Chitosan oligosaccharide (COS) from the acidolysis of chitin has plenty of potential for an extensive range of application. Due to its antimicrobial activity against pathogenic and nontoxicity for organism, it can be formed into films for the use of packaging material to improve the quality of food (Dutta et al. 2012). What's more, COS can play a vital role in modulating the status of intestine, so it is indispensable for the production of yogurt (Qin et al. 2014). China was the coastal country which has abundant marine sources for the production of COS. The annual output of COS is maintained in a high level with the yield for 2,000–3,000 tons in 2014. At present, the selling price of COS was about $118–145 which means the oligosaccharide implied the huge profits. Soybean oligosaccharide (SBOS) was the general term for several soluble oligosaccharides, such as sucrose, stachyose, and raffinose (Guillon and Champ 2002). In 2011, because of the extensive cultivation of soybean, the yield of SBOS in China was 10,000 tons which was only next to America. And SBOSs were used in beverages, yogurts, infant formula, and bakery goods.

As the golden standard, breast milk is tailored by mothers to provide their newborn babies with essential nutrients (Akkerman et al. 2019). But not every mother has adequate breast milk for their baby, and there were about 60% mothers who need to work after delivery. HMOs are the third most abundant components in breast milk, which are precious nutriments that no other normal milk can offer. Some synthesized oligosaccharides were added to infant formulas to mimic the breast milk, such as lacto-*N*-neotetraose (LNnT) and 2'-*O*-fucosyllactose (2'-FL) which were applied to infant and toddler formula in Europe and the United States. However, since there are limited source of HMOs and insufficient technology for commercial generation, the extensive use of HMOs in market was blocked (Grabarics et al. 2017). In 1930, the HMOs were firstly extracted from human milk, and with the following years, numerous experiments were carried out to identify the structure and function of HMOs (Plaza-Diaz et al. 2018), and the research on HMOs becomes a hot topic and is associated with the production method since 2010. Health benefits associated with the consumption of human milk oligosaccharides include maintaining gut microbiota and inhibition of pathogen in infants. These are factors likely to drive the growth of the global human milk oligosaccharide market.

Human milk oligosaccharides are jumping into popularity due to the potential protective effects as a prebiotic to maintain a healthy immune system in infants. According to the WHO, the total world population is estimated to increase by approximately one billion in the next 10 years and reach 9.5 billion by 2050. The health of large populations of newborn infants needs the increasing demand for high-quality nutritional products. According to the estimate of Future Market Insights, the fucosyllactose segment is estimated to occupy a market share of around 48% in terms of value among the various product type segments and sialyllactose with a value share of 28% by 2017 end. The fucosyllactose product type segment is reported to be valued at more than $9 million by the end of 2017 and is estimated to increase with a CAGR (compound annual growth rate) of 14.4% over the forecast period. On the other hand, the market value of sialyllactose is estimated to more than $5 million by the end of 2017 and is expected to increase with a speed of 15.1% per year and valued at more than $20 million by the end of 2027.

31.5 Safety: Toxicity and Side Effects

The toxicity and side effects of oligosaccharides determine their applications in food. Functional oligosaccharides, which were applied in food, must be tested that there was no side effect to organism. Fructo-oligosaccharides, used as sweetener in food, were tested and have no deleterious effects on diabetic rats. Meanwhile, it acts as probiotic applied in anticancer drugs and also has no gastrointestinal discomfort effect on pediatric patients (Bali et al. 2015). Early in 1995, Food Standards Australia New Zealand (FSANZ) revised Australian Food Standard Code and allowed FOS as dietary fiber to be added into food. Following Australia, Denmark, Norway, and Sweden successively published the same code in 1995, 1998, and 1999. The FOS was registered as GRAS (generally regarded as safe) by the FDA for use as food ingredients in November 2000. In China, according to the standard of food nutrition reinforcement (GB14880–2012), FOS can be used into food including infant formula. Nowadays, almost all countries have no limitation on the additive dose of FOS. And the recommend daily intake of FOS in Europe is 20 g and in China is 10 g.

The safety of GOS was assessed by toxicity research in rats and in human. The male and female rats with repeated oral administration of 2,000 mg/kg/day had no GOS-related changes in clinical signs (body weight, feed intake, organ weight, and urine assessment) (Kobayashi et al. 2009). The clinical safety analysis was carried out, in this study, in 50 healthy adults, and 103 constipated patients were treated with 5 g GOS per day, and there was no significant impaired effect in volunteers. Totally, the effective intake of GOS is 3–10 g/d; the maximum daily limit of it is 0.3–0.4/d. Japan is the first country to authorize GOS as Food for Specified Health Uses (FOSHU). Europe had given a license to GOS as food ingredient. US FDA had ruled that GOS was GRAS and given permission to be sold on the market as diet supplement in 2000 (Torres et al. 2010). In addition, GOS had already been

authenticated as new resource food by the State Food and Drug Administration of China in 2008.

As the research moves along, the health function of inulin was deeply investigated. So implying the inulin into the food or drugs is urgent. The safety of inulin was invested in vivo and clinical test. There was an experiment on young adult male mice; the mice treated with 15% inulin incorporated in the basal diet were started 4 weeks before intramuscular transplantation of TLT tumor cells into of the NMRI strain and were continued until the end of the experiment. And they found that dietary treatment with inulin clearly inhibited the growth of a transplantable mouse liver tumor (TLT) and the inulin was nontoxic (Akkerman et al. 2019). Closa-Monasterolo aimed to test the efficacy, safety, and tolerance of Orafti®Synergy1 (oligofructose-enriched inulin) with the dose of 0.8 g/dL on the 4-month-old baby, which was supplemented with infant formula. And they found it is safe and effective with the dose of 0.8 g/dL SYN1-supplemented infant formula for infant and the gut microbiota is closer to that of breastfeeding (Closa-Monasterolo et al. 2013). International Scientific Association for Probiotics and Prebiotics (ISAPP) declared that the inulin was the only prebiotic which was widely accepted by the society in 2016. According to the Europe Union (EU) Commission Regulation 2015/2314 of 7 December 2015, chicory inulin was able to maintain the normal function of gut. What's more, the America Food and Drug Administration (FDA) affirmed that the inulin was generally regarded as safe (GRAS) in 2000 and regarded it as the dietary label in 2016. But recently, Vijay-Kumar et al. found that the mice with dysregulated microbial suffered from liver cancer when fed with inulin. It's no doubt that the latest investigation will subvert the fundamental conception of inulin and other soluble fibers. And it needs relative scientists and organisms make joint effort to explore the safety of inulin.

