit (*Phyllanthus emblica*), green mango (*Mangifera indica*) and lemon juice (*Citrus aurantifolia*) extracts; and palmarosa (*Cymbopogon martinii*) lemongrass (*Cymbopogon flexuosus*), cinnamon (*Cinnamomum zeylanicum*) and vetiver (*Chrysopogon zizanioides*) oils (Raji et al. 2016).

13.6.5 *Xanthomonas campestris*

The below components have been reported as effective compounds against *Xanthomonas campestris*: *Mentha citrata* essential oils at 10^{-1} dilution (Maiti et al. 1985), herb and seed essential oils of *Coriandrum sativum* L. (Minija and Thoppil 2001), coriander and hyssop essential oil (Kizil et al. 2005), eugenol (Cantore et al. 2009), hydro-distilled essential oil of seeds of *Citrullus colocynthis* (Mehr et al. 2012) and *Cinnamomum cassia*, *Cinnamomum zeylanicum*, *Syzygium aromaticum*, *Thymus vulgaris*, *Laurus nobilis*, *Salvia sclarea*, *Boswellia carterii*, *Rosmarinus officinalis*, *Ocimum basilicum*, *Calendula officinalis* and *Cassia tora* essential oils (Chudasama and Thaker 2012).

13.6.6 *Xanthomonas axonopodis*

Thymbra spicata essential oils were bactericide at 323 mg/ml on *Xanthomonas axonopodis* pv. *vesicatoria* (Basim et al. 2000). *Mentha arvensis* and *Ocimum sanctum* oils showed the highest inhibition zone (17 and 12 mm, respectively) against *Xanthomonas axonopodis* pv. *malvacearum* (Thakare et al. 2003). The essential oil of *Rosa damascena* petals had inhibitory effect against *Xanthomonas axonopodis* spp. *vesicatoria* (Basim and Basim 2003). The pure carvacrol and thymol showed the highest inhibition zone (85 mm), and MIC value was 3.125 µl/ml on *X.*

axonopodis. Also, *Thymus canoviridis*, *Satureja hortensis*, *Melissa officinalis inodora*, *Helichrysum plicatum*, *Thymus haussknechtii*, *Thymus sipyleus* and *Thymus sipyleus rosulans* essential oils were the most active on *X. axonopodis* showing an inhibition zone of 22–46.3 mm and a MIC of 25–200 µl/ml (Kotan et al. 2007). Hydro-distilled essential oils from *Origanum acutidens*, *O. rotundifolium* and *O. vulgare* showed a wide spectrum of antibacterial activity on *X. axonopodis* pathovars (*malvacearum, vesicatoria, campestris, vitians and pelargoni*). It was also shown that carvacrol, thymol and other main components such as terpinen-4-ol and linalool possess antimicrobial activity (Dadasoglu et al. 2011). Leaf solvent (methanolic, ethanolic, petroleum ether and water) extracts of *Juniperus communis* L. and *Vitex negundo* show inhibitory effect on linear growth of *Xanthomonas axonopodis* pv. *punicae*.

Among these plant extracts, methanolic and ethanolic extracts at 300 ppm were more effective than that of other extracts for both plants (Digvijay et al. 2014). *Satureja hortensis* and *Calamintha nepeta* oils showed a strong antimicrobial effect against *Xanthomonas axonopodis* pv. *campestris* (Gormez et al. 2015).

13.6.7 *Erwinia amylovora*

It has been shown that *Erwinia amylovora* is sensitive to essential oils from *Melissa officinalis*, *Mentha arvensis*, *Origanum compactum*, *O. vulgare*, *Thymus vulgaris*, *Eugenia caryophyllata*, *Mentha pulegium* and *Nepeta cataria* (Kokoškova and Pavela 2007); *Citrus maxima* essential oil (Măruţescu et al. 2009); *Satureja montana* spp. *montana* L. (inhibition zone 25 mm) and *S. adamovici* (MIC= MBC= 0.09 µlml^{-1}) essential oils (Mihajilov-Krstev et al. 2010); *Satureja hortensis* L. and *Thymus vulgaris* L. essential oils and their major constituents thymol and carvacrol (Karami-Osboo et al. 2010); *Thymus vulgaris*, *Origanum compactum*, *Origanum vulgare*, *Nepeta cataria*, *Mentha arvensis* and *Mellissa officinalis* essential oils (Kokoskova et al. 2011); *Pelargonium odoratissimum*, *Salvia officinalis* and *Tagetes patula* oils (Chiriac and Ulea 2012); and sage and clove oils (Mikiciński et al. 2012).

13.6.8 *Xylella fastidiosa*

Ribeiro et al.(2008) investigated the antibacterial activity of a number of flavonoids, coumarins, alkaloids, dihydrocinnamic acid derivative, anacardic acid, triterpenes and limonoids on the growth of *Xylella fastidiosa*. Their experiments showed that sesquiterpenoid components were more effective than monoterpenoid components of the leaf oil. These results revealed that azadirachtin A was the most active and hesperidin showed a moderate activity. Screening of essential oil from 17 plant species against *Xylella fastidiosa* causing citrus variegated chlorosis (CVC) disease was carried by Massuco et al. (2013)). The essential oil of sandal proved bactericidal on *Xylella fastidiosa* at 125 µg/mL concentration followed by the oil of *Salvia sclarea*, cinnamon, cedar, patchouli and myrrh with concentrations ranged between

250 µg/mL and 500 µg/mL. The inhibitory effect of 12 phenolic compounds, representing phenolic acid, coumarin, stilbene and flavonoid, against *Xylella fastidiosa* was investigated by Maddox et al. (2010). They found that catechol, caffeic acid and resveratrol showed strong anti-*Xylela* activities.

13.6.9 *Dickeya* (*dadantii and solani*)

Several studies have demonstrated antimicrobial activity of essential oils against *Dickeya* spp. (*dadantii* and *solani*). Stefanova et al. (2005) found that *Erwinia chrysanthemi* is sensitive to the extracts of the two oregano species (*Hyptis suaveolens* and *Coleus amboinicus*) at 1 %, with inhibition areas of 20.6 mm. *Artemisia santonicum* and *Artemisia spicigera* essential oils showed a weak activity on *E. chrysanthemi* (Kordali et al. 2005). Sqalli et al. (2009) have reported the inhibition of *Erwinia chrysanthemi* (*Dickeya dadantii*) by the aqueous and ethanolic extracts and the essential oil of *Thymus pallidus* Batt. Paradza et al. (2012) demonstrated that the botanical extract of neem (*Azadirachta indica* A. Juss.) leaf and garlic (*Allium sativum* L.) inhibited the growth of *Dickeya dadantii* at concentration of 10 and 25 % (w/v). Among 100 plant essential oils tested for their antibacterial activity on *E. chrysanthemi*, *Cinnamomum cassia*, *Cinnamomum zeylanicum* and *Citrus bigaradia*, EOs were very active on these phytopathogenic bacteria (Chudasama and Thaker 2012). Ethanol and methanol extracts of *Juniperus squamata* were found effective by showing a mark zone of inhibition, MIC and MBC on *Erwinia chrysanthemi* (21 mm, 31.25 µg/ml and 125 µg/ml for ethanol extract) (16 mm, 250 µg/ml and 500 µg/ml for methanol extract) (Sati and Kumar 2015). In another research, Sati et al (2015) reported that *Berberis aristata*, *Chenopodium ambrosioides* and *Tinospora cordifolia* extract displayed a weak antibacterial activity on *E. chrysanthemi.* Essential oils from *Eugenia caryophyllata*, *Lavandula angustifolia*, *L. latifolia*, *Melaleuca quinquenervia*, *Melissa officinalis*, *Mentha pulegium*, *Origanum majorana*, *Pelargonium graveolens*, *P. roseum*, *Rosmarinus officinalis*, *Salvia officinalis*, *Thuja occidentalis* and *Thymus mastichina* (Kokošková and Pavela 2005), essential oil from *Salvia mukerjeei* (Mohan et al. 2011) and essential oil from *Thymus bleicherianus*, *Thymus algeriensis* and *Thymus zygis* (Zayyad et al. 2014) were active against *E. chrysanthemi*. Recently, Sledz et al (2015) have investigated the effect of caffeine *Dickeya solani* and found 18.3 mM as MIC and 80.0 mM as MBC.

13.6.10 *Pectobacterium carotovorum* (and *Pectobacterium atrosepticum*)

Essential oils of many medicinal plants have been used for evaluation of their antibacterial on *Pectobacterium carotovorum* and *Pectobacterium atrosepticum* by many workers. The antibacterial activity of the aqueous extracts of 20 plants against

Erwinia carotovora subsp. *carotovora* syn. *Pectobacterium carotovorum* subsp. *carotovorum* was studied by (Bhardwaj and Laura 2008). The strongest inhibitory effect was of the leaf extracts of *Camellia sinensis* and bark extracts of *Acacia arabica* and *Acacia catechu.* The inhibitory effect against tested bacteria was also shown by leaf extracts of *Azadirachta indica*, root extracts of *Asparagus racemosus*, seed extracts of *Acacia farnesiana* and fruit extracts of *Aegle marmelos.*

The extract of neem (*Azadirachta indica A. Juss*) leaf and garlic (*Allium sativum* L.) cloves inhibited *Pectobacterium atrosepticum* at a concentration of 10 and 25 % (w/v) (Paradza et al. 2012). Recently, Ikeura and Kobayashi (2015) reported that essential oils of coriander (*Coriandrum sativum* L.) inhibited 40.94 % of *P. carotovorum.*

Acetone extracts of *Olea europaea* L. leaves and methanol extracts of *Salvia officinalis* and *Olea europaea* L. leaves with 400 mg/ml (Zaidi-Yahiaoui et al. 2008), essential oil of *Cymbopogon citratus* (Jeong et al. 2009) and the extracts of *Artemisia kermanensis*, *Lavandula officinalis*, *Rosmarinus officinalis* and *Eucalyptus caesia* are reported to have inhibitory effect on *Pectobacterium carotovorum* (Mehrorosh et al. 2014). Thyme oil (Rojas Fernández et al. 2014; Alamshahi and Nezhad 2015) was active against *P. carotovorum*. In another study, the hydrodistilled essential oils of *Coriandrum sativum*, *Thymus vulgaris*, *Cuminum cyminum*, *Rosmarinus officinalis* and *Eucalyptus globulus* showed a weak antibacterial activity on *P. carotovorum* at high concentrations (Nezhad et al. 2012).

The inhibitory effect of caffeine against *P. atrosepticum* and *P. carotovorum* was investigated by Sledz et al. (2015). They found that caffeine was able to significantly inhibit bacterial growth. The MIC and MBC values for growth inhibition were 8.7 and 100.0 mM for *P. atrosepticum* and 9.0 and 100.0 mM for *P. carotovorum*.

13.7 Conclusion

Different studies have demonstrated the effectiveness of essential oils or their active compounds on a range of plant pathogenic bacteria and fungi responsible for pre- and postharvest diseases. Also, because of the increasing demand for effective, safe, natural products, quantitative data on plant oils and extracts and the resurgence of interest in natural control of plant infectious bacterial and fungal pathogens are required and could lead to a new antimicrobial agent, which could support the use of the plant to treat various infective diseases. Nonetheless, plant essential oils have several important benefits; they are superior for disease control, effective at very low dosages of even less than one gallon per acre, excellent in spreading and sticking properties on leaf surfaces and at low cost and have little or no toxicity to man and animals and have much lower level of risk to the environment than with current synthetic pesticides.

Halophilic Bacteria: Potential Bioinoculants for Sustainable Agriculture and Environment Management Under Salt Stress

14

Anjney Sharma, Anukool Vaishnav, Hena Jamali, Anchal Kumar Srivastava, Anil Kumar Saxena, and Alok Kumar Srivastava

Abstract

Salinity is one of the most critical environmental constraints which cause soil degradation and hampering agricultural production throughout the world. In the present time, a total 831 million hectares of land is affected by salinity. The salinity affects the processes in plant life from its germination to maturation stage. Regulation of phytohormones, root/shoot development, nutrient uptake, and photosynthesis are severely affected by salt stress and ultimately reduce agricultural productions. The loss of agriculture production due to salinization is one of the major constraints to feed to the growing population. High salt levels in the soil limit its agroecological potential and represent a considerable ecological and socioeconomic threat to sustainable development. In this context, the use of halophilic bacteria has been gained a great interest in eco-friendly and sustainable agriculture approach with emphasis on plant growth promotion in salt stress. This chapter paid attention to the use of halophilic bacteria in agriculture system toward producing salt stress-tolerant crops and an understanding the mechanisms of plant and halophilic bacterial interaction. Halophilic bacteria help plants to cope with salinity by supporting them in the restoration of essential activities such as nutrient uptake efficiency, ROS scavenging, and phytohormone production. The second part of this chapter describes different enzymatic potentials of halophilic bacteria and their uses in food processing, industrial bioconversions,

and bioremediation. After that, a brief outline of characterization of halophilic bacteria by phenotypic, biochemical, chemotaxonomy, and molecular methods is discussed. The exploitation of halophilic bacteria in agriculture is required for environment and human welfare.

14.1 Introduction

A major challenge for present agriculture is to cope with the increasing demand for food production for constantly rising world population. This increasing demand for food production is paralleled by continuous losses of arable land due to enhanced soil destruction and erosion. Soil salinity is one of the most critical environmental constraints that affect more than 831 Mha of land throughout the world equating to more than 6 % of the world's total land (FAO 2015) and hampering plant growth and development. Salinity not only decreases the agricultural crop production but also affects the associated ecological balance of the area by changing soil physicochemical properties. The negative impacts of soil salinity include low agricultural crop production and low economic returns due to high cost of cultivation, reclamation, and management. High salt levels in the agriculture soil limit its agroecological potential and represent a considerable socioeconomic and ecological threat to sustainable development. Different region-wise distributions (world level) of salt-affected soil are presented in Table 14.1.

Accumulation of salts over long periods of time in arid and semiarid zones is the main factor behind development of the salt-affected land (Bui 2013). Recent report of ICAR-Central Soil Salinity Research Institute (2012) exhibits that India covers 1.7 Mha saline, 3.8 Mha sodic–saline, and 1.2 Mha coastal saline soil, i.e., a total of 6.7 Mha area of the country is saline (Fig. 14.1 and Table 14.2).

Soil salinity is the concentration of dissolved different mineral salts present in the soils and waters, in which the electrical conductivity (EC) of the saturation extract (ECe) in the root zone exceeds >4 dS m^{-1} (40 mM NaCl approximately) at 25 °C and has exchangeable sodium of 15 %. The dissolved mineral salts consist of

the electrolytes of major cations (Na^+, Ca^{2+}, Mg^{2+}, and K^+) and major anions (Cl^-, SO_4^{2-}, HCO^{3-},CO_3^{2-}, and NO_3^-). Excess of these salts in the soil solution adversely affects every aspect of plant physiology and metabolisms through osmotic stress in an early growth phase and ionic stress at later growth stage (Rojas-Tapias et al. 2012). The physiological processes affected by salt acclimation include ionic toxicity, osmotic stress, nutrient deficiency, and changes in oxygen-scavenging enzymes (Munns and Tester 2008; Daneshmand et al. 2009). Specific ion effects cause direct toxicity, or, alternatively, the competitive absorption or insolubility of ions may affect the plant's metabolisms by nutritional imbalance. Under salt stress conditions, excessive uptake of Na^+ results in a drastic decline in K^+ uptake. This is because Na^+ ions compete with K^+ for binding sites essential for various cellular functions (Rus et al. 2001). Potassium ion is involved in activation of enzymes, stomatal movements, and protein synthesis (Wang et al. 2013; Ahmad et al. 2014). Higher salinity reduces the K^+/Na^+ ratio, disturbs ionic balance of the cytoplasm, and ultimately affects plant growth and productivity.

The salinity stress constraint is most acute for agriculture and developing countries like India. A sustainable management practice is a major challenge for successful remediation of salt-degraded areas. In addition, sustainable management practices in agriculture are one of the potentially important factors to meet our future agricultural needs, something that conventional agriculture will not be able to do. Synthetic fertilizers, development of genetically modified and salinity-tolerant varieties, resource management practices, etc. are cost-intensive and give negative effects on human and environment. Recently, the use of halophilic beneficial microorganisms gained interest in eco-friendly and sustainable agriculture (Paul and Lade 2014), which can help crops to cope with salinity stress. Since microorganisms are an integral part of any ecosystem, interest has been renewed in the nature and properties of microbes that play a major role in nutrient cycling in salt ecosystems. The ability of halotolerant bacteria to grow in a broad range of NaCl (0–33 %) makes them one of the suitable organisms for its interaction with plants under saline condition (Oren 2008). Hence, it was hypothesized that the bacteria with PGP activities from naturally saline habitats could help to ameliorate saline stress effect on plants.

The mechanism for growth and survival of halophilic bacteria in environments with elevated osmolarity has been studied well (Grover et al. 2011). The members of *Halobacteraceae* normally posses the compatibility of high salt concentrations within the cell cytoplasm because of extensive structural and enzymatic modifications. Whereas, other prokaryotes have evolved the mechanism to accumulate a

specific group of molecules of low molecular mass, termed compatible solutes, as a general mechanism to cope with environments of elevated osmolarity. They balance the external osmolarity with high intracellular concentrations of these osmolytes and protect cellular processes (Sleator and Hill 2001). The role of these microorganisms is well reported in plant growth promotion, nutrient management, and disease control (Dodd and Pérez-Alfocea 2012). The rhizobacteria play a significant role in stress alleviation in the crops grown in saline soils due to their unique properties of tolerance to extremities, their interaction with crop plants, and their potential deployment methods. Several recent studies have demonstrated that these beneficial halotolerant bacteria colonize the rhizosphere/endorhizosphere of plants and promote plant growth and ameliorate the salinity stress in crop plants through various direct and indirect mechanisms such as phosphate solubilization, secretion of various phytohormones, and production of antioxidant enzymes and siderophores (Alizadeh and Parsaeimehr 2011; Chakraborty et al. 2011; Kohler et al. 2009). Furthermore, the halotolerant plant growth-promoting bacteria (PGPB) have reduced the negative effects of saline stress by increasing the relative water content in leaves and enhancing photosynthetic pigment production under stress conditions (Saghafi et al. 2013).

The studies about the utilization of halotolerant and halophilic plant growth-promoting bacteria in mitigation of the deleterious effects of salt stress have been performed using *Bacillus*, *Pseudomonas*, *Rhizobium*, *Azospirillum*, and *Planococcus* (Mayak et al. 2004; Egamberdiyeva 2005; Sapsirisopa et al. 2009; Rajput et al. 2013; Sharma et al. 2015). The effects have been demonstrated well in wheat seedlings (Nabti et al. 2012; Ramadoss et al. 2013), tomato plants (Tank and Saraf 2010; Shen et al. 2012), and maize and soybean plants by application with osmotolerant rhizobacteria (Naz et al. 2009; Vaishnav et al. 2015). The improvement of nutrient elements was recorded in sunflower under high salinity (Shirmardi et al. 2010) and the increase in growth of barley by the inoculation with novel halotolerant rhizobacteria (Cardinale et al. 2014).

14.2 Halophilic Bacteria

Halophilic bacteria are salt-loving organisms inhabiting various environments with the capacity to balance the osmotic pressure of the environment. The halophilic microorganisms are highly diverse in nature and belong to three domains of life, i.e., Archaea, Bacteria, and Eukarya. They inhabit salt ponds, soda lakes, and even rock salt crystals as dormant cells or as biopolymers. These prokaryotic organisms are likely evolutionary adaptations of more conventional bacterial forms rather than a more fundamental group or branch on the evolutionary tree (Woese 1993). A distinction must be made between "tolerance for salt" and "requirement for salt" (Larsen 1986). Halotolerant microorganisms do not specifically require salt, more than the usual concentration of 100–200 mM NaCl which is needed by all microorganisms including non-halotolerant, but they could grow up to ~1.25 M NaCl. Within the group of halotolerant microorganisms, a distinction can be made between

those for which growth rate is decreased by the addition of any salt and those for which the growth rate reaches an optimum with the addition of some salt. There are several different definitions and classifications for halophiles. The definition proposed by Kushner (1993) is widely accepted (Oren 2008). The halophiles have been classified as (1) slight halophiles, able to grow optimally between 1 and 3 % (0.2–0.5 M) NaCl; (2) moderate halophiles, growing optimally in media with 3–15 % (0.5–2.5 M) NaCl; and (3) extreme halophiles, able to grow optimally in media with 15–30 % (2.5–5.2 M) NaCl. There are aerobic as well as anaerobic halophiles; heterotrophic, phototrophic, and chemoautotrophic types are found within halophilic bacteria. The unique properties of the halophilic microorganisms make them valuable resources in the development of novel biotechnological processes and industrial applications, e.g., proteases and amylases in detergent industry, biosurfactant production, poly-beta hydroxyalkanoate and exopolysaccharide as biodegradable plastic, biopolymers in oil recovery, bioremediation of contaminated hypersaline brines, etc. (Kanekar et al. 2012).

14.3 Taxonomy of Halophilic Bacteria

The halophilic bacteria belong to the order *Halobacteriales*, which contains only a single family, the *Halobacteriaceae* previously. After publication of *Bergey's Manual of Systematic Bacteriology*, a total number of 19 genera and 57 validated species have been recognized. The first halophilic bacterial species *Halanaerobium praevalens* was isolated from the sediments of the Great Salt Lake (Utah), and after characterization it was placed in the family *Bacteroidaceae* as a genus with uncertain affiliation (Zeikus et al. 1983). Later, new families and different orders of halophilic bacteria were proposed time to time on the basis of 16S rRNA sequence similarity and membrane lipid profiling. The most commonly recognized genera and species of the halobacteria are listed in Table 14.3.

Most of the halophilic bacteria contained ether-linked phosphoglycerides (C20C20; diphytanyl isoprenoids) and methyl ester-linked phosphatidyl glycerol phosphate (C20C25; phytanyl-sesterterpanyl isoprenoids). These polar lipid compositions have proved to be remarkably consistent in different halophilic bacterial taxonomy as compared to 16S rRNA gene sequence. The 16S rRNA gene sequence of halophilic bacteria showed most distantly related species in phylogenetic tree with 83.2 % similarity. The methanogens are their closest relatives with less than 80 % similarity (Aljohny 2015).

14.4 Mechanisms for Adaptation of Halophilic Bacteria in Saline Environments

Adaptation of microorganisms to such saline environments is a complex multilevel regulatory process in which different types of genes may be involved for protecting organisms against the lethal effects of dehydration (Srivastava et al.

Table 14.3 Introduced halophilic bacterial species since 2010

Halobacterial species	Salt concentration range for growth (%)	Reference
Bacillus halochares	6–23	Pappa et al. (2010)

Oceanobacillus aidingensis	0–21	Liu and Yang (2014)
Spiribacter salinus	10–25	León et al. (2014)

2008). The optimum metabolic processes like enzymatic activities and membrane stability occur at high salinity in certain halophilic bacterial species (Oren 1999), whereas other microorganisms develop different adaptation mechanisms to combat the stress such as the salt-in and compatible-solute strategy and exopolysaccharide production.

The cytoplasm is exposed to high ionic strength to achieve osmotic equilibrium by maintaining a cytoplasmic salt concentration similar to that of the surrounding media. Microorganisms that grow optimally in the presence of extremely high salinities (up to 5 M NaCl), accumulate intracellular potassium and chloride ions in concentrations higher than the external NaCl concentration to maintain a turgor pressure. This is called "salt-in" strategy found in *Halobacteriales* (Archaea) and *Halanaerobiales* (anaerobic halophilic bacteria) (Hanelt and Muller 2013).

Compatible-solute strategy is a more flexible strategy, mostly found in halotolerant as well as moderately halophilic microorganisms that grow over a wide range of salinities (typically 0.5–3 M NaCl) (Roessler and Muller 2001). In this strategy, "the low-salt-in" strategy depends on the accumulation of high concentrations of organic compatible solutes. Compatible solutes are small, mainly neutral but polar compounds, which are highly soluble in water and do not interfere with the cellular metabolism. Such solutes include glutamate and proline (amino acids), peptides, and N-acetylated amino acids (amino acid derivatives), glycine, betaine, and carnitine (quaternary amines), sucrose and trehalose (sugars), and ectoines (tetrahydropyrimidines) (Paul and Lade 2014). Paul and Nair (2008) reported that *Pseudomonas fluorescens* MSP-393, a PGPR strain, as a means of salt tolerance, de novo-synthesized the osmolytes, alanine, glycine, glutamic acid, serine, threonine, and aspartic acid in their cytosol. The uptake or synthesis of compatible solutes retains a cytoplasm iso-osmotic with or slightly hyperosmotic compared to its surroundings. In addition to their well-studied function as osmoprotectants, compatible solutes also have protein-stabilizing properties that support the correct folding of polypeptides under denaturing conditions both in vitro and in vivo (Street et al. 2006). Compatible solutes confer the changes in structure of solvent and/or elusive changes in protein's dynamic properties, not by structural changes in the protein itself (Lamosa et al. 2003),but it also helps in protein–DNA interaction (Kurz 2008).

Certain Gram-negative bacteria survive under abiotic stress conditions through exopolysaccharide (EPS) production, which protects bacteria from hydric stress and fluctuations in water potential by enhancing water retention and regulating the diffusion of carbon sources in microbial environment (Sandhya et al. 2009a, b). In addition, exopolysaccharides possess unique water holding and cementing properties, thus play a vital role in the formation and stabilization of soil aggregates and regulation of nutrients and water flow across plant roots through biofilm formation (Bezzate et al. 2000).

14.5 Role of Halophilic Bacteria in Plant Growth Promotion Under Salt Stress

Any living organisms under stressful condition opt either fight or flight strategy. Since plants are sessile, they cannot run away from adverse conditions, so they fight back; their tolerance capacity, growth, and production can be increased with the help of several mechanistic actions of salt-tolerant PGPRs as shown in Fig. 14.2. Bacteria that help plants overcome the negative effects of abiotic stress are endowed with certain specialized functional traits. Previous studies reported that plant growth promotion and amelioration of salinity stress in crop plants by salt-tolerant bacteria could involve different mechanisms such as secretion of various phytohormones, ACC-deaminase activity, phosphate solubilization, antioxidant enzymes, and siderophore production (Chakraborty et al. 2011). The use of halotolerant PGPB possessing the traits of PGP under saline stress is becoming prevalent worldwide to achieve sustainable agriculture along with soil reclamation through phytoremediation as well

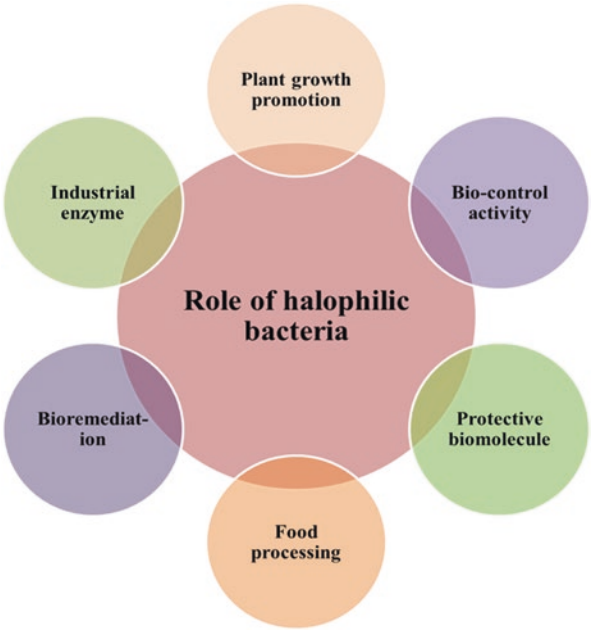

Fig. 14.2 Application of halophilic bacteria in different environmental aspects

as bioremediation (Tank and Saraf 2010). The ameliorative effects of PGPR on plant growth under saline conditions have been shown for various plant species, such as tomato, pepper, canola, bean, lettuce, soybean, and mung bean (Barassi et al. 2009; Kang et al. 2009; Egamberdieva 2009; Vaishnav et al. 2013; Kumari et al. 2016). Kohler et al. (2006) demonstrated the beneficial effect of PGPR *Pseudomonas mendocina* strains on stabilization of soil aggregate. The three PGPR isolates *Pseudomonas alcaligenes* PsA15, *Bacillus polymyxa* BcP26, and *Mycobacterium phlei* MbP18 were able to tolerate high temperatures and salt concentrations and thus confer on them potential competitive advantage to survive in arid and saline soils such as calcisol (Egamberdiyeva 2007). Heidari et al. (2011) also reported increase in plant growth of *Ocimum basilicum* with increased auxin and protein contents under drought stress conditions when inoculated by *Pseudomonas* sp. Two strains of *Azotobacter* sp. have shown increased growth of *Zea mays* under high NaCl concentration (Rojas-Tapias et al. 2012); the experiment revealed a significant restoration of plant biomass (length and weight), exclusion of Na^+ and K^+, improvement of chlorophyll and polyphenol contents, and maintenance of nitrogen fixation and phosphate solubilization activities under saline stress conditions. In another study Egamberdieva et al. (2013) demonstrated that the colonization of *G. officinalis* root tips by *Rhizobium* cells increased almost twofold under saline conditions when the plants were inoculated besides *Rhizobium* with *Pseudomonas* strains. This combined inoculation could also enhance formation of nodules on legumes grown in salinated potting soil. Vaishnav et al. (2015) reported that salt-tolerant *Pseudomonas simiae* strain AU have

growth promotion attributes at 100 mM NaCl on soybean seedling and showed significant improvement of shoot/root length, K^+/Na^+ ratio, and P content of soybean seedling after 10 days of germination. Upadhyay et al. (2011) studied the effect of PGPR on growth and oxidative stress in wheat in saline soil and reported that co-inoculation of *B. subtilis* and *Arthrobacter* sp. alleviates the adverse effects of soil salinity with an increase in proline content, total soluble sugars, and dry biomass. Similar reports were given by Shukla et al. (2012) in peanuts (*Arachis hypogaea*) where an increase of NaCl stress inhibited growth which could be alleviated after inoculation with the diazotrophic rhizosphere bacterium *Brachybacterium saurastrense* and other halotolerant isolates from the halophyte *Salicornia* (Jha et al. 2012). Most recently, Ramadoss et al. (2013) studied the effect of five plant growth-promoting halotolerant bacteria on wheat growth and found that inoculation of those halotolerant bacterial strains to ameliorate salt stress (80, 160 and 320 mM) in wheat seedlings produced an increase in root length of 71.7 % in comparison with uninoculated positive controls. Another study was conducted on the utilization of marine bacteria as salt-tolerant PGPB to mitigate the effect of stress on inoculated plants (Kim et al. 2014). Maziah et al. 2009 and Das et al. 2011 performed studies even on trees such as banana and mangrove forest growing under hard environmental conditions caused by salinity. Halophilic bacteria are also reported for biological control activity. The biological control referred as microbial activity to control plants diseases. The different genera of halophilic bacteria like *Virgibacillus*, *Terribacillus*, *Halomonas*, *Halobacillus*, *Planococcus*, *Staphylococcus*, *Marinococcus*, *Salinococcus*, *and Halovibrio* have been identified in biocontrol activity by producing chitinase and β-1,3-glucanase enzyme activity (Sadfi-Zouaoui et al. 2007).

14.6 Mechanism of Plant Growth Promotion by Halophilic Bacteria

14.6.1 The Role of Bacterial Phytohormones

Phytohormones are naturally occurring, organic substances which influence physiological processes of plants at low concentrations. These hormones affect differentiation and development of plant growth through the regulation of diverse processes. The plant growth hormones of microbial origin in the vicinity of plant roots could evoke a physiological response in the host plant. Production of indole acetic acid, cytokinins (CK), gibberellins, abscisic acid (ABA), and other growth regulators produced by halotolerant PGPB apparently supports the rooting with increased root length, surface area, and number of root tips; ultimately it leads to enhanced uptake of nutrients and thereby improves plant health under stress conditions (Egamberdieva and Kucharova 2009; Jha et al. 2013). Furthermore, Jha and Subramanian (2013) showed clearly the direct and potential effect of some osmotolerant bacteria on germination of paddy seeds under saline conditions. Kumari et al. (2015) reported that two IAA-producing bacterial strains *Bacillus* and *Pseudomonas* enhanced soybean growth under 100 mM NaCl stress by enhancing antioxidant enzyme activity and lowering lipid peroxidation.

14.6.2 Aminocyclopropane-1-Carboxylate (ACC) Deaminase

Ethylene is a volatile phytohormone and plays an important role in plant growth regulation at very low concentrations such as development of different vegetative plant parts, nodulation, or rooting of cuttings (Davis 2004) and also involved in the transduction of a signal for the recognition of salt stress (Selvakumar et al. 2012). The overproduction of ethylene in response to abiotic stresses leads to inhibition of root growth and, consequently, growth of the plant. Chemical inhibitors of ethylene synthesis, such as cobalt ions and aminoethoxyvinylglycine, are often used to overcome the problems associated with salt stress. However, these chemicals are not only expensive, but they have harmful effects on the environment (Dodd 2009). Halotolerant PGPB contains aminocyclopropane-1-carboxylate (ACC) deaminase which hydrolyzes ACC into ammonia and α-ketobutyrate, thereby lowering the level of ethylene in stressed plants. In the presence of 1-aminocyclopropane-1-carboxylate deaminase-producing bacteria, plant 1-aminocyclopropane-1-carboxylate is sequestered and degraded by bacterial cells to supply nitrogen and energy (Mayak et al. 2004), facilitating plant growth under the salinity stress condition (Nadeem et al. 2010; Aamir et al. 2013). ACC-deaminase has been widely reported in numerous microbial species of Gram-negative and Gram-positive halotolerant bacterial strains that belong to different bacterial genera, i.e., *Bacillus*, *Brevibacterium*, *Planococcus*, *Zhihengliuella*, *Halomonas*, *Exiguobacterium*, *Oceanimonas*, *Corynebacterium*, *Arthrobacter*, and *Micrococcus*, that were originally isolated from saline environments and have a real potential to enhance plant growth under saline stress via 1-aminocyclopropane-1-carboxylate deaminase activity (Siddikee et al. 2010; Hussain et al. 2013). In a recent study, an overproducing ACC-deaminase mutant bacterial strain *Pseudomonas simiae* AU5 was found most prominent to alleviate salt stress in mung bean plants as compared to wild strain AU. *P. simiae* AU5-inoculated plants showed lower level of ethylene hormone and salt-induced membrane injury (Kumari et al. 2016).

14.6.3 Phosphate Solubilization

Phosphorous is the major nutrient for plant growth as it is an integral part of different biochemicals like nucleic acids, nucleotides, phospholipids, and phosphoproteins. In most cases, salinity decreased P accumulation in plant, which developed P deficiency symptoms (Parida and Das 2005). Phosphorus exists in two forms in soil, as organic and inorganic phosphate, and, like other nutrient elements such as potassium, iron, zinc, and copper, possesses limited mobility in the soil (Hayat et al. 2010). The conversion of insoluble phosphate compounds (both organic and inorganic) in a form accessible to the plant is an important trait of PGPB strains. This is achieved through the acidification, chelation, ion-exchange reactions, and production of low-molecular-weight organic acids such as gluconic acids. Halotolerant PGPBs have been proved to be vital for circulation of plant nutrients in many ways, thereby reducing the need for chemical fertilizers. Apart from phytohormones and

ACC-deaminase activity, many strains of bacteria can affect plant growth directly by solubilizing inorganic phosphate, improving nutrient uptake, and mineralizing organic phosphate (Ogut et al. 2010). Solubilization of phosphate in the rhizosphere is the most common mode of action implicated in PGPR that increase the nutrient availability to the host plant (Rashid et al. 2004). These rhizobacteria are critical for the transfer of P from poorly available forms and are important for maintaining P in readily available pools. Diby et al. (2005) reported enhanced nutrient mobilization in the rhizosphere of black pepper and significant uptake of nitrogen (N) and phosphorus (P) in the PGPR-treated black pepper vines that resulted in root proliferation and enhanced plant growth. Strains of rhizobacteria that have efficient phosphate-solubilizing ability even under high saline (60 g L^{-1} NaCl) conditions have been reported (Upadhyay et al. 2011). *Pseudomonas* inoculation had favorable effect on salt tolerance of *Zea mays* L., under NaCl stress (Bano and Fatima 2009). Baldani et al. (2000) inoculated phosphate-solubilizing bacteria, *Herbaspirillum seropedicae* and *Burkholderia* sp., to the soil and showed that these bacteria increased the weight of crop 1.5–21% over uninoculated controls under saline conditions. *Azospirillum*-inoculated lettuce seeds had better germination and vegetative growth than non-inoculated controls after being exposed to NaCl (Barassi et al. 2009). Dardanelli et al. (2008) reported as salt stress affects nodulation during *Phaseolus–Rhizobium* interaction that a secondary inoculation of the salt-stressed plants with *Azospirillum* caused an extended exudation of plant flavonoids compared to *Rhizobium* alone. This co-inoculation of plants with different bacterial strains contributed to relieving of the abiotic stress. Vaishnav et al. (2015) proposed that *P. simiae*-mediated volatile compounds enhanced vegetative storage protein (VSP) expression, which is responsible for acid phosphatase activity and enhanced P uptake in soybean plants under 100 mM NaCl stress.

14.6.3.1 Antioxidative Activity

During salt stress, the ROS level is high which causes oxidative damage to biomolecules such as lipids and proteins and finally leads to plant death (Del Rio et al. 2003). Plants cope up with these ROS through their antioxidant machinery. Major antioxidative enzymes SOD, APX, and CAT and nonenzymatic antioxidants such as ascorbic acid and glutathione participate in ROS-scavenging mechanism (Miller et al. 2010). PGPRs such as *S. proteamaculans* and *Rhizobium leguminosarum* are reported to produce antioxidant enzymes such as superoxide dismutase (SOD), peroxidase (POX), and catalase (CAT) and nonenzymatic antioxidants such as ascorbate, glutathione, and tocopherol. Ruiz-Lozano et al. (2001) reported that mycorrhizal-inoculated lettuce plants exhibited higher superoxide dismutase (SOD) activity under drought stress, and this was correlated to plant protection. Stress resistance in plants has been related to more effective antioxidant systems (Bor et al. 2003). A recent study reports that salt-tolerant bacteria *P. simiae* AU enhanced peroxidase and CAT gene expression in soybean plants when inoculated under 100 mM NaCl stress (Vaishnav et al. 2016). Reduction in the activity of antioxidant enzymes was also observed in bacterial inoculated plants. Five potential drought-tolerant plant growth-promoting *Pseudomonas* spp. strains were found to alleviate drought

stress effects in maize plants. Inoculated plants showed significantly lower activity of antioxidant enzyme plants as compared to uninoculated plants (Sandhya et al. 2010). Omar et al. (2009) reported that catalase and peroxidase activities were increased in non-inoculated plants during salinity, whereas *Azospirillum brasilense*-inoculated plants exhibited lower enzyme activity and significantly ameliorated the deleterious effects of salinity.

14.6.4 Siderophore Producers

Iron is an essential micronutrient of plants as it serves as a cofactor of many enzymes with redox activity. A large portion of iron in soils is present in highly insoluble form of ferric hydroxide; thus iron acts as a limiting factor for plant growth even in iron-rich soils. Its availability to the organism is very limited due to the rapid oxidation of ferrous (Fe^{++}) to ferric (Fe^{+++}) state. Ferric ion is highly insoluble under physiological conditions and makes its acquisition by microorganisms a considerable challenge (Neilands 1995). Microorganisms have evolved specialized mechanisms for the assimilation of iron, including the production of low-molecular-weight iron-chelating compounds known as siderophores, which transport this element into their cells. Siderophores have been implicated for both direct and indirect enhancement of plant growth by rhizospheric microorganisms (Neilands 1981). Siderophores provide an advantage in the survival of both plants and bacteria because they mediate competition that results in exclusions of fungal pathogens and other microbial competitors in the rhizosphere by a reduction in the availability of iron for their survival (Masalha et al. 2000; Wang et al. 2000).

14.7 Other Applications of Halophilic Bacteria

14.7.1 As a Source of Industrially Important Enzymes

Under extreme salt or temperature conditions, the stability and characterization of industrially important enzymes of microbial origin is an important factor. A few enzymes of halophilic bacteria make them desired candidates for industry because of its stability under high ionic circumstance during process. In addition, mostly these halophilic bacterial enzymes not only remain active and stable in high-salt environments but are also thermotolerant and alkaliphilic. Thus, halobacteria have attracted much attention in recent years due to beneficial production of halophilic exoenzymes that can be used in diverse fields of biotechnology. The most well-investigated haloezymes are hydrolases such as amylases (Amoozegar et al. 2003), lipases, esterases, xylanases, chitinases, proteases, cellulases, nucleases, etc. (Oren 2010; Moreno et al. 2013). The use of these enzymes in industrial products and processes has been an accepted technology for several decades because they are safe, environmental-friendly biological molecules that make a substantial contribution to the environmental sustainability of industrial processes.

14.7.1.1 Amylases

Amylases catalyze the hydrolysis of starch and their related saccharides and are used widely in several fields of biotechnology and are one of the most commonly used industrial enzymes. The best-known enzymes of this group are α-amylase, β-amylase, and glucoamylase. Halophilic α-amylases have received more attention due to their ability to remain active in the presence of high salt concentrations. α-Amylases could be used in food, pharmaceutical, biofuel, fermentation, paper, detergent, and textile industries (Kadziola et al. 1998; Machius et al. 1995; Souza 2010). The amylases produced by halophilic bacteria such as *Micrococcus varians* subsp. *halophilus* has two protein components of 86 and 60 kDa molecular mass (Kamekura 1986) with optimal activity at 4.5–6 % NaCl and pH 6–7. Similarly, an extracellular α-amylase from *Halomonas meridiana* exhibited maximal activity at pH 7.0, 37 °C and 10 % (w/v) NaCl, respectively (Coronado et al. 2000a, b). Another extracellular α-amylase isolated from a haloalkaliphilic bacterium was active up to 4 M salt, with optimal activity at 2 M salt, pH 10.0–11.0 and 50 °C (Pandey and Singh 2012). The amylases have significantly applied for treatment of wastewater. The extracellular amylase production from *Halomonas meridian* was highest at 5 % salt concentration with maximal activity at pH 7; its amylase gene, AmyH, has also been isolated.

14.7.1.2 Cellulases

Cellulases are one of the important enzymes for biomedical science, paper, agriculture, food and laundry industries (Zhang et al. 2012). The cellulolytic enzymes hydrolyze the β-1,4-D-glucosidic linkages in cellulose, lichenin, and cereal β-D-glucans. The enzyme has been categorized in three main groups, viz., endocellulase, exocellulase, and β-glucosidase (ShaoMin and Guang 2013; Karnchanatat et al. 2008), which completely hydrolyze the β-1,4-D-glycosidic bonds of cellulose to form glucose by acting together (Bhat and Bhat 1997; Bhat 2000). Huang et al. (2010) identified a novel endoglucanase from halophilic bacterium *Halomonas* sp. S66-4, cloned in *E. coli*, the purified recombinant enzyme, which showed the highest activity (4.9 U/mg) at pH 5 and 6 % NaCl. Shivanand et al. (2013) also reported production of cellulases from *Halomonas* sp. PS47 at 6 % NaCl. The maximum activity was at pH 7.1 and 50 °C. A novel salt-tolerant endo-β-1,4-glucanase Cel5A was also identified from *Vibrio* sp. G21; it has a cellulose-binding domain and a catalytic domain of glycosyl hydrolase (Gao et al. 2010).

14.7.1.3 Xylanases

Xylan is the second most abundant hemicellulose in nature after cellulose, which together with lignin, cellulose, pectin, and other polysaccharides constitutes the major components of plant cell walls and maintains cell wall integrity. Xylan is generally insoluble in nature but enzymatically degradation of it converts into useful products like xylose, xylitol, and ethanol. Biodegradation of these xylans, i.e., hydrolysis of 1,4-*β*-D-xylosidic linkages, involves catalysis by the action of two major xylanolytic enzymes, endoxylanase (1,4-β-D-xylan xylanohydrolase) and β-xylosidase (1,4-β-D-xylan xylohydrolase). There has been resurgence in interest

in microbial xylanases due to their numerous uses in industrial applications, such as biobleaching of pulp and most notably the conversion of lignocellulosic materials into fermentable substrates for production of economical and environmental-friendly biofuels (Oksanen et al. 2000). Pioneer work on characterization and purification of halotolerant endoxylanases was done by Wejse et al. (2003) from a novel halophilic bacterium, strain CL8, which had highest sequence similarity with *Oceanospirillum linum* and *Marinobacter* sp. str. CAB. Xylobiose and xylotriose are the major products of these enzymes. Though the optimal activity of these enzymes was at IM NaCl, it remained stable at 5 M NaCl. Sustainable xylanase activity was demonstrated up to 30% NaCl from *Gracibacillus* sp. TSGPVG at 60 °C (Giridhar and Chandra 2010). This kind of stability would be essential for the extracellular activity in a high-salt environment in industry.

14.7.1.4 Lipases

Lipases (triacylglycerol acylhydrolases EC 3.1.1.3) catalyze esterification, transesterification, and aminolysis and have considerable physiological significance and industrial potential (Babu et al. 2008). The characterization of salt stable lipases from halophilic source has been a growing interest nowadays. Lipases have emerged as one of the leading biocatalysts with proven potential of contribution to the under-exploited lipid industry with several applications: esterification, interesterification, transesterification fat hydrolysis, and organic biosynthesis during production of drugs in the pharmaceutical industry. These lipases could be used for the hydrolysis of milk fat in the dairy industry, for the removal of subcutaneous fat in the leather industry, for the removal of impurities from raw cotton in the paper industry, and as additives in detergents (Gomes and Steiner 2004). A moderately halophilic *Salinivibrio* sp. SA-2 produces extracellular lipase; its maximum activity was reported at pH 7.5 and 50 °C. The enzyme remained active in presence of 17% NaCl (Amoozegar et al. 2008). Similarly, an intracellular lipase enzyme from *Salicola marasensis* LipL shows maximum activity at 1 M NaCl; however, it could tolerate up to 4 M NaCl with 6 mM of betaine (Moreno et al. 2013). *Halobacillus* sp. strain LY5 from the saline soil in Yuncheng, China, produced extracellular esterase of molecular mass of 96 kDa. Its optimum enzyme activity was found at 10% (w/v) NaCl at pH 10.0 at 50 °C (Li et al. 2012). In another study, a novel moderate halophile *Marinobacter lipolyticus* isolated from a hypersaline habitat exhibited lipolytic activity optimally at 7.5% NaCl (Martín et al. 2003).

14.7.1.5 Proteases

Bacterial proteases are one among the largest studied groups of hydrolytic enzymes with diverse applications in industrial and biotechnological fields (Joshi et al. 2008; Singh et al. 2012). Extensive research has been done on the extremophile proteases because of their utility in food industries, detergents, laundry, wool quality improvement, and waste treatment (Vijayaraghavan et al. 2012). Recently, proteases in the pharmaceutical industry and bioremediation process have attracted more attention. A moderately halophilic *Geomicrobium* sp. EMB2 produces an extracellular protease stable at 20% salts, 75% organic solvents, 2.0% detergents, and 1.0%

surfactants (Karan et al. 2011). *Pseudomonas* sp. strain A-14 also produces extracellular protease which has its optimal activity at pH 8 at 18 % NaCl (Van Qua et al. 1981). *Chromohalobacter* sp. strain TVSP101 produces halothermophilic protease with maximum activity at 4.5 M NaCl at pH 8 (Vidyasagar et al. 2007). Similarly, the extracellular proteases produced by *Halobacillus blutaparonensis* were stable up to 20 % NaCl concentration and organic solvents (Santos et al. 2013).

14.7.1.6 Chitinase

Chitinase is one of the most potential enzymes of biocontrol in agriculture and environmental investigations (Duo-Chuan 2006). Chitinases hydrolyze the chitin from the cell wall of fungi and are used to produce protoplasts; they are also used during production of biologically active oligosaccharides (Bhattacharya et al. 2007). The bacterial strains *Arhodomonas* HCh2 and *Saccharospirillum* HCh1 isolated from hypersaline lakes in Russia had optimal growth on chitin at 1.5–1 M NaCl and growth range 0.5–3.25 M NaCl (Sorokin and Kolganova 2013). *Virgibacillus marismortui*, a moderately halophilic bacterium isolated from shallow salt lakes, had the ability to produce chitinase (in absence of salt as well as in presence of high salinity, 25–30 % NaCl w/v). Such strains can be significant for biocontrol purposes (Essghaier et al. 2012).

14.7.2 Bioremediation of Polluted Environments

Generally, the wastes coming into the environment have high salt concentration; hence the use of halophilic bacteria could be a promising alternative in waste treatment and management. Industrial processes like tannery or food processing produce large volumes of saline wastewater that cannot be treated by conventional methods due to low efficiency. Application of halophilic bacteria can improve the removal efficiency of COD from saline wastewater. Tannery wastewater-adapted bacteria *Pseudomonas aeruginosa*, *Bacillus flexus*, *Exiguobacterium homiense*, and *Staphylococcus aureus* showed 80 % decrease in COD at 8 % salinity (Sivaprakasam et al. 2008). Introducing halophilic bacteria in textile effluents is a prominent approach for treatment of synthetic dyes, where other microorganisms are not able to degrade. In a study, *Halomonas* sp. strain IP8 showed decolorization of dye from 50 to 20 mg/L, during 16–24 h at 1–1.5 M NaCl salt concentration, at temperature range of 25–45 °C (Pourbabaee et al. 2011). Presence of high salt concentrations in heavy metal and hydrocarbon contamination sites also arises great demand of halophilic microorganisms for biotreatment of these sites.

14.7.3 Halophiles in Food Biotechnology

The use of halophilic bacteria has a number of advantages in relation to the production of salt-containing food. Halophilic fermentation gives taste, aroma, and flavor to food, and acetate production during fermentation protects food from

contamination. Protease secretion from halophilic bacteria in fermented product plays an important role in lowering the fermentation time. Halophilic fermentative bacteria are used to produce a wide variety of food products, notably fermented fish, shrimp, meat, fruits, and vegetables (pickles), Asian fish and meat sauces, rice noodles and flours, and Indonesian soy sauce. The major species of the genera *Lactobacillus*, *Halobacterium*, *Halococcus*, *Bacillus*, *Pediococcus*, and *Tetragenococcus* are involved in food production (Aljohny 2015).

14.8 Tools for Characterization of Halophilic Bacteria

Characterization of different halobacterial strains from saline environments could be done based on the following three different approaches: (1) morphological and biochemical characterization (phenotypic), (2) chemotaxonomic characterization (chemotypic), and (3) molecular or genomic characterization (genotypic). It is difficult to classify all bacterial species based on only phenotypic characteristics; therefore, polyphasic approach employing all phenotypic, chemotypic, and genotypic characteristics is suggested. A complete integrated information would allow a confident classification and a reliable grouping of the organism.

14.8.1 Phenotypic and Biochemical Characterization

The phenotypic characterization of microorganisms is done by morphological, physiological, and biochemical properties of the microorganism (de Vos et al. 2009). Traditionally, colony morphology (color, dimensions, form) and microscopic appearance of the cells (shape, endospore, flagella, inclusion bodies); characteristics of the organism on different growth substrates; growth range of microorganisms on different conditions of salt, pH, and temperature; susceptibility toward different kinds of antimicrobial agents; etc. are measured in phenotypic characterization. Even if cell wall composition is analyzed, the Gram reaction is still a valuable diagnostic character. Biochemical tests in bacterial identification include the relationship with oxygen, fermentation reactions, carbon utilization, and nitrogen metabolism. A Biolog system has been developed for determination of carbon utilization pattern in different bacterial communities (Garland and Mills 1991). In this culture-dependent technique, a 96-well Biolog microtiter plate containing 95 different carbon sources and one control well per plate with growth medium are used with the redox dye tetrazolium salt. The color changes in tetrazolium salt because of bacterial metabolic actions on the substrate. Other tests may be performed as appropriate, depending on the bacterial strains studied (Heritage et al. 1996; Rodríguez-Díaz et al. 2008). However, reproducibility of results from phenotypic tests between different laboratories is a major concern, and only standardized procedure should be used during execution of experiment. Other major disadvantage with phenotypic methods is the conditional nature of gene expression wherein the same organism might show different phenotypic characters in different environmental conditions.

Therefore, phenotypic data must be compared with similar set of data from type strain of closely related organism(s). Miniaturized versions of traditional biochemical tests are available for taxonomical studies and mostly contain a battery of dehydrated reagents. Addition of a standardized inoculum initiates the reaction (growth, production of enzymatic activity, etc.). The results are interpreted as recommended by the manufacturer and are readily accessible with a minimal input of time. The phenotypic fingerprinting system API 50CH has the highest rate of correct identification; it uses forty-nine different carbohydrates and one negative control to identify different bacterial genera including *Bacillus* (Logan and Berkeley 1984), *Paenibacillus*, and *Pseudomonas* species (Barr et al. 1989).

14.8.2 Chemotaxonomic Characterization

Chemotaxonomy is the method of biological identification and classification based on similarities in the structure of certain compounds, i.e., cellular fatty acid among the organisms being classified. In cellular fatty acid analysis, chemical and physical techniques are employed to elucidate the chemical composition of whole bacterial cells and/or their individual cellular components in order to produce a chemical signature or profile of taxonomic significance. One successful and commercialized chemotaxonomic approach for obtaining bacterial fatty acid profiles is based on the fatty acid methyl ester (FAME) analysis by gas chromatography (GC) (Fang et al. 2001). In microorganisms, PLFAs are found exclusively in cell membranes and not in other parts of the cell such as storage products. This method provides information on the microbial community composition based on groupings of fatty acids (Ibekwe and Kennedy 1998). Fatty acids make up a relatively constant proportion of the cell biomass, and signature fatty acids exist that can differentiate major taxonomic groups within a community. Therefore, a change in the fatty acid profile would represent a change in the microbial population. However, the fatty acid composition of microorganisms does not change by plasmid loss or gain or by simple mutations. Fatty acid profiles showing variability in double-bond position, chain length, and substituent groups are perfectly suitable for taxon description and also for comparative studies of profiles that have been obtained under similar growth conditions (Suzuki et al. 1993). The automated MIDI Sherlock Microbial Identification System identifies microorganisms based on unique FAME patterns of known strains (Whittaker et al. 2003).

14.8.3 Molecular Characterization

Because of the inherent limitations of conventional phenotyping methods for detecting microorganism strains within culture-dependent techniques, as well as their mechanisms of resistance, molecular techniques that complement the information provided by these methods have been developed (Perez et al. 2007). The application

of molecular biological methods to study the identification, diversity, and ecology of microorganisms in natural environments has been practiced since the mid-1980s. Methods that use this approach are directed toward DNA or RNA molecules and comprise measurements of DNA relatedness over the entire genome; comparisons of restriction patterns, especially ribotyping; and comparative analyses of sequences of homologous genes. DNA–DNA relatedness and ribotyping are best suited for the identification of closely related species or strains within a single species. Presently, a direct comparison of rRNA sequences is probably the most powerful tool for the identification of many bacteria. Indeed, rRNA genes (rDNA) are present in all bacterial species, are truly homologous in all organisms, are easily sequenced, and now offer a large and ever-increasing database of sequences and allow the identification of cultured as well as uncultured bacteria.

Studies of microbial isolation, identification, and characterization have always been intimately entwined. Comparative analysis of rRNA sequences not only provided the phylogenetic framework which was lacking in microbial diversity but also allowed the development of tools to address this vast microbial wealth. The ubiquity of rRNA molecules (small subunit 5S, 16S, large subunit 23S) in all cellular life forms and comparative analysis of their sequences can be universally applied to infer relationships among organisms. Among the three rRNA molecules, 16S rRNA gene (1500 bp) is the most commonly used marker. It has a universal distribution, highly conserved nature, fundamental role of ribosome in protein synthesis, no horizontal transfer, and its rate of evolution which represents an appropriate level of variation between organisms (Stackebrandt and Goebel 1994). The 16S rRNA molecule comprises highly conserved sequence domains interspersed with more variable regions.

The most commonly used form of comparative rRNA sequence analysis involves the construction of phylogenetic trees. Ribosomal RNA sequence analyses have been greatly facilitated by the availability of an excellent, indispensable, curated database of rRNA sequences (the ribosomal database project, RDP-II) (Maidak et al. 2001; Cole et al. 2007). Sequences can be retrieved from these databases for comparative phylogenetic analysis of the microbial species. The sequence-comparing tools such as BLAST and CLUSTAL X are used to align the 16S rRNA gene sequence in which after alignment the relatedness between bacterial species can be scrutinized by the construction of phylogenetic trees or dendrograms. The phylogenetic tree ascertains the identity to the genus and its nearest neighbors. At present, by correlation with experimental data obtained in the comparison of total genomic DNA (DNA–DNA hybridization), it is accepted that a similarity below 98.7–99 % on the 16S rRNA gene sequences of two bacterial strains is sufficient to consider them as belonging to different species.

Besides ribosomal genes, other structural, metabolic, or housekeeping gene sequences have also been used to differentiate bacterial strains to species or subspecies level. Among them, highly conserved housekeeping or other protein-encoding genes such as *rpo*B (the RNA polymerase β-subunit-encoding gene), *rpo*D, *gyr*B (gyrase subunit β-gene), *rec*A (encoding a protein involved in repairing damaged DNA in the SOS regulon), and multilocus sequence analysis (MLSA) (Carro et al.

2012; Jacques et al. 2012) are more informative than that of 16S rDNA because of their size and conserved and alternating variable regions and are used for taxonomic and phylogenetic studies, especially when it is suspected that the tested strain may be a new species (Meintanis et al. 2006).

Currently, there are several genetic fingerprinting techniques that can be used to characterize bacterial communities or single bacterial isolates which include amplified ribosomal DNA restriction analysis (ARDRA), enterobacterial repetitive intergenic consensus–polymerase chain reaction (ERIC–PCR), and rapid fragment length polymorphism (RFLP). The genetic fingerprinting of microbial communities provides a pattern or profile of the community diversity, based upon the physical separation of unique nucleic acid sequences (Meyer et al. 2007). The use of molecular methods for study of genetic diversity primarily the sensitive and accurate PCR-based genotyping methods enables differentiation among closely related bacterial strains and the detection of higher bacterial diversity than previously considered (Tan et al. 2001).

At present, temperature gradient gel electrophoresis (TGGE) and denaturing gradient gel electrophoresis (DGGE) are predominantly being used. These are based on the direct extraction of DNA or RNA from soil; the amplification of this DNA is done by PCR, followed by electrophoretic separation in a temperature gradient for the former, or by using chemical denaturing substances for the latter. These techniques allow the separation of DNA fragments of exactly the same length but with different sequences, based on their melting properties. Each of the methods described above possesses its own distinctive advantages and disadvantages. Generally, the more selective the method, the less able it is to detect global changes in communities and vice versa. These tools can provide an estimate of the rhizosphere diversity in the soil.

14.9 Conclusion

Salinity is one of the most critical factors which have many detrimental effects on agriculture and the environment. Many resident microflora in this ecology perform all functions of life for survival of their own and associated biological entities. Halophilic bacteria have evolved the capacity to function under so-called unusual conditions. The studies on halophilic bacteria and their metabolites have clearly demonstrated its potential for wide agricultural, industrial, and environmental applications. The successful restoration of plant growth under saline environment after inoculation with halophilic bacteria provides insight for a better alternative to improve crop growth and yield in saline soils. Additionally, halophilic bacteria are also involved in production of haloenzymes, bioremediation, and biodegradation of effluents from saline-based industries. Understanding and exploitation of the beneficial characters of halophilic microorganisms would provide better tool kits for sustainable agricultural and industrial productivity and monitor and regulate anthropogenic detrimental activities that affect biological and environmental health.

Abiotic Stress Mitigation Through Plant-Growth-Promoting Rhizobacteria

15

Palika Sharma, Veena Khanna, and Suman Kumari

Abstract

Abiotic and biotic stresses highly impacts production of principal crops all around the world. Due to climate change, extreme abiotic factors like high and low temperatures, droughts, salinity, osmotic stress, heavy rains, floods and frost damages are posing grave threats to crop production. There is a dire need to mitigate these stresses, so in order to cope with such impacts, microorganisms can be employed as best alternatives to chemical inputs by exploiting their unique properties of tolerance to extreme environments, their ubiquity, their genetic diversity and their interaction with crop plants and by developing methods for their successful employment in agriculture production. Plant-growth-promoting rhizobacteria (PGPRs) mitigate abiotic stresses on plants most effectively through degradation of ACC, the ethylene precursor by bacterial ACC-deaminase and through biofilm and exopolysaccharide production. Alleviation of environmental stresses in crop plants using these microorganisms opens new and emerging applications in sustainable agriculture.

15.1 Introduction

Agriculture is considered to be one of the most vulnerable sectors to climate change. Elevation in abiotic and biotic stresses has become major cause for stagnation of productivity in principal crops. Exposure of plants to a large number of different environmental stresses like flooding, drought, extremes of pH and temperature, high salt, heavy metals and various pathogens affect plant growth and productivity.

Under these environmental stresses, plants synthesize raised levels of the plant hormone ethylene which halts growth and proliferation of plant to greater extent, until the stress is mitigated by lowering ethylene level (Gamalero and Glick 2012). The decline in yield of wheat and paddy in various parts of South Asia has been evidenced due to increased osmotic stress and temperature and reduced rainfall. The average temperature in the Indian subcontinent is likely to rise to 5.8 °C by 2100 (Grover et al. 2011). Besides elevated temperature, droughts, increased CO_2, heavy rainfall, flooding, cold and heat waves, and other huge natural disasters causing severe economic losses are being witnessed globally. These events cause serious negative impacts on crop growth and yields and impose severe pressure on our land and water resources. The major abiotic stress in India is drought or osmotic stress due to high temperatures, soil salinity/alkalinity, low pH, and metal toxicity affecting about two-thirds area, leading to formation of the arid and semiarid regions. Nearly 11 m ha area is affected by salinity, a chemical stress and another 16 m ha by water logging, a physical stress (Grover 2010). It is a major challenge to develop efficient, low-price, and easily adaptable methods for the abiotic stress mitigation. Globally, extensive study is being conducted, to develop strategies to deal with abiotic stresses by developing heat- and drought-tolerant crop varieties, shifting the crop calendars, resource management practices, etc. (Venkateswarlu and Shanker 2009). An unanticipated amplification in agricultural practices aimed to improve the crop production at an unprecedented rate has exploited the cost-intensive technologies and strategies which are unfavorable for the sustainability of soil health (Kumar et al. 2010). The ill-advised exceeding use of agro-chemicals in agricultural land is posing grave threats to the soil fertility. In this context, there should be a paradigm shift toward eco-friendly strategies to mitigate abiotic stress and enhance crop yields. Recently, it has been indicated that some microorganisms can also help crops to tolerate environmental stresses and promote plant growth through nutrient management and biocontrol. This beneficial group of bacteria colonizing plant's rhizosphere/endorhizosphere promotes plant growth through varied direct and indirect mechanisms (Shahzad et al. 2014). However, recently, the microbes alleviating biotic and abiotic stresses has attained great importance. The concept of PGPR-eliciting tolerance to abiotic stresses has been reviewed recently (Yang et al. 2004). The present review compiles the recent work on the role of rhizobacteria aiding crops to tolerate various abiotic stresses due to climate change like heat, salinity, drought, chilling injury, and waterlogging. Plant-growth-promoting rhizobacteria (PGPRs) with ACC-deaminase activity facilitate the proliferation of plants under stressed conditions.

15.1.1 Plant-Growth-Promoting Rhizobacteria

There exists diverse group of bacteria in the soil which are associated with the roots of all higher plants. These efficient bacteria compete in the rhizosphere resulting in plant–microbe interactions which could be positive, neutral, or negative (Shahzad et al. 2014). Bacteria colonizing plant roots aggressively are able to stimulate plant

growth through various mechanisms and are referred as plant-growth-promoting rhizobacteria (PGPR) (Kloepper et al. 1986).

Plant-growth-promoting rhizobacteria are the beneficial group of rhizobacteria that are known to enhance plant growth via direct and indirect means and are viable options for meeting demand of sustainable agriculture alternate to chemical inputs which are hazardous to living forms and impose harmful impact on environment. PGPR acts as (1) biofertilizers (enhancing nutrient (N, P, K, Zn, Fe, etc.) availability to plant), (2) phytohormone producers, (3) rhizoremediators (degrading organic pollutants), and (4) biocontrol agents (Antoun and Pre 'vost 2005). These PGPRs can be extracellular (ePGPR), existing in the rhizosphere, on the rhizoplane, or in the spaces between root cortex cells, or can be intracellular (iPGPR) residing in root cells or in specialized nodular structures (Sundaramoorthy and Balabaskar 2012). *Arthrobacter*, *Agrobacterium*, *Azotobacter*, *Azospirillum*, *Bacillus*, *Burkholderia*, *Pseudomonas*, and *Serratia* are some examples of ePGPR, whereas iPGPRs are *Azorhizobium*, *Bradyrhizobium*, and *Mesorhizobium* (Bhattacharyya and Jha 2012). PGPR can promote plant growth mainly via following means:

1. ACC-deaminase production to lower ethylene levels in plant roots
2. Phytohormone production like indoleacetic acid, gibberellic acid, cytokinins, and ethylene
3. Symbiotic nitrogen fixation
4. Exhibiting antagonistic activity against phytopathogens through siderophores, b-1,3-glucanase, chitinases, antibiotics, fluorescent pigment, and cyanide production
5. Solubilization of mineral phosphates and other nutrients (Shahzad et al. 2014)

These PGPRs when inoculated with crops not only promote their growth and yield but also maintain soil fertility; thus, PGPR as biofertilizer is an eco-friendly approach.

15.2 PGPR-Mediated Stress Tolerance Mechanisms

PGPRs use various mechanisms to protect plants from abiotic stresses which pose grave threats to agricultural production (Fig. 15.1).

15.2.1 Ethylene Biosynthesis and Role in Plant Physiology

Ethylene is a gaseous plant hormone which is produced by almost all plants and imposes different effects on plant growth depending on its concentration in root tissues. Ethylene at low levels plays an active role in seed germination, tissue differentiation, anthocyanin synthesis, root and shoot primordia formation, root elongation, lateral bud development, flowering initiation, opening and senescence of flower, pollination, ripening and degreening of fruit, and the production of volatile organic

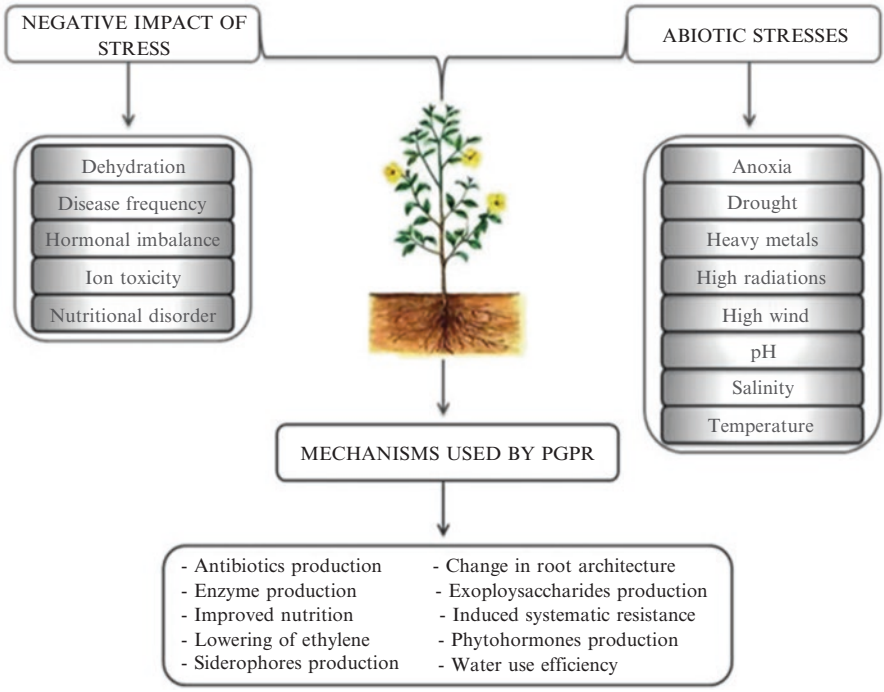

Fig. 15.1 Mechanisms used by PGPR for abiotic stress mitigation

compounds, which imparts aroma to fruits and is also involved in plant–microbial symbiotic interactions that are important for establishment of the legume–*Rhizobium* association (Lynch and Brown 1997). At high concentrations, ethylene is usually deleterious to plant growth and health as it leads to defoliation, inhibition of stem and root growth, as well as premature senescence and also causes decreased vegetative period, which ultimately reduces crop performance. The classical "triple" response in etiolated dicot seedlings due to ethylene is a renowned example of ethylene as stress hormone. This effect includes three distinct morphological changes in the seedling shape, inhibition of stem elongation, increased stem diameter, and horizontal growth (Khalid et al. 2006).

Ethylene is generated by most of the plant tissues. Synthesis of this hormone begins biologically with S-adenosylmethionine (SAM) compound (Fig. 15.2) that acts as a precursor in many other pathways and is, therefore, present in abundance within plant tissues. The ethylene pathways along with the Yang cycle (Yang and Hoffman 1984) initiate with the enzyme ACC-synthase that converts SAM to 1-aminocyclopropane-1-carboxylic acid (ACC) and 5 V methylthioadenosine (MTA). It has been considered to be the foremost step in the ethylene biosynthetic pathway, whereas the extremely labile ACC-synthase enzyme has been shown to be rate limiting which rises proportionally to ethylene levels within the plant tissue.

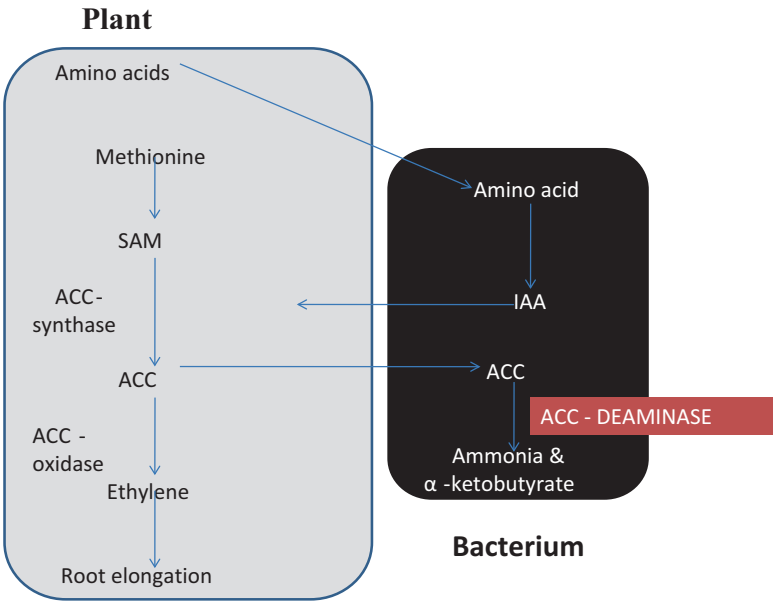

Fig. 15.2 Ethylene biosynthesis and degradation by ACC-deaminase

The next step is the conversion of ACC to ethylene by ACC-oxidase, which is present in most tissues at very low levels. A huge increase in ethylene production is activated due to ACC-synthase and/or ACC-oxidase when ethylene is applied exogenously to plant (Wang et al. 2002). Stimulation of ethylene by IAA also occurs in etiolated pea seedlings, via a rapid increase in the buildup of ACC-oxidase (Peck and Kende 1995).

Ethylene is also known as "stress" hormone, and its accelerated production is associated with both biotic and abiotic stresses (Arshad et al. 2008). When "stress" ethylene synthesis increases, it causes senescence in response to stress in the plant, leading to physiological changes in cells near to the site of stress. As a consequences of different types of environmental stress, viz., chilling, drought, flooding, pathogens, and heavy metal toxicity, plants respond by synthesizing 1-aminocyclopropane-1-carboxy late (ACC), a precursor for ethylene (Glick et al. 2007). An increased ethylene concentration in the root zone is also known to inhibit nodulation and subsequently nitrogen fixation in lentil plants; PGPR can help overcome these deleterious effects.

15.2.2 ACC-Deaminase Production

A pyridoxal phosphate-dependent enzyme, 1-aminocyclopropane-1-carboxylate deaminase (ACCD) is widespread in various bacterial and fungal species. Ethylene production is accelerated endogenously in response to abiotic and biotic stresses via

elevated levels of the ethylene precursor ACC which has adverse affects on the root and plant growth (Shrivastava and Kumar 2013). Owing to ACCD activity, certain plant-associated bacteria help plant to proliferate under abiotic and biotic stresses by lowering the "stress ethylene" level which inhibits plant growth. Many PGPRs have 1-aminocyclopropane-1-carboxylate deaminase activity which can cleave ACC to α-ketobutyrate and ammonia to reduce ethylene level in developing or stressed plants. acdS is a gene which encodes this enzyme, and it is under tight regulation and regulated differentially under different environmental conditions (Singh et al. 2015). Hontzeas et al. (2005) have elaborated the crystal structure of ACC-deaminase from *Pseudomonas putida* UW4 along with the biochemical and thermodynamic properties. One of the characteristic features of all ACC-deaminase enzymes is their low affinity toward the substrate ACC, which is always in the millimolar range. In the past few years, a large number of bacteria have been isolated encoding ACC-deaminase activity (Glick 2005). ACC-deaminase has been widely reported and extensively studied in numerous microbial species of PGPR like *Agrobacterium genomovars*, *Azospirillum*, *Bacillus*, *Burkholderia*, *Enterobacter*, *Pseudomonas*, *Rhizobium*, *Rhodococcus*, *Sinorhizobium meliloti*, etc. (Ali et al. 2014). ACC-deaminase active PGPR strains have improved the maize production under dual stress conditions, i.e., drought and soil salinity/sodicity (Zafar-Ul-Hye et al. 2014). Plants inoculated with ACC-deaminase-positive rhizobacteria are highly resistant to the injurious effects of the stress ethylene produced under flooding (Grichko and Glick 2001), drought (Creus et al. 2004), and high salt concentrations (Nadeem et al. 2007).

15.2.3 EPS Production

Extracellular exopolysaccharide (EPS) accumulation is commonly observed feature in many bacteria. Bacterial EPS production in saline soil can prevent osmotic stress in plants, and it also shields microorganisms from water stress by increasing water retention and by regulation of organic carbon source permeability. Role of EPS producing root-colonizing bacteria in improving plant growth has been variously reported (Ali et al. 2014). EPS aids the microorganisms to attach and colonize the plant roots irreversibly involving a network of fibrillar material that results in firm gripping of bacteria to the root surface. Sandhya et al. (2009) have reported that exopolysaccharide secretion by PGPR forms an organo-mineral sheath around microbial cell which enables specific bacteria to survive under stressed conditions such as drought, and it also improves drought tolerance in plants through osmotic and intracellular adjustment. The type of polysaccharide determines water retention capacity, but water retention capacity by EPS may exceed 70 g water per g polysaccharide. A study revealed that inoculation of barley with exopolysaccharide-producing PGPR exhibited extended drought tolerance in comparison to uninoculated control (Timmusk 2003).

15.2.4 Biofilm Production

Most bacteria in natural environments persist as "biofilm" communities where cells are encased in an extracellular polymeric matrix. Biofilms established on varied surfaces like root zones and soil particles and cement soil particles form aggregates which improve crop production and physiochemical properties of soil (Qurashi and Sabri 2012). Under stressed conditions, bacteria persist in the form of biofilm communities for their better survival, as an extracellular matrix provides an infinite range of macromolecules. The dense biofilm matrix regulates diffusion of bioactive substances and nutritional secretions by rhizobacteria which therefore remain concentrated at the root surface in order to affect plant growth. Timmusk (2003) suggested that the major components of biofilm in the model bacterium *Bacillus subtilis* are polysaccharides and a Tas A protein, and when these components get mutated, they pose severe effects on biofilm production. The sugars in biofilms can be divided into simple sugars (monosaccharides, oligosaccharides, polysaccharides) and complex sugars: all of which can play various roles in host–microbe interactions (Vu et al. 2009). The biofilm improves water retention and enhances soil aggregation and microbial biomass which in turn stimulates root exudation under stress. Hence, there is a great advantage of a slimy layer of extracellular matrix produced in the rhizosphere, especially under stressful conditions; it contributes to mechanical stability of the biofilm and interacts with other macromolecules and micromolecules, creating a microenvironment within the biofilm (Timmusk 2003).

15.2.5 Nutrient Deficiency Tolerance

Plants require various macro (N, P, and K) and micro (Zn, Mn, and Fe) nutrients for their growth and metabolism; thus, their deficiency in plants may lead to reduction in crop yields to greater extent. The deficiency of macro- and micronutrient is the major factor contributing not only to yield plateaus but also to declining crop production, shrinking profits, and environmental footprint (Velu et al. 2013).

15.2.6 Biological Nitrogen Fixation

Nitrogen (N) ranks first among the major plant nutrients, yet its low availability to plants due to the high losses by emission or leaching is a limiting factor in agricultural ecosystems. Some microorganisms are capable of making atmospheric N available to plants through biological nitrogen fixation (BNF) which is of great importance (Martínez-Viveros et al. 2010). For agricultural sustainability advancement, an increase in the utilization of BNF as a major source of nitrogen for plants is required. PGPRs with biological nitrogen fixation (BNF) property include symbiotic nitrogen fixers (*Rhizobium* in leguminous plants and *Frankia* in nonleguminous trees) and nonsymbiotic N_2-fixers (*Azospirillum*, *Azotobacter*, *Gluconacetobacter*, *Achromobacter*, *Azoarcus*, *Acetobacter diazotrophicus*, *Bacillus*, *Klebsiella*, and

Pseudomonas). Nonsymbiotic nitrogen fixation has a great agronomic significance. Free-living diazotrophs carrying out nonsymbiotic BNF can promote growth in nonleguminous plants. Studies by Antoun et al. (1998) have revealed that N-fixers, free-living bacteria, as well as symbiotic *Rhizobium* strains can stimulate the growth of radish which is a nonlegume.

15.2.7 Phosphorus Solubilization

Element phosphorus (P) ranks second after nitrogen among mineral nutrients which also limits the growth of crops. Phosphorus as an essential mineral nutrient participates in numerous metabolic processes such as transfer of energy, respiration, biosynthesis of macromolecules, and signal transduction (Khan and Joergensen 2009). The P content in soil (organic plus inorganic) is 100–400 g/ha which usually exceeds plant requirements; however its bioavailability to plant is one of the major constraints in limited plant growth. Even if phosphorus is added to soil as phosphatic fertilizer, it may get fixed and precipitate in calcareous and alkaline soils and become unavailable to plant. Phosphate anions due to their extreme reactivity get precipitated with cations such as Ca^{2+}, Mg^{2+}, Fe^{3+}, and Al^{2+} and become immobilized. On the other hand, much of this P is in mineral form and is available to plants only at gradual basis (Richardson et al. 2009).

In order to meet sustainable agricultural demands, the use of special microorganisms as inoculum for mobilization of a large pool of soil phosphorus is one of the useful strategies to improve crop yields. A group of PGPRs referred to as phosphate-solubilizing bacteria (PSB) are employed as solubilizers of insoluble inorganic P compounds at frequent basis through production of low-molecular-weight organic acids such as gluconic and keto-gluconic acids, and genera belonging to *Azotobacte*r, *Bacillus*, *Enterobacter*, *Klebsiella*, *Pseudomonas*, and *Rhizobium* are the potent phosphate solubilizers (Verma et al. 2013). In addition, inorganic acids such as carbonic acid, sulfuric acid, and nitric acid produced by PSB could also facilitate the solubilization of P and Zn compounds.

The PSB constitute 1–50 % whereas phosphorous solubilizing fungi (PSF) contribute only 0.1–0.5 % in P solubilization potential among the whole microbial population in soil (Chen et al. 2006). The microorganisms involved in P solubilization can enhance plant growth also by enhancing biological nitrogen fixation efficiency and the availability of other trace elements such as Fe, Zinc, etc. (Gyaneshwar et al. 2002).

15.2.8 Siderophore Production

To satisfy nutritional requirements of iron, microorganisms are blessed with a special mechanism that assimilates iron via secretion of low-molecular-weight (500–1000 Da) chelators having greater affinity for iron which are termed as siderophores

and are generally produced in response to iron starvation (Sarode et al. 2009). Strains of *Pseudomonas*, *Enterobacter*, *Azotobacter*, *Gluconacetobacter*, *Bacillus*, and *Rhodococcus* genera are known to produce siderophores classified as catecholates (phenolates), carboxylates, and hydroxamates by the ligands used to chelate the ferric iron (Saharan and Nehra 2011). Under aerated environment at physiological pH, the unstable reduced ferrous (Fe^{2+}) form is readily oxidized to the ferric (Fe^{3+}) form, which is unavailable to biological systems, and its concentration is less than optimal for bacteria which necessitates special mechanisms for iron acquisition; thus, secreted siderophores by microorganisms solubilize iron by forming a complex ferric siderophore (Sharma and Johri 2003). Although some siderophores are known to chelate other ions along with iron, many siderophores chelate iron not only for microbial nutrition but also for microbial infection and the antagonism of PGPR against plant pathogen by sequestering Fe^{3+} in root area (Beneduzi et al. 2012); thus, siderophores have been implicated for both direct and indirect mechanisms of plant growth promotion.

Siderophores such as salicylic acid and pyoverdine are known to induce systemic resistance. Further, most of the catechols are derivatives of 2,3-dihydroxy benzoic acid (DHBA) and consist of 2,3-DHBA and one or more amino acid residues. *Pseudomonas fluorescens* is known to secrete pyoverdines which are yellow-greenish fluorescent siderophores involved in the transport of iron into the cell (Meyer et al. 2002). Siderophore enterobactin secreted by *Escherichia coli*, bacillibactin from *Bacillus subtilis* and *Bacillus anthracis*, and vibriobactin produced by *Vibrio cholera* are some of the examples of catecholates. Ferrichromes produced by *Ustilago sphaerogena*, desferrioxamine B (deferoxamine) by *Streptomyces pilosus* and *Streptomyces coelicolor*, and desferrioxamine E by *Streptomyces coelicolor* belong to the hydroxamate class of siderophores (Sarode et al. 2009).

In recent years, considerable interest has been paid to rhizobacteria, which are aggressive root colonizers and produce siderophores. The role of microbial siderophores in N-fixation has also been implicated. Indirect mode of plant growth promotion is the ability of siderophore to protect from heavy metal toxicity (Glick 2005). Thus plants are benefitted in a number of ways, i.e., by direct uptake of iron, suppression of proliferation of fungal pathogens, improved N-fixation, and prevention from heavy metal toxicity.

15.2.9 Zinc Solubilization

Zinc is an imperative micronutrient necessary at low concentrations (5–100 mg kg^{-1}) in plant tissues for healthy growth and reproduction and acts as a cofactor in many enzymes. Zn deficiency is currently listed as a major risk factor for both plant and human health globally. As a result of prevalent Zn deficiency, the production of cereal crops suffers twin problems of low food production and Zn malnutrition in the population using cereals as their staple diet (Vaid et al. 2013). In plants, its deficiency results in reduction in membrane integrity and synthesis of starch, protein,

growth hormones, nucleotides, chlorophyll, and cytochromes and also leads to development of susceptibility to heat stress. Zn influences basic life processes of plant, such as (a) nitrogen metabolism–nitrogen uptake and protein quality, (b) photosynthesis–chlorophyll synthesis and carbon anhydrase activity, (c) abiotic stress tolerance, and (d) rate of protein synthesis and protein content (Potarzycki and Grzebisz 2010). On the other hand, dietary deficiency of zinc (Zn) leads to human health complications including impairments in the immune system together with incidence of infectious diseases such as severe acute malnutrition, diarrhea, and pneumonia which affects more than two billion people worldwide (WHO 2012).

Like phosphorus zinc is also present in soil in insoluble form that so plants are unable to utilize it. The problem of Zn deficiency in crops is attributed to its lesser solubility in soils instead of its low total amount. Solubilization of zinc through PGPR can be achieved by various mechanisms, including excretion of metabolites such as organic acids and chelating agents or through proton extrusion (Ramesh et al. 2014). Rhizobacterial genera belonging to spp. *Pseudomonas* and *Bacillus* have been reported to solubilize zinc through proton extrusion, chelating ligands, and oxidoreductive systems established on the cell surface and membranes (Goteti et al. 2013). Reduction in pH through organic acid production by microbial isolates is regarded as one of the major mechanisms of Zn solubilization. Solubilization of Zn compounds using soil bacteria has been reported by Fasim et al. (2002).

15.2.10 Phytohormone Production

PGPRs are known to secrete phytohormones, viz., auxins, cytokinins, gibberellins, and ethylene. The naturally occurring auxin is indoleacetic acid (IAA) which exists in abundance and has the ability to control many aspects of plant growth and development such as differentiation of vascular tissues, apical dominance, root elongation, initiation of lateral roots, and fruit setting and ripening (Maheswari et al. 2013). Gibberellins (GA) are plant-growth-promoting hormones that are engaged in the germination of seeds, seedling emergence, stem and leaf growth, induction of flowering, regulation of vegetative and reproductive bud dormancy, and fruit growth (Maheswari et al. 2013). The phytohormones produced by rhizospheric and endophytic bacteria (*Enterobacter*, *Pseudomonas*, *Stenotrophomonas*) play a key role in modifying root morphology in plants exposed to drought, salinity, high temperature, and toxicity of heavy metals (Spaepen and Vanderleyden 2010). Plants inoculated with IAA producers have resulted in stimulation of seed germination which accelerates root growth and also leads to modification in root architecture to increase the root biomass even under stressed conditions. IAA-producing bacteria are considered as potential plant growth promoters as they increase the root surface and create a larger infection area for colonization of potential diazotrophs (Molla et al. 2001).

Ethylene, a phytohormone, is produced almost in all plants and is known to mediate several responses to environmental and developmental signals in plants. Arshad and Frankenberger (1998) have shown that ethylene when exudated by the roots exhibits involvement in plant growth. The fate of rhizobial infection in legume

root hairs is regulated by the levels of ethylene in the underlying plant cortex; a low level of ethylene allows proper deposition of infection thread, whereas a higher level of the hormone induces abortion of the infection thread by inducing cross-linking of its matrix glycoproteins (Ma et al. 2003). Certain free-living rhizobacteria with ACC-deaminase activity promote nodulation in plant roots by endogenously regulating the biosynthesis of ethylene.

15.2.11 Induced Systemic Tolerance

Plant-growth-promoting rhizobacteria are known to alleviate the impact of abiotic stresses on plants effectively through induced systemic tolerance (IST), via (a) cytokinin production by bacteria, (b) antioxidants, and (c) enzyme ACC-deaminase degrading ethylene precursor ACC. The terminology, induced systemic tolerance, has been proposed for PGPR-induced physical and chemical changes resulting in increased tolerance to abiotic stress. Another term, "induced systemic resistance," (ISR) refers to a process involving physical or chemical changes related to plant defense by PGPRs. PGPR eliciting ISR has been reported to suppress plant diseases caused by a range of phytopathogens both in the greenhouse and field (Kloepper et al. 2004). However, few reports on PGPR as elicitors of tolerance to abiotic stresses, such as drought, salt, and nutrient deficiency, have also been published. More recently, the subject of PGPR-eliciting tolerance to heavy metal toxicity has also been reviewed. The term "induced systemic tolerance" (IST) is proposed here for physical and chemical changes induced in plants by PGPR resulting in enhanced tolerance to abiotic stress only whereas biotic stress is excluded from IST because conceptually it is part of biological control and induced resistance (Yang et al. 2004).

PGPR strain, *Achromobacter piechaudii* ARV8, producing ACC-deaminase, conferred IST to drought stress in pepper and tomato (Mayak et al. 2004). Under stressed environment, the stress hormone ethylene endogenously regulates plant homeostasis resulting in decreased root and shoot growth. However, breaking down of the ethylene precursor ACC by bacterial enzyme ACC-deaminase releases plant stress and rescues normal plant growth (Glick 2005).

15.2.12 Proline Accumulation in Plants Under Stress Conditions

A proteinogenic amino acid, proline is an indispensable component for primary metabolism which regulates plant development and also acts as a signaling molecule. However, accumulation of proline is known to influence stress tolerance in various ways. It has also been reported that proline can work as a molecular chaperone in order to protect protein integrity and to activate different enzymes. An antioxidant feature has been attributed to proline which suggests its ROS scavenging activity and its role as a singlet oxygen quencher (Matysik et al. 2002). Accumulation of proline could be due to de novo synthesis or decreased degradation or both. Many studies have revealed that under different stress conditions, an increase in proline

content in higher plants has been reported (Yang et al. 2004). It was first discovered in bacteria that proline functions as an osmoprotective agent, where a correlation between accumulated proline and salt tolerance has long been demonstrated. Numerous reviews have emphasized on protective function of proline which get accumulated in plants under stressed conditions (Verbruggen and Hermans 2008). However, the correlation between proline accumulation and abiotic stress tolerance in plants is not always apparent.

The potential of PGPR for enhancing plant growth and yield was also tested under different abiotic stresses, i.e., water shortage, high and low temperature, salinity, and under-deficiency nutrients (Table 15.1).

15.3 Future Prospects

Tremendous progress has been attained worldwide, in the field of PGPR biofertilizer technology as they are very effective plant growth promoters and have potential to alleviate various environmental stresses, enrich soil fertility and food nutritional

quality, and enhance the agricultural production. The use of PGPR as stress mitigators, biofertilizers, biocontrol agents, and biofortifiers is an efficient alternative to the use of chemicals for sustainable crop cultivation at global level. Thus, present and future progression in understanding of diversity of PGPR, their ability to colonize plant roots, and their mode of action, formulation, and application can lead to their development as reliable components in the management of sustainable agriculture.

Plant-Microbe Interaction and Plant Productivity

Growth Promotion Features of the Maize Microbiome: From an Agriculture Perspective

16

Ubiana de Cássia Silva, Christiane Abreu de Oliveira, Ubiraci Gomes de Paula Lana, Eliane Aparecida Gomes, and Vera Lúcia dos Santos

Abstract

Microorganisms associated to maize can present a diversity in its composition according to maize genotype and soil properties, such as pH, texture, water availability, nutritional status, weather conditions, and agricultural practices. These microorganisms can stimulate plant growth by nutrients acquisition in poor soils through nitrogen fixation, phosphate solubilizing, phytate mineralization besides of the phytohormone production that help in the survival stress and can stimulate growth of plant parts several. Some molecules produced by microrganisms inhibits the action of phytopathogenic agents or can induce the plant resistance. Thus, the maize microbiome investigation can contribute for prospecting of microorganisms with potential for use as plant inoculant focused on the development of cheaper, environmentally-sound and sustainable agricultural techniques.

16.1 Introduction

Cereals have been the principal component of animal and human diet for thousands of years and have played a major role in the establishment of human civilization. Moreover, they can be used for numerous applications in general for fuels such as ethanol production industrially. From cereals, the maize (*Zea mays* L.) is the most produced worldwide, and it has an average of 800 million tons produced annually of which the United States is the largest producer, followed by China and Brazil. Maize has a large genetic variability, which allows its cultivation in tropical, subtropical, and temperate climates. However, production systems are highly dependent on chemical inputs, especially nitrogen and phosphate fertilizers, pesticides to control pests, diseases, and weeds, which raise production cost. In addition, intensive use of agricultural inputs can cause environmental impacts. Therefore, there is a large demand for technological innovations that reduce the production costs, the inputs, and energy consumption of nonrenewable sources.

Microorganisms are attractive and viable alternatives for the reduction of fertilizer and pesticide use, easing the burden farming imposes on the environment, and reduction of production costs. Microbial inoculants that promote plant growth (PGPM) may be developed based on microbiota residing inside plants without harming their host (endophytes) or only the surface of the plant organs (epiphytic) or those found in the rizosphere of plants (Wu et al. 2005; Montanez et al. 2012; Mendes et al. 2013). The study of these microorganisms involves the investigation of the microbial community profile associated to plants and evaluation of cultured strains *in vitro* in order to identify genes related to vegetal growth promotion and ability of tissues colonization of the plant besides genes that help in the vegetal survival to biotic and abiotic stress (Table 16.1).

The microorganisms that penetrate and colonize plant tissues have evolved an elaborate system to bypass the natural defense system of plants and persist in it, named "competent endophytes" (Rosenblueth and Martinez-Romero 2006; Hardoim et al. 2008). The system involves inactivation of reactive oxygen species (ROS) and plant secondary metabolites by anti-oxidative enzymes such as catalase and superoxide dismutase. The colonization of endosphere requires indeed mechanisms to increase the nutrient acquisition including siderophore production and membrane transporters (Barret et al. 2011; Loaces et al. 2011).

Microorganisms also show essential functions for effective bacterial colonization and survival of the rhizosphere ("rhizosphere competence"). Although considered a nutrient-rich environment, this region also exerts a selective pressure on microorganisms by releasing plant-derived toxic compounds such as indoles, terpenoids, benzoxazinones, flavonoids, and isoflavonoids that induce a stress response in certain bacteria (Miche et al. 2006; Bais et al. 2006). The strategies employed by bacteria to cope with a toxic compound are to extrude it out of cell by efflux pumps, production of oxidative enzymes of aromatic compounds present in exudates, and alteration of composition of fatty acids and phospholipids to compensate increased fluidity of membrane due to interaction with phenolic compounds. The presence of these adaptation mechanisms can explain the selection of specific microbial populations by diverse plant species or cultivars, which can show exudates of variable

Polyhydroxybutyrate (PHB) metabolism genes	PHB is a compound intracellularly stored granules. It helps in tolerating high temperatures, exposure to UV irradiation, and desiccation

chemical composition. The root exudation varies also with plant age (Aira et al. 2010; Ramachandran et al. 2011).

Beyond the microorganism competence, other factors such as geo-location, climatic conditions, host plant genotype, growth stage and physiological status, and type of plant tissue determine microbial community colonization (Hoffman and Arnold 2008; Sun et al. 2012; Giauque and Hawkes 2013). In general, the continuation of

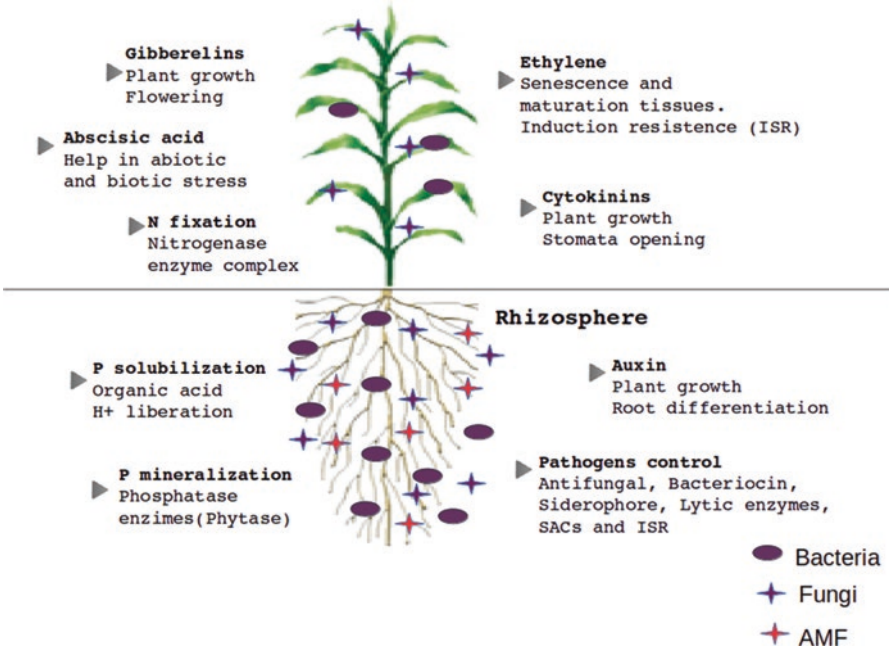

Fig. 16.1 Overview of growth-promoting factors triggered by microorganisms associated with maize

plant host–endophyte symbiotic interactions changes from antagonistic to mutualistic (Saikkonen et al. 1998); the mutualistic microbial processes involve nitrogen fixation, solubilization of phosphorus and potassium, the production of siderophores and phytohormones, surface-active compounds (SACs) and bioactive molecule production, and induction of systemic resistance (ISR) (Fig. 16.1) (Bulgarelli et al. 2013).

Several studies have prospected specific functional microbial groups associated with maize and adapted to the several ecosystems for development of PGPM inoculants with emphasis on the traits that improve the fitness of plants (Hameeda et al. 2008; Montanez et al. 2012; Szilagyi-Zecchin et al. 2014). However, the inconsistencies between results obtained in vitro compared with field trial tests have led to the unsuccessful commercialization of microbial inoculants.

Thus, to obtain effective inoculant is necessary to evaluate the ideal characteristics of candidate microorganisms, the environmental parameters that interfere with the success of colonization and sustaining bacterial life within host plants in field experiments. Soil health is another factor that affects the inoculation efficiency, due to several characteristics such as type and structure of soil, soil moisture and pH, nutrient level and toxic metal concentrations, microbial diversity, and soil disturbances caused by management practices. Furthermore, another important function of soil microbiota is the aggregation of soil particles, which can be promoted by microbial inoculants.

This chapter presents an overview of the importance of the microbiome to the plant growth promotion, focusing on the functional and taxonomic diversity of the

microbiota associated with maize and the desirable characteristics of microorganism's candidates to the use in PGP formulations.