COS as the functional oligosaccharide was able to be absorbed by intestinal epithelia and distributed to the liver, spleen, and kidney (Kean and Thanou 2010). What's more, the liver plays a crucial role in the degradation of COS (Muanprasat and Chatsudthipong 2017). The mutagenicity, cytotoxicity, and systemic toxicity of COS were evaluated by using in vivo and in vitro models. The experiment on mice with the oral administration for 5 g/kg/d for 180 days showed that the COS has no mutagenicity. And COS has no toxicity on mouse fibroblasts and human lymphocytes. Besides, COS at dose reached for 10 g/kg did not induce the abnormal behavior and has no lethal effect on mice. As for the toxicity of SBOS, there were few experiments to identify the edibility safety and only several toxicological tests toward certain brand products in animals. COS was the preferred functional health product to keep fitness and prevent disease and aging in Japan. Besides, it is the only product which is authorized by the Japanese government for its therapeutic effect. After that, European Community and US FDA had ratified to full product.

As described above, LNnT as a chemically synthesized HMO was applied into infant formula, and its safety was tested through genotoxicity experiment in rats. The study showed that the oral dose reached 5000 mg/kg bw/day on both male and female rats more than 90 days and has no adverse effect by detecting the body weight, fodder consumption, organ weight, and histopathology. What's more, LNnT

was better tolerated compared with fructo-oligosaccharides (Coulet et al. 2013). At the same time, the toxicity of 2'-O-fucosyllactose (2'-FL) was also detected through in vitro assay. And there was no observed adverse effect level with the oral dose for 5,000 mg/kg bw/day on both male and female rats. These findings support the safety of LNnT and 2'-FL to be used in infant formula. European Commission had given permission to use 2'-FL and LNnt into food as additives in 11 March 2016. Two months later, US FDA published same approval. China had solicited public opinion about the use of 2'-FL as food ingredients in 2016.

Nutrition and Allergies (NDA) was asked to have a comment on 2'-FL and LNnT as a novel food ingredient at a request of European Commission, the EFSA Panel on Dietetic Products. After comprehensive consideration on the comments and objections of a scientific nature raised by member states, NDA permitted 2'-FL and LNnT to be used in infant formula foods for specific medical objectives for infants and young children and other foods for infants, young children, and adults (Regulation (EC) No 258/97). This major policy decision took account on a sub-chronic 90-day toxicity study in rat, in which the study found the rats with a dose of 2,000 mg/kg body weight per day had no observed adverse effect. Then applicant conducted a double-blind, random, controlled clinical experiment on infants (before the age of one) orally with 1.2 g/L of 2'-FL and 0.6 g/L LNnT. The 2'-FL and LNnT at a ratio of 2:1 in formulae is safe for infant. The Panel also observed that 2'-FL is nontoxic when combined with other foods at use levels (Coulet et al. 2013).

31.6 Marketed Product

With regard to the function of fructo-oligosaccharides described above, many products including fructo-oligosaccharides were designed in market aiming to improve intestinal tract function and to prompt bowel movement. The form of products is mainly powder. What's more, the products could be used in different age groups. For baby and old, it can be added to the milk powder to enhance the gut health. For adult, it can be mixed with fruit juice to reach the aim of losing weight.

Nowadays, because GOS structurally resembles HMO, it is comprehensively applied in infant formula as functional alternatives to mimic the function of HMO (Moossavi et al. 2018). What's more, the sialylated GOS is also used in infant formula (Wang et al. 2015). Recently, a powdered GOS (Bimuno) product was produced by Clasado Ltd., which was composed of 52% GOS and syrup to modulate the gut stability (Rastall 2010). Inulin as the soluble fiber can regulate intestinal homeostasis and was applied into the food and pharmaceutical. In addition, some weight-losing products were added to inulin with the aim to increase satiety and reduce caloric intake of people. Some infant formulas try to mimic the beneficial effect of human milk using inulin supplementation, mainly because the intestine of newborn is rapidly colonized with microbes and the foods could affect this process.

As mentioned above, the chitin oligosaccharides have the potential to enhance the growth of *Lactobacillus*. So it is made into pressed candy together with the natto to improve the immunity and gut health of organism. Also, there are many brands to

sell the chitosan oligosaccharides in the shape of powder or capsule in the market all over the world. Besides, the chitin oligosaccharides were applied into toothpaste to prevent caries and bad breath. On account of the bioactive physical properties, COS was applied to the potential therapeutic drug, especially the anticancer drug. Recently, Micelle-forming polymeric and chemically modified COS (polycaprolactone-g-COS micelles or ferrocene-modified COS) have been developed as drug carrier and applied to improve drug absorption through epithelial barriers. In recent market, the commercial product of SBOS has well received the attention of customers, such as product manufactured by Calpis Food Industry Company, which is a concentrated syrup, containing 35% SBOSs and solid (Rastall 2010).

The public in the fierce competition must work harder to stay competitive, along with the enormous pressure. Recently, Panasevic created a new formula to ease the pressure of nervous person. The formula contained at least one of HMOs, such as 3′-sialic acid lactose, 6′-sialic acid lactose, lactoyl-*N*-tetrose, and 3′-fucosolactose, which can effectively relieve the pressure. There were various kinds of infant formula milk powder designed for different age group which were sold in the market, such as the high-calcium milk powder and anti-lactoprotein allergy milk powder produced from cow, goat, and donkey milk (Di Renzo et al. 2013). With the aim to provide the most desirable milk powder for infants whose mother could not secrete enough milk, there were part of milk powder which was loaded with human milk oligosaccharides. Abbott Laboratories of the United States firstly launched the HMO formula milk powder in 2016; the additive amount of HMO (2'-FL) is 20 mg/100 mL to mimic breast milk. The HMO formula milk jumped into popularity since it was launched. Now, millions of babies in America have enjoyed the benefits coming from HMO. After that, Wyeth Nutritionals Ireland Company also published 2'-FL formula milk powder with the content of 25 mg/100 mL in 2017. While in 2018, Nestlé company heavily launched the supreme HMO infant milk powder which contained two human milk oligosaccharides (2'-FL and LNnT), and the ratio of 2'-FL and LNnT is 2:1 (100 mg/100 mL, 50 mg/100 mL). The total content of these two oligosaccharides is pretty close to that in breast milk (50–150 mg/100 mL).

31.7 Patents

There were approximately 443 oligosaccharides patents which were retrieved using the oligosaccharide as key word via MedLink online, and there were 195 patents invented in China, 77 patents invented in the United States, 60 patents invented in Korea, 48 patents invented in Japan, 23 patents invented in Europe, and 8 in Germany, and the 24 patents left were published in world class (Fig. 3). What's more, Japan is the earliest country to invent the patents associated with oligosaccharide. The majority of published patents are associated with the manufacture method and application of oligosaccharide. Juan et al. have used the brown algae as the material to produce the brown algae oligosaccharides through enzymolysis approach; in this way, the nondigestible and high-viscosity polysaccharides in kelp were degraded into some low-weight bioactive substance to increase the utilization

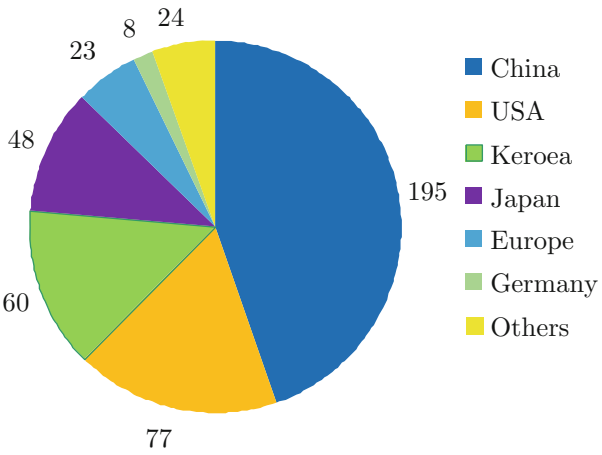

Fig. 3 The number of patents about oligosaccharides in each country

of brown algae. Li et al. have applied for a patent about the craftsmanship and application of core fucosylation oligosaccharide. The feature of this oligosaccharide was the enhanced effect for the growth of *Bifidobacterium* and *Lactobacillus*, which can regulate the intestinal microbial to improve immune function.