16.2 Maize Microbiome Diversity

Microbial community which colonizes maize has been intensively investigated by a number of strategies, such as cultivation of microorganisms, techniques that evaluate the community profile as terminal restriction fragment length polymorphism (T-RFLP) and others based in cloning and sequencing in small scale or high throughput as the next-generation DNA sequencing technologies. For rhizospheric community of maize, regardless of the strategy used, most of the work describes the phylum *Proteobacteria* as dominant, particularly classes α-, β-, and γ-*Proteobacteria* (Chauhan et al. 2011; Peiffer et al. 2013; Turner et al. 2013; Johnston-Monje et al. 2016). The genera *Burkholderia*, *Pantoea*, *Enterobacter*, *Pseudomonas*, *Massilia*, *Sphingobium*, *Sphingomonas*, *Agrobacterium*, *Rhizobium*, *Bradyrhizobium*, and *Ochrobactrum* are most commonly found in maize rhizosphere, many of them could also be found as endophytes (Johnston-Monje et al. 2016). *Proteobacteria* are also dominant in the maize rhizosphere of different regions in the world, as shown in the study that assessed soils of Canada and Brazil and of the states of Florida and Illinois, USA (Roesch et al. 2008). In this work, the β-*Proteobacteria* subphylum was dominant in all soils, except from Brazil, which is predominated by γ-*Proteobacteria*. Then, the phyla *Actinobacteria*, *Firmicutes*, *Bacteroidetes*, *Planctomycetes*, *Verrucomicrobia*, and *Acidobacteria* were frequent in all these regions (Roesch et al. 2008; Turner et al. 2013). Bacterial community rhizosphere of other plants has also displayed predominance of *Proteobacteria* phylum, such as potato, beet, and *Arabidopsis* (Weinert et al. 2011; Lundberg et al. 2012). Peiffer et al. (2013) characterized the bacterial diversity of the rhizosphere of maize lineages during flowering grown in the field in five different environments in the United States and noted that some orders such as *Burkholderiales*, *Oceanospirillales*, and *Sphingobacteriales* of the *Proteobacteria* phylum were consistently enriched in maize rhizosphere. According to authors, sampling area and its geographical origin were the main variation source in microbiota composition followed by root proximity (rhizospheric and non-rhizospheric soil). In the rhizosphere, strains belonging to *Proteobacteria* phylum predominated because in general show rapid growth capacity in response to sources of labile carbon released by plant. In contrast, non-rhizospheric soil is predominantly enriched by slow-growth microorganisms that has more stable populations, such as Acidobacteria, Chloroflexi, Planctomycetes, and Verrucomicrobia, which are also described as oligotrophic (Fierer et al. 2007).

Some studies suggest that maize plants can select specific bacterial communities depending on soil properties (Castellanos et al. 2009), genotypes (Aira et al. 2010), management techniques, such as fertilizers (Aira et al. 2010), and growth stage of the plant (Gomes et al. 2001). For example, Bouffaud et al. (2012) showed that the genotype influenced the microbiota composition of the maize rhizosphere. These authors evaluated the community rhizobacteria of five main genetic groups of maize by of

microarray and 16S rRNA analysis that revealed a clear effect of genotype in the selection of rhizobacteria community. It was observed that main differences were related to the group of Betaproteobacteria, especially *Burkholderia*. However, other works show that the composition of the bacterial community is not dependent of the cultivar type or genotype (Schmalenberger and Tebbe 2002) or soil type (Johnston-Monje et al. 2016). This apparent disparity in results may be due to interactions between plants and soil types and according to methodology employed. The use of techniques that have different resolution and detection limits can also influence the results. Chelius and Triplet (2001), for example, observed that dominant bacteria group belongs to the *Actinobacteria* phylum when cultivation techniques were used, whereas the sequencing of clone libraries showed the α-*Proteobacteria* as predominant group.

The plant development stage has also been described as important factor to determine the microbial community. Gomes et al. (2001) evaluated the rizosphere bacterial community of two maize genotypes by cultivation-based techniques and TGGE. Differences were observed in the community composition of young roots when compared to mature plant, especially, in the α- and β-*Proteobacteria* population. Similarly, Li et al. (2014) using the pyrosequencing described alteration of the microbiome rhizosphere of maize with the plant growth stage. The genera *Massilia*, *Flavobacterium*, *Arenimonas*, and *Ohtaekwangia* were abundant in the early stages, while the population of *Burkholderia*, *Ralstonia*, *Dyella*, *Chitinophaga*, *Sphingobium*, *Bradyrhizobium*, and *Variovorax* was dominant in the later stages.

In addition, other characteristics can modulate the structural and functional diversity of the plant microbiome, as abiotic factors including soil properties such as pH, texture, water availability, nutritional status, weather conditions, and agricultural practices (Berg and Smalla 2009). The effect of different fertilizers in the bacterial and mycorrhizal fungi community of maize was assessed by T-RFLP, cloning, and sequencing, respectively (Toljander et al. 2008). Changes in microbial community were mainly correlated with pH changes induced by fertilization type, but other factors also contributed to the observed changes, including carbon and phosphate of the soil.

Furthermore, although the effects of the genotype and fertilization are important separately, the interaction between them can be determinant for the microbial community, as the exudation from plants is influenced by these factors; therefore, the microbial community structure of the rhizosphere will be modified. Aira et al. (2010) evaluated the effect of different strategies of maize fertilization and detected change in the composition of the exudates from the roots leading to an increase in biomass and modification in the bacterial community structure.

In addition to rhizosphere, a wide variety of endophytic microorganisms also colonizes maize. This microorganism group is characterized for living within the plant tissues at least part of the life cycle; they can colonize the apoplast, including intercellular spaces and cell walls of roots, stems, and leaves. They are generally nonpathogenic for the plant, but may include latent pathogens that depending on the environmental conditions can cause disease. The high number of bacteria into plant tissues are originated from soil suggesting that the roots as the main entry point of the endophyte in the host plants (Miliute et al. 2015).

In general, species of endophytic bacteria present in maize belong to subphylum α-, β-, and γ-*Proteobacteria*. Among these groups, γ-*Proteobacteria* is dominant

and has greater diversity. But *Bacteroidetes*, *Actinomycetes*, and *Firmicutes* are also commonly observed in maize endophytic community. The genera *Rhizobium*, *Burkholderia*, *Enterobacter*, *Erwinia*, *Pseudomonas*, *Flavobacterium*, and *Bacillus* are the most described in studies of maize endophytic microbiome (Kobayashi and Palumbo 2000; Seghers et al. 2004; Rai et al. 2007; Pereira et al. 2011; Bulgarelli et al. 2013; Philippot et al. 2013).

Most studies of maize endophytic microorganisms were conducted in temperate climate (McInroy and Kloepper 1995; Fisher et al. 1992; Seghers et al. 2004). However, studies conducted by our research group in tropical conditions showed that the microbiota colonizing maize plant organs varied, being observed was the predominance of genera *Microbacterium* (16 isolates), *Pseudomonas* (three isolates), *Staphylococcus* (nine isolates), *Curtobacterium* and *Lactococcus lactis* (seven isolates each), *Pantoea* (four isolates), and *Psychrobacter* (three isolates) on the leaf. On the roots, the predominant genera were *Bacillus* (11 isolates), *Leuconostoc* (four isolates), *Enterobacter* (six isolates), *Pseudomonas* (seven isolates), and *Serratia* (five isolates) (Vieira 2015). Rai et al. (2007) also evaluated maize endophytic bacteria in tropical soils. They observed that the bacteria density in maize ranges from 1.36×10^5 colony-forming units per gram of fresh tissue (UFC/g) in the first week of seedling emergence to 6.12×10^5 UFC/g at the end of growing season, after 10 weeks. The peak of bacteria density was 12×10^5 UFC/g at 28 days after emergence. The predominant species were *Bacillus pumilus*, *B. subtilis*, *Pseudomonas aeruginosa*, and *P. fluorescens.* The genera *Pseudomonas* and *Bacillus* also predominated in the study of McInroy and Kloepper (1995), which recovered 232 endophytic bacteria of maize distributed in more than 40 distinct genera.

Although most studies report that the soil is an important source of endophytic microorganisms, they also may be transmitted through vectors like insects and vertically through propagules such as seeds, rhizomes, and cuttings (Hardoim et al. 2011). These sources are more relevant for the microbiota associated with stems and leaves of plants, both as epiphytic or endophytic lifestyle. Seeds can also be an important source of these microorganisms. Johnston-Monje et al. (2016) found that the most abundant bacteria in the rhizosphere originated from endophyte or epiphyte transmitted by seeds, colonizing approximately 55 % of the bacterial population when maize plants were grown in non-sterile conditions and up to 90 % of the bacterial population when maize was grown in sterile sand (Johnston-Monje et al. 2016).

16.3 The Microbial Role in the Maize Growth Promotion

16.3.1 Acquisition of Nutrients

Nitrogen (N) and phosphorus (P) are nutrients required to plant growth and to ensure the productivity of crops. Farming systems are highly dependent on fertilizers, especially nitrogen and phosphorus. These fertilizers are the largest part of grain production costs as maize and may negatively impact the environment (Novais and Smyth 1999).

Microorganism prokaryotes have the capacity of N fixing of the air and convert it to chemical species readily utilized by plants, such as ammonium and nitrate (Nunes et al. 2003). N-fixing bacteria are called diazotrophs and are found free-living in the rhizosphere, endophytically associated with some species or establishing mutualistic symbiosis with the plants as observed in the nodulating bacteria of Leguminosae (Didonet et al. 2000).

N biological fixation is a complex process that requires joint expression of various genes, including the *nif* genes that are responsible for the synthesis of the nitrogenase complex, and its homologous *nif*H I are the most widely used for phylogenetic studies of diazotrophic symbionts (Zhao et al 2010; Gaby and Buckley 2012). Several groups of endophytic N-fixing bacteria in plants have been reported, including the genera *Acetobacter*, *Azoarcus*, *Gluconacetobacter*, *Herbaspirillum*, *Methylobacterium*, and *Burkholderia* (Donato et al. 2005; Balachandar et al. 2006; Govindarajan et al. 2007).

Maize plants can be simultaneously colonized by a wide variety of diazotrophic bacteria (Table 16.2) (Chelius and Triplett 2001; Lodewyckx et al. 2002), and the genera *Azospirillum*, *Herbaspirillum*, and *Klebsiella* are the most frequently observed (Baldani et al. 1986; Chelius and Triplett 2001; Alves et al. 2015). The genus *Burkholderia* has also been appointed as widely spread in association with maize cultivated in tropical conditions, including the species *B. tropica* and *B. unamae* (Govindarajan et al. 2006; Perin et al. 2006). More recently, *Bacillus pumilus* was efficient in biological nitrogen fixation in maize in greenhouse conditions (Kuan et al. 2016). The N-fixing bacteria are located most often in roots, followed by stems and leaves of maize (Mendonça et al. 2006), and high densities are observed during the plant growth cycle that match with the N-fixing peak (Siqueira and Franco 1988). Additionally, several studies have indicated that the bacterial N fixation efficiency in maize is strongly influenced by the plant genotype (Montanez et al. 2009; Araújo et al. 2014).

Arbuscular mycorrhizal fungi (AMF) play an essential role in the absorption of nutrients in the most land plants. Although the contribution of the symbiosis of AMF with plants has been recognized for phosphate nutrition, its role in nitrogen nutrition is still controversial (Bucking and Kafle 2015). Several works have demonstrated an increased N uptake by roots infected with AMF (Saia et al. 2014; Correa et al. 2015; Mensah et al. 2015). However, in some cases, the N fixation has been attributed the bacteria associated with mycorrhizal fungi (Minerdi et al. 2001).

P is the second most nutrient limiting to plant development, participating as a structural component of nucleic acids, phospholipids, and adenosine triphosphate (ATP); it is a key element of metabolic and biochemical pathways that can also affect the grain yield in cereals (Khan et al. 2009). In the soil, P is distributed in the inorganic and organic forms. Although the organic P corresponds between 30 and 80 % of total P, found mainly in the form of phytate (Richardson and Simpson 2011), it is not readily available for uptake by plant root system (Mudge et al. 2003; Tarafdar and Gharu 2006). Insoluble mineral complexes are also important sources of P in the soil (Rodríguez et al. 2006), but the levels of reactivity of the P linked to iron and aluminum in acid soils (pH < 5) and linked to calcium in alkaline soils

[a]Plant growth promotion

(pH > 7) are low (McLaughlin et al. 2011). This, only a small proportion of P, is readily available for uptake by plants (Tinker and Nye 2000).

Several microorganisms solubilizing inorganic P and mineralizing phytate have been identified and characterized (Table 16.2). *Acinetobacter*, *Bacillus*, *Burkholderia*, *Bradyrhizobium*, *Enterobacter*, *Mesorhizobium*, *Paenibacillus*, *Pantoea*, *Pseudomonas*, *Rhizobium*, *Serratia marcescens*, *Penicillium*, *Aspergillus*, and *Micromonospora* stand out within the group of bacteria, fungi, and actinomycetes (Marra 2012; Silva et al. 2014). Many of these have already been evaluated as biofertilizers (Goldstein et al. 2003; Oliveira et al. 2009; Jorguera et al. 2011; Mander et al. 2012).

The mechanisms associated with the increased P availability in the soil by microorganisms are varied and are related mainly to the release of organic acids (Whitelaw 2000; Goldstein et al. 2003), release of cations H^+ and consequent reduction of the soil pH (Villegas and Fortin (2002)), production of exopolysaccharides (Yi et al. 2008) and siderophores (Hamdali et al. 2008), and action of phosphatase enzymes (Richardson et al. 2009; Ogbo 2010), mainly as phytases (Greiner 2006). Some genes involved in the P solubilization and mineralization, including *pqq* and *bpp*, have been identified and isolated in different species of microorganisms (Table 16.1) (Rodríguez et al. 2006; Jorguera et al. 2011; Kim et al. 2003).

Several studies have reported increased growth and absorption of nutrients in maize plant inoculated with P-solubilizing microorganisms under greenhouse or filled conditions (Hameeda et al. 2008; Kumar et al. 2007). Some species have been cited such as *Pantoea cypripedii*, *Pseudomonas plecoglossicida* (Kaur and Reddy

2015), *Pseudomonas tolaasii* (Viruel et al. 2014), *Serratia marcescens*, *Bacillus coagulans*, and *Enterobacter asburiae* (Hameeda et al. 2008). These bacteria have significantly positive effects on grain yield, biomass and P content of the plants.

Microorganisms isolated from the maize rhizosphere have also been identified and showed effective solubilization and mineralization of sources of insoluble inorganic P (Table 16.2). Oliveira et al. (2009) evaluated bacteria and fungi of the maize rhizosphere to P solubilization and mineralization. The species of *Burkholderia* and *Bacillus* were more efficient to P solubilization releasing up to 67 % of total P in the medium. For phytate, the most effective were fungal species *Talaromyces rotundus* and *Aspergillus terreus* and *Burkholderia cepacia.* The genera *Aspergillus* and *Penicillium* have also been associated with P solubilization in other works (Coutinho et al. 2012; Gomes et al. 2014).

The mycorrhizal fungi (AMF) also play an important role in increasing the P availability for plants. These microorganisms contribute to higher P uptake due to the larger volume of soil explored by higher branching and extension their hyphae (Berbara et al. 2006). Additionally, AMF may contribute to the mineralization of organic P by phosphatase enzyme production (Yao et al. 2001; Cardoso and Kuyper 2006). Some studies suggest that the AMF interacting with plants help in the tolerance of crops to certain tensions present in many agricultural soils, especially in the nutrient starvation such as phosphorus and water deficiency (Abbott and Robson 1991, Williams and Sylvia in 1992; Chu et al. 2013). For maize, species of AMF of the *Glomus* genus have been used as inoculant (Chu et al. 2013; Dhawi et al. 2015). The positive effect of this interaction is gain in plant growth by increase of the biomass-infected plants in many crops such as maize (Hu et al. 2009; Souza et al. 2015; Cozzolino et al. 2013).

16.3.2 Phytohormone Production

Microorganisms are able to produce phytohormones that promote plant development and growth, including auxins, cytokinins, gibberellins, abscisic acid, and ethylene (Zahir et al. 2003). These molecules can also stimulate the reproduction and colonization of beneficial microorganisms, besides indirectly contributing to plant development by regulating the immune response of the plant against pathogens and herbivorous insects (Pieterse et al. 2012). For maize, bacteria and fungi, rhizosphere, and endophyte have been described by their capacity to produce phytohormones (Table 16.2) and help in its development directly or indirectly by increasing the protection of plants against pathogens (see Sect. 16.3.3).

Auxin is a group of aromatic ring compounds with a carboxyl group, and its main member is indole-3-acetic acid (IAA) (Korasick et al. 2013). IAA can act in the stimulation of stem growth, cell division, initiation and differentiation of the roots, differentiation of the vascular tissues in phloem and xylem, and promotion of the flowering and help in the formation of fruit. In addition, auxin can contribute to delay leaf senescence and fruit maturation (Davies 2010).

Cytokinins are adenine-type compounds, being cytokinin zeatin the most commonly found in plant tissues (Davies 2010). Cytokinins are present in all parts of the plants, but root region, apical part of shoots, and seeds have higher concentrations of this hormone, which is explained by its function of triggering cell divisions in these plant parts (Santner and Estelle 2010). Furthermore, cytokinin is also involved in the germination, initial formation of branches, growth of lateral buds, leaf expansion, opening of stomata, chloroplast development, and leaf senescence and still plays an important role in the formation of nodules during nitrogen fixation (Murray et al. 2007; Davies 2010).

Gibberellins are diterpene compounds (Bomke and Tudzynski 2009), and the gibberellic acid (GA) is the most known and active. However, there are over 130 different molecules belonging to gibberellin group (Dodd et al. 2010). Gibberellins are involved primarily in cell division and elongation within the apical meristem. It also stimulates seed germination, pollen tube growth, and plant flowering. Various functions triggered by gibberellins are a result of their interaction with DELLA proteins (repressors of transcription GA-dependent processes). Gibberellin operates in destabilization or degradation of DELLA, for example, DELLA degradation by GA suppresses the defense response dependent on jasmonic acid and stimulates dependent response of salicylic acid (Pieterse et al. 2012). As auxin and cytokinin molecules, gibberellins act in combination with other hormones and are affected mainly by auxin and ethylene (Tsavkelova et al. 2006).

Abscisic acid (ABA) is a phytohormone synthesized via isopentenyl diphosphate and carotenoids from glyceraldehyde-3-phosphate (Davies 2010) and is involved in plant responses to biotic and abiotic stresses, such as the inhibition of seed germination and flowering in response to stress by drought, salinity, and toxic metals (Smyth 2011). High ABA concentration, for example, stimulates the gene transcription involved in the protection against dehydration and osmotic stress. In this case, ABA leads to protein expression that helps in osmotic stabilization, enzymes for detoxification of reactive oxygen species, and aquaporins, which facilitate the water and ion movement across membranes, also regulating water loss rate by stomatal opening (Davies 2010).

Ethylene is a gaseous hormone (C_2H_4) synthesized from methionine. It is produced from conversion of S-adenosyl methionine to 1-aminocyclopropane-1-carboxylate (ACC) by activity of the ACC synthase enzyme (Giovanelli et al. 1980). Ethylene is synthesized by most tissues in response to abiotic and biotic stress being mainly produced in tissues undergoing senescence and maturation and in response to pathogen attack. It can act synergistically with jasmonic acid. Furthermore, ethylene may contribute to plant growth by stimulating rooting, opening of flowers, and release of dormancy and may act in the detoxification of reactive oxygen species in stressed cells (Davies 2010; Pieterse et al. 2012)

Rhizobacteria of the *Pseudomonas* genus, isolated from maize, presented capacity to produce AIA (Picard and Bosco 2005). In this work, the authors also found that in hybrid plants, roots have increased the AIA-positive *Pseudomonas* sp. colonization, showing a superiority of hybrid plants in comparison to their parental lines for the recruitment of beneficial bacteria. Besides *Pseudomonas*, rhizobacteria of the

genera *Bacillus*, *Burkholderia*, and *Micrococcus* also presented the phytohormone production, such as AIA (Pal et al 2001; Naveed et al. 2015) and cytokinin (Raza and Faisal 2013), and contributed to the maize growth during its colonization. The *Azospirillum lipoferu*m bacterium has also stimulated the development of maize plants; in this case, the production of the gibberellic acid and abscisic acid hormones stimulates the growth and tolerance of the plants during colonization under drought period (Cohen et al. 2009). In another study, endophytic bacteria *Azospirillum brasilense* inoculated in maize promoted its growth also due to production of gibberellic acid (Lucangeli and Bottini 1997). Other genera of endophytic bacteria from maize have shown potential to AIA production, such as *Microbacterium*, *Pseudomonas*, *Bacillus*, *Enterobacter*, *Curtobacterium*, *Serratia*, and *Pantoea* (Vieira 2015).

For fungi group, *Trichoderma harzianum* species showed capacity to produce phytohormones such as gibberellins and auxin and contributed to maize plant growth (Akladious and Abbas 2012). Furthermore, during maize colonization by *Glomus intraradices* (mycorrhizal fungus), there was also an observed increase in auxin production (IBA, indole-3-butyric acid), as well as increased activity of IBA synthetase enzyme (Ludwig-Müller et al. 1997). Given the beneficial effects of auxin on the root system structure, for example, to root growth, it can be important to AMF interaction establishment (Sukumar et al. 2013).

16.3.3 Biocontrol

Biocontrol of phytopathogens by plant-associated microbiota can be based on several mechanisms which include antibiosis, competition for nutrients and niches, as well as induction of host defense genes to avoid pathogen attack or reduce pathogen growth (Beneduzi et al. 2012). The act of antagonism against pathogen growth is viewed as the most powerful and best-characterized mechanism that explains the capacity of the microbiota to pathogen control. *Bacillus* and *Paenibacillus* species actually devote larger part of the genome (4–8 %) to antibiotic synthesis and, therefore, display potential to produce a vast array of structurally diverse antimicrobial compounds (Chen et al. 2009; Aleti et al. 2015). These genera and others plant-associated are considered a source of great biotechnological potential of bioactive metabolites that not yet fully known. Strains of *Pseudomonas* sp. EM85, *Bacillus* sp. MR-11(2), and *Bacillus* sp. MRF from maize rhizosphere antagonized the fungi pathogens as F*usarium moniliforme*, *F. graminearum*, and *Macrophomina phaseolina* (Pal et al. 2001). *Pseudomonas* sp. produced antifungal compounds, siderophore, cianidric acid and fluorescent pigments; while *Bacillus* sp. MR-11(2) produced siderophore, antibiotics, and antifungal volatiles and *Bacillus* sp. MRF exhibited the production of antifungal, antibiotics and siderophores. In this study, the combined application of two bacilli reduced 56.04 % of the *Macrophomina*-induced charcoal rots of maize. Positive effects with purified antifungal, antibiotics and/or fluorescent pigment of *Pseudomonas* sp. EM85 and purified antifungal,

antibiotics of bacilli along with the successful colonization of all the isolates might be involved in the biological suppression of the maize root diseases.

Paenibacillus sp. produces diverse antifungal compounds including polymyxins, fusaricidins, colistins, volatile compounds, and lytic enzymes (Raza et al. 2015; Naghmouchi et al. 2012). *Paenibacillus polymyxa* strain and *Citrobacter* sp. isolated from diverse maize genotypes suppressed the growth of *Fusarium graminearum* and other 20 fungi (Mousa et al. 2015). These microorganisms reduced deoxynivalenol mycotoxin concentrations produced by *F. graminearum* during storage to levels significantly below acceptable safety limit. *P. polymyxa* fungicidal action mechanism involved the fusaricidin production and induction of systemic host resistance (Mousa et al. 2015; Mei et al. 2014).

Pyrrocidines A and B are polyketide amino acid-derived antibiotics produced by endophytic fungus *Acremonium zeae* of *Zea mays* (Wicklow et al. 2005). These biomolecules displayed significant activity against kernel rotting and fungi mycotoxin produced by *Aspergillus flavus* and *Fusarium verticillioides* (Wicklow and Poling 2009). In equivalent assays performed with conidia or hyphal cells as inoculum, pyrrocidine A was active against major stalk and ear rot pathogens of maize, including *F. graminearum*, *Nigrospora oryzae*, *Stenocarpella* (*Diplodia*) *maydis*, and *Rhizoctonia zeae*, besides activity against *Clavibacter michiganensis* subsp. *nebraskensis*, causal agent of Goss's bacterial wilt of maize. Pyrrocidine A displayed also significant activity against seed rot saprophytes *A. flavus* and *Eupenicillium ochrosalmoneum*, as well as seed-infecting colonists of the phylloplane *Alternaria alternata*, *Cladosporium cladosporioides*, and *Curvularia lunata*, which produces a damaging leaf spot disease (Wicklow and Poling 2009). This antibiotic also exhibited potent activity against *Bacillus mojavensis* and *Pseudomonas fluorescens*, maize endophytes applied as biocontrol agents, but was ineffective against the wilt-producing bacterium *Pantoea stewartii*.

Bacteriocins are proteins or ribosomally bacteria-synthetized peptides with bactericidal or bacteriostatic effect against closely related species and strains unrelated (Klaenhammer 1993; Cotter et al. 2013). Most bacteriocins kill target cells by formation of pores or channels in the inner membrane that results in the leakage of cytoplasmic compounds, destruction of electrochemical gradient, ion loss, and cell death (Riley and Wertz 2002). Others interfere with DNA, RNA, and protein metabolism (Riley 1998) or contain DNase, 16S rRNase, and tRNase activities (Riley and Wertz 2002). Others can degrade the peptidoglycan precursor, leading to an inability to synthesize peptidoglycan and bacterial death (Cascales et al. 2007), or prevent spore outgrowth (Mazzotta et al. 1997). The higher number of described active biomolecules was associated with *B. thuringiensis*, such as thuricin (Favret and Yousten 1989), tochicin (Paik et al. 1997), entomocin 9 (Cherif et al. 2003), and bacthuricin F4 (Kamoun et al. 2005). Furthermore, the genus *Pseudomonas* produces bacteriocins that are structurally and mechanistically diverse, including polypeptides of middle size, such as colicin-like S pyocins produced by *P. aeruginosa* (Parret et al. 2003); large phage taillike multiprotein complexes, such as syringacin M and R- and F-type pyocins produced by *P. syringae* and *P. aeruginosa*, respectively (Nakayama et al. 2000; Michel-Briand and Baysse 2002); lectin-like bacteriocins,

such as putidacin A (Parret et al. 2003); and colicin M-like colicins, such as PaeM produced from *P. aeruginosa*, PsyM from *P. syringae*, and PflM isolated from *P. fluorescens* (Barreteau et al. 2012).

Surface-active compounds (SACs) act also as biocide agents. Several of these biomolecules play essential roles for the survival of producer microorganisms in natural and artificial environments facilitating nutrient transport; they are important for gliding and swarming motility as well as de-adhesion from surfaces or microbe–host interactions (Compant et al. 2010; Chrzanowski et al. 2012). In addition, SACs have been reported to be involved in the stimulation of immunity in plants and animals. Due to a broad range of physicochemical properties of the SACs, their low toxicity, high biodegradability, and antimicrobial properties are promising molecules to be used against pathogens in agriculture (Sachdev and Cameotra 2013). The *Bacillus*-related lipopeptides, cyclopeptides (iturins) (Gong et al. 2015), or macrolactones (fengycins and surfactins) (Gong et al. 2015; Snook et al. 2009) are characterized by the presence of L- and D-amino acids and variable hydrophobic tails. They are among the most documented lipopeptides by their activity against plant pathogens in maize. As example, Leu(7)-surfactin, a cyclic heptapeptide linked to a β-hydroxy fatty acid, was identified as the inhibitory substance of the *Bacillus mojavensis* culture extracts, an endophytic bacterium patented for control of fungal diseases in maize. The bacteria antagonize the pathogenic and mycotoxic fungus *Fusarium verticillioides* (Snook et al. 2009).

The ability to produce siderophore and capture the iron allows a great competitive advantage against pathogens (Radzki et al. 2013). Siderophores are compounds with low molecular weight (200–2000 Da) produced by microorganisms and plants, especially under Fe-limiting conditions. There are three main kinds of siderophore: hydroxamate, catecholate and carboxylate. These molecules show high specificity and affinity for binding Fe^{3+} (Schwyn and Neilands 1987; Krewulak and Vogel 2008). Thus, siderophores can display role of biocontrols, biosensors, and chelation agents as well as helps in the plant growth in weathering soil (Dimkpa et al. 2008; Tortora et al. 2011). The excretion of siderophores by bacteria might stimulate plant growth by direct effect (improving nutrition) or indirectly by inhibiting of phytopathogens establishment through Fe sequestration from environment, limiting mineral available to the pathogen growth. Unlike microbial pathogens, plants are not affected by bacterial-mediated Fe depletion and some plants can also capture and utilize Fe^{3+} from bacterial siderophores complexes (Dimkpa et al. 2008). Bacteria of the genera *Pseudomonas*, *Azotobacter*, *Bacillus*, *Enterobacter*, *Serratia*, *Azospirillum* and *Rhizobium* are related to siderophore production (Loper and Buyer 1991; Neilands 1995). In maize, endophytic strains belonging to genus Bacillus showed siderophore production and were efficient against the growth of *Fusarium verticillioides*, *Colletotrichum graminicola*, *Bipolaris maydis*, and *Cercospora zeae-maydis* (Szilagyi-Zecchin et al. 2014). Siderophores produced by *A. brasilense* showed also antifungal activity in vitro against Colletotrichum acutatum, the causal agent of anthracnose (Tortora et al. 2011).

Moreover, microorganisms can parasitize disease-causing fungi by the production of hydrolytic enzymes. These can hydrolyze a wide variety of polymeric compounds,

including chitin, proteins, cellulose, hemicellulose, and DNA. Production of extracellular cell wall-degrading enzymes such as glucanases and chitinases has been associated with biocontrol abilities of the producing bacteria (Fridlender et al. 1993; Valois et al. 1996). Ordentlich and coworkers (1988) have reported the potential of *Serratia marcescens* to control fungus *Sclerotium rolfsii* by degrading the cell walls of the fungus through production of chitinase enzymes.

Several studies have attributed the increased production of plant biomass to antagonist activity of microbial inoculants or the combination of this activity with other PGP features. Johnston-Monje and Raizada (2011) reported that maize endophytes of the genera Luteibacter, Microbacterium, Arthrobacter, Cellulomonas, and Burkholderia showed antagonist activity against *Escherichia coli* DH5α, *B. subtilis* spp., and yeast. These strains were also active against bacteria (Pseudomonas aeruginosa and *Bacillus subtilis*) and fungi (*Fusarium moniliforme, Aspergillus flavus* and *Helminthosporium sativum*) in *in vitro* assays, besides showing siderophore production, phosphorus solubilization and bacteriocin production. The high antioxidant enzyme activity including superoxide dismutase, peroxidase, catalase and ascorbate peroxidase were also enhanced in these bacteria inoculated to maize.

Besides the control of plant pathogens by production of bioactive molecules, many microorganisms can suppress plant diseases through induction of plant resistance against pathogens and herbivores. Various elicitor compounds produced by microorganisms can stimulate plant resistance systems, for example, surfactin, fengycin, rhamnolipids (Ongena et al. 2007; Sanchez et al. 2012), acyl-homoserine lactones, N-alkylated benzylamines (Van Loon et al. 1998), exopolysaccharides, volatile organic compounds (Ryu et al. 2004), phenylacetic acid (Akram et al. 2016), antibiotics such as 2,4-diacetylphloroglucinol (Weller et al. 2012) and pyocyanin (De Vleesschauwer et al. 2006), flagellum, phytohormones, and siderophores such as salicylic acid that has been reported as inducers of plants resistance (van Loon et al. 1998).

From the induction of plant defense genes, the response can be triggered by defense systems dependent on jasmonic acid (JA) or salicylic acid (SA) (Vlot et al. 2009). Briefly, the systemic acquired resistance (SAR) is a way that usually depends on the SA. The plant defense capability is acquired after the first infection, taking effect mainly against biotrophic pathogens. The NPR (non-expressor of PR genes) regulatory protein is activated after recognition of pathogen attack by receptors' extracellular surface that recognizes molecular patterns associated with pathogens (PAMPs) and acts as a transcriptional cofactor of genes related to defense plant (Moore et al. 2011), stimulating the production of reactive oxygen species (ROS), the SA accumulation, and increased expression of proteins related to direct attack of pathogens such as chitinase, proteases, and antimicrobial compounds (Vlot et al. 2009).

In the induced systemic resistance (ISR), JA can act synergistically with ethylene (ET) in response to necrotrophic and herbivore pathogens. The route of JA-dependent resistance, in general, has two branches: (1) triggered in response to herbivorous attack controlled by the MYC transcription factors (Lorenzo et al. 2004), there is induction of the expression of genes that affect digestive ability of the insects,

defense protein genes with large antimicrobial spectrum, and the production of volatiles that attract carnivorous arthropods or parasites and herbivorous insects; (2) during response to necrotrophic pathogens regulated by JA/ET, there is induction of the expression of chitinase enzyme genes and glucanase that degrade the cell walls of phytopathogenic fungi and peroxidases to produce reactive oxygen species that has antimicrobial action (Berrocal-wolf et al. 2002; Sobrinho et al. 2005).

Among the microorganisms with potential already known to stimulate the resistance of plants, *Pseudomonas* and *Bacillus* within the bacteria group are most frequently reported. Aside from these, other species of bacteria such as *Serratia marcescens* (Press et al. 1997), *Rhizobium etli* (Reitz et al. 2002), *Streptomyces* sp. (Salla et al. 2016), and *Paenibacillus lentimorbus* (Kumar et al. 2016) also showed ability to stimulate plant resistance. For fungi, *Trichoderma* sp. (Saxena et al. 2015), *Piriformospora indica* (Wang et al. 2015) and *Penicillium simplicissimum* (Elsharkawy and Mousa 2015) have been related as stimulators of the resistance of plants.

In maize, some nonpathogenic bacteria have shown potential to stimulate resistance system to diseases. *Pseudomonas putida*, for example, induced resistance against maize anthracnose caused by *Colletotrichum graminicola* (Planchamp et al. 2014). This work shows a strong reduction of the pathogenic fungus growth and leaf necrosis on inoculated plants with *P. putida*. There was also a correlation between the induction of resistance during inoculation depending on the phospholipid metabolism and phytohormone production, indicating that these molecules stimulated the expression of ABA, ET, auxin, JA, and cytokines. All these phytohormones are involved with plant defense system stimulation. In another study, *Pseudomonas aurantiaca* showed ability to induce resistance of maize plants infected with the fungus *Bipolaris maydis*. Both extracts as supernatant of free cells of *P. aurantiaca* were effective for reduction of leaf necrosis caused by pathogenic fungus, leading to reduction of about 30 % disease severity (Fang et al. 2013).

Bacillus subtilis and *Azospirillum brasilense* were also related to capacity of inducing the maize defense system (Santos et al. 2014). *B. amyloliquefaciens* and *B. subtilis* stimulate the expression of resistance genes (PR-1 and PR-4) in maize plants infected with *Fusarium moniliforme* through the production of iturin A, fengycin, and bacillomycin and prevent the emergence of root lesions (Gong et al. 2015). *Azospirillum brasilense* induce also the maize resistance against the herbivorous insect (*Diabrotica speciosa*) attack (Santos et al. 2014).

For the fungi, *Trichoderma* genus is the most reported with the ability to induce the defense of maize plants. Many studies have demonstrated the effect of *Trichoderma* sp. in the induction of maize resistance against pathogens such as *Fusarium* sp. (Luongo et al. 2005), *Colletotrichum graminicola* (Djonovic et al. 2007), *Fusarium verticillioides* and *fumonisins* (Nayaka et al. 2010), and *Curvularia lunata* (Fan et al. 2015). In the working of Mukherjee et al. (2012), there was a detected activity of the polyketide synthase and phenylalanine ammonia lyase enzymes of *Trichoderma virens* interacting for inducing maize plant resistance. In an investigation of the *Trichoderma virens* secretome during interaction with maize plants, there was a detected presence of small cysteine-rich proteins that possibly

act as effectors to reduce the level of plant stress, which can be part of a slight induction of systemic resistance against plant pathogen attack (Lamdan et al. 2015).

16.4 Microorganisms as Bioinoculants: Challenges to Microbial Diversity Use in the Sustainable Agriculture

Some microorganisms have shown the potential as bioinoculant. These microbial formulations are cheaper alternative according to requirement of sustainable environmental practice (Singh and Ratna 2016). Different microorganisms belonging to various taxa of bacteria, fungi, and possibly protozoa can colonize the rhizosphere or plant tissues and promote plant growth (Malusa et al. 2016; Szilagyi-Zecchin et al. 2016).

Among the main groups of microorganisms investigated for use as biofertilizer, it has been especially multifunctional strains. These microorganisms are both rhizosphere as endophytes that have capacity to produce many beneficial factors for the plant development (Montanez et al. 2012). Besides, protection to abiotic stresses such as drought in maize was observed after inoculation with microorganisms in experiments performed by Zoppellari et al. (2014).

Research related to the application of microbial biofertilizer has been carried out, and there are some bacteria-based commercial products (Hungria et al. 2010). However, only particular types of N-fixing bacteria have been used most extensively in agriculture as inoculants, such as those based in *Rhizobium* spp. to soybean in Brazil (Hungria et al. 2015). For grasses, as maize, the use of microorganisms of the rhizosphere have not been promising, probably due to the weak interaction with the plant comparing to endophytic microorganisms that have a much close symbiotic relationship with the plant, and it can be an advantage for its use as inoculant in relation to the rhizosphere (Sharma and Nowak 1998; Souza et al. 2015).

Maize is a C4 plant of annual cycle and therefore has a high nutrient demand. The maize association with bacteria of the *Azospirillum* genus has shown increasing up to 40 % of grain yield, this is equivalent to addition 80 kg/ha of N under field conditions (Marriel et al. 2008; Hungria et al. 2010). However, the inoculant based on the *Azospirillum* has shown variable effectiveness according to environmental conditions, plant genotype and especially bacteria species evaluated (Dobbelaere et al. 2001; Hungria et al. 2010).

Some phosphate fertilizer products for maize have been in the market in countries such as Canada, Australia, Egypt, and India, obtained from the rock phosphate mixture, solubilizing microorganisms, and a carbon source derived from sugarcane waste or cassava (Khalil et al. 2002; Faye et al. 2013). The combined use of rock phosphates and P-solubilizing microorganisms has been considered a promising strategy in environmental and economic terms (Singh and Ratna 2016). Results demonstrated productivity gains and plant mass of maize (Patil et al. 2016). Hameeda et al. (2008) observed increase approximately 30 % of the productivity gains related to control without microorganism inoculation and accumulation of 66

% of P in maize plants. Mineralizing microorganisms of phytate (MMP) has also been assessed for their use as biofertilizer in several crops (Goldstein et al. 2003; Jorguera et al. 2011; Mander et al. 2012) including maize (Oliveira et al. 2009). Under controlled conditions, in the maize inoculated with MMP and fertilized with rocks, an increase of the biomass of root up to 76 % and of the P content in the dry mass of maize was found (Oliveira et al. 2013). Regarding the inoculant-based AMF in maize, there are many difficulties for cultivation and application of AMF on a large scale. Part of this difficulty is because the interaction with AMF and plants is species specific, which affects the adaptation of the fungus according to the host plant (Bagyaraj et al. 2015; Zoppellari et al 2014). However, some studies also report the combined effect of biofertilizers containing microorganism solubilizing P, AMF, and diazotrophs in maize (Wu et al. 2005; Mohamed et al. 2014; Manzoor et al. 2016).

The use of microorganisms with ability to solubilize potassium (K) has also been investigated (Basak and Biswas 2009; Lopes-Assad et al. 2010; Meena et al. 2014; Zhang and Kong 2014; Silva et al. 2015), showing potential of the microorganisms to release K in the soil–plant system, promoting plant development (Alves et al. 2010; Verma et al. 2013; Prajapati et al. 2012; Zhang and Kong 2014). In maize, Singh et al. 2010 observed a higher biomass and K content accumulation in plants inoculated with *Bacillus mucilaginosus* in soil added with mica rock, as K source.

The microorganism selection process for inoculant formulation involves the isolation and identification of species responsible for promoting growth for a specific plant type and then evaluation of the survival rate, adaptation and multiplication of the microorganisms in the rhizosphere (rhizosphere competence), and infection and colonization of the host plant (endophyte competence) (Sathya et al. 2016), in laboratory and field tests. Thus, there are many challenges to achieve efficient inoculants on a large scale; any microorganisms found effective in in vitro studies can fail in promoting plant growth in the field conditions. Moreover, some strain characteristics are important to the successful growth promotion: ability to survive in the inoculant formulation, capacity to maintain its properties during storage, and tolerance to stress factors such as acidity, desiccation, high temperatures, chemical pesticides, and competition with other microorganisms. The high concentration of viable microbial cells and contaminant absence are essential factors for the quality of the inoculant (Leggett et al. 2007).

The adequate choice of the vehicle used in the formulation is another key factor to cell viability and inoculant quality (Silva et al. 2012). It can be used as vehicle in soil and inert material as turf or waste of industrials and of plant. Biodegradable polymers such as sodium alginate have also been identified as ecologically safe vehicles (Sahu and Brahmaprakash (2016)). These polymers promote encapsulation of cells and protection from environmental stress; the cells will be released after degradation in the environment.

The use of inoculants has found barriers with regard to reducing or replacement of industrial fertilizers by farmers, but its use as complement to fertilizer is becoming more acceptable and already has results from productivity gains (Oliveira et al. 2013). Considering the low cost of inoculant and its environmental role, the use of

inoculants based in PGPM in the maize becomes a viable and promising practice within of the context of sustainable agriculture (Singh and Ratna 2016). However, many advances in understanding of the microbes, plant, and environment interactions are still required. Among the challenges, the methods to manage the introduction of the microorganism, its adaptation and colonization in several hosts, growth in regions with different soil and climatic conditions, and the determination of its effectiveness and agronomic validation stand out.

Biofertilizers: A Timely Approach for Sustainable Agriculture

17

Supriya Tomer, Deep Chandra Suyal, and Reeta Goel

Abstract

Chemical fertilizers are extensively being used all around the globe in order to get the high yield of the crops. However, their indiscriminate use has imposed detrimental impact on soil animal health as well. A better alternative of these chemicals might be to exploit the microbial capabilities to be served as biofertilizer. Crop growth and yield are closely related to the soil microbiota, especially those in close proximity to plant roots, generally termed as "rhizosphere." These microbes are known to play a number of vital roles in soil fertility, crop productivity, and production in agriculture and are the best supplement of chemical fertilizers.

17.1 Introduction

Agriculture is the largest private enterprise in India and will continue to be the lifeline of Indian economy in the future. Indian agriculture sector has only 0.2 % growth rate. It comprises 13.7 % of total GDP in 2015 and half of the total work force (BANR/NRC 2015; Roychowdhury et al. 2014). It is estimated that overall food demand will rise in the proportion of world population. Global population is continuously increasing at the rate of above 1.8 % annually, and it will reach to the point from today's calculated 7.4 billion to an anticipated demographical data of 9.6 billion by 2050 (United Nations 2013). After green revolution, the chemical-based fertilizers and pesticides have enormously boosted the agricultural production. However, their indiscriminate use, besides imposing a detrimental effect on

atmosphere has developed the resistance in insects against common pesticides. Therefore, establishing an environmental friendly coexisting mechanism on our planet Earth is of utmost importance.

Most of the fertile soils in favorable environments are being diverted toward alternate uses due to increasing urbanization which creates pressure to expand agriculture. The agrochemicals cannot increase crop yield beyond a threshold level. Moreover, due to lack of knowledge, farmers use more agrochemicals than the recommended level. This excessive application of agrochemicals leads to negative impact on consumer health and loss of soil fertility as they increase salt content of the soil (Swapna 2013). This poor cropping has resulted in new challenges for agricultural productivity. External environments such as biotic (plant pathogens) and abiotic (excess or deficient water and nutrients, high or low temperature, and soil salinity) are dominant factors affecting crop production. Therefore, to increase actual yield of various crops, there is a need to modify abiotic and biotic factors in such a way that they will become capable to fulfill our agricultural demands, where the conventional agriculture practices disappoint. Recently, toxic effects of agrochemicals on human life and environment have shifted the focus on eco-friendly alternatives. Promotion of biofertilizer-based organic farming is need of the hour as demand for safe and residue-free food is gradually rising with high pace.

17.2 Biofertilizers: An Alternative of Chemical Fertilizers

Biofertilizers are the microbial inoculants that colonize the rhizosphere and improve plant growth by enhancing nutrient accessibility to plants. Microorganisms residing in rhizosphere immensely facilitate trace element's uptake. They may act as biocontrol agent, by means of antagonistic activity against phytopathogenic microorganisms, interfering in the bacterial quorum sensing systems, etc. However, biofertilizers perform more than one mechanism for accomplishing plant growth enhancement (Rani et al. 2013; Suyal et al. 2014a; Kumar et al. 2014). These abilities are of great agriculture importance as far as crop yield and soil fertility improvement is concerned, thus decreasing the ill effects of chemical-based fertilizers in our environment. For instance, excessive use of chemical N fertilizers causes soil acidification and, thus, groundwater and atmospheric pollution. Nonetheless, synthesis of chemical fertilizers is highly energy-consuming processes. Chemical-based fertilizers impose long-lasting effects on the atmosphere in terms of carbon footprint, eutrophication, and soil fertility decline. Vast research program on beneficial microbes has resulted in the formulation of biofertilizers, which are capable to satisfy the needs of sustainable agricultural plans (Table 17.1). Sustainable agricultural practices using biofertilizers and biopesticides consisting potential microbes elevate plant health by multiple means in comparison of their synthetic counterparts. Such agricultural practice uses special farming techniques in order to fully utilize environmental resources besides ensuring that no harm was done to it.

17.3 The Rhizosphere Microbiome

The soil portion which is in immediate vicinity of root is termed as "rhizosphere," while soil-inhabiting bacteria, able to colonize the rhizosphere, are termed as "rhizobacteria." Besides giving the physical support and facilitating nutrient and water absorption, plants secrete a versatile range of compounds. These compounds may attract a wide range of metabolically diverse soil-inhabiting microbial communities.

Root exudates are organic compounds secreted by plant roots. Various chemical compounds which are found in root exudation alter the soil's physiochemical qualities. By this way root exudates regulate microbial community structure and function. Furthermore, root exudates secreted by different plant species have versatile array of chemicals. Thus, amounts and composition of exudates may constitute the variation in microbial community dynamics. Root exudates provide a highly nutritious carbon diet to the rhizobacteria. Predominant molecules found in exudates are organic acids, sugars, amino acids, nucleobases, and vitamins (Keiluweit et al. 2015) (Table 17.2). However, root exudates composition is dependent upon both plant and microorganism's species and their physiological condition (Wang et al. 2015). Additionally, root exudates help in developing symbiotic plant microbe interactions. Root exudates also hamper the growth of the competing plant (Wang et al. 2015). Some amount of exudates are utilized by adjacent microbes as nutrient source in their metabolic processes, while few microorganism-derived compounds are further absorbed by plants for their developmental benefits (Keiluweit et al. 2015).

Table 17.2 Various compounds in root exudates of different plant species

Amino acids	α-Alanine, β-alanine, asparagines, aspartates, cysteine, cystine, glutamate, glycine, isoleucine, leucine, lysine methionine, serine, threonine, proline, valine tryptophan, arginine, ornithine, histidine, phenylalanine, homoserine, α-aminoadipic acid, γ-aminobutyric acid
Organic acids	Citric acid, oxalic acid, malic acid, fumaric acid, succinic acid, acetic acid, butyric acid, tetronic acid, aldonic acid, erythronic acid, valeric acid, glycolic acid, formic acid, piscidic acid, pyruvic acid, lactic acid, aconitic acid, malonic acid, glutamic acid
Sugars	Glucose, galactose, fructose, rhamnose, ribose, xylose, maltose, arabinose, raffinose, oligosaccharides
Vitamins	Thiamine, riboflavin, niacin, pantothenate, biotin
Nucleosides (purines)	Adenine, guanine, cytidine, uridine
Enzymes	Amylase, protease, invertase, acid phosphatase, alkaline phosphatase
Inorganic ions	H^+, OH^-, HCO_3^-
Gaseous molecules	CO_2, H_2

Adapted from Dakora and Phillips (2002)

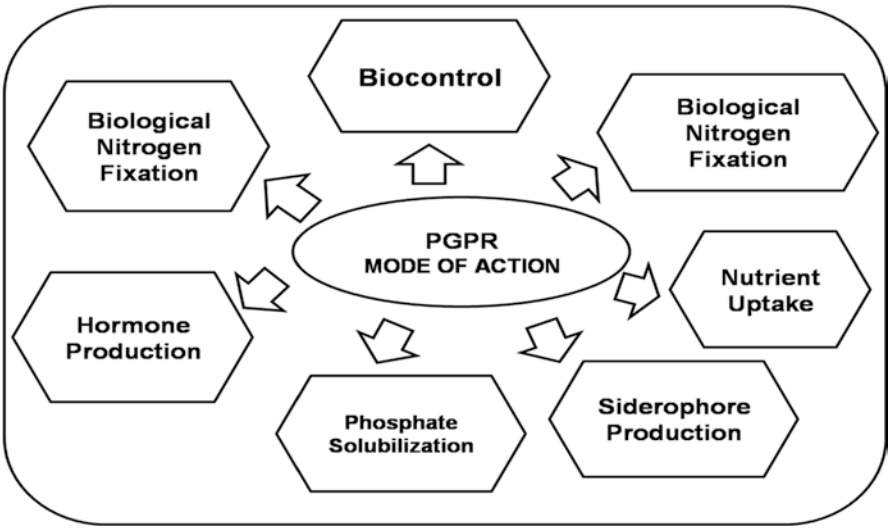

Fig. 17.1 Mode of action of PGPR

Plant growth-promoting rhizobacteria (PGPR) are the group of soil bacteria residing either around or at the plant root surface and benefitting plant through different means.

PGPR have direct or indirect role in plant growth and development through synthesis of different chemical regulators in the rhizosphere's close proximity. PGPR directly help plant development by helping them in macro and micro mineral nutrient uptake as well as by modulating plant hormone levels. Indirectly PGPR boost plant health through declining the detrimental effects of different phytopathogens on plant development (Fig. 17.1). The rhizobacterial potential to utilize organic acids as carbon resources is correlated with rhizosphere competence (Lagos et al. 2015). *Pseudomonas* spp. has the potential to metabolize malate and succinate by greater efficiency than glucose and fructose, during the course of rhizosphere competence. Flagellar mobility, lipopolysaccharide (LPS) structure, chemotaxis, the outer membrane protein OprF, and, to some extent, pili are all crucial for competitive root colonization (Lugtenberg and Kamilova 2009). Agglutinin is a glycoprotein complex of roots thought to facilitate short-term adherence of *Pseudomonas* sp. (Zhang et al. 2014).

17.4 Endophytic Bacteria as Potent Biofertilizer

Endophytic bacteria enhance plant development in nonleguminous crops and enhance their nutritional level through N_2 fixation, phosphate solubilization, and siderophore production (Szilagyi-Zecchin et al. 2014). Besides biofertilization, endophytic bacteria also increase plant growth and yield through producing phytostimulators, like phytohormones, the cofactor pyrroloquinoline quinone (PQQ), and

the volatile acetoin. Endophytic bacteria can help plant to combat stress through the production of stress modulators like the enzyme ACC-deaminase, which helps in plant growth and development by reducing plant ethylene levels as well as indirectly through biological control or biotization. Some fungi are also associated in endophytic association, viz., *Trichoderma stromaticum*, *T. evansi*, *T. amazonicum*, *T. martiale*, *T. theobromicola*, *T. taxi*, etc. Few reports reveal that *Trichoderma* spp. induce transcriptomic changes in plants when associated with them as endophytes. Few species of Trichoderma aid plants to escape diseases and abiotic stresses (Bae et al. 2009). Few fungal endophytes prefer to inhabit surface of glandular trichomes and form structures termed as appressoria (Bailey et al. 2009).

17.5 Groups of Biofertilizers

17.5.1 Nitrogen Fixers

Nitrogen plays a vital role to sustain life on Earth. It is a major component of nucleic acids, proteins, and macromolecules. Nitrogen contributes to 4 % and 3 % dry weight of plants and human body, respectively (Cheng 2008). Nitrogen facilitates photosynthesis in plants as it is essential for chlorophyll synthesis. Even though nitrogen is one of the most abundant elements (nitrogen gas (N_2) contributes to 78 % of the Earth's atmosphere), plants can only utilize reduced forms of this element.

To sustain life processes, nitrogen gets converted from one form to another. During this transformation nitrogen moves in between the atmosphere, land, and living system, and this is called nitrogen cycle. Thus, nitrogen cycle results in the conversion of nitrogen to distinct chemical forms (Fig. 17.2). This conversion may happen *via* biological as well as physical means. Main steps in the nitrogen cycle are fixation, nitrification, denitrification, and ammonification.

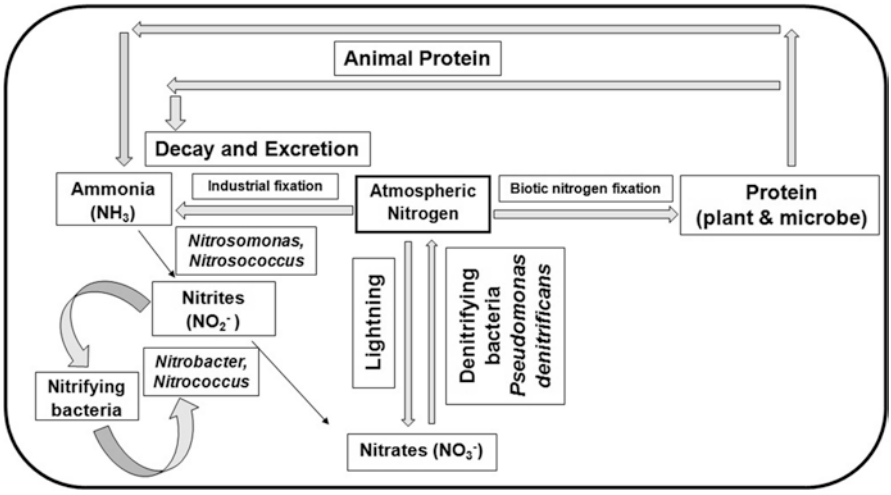

Fig. 17.2 Schematic representation of nitrogen cycle

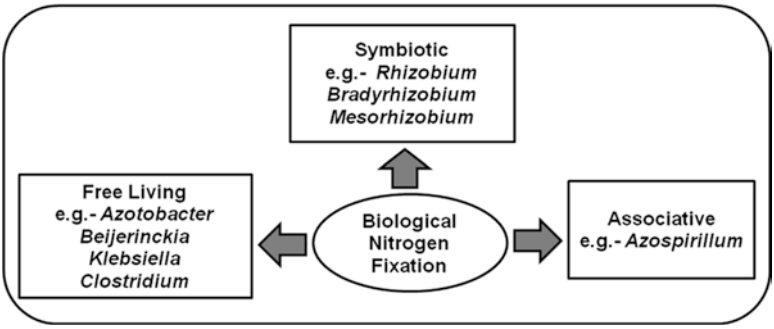

Fig. 17.3 Nitrogen-fixing microorganisms

There are many routes to fix atmospheric nitrogen. Lightning fix nearly 1 % of the total N_2 per year ($\sim 3 \times 10^{14}$ g/year). In order to fix large amount of nitrogen for commercial utility, Haber–Bosch process is used especially for the production of nitrogenous fertilizer (~49 % of the total N_2 fixed/year). In 1908, Fritz Haber invented the process of industrial N_2 fixation. Later Carl Bosch increased the efficiency by using high pressure (200 atm) and temperature (450 °C) to convert atmospheric N_2 to NH_3 in the presence of Fe as catalysts (Smil 2001). Every year early 50 % of the nitrogen is biologically fixed. Among microbes, diazotrophs play a crucial role in this process. They utilize various metabolic pathways in the presence of nitrogenase that is a chief metalloenzyme which facilitates the conversion of N_2 to NH_3.

Diazotrophs are widely distributed in nature and are emerging as an economically beneficial alternative against chemical fertilizers. They can be classified as:

(a) Symbiotic nitrogen fixers are from rhizobiaceae family. They form symbiotic association with leguminous plants (e.g., *Rhizobium*, *Mesorhizobium*, *Bradyrhizobium*) while *Frankia* with nonleguminous trees. Symbiotic relation is established by unique interaction between host and bacteria that results in nodulation. Rhizobium resides intracellularly within root nodules.
(b) Nonsymbiotic (free-living/associative or endophytic) example of nitrogen-fixing nonsymbiotic forms are *Cyanobacteria* (*Anabaena*, *Nostoc*), *Azospirillum*, *Azotobacter*, *Beijerinckia*, *Klebsiella*, *Clostridium*, etc. However, they provide a little fraction of the total nitrogen fixed to the host plant (bacterially associated) (Fig. 17.3).

17.5.1.1 Nitrogenases

Biological conversion of N_2 to NH_3 is by nitrogenases which act as catalyst. Nitrogenases are metalloenzymes with complex and conserved structural features. They comprise of two parts: the small dimeric component called iron (Fe) protein and a heterotetrameric component, molybdenum–iron (Mo–Fe) protein. Fe protein

actively donates electron to Mo–Fe protein-containing catalytic site. Other families of nitrogenase share common features except different central metal atoms (Mo, V, Fe). All nitrogenase contains a small component called Fe protein, i.e., dinitrogenase reductase. Fe protein comprises of [4Fe-4S] cluster that actively delivers electron to the Mo–Fe protein (dinitrogenase) in the presence of Mg ion. Larger component protein contains two metal clusters. One is active metal cluster and another is P-cluster, i.e., [8Fe-7S] that is an intermediate during electron transfer. In general nitrogen fixation reaction is represented as:

$$N_2 + 8e^- + 8H^+ + 16MgATP \rightarrow 2NH_3 + H_2 + 16MgADP + 16P_i$$

A set of operons encode the nitrogenase in nitrogen-fixing bacteria that is comprised of structural genes (*nif*HDK), regulatory genes (*nif*LA), and rest which are supplementary genes. Free-living diazotrophs, *K. pneumoniae*, are studied as a model organism to examine nitrogenase regulation, its biosynthesis, and how it assembles (Desnoues et al. 2003). *K. pneumonia nif* cluster consists of 20 genes located in 24 kbp DNA region (Fischer 1994). Group of structural genes, i.e., *nif*-HDK encodes for three entities of Mo nitrogenase. In maximum nitrogen-fixing prokaryotic microorganism, *nif*HDK genes form one unit to transcribe *nif*H gene. To ensure the activation of apo–Fe protein, i.e., NifH, products of *nif*M *nif*H, *nif*S, and *nif*U are essential, while activation of apo–MoFe protein needs minimum six genes *nif*H, *nif*Q *nif*E, *nif*B, and *nif*N to facilitate FeMoCo biosynthesis. There is significant similarity between *nif*DK and *nif*EN. Now it is well established that product of *nif*EN forms a scaffold for the synthesis of FeMoCo which is then transferred to *nif*DK complex. The gene product of *nif*B, termed NifB-co, is an iron- and sulfur-containing precursor of FeMoCo. Gene product of *nif*Q is suspected to be engaged in forming molybdenum sulfur precursor and has specific metal-binding sequences (Cys-X4-Cys-*X*2-Cys-X5-Cys) (Einsle et al. 2002). The gene product of *nif*V is homocitrate synthase and is essential for FeMoCo biosynthesis. The *nif*W is involved in the early assembly of MoFe protein but gene product of *nif*W prevents MoFe protein from oxygen. The function of *nif*Y gene product is same as that of γ protein. The *nif*F and *nif*J gene products are required to synthesize specific components of electron transfer chain. In this electron transfer chain, electrons are transferred from pyruvate to flavodoxin and received by Fe protein of nitrogenase. *nif*M gene product is important for both stabilization and maturation of *nif*H gene product though its major role is still unknown. Further, many organisms have *nif*S and *nif*U. Thus, the products of at least 12 *nif* genes are necessary to initiate synthesis of active and stable molybdenum nitrogenase (Rubio and Ludden 2008). The *nifH* gene is a useful tool to characterize the diazotrophic communities (Suyal et al. 2014b).

The bioavailable form of nitrogen is limited and crop growth depends upon bioavailable nitrogen. Because of all these facts, nitrogen fertilizer-manufacturing industries have flourished all over the world (Reich et al. 2014). Nowadays nearly 60 % synthetic nitrogen fertilizer is being consumed solely by cereals, while irrigated paddy cultivation uses approximately 10 % of such fertilizers. Half of the total fertilizer applied to field is used by plants, and the rest half results in nitrate

contamination in ground and soil water, therefore leading to serious health problems and imparting threat to the concept of sustainable development. Furthermore, manufacturing N fertilizer is highly energy-consuming process. It consumes six times more energy than that is required to produce either potassium or phosphate fertilizers. Nevertheless, the efficiency of added nitrogen fertilizer is very low. The primary causes of low nitrogen fertilizer efficiency are denitrification, leaching losses, and NH_3 volatilization. Denitrification and NH_3 volatilization produce greenhouse gases like N_2O and NH_3 and thus cause atmospheric pollution and groundwater toxicity. Moreover, the long-term use of nitrogen fertilizer depletes the soil organic matter (Liao et al. 2015). One way to overcome the harmful effects of synthetic nitrogen fertilizer is to use plant growth-promoting diazotrophic bacteria as bioinoculants (Suyal et al. 2014a; Kumar et al. 2014). The need of the hour is to promote sustainable agricultural practices by making use of PGPR (plant growth-promoting rhizobacteria) especially in economically important crops.

17.5.2 Phosphate Solubilizers

P is present in abundance in both organic and inorganic form in soil; still plant available form of P is usually low. Insoluble forms of P are found relatively in higher amount. But, plants only absorb P that is available in two forms, one in monobasic form ($H_2PO_4^-$) and other in form of diabasic (HPO_4^{-2}) ions (Bagyaraj et al. 2015). However, as per the reports, of the total P existing, only 0.1 % is present in soluble form and is free for plant assimilation.

The unavailable phosphorus exists either as an inorganic mineral such as apatite or as one of the many organic forms such as soil phytate, phosphotriesters, and phosphomonesters (Bagyaraj et al. 2015). Farmers apply phosphatic fertilizers in agricultural fields to combat the P deficiency in soils. Plants have restricted efficiency toward utilization of applied phosphatic fertilizers. Remaining unused phosphatic fertilizers get quickly transformed into inaccessible P complexes. Regular long-term application of phosphate fertilizers is detrimental to environment, and sometimes it is unaffordable to the farmers of developing nations. Microorganisms having the potential to convert plant unavailable insoluble P into plant available soluble P are called P-solubilizing microorganisms (PSMs). PSMs are environmentally safe and economically feasible alternative of chemical-based phosphatic fertilizers. Most significant phosphate-solubilizing bacterial genera are reported *Azotobacter*, *Beijerinckia*, *Bacillus*, *Burkholderia*, *Erwinia*, *Enterobacter*, *Flavobacterium*, *Pseudomonas*, *Microbacterium*, *Serratia*, *Rhizobium*, etc.

Solubilization of inorganic phosphorus involves the synthesis of organic acids which are of low-molecular weight by different soil-inhabiting bacteria (Singh et al. 2012; Rani et al. 2013). Conversion of organic phosphorus into inorganic phosphorus is called phosphorus mineralization. Phosphorus mineralization takes place via several phosphatases synthesized by soil microorganisms (Bagyaraj et al. 2015). However, a sole bacterial strain is found to be able to mineralize organic phosphorus and phosphate solubilization as well (Tao et al. 2008). Inoculation of phosphate

solubilizer either alone (Singh et al. 2012) or in combination with some other potential PGPR has been well reported (Zaidi and Khan 2005; Vikram and Hamzehzarghani 2008). Besides increasing accessibility of plant available P to the plants, PSB also made other elemental nutrients available through synthesizing plant growth promontory substances (Ahemad and Kibret 2014).

17.5.3 Siderophore Producers

Iron is required nearly by all life forms except certain lactobacilli to carry out respiration and DNA synthesis. Regardless of being the fourth most plentiful element on Earth (approximately 5 % by weight), the bioavailability of iron is limited. In non-acidic, aqueous, and oxygenated environment, ferric ion is the widespread state of iron. Iron is accumulated to form common mineral phases. These common mineral phases are iron oxides and oxyhydroxides. Hence, it is not easy for organisms to readily utilize it. Microbes obtain Fe^{3+} by secreting low-molecular mass iron scavengers known as siderophores. To solubilize iron, these mineral compounds bind in the form of soluble ferric ion. Fe^{3+} complex uptake by microbial cell is through active transport system and, thus, makes iron unavailable for phytopathogens; however, plants can assimilate iron from bacterial siderophores by special mechanisms. Thus, phytopathogens are deprived of essential macronutrient while plants gain iron through siderophore producing PGPR.

Iron uptake plays a crucial role in microbial competition particularly in the regions of intense competition like rhizosphere. Siderophores are classified into two types, viz., extracellular and intracellular. These are mostly soluble in water. The intracellular siderophore ferricrocin is responsible for iron storage and prevents cellular oxidative stress (Wallner et al. 2009). Rhizobacteria differs regarding cross-utilizing ability of siderophore. Some can utilize siderophores of the like genera, i.e., homologous siderophores, whereas others are proficient in using siderophores produced by rhizobacteria of unlike genera, i.e., heterologous siderophores. In rhizobacterial cell membrane, iron in ferric ion-siderophore complex is converted to ferrous ion that is released in cell (Khan et al. 2009). This release of iron from such complexes takes place through gating mechanism l. In the course of reduction, siderophore's iron complex is either destroyed or recycled (Rajkumar et al. 2010). Thus, when there is iron-limiting situation, siderophores help in iron solubilization from complex compounds (Indiragandhi et al. 2008). Siderophores make stable complexes with several heavy metals which could have been otherwise dangerous to environment, viz., aluminum, cadmium, copper, gallium, lead, zinc, as well as radionuclides (Rajkumar et al. 2010).

Siderophores produced by bacteria alleviate plant stress due to high concentrations of heavy metals in soil. Assimilation of iron by plants via bacterial siderophores is done by various mechanisms such as through ligand exchange, chelation, and release of iron and direct acquisition of iron siderophore complexes (Colo et al. 2014).

17.5.4 Phytohormone Producers

Phytohormones are organic substances produced in specific plant organs. They are either transferred to different sites or active in the same tissue where they are synthesized. They are signal molecules which control overall plant growth. Expression of plant intrinsic genes is regulated by them.

Phytohormones are available for the plants by two sources. They are either endogenously synthesized by plant tissues itself or exogenously synthesized by associated PGPR. Many species of soil-inhabiting bacteria and fungi are known for phytohormone production, viz., *Galactomyces geotrichum*, *Pseudomonas*, *Azospirillum*, *Bacillus*, and *Arthrobacter* (Waqas et al. 2014; Lei and Ya-qing 2015).

17.5.4.1 Indole-3-Acetic Acid/Indoleacetic Acid (IAA)

IAA is synthesized as secondary metabolites. Endogenous pool of plant indoleacetic acid is modified through rhizobacterial indoleacetic acid. This alters plant growth (colo et al. 2014). IAA plays prominent role in rhizobacteria–plant interactions. It is also a signaling molecule which is involved in the plant's defense mechanisms. It influences all aspects of plant development and growth in overall cell cycle of plant by regulating cell elongation, differentiation, cell division, apical dominance, root initiation (lateral and adventitious), flowering, fruit ripening, and senescence. It stimulates tuber and seed germination, promotes xylem development rate and root development rate, regulates vegetative growth of plants, mediates tropistic responses (to gravity, florescence, and light), and affects formation of pigment and photosynthesis. Auxin's synthesis, transport, and signaling pathways are complex. Microbial auxins enhance length and surface area of root. Thus, plant will be able to utilize more soil nutrients due to larger root surface. Auxins secreted by PGPR act as crucial hormone for interaction of plant and microbe. It plays roles in pathogenesis as well as in phytostimulation (Spaepen and Vanderleyden 2011).

Main precursor for IAA biosynthesis is the amino acid tryptophan. Tryptophan synthesis initiates from chorismate. It takes place through five stepped reactions. The trp operon encodes the enzymes which catalyze these reactions. Chorismate is biosynthesized by PEP (phosphoenolpyruvate) and erythrose 4-phosphate through shikimate pathway. This shikimate pathway is a common pathway for the biosynthesis of aromatic amino acids (phenylalanine, tyrosine, tryptophane) and several other secondary metabolites.

17.5.4.2 Gibberellins/Gibberellic Acid/Gibberellin-A3/GA_3 (GA)

Gibberellic acid has molecular formula $C_{19}H_{22}O_6$. These are hormones found in fungi and plants. Gibberellins are the derivatives of gibberellic acids commonly known as GAs. *Gibberella fujikuroi* is the most common fungi which synthesize about 20 different types of gibberellins. GA_3 is the most abundant gibberellic acid among all. The number in the molecular formula is according to the approximate order of their discovery. GA_1 is the most common gibberellic acid responsible for stem elongation. Gibberellins promote stem growth and root growth, instigate mitotic division in some plant leaves, and trigger seed germination. These hormones

are also used in greenhouse and laboratory to initiate sprouting in dormant seeds. The biosynthetic pathway of GA synthesis consists of three classes of enzymes. The first class comprises terpene cyclases which synthesize ent-kaurene. The second class consists of cytochrome P450 monooxygenase, which catalyzes formation of GA_{12} from ent-kaurene, and the third class is comprised of dioxygenases. The final step is catalyzed by these dioxygenases. Recently, Ullah et al. 2014 gave affirmation that unlike forms of GA are produced by entomo-pathogenic bacterium named *Photorhabdus temperata*.

17.5.4.3 Cytokinins

This phytohormone stimulates cell division, enlargement of cell, and expansion of tissue in specific plant parts. Cytokinins are responsible mainly for cellular growth and cellular differentiation. They influence apical dominance and leaf senescence and axillary bud growth. It doesn't influence parenchyma cells only by itself. Auxi-to-cytokinin ratio influences plant growth. When auxin and cytokinin are present equally, the cells of parenchyma form an undifferentiated callus but, when cultured only with auxin cell, grow large but do not divide. When cytokinins are introduced, the cells differentiate along with increment in size; it is observed that more cytokinin stimulates shoot bud growth, while more auxins stimulate formation of root. The most common producers are *Azotobacter chroococcum*, *Azospirillum* sp., *Azotobacter beijerinckii*, *Paenibacillus polymyxa*, *Pseudomonas putida*, and *P. fluorescens* (Kudoyarova et al. 2014; Arkhipova et al. 2007).

17.5.4.4 ACC-Deaminase/1-Aminocyclopropane-1-Carboxylic Acid

Ethylene is crucial stress hormone that works as growth regulator (Magnucka and Pietr 2015). Ethylene is synthesized by almost all plants through biotic and abiotic processes in soils. It is essential for normal growth, development, and induction of various physiological changes of plants (Magnucka and Pietr 2015).

Drought, salinity, flooding, extreme high temperature, heavy metal contamination, and pathogenicity like stress conditions induce the ethylene overproduction. Significant increase in ethylene hampers the root growth and defoliation and thus retards overall plant growth. Ethylene biosynthesis is initiated by methionine. Initial step is synthesis of S-adenosyl-methionine which is then transformed into ACC (1-aminocyclopropane-1-carboxylic acid) (Fig. 17.4).

In plants, ACC is an intermediate precursor for ethylene biosynthesis. ACC-deaminase is the enzyme which catalyzes ACC cleavage into α-ketobutyrate and NH_3, consequently decreasing ethylene levels in plants. ACC-deaminase which is in the form of homo-trimer protein needs a cofactor which is pyridoxal-phosphate. The *acdS* is transcribed into ACC-deaminase. *acdS* has already been cloned from *Pseudomonas*, *Rhizobium*, and *Enterobacter cloacae* (Magnucka and Pietr 2015). PGPR consisting of enzyme ACC-deaminase are able to enhance plant growth (Gontia-Mishra et al. 2014). PGPR synthesizing ACC-deaminase minimizes drought stress and induces tolerance against high salt concentration in plants (Zahir et al. 2008, 2009). Its activity has been observed in several rhizobacteria like *Acinetobacter*, *Azospirillum*, *Agrobacterium*, *Achromobacter*, *Ralstonia*, *Enterobacter*, *Bacillus*,

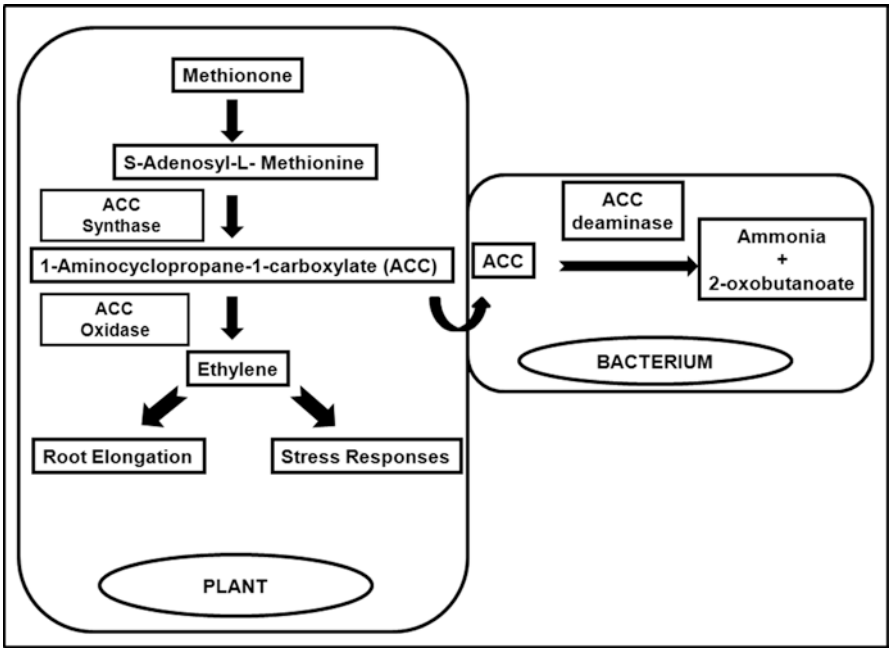

Fig. 17.4 Mode of action of ACC-deaminase (Kang et al. 2010)

Rhizobium, *Burkholderia*, *Serratia*, *Pseudomonas*, etc. (Kang et al. 2010). Recently, ACC-deaminase synthesizing *Pseudomonas stutzeri* A1501 is reported to facilitate rice cultivation in salt and heavy metal presence (Han et al. 2015). Rhizobacteria capable of synthesizing ACC-deaminase also provide stress resistance from radiation, poly-aromatic hydrocarbons, high salt concentration, insect predation, wounding, and high light intensity (Glick 2012). ACC-deaminase synthesizing rhizobacterial inoculation induces the plant shoot growth and root elongation and increases nodulations in rhizobium. It also promotes mycorrhizal colonization and thus nutrient uptake in several agricultural crops (Glick 2012).

17.6 Indirect Mechanism of Plant Growth Promotion

The traits involved in boosting plant health never work independently; rather, they act additively and synergistically. Biological control is environmentally friendly way to control diseases through application of microorganisms. One of the mechanisms adopted by rhizobacteria to improve plant health is an antagonistic action against plant pathogens. Biocontrol activity in PGPR is possible through conflict for food and space. Rhizobacterial synthesis of antifungal metabolites and induction of induced systemic resistance by them also suppress plant pathogens (Lugtenberg and Kamilova 2009). Chief antifungal metabolites effective in suppressing phytopathogens are HCN, 2,4-diacetylphloroglucinol, viscosinamide, pyoluteorin, tensin,

pyrrolnitrin, phenazines, and peptaibols (Bhattacharyya and Jha 2012). A vast group of peptides having good antibiotic ability are reported and termed as "peptaibols." Soil-inhabiting fungi like *Trichoderma* sp., *Gliocladium* sp., and *Emericelopsis* sp. are reported to be able to synthesize peptaibols (Daniel and Filho 2007; Brito et al. 2014). Peptaibols having antimicrobial potential isolated from *Trichoderma pseudokoningii* regulate apoptosis (programmed cell death) in phytopathogens (Shi et al. 2012). Some other fungal metabolites, having biocontrol potential, are:

1. **Daucanes**—Daucane sesquiterpenes or carotanes, found in plant families Umbelliferae and Compositae, are rare fungal metabolites. *T. virens* one strain produces a novel metabolite consisting antifungal properties against various yeast and dermatophytes. Daucanes have a significant inhibitory effect on *Candida albicans*.
2. **6-Pentyl pyrone (pyrones)—**These compounds are obtained from *Trichoderma* spp. It has a specific coconut aroma. Pyrones suppress fungal phytopathogens and henceforth promotes plant health**.**
3. **Terpenoids/steroids—**Terpenoid or steroids are versatile group of compounds. They are produced from pentacarbon iso-pentenyl units. The *T. virens* synthesizes viridin. It is found to be an efficient fungistatic and anticarcinogenic compound. Trichodermin is trichothecene-type terpenoid toxin; chemically it is fungitoxic and phytotoxic produced by *Trichoderma brevicompactum* (Mukherjee et al. 2012).
4. **Polyketides**—These metabolites have anticarcinogenic properties. They possess antimicrobial activities and also suppress immune system. They are synthesized by filamentous fungi and by many other organisms. They facilitate communication between organisms and also promote struggle for substrate (Khosla 2009). Polyketides may have possible role in mycoparasitism. This phenomenon has been noticed while *T. atroviride* encounters with *Rhizoctonia solani.* Two polyketide genes were expressed in *Trichoderma* during the course of phytopathogen confrontation (Mukherjee et al. 2012).
5. **Gliotoxin and gliovirin**—These are fungistatic compounds. Their discovery was based on its antagonistic properties. Gliotoxin is beneficial to *Aspergillus fumigatus* in soil habitat due to its antagonistic properties (Giles et al. 2011). Gliotoxin producing microbes may be an excellent biopesticide to control plant disease caused by the soilborne phytopathogen (Mukherjee et al. 2012).

Induced systemic resistance is a well-known phenomenon in which plants defend themselves against phytopathogen infection through several mechanisms. These mechanisms might be local, constitutive, or inducible. Induced resistance mechanism is plant defense response which is biologically induced either by exposing plant with certain weak pathogenic strain or by exposing it to natural/synthetic chemicals. Bacterial components such as cell wall-derived oligouronides, glycoproteins, lipopolysaccharides (LPS), 2,4-diacetyl phloroglucinol, cyclic lipopeptides, homoserine lactones, volatile chemicals like 2,3-butanediol and acetoin, and siderophores and flagella induce defense responses in host plant (Lugtenberg and Kamilova

2009). These defense responses involve cell wall thickening by lignification, accumulation of callose, phytoalexins, and synthesis of various proteins (e.g., chitinases, peroxidases, glucanases, and other pathogenesis-related proteins).

17.7 Tripartite Relationship Between N_2 Fixers, P-Solubilizers, and Arbuscular Mycorrhizal Fungi

Little is known regarding the effects of inoculation of plant with phosphate solubilizers as well as diazotrophs simultaneously in the occurrence of arbuscular mycorrhizal fungi (AMF). PSMs increase plant growth by providing plant utilizable phosphates, while on the other hand, diazotrophs increase nitrogen content in the soil which is used by plants to enhance their growth. When there is deficiency of both phosphorous and nitrogen, AMF helps in the assimilation of phosphates, hence supporting plant growth. In plants high level of phosphorous supports the diazotrophs and increases nitrogenase activity. By this nitrogen fixation is enhanced which facilitates root growth and mycorrhizal development. This is the beauty of intergeneric interaction.

17.8 Biofertilizers for Mountain Ecosystems

Diazotrophy at mountain ecosystems is considered good plant growth-promoting property for cold climate agriculture and is reported by distinct research teams (Breitbarth et al. 2007; Suyal et al. 2014a, 2015). These ecosystems contain a series of different climatic zones within small distances and elevations, displaying the diverse microhabitats (Regato and Salman 2008). They are delicate and susceptible to any change and thus grow well only in specific environmental conditions. Moreover, changes caused by infrastructure development, excessive tourism, overutilization of natural resources, land use pattern, habitat loss, and long-term changes in the Earth's climate are exerting an additional pressure on these ecosystems. They harbor a variety of psychrophilic and psychrotolerant bacterial communities (Suyal et al. 2015). Kumar et al. 2014 and Shukla et al. 2015 reported the effect of psychrotolerant diazotrophic bacteria isolated from Western Himalayan region on plant growth promotion of various hill cultivated crops. Few psychrotolerant species of genus *Pseudomonas* have been found capable to fix nitrogen at low temperature 4–10 °C but with a significant reduction in the nitrogenase activity (Eckford et al. 2002; Kumar et al. 2014). Further, occurrence of *nif*H gene, an indication of diazotrophy, is also reported in psychrotolerant species of *Paenibacillus* (Rodríguez-Diaz et al. 2005), *Arthrobacter*, and *Rhodococcus* (Suyal et al. 2014b). Low temperature adversely affects the rate of N_2 fixation (Soni et al. 2015). Temperature below 9 °C is generally considered as the limiting temperature for nitrogen fixation (Simon et al. 2014). In recent past, seven diazotrophs which are able to survive in low temperature have been isolated from kidney bean's rhizosphere from Kumaun, Himalaya. Among them proteome of *Pseudomonas migulae* strain S10724 has already been listed (Suyal et al. 2014a).

17.9 Indirect Mechanism of Crop Improvement

Increased level of salt in soil possesses major threat to crops and other important plants. The bacteria *Pseudomonas* is of utmost importance in these areas as it is able to use many substrates, produces a diverse range of compounds, as well as easily conquers rhizosphere, thus helping plant to withstand unfavorable situations. PGPR can act as prominent substitute to overcome plant stress caused by salinity, as well as it induces the host resistance mechanism and direct antagonistic interaction with pathogens.

17.10 Application of Genetic Engineering in Developing New Strain

Biofertilizer performance mainly depends on its potential to colonize a certain rhizospheric habitat. Biofertilizer colonization study gives information about its success. Plate count enumeration method and most probable number (MPN) method are helpful in understanding those rhizospheric bacterial communities which act as biofertilizers. Not even 1 % of the total bacterial communities inhabiting in the environment are cultivated by known standard techniques. Strain-specific DNA probes help to estimate the diverse microbial population in the rhizosphere. With the advancement of techniques in molecular biology, it is now possible for microbiologists to decipher the non-culturable microbial communities (Soni et al. 2010; Suyal et al. 2015). Thus, molecular biology techniques are extensively useful to characterize microbial communities in different habitats.

Cloning and sequencing techniques are commonly used techniques which are helpful in determining composition of microbial community. Besides them, hybridization and probing techniques can also determine the same with the advantage that they are less time consuming; however, it is mandatory to have adequate information of microbial community in order to select desired target sequence. Alternative methods such as ribosomal intergenic spacer analysis (RISA) and amplified ribosomal DNA restriction analysis (ARDRA) are helpful to analyze community structure and colonization ability of biofertilizers. They are often used to analyze bacterial diversity from varied environments. ARDRA can mark genotypic transformation occurring in a community with respect to time. However, RISA aids in comparative analysis of microbial communities exposed to unlike habitats or treatment without any kind of biasness enforced through culture-dependent methods. In short, it includes PCR amplification of intergenic spacer region (ISR). These techniques involving molecular biology have higher quantitative effectiveness and are further used to characterize bioinoculants in situ.

In case of PSM, organic acids help to solubilize mineral phosphate. Solubilization of phosphorus is carried out by reducing pH or by chelation of cations accompanying phosphorus. Knowledge of the genes governing the production of organic acids would make it possible to transfer the ability of P-solubilization to those bacteria which are able to colonize a specific rhizosphere. It is now understood that

rhizosphere competence is an important factor to determine the fate of victory or defeat of microbial inoculum. Rhizosphere has versatile carbon sources that can be utilized by the diversified microbial communities residing in soil for the production of different organic acids. Available phosphate is readily utilized by plant before its precipitation to unavailable form. In gram-negative bacteria, gluconic acid has been proved to aid phosphate solubilization (Oteino et al. 2015). Oxidative metabolism of glucose to gluconic acid occurs in the presence of glucose dehydrogenase (GDH). GDH in turn needs pyrroloquinoline quinone (PQQ) as a cofactor. Therefore, genes associated in the transfer and synthesis of PQQ are cloned from bacteria of one type and passed to other type (Bruto et al. 2015). If the PQQ-synthesizing genes are transferred to *Rhizobium* strain that possess apo-GDH and that is rhizosphere competent too, then, the resulting strains will possess the ability to solubilize phosphate activity as well as will fix atmospheric nitrogen. Enhanced expression of GDH genes along with PQQ biosynthesis in *Pseudomonas* spp. also produces gluconic acid via oxidative metabolism of glucose. Similarly, Ambrose et al. (2015) have successfully characterized salicylate hydroxylase gene from the fungal endophyte *Epichloë festucae*.

17.11 Conclusion

The integrated approach is vital to improve crop productivity and to maintain the soil fertility. As PGPR have multidimensional approach toward sustainable agricultural system, it is important to determine the most favorable plant–microbial interaction. Biofertilizers not only exhibit plant growth promotion but are also effective in bioremediation by detoxifying detrimental pollutants such as pesticides and heavy metal pollutants. Nevertheless, they are potential biopesticides, as they can control a wide variety of phytopathogens. Few reports reveal that in case of controlled soil conditions, significant enhancement in crop production was achieved through biofertilizer applications. But soil is an unpredictable natural ecosystem. Biofertilizer efficacy in crop productivity may vary between controlled condition of laboratory and farm, and therefore, desired results are not always attained. Besides it, effectiveness of biofertilizers also depends upon climatic changes among different geographical locations. However, their performance can be optimized through acclimatization according to prevailing natural soil environment. In present scenario, where genetically modified food crops have a big question mark, biofertilizers may be a boon to humanity. This is a technology which is easy access even to the farmers of developing nations including India. PGPR-mediated organic farming would pave the way to prosperous, healthy, and sustainable nation. Thus, this trend of least possible input of chemicals in sustainable agricultural systems may help to achieve the goal of holistic well-being of planet Earth.

Role of Beneficial Fungi in Sustainable Agricultural Systems

18

Mehrnaz Hatami and Fereshteh Ahangarani

Abstract

Sustainable agriculture is a farming technique on the basis of knowledge of ecosystem services, the study of relationships/interactions between organisms and their physical environment. In sustainable agricultural systems, the inhabitant soil microflora is more crucial for ecosystem processes including nutrient availability and pest/disease suppression.

The rising demand for environmental friendly, organic, and sustainable agricultural practices are driving the application of fertilizers based on beneficial biological products. The use of beneficial fungi in agriculture sector is potentially useful for improved plant health and growth, water uptake, nutrient availability, stress tolerance, and biocontrol. Fungi also play a fundamental role in multifarious physiological processes including mineral and water uptake, photosynthesis, stomatal movement, and biosynthesis of compounds termed biostimulants, auxins, lignan, and ethylene to enhance the ability of plants to establish and cope environmental stresses such as drought, salinity, heat, cold, and heavy metals. This chapter describes the mechanisms underlying beneficial impacts of fungi on growth promotion of the host plant.

18.1 Introduction

Many of the world's ecosystems are in different moods of decline affirmed by erosion, low fertility and productivity, poor water quality, etc. caused by forest clearing, high-input agricultural production, and stay using land resources for multiple purposes that are not sustainable. However, sustainable agriculture prepares high yields without causing weakness or damages the natural systems and resources that productivity depends on. This kind of agriculture utilizes a special cultivation technique wherein the environmental resources may be entirely used and at the same time guarantee that no injury was executed to it. Therefore, the method of performance is environmental friendly and assures safe and healthy agricultural crops and products. In low-input organic and sustainable agroecosystems, the natural function of microorganisms in supporting soil fertility and/or control of plant pathogens may be more important than in conventional agriculture practices where their importance has been marginalized using high inputs of chemical fertilizers and other agrochemicals.

The status of soil microbial populations is beneficial to vital processes that compel fertility, productivity, and stability of agricultural systems. Several investigations are directed to enhancing knowledge of the diversity, structure, dynamics, and significance of soil microbial communities and their advantageous and cooperative actions in soil fertility and crop productivity.

There is a growing body of evidence that exhibits the potential of different microorganisms to improve plant growth and productivity in agricultural systems. Understanding the potential of soil-beneficial microorganisms needs comprehension of the action of microorganisms in growth enhancement, especially in terms of nutrient supplement and disease suppression, the underlying mechanisms, and the challenges in implementation and commercialization of plant growth-promoting (PGP) microorganisms (Johansson et al. 2004; Pereg and McMillan 2015).

Soil microorganisms possess a close, symbiotic (reciprocal) relationship with plants. They are the most plentiful of all the biota in soil and responsible for promoting nutrition and organic matter cycling, soil fertilization and restoration, and plant health and growth as well as ecosystem primary production. Two examples include rhizobia and mycorrhizae. Mycorrhizae are known as very host-specific fungi that create symbiotic associations with roots of host plant. The beneficial fungi play an important role in improving plant growth and increasing plant yield and also involved in biotic and abiotic stress tolerance, hazardous materials remediation, sustainable crop production, and food safety (Borde et al. 2009). Some of the fungi do not permit the deleterious fungi to colonize the root surface area and are beneficial as biocontrol agents (Ha 2010). In this chapter, we explain the mechanisms behind the positive role of symbionts to host partners.

18.2 General Mechanisms Involved in Plant Growth Promotion Elicited by Microorganisms

Plant growth and performance is remarkably affected by the interactions between plant roots and the surrounding relative soil involving the microbial community inside the soil. The rhizosphere supports microorganisms that may have both positive and negative or inconsequential impact on plant growth and productivity. Although most rhizospheric microorganisms seem to be desirable, harmful microbes such as pathogens and microorganisms generate toxins that prevent root growth or those that eliminate essential substances from the soil. In contrary, the major mechanisms for promoting plant growth include improvement of nutrient availability (biofertilization), suppression of parasitic and nonparasitic pathogens (biocontrol), and production of plant hormones/and or plant growth-promoting substances (phytostimulation) (Martinez-Viveros et al. 2010; Bhattacharyya and Jha 2012).

Many factors are affecting the population of the indigenous rhizospheric microbes including agricultural practices (e.g., soil cultivation, stubble maintenance, burning, season, and so on), plant species, variety/cultivar and genotype, and soil type (Berg and Smalla 2009; Reeve et al. 2010). Plant exudates may cause alterations to soil characteristics including carbon availability and pH, influencing the diversity and activity of microbial communities (Haichar et al. 2008). It is acknowledged that the addition of microorganisms to cropping systems and agricultural soils (bioaugmentation) exhibit an important action on soil microbial processes. The application of agrochemicals such as chemical fertilizers and pesticides/and or fungicides caused concerns about their potential risks to living organisms and pathogen resistance, imposing continuous expansion of novel agents (Fernando et al. 2006). Rhizospheric microorganisms that prevent plant pathogens could be applied as biocontrol agents and may be considered as efficient and alternative to chemical pesticides. Some of the mechanisms for suppression of plant pathogen are direct inhibition of pathogen growth via production of antibiotics, hydrogen cyanide (HCN), and toxins and activation of hydrolytic enzymes (e.g., lipases, proteases, and chitinases) that degrade toxicity agents or pathogen cell-wall components (Whipps 2001; Compant et al. 2005).

18.2.1 Mechanisms of Biofertilization

"Biofertilizers" are beneficial microbes that improve nutrient uptake and availability to inoculated plants, contributing to plant nutrition through increasing nutrient uptake and/or through accelerating primary nutrient availability in the rhizosphere. Also, they could be applied for improving crop yield when used complementary to, or as alternative for, synthetic fertilizers.

Nitrogen (N) is an important plant macronutrient that is frequently limited in agricultural soils because of high losses through leaching and emission. Biological nitrogen fixation can be performed by nonsymbiotic bacteria including *Azospirillum*, *Gluconacetobacter*, *Burkholderia*, and *Pseudomonas* species (Dobbelaere et al.

2003) and may be employed in biofertilization of nonleguminous plants including wheat (Egamberdiyeva and Hoflich 2002), rice (Mirza et al. 2006; Muthukumarasamy et al. 2007), maize (Estrada et al. 2005), and sugarcane (Suman et al. 2005). Also, the *Azotobacter* Azo-8 strain was introduced as an efficient bio-inoculant for wheat plant grown under water scarcity conditions along with urea and manure (Singh et al. 2013).

Although agricultural soils usually have considerable total phosphorus, available phosphorus is frequently exhausted from the rhizosphere (Richardson et al. 2009). Soil microorganisms play an essential role in the phosphorus cycle and, therefore, in facilitating phosphorus availability to plants, improving the capacity of plants to obtain phosphorus from the soil through solubilizing and mineralizing inorganic phosphorus, or via accelerating the mobility of organic phosphorus by microbial turnover and/or extending the root system of crop species (Richardson and Simpson 2011). A great number of soil microorganisms with the ability of solubilizing inorganic phosphorus have been isolated, such as *Actinomycetes*, *Pseudomonas*, *Rhizobium*, and *Bacillus* spp. (Richardson et al. 2009; Richardson and Simpson 2011; Bhattacharyya and Jha 2012). Moreover, some fungal from the *Penicillium* genus excrete compounds (organic acids) that expedite the conversion of immobilized phosphorus into soluble forms available for root uptake and plants (Wakelin et al. 2004).

The response of root growth and the flexibility of root system architecture along with the expansion of the rhizosphere, via either root growth or root hair development, are obviously significant for impressive exploration of soil environment and interruption of nutrients. Root hair may form up to 70 % of root volume and can take up to 80 % of phosphorus in non-mycorrhizal inoculated plants (Fohse et al. 1991). Mycorrhizal fungi generally colonize the root cortex of plant and enlarge exteriorly, joining the roots with soil environment and enhancing efficacy of phosphorus absorption by mycorrhizal inoculated plants (Barea et al. 2008).

Mycorrhizal symbiosis can increase plant growth by improvement of plant establishment, protection against different types of stress, and enhanced soil structure and nutrient uptake, especially as fundamental macronutrients (e.g., P, Mg, Ca, K) and micronutrients (e.g., Zn, Cu,) depend on soil pH (Clark and Zeto 2000; Richardson et al. 2009).

It has been reported that enhanced absorptive surface area of the inoculated plant-root systems caused increased area for interactions with other soil microorganisms through formation of hyphae of these symbiotic fungi which also act as a significant route for the translocation of energy-rich plant assimilates to the soil (Johansson et al. 2004). Generally, the effect of plant assimilates on microbial populations has been described in relation to the rhizosphere (Hiltner 1904). The rhizosphere (the narrow region of soil surrounding living plant roots) is characterized by improved microbial activity stimulated by root exudates (Grayston et al. 1997). However, since plant roots in natural habitats are prevalently mycorrhizal, the concept of rhizosphere has been broadened to comprise the fungal component of the symbiosis, causing the term “mycorrhizosphere” (Rambelli 1973; Johansson et al. 2004) (Fig. 18.1).

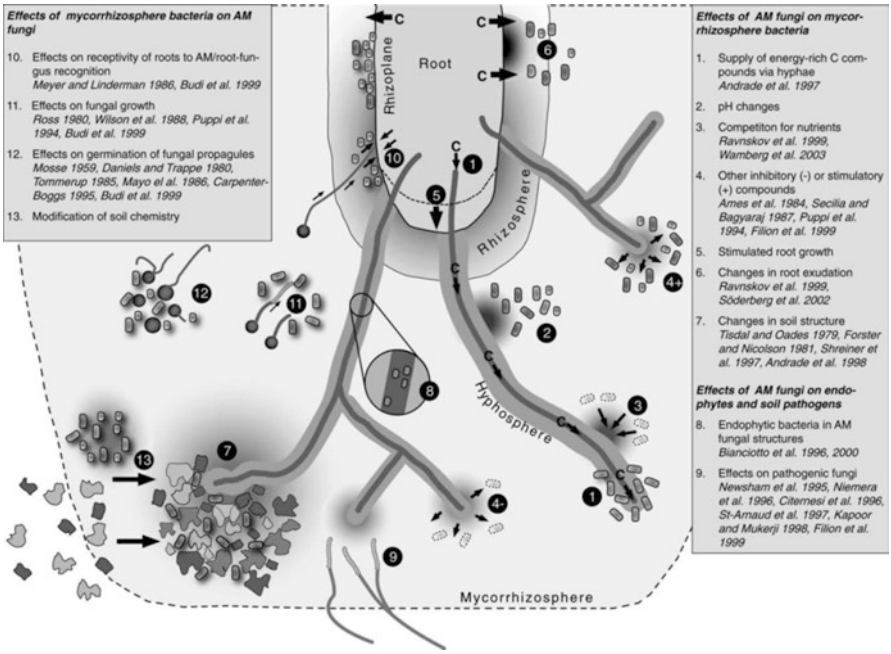

Fig. 18.1 Schematic model of possible interactions between various components of the mycorrhizosphere (Johansson et al. 2004)

18.2.2 Mechanisms of Disease Suppression

Generally, protection of plant growth is consecutively challenged through emerging, reemerging, and indigenous plant pathogens (Miller et al. 2009). As mentioned above, there are a number of mechanisms for plant-pathogen suppression including direct inhibition of pathogen growth by production of antibiotics and other toxins (Whipps 2001; Compant et al. 2005).

Antibiotics are a common section of the self-protective arsenals of bacteria, including *Pseudomonas* species (e.g., *Pseudomonas fluorescens* strains) (Haas and Defago 2005) and *Bacillus* species (e.g., *Bacillus subtilis*) (Kim et al. 2003), as well as fungal species including *Trichoderma*, *Gliocladium*, *Ampelomyces*, and *Chaetomium* (Kaewchai et al. 2009); therefore, these living organisms have great potential for soil conditioning process.