31.8 Perspectives

Various functions of oligosaccharides lead to the large-scale production and diverse commercial application in nutraceutical, beverage, infant formula, bread, cheese, and manufactured meat. And there needs more relative research on developing more oligosaccharides with high-function properties to replace antibiotics which can bring side effect to human body. Also translation from the laboratory to clinic faces a large of obstacle, which needs the joint effort of scientists and government. The level of development and research in each country all over the world is uneven, which may indirectly reflect the public demand and cognition of functional oligosaccharide. The health benefits of oligosaccharides are known in varying degrees; there are almost 70% people in Japan who have a deep realization on oligosaccharide, France with 16%, Germany with 9%, and Britain with 3%. So the relevant departments need to strengthen publicity to improve social awareness of functional oligosaccharides. Improving the flavor and nutritional value of nutraceuticals, beverages, and daily food is also an effective method for wider usage in food.

The market for oligosaccharides is already steady and continues to grow gradually. Among the markets, the production levels of some oligosaccharides like FOS and GOS are quite mature and widely deployed. However, the quantity production of the novel oligosaccharides like HMOs still remains in the primary stage. Now, manufacturers of infant formula are using FOS and GOS as affordable substitutes to HMOs because of the low cost and good effect. Hence, these alternatives to human milk oligosaccharides may restrict the application of oligosaccharides in

infant formula to a large scale. Several companies have applied oligosaccharides into food around the world, but applying HMOs into infant formula or other food are costly. However, to decide which compound should be added, the concentrations or combinations of oligosaccharides are needed to correctly determine across abundant tests. Synthetic method is an area which is not fully explored. The output of oligosaccharides can be further increased by efficient separation technique from much more resources. Recently, daily foods and infant foods contain more than one type of oligosaccharide, which encouraged the manufactures and food developers to explore a new and efficient combination of these oligosaccharides used in food. The desired combination of oligosaccharides may help to meet the human body's needs for nutrient and to improve the health value and texture of daily foods.

Growing evidence also clearly demonstrates that the functional oligosaccharides have plenty of physiological function, and part of them are applied in food as nutrient supplements. But in 2018, a new republished article pointed out that the soluble fiber leads mice to liver cancer under the condition of intestinal flora imbalance. Moreover, a mass of clinical trials are expected to confirm the protective effects of the functional oligosaccharide. The public had best abide by dietary guideline in their countries with a proper diet to avoid gut dysfunction. The daily intake dose of oligosaccharides in a safe threshold value is also important. Patents are the sign of inventiveness which can promote the application of oligosaccharides in a larger market. It is necessary to invent more valuable patents in oligosaccharides area to decrease the production cost, increase profits, and range extension application with new technologies and idea. The future of oligosaccharides products seems to be highly promising.

Acknowledgments This study was supported by the Science and Technology Innovation Project (CXZX2017291) and International Science and Technology Cooperation and Exchange Program (KXb16011A) of Fujian Agriculture and Forestry University.

Abstract

Saponins belong to the group of plant glycosides widely distributed in more than 100 families of both wild and cultivated plants and in some marine organisms. They consist of the steroidal or triterpene hydrophobic aglycone and one to three sugar chains (hydrophilic part) attached by ester or ether linkage. Based on number of chains attached to the aglycone, they can be categorized as monodesmosides, bidesmosides, or tridesmosides. To this group of compounds, the glycoalkaloids are also included. Some saponins may contain in their structures (in aglycone part or in sugar chain) glucuronic acid, what makes them acidic. A big number of structurally divergent compounds have been described. Their structures and concertation can be different even in the organs (roots, rhizomes, stems, bark, leaves, seeds, and fruits) of the same plant species. Depending on the structure, they express different biological activities. Triterpenoid saponins can be found in many legumes (alfalfa, soybean, chickpeas, beans, peanuts, broad beans, kidney beans, and lentils), ginseng roots, sunflower seeds, horse chestnut, liquorice roots, spinach leaves, tea leaves, quillaja bark, quinoa seeds, sugar beet, or alliums species. Steroidal saponins can be found in oats, *Yucca*, tomato seeds, yam, fenugreek seeds, ginseng roots, asparagus, aubergine, or capsicum peppers. Glycoalkaloids are characteristic compounds mostly for Soalanaceae species. In general these compounds show no or little toxicity and do not seem to be of hazard for consumers. Depending on the structure, they express different biological activities. In general, saponins have been related to immunostimulatory, hypocholesterolemic, antitumor, anti-inflammatory, antibacterial, antiviral, antifungal, and antiparasitic activities. The major feature of these compounds is their sterol affinity, which seem to be responsible for most of activities they express. When consumed they may provide different health benefits, out of which cholesterol reducing activity is most pronounced.

Keywords

Steroidal saponin · Triterpene saponins · Glycoalkaloids · Sterol affinity · Cholesterolemic activity

32.1 Introduction

Saponins are the group of naturally occurring glycosides which predominate mainly but not exclusively (lower marine animals), in the plant kingdom. They can be found in different plant parts including roots, shoots, flowers, and seeds. The common feature of most of the saponins is the formation of soapy lather when shaken in water solution. In earlier work, saponin distributions in plants were based on this test. In Orient, saponins were used in traditional folk medicine or as a soap, and thus, in many cases, common names of saponin rich plant species are derived from this feature, e.g., soapwort (*Saponaria officinalis*), soaproot

(*Chlorogalum pomeridianum*), soapbark (*Quillaja saponaria*), soapberry (*Sapindus saponaria*), and soapnut (*Sapindus mukurossi*) (Hostettmann and Marston 1995). Some of them find a commercial application as drugs and medicines, adjuvants, taste modifiers, emulsifiers, precursors of hormone synthesis, and sweeteners.