Multifunctional microorganisms including *Trichoderma harzianum* Rifai appear to improve plant growth through solubilizing phosphate and essential micronutrients required for plants, including iron (Fe) and manganese (Mn), and suppress plant pathogens (Altomare et al. 1999). Hydrogen cyanide production inhibits microbial growth and may suppress pathogens including root-knot, black rot, and bacterial canker in tobacco and tomato plants (Lanteigne et al. 2012; Voisard et al. 1989; Siddiqui et al. 2006). However, it has been reported that HCN might be

injurious to plants through reducing energy metabolism and inhibiting root growth (Siddiqui et al. 2006). Many various bacterial genera produce HCN, such as *Rhizobium*, *Alcaligenes*, *Bacillus*, *Aeromonas*, and *Pseudomonas* spp. (Ahmad et al. 2008). Also, pathogen suppression may take place competitively by indirect inhibition. There is evidence that a number of bacteria and fungi produce siderophores as iron-chelating sources particularly in times of iron deficiency (Sharma and Johri 2003), such as *Azospirillum*, *Pseudomonas*, *Bradyrhizobium*, *Rhizobium*, *Serratia*, and *Streptomyces* (Martinez-Viveros et al. 2010). Their ability to reduce iron from their surrounding environment makes it unavailable form to pathogenic fungi, resulting in a competitive benefit (Loper and Henkels 1999; O'Sullivan and O'Gara 1992).

Carrillo-Castaneda et al. (2002) reported that inoculation of alfalfa (*Medicago sativa*) with siderophore-producing bacteria grown under iron-limiting conditions resulted in a positive effect on plant growth; however, the possible role for a combination of several growth-promoting mechanisms and not siderophore generation alone cannot be ignored. Moreover, activation of the plant's own defense system, termed induced systemic resistance (ISR), may be considered as another mechanism that is involved in disease suppression. Release of a blend of volatile organic compounds by plant growth-promoting bacteria and fungi may initiate ISR, causing enhanced expression of defense-related genes in the inoculated plants (Naznin et al. 2014).

18.2.3 Mechanisms of Phytostimulation

One of the most important mechanisms involved in plant growth enhancement through some rhizospheric living microorganisms is the production of plant hormones, or phytostimulation; plant growth-promoting microbes stimulate plant growth by producing growth hormones, including auxins, gibberellins, and cytokinins in the adjacency of the roots, or by regulating the levels of ethylene produced by plants. Root characteristics, size, and depth affect the capacity of plants to effectively entrap nutrients from soil environment and vice versa; root elongation and morphology can alter in response to soil nutrient availability (Wijesinghe et al. 2001). Plants bearing both deep and shallow root systems are able to acquire mineralized nitrogen available in top of soils and leached nitrogen in the subsoils (Ho et al. 2005). Therefore, application of phytostimulation for improving plant-root growth could play an important role in facilitating nutrient uptake, particularly if employed in combination with biofertilization.

The main phytohormone, auxin (IAA), promotes root growth and root architecture attributes such as root hair cluster positioning, lateral root extension, and root vascular tissue development (Aloni et al. 2006). Many rhizobacteria, such as beneficial, pathogenic, associative, and free living, are potentially proficient to produce IAA (Tsavkelova et al. 2006). These include *Azospirillum*, *Azotobacter*, *Aeromonas*, *Bacillus*, *Burkholderia*, *Enterobacter*, *Rhizobium*, and *Pseudomonas* (Spaepen et al. 2006; Martinez-Viveros et al. 2010). Cytokinins promote plant cell division

and regulate root growth and development through reducing primary root elongation and lateral root formation and stimulating root hair formation (Werner et al. 2003; Riefler et al. 2006). These substances are produced by some plant growth-promoting rhizobacteria, including *Arthrobacter*, *Azospirillum*, *Pseudomonas*, and *Paenibacillus* species, but their participation in plant growth promotion is not well known (Richardson et al. 2009).

Likewise, gibberellins induce the development of stem tissue, root growth, and lateral root branching and are produced by different species of plant growth-promoting rhizobacteria, including *Azotobacter*, *Azospirillum*, *Bacillus*, *Herbaspirillum*, *Rhizobium*, and *Gluconobacter* (MacMillan 2002; Bottini et al. 2004).

Another important hormone involved in plant growth and development is ethylene, although it may have distinctive impacts on plant growth depending on its doses in plant roots (Pierik et al. 2006). Ethylene synthesis is necessary for the initiation of systemic resistance during interaction with associative microorganisms, and higher doses are mediated in plant defense against a range of stresses and upon pathogen infection (Broekaert et al. 2006). Certain growth-promoting bacteria, including *Azospirillum brasilense*, may produce lower levels of ethylene, which may enhance root hair formation (Ribaudo et al. 2006). In plants, ethylene has previously been found to be produced from the precursor 1-aminocyclopropane-1-carboxylate (ACC), which is released by roots within the rhizosphere during stress and reabsorbed through the roots, which is in turn converted to ethylene. However, accumulation of ethylene in the roots causes decreased root growth, aggravating plant stress (Babalola 2010). Rhizospheric plant growth-promoting fungi and bacteria that can break down ethylene precursor ACC diminish the adsorption of ethylene through the root tissues and permit the plant to reestablish a healthy root and cope with environmental biotic and abiotic stresses (Glick 2005). Plant growth enhancement by ACC (a source of nitrogen) degrading microorganisms seems to be specifically significant under stress conditions including drought, cold, salinity, or heavy metal stress (Mayak et al. 2004; Grichko and Glick 2001). Root zone microorganisms are able to degrade ACC including *Azospirillum*, *Achromobacter*, *Enterobacter*, *Bacillus*, *Pseudomonas*, and *Rhizobium* strains (Martinez-Viveros et al. 2010).

18.3 The Arbuscular Mycorrhizal Symbiosis

The oldest (>460 million years BP) and the most popular kind of mycorrhizal association is *arbuscular mycorrhizal* (AM) symbiosis. Many terrestrial plants (~250,000 species of plants worldwide) are capable of forming the symbiosis (Smith and Read 1997).

According to Schussler et al. (2001), almost 160 fungal taxa of the order *Glomales* (*Glomeromycota*) have been explained in terms of their spore morphology, although new molecular technique exhibit that the real number of AM taxa may be much higher (Daniell et al. 2001; Vandenkoornhuyse et al. 2002).

It has been reported that in time of AM symbiosis formation, the fungus permeates the cell walls of root cortical and constitutes haustoria-like structures that

interact with the host cytoplasm (Smith and Read 1997). These fungal structures and highly branched arbuscules in particular prepare an improved surface area for metabolic conversions between the fungus and the plant. Moreover, production of certain structures, vesicles, by some of the AM believed to act as storage tissues (Smith and Read 1997). According to Johnson et al. (2002), plants in natural terrestrial ecosystems colonized with AM may instate about 10–20 % of the fixed carbon through photosynthetic process in their fungal confederate. Obviously, this exhibits an important input of energy to the soil environment, and this source of carbon may be vital to living microbes associated with the mycorrhizosphere.

It has been acknowledged that AM fungi also interact directly with the soil through producing extra radical hyphae that may spread out several centimeters within the soil (Rhodes and Gerdemann 1975). The extra radical hyphae structures constitute a greater total surface area than that of roots solely, which enhances the potential for nutrient and water uptake (Auge 2001; Rhodes and Gerdemann 1975). Besides, the extra radical hyphae structures seem to be significant to the plants for phosphorus acquisition efficiency and other mineral nutrients uptake (Read and Perez-Moreno 2003). Also, Hodge et al. (2001) suggested that the extra radical mycelium of AM fungi may improve mobilization of organic nitrogen forms from plant residue. It was previously believed that mycorrhizal symbiosis may also mitigate adverse effects of plant pathogens (Newsham et al. 1995; Niemira et al. 1996; St-Arnaud et al. 1997; Azcon-Aguilar and Barea 1996) and negative role of metals (Khan et al. 2000). Moreover, the extra radical hyphae may interface with other soil microbes either directly through physically and/or metabolically interfacing with other soil-living organisms in the mycorrhizosphere or indirectly through altering host plant physiology (e.g., root morphogenesis and patterns of exudation within the mycorrhizosphere) (Johansson et al. 2004).

18.3.1 Effects of AM Fungi on Fungal Pathogens

Arbuscular mycorrhizal fungi may interact with other root-associated microbes, like pathogenic fungi. The potential mechanisms of interaction are similar as those mentioned above. The differential impacts of a crude extract from the growth medium of the AM fungus *Glomus intraradices* were studied on spore formation of two pathogenic fungi and on the growth of two bacterial species (Filion et al. 1999). Conidial germination of *Fusarium oxysporum* (a plant-root pathogen) was inhibited, while conidial germination of *Trichoderma harzianum* (a mycoparasitic fungus) and the growth of *Pseudomonas chlororaphis* were promoted, and *Clavibacter michiganensis* growth was uninfluenced. The assayed impacts were correlated with extract dose, and no significant effect of pH on germination or growth was found. They concluded that the unspecified substances released by the AM fungus to the growth medium were the major factor describing the differential growth of the employed microbes.

Citernesi et al. (1996) screened bacteria separated from 17-year-old *Glomus mosseae* pot culture. They reported that many of the bacterial strains within the

various zones of the mycorrhizosphere were vigorously antagonistic against in vitro growth of *Fusarium* and *Phytophthora*. Their findings also suggest the probability of integrated application of AM fungi and their associated bacteria in biocontrol of soilborne pathogenic fungi. Many researchers have mentioned that the ability of AM-inoculated plants to better stand up to an attack from root pathogens may be described to an improved nutritional status in the host plant because of the attendance of the AM fungus. However, there are contradictory reports on this theory. In a field experiment, Newsham et al. (1995) transplanted *Glomus* sp.-treated and *Glomus* sp.-non-treated seedlings of *Vulpia ciliata* into a natural ecosystem and found that inoculation of AM did not influence phosphorous content in the plants. However, the AM protected the plants from the adverse impacts of *Fusarium oxysporum* attack on root and shoot growth. Obviously, the AM inhibited pathogen development in the root tissues. The results also showed that root-infecting mycofloras of AM plants had fewer naturally occurring infections of *F. oxysporum* and *Embellisia chlamydospora* compared to AM plants following transplantation (Newsham et al. 1995). They suggested that the main advantage granted by AM fungi to *V. ciliata* seedlings is the protection from deleterious fungi, rather than enhanced phosphorous acquire. In a study, Niemira et al. (1996) employed a peat-based medium containing *Glomus intraradices* to test whether it could inhibit *Fusarium sambucinum* (a common tuber dry rot) in minitubers of potato plants. Results revealed less (20–90 %) tuber dry rot for minitubers grown in this medium. Furthermore, St-Arnaud et al. (1997) reported that the presence of *Tagetes patula* plants inoculated with AM fungus *G. intraradices* may suppress root pathogen development in soil and by means of that decrease severity of disease in cocultured non-mycorrhizal carnation (*Dianthus caryophyllus*). In other study, Caron (1989) found significant decrease in Fusarium populations in the soil surrounding mycorrhizal tomato (*Lycopersicon esculentum*) roots and subsequently proposed a possible role for AM fungi in biocontrol of the soilborne pathogens.

18.3.2 Soil Fungal Communities Confer Agroecosystem Stability

Beneficial soil microorganisms such as AM fungi are key component in natural agroecosystem through providing crucial ecosystem services including nutrient uptake, organic matter recycling, and antagonism versus plant pests/disease (Borie et al. 2010; Pozo et al. 2009; Ramos-Zapata et al. 2012). *Arbuscular mycorrhizal* fungi, saprophytes, use up the destroyed organic materials in soil and are definitely innocuous and often beneficial for mobilization of mineral nutrients (Hodge et al. 2001; Lopez-Roez and Pozo 2013).

The ecological importance of *Perisporiopsis lateritia*, *Phanerochaete velutina*, and *Pleurotus* sp. can be described by their function in dead vegetation recycling process through converting hard wood to usable forms (Chaverri and Gazis 2010; Wells et al. 1998; Cohen et al. 2002). Some fungi (e.g., *Navisporus floccosus*), characterized in digesting the secondary compounds such as lignin, tannin, and cellulose in soils; preparing nutrients availability for offspring of the present plant generation

(Parihar et al. 2012). It has been reported that soil AM fungi may be considered as an essential component of an ecosystem to help the carbon and nitrogen recycling in soil environment (Phillips et al. 2012).

Generally, mycorrhizal fungi include higher value of carbon (10/1 C/N) and less amount of nitrogen (N ¼ 10 %) in their cells than those of bacteria (Hoorman 2011). Mycorrhizal fungi contribute in recycling of both nitrogen and phosphorus to improve availability of mineral nutrients for the plants. Their properties, small size and high surface area, are more efficient in mineral acquisition from the soils when compared to the plant-root hairs (Hoorman 2011). Evidence suggests, however, that plant's roots cultivated with particular species of fungi caused significant nutrient acquisition and higher nutritional levels of crop plants (Yaseen et al. 2011; Albrechtova et al. 2012). In addition to symbiont, free-living soil fungi including *Trichoderma* are established to be responsible for improved plant growth and development, higher biomass production, and lateral root branching via the mechanism mediated by synthesis of auxins (Contreras-Cornejo et al. 2009). Specific fungi, including *Piriformospora indica* and *Trichoderma*, are beneficial in plant-soil systems and act as biocontrol agents (Harman and Mastouri 2010; Serfling et al. 2007) to support agricultural crops from severe injury caused by pathogen attack (Ha 2010). According to Chalot and Brun (1998), ectomycorrhizal fungi can effectively degrade the undesirable phenolic constituents in the forest soils.

The ecto- and endo-AM fungi may prepare definite advantages to host plants through expanding surface area for sufficient water and nutrient uptake, improving stomatal regulation to preserve proper water potential, and increasing twofold the minimal stomatal conductance (Aroca et al. 2008; Arnold and Engelbrecht 2007) for better gaseous exchange which subsequently result in amplified photosynthetic quantum yield (Wu and Xia 2006; Xian-Can et al. 2010) (Table 18.1).

18.3.3 Relevance of Mycorrhizosphere Interactions to Sustainable Agriculture

Soil-beneficial fungi are specifically useful for the plant partner in agriculture and take part in several services including water levels, nutrient improvement, stress tolerance, pest and disease protection, and weed control. Sustainable agroecosystem relies on beneficial fungi due to its contribution in decomposition of soil organic matter, nutrient uptake, organic matter and nutrient recycling, antagonism against plant pathogens/pests, and crop management (Ansari et al. 2013). Generally, two main groups of soil endophytic fungi have been previously recognized, exposing dissimilarity in evolutionary interaction: (1) the clavicipitaceous endophytes (C-endophytes), which associate with grasses and systemically infect their hosts, and (2) the non-clavicipitaceous endophytes (NC-endophytes), which can be reproduced from asymptomatic parts of a broad range of plant (nonvascular) hosts, belonging to angiosperms (Singh et al. 2011).

Mycorrhizal fungi colonizing the plant-root systems (rhizosphere) extend within the rhizosphere and are efficiently involved in enhancing soil fertility and crop

Table 18.1 Soil-beneficial fungi effects on different physiological and catabolic processes in various host plant species

productivity in natural and agroecosystems (Bonfante and Genre 2010). It has been reported that mutualistic symbioses (intimate interspecies interactions) contribute to plant's life cycle through supplying micro- and macronutrients, enhanced growth, and improved thermotolerance and resistance from different environmental biotic and abiotic stresses such as drought, salinity, herbivore, and pathogen infection (Lingua et al. 2012; Singh et al. 2011; Rodriguez et al. 2008). A strong growth-promoting activity was found during the symbiosis of *Piriformospora indica*, a plant-root-colonizing basidiomycete fungus, with a broad spectrum of plant species

(Verma et al. 1998). The *P. indica* produces thin-walled, white color, and hyaline hyphae throughout the life cycle which exhibits multinucleated character. Following to anastomosis between various types of hyphae, the formation of certain chlamydospores (thick-walled big resting spore) occurs either separately or in clusters at their tip. The released chlamydospores then trigger germination in the soil and subsequently infect other host through creating intra- and intercellular hyphal network (Das et al. 2012). Moreover, *P. indica* imitate the potentiality of specific AM fungi in different morphological, functional, and growth promotional points of view (Das et al. 2013) with supplemental profit that it can grown axenically. Tsimilli-Michael and Strasser (2013) confirmed that the *P. indica* may be a novel candidate symbiont for supplying immense growth-promoting activity with a broad spectrum of plants species. This symbiotic interaction caused in higher biomass production of the shoots and floral parts of the plant which can be used for biologically active compounds in pharmaceutical industries (Kumar et al. 2011; Oelmuller et al. 2009). *P. indica* (the growth-promoting endophyte) in many cases acts as a biofertilizer, bioregulator, and bioprotector both in mono- and dicotyledonous plant species (Das et al. 2012). The mutually beneficial relations between *P. indica* and roots are valuable being its wide spectrum of uses in farming systems (Franken 2012). It is acknowledged that specific biochemical and/or genetic processes are involved in biosynthesis of ethylene and signaling to maintain an interaction between the symbionts and host plants (Khatabi et al. 2012).

18.3.4 Sustainable Nutrient Supply

It has been well known that AM may improve phosphorous level, enhance nitrogen uptake, or increase disease resistance in their host partners. Other soil microorganisms, such as nitrogen fixing and or phosphate solubilizing bacteria, can synergistically interact with AM fungi and stimulate plant growth through a range of mechanisms (Puppi et al. 1994). The symbiotic association between fungi and host plants becomes even more important in low sustainable input and organic agricultural systems. Under these situations, AM mycelium may act an influential role in nutrient mobilization from plants litter (Johansson et al. 2004).

Hodge et al. (2001) suggested that the inoculation with AM *Glomus hoi* improved decomposition of plant litter in soil and caused increased nitrogen acquisition from the litter as well. Hyphal growth of the fungal symbiont was also improved in the presence of the complex organic material in soil (Fig. 18.2). Bacteria associated with the AM may assist the nutrient cycling in soil. Several examples of this kind of association are available from bacterial-AM fungal-legume tripartite symbiosis, where diazotrophic bacteria prepare fixed nitrogen for both the plant and the fungus. Interestingly, legume nodulation by nitrogen-fixing bacteria and AM establishment often take place synchronously and synergistically.

The presence of nitrogen fixation genes in endosymbiotic bacteria (*Burkholderia*) in AM hyphae has been previously showed by Minerdi et al. (2001) who suggest that there may be a potential for enhanced nitrogen source to mycorrhizal infected

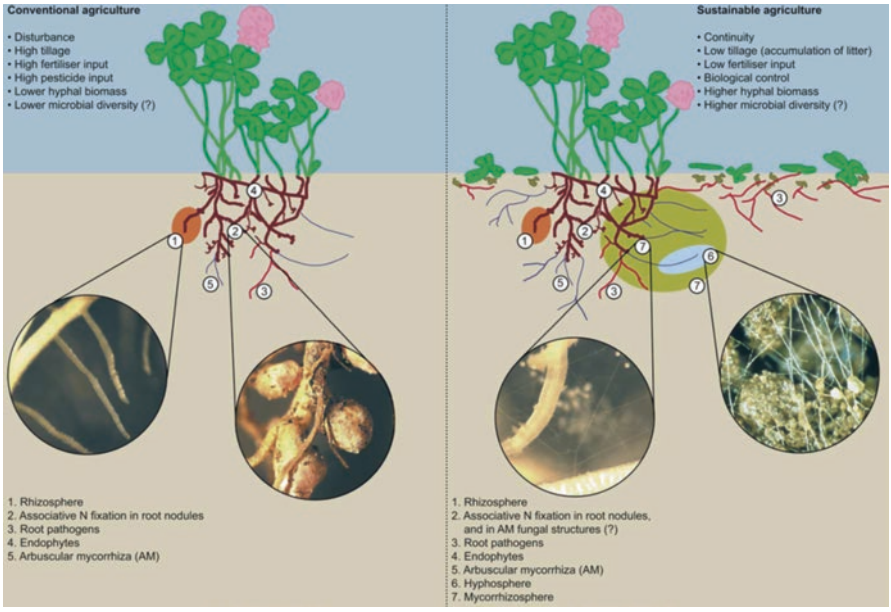

Fig. 18.2 Schematic model of the mycorrhizosphere concept compared to the rhizosphere concept: characteristics of conventionally managed agricultural soils (*left*) in contrast to sustainably managed agricultural soils (*right*) (Johansson et al. 2004)

plants through atmospheric nitrogen fixation. More study is also required on the possible interactions of mycorrhizal fungi with decomposition processes. There is now a growing consciousness of functional differences among various AM fungi, and as our ability to perceive of their functional capacities raises we may be able to select appropriate species for maximize of nutrient recycling (Johansson et al. 2004).

18.3.5 Biocontrol

Microbial inoculants may be utilized as alternative and efficient tools for suppression of disease and pests in agricultural cropping systems, allowing the decreased application of chemical pesticides that could otherwise display threats to human health and nontargeted living organisms. The biological control agents may influence AM fungi, or be influenced themselves by AM fungi, in the same manner to the interactions as mentioned above. Biocontrol organisms against particular pathogenic fungi may have adverse impacts on nontarget soil AM fungi. Studies have shown that the mechanisms of antagonistic interactions causing biocontrol may involve competition for soil nutrients and colonization sites as well as production of fungistatic compounds. However, few researches have explicitly investigated

interactions involving AM fungi (Johansson et al. 2004). Some beneficial impacts of rhizobacteria on AM fungal colonization of roots could be because of antagonistic effects on competing pathogens (Azcon-Aguilar and Barea 1996), as well as direct synergistic effects on mycorrhizal colonization itself (Budi et al. 1999). Different plant-root-colonizing or seed-borne *Pseudomonas* spp. have been reported to be influential microbial control agents in plant-pathogen systems under in vitro (Chin-A-Woeng et al. 2003; Leeman et al. 1996), greenhouse (Knudsen et al. 1999), and field (Johnsson et al. 1998; Knudsen et al. 1997) conditions. Chin-A-Woeng et al. (1998) reported that *Pseudomonas chlororaphis* PCL1391, an effective bacterial strain for colonizer of tomato roots, revealed efficient antagonistic activity against *Fusarium oxysporum*. The aforesaid bacterial strain produced a broad spectrum of antifungal compounds, such as hydrogen cyanide, phenazine-1 carboxamide, proteases, and chitinases (Chin-A-Woeng et al. 1998).

By knocking out the phenazine biosynthetic operon, it was shown that the mutants exhibited significantly lower biocontrol activity, indicating that this substance was an important antifungal factor for suppressing disease in tomato roots. It has been reported that the presence of the biocontrol bacteria caused in 70–80 % reduction of the density of the hyphal network inside part of tomato roots (Bolwerk et al. 2003). However, the effects on AM fungal hyphae were not investigated. Besides producing antifungal substances, the capacity of bacteria to colonize root surfaces and thereby closely interact with pathogens may further promote pathogenic suppression (Lagopodi et al. 2002).

Despite the rising number of studies over the last years, the underlying mechanisms are poorly understood. Some fundamental mechanisms have been previously proposed: enhancement of plant nutrition and competition for photosynthates (Azcon-Aguilar and Barea 1996); however, AM caused suppression of root pathogens and promotion of saprotrophs and plant growth (Kapoor and Mukerji 1998). The other mechanisms that tend to be inconsistent among studies include changes in morphological and anatomical features of root system induced by the AM fungus and triggering plant defense mechanisms by AM fungi (Gianinazzi-Pearson et al. 1994). The combination of AM fungi with growth-promoting rhizobacteria may prefer the inoculum production (Singh 1992).

Many studies have shown that some AM fungi present biocontrol characteristics (Niemira et al. 1996; Caron 1989; Newsham et al. 1995) against plant-root pathogens. Whether AM fungi may be applied as biological control agents virtually or potentially act as vectors for associated bacteria with biocontrol characteristics remains to be further explored.

18.4 Conclusions

Interactions between symbiotic microbial and host plant are prominent to keep the continued existence of both microorganism as well as the host under environmental restrictions. These interactions are important for soil-plant-water relations, mineral uptake, stomatal regulation, gas exchange, and photosynthetic process. Moreover,

symbiotic root-associated fungi are critically efficient in enhancing plant growth and conferring plant tolerance to different types of stresses. In view of the fact that process of plant growth and development, which conclude crop yield, cannot be correctly described without possessing idea of microbial interactions. Thus, it is required to study plants from a symbiotic systems attitude to understand the contributions of all organisms in a symbiotic relationship for better plant health, growth, and survival.

Significance of Arbuscular Mycorrhizal Fungi and Rhizosphere Microflora in Plant Growth and Nutrition

19

Hindumathi Amballa and Narasimha Reddy Bhumi

Abstract

Arbuscular mycorrhizal fungi are common components of soil microorganisms inhabiting the rhizosphere. The rhizosphere is a dynamic microhabitat where microorganisms, plant roots and soil constituents interact with constituting root-soil interface. The rhizosphere of mycorrhizal plants – the 'mycorrhizosphere' – harbours a wide range of microbial activities responsible for several ecosystem processes. Arbuscular mycorrhizal fungi interact with microorganisms colonizing the rhizosphere. The microbial interactions in the mycorrhizosphere are the primary determinants of plant health and soil quality. This chapter summarizes various microbial interactions between mycorrhizal fungi and other soil microbial communities. This chapter discusses (1) microbial communities in the soil, (2) arbuscular mycorrhizal fungal interaction with plants, (3) interaction with rhizosphere microorganisms, (4) interaction with soilborne pathogens, (5) potential benefits of arbuscular mycorrhizal fungi in plant growth and disease control and (6) effect of soil microorganisms on mycorrhizal symbiosis. The main conclusion is that the microbial population interactions with arbuscular mycorrhizal fungi in the rhizosphere majorly influence plant health, crop productivity and soil fertility. Arbuscular mycorrhizal fungi in corporation with other rhizosphere microbial organisms can contribute to improve plant growth and nutrition.

19.2 Introduction

Soil is a dynamic medium and supports different microbial communities such as bacteria, fungi, actinomycetes, algae, viroids, viruses, protozoans, nematodes, etc., which play a vital role in maintaining soil fertility, cycling of nutrient elements in the biosphere, humus formation, biological conversions, geochemical cycling, ecosystem sustenance, etc., besides supporting plant life and plant productivity. Plant-microbe interactions are an integral part of our terrestrial ecosystem that contribute to sustainable agriculture. The different interactions of rhizosphere microorganisms with each other and with plants influence plant health and soil quality.

The plant roots grow into the soil creating plant-root interface named 'rhizosphere', the term first coined by Hiltner (1904). The rhizosphere probably represents a unique habitat on the Earth. In particular, the major factor that determines the availability of nutrients to the plants in the rhizosphere is the microbial activity that has significant influence on plant growth as well as soil health and productivity. It is very important to understand the basic principles of rhizosphere microbial ecology, viz. the function and diversity of the microorganisms that reside there, before soil microbial technologies can be applied.

19.3 The Rhizosphere

The rhizosphere is best defined as the volume of soil in close proximity to roots characterized by high microbial populations of active microorganisms than the soil away from the plant roots (Hiltner 1904). The rhizosphere is under continuous influence of living roots and the microbial activities in such microsite makes rhizosphere the most dynamic habitat for soil microorganisms on Earth. It differs from the bulk soil in its physicochemical characteristics such as low pH, low water potential, low partial pressure of O_2 and higher concentrations of soluble carbohydrates due to root exudates.

The rhizosphere is known to be a hot spot of microbial activities as the plant roots influence microbial communities by depositing photosynthates (amino acids, low molecular weight organic acids or phytosiderophores) into the rhizosphere (rhizodeposition). The root activities can also modify soil physicochemical properties. Rhizodeposition is influenced by plant and soil biotic and abiotic factors. Some plant biotic and abiotic factors that influence rhizosphere comprise mycorrhiza, root architecture, nutrient deficiency, photosynthesis, temperature, light intensity and

physical disturbance, while soil biotic and abiotic factors include pathogens, biocontrol agents, root herbivores, metal toxicity, soil pH, soil texture and water availability (Jones et al. 2004).

Root exudates constitute a major part of rhizodeposition, mainly composed of flavonoids, phenolic compounds, carbohydrate monomers, organic acids and plant hormones (Lynch and Whipps 1990). Rhizodeposition also corresponds to 15–30 % of total carbon produced by plants during photosynthesis transferred towards microorganisms of the rhizosphere.

The organic materials released as root exudates act as signal molecules or growth substrates to the heterotrophic microbial communities (Werner 1998) and regulate different kinds of associations between the plant and soil microorganisms affecting microbial composition and diversity. Rhizosphere functioning is known to significantly influence plant fitness and soil quality because microbial activities in such habitat can help the host plant to adapt to stress conditions like water and mineral deficit and also soilborne plant pathogens (Lynch 1990; Bowen and Rovira 1999).

The overall influence of plant roots on soil microorganisms is termed 'rhizosphere effect'. The microbiological activity is greater in rhizosphere than in the soil away from the plant roots. The intensity of such activity depends on the distance to which exudations from the root system can diffuse. Hence, the rhizosphere microflora differ both qualitatively and quantitatively from that of bulk soil, i.e. beyond the influence of roots (Parkinson 1967). The number of microorganisms (cfu) per gram soil is greater by two- to threefolds in the rhizosphere than in the non-rhizosphere soil (Mehrag and Killham 1995). The rich nutrient supply and close contact to the living roots enable rhizosphere microorganisms to have a direct influence on plant growth and phytopathogens. The rhizosphere has been described as both a 'playground' and a 'battlefield' for beneficial microorganisms and soilborne pathogens (Raaijmakers et al. 2008).

Though it may be difficult to physically separate rhizosphere and bulk soils, they differ in inherent biological, chemical and physical characters (Barea et al. 2005). The rhizosphere is characterized by altered microbial diversity and activity.

The major soil ecological environment for plant-microbe interactions is the plant rhizosphere which involves colonization of different microorganisms in and around growing roots which result either in associative, symbiotic, neutralistic or parasitic interactions depending upon plant nutrient status, soil environment, plant defence mechanism and the type of microorganism proliferating in the rhizosphere. In response to the adhesion of microorganisms very close to the epidermis, plants secrete signal molecules for protection against invasion of the heterogeneous microbes into the root zone. Plant signal molecules such as flavonoids and flavones produced in the rhizosphere in response to microbial adhesion remain attached to plant cell walls to act as antimicrobial agents (phytoalexins). The microorganisms inhabiting the rhizosphere produce a variety of compounds that stimulate plant growth or can be antagonistic to plant pathogens. These interactions may be beneficial or detrimental. The beneficial interactions are caused by symbiotic and non-symbiotic bacteria and by a highly specialized type of fungi, the mycorrhizae. The pathogenic or detrimental interactions involve microbes such as viroids, viruses, bacteria and fungi.

19.4 Microbial Communities in the Rhizosphere

Plants live in association with a rich diversity of microorganisms during their entire development. Of the various microbial communities colonizing rhizosphere, mycorrhizal fungi, nitrogen-fixing bacteria, soilborne pathogens, free-living fungi and bacteria and antagonistic/plant growth-stimulating fungi and bacteria are commonly known to share the microhabitat.

Of the different interactions of rhizosphere microorganisms with each other and also with the plants, the beneficial plant microbial interactions in the rhizosphere are the primary determinants of plant health and soil fertility (Jeffries et al. 2003).

The most abundant and important members of the soil microbial community that develop mutually beneficial relationship with plant roots and contribute majorly to plant growth by nutrient acquisition and pathogen control are the mycorrhizal fungi. Mycorrhizal symbiosis plays a key role in the productivity and diversity of natural plant ecosystem. Mycorrhizal fungi are the relevant members of the rhizosphere, mutually symbiotic population known to carry out many critical ecosystem functions such as improvement of plant establishment, enhancement of plant nutrient uptake, plant protection against various abiotic and biotic stresses and improvement of soil structure (Smith and Read 1997).

The term 'mycorrhiza' that literally means 'fungus root' was coined by Frank (1885) to describe symbiotic relationship of plant roots with certain soilborne fungi. Mycorrhizal fungi differ from other plant-fungus associations because of their ability to create an interface for nutrient exchange which occurs within living cells of the plant (Brundrett 2002, 2004). There are different types of mycorrhizal interactions which have been broadly classified into ectomycorrhiza, endomycorrhiza and ecto-endomycorrhiza based on the presence of various extraradical or intraradical hyphal structures. Based on the type of fungus involved and the resulting structures produced by the root-fungus combination, seven different types of mycorrhizal associations have been identified. They are ectomycorrhiza, ecto-endomycorrhiza, monotropoid mycorrhiza, ericoid mycorrhiza, arbutoid mycorrhiza, orchid mycorrhiza and vesicular arbuscular mycorrhiza (VAM) (Fig 19.1). All these mycorrhizal types differ from each other by the characteristic host plant that they associate with, fungal species involved and morphology within the roots (Brundrett 2002).

Of the seven mycorrhizal types that have been identified, the most common type of endomycorrhizas are the vesicular arbuscular mycorrhizas that are most commonly found in agriculturally important crop plants and are one of the most important symbiotic associations on earth linking the root and the soil system (Koide and Mosse 2004). VAM fungal association is the oldest and probably the most abundant plant-microbe association on earth (Simon et al. 1993; Smith and Read 1997).

19.5 Arbuscular Mycorrhizal Fungi

Vesicular arbuscular mycorrhiza (VAM) is the most common type of mycorrhiza found associated with some bryophytes, pteridophytes, gymnosperms (excluding Pinaceae which have sheathing mycorrhizas) and in virtually all families of

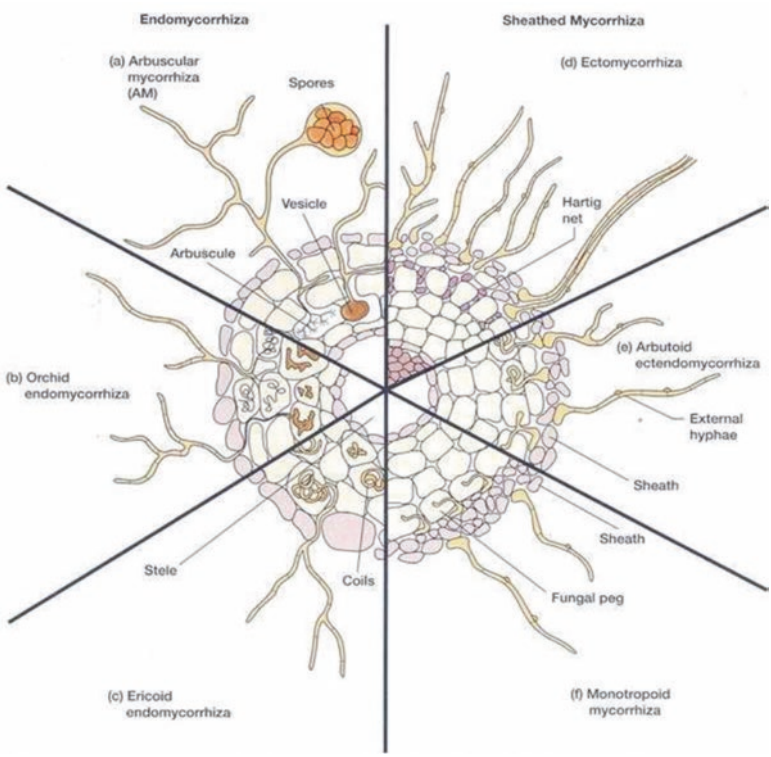

Fig. 19.1 Root cross section: illustrating different types of mycorrhizal relationships that exist within plants (Courtesy: Saved from davidmoore.org.uk)

angiosperms. They generally occur in Gramineae, Palmae, Rosaceae and Leguminosae which include many crop plants. They have a very ancient origin, dating back to early land plants (Simon et al. 1993), and they could even have been a major factor in the colonization of land.

Several aspects of plant physiology such as mineral nutrient composition, hormonal balance, C allocation patterns, etc. are responsible to be modified by the mycorrhizal establishment (Harley and Smith 1983; Smith et al. 1994). Bidirectional movement of nutrients characterizes this symbiosis where photosynthetically derived carbohydrates flow to the fungi and inorganic nutrient get transported to the plant through mycelial network, thereby providing a critical linkage between the plant root and rhizosphere. They are of ecological significance for higher plants as they govern their growth and survival. Hence, they are employed to augment the production of forest and crop ecosystem.

AM fungi are widely distributed being abundant in phosphorus- and mineral-deficient soils. AM fungi are characterized by the formation of arbuscules and vesicles inside the cortex cells. Their presence led to the former common name vesicular arbuscular mycorrhizal (VAM) fungi, but the term arbuscular mycorrhiza (AM) is

now preferred (Friberg 2001) because not all fungi produce vesicles. But there is some disagreement about the two terms as arbuscules are not always present in the mycorrhizal roots. Vesicles are not formed by the genera belonging to the order Gigasporales but are found in the other genera of the Glomeromycota (Isaac 1992).

The arbuscular mycorrhizal (AM) fungi are the most common obligate symbiotic fungi, belonging to phylum Glomeromycota (Schüßler et al. 2001). This association is geographically ubiquitous, occurring in arctic, temperate and tropical regions over a broad ecological range from aquatic to desert environment (Gerdemann 1975). From fossil records of Ordovician age, the evolution of symbiotic fungi was thought to have existed at least 470 million years ago.

19.6 Taxonomy

Traditionally the taxonomy of AM fungi was largely based on the morphological and anatomical characteristics of their spores and sporocarps, spore germination and the method of spore formation on the hypha (Morton 1988). The spores are relatively large (40–800 μm) with layered walls and lipids in their cytoplasm. Spores are important for identification of AM fungi. AM fungal species isolated from the rhizosphere soils of safflower were identified based on their morphological characters are represented in Figs. 19.2 and 19.3. Among them *Acaulospora alpina, A. myriocarpa, G. australe*, *G. diaphanum*, *G. heterosporum*, *G. manihotis*, *G. microaggregatum*, *G. multicaule* and *Gigaspora rami sporopora* are the first reports from Telangana state (Hindumathi and Reddy 2016a).

Now, several modern methods like serology, isozyme variation by electrophoresis (Hepper et al. 1988), fatty acid variation (Bentivenga and Morton 1994) and molecular techniques such as DNA-based methods (Helgason et al. 1999; Schüßler et al. 2001) have aided in a clearer phylogenetic analysis that was possible using morphological and microscopic identification.

19.7 Classification

In earlier systems of classification, the AM fungi were placed in the order Glomales within the division Zygomycota. They have nonseptate hyphae, a similar characteristic to that found in hyphae of most Zygomycota. However, AM fungi are distinguished from the zygomycotan lineages due to some spore characteristics, e.g. mutualistic symbiotic nutrient habit and lack of formation of characteristic zygospores. The rDNA analysis exposed a clear separation of AM fungi from other fungal groups, and the AM fungi have been elevated and now placed in a separate new phylum Glomeromycota (Schüßler et al. 2001). Three glomeromycotean classes (Archaeosporomycetes, Glomeromycetes and Paraglomeromycetes), five orders (Archaeosporales, Diversisporales, Gigasporales, Glomerales, Paraglomerales), 14 families, 29 genera and approximately 230 species have been recognized (Table 19.1). The classification of arbuscular mycorrhizal fungi (Oehl et al. 2011) up to genus level is presented in Table 19.1.

19.8 Interaction of Arbuscular Mycorrhizal Fungi with Plants

Arbuscular mycorrhizal fungal associations are established in the presence of a variety of microorganisms, and some of these microbes interact in rather specific ways to influence this association and its effect on plant growth. About 80 % of plant families of land plants and majority of agricultural crops are estimated to be colonized by AM fungi. The remaining plant species are either non-mycorrhizal or non-hosts of AM fungi. Plant species belonging to the Cruciferae and Chenopodiaceae are not known to form AM fungal symbiosis (Smith and Read 1997). Giovannetti and Sbrana (1998) suggested that this is due to the lack of any recognition event leading to the establishment of a functional symbiosis. The inability of these plants to support mycorrhizas may also be related to accumulation of chemicals like alkaloids, cyanogenic glucosinolates and antifungal compounds in the root cortical tissues or in root exudates (Brundrett 2002). The degree of host specificity could be under the genetic control of the host, the AM fungus or more likely a complex interaction of both symbionts with the soil environment (Sylvia et al. 2003).

19.9 Arbuscular Mycorrhizal Fungal Root Colonization

The spores of most species do not require host factors for germination and initiation of the hyphal growth, but continuous hyphal growth, differentiation into infection structures and penetration into the host are reported to be affected by plant signals (Bécard and Piché 1989). Three major parameters such as specificity, infectivity and effectivity determine root colonization. The process and rate of colonization determine the effectiveness of an AM fungus or a mycorrhizal association.

As the infection spreads within the root cortical cells of the host, extraradical hyphae grow out into the soil, play an important role in nutrient acquisition and, furthermore, form a source of secondary colonization (Harley and Smith 1983).

The other important structures involved in the colonization of roots are spores and extraradical auxiliary bodies (Fig. 19.4) produced in the soil and unique structures such as hyphae, arbuscules and vesicles produced inside the roots (Fig. 19.5). Arbuscules are dichotomously branched intracellular structures and are considered as the major sites of carbon needed for energy and nutrient exchange between the fungus and host plant. Vesicles are storage organs and store phosphorus as phospholipids and sometimes help in vegetative reproduction. The establishment, development, survival and performance of AM fungi are affected by soil fertility, cropping patterns, environmental factors and host-plant genotype.

The extraradical hyphae (ERH) also known as soil hyphae or external hyphae associated with the root radiate out into the soil. These hyphae are distinguished as thin highly branched ‘absorptive’ hyphae responsible for nutrient acquisition (Friese and Allen 1991) and thick ‘runner’ or ‘distributive’ hyphae (infective hyphae) running towards and along the root surface to establish new entry points. Maximum root colonization and sporulation is most prevalent in soils of low fertility. External

input of mineral N or P to the soil decreased mycorrhizal development in several legumes (Abbott and Robson 1977) and nonlegumes (Krishna and Bagyaraj 1982).

Plant growth hormones like auxins and other compounds such as flavonoids, phenolics and carbon dioxide are known to play an important role in spore germination, development, proliferation and stimulation of hyphal growth and mycorrhizal colonization. The association/colonization of AM fungi is usually not detected by the naked eye as there are no external or morphological root changes. Root colonization structures (Fig. 19.6) are visible only when they are cleared, stained and examined under the microscope following the most commonly and frequently adopted method (Phillips and Hayman 1970). Detection and quantification of AM fungal colonization in the roots is very essential for mycorrhizal research. A range of light microscopy-based, biochemical and molecular techniques were also used for identification and/or quantification of AM fungi in roots. Nonvital staining with various stains such as trypan blue, cotton blue, aniline blue, ink, vinegar and chlorazol black E (CBE) are some of the methods used to visualize AM fungi in roots (Vierheilig et al. 2005).

19.10 Mycorrhizal Dependency

In natural ecosystems, plants have varying degrees of dependence on mycorrhizal associations, based on the availability of nutrients in the soil in which they naturally occur. Mycorrhizal dependency is a measure of the benefit provided by mycorrhizae and depends on relative contribution of root and mycorrhizal-mediated nutrient uptake to plants. AM fungi are not host specific because many species have been shown to colonize a wide range of hosts, and the same plant root may be colonized by a mixture of AM fungal species (Helgason et al. 1999; Klironomos 2000). Vandenkoornhuyse et al. (2002) demonstrated that distinct AM fungal communities are associated with different plant hosts, and Van der Heijden et al. (1998) reported plants might select AM fungal species. The magnitude of response to root colonization varied with different cultivars of sorghum (Hindumathi and Reddy 2011c).

19.11 Mycorrhizosphere

The mycorrhizal symbiotic status of the plant changes the chemical composition of root exudates and modifies the root functions and microbial communities. This zone of soil influenced by combined activities of the root and mycorrhizal fungus is termed as 'mycorrhizosphere' (Linderman 1992, 2000; Barea 1997, 2000; Gryndler 2000). The fungal soil mycelium serves as carbon source to the rhizosphere microbial communities. These changes therefore affect the microbial communities in the rhizosphere of mycorrhizal plants both qualitatively and quantitatively producing the 'mycorrhizosphere effect' (Linderman 1988). As the mycorrhizal fungus uses the root exudates and modifies root functions, microbial communities in the mycorrhizosphere differ from those in the rhizosphere soil (Garbaye 1991; Barea et al. 2002c).

Mycorrhizosphere has two components: one is the layer surrounding the mycorrhizal roots (colonized by AM fungi) referred to as the 'mycorrhizosphere', and the other is the layer of the soil surrounding the hyphae of AM fungi referred to as 'hyphosphere' (Marschner 1995), 'hyphorhizosphere' (Klynchnikov and Kozherin 1990) or 'mycosphere' (Gilbert and Linderman 1971). Microbial interactions in the rhizosphere of mycorrhizal plants improve plant fitness and soil quality, the critical issues for a sustainable agricultural development and ecosystem functioning (Barea et al. 2002b).

19.12 Potential Benefits of AM Fungi

The beneficial effects of AM fungal inoculation on plant growth and yield promotion have generally been attributed to improved nutrition uptake, mobilization of nutrients (Abbott and Robson 1977), production of enzymes (Tarafdar and Claassen 1988) and plant protection against pathogen infection (Dehne 1982). AM fungal partner has been shown to acquire mineral nutrients from the soil, especially

immobile elements such as P, Zn and Cu, and also more mobile ions such as S, Ca, K, Fe, Ni, Pb, Mg, Mn, Cl, Br and N (Tinker 1984). In the soils where such elements may be deficient or otherwise less available, mycorrhizal fungi increase efficiency of mineral uptake, resulting in enhanced plant growth.

The fungal hyphae in ERH phase extending into the soil serve as extensions of the root systems, which are both physiologically and geometrically more effective in the absorption of nutrients, especially phosphorus (P), than the roots themselves, and translocate to the root. AM fungal hyphae are not only structurally efficient in extraction of nutrients from exchange sites in soil, they also produce exogenous enzymes such as phosphatases, phytases and nitrate reductase, which are important in uptake and metabolism of nutrients (Ho and Trappe 1980).

The absorbed 'P' is probably converted into polyphosphate granules in the external hyphae (Callow et al. 1978) and passed to the arbuscules for transfer to the host. This flow of phosphates is known to occur in the presence of acid phosphatases (Gianinazzi et al. 1979) during arbuscule life span or senescence.

Exogenous enzymes, like phosphatases produced by AM fungal extraradical hyphae, hydrolyse unavailable sources of P and release P from organic P complexes and facilitate absorption of P especially under humid tropical conditions (Koide and Kabir 2000; Carlile et al. 2001).

AM fungal extraradical hyphae obtained nitrogen in different forms such as amino acids, peptides, ions (No_3^- or NH_4^+) and recalcitrant organic nitrogen forms (Hawkins et al. 2000; Giri and Mukerji 2004).

AM fungal influence on plant N nutrition is not as high as 'P', but they give their host access to different forms of N, thereby increasing plant N uptake (Hodge et al. 2001). Hodge et al. (2001) demonstrated that the ability of AM fungi to decompose organic matter and acquire N from organic source. They also found that AM fungi increased N diffusion rate into its host. Hence, mycorrhizal plants have additional access to N sources compared to non-mycorrhizal plants. AM fungal extraradical hyphae were reported to absorb inorganic N and transfer it to intraradical hyphae as amino acids (arginine). They have also evidenced intraradical hyphae decompose the amino acids to access the C and then transfer the remaining N as ammonium to the host plant.

ERH or external fungal mycelial network extend beyond the nutrient depletion zone for enhanced nutrient acquisition and water uptake and provide to the plant. In addition, fungal hyphae are better adapted to explore patch nutrients through rapid proliferation and competitive ability with soil microbe (Smith and Read 1997).

AM fungi also play an important role in the water economy of plants. Their association improves hydraulic conductivity of roots which contributes towards better uptake of water by the plants. It has been suggested that mycorrhizal fungi help the plants in better absorption of water by the roots by exploiting in wider zones of soil and result in better performance (Safir et al. 1971; Kehri and Chandra 1990). It has been demonstrated that in extremely dry conditions, mycorrhizal plants showed a better survival over non-mycorrhizal ones. The most established benefit from AM fungus to the host plant is due to the widespread mycelial network that penetrates deeper and wider in the soil in search of water and nutrients, thereby widening the zone of activity.

AM fungal effects extend to production of phytohormones such as gibberellins, cytokinins, ethylene and other growth hormones suggesting that mycorrhizae play a key role by influencing regulatory systems in plants.

Other major benefits include improved tolerance to drought and salinity (Augé 2004; Augé et al. 2015), high soil temperatures, adverse soil pH, heavy metal toxicity alleviation (Lingua et al. 2008; Meier et al. 2015), toxicities related to mine spoils or landfills, toxicities due to minor element imbalance such as Mn, increased uptake of macronutrients (N, K and Mg) other than P as well as uptake of micronutrients and overcoming transplantation shock compared to non-mycorrhizal plants.

It was demonstrated that AM fungal inoculation increased mineral nutrient uptake with consequent increase in plant growth and seed yield over control plants (Bagyaraj et al. 1979a; Hindumathi and Reddy 2012a; Satya Vani 2012; Satya Vani et al. 2015).

Mycorrhizal symbiosis plays an important role in the tropical agriculture because the soils are phosphorus deficient and P fixing. The soil phosphate (P) availability is the most limiting factor in legume growth and biological N_2 fixation, and AM fungal symbiosis with legume can overcome this limitation. Nodules require relatively large amounts of P indicating high demand for P by the nodules. It has been suggested that P level influences not only mycorrhizal infection frequency but also process of nodulation in legume species since legumes are poor competitors for soil phosphates. It was demonstrated that mycorrhizal nodulated plants exhibited higher levels of nitrogenase and nitrate reductase activity compared to non-mycorrhizal plants (Carling et al. 1978).

Inoculation of AM fungi in legume-*Rhizobium* symbiosis in the presence of the pathogen resulted in better nodulation, biological N_2 fixation, enhanced plant growth and nutrition and biological control of root rot pathogens and increased soil nitrogen content (Bagyaraj et al. 1979a; Hindumathi and Reddy 2012a; Hindumathi et al. 2016b). Experimental evidence showed that dual inoculation of AM fungi with *Rhizobium* strain in legume tripartite (AM + *Rhizobium* + legume) symbiosis enhanced nutrient uptake (Krishna and Bagyaraj 1982; Morton et al. 1990; Hindumathi and Reddy 2012a; Hindumathi et al. 2016b) compared to single inoculations. Legumes cultivated in soil with low P were most responsive to combined inoculation of AM fungi and *Rhizobium* as increased 'P' availability stimulates biological N_2 fixation and growth of the host legume.

Furthermore, AM fungi improve soil structure through the secretion of proteinaceous substance called glomalin (Steinberg and Rillig 2003). It can have a direct effect on the ecosystem, as they improve the soil aggregation by forming structure of macroaggregates through physical binding of soil particles and organic material (Rillig and Mummey 2006; Leifheit et al. 2014, 2015; Rillig et al. 2015). Such aggregates enhance carbon and nutrient storage and create conducive environment for survival and growth of soil microorganisms. They also influence soil porosity, which promotes aeration and water movement, essential for better root growth, root development and microbial activity, thereby driving the structure of plant communities and productivity.

Some mycorrhizal fungi produce metabolites that can alter the plant's ability to produce roots from cuttings or alter root regeneration and root morphology resulting in greatly increased absorptive surface area and feeder root longevity (Linderman and Call 1977).

One of the major changes in mycorrhizal plants is reduced membrane permeability primarily due to increased P nutrition affecting quality and quantity of root exudates which, in turn, has the potential to induce significant changes in the rhizosphere microflora.

19.13 AM Fungi in Disease Tolerance

AM fungal colonization in plant roots has been found to increase plant tolerance to root/soilborne plant pathogens, thereby acting as a biocontrol agent (Chhabra et al. 1992; Azcón-Aguilar and Barea 1996). Several mechanisms or combination of mechanisms could account for the observed bioprotection of plants by AM fungi.

Smith (1988) proposed that the interaction of AM fungi with soil root pathogens enhanced uptake of P and other nutrients. Through this action, the fungus increases the plant tolerance to pathogens, through mechanisms such as alteration of root exudates, increased root growth and function and competition for space of infection sites. Chhabra et al. (1992) reported that increased nutritional status of plants with AM fungi might increase tolerance to root pathogens. But no effect was observed on the development of leaf diseases caused by *Helminthosporium maydis* and *Acremonium kiliense* in maize. AM fungi were found to increase *Zea mays* tolerance to leaf rust showing less than 5 % over pathogen-inoculated plants with 80 % leaf rust.

In addition, microbial changes in the mycorrhizosphere and anatomical changes in the root induced by AM formation may bring about stimulation of specific functional groups in the microbiota that are antagonistic to pathogens (Azcón-Aguilar et al. 2002; Sylvia et al. 1998; Azcón-Aguilar and Barea 1996; Linderman 1994). Several studies on biocontrol potential of AM fungi used as inoculant on root/plant pathogens proved to increase plant tolerance to the pathogen.

Systemic acquired resistance (SAR) plays an important role in the ability of plants to defend themselves against pathogens. SAR occurs in most plants in response to colonization of AMF. A number of biochemical and physiological changes have been associated with AM colonization including the production of antifungal or oxidative enzymes, cell death and deposition of lignin.

The AM fungus-plant combinations also proved to be useful in conferring localized or induced systemic protection against pathogens to plants. It was indicated that this mechanism is signalled by modulations such as lignifications, induction of cell wall appositions containing callose and accumulation of pathogenesis-related (PR) proteins or phenolic compounds (Pozo et al. 2002).

AM fungi not only have synergistic interaction with beneficial soil microorganisms but also exihibit antagonistic interaction with root pathogenic microflora and microfauna, thereby promoting plant growth (Dehne 1982).

19.14 Interaction of Arbuscular Mycorrhizal Fungi with Rhizosphere Microorganisms

19.14.1 Interaction of AM Fungi with Bacteria

A variety of microorganisms interact with mycorrhizal fungi which include phosphate solubilizers, free-living and symbiotic nitrogen fixers, antibiotic, plant growth hormone, siderophore and chitinase producers, saprophytes, plant pathogens, predators and parasites. These soil bacteria possess the ability to produce antibiotics or siderophores which are Fe chelators that may act as inhibitors against pathogens or stimulate plant growth.

AM fungal hyphae, in addition to having enhanced nutrient absorption capability of their host plant, provide area for the interaction of plants with other soil microorganisms that have effect on root development and performance. These interactions can be found at all stages of AM fungal life cycle, from spore formation and germination through root colonization to external hyphae (Bianciotto and Bonfante 2002; Bianciotto et al. 1996, 2003; Toljander et al. 2006). The nature of these interactions may be inhibitory or stimulatory and competitive or mutualistic to each other for the plant.

Mycorrhizal establishment changes the microbial population in the rhizosphere both quantitatively and qualitatively (Azcón-Aguilar and Barea 1992; Linderman 1992; Barea 1997; Cordier et al. 1999). Mycorrhizal formation can directly or indirectly affect microbial communities in the rhizosphere through induced changes on root exudates and transport of carbon compounds to the mycorrhizosphere (mycorrhizosphere effect).

Two main groups of microorganisms, the saprophytes and symbionts, interact with mycorrhizal fungi in the rhizosphere environment, both of them comprising detrimental, neutral and beneficial bacteria and fungi. Detrimental microbes include the major plant pathogens, as well as minor parasitic and nonparasitic deleterious rhizosphere organisms (Weller and Thomashow 1994; Nehl et al. 1996). Beneficial microbes include nitrogen fixers, phosphate solubilizers, growth promoters and biocontrol agents which are known to play a major role in soil-plant systems (Barea 1997). Important among them are rhizobacteria (Kloepper 1994, 1996) that are known to show a specific ability for root colonization, some of them able to improve plant development, therefore they are termed as *plant growth-promoting rhizobacteria* (PGPR).

19.14.2 Interaction of AM Fungi with Plant Growth-Promoting Rhizobacteria

Interaction of AM fungi with PGPR carries out many important ecosystem processes and contributes to the productivity of agricultural system (Adesemoye and Kloepper 2009), and also they are known to involve in the biological control of plant

pathogens, nutrient cycling and/or seedling establishment and soil quality (Kloepper et al. 1991; Barea 2000; Jeffries and Barea 2001).

PGPR belonging to genera *Paenibacillus*, *Burkholderia*, *Pseudomonas* and *Bacillus* spp. exert direct or indirect effects on plant growth. The direct effects are through the release of phytohormones, nitrogen fixation and mineralization of organic phosphates into available forms for plants, while the indirect effect on plant growth is by decreasing or preventing deleterious effects of pathogens mainly through synthesis of antibiotics or production of siderophores.

The AM fungi interact with different types of soil bacteria that can influence their development and symbiotic establishment. The interaction between AM fungi and bacteria can be positive (Gryndler et al. 1996), negative (Gryndler et al. 1996) or neutral (Edwards et al. 1998). The positive interactions include enhanced mycorrhizal development and function. Synergistic positive interactions have been reported between AM fungi and PGPR such as N_2 fixers, fluorescent pseudomonads and sporulating bacilli (Hameeda et al. 2007). Negative interactions include reduced spore germination and hyphal length in the extrametrical stage, decreased root colonization and a reduction in metabolic activity of the internal hyphae. Studies of Walley and Germida (1997) on dual inoculation of *Pseudomonas* strains with AM fungi evidenced varying effects, i.e. *Pseudomonas* strains hindered AM fungal germination. Hence, this indicates that not all PGPR are mycorrhizal-helper bacteria (MHB) or vice versa.

Pseudomonas strains produce non-volatile diffusible compounds such as methane, acetaldehyde, acetoin and diacetyl that may or may not reduce mycorrhizal volume (Aspray et al. 2006; Gryndler 2000; Linderman 1992). It was demonstrated that incorporation of fungus *Trichoderma harzianum* with *Pseudomonas fluorescens*, *Azospirillum* sp. and AM fungal species *G. mosseae* and *G. deserticola* did not affect the establishment of AM fungal spp. in maize (Vázquez et al. 2000). However, an increase in phosphatase, esterase, trehalase and chitinase enzymatic activity was observed. These soil enzymes are mainly used as indicator to detect microbial functioning in the rhizosphere as influenced by AM fungi. Phosphatases which are produced both by bacteria and AM fungi catalyse organic bound P into inorganic P. Esterases indicate catabolic activity in the soil which is directly correlated with microbial activity (Vázquez et al. 2000). Trehalase hydrolyses trehalose, a common sugar found in plant symbiosis, while chitinase degrades chitin, a major compound of fungal cell walls that plays a major role in plant defence mechanisms (Pozo et al. 2002; Vázquez et al. 2000).

Ravnskov et al. (1999) observed that *G. intraradices* showed negative effect on the growth and survival of *Pseudomonas putida* under controlled conditions which may likely be due to competition for nutrients. The bacterial population composition in the mycorrhizosphere of AM plants can affect the interaction between plant and AM fungi (Andrade et al. 1997), or alternatively the AM fungi can influence a shift in specific groups of bacteria in the rhizosphere of mycorrhizal plants towards more facultative anaerobic bacteria and fewer fluorescent pseudomonads. Klyuchnikov and Kozherin (1990) demonstrated proliferation of fluorescent pseudomonads in the hyphosphere. Vosatka and Gryndler (1999) reported the most

common bacteria in the mycorrhizosphere were *Pseudomonas*, while *Arthrobacter* and *Bacillus* were common in the hyphosphere. It was suggested that AM fungi can regulate the microflora for its own benefit which, in turn, can benefit the host plant.

Marschner et al. (1997) studied the effect of mycorrhizal colonization by *G. deserticola* and *G. intraradices* on the changes in root exudation pattern and rhizosphere microflora using split root system. The results evidenced the latter species colonizing the root on one-half of the split root system significantly altered the root exudation pattern compared to the former. It was found that root colonization by *G. intraradices* in one-half of the root system reduced the population of *Pseudomonas fluorescens* on both sides of the split root system. Further, it was observed that *G. deserticola* could also reduce population density of *P. fluorescens* on the side where fungus colonized the root system, suggesting that colonization by AM fungi could significantly influence the organisms colonizing the rhizosphere.

19.14.3 Interaction of AM Fungi with Phosphate-Solubilizing Bacteria

Phosphate-solubilizing bacteria (PSB) have great potential to improve plant growth under P-deficient conditions when used in combination with AM fungi (Gryndler 2000). They are known to solubilize sparingly soluble organic and inorganic P sources and mobilize phosphate ions to the plants. However, the released P does not reach root surface due to inadequate diffusion (Barea et al. 2005; Azcón-Aguilar and Barea 1992). It was demonstrated that AM fungi could improve uptake of solubilized P. Hence, combined interaction should improve P nutrition and transfer to the plants (Barea et al. 2002a, b, c). Dual inoculation of PSB such as *Bacillus circulans* together with AM fungi resulted in increased uptake of 'P' and enhanced plant yield.

Raj et al. (1981) studied the effect of *G. fasciculatum* and non-phytohormone-producing PSB strain *Bacillus circulans* on phosphate solubilization, growth of finger millet and 'P' uptake from isotope labelled ^{32}P-tricalcium phosphate and super phosphate. Their results clearly indicated that though AM fungi did not solubilize unavailable form of 'P', it enhanced 'P' uptake, which was attributed to better exploration of soil. The synergistic interaction effect between AM fungi and PSB was further confirmed by Karthikeyan et al. (1995) on neem and by Singh (1995) on *Pennisetum* grass.

By using split-dish in vitro carrot mycelial system, it was demonstrated that AM fungi are capable of hydrolyzing organic phosphorus sources and are able to translocate 'P' to plant roots (St. Arnaud et al. 1996). These findings indicated that mycorrhizal plants have access to organic 'P' sources and successfully compete with soil microorganisms for 'P'. Van der Heijden (2010) established that AM fungi have the capacity to increase available soil 'P' and reduce losses of 'P'.

Free-living microorganisms solubilize phosphate ions from sparingly soluble organic and inorganic P compounds (Whitelaw 2000), increase soil phosphate pools and make available for extraradical AM fungal mycelium to absorb. Barea et al. (1997) and Kim et al. (1998) demonstrated in their experiments the symbiotic microbial interaction involving phosphate-solubilizing bacteria (PSB) and AM fungi.

By using a soil microcosm system integrated with ^{32}P dilution, the interactive effects of AM fungi and PSB were studied on plant use of soil in the form of either endogenous or added rock P. The results revealed that the PSB (*Enterobacter* sp. and *Bacillus subtilis*) promoted mycorrhizal establishment of *G. intraradices*, and their dual inoculation increased biomass and N and P accumulation in plant tissues of onion (Toro et al. 1997). They also found that mycorrhizal formation increased the density of PSB population.

The interactive effect of PSB, AM fungi and *Rhizobium* with regard to agronomic efficiency of rock phosphate for legume crops (*Medicago sativa*) was evaluated using isotopic ^{32}P and ^{15}N dilution technique under controlled conditions and further validated under field conditions (Barea et al. 2002a, b). They have observed that the tested microbial interaction improved plant growth and N and P acquisition under normal cultivated conditions. Similar results were obtained by using *Medicago arborea*, a woody legume of interest for revegetation and biological reactivation of desertified semiarid Mediterranean ecosystem (Valdenegro et al. 2001).

Multi-microbial interactions between AM fungi, PSB and *Azospirillum* when inoculated combinedly have reported to show synergistic effect (Muthukumar et al. 2001). They have confirmed by inoculating *G. intraradices*, *G. geosporum*, *Azospirillum brasilense* and PSB individually or in various combinations on neem tree seedlings under nursery conditions. Mycorrhizal colonization, leaf area and number, plant height, biomass, nutrient content (N, P, K) and seedling quality showed significant increase because of combined interaction of microbial inoculants.

Dual inoculation of mycorrhizal fungi and mycorrhizal-helper bacteria (MHB) showed significant increase in biomass and N and P accumulation in plant tissues compared to controls. The dual inoculated plants also showed lower specific activity ($^{32}P/^{31}P$) than their controls suggesting that these mycorrhizal interaction contributed to biogeochemical 'P' cycling, thereby promoting plant nutrition.

The synergistic interaction of mycorrhizal fungi and N_2-fixing bacteria and phosphate-solubilizing microorganism has been demonstrated to improve the bioavailability of major plant nutrients N and P. These interaction effects are a promising approach for low-input agricultural technologies (Bethlenfalvay and Linderman 1992; Jeffries and Barea 2001).

19.14.4 Interaction of AM Fungi with *Rhizobium*

The interaction of AM fungi with *Rhizobium* has received much attention due to high 'P' demand for N_2 fixation. Studies have shown that co-inoculation of legumes with AM fungi and *Rhizobium* increased plant growth compared to plants inoculated with *Rhizobium* alone (Hindumathi and Reddy 2012a; Hindumathi et al. 2016b). This was attributed to the fact that under N- and P-limiting conditions, AM fungi improves P uptake, thereby enhancing the plant nitrogenase activity, which in turn promotes root and mycorrhizal development (Sylvia et al. 1998; Fitter and Garbaye 1994). Several reported results on synergistic interaction between AM

fungi and *Rhizobium* showed that AM fungi have been found to improve nodulation and N_2 fixation, with consequential benefit to plant growth and soil quality (Azcón-Aguilar and Barea 1992; Barea 2000; Hindumathi and Reddy 2012a; Hindumathi et al. 2016b). Thus the symbiotic effect of *Rhizobium* is said to be dependent on the beneficial nutrient effect of AM fungi. Apart from enhanced P uptake, other nutrients such as Zn, Cu and Ca by AMF can also influence the symbiotic effectiveness of *Rhizobium* as well as other microbial processes that occur at root nodule level (Barea et al. 2002a, b; Azcón-Aguilar and Barea 1992).

Rhizobium is a well-known inoculant for legumes; they have also been used as inoculants for nonleguminous plants (Chabot et al. 1996). Galal et al. (2003) studied effect of P and N fertilization on the growth and yield of wheat on inoculation with AM fungi and *Rhizobium* using radiolabelled ^{15}N technique. They found increase in growth of wheat when both AM fungi and *Rhizobium* co-inoculated at high levels of N and P. This dual inoculation also showed increase in the uptake of N and P, while plants inoculated with AM fungi alone increased grain yield of wheat indicating the ability of both organisms to stimulate plant growth and accumulate P and N.

Harrison (1997) reported that certain nod factor stimulated mycorrhizal colonization in soybean. Dual inoculation by the two symbionts showed greater advantage in field experimental studies. These studies have additional advantages in the tropics because of the grain legume programmes introduced to increase protein content of the diet. The reason is that the tropical soils are deficient in 'P'.

Genetically modified (GM) *Rhizobium* developed to improve the nodulation competitiveness of the wild type (WT) strain (Sanjuan and Olivares 1991) was inoculated with *Glomus mosseae* on *Medicago sativa* (Tobar et al. 1996). The results indicated that GM *Rhizobium* strain did not interfere with any process related to mycorrhizal formation (spore germination, mycelial growth) and 'entry point' formation on developing root system of host plant. Indeed, the GM *Rhizobium* increased the number of colonization units and the nutrient acquisition ability in mycorrhizal plants compared with WT *Rhizobium* strain. This symbiotic interaction establishment also induced changes in the root morphology; particularly the degree of branches increased and the number of lateral roots was higher in mycorrhizal plants inoculated with the GM *Rhizobium* strain (Barea et al. 1996).

Rhizobium strains have also been shown to colonize the rhizosphere of nonlegume hosts and established interactions with mycorrhizal fungi (Galleguillos et al. 2000). Several experiments have demonstrated a positive effect on the interaction between mycorrhizal fungi and nodule rhizobacteria under drought stress conditions.

A synergistic effect was observed between *Glomus fasciculatum* and *Azotobacter chroococcum* in tomato plants. The latter helped to enhance fungal colonization and spore production, while the former increased the bacterial population in the rhizosphere (Bagyaraj 1984). Similar interactions have also been observed between *Azotobacter paspali* and AM fungi in *Paspalum* (Barea et al. 1973) and *A. chroococcum* and *G. fasciculatum* in tall fescue (Ho and Trappe 1979). Biro et al. (2000) reported an increase in nodulation of alfalfa plants with combined inoculation of *G. fasciculatum, Azospirillum* and *Rhizobium* under sterile and normal soil conditions.

Synergistic interaction was reported between AM fungi and *Azospirillum* species (Saxena and Tilak 1997) and *Acetobacter diazotrophicus* (Paula et al. 1992). An interaction study between the *Beijerinckia mobilis*, phosphate-solubilizing fungi *Aspergillus niger* and *G. fasciculatum* was reported to show symbiotic beneficial effect on the growth of onions with all three organisms (Manjunath et al. 1981). It was attributed to the production of hormones. Mosse et al. (1981) suggested that hormones produced by these three bacteria could exert symbiotic effect on plant growth or mycorrhizal effect.

In the studies conducted between free-living N_2-fixing bacteria and AM fungi in the rhizosphere, a positive interaction was observed with consequent improvement in plant growth.

The actinomycetes *Frankia* is known to produce N_2-fixing nodules on roots of nonlegumes like *Alnus*, *Casuarina*, *Ceanothus*, *Myrica*, etc., fix atmospheric nitrogen and made available to the host plant. Dual inoculation of AM fungi with *Frankia* increased total dry weight of shoots and roots, number of nodules, weight of nodular tissues, as well as levels of N and P in *Casuarina* (Vasantha Krishna et al. 1994).

The importance of this type of symbiotic fungal association for plant mineral nutrition and more generally plant health makes it one of the potentially more useful biotechnological means of assuring plant production with a minimum input of chemicals such as fertilizers or pesticides.

19.15 Effect of Rhizosphere Microorganism on Mycorrhizal Symbiosis

Rhizosphere microorganisms are known to either interfere with or benefit mycorrhizal development and symbiotic establishment. AM fungi interacting with different types of rhizosphere bacteria can influence their development and symbiotic establishment. These interactions can be found at all stages of the AM fungal life cycle, from spore formation and germination through root colonization to external hyphae (Bianciotto and Bonfante 2002; Bianciotto et al. 1996, 2003; Roesti et al. 2005; Toljander et al. 2006). The nature of interaction between AM fungi and bacteria can be positive, negative or neutral. Negative effects are reduced spore germination and hyphal length in the extramatrical stage, decreased root colonization and a decline in the metabolic activity of the internal mycelium. Positive beneficial interactive effects include enhanced mycorrhizal formation and function. One example among the beneficial effects is that exerted by mycorrhizal-helper bacteria (MHB) known to stimulate mycelial growth of mycorrhizal fungi and/or enhance mycorrhizal formation (Garbaye 1994; Barea 1997; Gryndler et al. 2000).

Rhizosphere microorganism can produce compounds that can influence increased rates of root exudation, which in turn stimulated mycorrhizal fungal mycelium in the rhizosphere or facilitated root penetration by the fungus. Plant hormone production by rhizosphere microorganisms is known to affect mycorrhizal establishment (Azcón-Aguilar and Barea 1992, 1995; Barea 1997, 2000).

Rhizobacteria are reported to affect the pre-symbiotic stages (Giovannetti 2000) of mycorrhizal development, like spore germination and mycorrhizal growth rate of AM fungi *G. mosseae* (Azcón-Aguilar and Barea 1992), which resulted in higher influence on plant root.

Dual inoculation with different species of AM fungi and *Pseudomonas putida* on subterranean clover and maize showed increase in plant growth and AM fungal colonization (Gryndler and Vosatka 1996). Azcón (1987) observed increased growth of emerging mycelium from *G. mosseae* spores in the presence of PGPR. The nodule-forming bacteria, *Frankia*, *Rhizobium* and *Bradyrhizobium*, generally form symbiotic interactions with AM fungi. It is evidenced that AM fungal symbiosis reduced phosphate stress for the plant, which is essential for N_2-fixing and nitrogenase activity of the bacteria, resulting in enhanced fixation and improved N status of the plant. This in turn promotes plant growth and mycorrhizal development. Thus, this type of interaction between AM fungi and bacteria depends on the soil environment, bacterial spp., AM fungal spp. and plant spp.

MHB are organisms that specifically promote mycorrhizal formation especially ectomycorrhiza by producing growth metabolites that encourages easy proliferation of fungal hyphae, thereby increasing its chances to colonize plant roots with a large surface area for absorption. When PGPR are found to stimulate mycorrhizal formation, they can be regarded as MHB (Fitter and Garbaye 1994).

Spanish workers reported that cell-free extracts of *Rhizobium* enhanced colonization of host by AM fungi and was attributed to the presence of extracellular polysaccharide production by *Rhizobium*, which might have increased the number of entry points of AM fungi per unit length of root (Azcón-Aguilar and Barea 1992).

Okon (1994) reported *Azospirillum* bacteria benefit plant development and yield under appropriate conditions and suggested that these bacteria mainly act by influencing the morphology, geometry and physiology of the root system. Volpin and Kaputnik (1994) demonstrated in their interaction study between AM fungi and *Azospirillum* that *Azospirillum* could enhance mycorrhizal formation and response, while AM fungi may improve *Azospirillum* establishment in the rhizosphere.

PGPR bacteria are extensively studied for their role in improvement of crop production in agriculture. Biological active substances such as amino acids, plant growth hormones, vitamins, volatile substances (CO_2) and other organic compounds produced by rhizosphere microorganisms can stimulate the growth rates of AM fungi. Positive interactive effect between AM fungi and PGPR was evidenced by Chanway et al. (1991).

19.16 AMF-Associated Bacteria

Mosse (1962) first showed that bacteria colonize the spores of AM fungi (AMB). Different studies have shown that the spore-associated bacteria can influence AM fungal spore germination, their growth (Walley and Germida 1996; Bianciotto and Bonfante 2002; Hildebrandt et al. 2002; Xavier and Germida 2003) and the formation of the mycorrhizosphere (Budi et al. 1999).

AM fungal structures such as external hyphae (Toljander et al. 2006) and spore or spore walls have been found to be associated with some bacteria (AMB) (Xavier and Germida 2003; Roesti et al. 2005). Spores of *Glomus fasciculatum* were found associated with *Azotobacter* sp. (Ho and Trappe 1979). Mosse (1962) reported certain bacteria on the surface of AM fungal spore aid infection and colonization of alfalfa roots by *G. mosseae. Pseudomonas* sp. associated with AM fungal spores was found to help mycorrhizal fungi in infecting the roots suggesting that it could be either due to production of enzymes or growth-promoting substances. There are also reports that bacteria associated with AM (AMB) fungal spores have the ability to influence spore germination and hyphal growth (Mosse 1962; Walley and Germida 1996; Xavier and Germida 2003). The AMB can degrade biopolymers such as protein, chitin and cellulose (Roesti et al. 2005), inhibit the growth of different plant pathogens (Budi et al. 1999) and improve the soil structure (Andrade et al. 1995).

Hildebrandt et al. (2002) reported that AMB have the potential to stimulate the growth of AMF up to the formation of fertile spores in the absence of a host. These reports indicate that AMB might be one important factor involved in AMF development, plant growth and plant protection.

Budi et al. (1999) found that some AMB have antagonistic potential against several soilborne plant pathogens. The antagonistic potential of spore-associated bacteria against pathogens is to be studied in order to obtain information on the plant health-promoting effect of the mycorrhizae.

Xavier and Germida (2003) reported the ability of *Bacillus pabuli* to enhance AMF root colonization and also improve plant growth (Artursson et al. 2006). Budi et al. (1999) reported that *Paenibacillus* sp. isolated from surface-sterilized *G. mosseae* spores significantly stimulated mycorrhizal colonization in *Sorghum bicolor*. Thus, AMB from spores can have potential both as mycorrhizal-helper bacteria (MHB) and PGPR. The multifunctional traits could confer an advantage to the AMB in colonizing the spore surface and spore walls and ensure their survival in specific microhabitats in competition for nutrients and space with other soil microbes.

Interest in research has been increasing on spore-associated bacteria because these have shown the potential to support AMF to complete spore production in vitro in the absence of a host (Hildebrandt et al. 2002).

19.17 Bacteria-Like Organisms (BLO)

Bacteria have also been reported to live inside the spores of certain AM fungal isolates (Bianciotto et al. 1996, 2003). The AMF also harbour bacteria-like organisms (BLO) in their cytoplasm. They are referred to as BLO because they are actually of true bacterial origin and have endobacterial properties, i.e. they complete their life cycle within fungal cells (Bianciotto et al. 1996). The BLOs are gram negative and rod-shaped and present in several AM fungal species such as *Acaulospora laevis, Gigaspora margarita* and *Glomus versiforme*. They are usually found in the cytoplasm of intracellular hyphae, arbuscules and resting spores.

19.18 Interaction of AM Fungi with Soilborne Pathogens

The role of AM fungi in biological control has been studied in a number of plant pathogen-host species combinations. Several reports suggested that mycorrhizal establishment has been shown to reduce damage caused by soilborne plant pathogens (Azcón-Aguilar and Barea 1996; Schenck 1987). Few reports have also indicated that there is either no effect or an increase in the severity of disease due to mycorrhizal colonization. Primarily, the ability of AM fungi to enhance plant vigour due to increased nutrient uptake enables it to resist pathogen infection. Different AM fungal species have been studied and found to be effective in reducing plant disease caused by the pathogens such as species of *Cylindrocladium*, *Fusarium*, *Macrophomina*, *Phytophthora*, *Pythium*, *Rhizobium*, *Sclerotium*, and *Verticillium* on different host species. AM fungi-mediated biocontrol potential of *Macrophomina* root rot on cowpea (Bagyaraj 1984; Caron et al. 1986), *Pythium aphanidermatum* on tomato (Reddy et al. 2006c) and *Verticillium* wilt in brinjal, chilli (Satya Vani 2012), tomato (Satya Vani et al. 2014b), sorghum (Hindumathi 1999), soybean (Hindumathi and Reddy 2012a) and mung bean (Hindumathi et al. 2016b) proved to increase plant tolerance to the pathogen, thereby acting as biocontrol agents.

Several mechanisms or a combination of mechanisms is reported to involve in bioprotection of plants by AM fungi against soilborne pathogens. One of the proposed mechanisms is based on the microbial population changes produced in the mycorrhizosphere. Azcón-Aguilar and Barea (1992) and Linderman (1994, 2000) evidenced changes in the microbial population shift in the mycorrhizosphere and suggested that the resulting microbial equilibrium could influence the general health of the plants. Earlier studies reported that mycorrhizal formation induced changes in the microbial population may lead to the stimulation of certain organisms of the resident microbiota that can be antagonistic to the root/plant pathogens. Caron et al. (1986) reported a reduction in the population density of *Fusarium oxysporum* f. sp. *lycopersici* on tomato colonization by *G. intraradices*.

Meyer and Linderman (1986) observed lower number of sporangia and zoospores of *Phytophthora cinnamomi* by adding extracts of rhizosphere soil from mycorrhizal plants. Secilia and Bagyaraj (1987) found that there were more pathogen-antagonistic actinomycetes in the rhizosphere of plants inoculated with mycorrhizal fungi than in that of non-mycorrhizal controls. Further studies have ascertained these findings and demonstrated that such an effect is dependent on the mycorrhizal fungi involved, as well as the substrate and the host plant (Azcón-Aguilar and Barea 1996; Linderman 2000).

Various synergistic effects of AM fungi and bacteria can also be exploited for pathogen control and nutrient acquisition in low-input agricultural systems (Artursson et al. 2006). Rhizosphere microbes antagonistic to soilborne pathogens are being used as biological control agents. Therefore, the prophylactic ability of mycorrhizal fungi has been exploited in association with these antagonists (Linderman 1994, 2000; Barea et al. l998; Budi et al. 1999). Several studies have demonstrated that microbial antagonism of fungal pathogens, either fungi or PGPR, exerts no microbial effect against mycorrhizal fungi (Barea et al. 1998; Vázquez et al. 2000).

19.19 Interaction of AM Fungi with Fungi

Saprophytic fungi are common in the rhizosphere of plants and live on dead organic material utilizing a wide range of complex organic molecules such as lignins, proteins, glycoproteins, cellulose and other polysaccharides. AM fungi have the ability to utilize stored C-related products in the hyphae of saprophytic fungi in the absence of plant photosynthates (Suresh and Bagyaraj 2002).

Saprophytic fungi can be classified into ecological functional groups such as phosphate solubilizers, antagonists or symbiotic organisms. As antagonists, they may affect the germination of AM fungal spores and development of mycorrhizal colonization by their competition for space and nutrients (Gryndler 2000).

Fusarium and *Trichoderma koningii* were tested for their effect on the growth and mycelial formation of *Glomus mosseae* in maize and lettuce (Mc Allister et al. 1994). They evidenced that mycorrhizal root colonization by *G. mosseae* was decreased in maize when inoculated before or at the same time with *T. koningii*, while *Fusarium* had no effect on colonization of maize. However, *T. koningii* showed no effect on mycorrhizal colonization in lettuce.

Gliocladium virens used as a biocontrol agent was tested for its effect on the pathogen *Pythium ultimatum* and colonization of AM fungi *Glomus etunicatum* in cucumber plants. *Gliocladium virens* showed no deleterious effect on AM fungi ascertained by the colonization of cucumber roots, while it showed biocontrol activity on *P. ultimatum*. This indicates synergistic interaction between AM fungi and *Gliocladium virens*.

Several reports suggest that the organisms such as *Trichoderma viride* (Reddy et al. 2016) are potential plant growth promoters and *Trichoderma harzianum*, *Aspergillus niger*, *Penicillium* variable, white-rot fungi and other filamentous fungi are capable of solubilizing P along with exhibiting biocontrol activity. This potential was known to be exerted by the production of siderophores, organic acids, lytic enzymes, glucose oxide and melanin-degrading enzymes.

The synergistic effects of phosphate-solubilizing fungi (*Penicillium bilaji*) and mycorrhizal fungi to effectively increase the absorption of P by the plant root system of wheat and bean plants were confirmed by Kucey (1987).

19.20 Conclusion

From the present information, it can be stated that interactions of arbuscular mycorrhizal fungi and rhizosphere microflora of plant roots play an important role in enhancing plant growth. AM fungi are promising for their potential use in sustainable agriculture.

Acknowledgments Dr. A. Hindumathi is grateful to DST, New Delhi for providing fellowship under Women Scientist Scheme-A (WOS-A) with grant No. *SR/WOS-A/LS-498/2011*.

Prospect of Phyllosphere Microbiota: A Case Study on Bioenergy Crop *Jatropha curcas*

20

Santosh Ranjan Mohanty, Garima Dubey, Usha Ahirwar, Ashok Kumar Patra, and Bharati Kollah

Abstract

Phyllosphere is the most abundant environment that supports microbial life. This ecosystem is a stress environment characterized by fluctuation in moisture, nutrients, radiation and plant's own immune system. However, plants support microbial community on the phyllosphere as a strategy for its survival and growth. This chapter addresses general characterization of phyllospheric environment, microbial association process, microbial population structure, quorum sensing and cross talk between plant and microbes. This chapter provides information on the microbial diversity of the phyllosphere of bioenergy crop *Jatropha curcas*. Major bacterial groups prevalent on the *J. curcas* phyllosphere and plant growth-promoting activities are addressed.

20.1 Introduction

Phyllosphere is one of the large habitats for microbial population accounting for ~6.4×10^8 km^2 on the earth. Leaf surface supports extensive bacterial populations which can be as high as 10^7 cm^{-2}. It is estimated that phyllosphere bacterial population could be of 10^{26} cells in the tropical plants (Morris et al. 2002). The phyllosphere is a stress environment because it is controlled by external factors like temperature, moisture and solar radiation. It is also a low-nutrient environment. The phyllosphere provides environmental niche for different microorganisms. Bacteria are the most predominant groups of the phyllosphere. Plant modifies phyllospheric bacterial community by changing leaf exudates and moisture like regulating leaf moisture

through stomata opening and closing. Some microorganisms invade into leaf tissue as a strategy to survive under water stress condition while others manage to survive under low moisture condition (Hardoim et al. 2008). The phyllospheric microorganisms play crucial role in plant's growth. These bacteria fix N and C protect plant from pathogens and produce phytohormones (Bulgarelli et al. 2013). Thus, the phyllospheric organisms provide ecosystem services like C sequestration, N fixation, and bioremediation, enhance crop yield and improve soil health (Bulgarelli et al. 2013). These microbial groups hold key to plant's solvability under extreme condition and sustainability in future climate change.

Jatropha curcas is also known as the biofuel/biodiesel crop. The *J. curcas* belongs to Euphorbiaceae family and is characterized as a drought-resistant perennial plant. It is propagated in tropical and subtropical countries for augmenting renewable energy. In addition, it has several beneficial properties that are significant for agriculture, ecology and environment. Plantation of *J. curcas* is generally recommended to manage degraded wasteland. *J. curcas*-derived biodiesel is a biodegradable and non-toxic fuel compared to petroleum-based diesel. *J. curcas* grows well in low to high rainfall areas. It is cultivated as a commercial crop or as a hedge plant to protect agricultural fields from grazing animals. It can improve socioeconomic status of poor farmers in Third World countries as a resource for biodiesel. It is interesting that this plant doesn't need much input like other plants. It can grow under various stress condition like low nutrient and water input. It is hypothesized that microbiome of this plant may hold the key for its sustainability and growth under limited environmental conditions.

Recently many studies elucidate the diversity of microorganisms prevalent in the rhizosphere of *J. curcas*. It harbours significant numbers of arbuscular mycorrhizae like *Acaulospora* sp., *Gigaspora* sp., *Glomus* sp., *Sclerocystis* sp. and *Scutellospora* sp. The major bacterial groups are *Pseudomonas* sp., *Enterobacter* sp. and several gram-negative and gram-positive bacteria. In addition, many plant growth-promoting bacteria including *Azotobacter*, *Rhizobium*, *Pleomorphomonas diazotrophica*, *Bacillus megaterium* and *Bacillus thuringiensis* have been isolated from its rhizosphere. *J. curcas* can fix 5100–6100 kg C ha^{-1} *as* biomass. Incorporation of *J. curcas* biomass into the soil results into significant increase in soil macro- and micronutrients. Keeping in view of the extent of microbial diversity in the rhizosphere of *J. curcas*, the basis of such microbial diversity is unclear. Further studies are required to link microbial diversity with the plant and environment. It is hypothesized that phyllospheric microbes might have significant role in framing the rhizosphere microbial community. To understand the plant-microbial interaction, this paper aims to address the diversity of phyllospheric microbes in different terrestrial plants and microbial species associated with the *J. curcas*.

20.2 Phyllosphere Environment and Microbial Diversity

The phyllosphere is a much intricate environment than the rhizosphere. It is a nutrient-poor environment for microbial activity compared to the belowground rhizosphere. The microbial colonization on leaves is not homogenous because leaf

veins, hairs and stomata affect surface uniformity. Microbial communities of phyllosphere are under constant variation of temperature, moisture and radiation over the day and night. These external factors also affect the phyllosphere microbiome by altering plant metabolism. Precipitation and wind also contribute to the temporal changes in the phyllospheric microbes.

There is limited information on the chemical characteristics of leaf surface that would explain for the high microbial activity. The unevenness of cuticle and complicated structures of veins and trichomes are the adverse structures for microbial growth. In addition, rain, dew and leaf exudates, pollutants and removal of nutrients after rain inhibit microbial proliferation. On the leaf surface, microorganisms assimilate carbon and nitrogen mainly from the leaf exudates. These organic compounds are generally glucose, sucrose and fructose. In addition to organic acids, alcohols and amino acids are also released from leaf. The concentration of the nutrients on the leaves is very low and occurs in the range of 1–20 ug/g leaf. The analysis of protein and genomic data revealed that phyllospheric microorganisms assimilate plant-derived NH_4-N, amino acids and simple carbohydrates as primary N and C sources. Microbial stress response protein porins, the component of ATP-binding cassette transporters and TonB-dependent receptors, remain at high level among the phyllospheric microorganisms. This suggests that phyllosphere is a nutrient-poor environment for the growth of microorganisms.

The methylotroph species are generally found on the phyllosphere of many plants. These methylotroph species actively assimilate and metabolize methanol from plant pectin. Several phyllospheric microbial species have rhodopsins. These light-sensing proteins and proton pumps have different absorption spectra than the host plants. This indicates that energy metabolism of the phyllospheric microorganisms is not dependent on the plant. Phyllospheric microbes are capable of coping with UV radiation. These species possess pigments which help them to withstand UV radiations. A group of bacteria isolated from peanut produced pink or orange pigments when exposed to UV as protectant mechanism. Limitation of water and nutrients is compensated by microorganisms with the help of various mechanisms. Some epiphytic *Pseudomonas* sp. produces surfactants that increase the water retention ability of leaf surfaces. This increases solubilization and diffusion of nutrients for the microbial metabolism. Some bacteria increase the diffusion potential of the leaf cuticle by producing toxins. These toxins affect the ion transport potential of cell plasma membranes and improve water and nutrient availability for the phyllospheric microorganisms (Quigley and Gross 1994; Hutchison et al. 1995; Schreiber et al. 2005). Epiphytes also produce extracellular polysaccharides. These compounds protect the bacteria from water stress and help in binding to the leaf surface (Morris et al. 1997; Gal et al. 2003).

Using molecular techniques, phyllospheric microbial diversity has been studied. Microbial species richness on the phyllosphere is high in warmer and humid climates than the temperate regions. The alpha and gamma classes of *Proteobacteria* are the dominant bacterial phyla in phyllosphere. The *Bacteroidetes* and *Actinobacteria* represent the most common species of these phyla. The phyllosphere of several Mediterranean plants is dominated by lactic acid bacteria. In

summer, the most dominant species associated with these plants are *Firmicutes*. The growth of *Firmicutes* on the phyllosphere increases plant's tolerance to the hot and dry weather. At higher taxa level, phyllospheric microbiomes of different plants are similar, but at the species level, strains vary significantly. This suggests that bacterial diversity of the phyllosphere is linked with the micro-environment.

The environmental parameters like UV radiation, relative humidity and temperature influence the association of *E. coli* with plants (Seo and Matthews 2014). The indigenous phyllosphere microorganisms are also influenced by these environmental parameters. Changes in the indigenous microflora contribute to the promotion or prevention of *E. coli*. However, the role of the indigenous microorganisms on the long-term persistence of the pathogens is unclear. However, the interaction between pathogens and indigenous microbiota is difficult to understand because the diversity of phyllosphere microbiota varies with geographical locations and environment.

20.3 Ecological Niche of Phyllospheric Bacteria

In the phyllosphere, bacteria colonize typically as aggregates or clusters. In a study, it was found that up to 50 % of *Pseudomonas syringae* bacteria on bean leaves were present in clusters of 10^3 cells or more. It is assumed that before colonization, the incoming bacteria first reach at the leaf as single cells on different parts of the leaf. Only a few sites on the leaf are suitable for bacterial multiplication. The growth of cells in the favourable sites of leaf results into microbial colonies. Secondly, the bacterial species colonize on the leaf surface vary in their ability to produce offspring. This suggests that the leaf surface consists of sites with different conduciveness for bacterial cluster formation.

Moisture is one of the major factors that shape the bacterial clustering on leaf surfaces. Water stays for longer period in the veins and trichomes of leaf than other parts (Esser et al. 2015). Prolonged presence of water at these sites increases the nutrient availability. Most leaf nutrients available on the leaf surface are the photosynthetic compounds diffused from the leaf cuticle. Water droplets on a leaf surface also act as the effective sink for the diffused nutrients. The rate of diffusion of nutrients from leaf to water droplet depends on the volume of water and the activity of bacteria in consuming the nutrients. It also depends on the hydrophobicity and thickness of the cuticle (van der Wal et al. 2013). These factors regulate nutrient availability for bacterial community and act as the major driving factors for the spatial and temporal variation in bacterial population on the leaf surface.

20.4 Microbial Communities on the Phyllosphere

The phyllospheric microbial communities represent bacteria, filamentous fungi, yeasts, algae, protozoa and nematodes. Filamentous fungi are considered transient inhabitants of leaf surfaces because they are present predominantly as spores. However, the rapidly sporulating fungal species and yeasts colonize easily on the

leaf surface. Phyllospheric bacterial populations differ sharply among and within the same plant species. Bacterial population vary with the growth phase of the host plant as the plant's growth is associated with colonization of microorganisms. Variation in bacterial population in phyllosphere is caused by the extensive fluctuations in the physical and nutritional status of the phyllosphere. Plant species vary with different carrying capacity of the leaf microbiota. For example, the broader leaves of cucumber and beans carry high number of bacteria than grasses or waxy broad-leaf plants. The physicochemical environments of phyllosphere substantially cause variation in the bacterial flora.

The phyllosphere-dominating microorganisms are unique, but their community can be reproduced with the same plant system. However, the biogeography of these phyllospheric bacteria is less known. In a study, the bacterial communities on the leaves of *Magnolia grandiflora* were analysed by sequencing the 16S ribosomal RNA (rRNA) gene. Bacterial assemblages were dominated by members of the *Alphaproteobacteria*, *Bacteroidetes* and *Acidobacteria*. Patterns in community composition are measured by both relative abundance and Jaccard metrics. Distance based on the analyses indicated that trees positioned closely had more similar bacterial communities than the distantly placed. Indirect gradient analyses indicated that environmental parameters like canopy cover, slope, elevation and aspect of the ground beneath trees significantly influence bacterial community (Finkel et al. 2012).

20.5 Phyllospheric Microbes and Plant Growth-Promoting Activities

Generally it is considered that the community composition of phyllospheric microbes to some extent is random. It is the plant who selects microbes by providing favourable environment in the rhizosphere or phyllosphere for the specific microbial communities. Phyllosphere microbial communities influence plant growth. These microbial communities also contribute to the ecosystem function. However, the host plant is mainly responsible to modulate the plant-microbial interaction. Environmental factors also affect biosynthesis of many photosynthates within the plants. This change in metabolite concentration in plant affects the association of the rhizospheric microbes and alters plant development. Occurrence of certain microbial groups on the leaves suppresses feeding by insect larvae. Some signal molecules produced by phyllospheric microorganisms enhances plant growth under abiotic stress. For instance, the phytomicrobiome of *Arabidopsis* senses drought to maintain growth.

Many phylloplane-inhabiting microbes produce phytohormones. Among different phytohormones, auxin is the most commonly found molecule in the phylloplane. Like phyllospheric microorganisms belowground, PGPRs also produce auxin. This phytohormone plays an important role in the development of root system and overall plant growth. Indole acetic acid (IAA), another potential phytohormone, is also produced by the phyllospheric microorganisms. Many of these

phytohormones stimulate root growth that eventually enhances plant's root contact surface with soil and increases nutrient uptake. Due to this ability, microbial inoculants are recommended as a substitute or supplement for chemical fertilizers.

Yeasts are also widely distributed in the nature and coexist with other microorganisms. In a study, 12 yeast strains were isolated from leaf samples of a carnivorous plant *Drosera indica* L. This plant is currently endangered because of restricted habitats and use in herbal industries. The 16S rRNA gene sequence revealed that these yeasts belong to the phylum *Ascomycota* and *Basidiomycota*. The isolated yeasts produced indole-3-acetic acid (IAA). The IAA produced by wild yeasts modifies auxin-inducible gene expression in *Arabidopsis*. Phyllospheric yeasts can promote plant growth and may be considered for inclusion into biofertilizer for sustainable agriculture.

20.6 Phyllospheric Microbes and Plant Protection

Generally plants are exposed to the attack of herbivorous insects and pathogens. Herbivorous insects induce production of phytohormone jasmonic acid in plant, while many phyllospheric bacteria induce salicylic acid production in the host plant. The proportion of the two phytochemicals decides whether a plant would be susceptible or resistant against the pathogens. In an experiment, the bittercress plant (*Cardamine cordifolia*, Brassicaceae) was applied with jasmonic acid or salicylic acid prior to damage. Changes in abundance of phyllosphere bacteria were monitored to examine if chewing of herbivores correlates with the bacterial abundance on leaves. Study revealed that jasmonic acid treatment reduced herbivory, while salicylic acid treatment increased herbivory. Phyllospheric bacterial abundance was higher in herbivore-damaged plants than the undamaged plants. It is hypothesized that the abundance and the complex diversity of phyllospheric microorganisms have significant role in the plant's defence mechanism.

The phyllosphere acts as a media that supports the survival or proliferation of diverse microorganisms that are epiphytes, saprophytes and pathogens. Some phyllospheric microorganisms complete their life cycle along with the plant's growth. On the contrary, pathogens enter the leaf and multiply in the interior leaf tissue. Natural surface openings, such as stomata, are important entry ports for microorganisms. Stomata are the key organ for water transpiration and gaseous exchange. This activity is important for plant's growth. Recent studies show that stomata can limit pathogen entry as part of the plant innate defence process. Some plant pathogens have developed counter defence system. For example, the plant pathogen *Pseudomonas syringae* produces coronatine which suppress plant's stomata-based defence system.

20.7 Quorum Sensing in Phyllosphere

The microbial community dynamics of phyllosphere is complex. Cross talk or signal exchange occurs among the various microbial groups present on the phyllosphere. These signals regulate activities and community dynamics of various

phyllospheric microbial groups. These signals either help the plants to initiate immune responses to the harmful pathogens or facilitate the entry of beneficial microbes (Hartmann et al. 2015). Some *Bacillus* sp. secretes antibiotic in the presence of plant root exudates. This process keeps off pathogens in the rhizosphere. Phyllospheric bacteria also interfere with signalling between plants and microbial strains. Lipo-chito-oligosaccharides produced by many microorganisms are cleaved by certain bacteria which produce chitinases. In this way, these bacteria interfere with plant-microbial interaction. Plant signalling compounds are carbohydrates, proteins, organic acids or the secondary metabolites like flavonoids, phenol, phytohormones etc. The PGPR-related signalling compounds are phytohormones, acyl homoserine lactones, phenols and peptides.

Like other ecological niches, bacteria in the phyllosphere communicate by quorum sensing. One of the best studied quorum-sensing molecules is *N*-acyl homoserine lactone. These molecules trigger immune responses and change the phytohormone profile of plants. Plants also detect signal molecules from pathogens and respond by activating their own defence systems. Aboveground microorganisms communicate with the belowground microorganisms and shape plant's microbiomes. It has been observed that change in aboveground microbial communities due to environmental factor or even herbivore activity alters microbial community composition of the below ground.