Saponins are complex molecules consisting of nonsugar aglycone coupled to sugar chain units. These sugars can be attached as one, two, or three sugar chains, and hence, the terms of monodesmoside, bidesmoside, and tridesmoside have been given to these saponins, respectively (Greek desmos = chain). The saponins can be divided into two groups containing triterpene or steroidal aglycones – sapogenins (Fig. 1). Some authors also include within the saponins steroidal glycoalkaloids of solanidans and spirosolan classes (Fig. 2). Both triterpene and steroidal aglycones may have a number of functional groups (-OH, -COOH, $-CH_3$). Thus, the number of functional groups and different possibilities of sugar chain composition and attachment causes great natural diversity of saponin structures. Even within one plant species, different parts may harbor saponins with different structures.

Saponins are widely distributed in plant species, being reported in nearly 100 families. They can be found in plants used as human foods such as soya, beans, peas, oat, *Solanum* and *Allium* species, tomato, asparagus, tea, peanut, spinach, sugar beet, yam, and blackberry; in plants used as animal feeding stuffs including alfalfa, clover, legumes, forage and cover crops, sunflower, horse chestnut, guar, and lupine; and in plants used as flavorings, herbs, edible seeds,

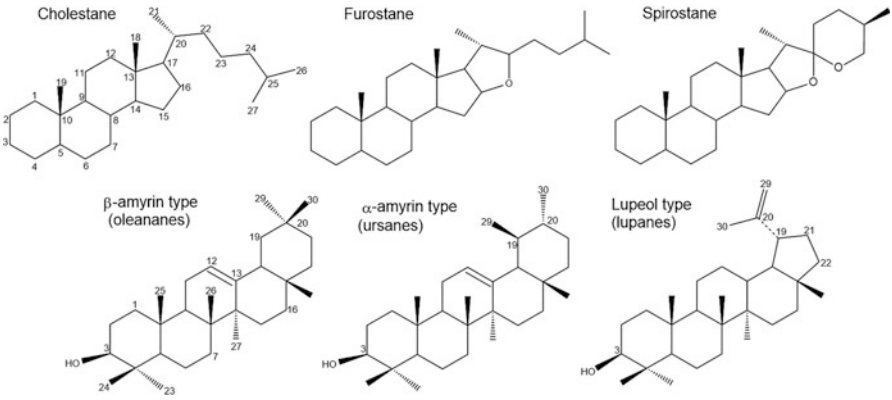

Fig. 1 Sapogenin skeletons – steroidal (upper raw), triterpene (lower raw)

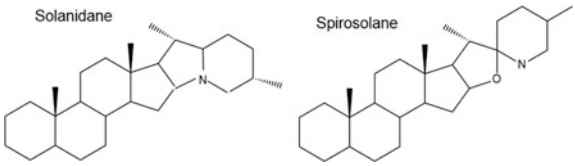

Fig. 2 Glycoalkaloid skeletons

health foods, tonics, etc. including fenugreek, liquorice, nutmeg, *Quillaya*, *Yucca*, *Gypsophila*, and ginseng. Their concentration in plants ranges from traces up to 10% of dry matter, as can be found in *Yucca schidigera* trunk. The concentration depends on the cultivar, plant age, physiological stage, and geographical location. There can be also considerable qualitative and quantitative variation among plant parts.

32.2 Bioactive Constituents of Food Products

32.2.1 Soybean

Soybean has been the world's largest source of protein for human and animal nutrition. Its global production reached about 348 million tons in 2016/2017 season. The key producers are the USA, Brazil, and Argentina, who collectively contribute to 81% to the global soybean production. Soybean seeds, besides having high protein content, contain some nutritionally important natural products such as isoflavonoids, vitamins, and fatty acids. Among these are also oleane-triterpene saponins. Early work on the structures of these compounds provided evidence that soybean saponins are composed of glycosides of three sapogenols, namely, soyasapogenol A (soyasaponins A1 and A2 (Fig. 3)), soyasapogenol B (soyasaponins I, II, III, IV, V, and VI) (Fig. 4), and soyasapogenol E glycosides (Kitagawa et al. 1982, 1984).

R1	R2	Soyasapogenol A
Glc (1-2)-Gal (1-2)-GlcA-	Glc (1-2)-Ara-	Soyasaponin A1
Gal (1-2)-GlcA-	Glc (1-2)-Ara-	Soyasaponin A2

Under acid hydrolysis, some additional soyasapogenols C, D, F, and G were also identified, but they were recognized as artifacts arising from soyasapogenol B (Jurzysta 1984). Later work of Shiraiwa and co-workers (1991a; b) introduced new nomenclature to the soyasaponins. The basic principles of this nomenclature is based on the recognition of only two aglycones, which are soyasapogenol A

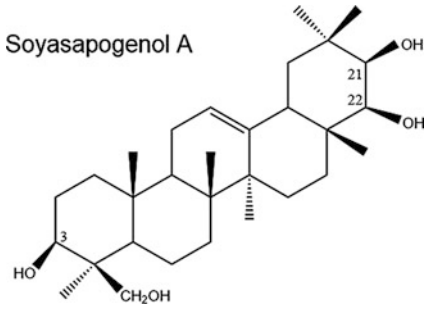

Fig. 3 Soyasapogenol A-derived saponins

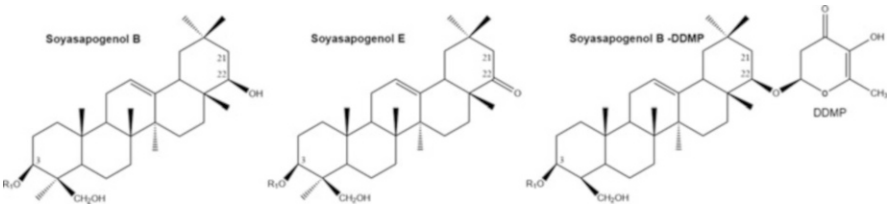

Fig. 4 Soyasapogenol B and E glycosides identified in soybean (soyasaponins according to Kitagawa et al. (1984) and names in parenthesis according to Tsukamoto and Yoshiki (2006))

(group A saponins) and DDMP (DDMP saponins). DDMP in this case was characterized as 2,3-dihydro-2,5-dihydroxy-6-methyl-4Hpyran-4-one(DDMP)-conjugated soyasapogenol B (Fig. 3). The DDMP saponins degrade easily to soyasapogenol B and E glycosides, which take place during separation and workup process. Similar γ-pyron substituted saponins (with trivial name chromosaponin I or soyasaponin VI) were identified in etiolated pea seedlings (*Pisum sativum*), mung bean (*Vigna mungo*), cowpea (*Vigna sinensis*), and alfalfa seeds.

Soyasapogenol A can be substituted with two sugar chains at the C-3 and C-22, and a number of different substitution combinations were identified. Substitutions at C-3 may include -GlcUA-Gal-Glc, -GlcUA-Gal-Rha, -GlcUA-Gal, -GlcUA-Ara-Glc, -GlcUA-Ara-Rha, and -GlcUA-Ara; the C-22 sugars include -Ara-Glc, Ara-Xyl, and Ara. The terminal sugars at C-22 can be fully or partially acetylated, which shows big structural diversity of this group of saponins. Tsukamoto and Yoshiki (2006) reported 50 structurally different saponins, while Chitisankul and co-workers (2018), using ultrafast chromatography system LC–PDA–MS/MS, were able to detect 105 structurally divergent saponins in hypocotyls and cotyledons of nine soybean varieties.