20.8 Phyllosphere Microbial Diversity of *J. curcas*

Bioenergy crop *J. curcas* is a renewable energy plant. In a study the diversity of bacteria prevalent in phylloplane and rhizosphere of *J. curcas* compared. The diversity of bacterial 16S rRNA gene was estimated by molecular technique known as terminal restriction fragment length polymorphism (T-RFLP). The terminal restriction fragments (ribotypes) obtained from both rhizosphere and phylloplane were affiliated to *Firmicutes*, *Actinobacteria*, *Bacillus*, *Chloroflexi*, *Acidobacteria*, *Verrucomicrobia* and *Methylobacteria*. Fluorescence intensity of TRFs was high in the phylloplane than the rhizospheric soil. The ribotypes TRF56, TRF65, TRF95 and TRF423 were the main variables in soil. The ribotypes TRF466, TRF475 and TRF483 were major TRFs in the phylloplane of *J. curcas*. Diversity indices were high in soil than phylloplane. Study indicated that both belowground and aboveground plant parts harbour selective bacterial groups with different level of diversity and abundance. In a study, it was observed that *Jatropha* plantation increased the members of *Proteobacteria* and *Bacteroidetes* compared to unplanted soil (Agarwal et al. 2015). Several diazotrophic bacterial species, like *Azospirillum*, *Herbaspirillum*, *Burkholderia* and *Gluconacetobacter*, are present in the rhizosphere of *J. curcas* (Zehr 2011). These PGPRs occur on the rhizoplane or as endophytes. Some of these PGPRs fix nitrogen and promotes plant growth (Liu et al. 2011). These strains have the ability to enhance *J. curcas* through the production of IAA, solubilize inorganic P and produce ACC-deaminase and siderophore (Jha and Saraf 2012).

Phylloplane of *J. curcas* possesses many gram-positive and gram-positive bacteria. Plants like *Mangifera indica* have more of gram-positive *Bacillus* sp. and *Corynebacterium* sp. than gram-negative bacteria (Jager et al. 2001). Gram-positive *Bacillus* sp. has been isolated from leaves of groundnut, and these strains stimulate plant growth when inoculated as seed coat (Kishore et al. 2005). Methylotrophs are found from the phylloplane of *J. curcas*. Many species of *Methylobacteria* colonize plants as epiphytes and endophytes (Kwak et al. 2014; Dourado et al. 2015). *Methylobacterium* has been isolated from bamboo phylloplane (Madhaiyan and Poonguzhali 2014). These methylotrophs use methanol as C source released by the plant during pectin demethylation process (Galbally and Kirstine 2002). These bacteria can also multiply using other simpler photosynthates (Iguchi et al. 2015).

The role of phyllospheric microbes and their interaction with the growth of *J. curcas* is not clearly known. In an experiment, the dominant phylloplane bacteria of *J. curcas* were isolated, and their plant growth-promoting activities were evaluated. The 16S rRNA gene sequences of these bacteria were similar to *Alphaproteobacteria*, *Betaproteobacteria*, *Gammaproteobacteria*, *Firmicutes* and *Actinobacteria*. Most of the isolates were motile and gram variable. Many novel species closely related to *Ralstonia*, *Methylobacter* and *Actinomycetes* detected. The isolates exhibited PGPR activities like ACC-deaminase, phosphatase, K solubilization and indole acetic acid (IAA) production activity. These isolates were further tested on maize plants to check their plant growth-promoting activities. The isolates significantly increased the shoot and root length of the maize seedlings. Linear regression model of the PGPR activities significantly correlated with growth parameters. Among the plant growth-promoting attributes, ACC-deaminase and IAA production were the major growth factors for improving the maize growth.

In *J. curcas* phylloplane, the most abundant species were *Firmicutes*, *Alphaproteobacteria*, *Gammaproteobacteria* and *Actinobacteria*. Species belonging to *Betaproteobacteria* were the least abundant. The 16S rRNA gene sequences of the *Alphaproteobacteria* were similar to *Brevibacterium* sp., *Methylobacterium extorquens* and *Agrobacterium tumefaciens.* Phylloplane of many terrestrial plants contains *Alphaproteobacteria*. Some of these plants are *Magnolia grandiflora*, *Prunus* species and bamboo. *Firmicutes* are predominant on the phylloplane of plum and dessert plants. *Actinobacteria* are a group of important plant-associated spore-forming bacteria, known for their role in the biocontrol of pathogens, plant growth promotion and interaction with plants. *Actinobacteria* were mostly related to *Nocardia*, *Micrococcus*, *Brevibacterium* and *Agromyces*. This group has been found on the phylloplane of apricot (Jo et al. 2015) and many salt-tolerant plants (del Rocío Mora-Ruiz et al. 2015). *Gammaproteobacteria* has been found on the phylloplane of *Prunus* species (Jo et al. 2015) and dessert tree (Belkin and Qvit-Raz 2010). The isolates stimulated the growth of the maize seedling through various plant growth-promoting attributes. Such relation between PGPR activities of phylloplane microorganisms and plant growth has been found in agroforestry plants (George et al. 2002). Probably, the phosphates and indole acetic acid (IAA) production potential of the phylloplane bacteria stimulated plant growth. IAA stimulates cells present on root tip and shoot tip. Further studies are essential to explore the

phyllospheric microbes of *Jatropha curcas* to develop microbial inoculants for agriculturally important crops.

Acknowledgment This work is part of the project entitled "Metagenomic characterization and spatiotemporal changes in the prevalence of microbes involved in nutrient cycling in the rhizoplane of bioenergy crop *Jatropha curcas.*" The authors acknowledge the Department of Biotechnology, Government of India, for financial support to SRM. The authors declare no conflict of interest of any type.

Sinker Root System in Trees with Emphasis on Soil Profile

21

S. Devi, R. Angrish, S. Madaan, O.P. Toky, and S.S. Arya

Abstract

Anchorage, water and nutrient uptake and transport are well-known functions of tree roots. However, recent studies ascribe more complex physiological and ecological role to tree roots. This is more particularly so in many tree species where roots have a characteristic dimorphic spread having (1) the surface roots that have a subterranean horizontal spread a few metres around the trunk and (2) sinker roots that go vertically downwards to 10 m and beyond. Increasing evidence is accumulating that the surface and sinker roots form a very dynamic water facilitating system in the soil. This is discussed under three main heads. Firstly, the sinker roots have access to groundwater moisture and even the capillary fringe of the deep water tables making the transpiration and the vital shoot processes sustainable, even when the upper soil profiles are dry. Such roots also cause biodrainage of the water table preventing it from rising to surface layers and making the soil waterlogged. Secondly, the sinker and surface roots form an integrated conduit in the soil that causes upward hydraulic redistribution of the deep soil water to soil surface. Interestingly, this water may also be used by shallow-rooted herbaceous vegetation for its sustainability during episodes of drought. Thirdly, a downward hydraulic redistribution from the surface roots in moist topsoil to the deep soil through the sinker roots may recharge the deep dry soil profiles for future use. The sinker root system, therefore, enables hydraulic redistribution sustaining dry season transpiration and photosynthetic rates of the

parent tree and surrounding shallow-rooted vegetation, prolonging the life span of fine roots and maintaining root–soil contact in dry soils and storing rainwater down into deeper soil layers for dry season utilization.

21.1 Introduction

Roots of a tree are its dynamic hidden half. These are essential conduits for water and mineral transport. They are equally important in anchorage of the shoot. Tree roots also store carbohydrates and are also involved in signalling to the shoot system in response to the soil–environment cues (Pallardy 2010). Tree roots have been found to be wonderfully opportunistic in their search for water and nutrients and follow moisture gradients up to 20 m horizontally or even vertically downwards (Knight 1999). Study of the structure of tree root spread in the soil has been limited as destructive soil excavation and safety issues are involved in such studies. However, the increasing use of non-destructive techniques like geoelectric measurements is becoming increasingly popular for detecting root placement in soil (Zanetti et al. 2011). Likewise the increasing use of sensitive thermal probes involving heat ratio method is being suitably used to measure up- and downstream movement of water (Hultine et al. 2003, 2004) through the root. In this article we specifically discuss some lesser-known ecophysiological functions attributed to the sinker roots that explore profiles of the soil some 5 m or more vertically downwards. Sinker roots have been known to be responsible for biodrainage or the vertical drainage of the groundwater through evapotranspiration so as to stabilize the water table. Further the sinker root-based phenomenon of hydraulic redistribution of water has been described in which water moves from the wetter soil profiles to the drier ones in both upward and downward directions. The ecological implications of these processes have been discussed along with.

21.2 Tree Root Spread

21.2.1 Surface and Sinker Roots

Trees have a diverse root spread. If water and nutrition requirements are available in the topsoils, roots remain confined to 1–2 m depth and a few metres around the trunk below the surface soil. In other cases, the tap root may extend deeper and deeper vertically downwards into the soil and explores the soil for water and nutrients. While the subterranean root system around the tree trunk is designated as surface root system, the singularly vertically downward roots are designated as sinker roots. Trees may have a dimorphic root system comprising of both the surface and sinker root system.

It may be noted that much length of a tree root is inactive on its surface so far as water uptake from the soil is concerned. This is due to secondary growth-related

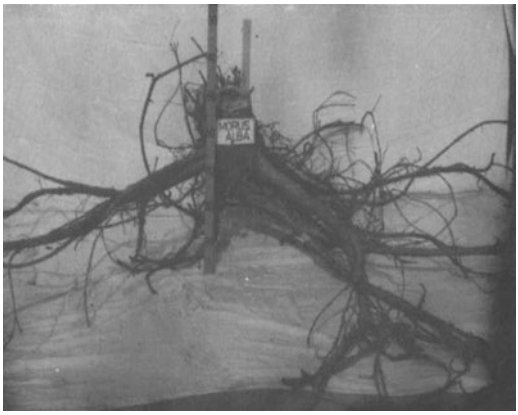

Fig. 21.1 Root system of *Morus alba*. Note the horizontal surface root system and lack of sinker roots

bark insulating greater lengths of the tree root system. These remain unaffected even if the soil becomes dry. It is only at the ends of the surface and sinker roots that non-lignified primary roots with root hairs make dynamic contact with the soil particles. These fine roots have to be in optimal soil moisture to remain functional. Mycorrhizal associations that assist in nutrient uptake are also found on the fine roots. In the perennial tree system, fine root viability must be maintained in soil profiles that may go dry.

21.2.2 Extent of Depth of Sinker Roots

An intensive study of 6-year-old tree species in semiarid north–west India was studied by one of the authors (Toky and Bisht 1992). It was seen that species like *Melia azedarach*, *Morus alba* (Fig. 21.1) and *Populus deltoides* showed a more or less horizontal surface root system confined to the top 80 cm of the soil profile and extending up to a radius of 120 cm.

On the other hand, species like *Prosopis cineraria*, *Acacia nilotica* and *Eucalyptus tereticornis* (Fig. 21.2) had a distinct sinker root system that penetrated more deeply to 250 cm in addition to a horizontal surface root system.

In a monograph on *Prosopis juliflora–Prosopis* complex, Pasiecznik et al. (2001) highlighted that the root system in these arid land species is dimorphic. It, characteristically, has a deep sinker root system and a superficial root system, both having different functions during different seasons. The sinker root system is made up of one, two or three (rarely more) main tap roots, which may divide at lower depths. They have the function of anchoring the tree but are primarily for sourcing groundwater reserves, whether a water table or other subterranean supply. They can become very thick and tens of metres long until a permanent water source is found. These authors quoted reports to show that in certain cases, *P. pallida* tap roots reach water tables at 20–25 m depth. Such plants are also designated as phreatophytes (Hultine et al. 2003). Phreatophytes are deep-rooted trees and shrubs that obtain a dependable water supply from the ‘phreatic surface’, i.e. from the

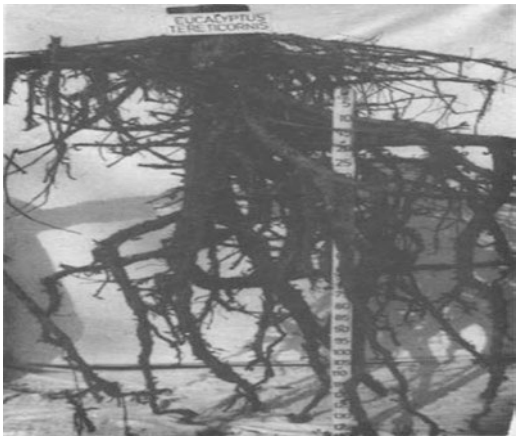

Fig. 21.2 Root system of *Eucalyptus tereticornis*. Note the presence of a surface root system and a deep sinker root system

saturated water table, and thus maintain water status that is largely independent of soil water derived from incident precipitation. These plants develop a zone of maximum root development in the capillary fringe above the water table, rather than in the oxygen-poor saturated zone within the water table. Jackson et al. (1996) surveyed literature and reported root depths of 253 plant species including trees. Maximum depth striking sinker roots were reported to be 68 m for *Boscia albitrunca* in the central Kalahari Desert. They reported 194 species had roots at least 2 m deep, 50 species had roots at a depth of 5 m or more, and 22 species had roots as deep as 10 m or more. Tropical grassland/savanna had maximum root depth of 15.0 ± 5.4 m. They computed that trees had an average root depth of 7.0 ± 1.2 m and concluded that deep root habits are quite common in woody species across most of the terrestrial biomes worldwide.

21.3 Sinker Roots and Biodrainage

21.3.1 Soil Water Use by Trees and Biodrainage

Biodrainage may be defined as the vertical drainage of water table through evapotranspiration of strategically planted vegetation, particularly deep-rooted trees. There is nothing new in the concept of consumptive use of water by trees. Also the fantastic volumes of water the trees can transpire are a matter of record. For example, an overstory *Eperua purpurea* tree in Amazonian rainforest was estimated to transpire 1180 kg day^{-1} of water (see Wullschleger et al. 1998). Equally noteworthy is the fact that at the ecological level, interaction of deep-rooted tree flora with groundwater table is recognized since long. Thus, Wilde et al. (1953) noted that tree species influence groundwater table by acting as biological pumps. However, large-scale scientific use of trees in water table control seems to be of more recent origin. The concept of biological drainage or biodrainage appears to have originated from the waterlogged agricultural areas where the conventional surface and

subsurface drainage techniques were in vogue. Frequent use of the term 'biodrainage' in scientific literature is only post 2000. Trees as plantations along the canal banks, in fields as agroforestry components and as commercial block plantations, have had always been a common sight. Their contribution as simple biological pumps cannot be disputed. It is the strategic component of their plantation that revolves around the concept of biodrainage (Anonymous 2003; Angrish et al. 2006; Toky and Angrish 2014).

21.3.2 Conventional Drainage and Biodrainage

Conventionally the control of the problems of waterlogging and soil salinity has been obtained through civil engineering techniques like surface drainage and horizontal subsurface drainage. In surface drainage, excavation of open trenches is done to immediately drain away surface water and to prevent ponded conditions, flooding and consequent damage to the crops. In the horizontal subsurface drainage, removal of soil water below the crop root zone is done through a network open tile drains or underground perforated pipes. However, these techniques, particularly horizontal subsurface drainage, are costly to install and maintain (Tanji 1991; Ritzema et al. 2008).

Biodrainage or the use of trees as a drainage system in problem areas is a green concept that is catching the fancy of technoscientific community in agriculture and even urban development. Its merits are economy in cost and environment friendliness. The limitations are requirement of land for tree plantations, slow lowering of water table, limited evacuation of salts from the system and vulnerability of trees to highly saline conditions. In planning of a biodrainage system, the concept of recharge and discharge zones should be clearly understood. Recharge areas are locations from where water seeps into the water table, e.g. leaky canals or distributaries, elevated areas receiving rainfall with runoff water. However, the most significant recharge areas are the agricultural fields where liberal canal irrigation is applied. The areas where biodrainage plantations are raised to offset the recharge water are known as discharge areas. On an average, about 10 % of land in a waterlogged agricultural landscape is to be marked as discharge area (Heuperman et al. 2002).

21.3.3 Impact of Biodrainage on Depression of Water Table

Biodrainage certainly depresses the water table immediately underneath the plantations, but in agroforestry set-up, the objective is to take the water table to a safer depth well below the crop root zone in the vast cultivated area that surrounds the plantation. Pumping from a well in water table aquifer (unconfined aquifer) is known to develop a cone of water table depression with lowest point near the cavity of the well. Further if two wells are operating simultaneously at suitable distance, two 'interfering' cones of depression shall be formed. It was clearly demonstrated

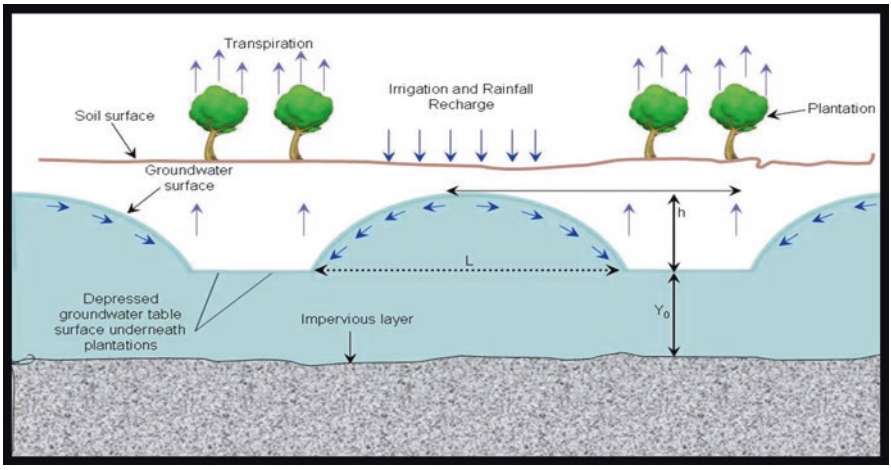

Fig. 21.3 Water table contours due to biodrainage by strip plantations and the associated flux of water (*arrows*). See text for symbols details (Use authorized by FAO, Heuperman et al. 2002)

by Ram et al. (2007) that the drawdown effect of two adjacent *Eucalyptus tereticornis* block plantations was similar to the combined interacting cones of depression of two pumping wells. Another interesting analogy was made by Heuperman et al. (2002), who showed that in case of parallel strip plantations of trees, the water table contours would be similar to the contours found between parallel open drain ditches. The relationship between water table depression, rate of recharge, hydraulic conductivity of soil, depth of barrier layer and distance between plantations can be computed by applying the equation developed by Donnan (see Heuperman et al. 2002) as follows (Fig. 21.3):

$$L = \sqrt{\frac{8KY_o h}{R} + \frac{4Kh^2}{R}}$$

Here L = distance between parallel strip plantations (m)
R = rate of recharge (m/day)
Y_o = water table height above impervious layer under the tree plantations (m)e
K = soil hydraulic conductivity (m/day)
h = head difference (m)

Taking rate of recharge (R) equal to 0.5 mmd^{-1}, head difference (h) of 10.0 m, depth of impervious layer underneath biodrainage plantations (Y_0) as 10 m and hydraulic conductivity value of (1) 10 m d^{-1} (2) 100 m d^{-1} and 1000 m d^{-1}, the distance between plantations for the three values of h is worked out to be 150, 500 and 1500 m, respectively. Thus, plantations shall provide effective biodrainage to greater distances in soils with greater permeability as compared to impermeable soils.

21.3.4 Practical Examples of Biodrainage Systems

First example of biodrainage by sinker roots pertains to the Australian continent. Here a pristine tree system with sinker roots was in a cut-off state of existence with underlying brackish water aquifers for the past thousands of years. This was because the annual rainfall was intercepted and evapotranspired by the native vegetation. Recent introduction of intensive agriculture in the past 100 years necessitated the clearing of this tree vegetation and its replacement with shallow-rooted annual crop plants. The annual consumptive water use of this vegetation was less than the rainfall, and as result water percolated to the underlying saline groundwater table causing its gradual rise. The twin menace of salinity and waterlogging appeared. Now suitable development of agroforestry systems incorporating tree flora with deep-rooted sinker roots has been planted to recede the salinity and water table down away from the root zone of commercially important annual crops. The Australian system is the most exhaustively studied disturbed agroecosystem that unambiguously demonstrates the necessity of harmony between water use by vegetation vis-à-vis its root depth and groundwater table (Heuperman et al. 2002; Crosbie et al. 2008)

In the second case, introduction of canal irrigation and intensive agriculture caused gradual seepage of the liberally used irrigation water which caused rise of saline water table. Productive lands became waterlogged and saline. For example, in western zone of Haryana, average water table depth was static at about 28 m from the ground surface from the 1930s to the early 1950s. After the commissioning of Bhakra canal system in 1956, a sharp increase in saline water table has brought the water table up to a peaked average of only 6 m from the ground surface towards 2002. As a matter of fact during the past two decades, nearly 50 % of the area of south-west Haryana has been critically waterlogged with water table hitting <3 m of the ground surface at one stage or the other. The phenomenon is worldwide but where biodrainage systems involving Eucalyptus trees which have robust sinker roots are being planted. This adoption of such biodrainage systems in Haryana and elsewhere in India has resulted in widespread drop of water table (Anonymous 2003; Angrish et al. 2006; Toky and Angrish 2014).

21.4 Hydraulic Redistribution

21.4.1 Definition of Hydraulic Redistribution

In literature different workers have used different terms and here the terms used have been defined after Neumann and Cardon (2012). When root systems span soil layers of different moisture content, water is moved in soil by roots in the direction of the difference in water potential involving the phenomenon of hydraulic redistribution. This phenomenon has been increasingly demonstrated in woody perennials with elaborate root systems with the help of sap flow movements and soil moisture measurements. Hydraulic redistribution is of two types. Firstly, when the surface

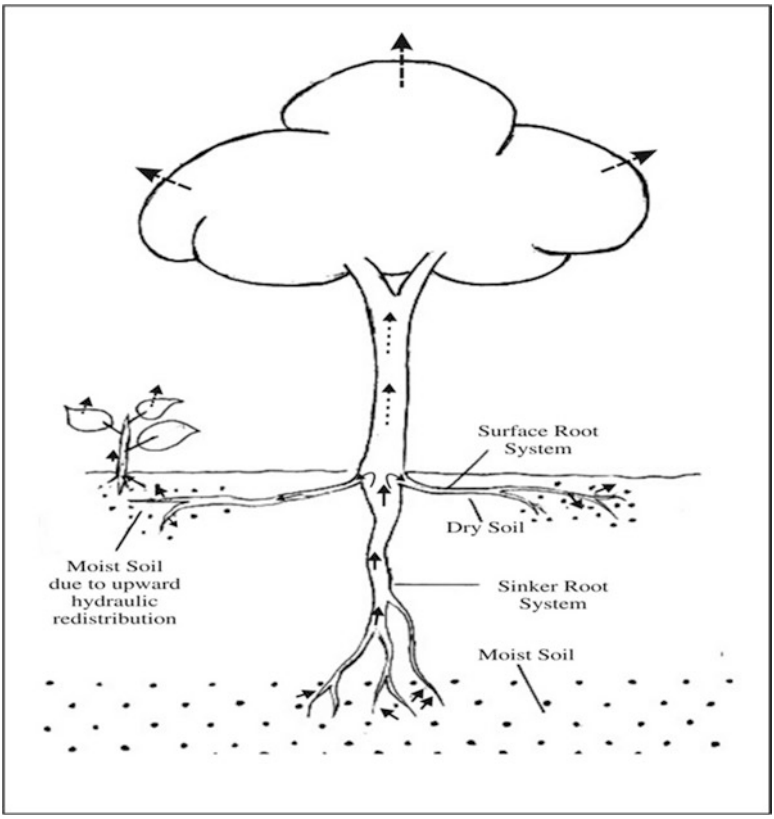

Fig. 21.4 Diagrammatic representation of upward hydraulic redistribution in trees (*dark dots* denote optimal soil moisture, *broken line arrows* indicate routine water movement due to transpiration pull, and line arrows denote water movement due to upward hydraulic redistribution). Note that the surface root system is in dry soil and the terminal ends of the sinker root system are in moist soil profile of the groundwater. Due to upward hydraulic redistribution (*line arrows*), water accumulation occurs in upper soil profile near the ends of the surface root system. Other shallow-rooted vegetation also utilizes this water

root system is in dry topsoil and the sinker roots are in wet soil near to the water table, a movement of water from the soil surrounding the sinker roots to the tips of the surface root occurs and is denoted as upward hydraulic redistribution or hydraulic lift (Fig. 21.4).

Conversely, when the surface roots are in wet topsoil and the ends of the sinker roots are in dry deep soil, a net movement of water occurs from wet topsoil to the dry deep soil at the end of the sinker roots due to downward hydraulic redistribution or hydraulic descent (Fig. 21.5).

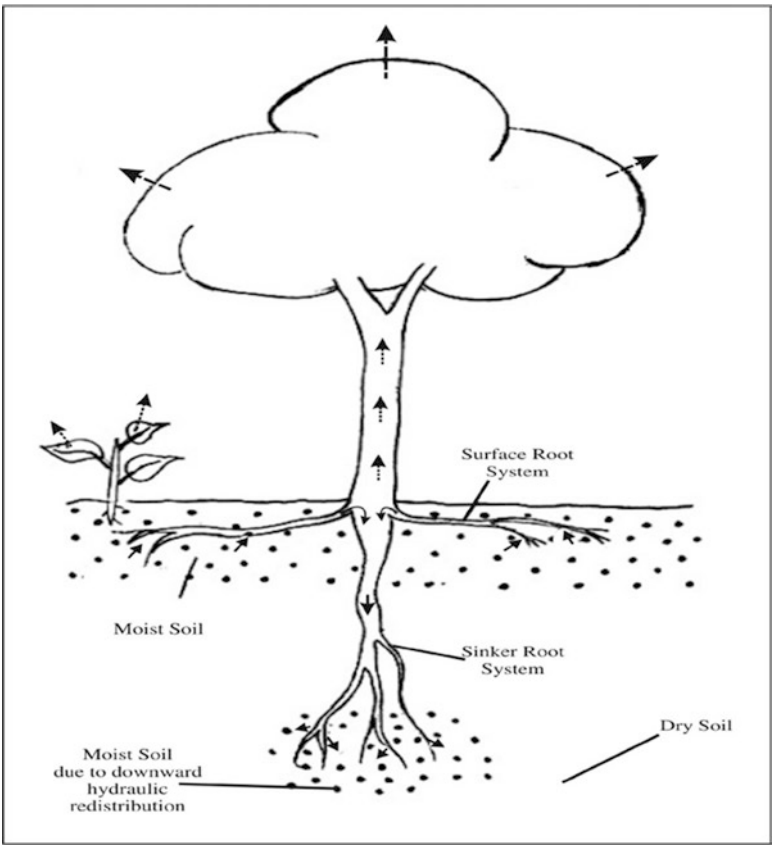

Fig. 21.5 Diagrammatic representation of downward hydraulic redistribution in trees (*dark dots* denote optimal soil moisture, *broken line arrows* indicate routine water movement due to transpiration pull, and *line arrows* denote water movement due to upward hydraulic redistribution). Note that the surface root system is in proper moist soil and the terminal ends of the sinker root system are in the dry soil profile. Downward hydraulic redistribution is due to which water accumulation occurs in the deeper soil profiles

21.4.2 Case Studies in Hydraulic Redistribution

Australian workers (Burgess et al. 1998; Stephen et al. 2001) were the first to provide convincing evidence on hydraulic redistribution using heat ratio method for sap flow measurements on a river red gum (*Eucalyptus camaldulensis*) and a coastal moort (*Eucalyptus platypus*). It was demonstrated that when root systems span soil layers of different moisture content, water is redistributed by roots in the direction of the difference in water potential. Tree sinker roots were shown to transfer significant quantities of water downwards to dry soil layers when surface soil layers become wet following rain. The benefits of this modification to the external environment include reduced waterlogging in surface soils and increased moisture content in dry subsoils.

Hultine et al. (2003) measured sap flow in sinker-tap roots, lateral roots and stems within a single individual in each of three co-occurring tree species *Fraxinus velutina*, *Juglans major* and *Celtis reticulata* in a Chihuahuan Desert to assess the seasonality and magnitude of hydraulic redistribution. The species showed hydraulic redistribution, but the patterns were not essentially similar. Nocturnal downward hydraulic redistribution in surface roots of *Fraxinus* was 0–120 g h^{-1} and 0–18 g h^{-1} in *Juglans*. No such downward hydraulic redistribution was recorded in *Celtis*. The workers concluded that species differences in nocturnal root function may have significant impacts on ecosystem hydrological fluxes and should be considered when scaling fluxes to catchment, landscape and regional levels.

Priyadarshini et al. (2015) demonstrated very interesting tree–grass coexistence involving hydraulic redistribution in semiarid savanna vegetation in South Africa. Experiment involved labelling deep soil (2.5-m depth) with a deuterium tracer. Trees and grasses used water from the topsoil after rainfall. All tree species shifted to groundwater or subsoil water use when there was no water in the topsoil indicating partitioning of water use. Grasses always used water from the topsoil. The seasonal changes in water source used by trees and grasses indicated possible shifts in tree–grass interactions during different periods of the year. The tracer experiment confirmed upward hydraulic redistribution in all the three tree species and water transfer to grasses via the topsoil. However, this occurred only in the dry season. An important facilitative mechanism maintaining tree–grass coexistence in savannas involving upward hydraulic redistribution was described for the first time.

Neumann and Cardon (2012) used data on hydraulic redistribution from 29 published papers focused on 16 different ecosystems and concluded that the movement of water from moist to dry soil through plant roots, both as upward and downward hydraulic redistribution, occurs worldwide within a range of different ecosystems and plant species. They computed average magnitude of hydraulic redistribution and reported it to vary by nearly two orders of magnitude across ecosystems, from 0.04 to 1.3 mm H_2O d^{-1} in the empirical literature and from 0.1 to 3.23 mm H_2O d^{-1} in the modelling literature. The authors considered these upward and downward hydraulic redistribution rates to be ecologically and hydrologically significant in many ecosystems, enhancing transpiration and photosynthetic carbon gain and conducting precipitation to deep soil layers.

21.4.3 Biological Significance of Hydraulic Redistribution

Some additional significance of the hydraulic redistribution is enlisted pointwise as follows:

During dry seasons, moisture content of the topsoil layers is rapidly depleted. Bulk of the root biomass of the shallow-rooted vegetation lies here and is prone to water stress. Growth during dry season may stop, and the very survival of the shallow-rooted plants may be at stake. By moving deep soil water to topsoils through upward hydraulic redistribution where bulk of root spread of the vegetation, particularly the shallow-rooted one, exists, the vital transpiration and photosynthesis of the

vegetation are sustained (Hawkins et al. 2009). Excessive dryness of the topsoils may also restrict or abolish the active microbial populations. In the event of upward hydraulic redistribution, the nutrient availability through microbial, particularly mycorrhizae, is improved in the moist soil zones (Aanderud and Richards 2009; Lehto and Zwiazek 2011).

Active root–soil contact through fine roots with root hairs is of utmost importance. During dry spells in soil, this fine root system is the first casualty. Upward and downward hydraulic redistribution can prevent fine root damage in upper or lower soil profiles, respectively, as the case may (Bauerle et al. 2008).

More recently, it has been shown by Yu and Foster (2016) that deep-rooted CAM plants in CAM-grass associations could perform upward hydraulic redistribution at a higher rate than trees in tree–grass associations in a relatively wet environment, as explained by a significant increase in grass transpiration rate in the shallow soil layer, balancing a lower transpiration rate by CAM plants. By comparison, trees in tree-CAM associations may perform downward hydraulic redistribution at a higher rate than those in tree–grass associations in a dry environment.

21.5 Concluding Remarks

This article, incorporating some work done in the authors' laboratory, provides information regarding some lesser-known but important function of the tree root system involving sinker roots. These are (1) biodrainage that stabilizes the groundwater tables and (2) hydraulic redistribution that causes upward or downward movement of soil water through the tree roots. Both the processes have ecophysiological implications and need more investigations.

Plant Growth-Promoting Rhizobacteria Play a Role as Phytostimulators for Sustainable Agriculture

22

Sapna Gupta, Ruchi Seth, and Anima Sharma

Abstract

During the past few decades, increasing use of chemical fertilizers has caused many negative effects in agriculture: development of infectious agent resistance, adverse impact on nontarget species, and reduction in crop yield resulting from the harmful effects of chemical fertilizers on soil quality parameters. Thus, the search for an eco-friendly approach has been emphasized during the past several years. Plant growth-promoting rhizobacteria (PGPR) perform varied functions as (1) biofertilizers, (2) phytostimulators, (3) rhizoremediators, and (4) biopesticides. Plants do not seem to be axenic in natural conditions, and typically are influenced directly by completely different microorganisms such as rhizobacteria, of which several have the ability to provide phytohormones. This chapter sums up data relating to the synthesis, metabolism, regulation, physiological role, and agronomic impact of plant products made by plant growth-promoting rhizobacteria. We have included information regarding the auxins, cytokinins, gibberellins, and ethylene.

22.1 Introduction

Soil is a mixture of organic matter, minerals, gases, liquids, and innumerable microorganisms and macroorganisms that can support plant life. Soil operates as an engineering medium, a locale for soil organisms, a reprocessing system for organic dissipation of nutrients, a means to modify atmospheric composition, a manager of water supply, and a medium for plant growth. Over the years crop demands have increased as the world's population has increased. Thus, dependency on

agrochemicals such as chemical pesticides and fertilizers has increased many fold. The increased use of chemical fertilizers and pesticides to support crop yield and to manage plant diseases has resulted in serious issues such as the accumulation of chemicals in plant products and their entry into the food chain. Moreover, their continuous use leads to the generation of resistant strains of pests and pathogens (Agrios 1988). Further, chemical fertilizers contaminate water resources and adversely affect the populations of naturally occurring beneficial organisms, which has resulted in the depletion of soil fertility (Kuhajek et al. 2003). Chemically based products generally persist in the environment: they are cyanogenic and nonbiodegradable in nature and also exert harmful effects on animals, human health, and our environment. These factors have generated alarms for limiting the usage of agrochemicals in regard to food quality and safety.

Soil fertility is directly or indirectly related to the microorganisms residing in the soil because they are a vital part of the soil ecosystem with a major role in plant growth. Microorganisms improve the value of the soil and are involved in different biotic activities of the soil bionetwork to enhance it for nutrient turnover and sustainable crop production (Ahemad et al. 2009; Chandler et al. 2008). Microorganisms support plant growth through collecting the nutrients in soils, fabricating many plant growth regulators, defending plants from phytopathogens by dominating or inhibiting them, enhancing soil structure, and bioremediating impure soils by sequestering toxic heavy metals and degrading xenobiotic compounds (such as pesticides) (Chandler et al. 2008; Podile and Kishore 2006; Barea et al. 2005; Kloepper et al. 1991; Kloepper and Okon 1994).

22.2 Rhizosphere and Rhizobacteria

The term “rhizosphere” was derived by the German expert and plant life scientist Lorenz Hiltner in 1904 to explain the plant–root interface: this word is fabricated from the Greek word “rhiza,” which means root (Hiltner 1904; Hartmann et al. 2008). According to wide-ranging opinion, the area around a plant root that is colonized by a distinctive population of microorganisms and roots of plants releasing chemical compounds would be termed the rhizosphere. The rhizosphere includes three major zones (endorhizosphere, rhizoplane, and ectorhizosphere), which are defined on the basis of their relative closeness to plant tissue. The endorhizosphere includes parts of the cortex and endodermis within which microbes and cations occupy the “free space” between cells (apoplastic space). The medial zone directly together with the foundation cuticle and mucilage is the rhizoplane. The outermost zone is the ectorhizosphere, which extends from the rhizoplane out into the bulk soil (Barea et al. 2005; Kloepper et al. 1991; Kloepper and Okon 1994). High levels of water content and nutrients within the rhizosphere attract larger numbers of

microorganisms than those further away within the soil. The composition and pattern of root exudates have an effect on microorganism action and population numbers that, in turn, have an effect on the different soil organisms which share this environment. The rhizosphere zone is about 1 mm wide and is supplemented with sugars, amino acids, secondary metabolites, DNA, and polysaccharides.

As plant roots grow through the soil, they release water-soluble compounds such as amino acids, sugars, organic acids, vitamins, enzymes, inorganic ions, and gaseous compounds that offer food for the microorganisms. All these activities make the rhizosphere the most active surroundings within the soil because the roots are underground and rhizosphere activity has been for the most part been unseen because of the occurrence of the advanced interactions of microbes among the roots. The exclusive biological, chemical, and physical properties of soils that are related to roots, compared to the soils far away from the root and root surface, are accountable for improved microorganism populations at the site of enhanced numbers and microorganism activity within the rhizosphere (Zaidi et al. 2009).

Bacteria present in the rhizospheric soil, called rhizobacteria, have an important function in plant growth and development. Rhizobacteria are divided into those that form a dependent relationship with the plants and those which do not. Those that do not form a dependent relationship are referred to as free-living (nonsymbiotic), closely connected with the root surface, or existing within the roots as endophytic bacteria (Kloepper et al. 1989). Rhizobacteria exert a beneficial effect through increasing soil fertility and crop improvement by their various direct and indirect mechanisms under various environmental conditions. The microorganisms lodging around or in the plant roots (rhizobacteria) are very adjustable in reworking, mobilizing, and solubilizing the nutrients as compared to different microbes present in bulk soils. Therefore, the rhizobacteria are the dominant deriving forces in utilization of soil nutrients and, as a consequence, they have a significant role in soil fertility and plant growth (Vaishnav et al. 2014).

22.3 Plant Growth-Promoting Rhizobacteria (PGPR)

Soil bacterial species growing in the plant rhizosphere that grow in, on, or around plant tissues and stimulate plant growth by numerous mechanisms are jointly referred to as PGPR (plant growth-promoting rhizobacteria). The term PGPR was coined by Kloepper and Schroth to explain the helpful microorganism population that colonizes the roots of plants within the rhizosphere, once attached to the root surface, to support plant growth and plant growth promotion activities (Chandler et al. 2008). PGPR can be classified into completely different subgroups on the basis of their application: (1) biofertilizers (increasing the availability of nutrients to plants), (2) phytostimulators (plant growth promotion, usually through

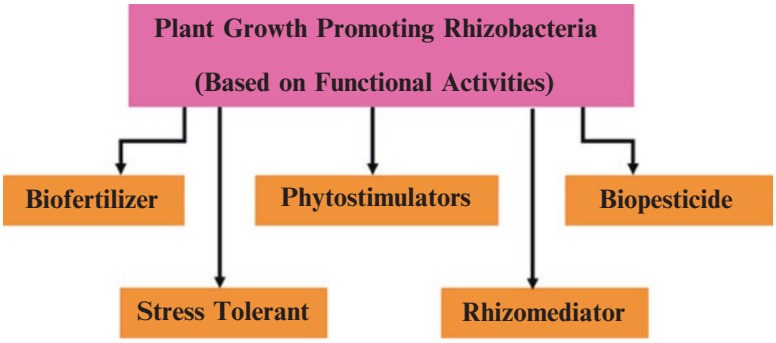

Fig. 22.1 Classification of plant growth-promoting rhizobacteria (PGPR)

phytohormones such as indole-3-acetic acid), (3) rhizoremediators (degrading organic pollutants), and (4) biopesticides (controlling diseases, chiefly by the production of antibiotics and antifungal metabolites) (Fig. 22.1) (Antoun and Prévost 2005). All PGPR perform either directly or indirectly to facilitate or support plant growth under nutritionary, biotic (biocontrol, PGPB), or abiotic stress conditions in three different ways by synthesizing explicit compounds for the plants (Dobbelaere et al. 2003; Zahir et al. 2004), facilitating the uptake of bound nutrients from the soil (Lucas et al. 2004a, b; Çakmakçi et al. 2006), and reducing or preventing plant diseases (Guo et al. 2004; Jetiyanon and Kloepper 2002; Raj et al. 2003) (Fig. 22.2). These mechanisms can work autonomously or simultaneously with one another. The indirect plant growth promotion inspired by biocontrol PGPB includes a variety of mechanisms such as rhizosphere competition, rhizospheric engineering, quorum sensing, production of volatile organic compounds, enzyme production, induced systematic resistance (ISR), reduction or prevention of deleterious effects of phytopathogens on plant growth by biosynthesis of stress-related phytohormones such as jasmonic acid (JA) or ethylene, and biosynthesis of antimicrobial molecules (Jain et al. 2014). In direct plant growth promotion mechanisms, PGPR assists the uptake of nutrients from the environment by nitrogen fixation, diminishes toxic compounds, provides phytohormones such as auxins, gibberellins (GAs), cytokinins (CK), and nitric oxide (NO), phosphate solubilization, and iron sequestration by siderophore production (Choudhary et al. 2015).

To provide tolerance to host plants under different environmental conditions, various bacteria belonging to different genera have been reported in the last decade, including *Achromobacter*, *Bacillus*, *Pseudomonas*, *Methylobacterium*, *Pantoea*, *Paenibacillus*, *Variovorax*, *Azospirillum*, *Microbacterium*, *Burkholderia*, *Rhizobium*, and *Enterobacter*, similar to the diagram (Choudhary 2012). PGPR enjoy a close in-depth organization with the plant and so they are vitally important candidates to be developed as tools for improving plant stimulatory factors and plant health, growth, and development.

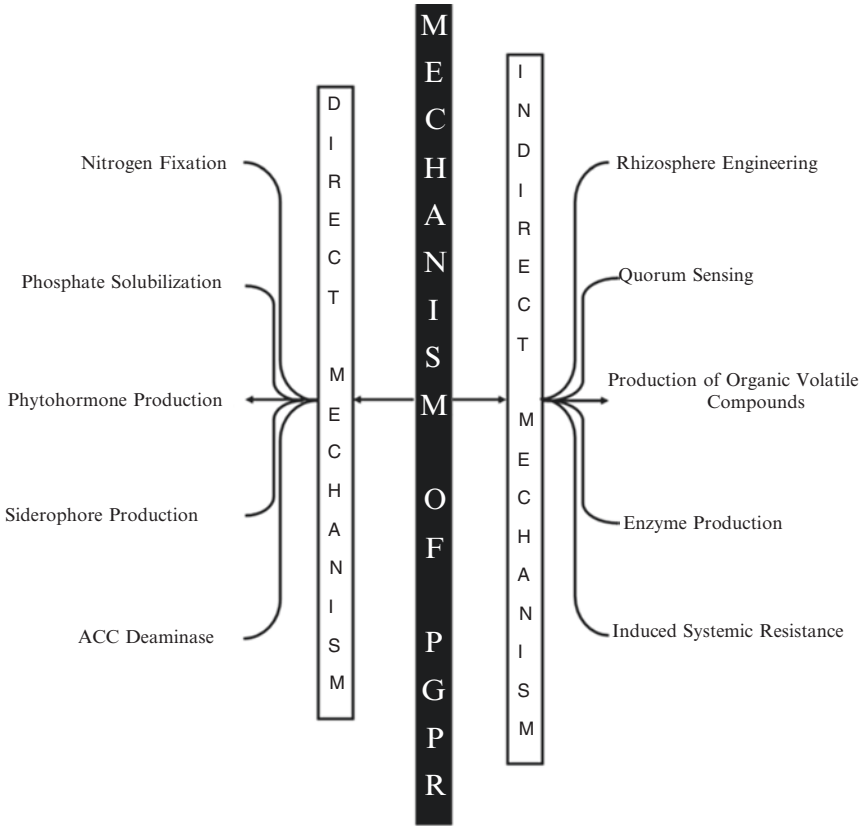

Fig. 22.2 Mechanisms of PGPR

22.4 PGPR: Phytohormone Producers

Phytohormones are naturally available to the plants from two sources: endogenous production by the plant tissues, and exogenous production by associated microorganisms. These phytohormones are iinvolved in several restrictive functions that comprise biological process and enlargement, cell division and expansion, cell elongation, stem elongation, root growth, activation of bud growth, branch maturity, promotion or delay of leaf senescence, and chlorophyll production (Kumar and Lonsane 1989; Arshad and Frankenberger 1991; Costacurta and Vanderleyden 1995; Patten and Glick 1996).

Phytohormone production by PGPR is one of the foremost imperative mechanisms that promote plant growth (Spaepen et al. 2007). Phytohormones are natural signal molecules acting as chemical messengers. They have an associated necessary role as growth and development regulators in extraordinarily low concentrations; as a result they influence biochemical, physiological, and morphological processes in plants, and their synthesis is finely regulated (Fuentes-Ramírez and

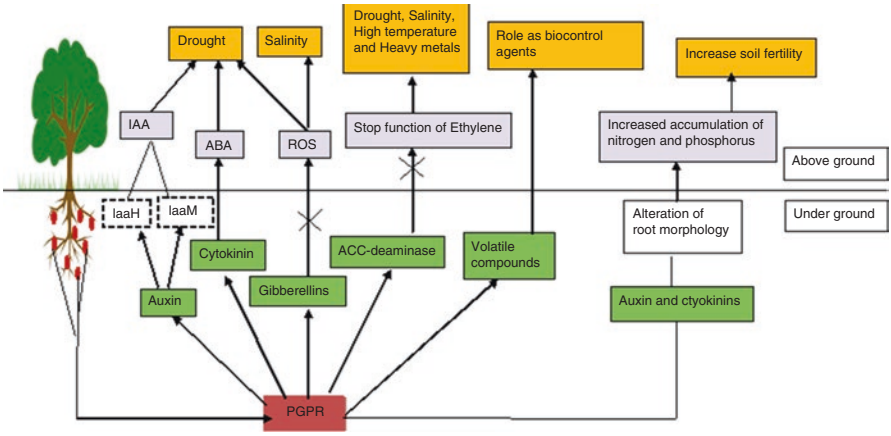

Fig. 22.3 Graphic representation of bacterially produced phytohormones in plant growth regulation

Caballero-Mellado 2006). The phytohormone manufacturing ability is widely distributed among microbes related to soil and plants. Various fungal and bacterial species, such as cyanobacteria, can produce phytohormones (Tsavkelova et al. 2006). Rhizospheric, epiphytic, and symbiotic bacteria known as PGPR are able to secrete hormones. However, free-living microorganisms are reported to provide phytohormones (Spaepen et al. 2007). Growth regulators (indole-acetic acid), cytokinins, gibberellins, and ethylene are the most important plant hormones. These plant hormones are also synthesized by bacteria that are directly associated with plant growth (Pirlak and Kose 2009; Bloemberg and Lugtenberg 2001; Bottini et al. 2004). The level of phytohormones in plant-associated bacteria is a critical factor in phytostimulation on the plant side (Spaepen et al. 2007) (Fig. 22.3).

22.4.1 Auxins

An auxin is a crucial cluster of chemical compounds distinguished by their capability to encourage cell elongation in the subapical region of the stem and to reproduce the physiological impact. Auxins have a crucial role in the regulation of numerous plant growth processes: (a) gravitropism and tropism, (b) plant tissue differentiation, (c) apical dominance, (d) lateral and adventitious root initiation, (e) stimulation of cell division, and (f) stem and root elongation (Teale et al. 2006). Indole-3-acetic acid (IAA) is a naturally occurring auxin molecule that is the most abundant chemical compound.

A number of molecules are categorized as auxins; however, IAA is among the foremost established and vigorous in biological systems. Different molecules are sensitive to indole-3-butyric acid (IBA) and phenylacetic acid (PAA), and in addition to the precursor indole-3-acetonitrile (IAN), are considered active auxins. A variety of inactive molecules, together with IAA halogenate compounds such

4-chloroindole-3-acetic acid and conjugated forms with sugars, alcohols, amino acids, and glycoproteins, are known in plants and bacteria (Glick et al. 1999; Korasick et al. 2013).

Various very important plant–microbial communications center on the fabrication of auxins; among them, IAA is the chief plant growth regulator (auxin). The ability to synthesize IAA has been detected in several bacterial species such as rhizobacteria, as in pathogenic, symbiotic, and free-living bacteria (Tsavkelova et al. 2006; Costacurta and Vanderleyden 1995). At present, auxin-synthesizing rhizobacteria are the foremost well-studied phytohormone producers (Spaepen et al. 2007; Tsavkelova et al. 2006).

The rhizobacteria synthesize IAA by two major pathways: the tryptophan (Trp)-independent and Trp-dependent pathways. In plants, two major pathways have been postulated for Trp-dependent IAA biosynthesis: (1) the indole-3-acetamide (IAM) pathway and (2) the indole-3-pyruvic acid (IPyA) pathway (Spaepen et al. 2007). The indole acetamide pathway is principally utilized by phytopathogenic bacteria for the production of IAA, which is responsible for tumor induction in plants. Utilization of the IAM pathway by beneficial bacteria for IAA biosynthesis is not clear. In contrast, the PGPB make use of the IPyA pathway for IAA biosynthesis (Patten and Glick 2002).