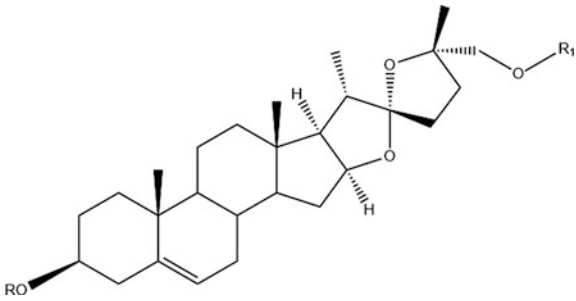
Glc(1-2)-Ara(1-2)-GlcA-	Soyasaponin VI	(Bx)	(Bf)	(αa)

32.2.2 Oats

Oats (*Avena sativa* L.) are very important source of livestock feed worldwide as nutritious grain or as forage. This is the grain crop with highest protein, fiber, and mineral content as compared to other grains. Its production worldwide decreased dramatically during last 50 years, but at present, it constitutes about 2% of global

Fig. 5 Oat saponins



grain production, but in some countries, this accounts for 5%. Oats are also used in the production of human food products, e.g., oatmeal, oat flower, oat bran, and oat flakes. These products are used for breakfast cereals and as ready-to-eat oat products. They can be included in gluten-free diets.

Chemically, oat hulled seeds are good source of water-soluble fiber, antioxidants, tocols, phenolic acids, aventhramides, flavonoids, and sterols. They also contain steroidal saponins. This is worth to notice that *A. sativa* is a unique plant species, which contains two types of saponins, steroidal saponins (avenacosides) in aerial parts and triterpene saponins (avenacins) in roots. The grain contains four saponin glycosides, including avenacoside A, avenacoside B, desglucoavenacoside A, and desglucoavenacoside B (Fig. 5). Very recently it was documented that one of the glucoses is sulfated, and the compounds were identified as nuatigenin 3-*O*-{α-L-rhamnopyranosyl-(1-2)-[β-D-6-*O*-sulfoglucopyranosyl-(Barakat et al. 2015; Böttcher and Drusch 2017; Bushway et al. 1994; Chitisankul et al. 2018)]-β-D-glucopyranoside}-26-*O*-β-D-glucopyranoside (Pecio et al. 2012). These sulfo-derivatives occurred in trace amounts. The average total concertation of saponins in oats grain as determined for sixteen varieties was 685 μg/g, while in oat husks, it was 25 μg/g of dry matter (Önning et al. 1993; Pecio et al. 2013).

Glycoside	R	R_1
Avenacoside A	Glc(1-4)[Rha(1-2)]Glc-	Glc
Avenacoside B	Glc(1-3)-Glc(1-4)[Rha(1-2)]Glc-	Glc

26-Desglucoavenacoside B	Glc(1-3)-Glc(1-4)[Rha(1-2)]Glc-	H

32.2.3 Alfalfa Seedlings

The human consumption of alfalfa products is generally low, but in some countries, especially in Orient, alfalfa sprouts are being used as a green salad. Sprouts are usually added to soups, on top of sandwiches, and to salads. It is estimated that 100 g of sprouts contain 23 cal, 2.1 g carbohydrates, 3.99 g protein, 0.69 g fat, 1.9 g fiber, 30.5 μg vitamin K, 8.2 mg vitamin C, 36 μg folate, 0.2 mg manganese, 0.2 mg

copper, 70 mg phosphorus, 27 mg magnesium, 0.1 mg riboflavin, 0.9 mg zinc, 1 mg iron, 0.1 mg thiamine, and 155 IU vitamin A.

But alfalfa contains also saponins, which at least in relation to animal nutrition, are recognized as antinutritional compounds. Early studies on alfalfa seedlings showed that they can be extremely rich with saponins (8–10% of DM) due to rapid synthesis of biologically active saponins in germinating seeds and sprouts. Reinvestigation of the germination process performed with analytical HPLC procedure provided completely different picture of saponin synthesis in alfalfa seedling (Oleszek 1998). It was documented that for the first 3 days of germination process, only soyasaponin I can be detected at the level of 2.12 μmol/g, the same as in genuine seeds. On the 4th day of germination, the synthesis of medicagenic acid glycosides started. The first compound of this group was monodesmosidic 3-*O*-glucoside of the medicagenic acid. Its concentration was increasing gradually and established at the level of 1.2–1.3 μmol/g after 11th day of germination. On the 5th day, bidesmosidic 3GlcA,28AraRhaXyl medicagenic acid and on the 6th day 3Glc,28Glc medicagenate were observed. Their concentrations ranged between 0.82% and 1.8% DM and between 0.06 and 1.04 μmol/g, respectively, and after 10 days showed quite stable levels. Zahnic acid tridesmoside (3GlcGlcGlc,23Ara,28AraRhaXylApi 16-OH medicagenate), one of the dominant compounds of alfalfa tops, appeared for the first time after 12 days of seedling growth at the concentration, which was comparable to that of medicagenic acid glycosides.

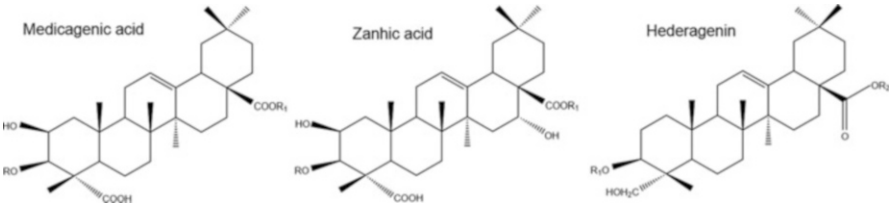

Fig. 6 Alfalfa saponins

Thus, 2-week-old seedlings presumably contain full spectrum of alfalfa root and top glycosides of medicagenic acid, zanhic acid, and hederagenin (Fig. 6). Additionally, soyasaponin I (for structure see section soybean) is also one of major components of roots and tops. The consumption of the sprouts as a garnish should not create health hazards. However, this should be kept in mind that medicagenic acid glycosides are hemolytic. They bind intestine membranes, increasing their permeability, while zanhic acid glycosides show throat irritating properties (Oleszek et al. 1992, 1994).

32.2.4 Beans and Peas

The worldwide production of bean and pea during last few years ranges around 22.5 and 13 million metric tons, respectively. They are recognized as a rich protein source in human and animal nutrition. The incorporation of legume ingredients into commonly consumed food products represents a viable alternative for complementing the protein deficiency in developing countries. Legume-based ingredients are being used to develop breads as a potential means of decreasing the risk of cardiovascular disease (Barakat et al. 2015).

All of the grain legumes possess saponins as a chemical ingredient, usually the group B saponins (Bb, Be, and βg). Soyasaponin I (Bb) has been found in numerous legumes, including kidney bean (*Phaseolus vulgaris*), runner bean (*P. aureus*), butter bean (*P. lunatus*), scarlet runner bean (*P. coccineus*), field bean (*Vicia faba*), lentil (*Lens culinaris*), and pea (*Pisum sativum*). Chickpeas

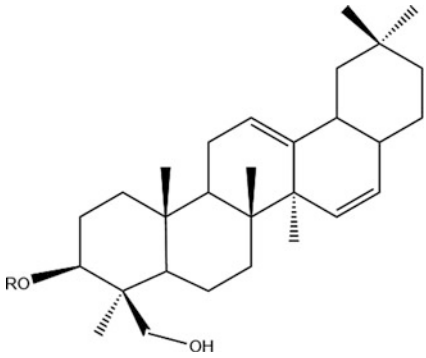

Fig. 7 Phaseollosides D and E

(*Cicer arietinum*) contain mainly soyasaponin βg and lower amounts of Bb and Be (Serventi et al. 2013).

Kidney bean (*Phaseolus vulgaris*) contains additionally glycosides of ursa-12,15-dien-3,24-diol, so-called phaseollosides A to E. Two major glycosides, phaseollosides D and E, are presented in Fig. 7.

Glycoside		R
Phaseolloside	D	Rha(1-6)[Gal(1-2)]Glc(1-4)Gal(1-2)Ara(1-3)GlcA-
Phaseolloside	E	Glc(1-4)Glc(1-4)Gal(1-2)[Rha(1-6)]Glc(1-4)Gal(1-2)Ara(1-3)GlcA-

The adzuki bean (*Vigna angularis*), known also as red mung bean, is widely consumed throughout East Asia. It contains, besides a high nutrient content, also the highest fiber content of all other beans. It contains also saponins which are glycosides of soyasapogenol B (azukisaponin II and V), sophoradiol (azukisaponin I), azukisapogenol (azukisaponin III and VI), and gypsogenic acid (azukisaponin IV) (Kitagawa et al. 1983a, b) (Fig. 8).

32.2.5 *Allium* Species

The genus *Allium* contains about 800 species distributed all over the world. They all contain saponins as natural products with different spirostanol, furostanol, and cholestane aglycones. Out of this huge number of species, three are important food products. This includes onions (*Allium cepa* L.), leek (*Allium porrum* L.), and garlic (*Allium sativum* L.).

Onions contain a number of saponins of furostanol and spirostanol nature with most dominant aglycones, namely, diosgenin (25*R*)-spirost-5(6)-ene-3β-ol), (25*S*), ruscogenin (25*S*)-spirost-5(6)-ene-1β,3β-diol), and cepagenin (24*S*,25*R*)-spirost-5(6)-ene-1β,3β,24-triol). The identified structures are listed in Table 1.

Leek contains glycosides of the following aglycones: diosgenin, gitogenin [(25*R*)-5a-spirostane-2α,3β-diol], β-chlorogenin [(25*R*)-5α-spirostane-3β,6β-diol], porrigenin B [(25*R*)-5α-spirostane-3β,6β-diol-2-one], neoporrigenin B [(25*S*)-5-α-spirostane-3β,6β-diol-2-one], 12-ketoporrigenin [(25*R*)-5α-spirostane-3β,6β-diol-12-one], porrigenin C [(25*R*)-5α-spirostane-3β,6β-diol-2,12-dione], agigenin [(25*R*)-5α-spirostane-2α,3β,6β-triol], neoagigenin [(25*S*)-5α-spirostane-2α,3β,6-β-triol], porrigenin A [(25*R*)-5α-spirostane-2β,3β,6β-triol], neoporrigenin A [(25*S*)-5α-spirostane-2β,3β,6β-triol], and 2,3-seco-porrigenin [(25*R*)-5-α-2,3-secospirostane-2,3-dioic acid-6β-hydroxy-3,6-c-lactone] (Lanzotti 2005).

Garlic contains furostanol saponins occurring as pairs of inseparable HO-22α and HO-22β isomers. These include voghieroside A1/A2 and voghieroside B1/B2, having agapanthagenin as an aglycone; voghieroside C1/C2, possessing agigenin aglycone; and voghieroside D1/D2 and E1/E2, with gitogenin as an aglycone (Lanzotti 2012).

It possess also two spirostanol saponins including agigenin 3-*O*-trisaccharide and gitogenin 3-*O*-tetrasaccharide. In some other varieties additionally sativiside-R2, F-gitonin, dideglucoerubo side B, iso-eruboside B, sativoside B1, proto-eruboside B, and proto-iso-eruboside B were also identified (Sobolewska et al. 2016) (Table 1)

32.2.6 *Asparagus* (*Asparagus officinalis* L.)

Only white young shoots of asparagus are commonly used as a food product. They quickly turn green and woody. White shoots contain 93% of water and are low in calories and sodium, but they contain different vitamins and minerals. White shoots, in contrary to green ones, are bitter, and steroidal saponins are recognized as responsible for this bitterness. Asparagus saponins belong to the group of steroidal glycosides, which can be divided into furostanol and spirostanol types. On the enzyme or microbial activities, Glc from position C26 can be eliminated, as happens in many cases with steroidal saponins, with the formation of spirostan derivatives. Such compounds have been reported in literature as asparagosides A to I. The dominant saponin identified in this species is protodioscin (asparasaponin I) (Kawano et al. 1977; Corinna and Hofmann 2012) (Fig. 9).

Aglycone	Saponin trivial name	R

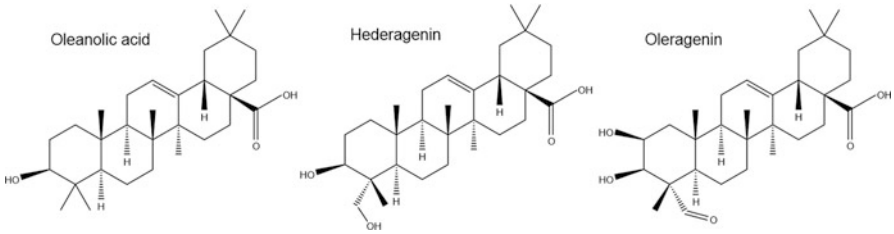

Fig. 10 Aglycones of the spinach saponins

32.2.7 *Spinach* (*Spinacia oleracea* L.)