Azospirillum is one of the simplest IAA producers among the PGPR species studied (Dobbelaere et al. 1999). From different rhizospheric soils, other IAA-producing bacteria belonging to the genera *Aeromonas*, *Azotobacter*, *Bacillus*, *Burkholderia*, *Enterobacter*, *Pseudomonas*, and *Rhizobium* have been isolated (Halda-Alija 2003; Ahmad et al. 2008; Swain et al. 2007; Shoebitz et al. 2009; Hariprasad and Niranjana 2009; Ghosh et al. 2008). IAA-manufacturing PGPR has been inoculated to stimulate seed germination, to extend the root biomass, to accelerate root growth, and to modify the design of the root system. An IAA-producing *Mycobacterium* sp. strain has been reported to extend the germination of orchid seeds (*Dendrobium moschatum*) (Tsavkelova et al. 2006). Besides stimulating root growth, IAA-producing bacteria can also be used to stimulate tuber growth. In one study, an IAA-producing *Bacillus subtilis* strain had a positive effect on the edible tubercle *Dioscorea rotundata* L. and increased the length and fresh weight of root/shoot and the root:stem ratio and numbers of sprouts as compared with noninoculated plants. There are several techniques for detection of IAA and related indole compounds (Fig. 22.4).

22.4.2 Detection Techniques of IAA

Indole is generated by indole pyruvic acid via subtractive deamination of tryptophan. Through the deamination reaction, during which tryptophanase catalyzes the amino alkane ($-NH_2$) group, the tryptophan molecule is removed, and therefore the final products of the reaction are indole, pyruvic acid, ammonium (NH_4^+), and energy. Pyridoxal phosphate is needed as a coenzyme. To determine the assembly of IAA from the culture, the most necessary requirement is that the medium

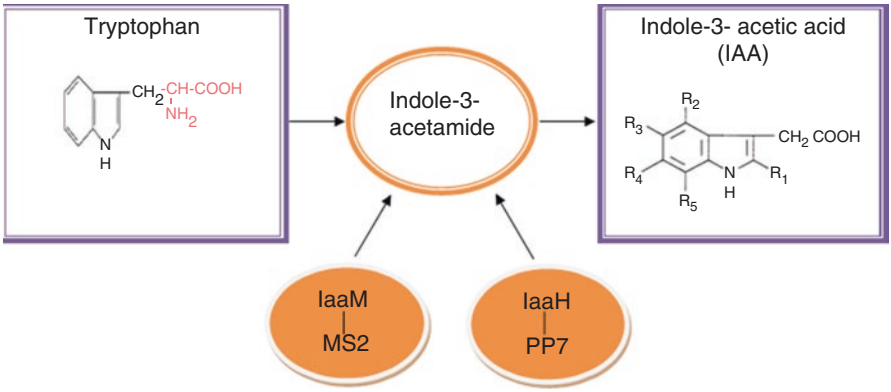

Fig. 22.4 Formation of indole-acetic acid via tryptophan

contains an adequate amount of tryptophan and a pinch of sodium chloride as per Difco to culture an organism before the indole test (Mac Faddin 1976). For an associated alternate approach to IAA production, casein peptone, sodium chloride, and tryptone are also used as a medium (Mac Faddin 1976). At the same time, deciding alternative characteristics such as motility and therefore the ability to produce hydrogen sulfide as a by-product of metabolism of the bacteria, the sulfide indole motility (SIM) medium could be a multi-test agar used to test for indole production (Mac Faddin 1976). Another multi-test agar is motility-indole ornithine (MIO) medium. In addition to testing for indole production, it is used to test for motility and ornithine decarboxylase, causing an rise in pH in the tube. The positive results of this test are indicated by the purple-gray color throughout the tube (Hiroya et al. 2004).

We can also detect the assembly of IAA production by many alternative strategies, such as detection IAA with biochemical assay, detection of IAA by capillary electrophoresis, qualitative detection of IAA by thin-layer chromatography (TLC) and paper chromatography, quantitative determination by high pressure liquid chromatography (HPLC), detection by the HPTLC method, detection of auxin (IAA) by chromatography/mass spectroscopy, and detection by Fourier transform infrared (FTIR) analysis.

22.4.3 Cytokinin

Cytokinins are units of phytohormones that control cell division, the cell cycle, and differentiation and stimulate developmental processes in plants (Srivastava 2002). By structure, cytokinins are divided into two subgroups: the adenine-type and the phenylurea-type cytokinin group. The adenine-type cytokinin group is pictured by natural and artificial compounds such as kinetin (K), zeatin (Z), or 6-benzylaminopurine (6-BAP), and therefore the phenylurea-type cytokinin group

is represented by the synthetic molecules diphenylurea and thidiazuron (TDZ). Chemically, adenine-type cytokinins are mostly purines and derived from adenine and modified by substitutions on the N6, which also contains their several ribotides, ribosides, and glycosides. The stimulatory or repressing functions of cytokinins are related to several physiological and biological processes, including senescence delay by chlorophyll accumulation and organ formation in a wide range of tissues, root and shoot development, leaf expansion, control of apical dominance in the shoot, and chloroplast development (Sakakibara 2006; Werner et al. 2001). By definition, once these compounds are combined with an optimal auxin concentration they induce cell division in plants. Miller et al. (1955) discovered the primary artificial cytokinin molecule that was named kinetin (K). In 1963, Letham knew 50 molecules referred to as zeatin (Z), and their metabolites have been classified as CKs. The biological activity for all CK-like compounds is not uniform and normally depends on many structural aspects such as a purine ring within the molecule, substitution of N6 with a simple ribosyl chain isopurine-derived unit, and substitution on positions two and nine of the ring for H, CH_3–S, or an unsaturated side chain (optimally five carbons). The natural and artificial adenine-type cytokinin molecules with confirmed biological activity on plant tissues are zeatin, isopentenyl adenine, kinetin, and 6-benzylaminopurine, and all have a double alkyl bridge at position N6.

By altering the size and activity of meristems, cytokinin influences cell division activity in embryonic as well as mature plants (Werner et al. 2001). Yang et al. (2002) demonstrated that the pace of reproductive structure cell division is intimately connected with the cytokinin level in the endosperm. They also reported that exogenous kinetin significantly increased the number of endosperm cells and grain weight. These various rhizobacterial strains (*Halomonas desiderata*, *Proteus mirabilis*, *P. vulgaris*, *Klebsiella pneumoniae*, *Bacillus megaterium*, *B. cereus*, *B. subtilis*, and *Escherichia coli*) were detected as phytohormones producing cytokinins (Arkhipova et al. 2005; Karadeniz et al. 2006; Ali et al. 2009). Different cytokinins are detected not only in the culture medium but also in the biomass of microorganisms (in free state or bound to certain tRNAs) within the type of either adenine derivatives, isoprenylated at N6 position, or their ribosides, such as 6-benzyladenine, N6-isopentenyl adenosine, and zeatin riboside (Serdyuk et al. 2003). Krall et al. repoted that *trans*-zeatine has also been found in the culture of *Agrobacterium tumefaciens* (Krall et al. 2002). Ryu et al. (2003) reported that cytokinin from a bacterial origin improves growth in *Arabidopsis*. Inoculation of a plant with bacteria-producing cytokinin has been shown to stimulate shoot growth and reduce root:shoot ratio in drought-stricken plants (Arkhipova et al. 2007). *Rhizobium* was reported to enhance cytokinin production in plants by regulation of expression of the communication pathway and to trigger cortical cells to divide in plants (Oldroyd 2007). A variety of these effects has been observed in wheat when cultured with *Paenibacillus polymyxa* strains B1 and B2 (Lindberg and Granhall 1984; Lindberg and Granhall 1986). One of every strain (B2) was, therefore, chosen for further investigation.

22.4.4 Detection of Cytokinin

Reverse section column under acidic condition is used for separation of cytokinin-like compounds. Acetic acid or formic acid and their ammonium salts are added to the solvent methanol/acetonitrile for better separation (Ge et al. 2005). UV detection is appropriate for detection of cytokinin because it exhibits strong UV absorbance between 200 and 300 nm. These differing kinds of ionization techniques were used for mass analysis of cytokinin together with reversed-phase (RP)-HPLC including thermospray, electrospray, atmospheric pressure chemical ionization, and fast atom bombardment (Novák et al. 2003).

22.4.5 Gibberellins (GAs)

Gibberellins (GAs) are a vast range of tetracyclic diterpene acids that elicit numerous metabolic functions needed throughout plant growth, at the site of seed germination, stem elongation, sex expression, flowering, fruiting, and senescence (Hedden 1997; Hedden and Kamiya 1997; Davies 1995). GAs are known and isolated from higher plants and from bacterial and fungal species. To date, 136 gibberelins from higher plants (128 species), 28 GAs from fungi (7 species), and only 4 GAs (GA1, GA3, GA4, GA20) from bacteria (7 species) are known (MacMillan 2002). Plant growth promotion and development by PGPR species that produce GAs has been previously reported (Atzhorn et al. 1998; Bastian et al. 1998; Gutierrez-Manero et al. 2001).

Gibberellins are present in two main forms, the free form and the conjugated form. Free gibberellins are subdivided into two subgroups. One subgroup possesses the entire complement of carbon atoms, or is referred to as C20-GAs; within the alternative subgroup, the C20 is lost so it is called the C19-GAs. Except GA12-aldehyde, all gibberellins are carboxylated at C7, and possess one (G4), two (GA1), three (GA8), or four (GA32) hydroxyl functions. The biological activity of the molecule is determined by the position of the hydroxylation (OH). Hydroxylation of C3 and C13 in their β- and α-positions, respectively, results in activation of the molecule, whereas the hydroxylation of C2 in the β-position has a strong negative effect on activity (Pearce et al. 1994). In addition to the opposite types of GAs, such as free forms, conjugated forms are known in plants: these include organic glycoside ethers (GA-G), in which a sugar molecule is connected to the structure of the GA by a hydroxyl group, and glycoside esters (GA-GE), in which a sugar residue is bound to the hormone through a carboxyl group on C7 (Sembder et al. 1980). The organic chemistry and physiological aspects of the GA conjugates have been discussed by Rood and Pharis (1987), who recommend that the most notable feature of those compounds is the lack of biological activity and therefore the potential reversibility to the active forms by hydrolytic enzyme activity. GA production by PGPR promotes the expansion and yield of many crop plants by deconjugation of gibberellin glucosyl in the root zone, causing 3β-hydroxylation of inactive 3-deoxy GAs to active forms such as GA1, GA3, and GA4 bacterial enzymes (Cassan et al. 2001a, b; Piccoli et al. 1996).

Bottini et al. (1989) were the first to validate the ability of *Azospirillum* sp. to produce gibberellins in a chemically outlined medium. Using gas chromatography–mass spectroscopy (GC-MS) analysis, they reported the production of GA1 and GA3 in a nitrogen-free medium culture of *Azospirillum lipoferum* Op33. Similar results were reported in *Azospirillum brasilense* Cd and in *A. lipoferum* AZm5 and *A. brasilense* VS9 (Janzen et al. 1992; Esquivel-Cote et al. 2010). In addition, the assembly of inactive precursors GA19 and GA9 in a chemically defined medium of *A. lipoferum* Op33 was reported (Piccoli et al. 1996). Kang et al. (2014) isolated *Leifsonia soli* sp. SE134 and detected different GAs by chromatographic analysis. Application of *L. soli* culture filtrate was found to have considerably increased biomass, hypocotyl, and root lengths of cucumber seeds as compared to noninoculated. Similarly, Pandya and Desai (2014) isolated and identified *Pseudomonas monteilii*. The culture filtrate of this bacterium was bioassayed on wheat and chana bean crops and was found to significantly promote growth in both plants. In the same manner, *Acinetobacter calcoaceticus*-inoculated cucumber plants exhibited higher GAs (GA1, GA4, GA9, GA20) as compared to noninoculated plants. The PGPR activated the GAs biosynthesis pathway, thereby promoting cucumber plant growth (Kang et al. 2012).

22.4.6 Detection of Gibberellin

The estimation of gibberellic acid should be done in a specific medium, wherever an organism can increase its biomass that results in the production of gibberellin or gibberellic acid-like substances. Gibberellic acid from *Fusarium* species was determined by the acid–base volumetric analysis technique, in which gibberellic acid was titrated with 0.1 or 0.25 N NaOH solution using phenolphthalein as an indicator and measured in 10^{-3} gram equivalents (milliequivalent) of gibberellic acid. The gibberellin phytohormone was also detected by several other techniques such as spectrophotometric assay: qualitative estimation by TLC, HPLC, and paper chromatography.

22.4.7 Ethylene

Another necessary hormone in plant growth and development is ethylene (Et). A protected Et was not thought to be a phytohormone because of its gaseous state under physiological conditions. Currently, totally different studies have shown that its synthesis and action are vital for certain physiological processes. A large number of publications have been found related to the synthesis of Et in higher plants, but only a few studies have been published on the microbial biosynthesis of ethylene (Arshad and Frankenberger 1993). It is a simple and symmetrical molecule composed of two carbon atoms (joined by a double bond) and four hydrogen atoms. It is water soluble, and at very low concentrations in plant tissues (about 0.1 ppm) will exert physiological effects. In higher plants, all tissues have the potential to

manufacture this hormone; however, in general its concentration is related to the developmental state and growth phase of the plant, with a higher concentration in those tissues involved in vigorous cell division, those which are under a stressful environment, or those in a senescence stage (Burg and Burg 1968). It is produced in principally all plants and mediates in an exceedingly wide selection of various responses and developmental processes (Arshad and Frankenberger 2002; Belimov et al. 2002). The presence of ethylene also in some instances has a stimulatory result, whereas in others it represses this result, depending upon its concentration in the tissues of the roots, the physiological nature being processed, and the stage of plant growth. The endogenous level of ethylene, which causes a change in a plant tissue, may modify growth and development (Arshad and Frankenberger 2002).

Ethylene influences varied physiological processes together with liberation of dormancy, shoot and root growth differentiation, adventitious root development, initiation of flowering, and amplified female function in dioecious plants, flowering, fruit ripening, leaf senescence, and leaf and fruit abscission (Abeles et al. 1992; Johnson and Ecker 1998). Different studies showed that Et was involved in premature shedding of leaves, the geotropism of etiolated pea seedlings on exposure to a revealing gas, premature flowering of pineapples treated with smoke, and maturation of oranges exposed to gas from fuel combustion (Arshad and Frankenberger 2002; Abeles et al. 1992). Aside from the positive effects of ethylene, its overproduction may lead to abnormal growth of roots and induce defoliation and cellular processes that also result in inhibition of stem and root growth as early senescence, all of which lead to reduced crop performance because of adverse affects on plant growth and development (Ovakim et al. 2000). Ethylene production in plant roots is accelerated in response to both biotic and abiotic stresses (Arshad and Frankenberger 2002; Abeles et al. 1992). Senescence of plant leaves is among the most important symptoms of accelerated ethylene levels (Arshad and Frankenberger 2002). There is a dire need to regulate ethylene production in the rhizosphere for normal growth and development of the plants.

Plants respond to different stresses by synthesizing 1-aminocyclopropane-1-carboxylate (ACC), which is the precursor for ethylene (Chen et al. 2002; Glick et al. 2007). Some of the ACC is secreted into the rhizosphere and is readsorbed by the roots, where it is converted again into ethylene. This accumulation of ethylene results in a downward-sloping spiral effect, because poor root growth leads to a diminished capability to obtain water and nutrients, which in turn leads to the promotion of stress. Thus, PGPR, with the ability to degrade ACC in the rhizosphere, can help to break this downward cycle and reinstate the healthy root system that is required to manage environmental stress. The primary mechanism that is used by rhizobacteria that degrade ethylene is the destruction of ethylene via the enzyme ACC-deaminase. This enzyme can diminish or prevent some of the harmful effects of high levels of ethylene (Glick et al. 1998). ACC-deaminase acts on ACC, an on-the-spot ethylene precursor in higher plants, degrading this chemical to alpha-ketobutyrate and ammonium (Glick et al. 1998; Grichko and Glick 2001; Mayak et al. 2004). Rhizosphere bacteria with ACC-deaminase activity belonging to the

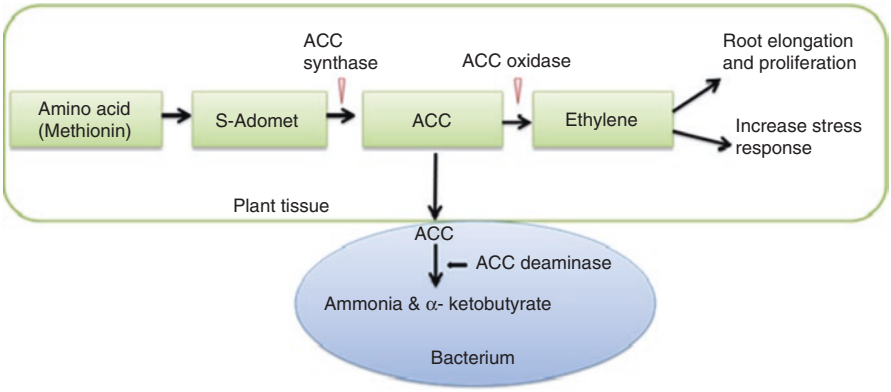

Fig. 22.5 Mechanism of bacteria that reduce ethylene levels in the plant root using bacterial 1-aminocyclopropane-1-carboxylate (ACC) deaminase

genera *Achromobacter*, *Azospirillum*, *Bacillus*, *Enterobacter*, *Pseudomonas*, and *Rhizobium* have been isolated from different soils (Ovakim et al. 2000; Govindasamy et al. 2008; Ghosh et al. 2003; Duan et al. 2009). Various studies have demonstrated that plants treated with PGPR bacteria that produce ACC-deaminase have increased their resistance to environmental stress. Grinchko and Glick (2001) inoculated tomato seeds with the ACC-deaminase expressing the bacteria *Enterobacter cloacae* and *Pseudomonas putida* and registered a rise in plant resistance on 55 days of aging to 9 consecutive days of flooding. Ghosh et al. (2003) found ACC-deaminase activity in three *Bacillus* species (*Bacillus circulans* DUC1, *Bacillus firmus* DUC2, and *Bacillus globisporus* DUC3), which stimulated root elongation of *Brassica campestri* plants. Mayak et al. (2004) evaluated tomato plants inoculated with the bacterium *Achromobacter piechaudii* under water and saline stress conditions. The authors reported a major increase in fresh and dry weight of inoculated plants. In soils with a high copper content, Reed and Glick (2005) reported an increase in dry matter content of the root and the air part in rape seeds inoculated with the ACC-deaminase-producing bacterium *Pseudomonas asplenii* (Fig. 22.5).

22.4.8 Ethylene/ACC Detection Assay

Ethylene can be detected by gas chromatography (GC) or GC–mass spectroscopy (GC-MS). We can indirectly check the amount of ACC by HPLC and spectrophotometric analysis. Several studies also detected ACC-deaminase (ACC-D) enzyme activity in ACC-D-producing bacteria. Bacterial cells were induced by ACC for a time period and then labeled by toluene, a supernatant used for the quantification of ACC-deaminase activity by observing the amount of α-ketobutyrate produced by ACC through the ACC-deaminase enzyme (Penrose and Glick 2003; Kumari et al. 2016).

22.5 Conclusion

Phytohormone production by bacteria has been a groundwork topic for several decades in either infective or beneficial plant-associated bacteria. Phytohormone-producing PGPR contribute to eco-friendly, sustainable, and organic farming, providing high yield and quality in sustainable agriculture and therefore alleviating food deficiencies. These phytohormones act as effector metabolites in plant–microbe interactions and phytostimulation in agro-ecosystems. Bacteria manufacturing phytohormones within the rhizosphere are helpful for plant growth and development by triggering nutrient accessibility, encouraging root colonization, and imparting protection from phytopathogens. However, the ecological significance of bacterially produced phytohormones still needs exploration. As each plant and bacteria secretes these hormones in the rhizosphere, it is difficult to determine the contribution of each one.

Acknowledgments Some of the research in the present review has been supported in part by JECRC University, Jaipur, and Rajasthan. The author acknowledges Mr. Anukool Vaishnav for his careful review of the content and for improvement of the text. The author also thanks Mr. Mohit Agrawal and Mr. Gaurav Kaushik for valuable suggestions and guidance.

23 Diversity, Quorum Sensing, and Plant Growth Promotion by Endophytic Diazotrophs Associated with Sugarcane with Special Reference to *Gluconacetobacter diazotrophicus*

Iqbal Ahmad, Mohd. Musheer Altaf, Jyoti Sharma, and Abdullah Safar Al-thubiani

Abstract

Endophytic bacteria are widely distributed among plants and colonize both intracellular and intercellular spaces and do not harm the host plant. However, the distributions of endophytic diazotrophs are limited. Endophytic diazotrophs like *Gluconacetobacter diazotrophicus* are mainly associated with sugarcane and some other plants and responsible for significant contribution of biological nitrogen fixation with sugarcane. In this article, we described the diversity and role of quorum sensing. We also discussed the contributions of different bacterial traits that are necessary for successful colonization of the plant interior part. Further mechanisms of plant growth promotion are elaborated. Molecular characterization and identification of endophytic diazotrophs will further help in better understanding of plant colonization and plant growth promotion.

23.1 Introduction

The Green Revolution had increased the agricultural productivity to a great extent by the increased application of high-yielding crop varieties, heavy farm equipments, synthetic fertilizers, pesticides, improved irrigation, better soil administration, and massive conversion of forest to agricultural lands (Tilman et al. 2002; Gomiero et al. 2011). But there is a growing apprehension that intensive practices employed for increasing agricultural output promote ecosystem deterioration and loss of yield. Adverse environmental effects include deforestation, soil degradation, large-scale greenhouse gas emissions, accumulation of pesticides and chemical fertilizers, pollution of groundwater, and decreased water table due to excessive irrigation (Tilman et al. 2002; Foley et al. 2011). The International Fertilizer Industry Association (IFA) agriculture committee projected that the global fertilizer consumption is expected to grow, and it will reach 199.4 million metric tons (Mt) of nutrients in 2019 (Heffer and Prud'homme 2015). The projected increase will be at the rate of 1.3, 2.1, and 2.4 % for nitrogen, phosphorus, and potassium, respectively. In reality, an intensive agricultural practice is considered to be the main source of loss of global biodiversity. Traditional agricultural practices like organic farming, which considerably decrease the input of chemical fertilizers, pesticides, energy, and mechanic stress, help us in extenuating the harmful effects of intensive agricultural practices and simultaneously boost the sustainable agriculture production (Gomiero et al. 2011).

World total population is presently around 7 billion, and this is anticipated to grow to approximately 8 billion people until the year 2025 and 9 billion by 2050. Considering the increase in worldwide population with the increase in environmental damage due to ever-increasing industrialization, it is clear that, in the coming next 50 years, it will be a daunting task to feed the existing population, a problem that will increase with time. Therefore, to provide food for the ever-growing population, there is an urgent need for tremendous increase in agricultural productivity in a sustainable and environmentally friendly manner. To produce more food, humankind will need a range of diverse schemes and approaches which should consist of feasible and environmentally favorable biological solutions (Glick 2014). The effective use of PGPR in agriculture in an integrated manner is an interesting technology to tackle these problems.

Microbes provide help to plants either directly by increasing crop nourishment or indirectly by minimizing the damage created by pathogens or environmental stress. Plants live in a close relationship with microbes that fulfill important functions in agricultural ecosystems. Microorganisms may live as free-living organisms in soils or may be associated with the surface of the roots or phyllosphere and may establish symbiotic relations with plants (Smith and Goodman 1999). Endophytic bacteria are a class of endosymbiotic microbes that live in inner plant tissues of apparently healthy host plants (Schulz and Boyle 2006). Unlike phytopathogens, generally such bacteria do not create any substantial disease symptoms, and occurrence of endophytes is not associated with morphological changes of plant tissues such as caused by root-nodule symbionts.

Endophytes inhabit plant apoplast, as well as the intercellular regions of the cell walls and xylem vessels present in roots, stems, and leaves; in addition to this, these bacteria also reside in tissues, flowers, fruits, and seeds (Compant et al. 2011; Pereira et al. 2012). Populations of endophytes are uneven in different plant parts and have been shown to vary from 10^2 to 10^9 of bacterial cells per gram of plant tissue (Jacobs et al. 1985; Chi et al. 2005). This density is governed by several factors, like the plant under study, the respective part under investigation, the developmental period of the plant, the genotype, and the cooperation with other microorganisms (Costa et al. 2012). Normally, the plant roots and other belowground tissues contain higher densities of endophytes as compared to aboveground plant parts.

The cooperation that takes place among sugarcane and other grasses with nitrogen-fixing endophytic bacteria has increased their importance for their utilization in agriculture, because of their positive response on root development and enhanced biomass and productivity. It is well known that close association between host plant and endophytes takes places through various compounds secreted by the microbes and the host plant (Reinhold-Hurek and Hurek 2011; Brader et al. 2014). The endophytes enhance nutrient availability and uptake, augment stress tolerance, and offer disease resistance (Ryan et al. 2008).

Sugarcane (*Saccharum officinarum* L.) is a high-rising, long-standing grass that belongs to the family Poaceae and subfamily Panicoideae, which is generally grown in tropical and warm-temperate regions between 35°N and 35°S. It belongs to the C4 plant category and has high photosynthetic efficiency, increased rate of biomass conversion from solar energy, and high efficiency of water use (Ward et al. 1999; Reis et al. 2007). Endophytic bacterial isolates have been obtained from sugarcane (*Saccharum* spp.) that promotes plant growth. The most distinguished sugarcane endophytic diazotrophs are *Gluconacetobacter diazotrophicus* (alpha subclass of Proteobacteria), *Herbaspirillum seropedicae*, *Herbaspirullum rubrisubalbicans*, and *Burkholderia* sp. (beta subclass of the Proteobacteria) (Reis et al. 2000).

The communication that takes place between the target plant and nitrogen-fixing endophytes depicts a different organization regarding advantageous plant–microbe associations, which showed distinctive properties that need description. In this article, we have attempted to review the scientific literature available on endophytic bacteria and their identification and impact on plant growth and health.

23.2 Diversity of Endophytic Diazotrophs Associated with Sugarcane

It has been proposed that the planet Earth consists of approximately 300,000 species of plants, the bulk of which consists of endophytes (Smith et al. 2008). Actually, endophytes (bacteria and fungi) have been reported to be present in each and every plant species that has been investigated. Partida-Martínez and Heil (2011) reported that an endophyte-free plant is a rare exception in nature. Timmusk et al. (2011) observed that a plant devoid of endophytes was unable to cope with environmental stress conditions and susceptible to pathogen attack. In case of sugarcane, the

majority of the study on endophytic microbes has been directed on diazotrophs. The major representative includes *Gluconacetobacter diazotrophicus*, *Herbaspirillum* spp. (Baldani et al. 1986; Cavalcante and Döbereiner 1988; James 2000; Boddey et al. 2003), and *Azospirillum amazonense* (Reis Júnior et al. 2000). However, the Indian sugarcane was found to contain a low population of diazotrophic bacteria among the entire populations of microbes (Suman et al. 2001).

Gluconacetobacter genus was suggested by Yamada et al. (1997) as one of the four genera for acetic acid bacteria. *Gluconacetobacter diazotrophicus* is known to be a plant growth-promoting bacteria (PGPB) which colonizes sugarcane, pineapple, wetland rice, sweet potato, corn, sorghum, coffee, wheat, and tomato plants (Cavalcante and Döbereiner 1988; Cocking et al. 2006; Saravanan et al. 2008; Luna et al. 2010). In addition to this, a significant feature of *G. diazotrophicus* is the tolerance to high sucrose level (30 %), demonstrating high osmotolerance, which is constant with its continued existence in sugarcane stems naturally (Cavalcante and Döbereiner 1988). However, on the contrary, this organism is susceptible to NaCl (Tejera et al. 2003; Boniolo et al. 2009).

G. diazotrophicus, associated with sugarcane, is known as "obligate endophytes," because it is not possible to isolate it from non-rhizospheric soils and can only be isolated from plants, fungi, insects, etc. The isolation of this bacterium can only be possible from roots, stems, and leaves of sugarcane (Gillis et al. 1989) and coffee. It normally inhabits the sugarcane tissues that lack dissolved carbon compounds, like root and stem xylem vessels. It was also found to inhabit intercellular apoplastic stem areas that contain the sucrose niche and phloem sieve tubes involved in sucrose translocation. The cells of this bacterium were reported to inhabit inside plant stems as microcolonies and haphazardly distributed on the plant surface in an apolar direction forming a monolayer wrapped around roots and leaves. *G. diazotrophicus* was also found compiling the lateral root junctions and inhabiting the damaged epidermal cells, where it does not penetrate beyond the epidermis of root. *G. diazotrophicus* is not capable to exist in the soil in the absence of their host plants and can only grow in low-pO2 environment, which is essential for the expression and normal performance of the nitrogenase system (James and Olivares 1997). Ahmad et al. (2004) isolated a total of eleven isolates of *Acetobacter diazotrophicus* (*Gluconacetobacter diazotrophicus*) from roots, stems, and leaves of the four locally grown varieties of sugarcane (Co-1148, UP 39, Satha-676, and Satha-91269) of Aligarh. These isolates along with three Brazilian strains of *Acetobacter diazotrophicus* (PR2-ATCC49039, Pal5-ATCC 49037, Ppe-4 ATCC49038) were considered for their biochemical characteristics and resistance traits. These isolates use sucrose, glucose, and ethanol (1 %), whereas all the isolates were found negative for maltose and ethanol (10 %). Fructose was consumed inconsistently. Similarly all the isolates were found positive for catalase and H_2S production and negative for oxidase, nitrate reduction, denitrification, gelatin liquefaction, and indole test. Antibiotic resistance was expressed by 12 isolates only. Metal resistance at MIC 100 μg ml^{-1} was found highest against lead followed by cadmium, mercury, nickel, and copper. Majority of the indigenous isolates demonstrate resistance to both antibiotics and heavy metals. However, three Brazilian isolates of *Acetobacter diazotrophicus* were

found sensitive to all five (Cu, Cd, Ni, Pb, and Hg) metals. Further, tolerance to salt (NaCl) was higher (1.0–1.5 %) within indigenous isolates compared to Brazilian isolates, which showed NaCI tolerance up to 0.5 % in agar medium.

Azospirillum species is a native soil bacteria commonly found as root-associated diazotrophs. They are attached to the roots by fibrillar material and are occasionally reported from the superficial film of the root cortex (Bashan and Levanony 1990). Majority of the *Azospirillum* species have been isolated from the surface-sterilized roots, which signifies that a portion of these cells get shielded from different sterilizing agents and are located inside the root tissues (Dobereiner and Day 1976; Hallmann et al. 1997). These bacterial species were obtained from different cash crops like sugarcane, palm trees, forage grasses, tuber plants, cereals, and sweet potato (Mohanta et al. 2010). Farrar et al. (2014) reported several different endophytic bacteria from sugarcane like *Gluconacetobacter diazotrophicus* (syn. *Acetobacter diazotrophicus*), *Burkholderia*, *Pantoea*, *Pseudomonas*, *Microbacterium*, *Citrobacter*, *Enterobacter*, *Klebsiella*, *Erwinia*, *Brevibacillus*, *Staphylococcus*, *Curtobacterium*, *Pseudomonas* sp., *Bacillus*, *Paenibacillus*, *Brevibacillus*, and *Burkholderia australis.* Velázquez et al. (2008) reported the genetic diversity of 29 endophytic bacteria from healthy grown sugarcane plant from Cuba and investigated using two primers, random amplified polymorphic DNA fingerprinting (TP-RAPD) and 16S rRNA gene sequencing, demonstrating that these isolates are associated to different phylogenetic groups being strongly connected to species of genera *Bacillus* and *Staphylococcus* from *Firmicutes*; *Microbacterium*, *Micrococcus*, and *Kokuria* from *Actinobacteria*; *Rhizobium* and *Gluconacetobacter* from *α*-Proteobacteria; *Comamonas* and *Xanthomonas* from *β*-Proteobacteria; and *Acinetobacter* and *Pantoea* from γ-Proteobacteria.

23.3 Cell-to-Cell Communication Among Endophytes

Gluconacetobacter diazotrophicus is a well-known endophyte obtained from the inner tissues of many crop plants. The plant growth-promoting capability of this *Alphaproteobacterium* has been associated not only to its ability to carry out biological nitrogen fixation but also through the production of siderophores, antimicrobial compounds, and solubilization of phosphate and other minerals by the production of gluconic acid (Saravanan et al. 2008). Colonization and persistence of an endophyte involve intricate regulatory pathways. Among them, quorum sensing systems (QS) are signaling methods connected with the regulation of numerous genes associated with microbial communications, host establishment, and survival under stress conditions. Quorum sensing is connected with the capability of a bacterium to react to autoinducers, hormone-like compounds which are capable of altering gene expression at a critical threshold population (Reading and Sperandio 2006).

The genes related to quorum sensing in *G. diazotrophicus* consist of one luxI autoinducer synthase gene and two luxR-type transcriptional regulator genes, which are associated with the expression of three N-acyl homoserine lactones (AHLs)

(Eskin et al. 2014). Analysis of *G. diazotrophicus* AHLs identified 8 different signaling molecules: C6-homoserine lactone (HSL), C8-HSL, C10-HSL, C12-HSL, C14-HSL, 3-oxo-C10-HSL, 3-oxo-C12- HSL, and 3-oxo-C14-HSL (Nieto-Penalver et al. 2012).

Research should also continue to focus on the importance of quorum sensing. It has been revealed that *G. diazotrophicus* contains 3 different AHLs; their precise roles have yet to be identified. Recently recognized molecular methods used for studying *G. diazotrophicus* such as mutational studies via Tn5 transposon mutagenesis could assist in identification of quorum sensing genes.

23.4 Methods for Detection and Characterization of Endophytes

The endophytic habitat provides defense against the adverse environmental conditions for bacteria that are capable of colonizing and residing *in planta*. These bacterial isolates usually take possession of the areas/voids present between cells, and they have been reported from almost all the sections of plant together with seeds (Posada and Vega 2005). Endophytic microbes have been described and obtained from both monocotyledonous and dicotyledonous plants. Classical research related to the diversity of endophytes (*Gluconacetobacter diazotrophicus*, *Herbaspirillum seropedicae*, and *H. rubrisubalbicans*) had paid attention on classification of isolates acquired from inner spaces of tissues after sterilization of plant outer areas using sodium hypochlorite or by culturing serial dilutions prepared from plant tissue macerates in nitrogen-free semisolid media which acts as semi-selective media for the species/genera (Miche and Balandreau 2001; Silva-Froufe et al. 2009). Fundamentally, the most probable number (MPN) procedure, using a McCrady table, has been used to enumerate the quantity of bacteria (Paula et al. 1991; Eskin et al. 2014). But, the MPN technique is not recognized to be very precise and should be directed for additional testing to authenticate isolates at a species level. The weakness of MPN method can be mitigated by using enzyme-linked immunosorbent assay (ELISA) (Silva-Froufe et al. 2009). Further, by the use of different microscopies like optical and transmission electron microscopy (TEM), the presence of *G. diazotrophicus* endophytic colonization can be confirmed (Luna et al. 2010). In addition to these methods used for localization of *G. diazotrophicus*, one of the most widespread techniques used is green fluorescent protein (GFP) labeling (Gaiero et al. 2013). Eskin et al. (2014) described the application of *gusA* and *gfp* reporter genes from strains containing pHRGFPGUS (*gfp::gusA*) and pHRGFPTC (*gfp*) plasmids, respectively. *G. diazotrophicus* UAP5541/pRGS561 constitutively expressing GUS and UAP5541/pRGS562 with a *nif* H::*gus*A transcriptional fusion is two supplementary strains that have been used in different investigations in which both intercellular and intracellular localization have been determined. Rouws and colleagues (2010) in their study related to G. *diazotrophicus* strain Pal5 carrying *gfp*::*gus*A plasmid pHRGFPGUS and *gfp* plasmid pHRGFPTC proved the validity of these techniques for colonization and localization of endophytes.

Different techniques are used to study plants for the occurrence of *G. diazotrophicus*. One of the key techniques for identification of *G. diazotrophicus* is through polymerase chain reaction (PCR). While a simple PCR is sufficient in identifying the bacterium at high colony numbers, a nested PCR in which a second round of PCR is used to amplify the product from the first round of PCR is instrumental in detecting the bacterium when found at very low colony numbers (Tian et al. 2009). While PCR is proficient to authenticate the presence of the bacterium, it is not capable of determining the number of bacterium present within a sample. Bacterial populations colonizing the stems, roots, and tubers of different plants were studied by 16S rRNA gene-associated methods like terminal restriction fragment length polymorphism analysis, denaturing gradient gel electrophoresis, as well as 16S rRNA gene cloning and sequencing. Characterization related to endophytes involves not merely the separation from sterilized tissues but also visualization by various types of microscopy within plant tissues (Sagarika et al. 2010). Endophytes normally present can be seen using different types of microscopy such as fluorescence in situ hybridization (FISH) together with confocal laser scanning microscopy (CLSM) using specific probes, scanning electron microscopy (SEM), transmission electron microscopy (TEM), and phase contrast microscopy (Amann et al. 1990; Loy et al. 2007). Nautiyal (2000) has reassessed new development which includes the use of various markers for studying root colonization. Microscopic researches related to gfp tagged endophytic inoculants disclose extremely diverse colonization arrangements.

23.5 Colonization of Plant by Endophytic Diazotrophs

Generally, the communities of endophytes were observed to be present in lower concentration as compared to root-associated bacteria or phytopathogens (Hallmann et al. 1997; Rosenblueth and Martínez-Romero 2006). Endophytes similar to their rhizospheric counterparts are hardened by biotic and abiotic components (Fuentes-Ramírez et al. 1999; Hallmann et al. 1997; Seghers et al. 2004). However, the endophytes received better protection from biotic and abiotic stress compared to root-associated bacteria (Hallmann et al. 1997). These bacteria also perform a crucial task in inhabitation.

Colonization related to bacterial species either in roots or on plant surfaces is a complicated procedure facilitated by the exchange of numerous bacterial character and genes. Colonization process is a step-by-step procedure, which involves (1) movement toward root surface, (2) adhesion, (3) dispersal along the root, and (4) persistence and survival of the bacterial communities. Among endophytes, besides the above-said steps, the colonization process involved one extra step, which involves the access inside the root and development of small colonies within and between tissues, which can be tracked by labeling the target bacteria with molecular indicator such as (gfp) or β-glucosidase (gus) and finally visualizing with electron or confocal laser scanning microscopy (Reinhold-Hurek and Hurek 2011). The mechanism implicated with endophytic colonization process is not fully inferred.

Experimental data based on genomic and other techniques revealed a similarity in the colonization process among pathogenic and plant growth-enhancing bacteria (Hardoim et al. 2008). The endophytic bacteria get entry into the plants using two modes: vertical transmission and horizontal transmission. In vertical transmission, endophytic bacteria might be transferred by seeds (vegetatively), and during horizontal transmission, endophytes may be selected by soil and most likely need a stage of rhizoplane colonization, for which they require properties assigning "rhizosphere competence."

Apart from sugarcane, *G. diazotrophicus* has been isolated from several different crops like coffee, pineapple, and wetland rice. The large part of these hosts consists of comparatively higher levels of sucrose which appeared to be a requirement for colonization by this bacterium (Riggs et al. 2001). *G. diazotrophicus*, an obligate endophyte, is incompetent of surviving in soil without a plant host for more than 2 days, with the exception of being capable of surviving within the spores of the vesicular arbuscular mycorrhizal fungus *Glomus clarum* and within the root hairs of a host plant's rhizosphere (James et al. 2001; Luna et al. 2010).

The bacterium is capable to achieve entry into its host plant through the roots, stems, or leaves. With respect to the roots, *G. diazotrophicus* enters through the root tips and cells of the root cap and meristem, at areas of lateral root emergence, and by root hairs (Rouws et al. 2010). In case of stems of host plants, especially sugarcane, the bacterium gets entry at cracks generated by the disjointing of plantlets into individuals. Finally, through the leaves, the endophyte gets entry via injured stomata. An added pathway used by *G. diazotrophicus* is accomplished through an insect vector, the pink sugarcane mealybug (*Saccharicoccus sacchari*), a plant sap-sucking insect (Franke-Whittle et al. 2005; Ortega-Rodes et al. 2011). Once inside the host plant, *G. diazotrophicus* was observed to mainly occupy intercellular apoplastic spaces, the xylem, and the xylem parenchyma (Boddey et al. 2001). However, new research showed that β -glucuronidase (GUS)-labeled *G. diazotrophicus* bacterium is also proficient in intracellular colonization with in membrane-bound vesicles in its host plant (Cocking et al. 2006). Recognized *G. diazotrophicus* colonies can grow up to 10^8 CFU per gram of tissue, as found within sugarcane. The above-mentioned methods of passage for *G. diazotrophicus* were found to be assisted by hydrolytic enzymes (Adriano-Anaya et al. 2005). Adriano-Anaya et al. (2005) established the secretion of endoglucanase, endopolymethylgalacturonase, and endoxygluconase within both PAL5 and UAP5541 strains of *G. diazotrophicus*, which utilizes sucrose as carbon source. These enzymes perform a key function in the entry of endophytic bacteria to host and its mobility inside host plant tissue.

The colonization of root surface by endophytes involves the arrival of bacteria to the rhizoplane as a result of chemotactic response, to surpass the additional microbes in order to get entry into root surface, express genes in a synchronized manner for intrusion in the plant, prevent host plant immune responses, and protect a place inside the plant tissue (Bais et al. 2006; Rosenblueth and Martínez-Romero 2006; Compant et al. 2010). Moreover, microbe–microbe communication and microbe–plant signaling are implicated at every point involved in the process of root colonization. The root endophytic bacterial populations can vary considerably compared

to the rhizospheric communities, signifying identification and collection of helpful microbes by roots (Compant et al. 2005). Lipopolysaccharides, flagella, pili, and twitching motility have been reported to influence endophytic colonization and bacterial motion inside host plants (Böhm et al. 2007). Additionally, the discharge of cell wall-degrading enzymes (CWDEs) is reported to be implicated in bacterial infiltration (Lodewyckx et al. 2002) and dispersal inside the plant. To inhabit the inner plant tissues, it has been suggested that bacterial endophytes contain genomic differences compared to root-colonizing bacteria, despite the fact that so far no ultimate group of genes has been recognized that is accountable for the endophytic way of life. However, a directory of genes which play a potential role in endophytic behavior was recently recognized by Ali et al. (2014) by analyzing the complete genomes of nine proteobacterial endophytes. At this junction, barely a few genes have been experimentally revealed to be implicated in colonization by endophytes.

Several defense reactions have been implicated throughout plant–endophyte associations. Reinforcement of cell walls, organization of adjoining substance within the cortex or xylem, as well as gum secretion inside vessels have been reported (Miché et al. 2006). Although several defense reactions have been reported for plant response to plant pathogens, merely a few defense responses have been explained in plant reply to endophytes. These differences may be illustrated through the discharge of several substances, which may be of extremely small quantity for endophytes (James et al. 2002). On the other hand, it has been observed that plants may demonstrate resistance response regulating colonization by endophytes (Iniguez et al. 2005). Dicotyledonous plants species are acknowledged for using salicylic acid (SA) and ethylene in communication, which manage colonization of some endophytes, as confirmed under laboratory conditions (Iniguez et al. 2005). However, among monocotyledonous plants like rice, accumulation of jasmonic acid (JA) but not ethylene was observed to obstruct the colonization of the diazotroph *Azoarcus* sp., signifying that plant protection reactions linking the JA signaling pathways may also be involved in managing endophytic colonization within the root system (Miché et al. 2006). However, in a well-matched endophytic organization, JA-related plant reactions were negligible and do not limit endophytic establishment (Miché et al. 2006).

23.6 Plant Growth-Promoting Effect of Endophytes

Plant growth-enhancing bacterial endophytes inhabit the inner part of plant and are capable of establishing a unique type of association, in which both the participants get benefitted from their relationship (Hallmann et al. 1997; Reiter and Sessitsch 2006). Bacterial endophytes increased plant growth using different mechanisms like production of phytohormones, siderophores, solubilization of phosphate, nitrogen fixation, and accessibility of key nutrients to their host plants (Lodewyckx et al. 2002; Lee et al. 2004; Puente et al. 2009), as shown in Fig. 23.1. Endophytes can also enhance plant growth as a result of the bacterium secreting the enzyme 1-amin ocyclopropane-1-carboxylate (ACC) deaminase which dissects ACC to

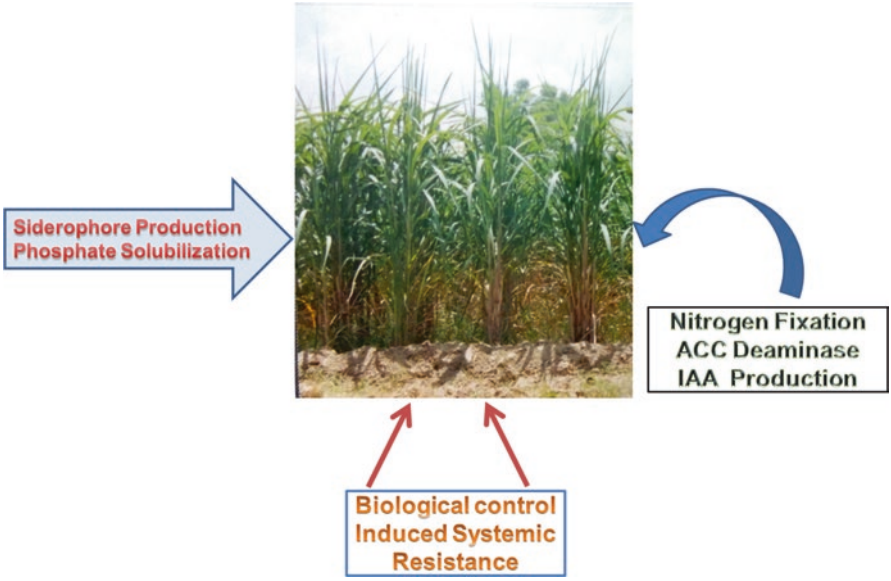

Fig. 23.1 Mechanism of sugarcane growth promotion by endophytic microbes

α-ketobutyrate and ammonia and thus diminishes ethylene levels in host plants (Glick 2014). Moreover, these plant growth-promoting endophytes are also playing a significant role in forest restoration and phytoremediation of polluted soils (Ryan et al. 2008).

Earlier researchers reported that endophytes promote plant growth by changing plant physiology (osmotic pressure regulation), modifying stomatal reaction, altering root dimensions and make, changing nitrogen buildup and metabolism, and enhancing uptake of necessary minerals (Compant et al. 2005). Endophytic microbes also work as a biocontrol agent. The mechanism used by the endophytes for working as biocontrol agents involves the secretion of antibiotics and lytic enzymes like hydrolases and chitinases (Chernin and Chet 2002; Ezra et al. 2004). Further, the bacterial endophytes were also found to activate induced systemic resistance (ISR)-based plant growth promotion (Ait Barka et al. 2000, 2002). Several workers reported the beneficial effect of application of *Gluconacetobacter* on enhancement of sugarcane growth under field conditions (Fig. 23.2).

Chauhan et al. (2010) isolated 11 species of *Gluconacetobacter* from different varieties of sugarcane, and under field trial, it was observed that the endophytes significantly increased plant height, chlorophyll content, cane girth, number of millable canes, and total nitrogen, ensuing the enhancement in cane yield by 42 % compared to control plant. Murumkar et al. (2016) under their field experiments observed that the use of *Gluconacetobacter diazotrophicus* + phosphate-solubilizing bacteria along with 75 % recommended N and 75 % recommended P_2O_5 considerably enhanced the growth, two eye bud-set yield, and quality of sugarcane. Hari (1995) and Srinivasan and Naidu (1987) observed that application of N-fixing bacteria to sugarcane has

Fig. 23.2 Plant growth-promoting effect of *Gluconacetobacter diazotrophicus* on sugarcane grown under field conditions

augmented the cane yield by 5–15 %, which helps in saving of 25 kg fertilizer N ha^{-1}, and also enhanced the juice quality factors, like sucrose and clarity. Schultz et al. (2014) also reported the similar results on sugarcane yield by inoculating endophytic diazotrophs. Oliveira et al. (2003, 2006) demonstrated the increased contribution of biological nitrogen fixation (BNF) in micropropagated sugarcane by inoculating with endophytic diazotrophic bacterial isolates. In addition to providing beneficial plant growth-promoting effect on sugarcane, the endophytic bacteria also conferred drought tolerance to sugarcane (Vargas et al. 2014).

23.7 Conclusion and Future Direction

Considerable research work has been carried out on endophytes including *G. diazotrophicus.* It is known that the endophytic bacteria *G. diazotrophicus* possess 3 different AHLs, but their precise function is yet to be discovered. Recently discovered molecular methods, employed in research for endophytes, can aid in discovering the role of quorum sensing genes and their role in biological nitrogen fixation. Although plenty of scientific data is available on endophytes, still there is a lot more to discover on how a PGPR changes onto plant endophytes. The sufficient understanding of plant–endophyte interaction will certainly play a significant part not only in the enhancement of plant growth and health but also in sustainable agriculture and in obtaining the biotechnological efficiency for various tasks.