Spinach leaves are commonly eaten as a vegetable, either fresh, frozen, canned, chipped, or dehydrated. Spinach, along with other green and leafy vegetables, contains an appreciable amount of iron, attaining 21% of the daily value in a 100 g. It also contains saponins, but the work on them is quite limited. An early work on spinach roots showed the presence of two monodesmodisic saponins – spinasaponin A, having oleanolic acids as the aglycone, identified as 3-*O*-[Glc(1-3) GlcA]-12-en-3β-ol-28-oic acid and spinasaponin B having hederagenic as the aglycone, identified as 3-*O*-[Glc(1-3)GlcA]-olean-12-en-3β,23-diol-28-oic acid (Tschesche et al. 1969). Next, a new bidesmosidic pentacyclic triterpenoid saponin, oleragenoside, was isolated from *Spinacia oleracea* L. plants (Mithöfer et al. 1999). Its novel aglycone, representing 2-hydroxy-gypsogenin, was named oleragenin. The structure was established on the basis of spectral data as oleragenin-28-*O*-β-D-glucopyranoside-3-β-*O*-D-glucuronopyranoside. All aglycones of spinach saponins are presented in Fig. 10.

32.2.8 Sugar Beet and Red Beet

The sugar beet root, as a row material for the production of sugar, was reported to contain triterpene saponin, being the glycosides of oleanolic acid (see Spinach saponins section). So far, two saponins were identified which were 3-*O*-GlcA and

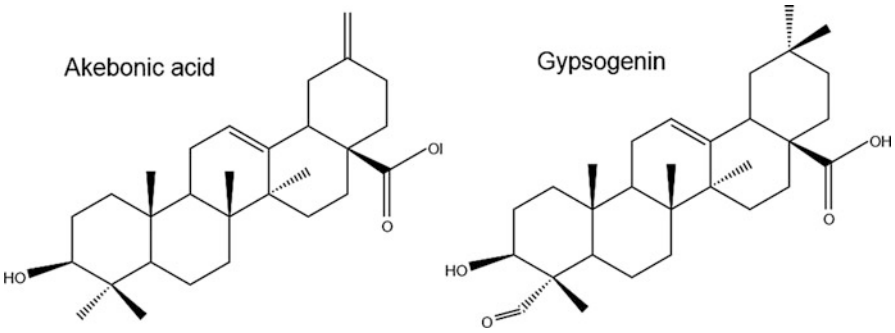

Fig. 11 Aglycones of red beet saponins

3-*O*-Glc of oleanolic acid. Similarly, ten betavulgarosides (I-X) were identified in red beet, with oleanolic acid glycosides as dominant saponins (Mroczek et al. 2012; Yoshikawa et al. 1996). Using hyphenated techniques, e.g., reversed-phase liquid chromatography, combined with negative-ion electrospray ionization quadrupole mass spectrometry, a number of minor saponins were identified in red beet extracts. In total, 44 saponins and 10 groups of isomers were detected and tentatively identified. The identified saponins were glycosides that consist of four different sapogenins, two of which were not previously detected in *B. vulgaris* L. These are akebonoic acid and gipsogenin (Mikołajczyk-Bator and Pawlak 2016) (Fig. 11). But again, the dominant saponins were confirmed to be oleanolic acid glycosides.

32.2.9 Tea Saponins

The total tea consumption of the world is 3,000,000 t a year. The highest consumption is recorded in India, China, and Japan. But, it is a popular drink almost all over the world. Tea leaves contain high amounts of phenolics with antioxidant activities. Nonetheless, they also contain saponins, which vary depending on the parts of plant (leaf, flowers, and seeds). The leaf saponins, that have so far been identified, contain theasapogenol B as an aglycone. Most of them are acylated with cinnamoyl group as a functional group, but acylation with angeloyl, tigloyl, and acetyl groups is also common. At present, ten different glycosides have been identified (Fig. 12).

Trivial name	R0	R1	R2	R3	R4
Theasaponin B1	Xyl(1-2)Ara(1-3)[Gal (1-2)]GlcA-	(E)-Cin	Ac	H	Ac

32.2.10 Potato Glycoalkaloids

Globally, potatoes are the world's fourth largest food crop after maize (corn), wheat, and rice. The tubers contain high amounts of carbohydrates (88% is starch) about 2% of protein and are a rich source of vitamin B6 and vitamin C. Nevertheless, potato aerial parts, as well as tubers, contain glycoalkaloids, which are generally recognized as toxic for consumers. Tubers contain glycoalkaloids, concentrated predominantly in a skin layer, and after peeling, they do not create health hazard. However, when exposed to the light, tubers may accumulate considerable amounts of glycoalkaloids and may be dangerous for health. New varieties of potatoes undergo screening for the glycoakaloid content, as their acceptable concentration in tubers should not be higher than 20 mg/100 g fresh weight. Concentration higher than 20 mg causes bitter taste of potatoes and a burning sensation in the mouth and throat. This should be also

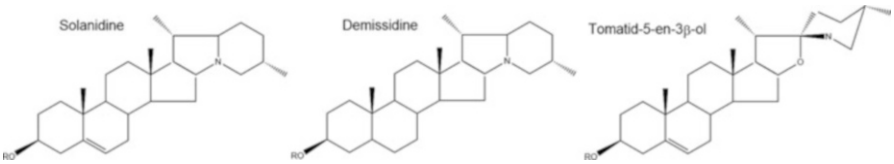

Fig. 13 Glycoalkaloids of potato tubers

mentioned that in animal feeding, tubers, peels, leaves, and sprouts are used. In such a case, care should be taken, as leaves, stems, and sprouts may contain 145, 32–46, and 997 mg/100 g fresh weight, respectively. Glycoalkaloids of the tubers are the mixture of two glycosides of solanidine, α-solanine, and α-chaconine, which are trisaccharides (Fig. 13), but some β and γ forms of these two glycosides, corresponding to di- and monosaccharides, were also detected. Moreover, the aglycone solanidine can also be present in plant tissue. The ratio of solanine to chaconine may widely vary in different varieties. The α-chaconine content may range from 1.7 to 13.5 mg/100 g fresh weight, while solanine values range from 0.58 to 5.9 mg/100 g (Kondamudi et al. 2017). This is an important issue for food safety as chaconine was proved to be more toxic than solanine. The aglycones are substantially less toxic as their glycosides. Nevertheless, generally, orally given potato glycoalkaloids are moderately toxic, because of relatively low gastrointestinal absorption. Some varieties of potato, which were bred for different kinds of resistance, using wild *Solanum* species, such as *Solanum chacoense*, *Solanum demissum*, and *Solanum commersoni*, may contain glycoalkaloids present in these species. Thus, other glycoalkaloids, such as α-solamarine and β-solamarine, demissidine and its glycosides demissine and commersonine (Fig. 12), as well as 3β-solanidan-3α-ol, can be found in new varieties (Friedman 2006).

Aglycone	Trivial name	R
Solanidine	α-chaconine	Rha(1-2)[Rha(1-4)]Glc-
Solanidine	α-solanine	Rha(1-2)[Glc(1-3)]Gal-
Demissidine	Demissine	Glc(1-2)[Xyl(1-3)]Glc(1-4)Gal-
Demissidine	Commersonine	Glc(1-2)[Glc(1-3)]Glc(1-4)Gal-
tomatid-5-en-3β-ol	α-solamarine	Rha(1-2)[Glc(1-3)]Gal-
tomatid-5-en-3β-ol	β-solamarine	Rha(1-2)[Rha(1-4)]Glc-

32.2.11 Tomato

The global production of tomatoes amounts to approximately 160 million tons annually, out of which a quarter is used for industrial processing, including pickled green, green fried, dried red, ketchup, pomace, etc. Nutritional value of these products is rather not high, but they contain antioxidants, carbohydrates, fiber, flavor compounds, minerals, proteins, vitamins, and calistegines. Health-promoting activities of some chemicals, e.g., lycopene, are well documented.

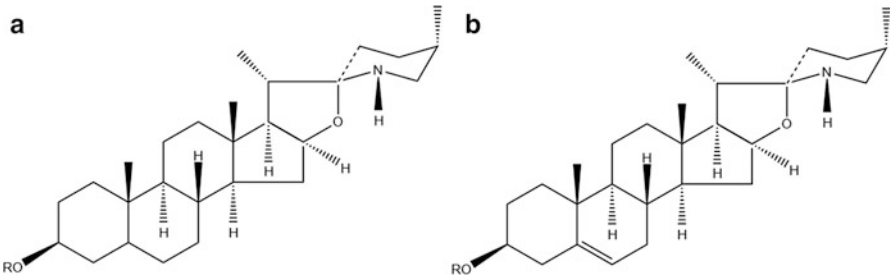

Fig. 14 Tomato saponins structures

However, tomatoes, like numerous solanaceous plant species, contain glycoalkaloids, which are recognized as not desired compounds. Tomatoes contain two glycosides – dehydrotomatine and α-tomatine (Fig. 14). Their concentration strongly depends on the fruit maturity. During ripening process, a sharp decrease in tomatine content is being observed, and fully mature fruits are almost free of these compounds. The tomatine content in green fruits (10 days after flowering) ranged from 500 to 800 μg/g, while the concentration of dehydrotomatine ranged from 40 to 70 μg/g of fresh weight. The ratio of dehydrotomatine to tomatine ranged from 1:9 to 1:12 and was similar in different varieties. In mini-tomato plants, total concentration of tomatines in green fruits was approximately 18,000 μg/g of fresh weight. Fifty days after flowering, total tomatine concentration dropped to nearly zero (1.5–3.7 μg/g of fresh weight) (Kozukue et al. 2004). The concentrations of tomatine in the processed tomato products, such as juice, red sauce, fried green, microwaved green, ketchup, pickled green, tomatillos, and canned tomato sauce, were 28, 57, 11, 12, 25, 28–120, 6, and 64 μg/g, respectively. Tomatine is a biologically active molecule, as shown by its ability to disrupt cell membranes, bind cholesterol, inhibit acetylcholinesterase, and perturb acid-base equilibria in vivo. Like some other saponins, it is also hemolytic and increases the permeability of membranes of the surface of averted rat jejunal sacs. Thus, the increase in gut permeability may be associated with some forms of food allergy.

Aglycone	Trivial name	R
A (25S)-22βN-5α-spirosolan-3β-ol	Tomatidine	H
	α-tomatine	Xyl(1-3){Glc(1-2)]Glc(1-4)Gal
B (25S)-22βN-spirosal-5-en-3β-ol	Tomatidenol	H
	Dehydrotomatine	Xyl(1-3){Glc(1-2)]Glc(1-4)Gal

32.2.12 Concentration of Saponins in Food Plants

The concentration of saponins in different raw plant products (Table 2) ranges for particular species from trace amounts to quite high concentrations. This depends strongly on many parameters, including variety, growth conditions (fertilization,

Table 2 Saponin contents in food and feed plants

Species	Common name	Concentration (% DW)
Allium cepa	Onion	0.02–0.5
Allium porum	Leek	0.10–1.0
Allium sativum	Garlic	0.09–1.5
Asparagus officinalis	Asparagus	1.5
Avena sativa	Oats	0.1–0.2
Beta vulgaris	Red beet	0.7–1.2
Cicer arietinum	Chickpea	0.26–6.0
Glycine max	Soybean	0.5–2.5
Lens culinaris	Lentil	0.1–0.5
Lycopersicon esculentum	Tomato	
	Green	0.03–0.12
	Red	0.00–0.05
Medicago sativa	Alfalfa sprouts	0.6
Phaseolus aureus	Runner bean	0.34
Phaseolus lunatus	Butter bean	0.10
Phaseolus vulgaris	Kidney bean	0.35–1.6
Pisum sativum	Pea	0.01–0.18
Solanum tuberosum	Potato	0.02–0.06
Spinacia oleracea	Spinach	0.07–4.7
Vicia faba	Field bean	0.35
Vigna angularis	Adzuki bean	0.02–0.4
Vigna mungo	Mung bean	0.05–0.57
Vigna sinensis	Cowpea	0.06–0.5

temperature, and water availability, light), the harvest stage, and some post-harvest storage conditions. Very important is also the technique of measurement. In older literature, where concentration was determined with gravimetric, spectrophotometric, or densitometric techniques, these values are usually quite high and should be considered as strongly overestimated. Modern techniques that include liquid chromatography with UV/MS detection provide lower values and are more reliable (Ha et al. 2014).

This should be considered that both steroidal and triterpene saponins are not toxic to humans and animals, or their toxicity is very low. Thus, even concentrations reaching 1–2% should not create any health problems.

Different situation appears in case of glycoalkaloids in potato and green tomato. USDA has defined consumption limits for total glycoalkaloids (TGAs) that should be lower than 200 mg/kg fresh weight (FW) or 1000 mg/kg dry weight (DW) in potato. It is well documented that concentration of α-solanine in potato higher than 140 mg/kg FW caused bitter taste and burning sensation in the throat and mouth. Moreover, in human, the noxious dose of TGA is 2–5 mg/kg body weight (BW), and the fatal dose is more or less 3–6 mg/kg BW. Most commercial potato tubers have been reported to contain between 200 and 600 mg/kg, and 40–120 mg/kg of

glycoalkaloids in freeze-dried material and FW, respectively. Concentrations of glycoalkaloids are typically three to ten times greater in the potato peel than flesh. Thus, peeling potatoes removes most of glycoalkaloids, but care has to be taken for storage of peeled potatoes, as glycoalkaloid concentration may drastically increase during 48 h after peeling. The concentration of glycoalkaloids may also substantially increase during the post-harvest storage of potatoes exposed to intensive light. Greening of tubers under such conditions is accompanied with substantial increase in glycoalkaloid level. Even though literature reports for total glycoalkaloid content in several potato varieties are available, the total glycoalkaloid content in commercial potato products is not reported, and its determination is often complicated by complex constituent mixtures of food ingredients. Thus, this is of great importance to measure glycoalkaloid content in raw material used for processing, as they are resistant to degradation by household or industrial food processing methods, including exposure to boiling water, oven baking, deep frying, and microwave irradiation.

For tomatoes, a range of 49.8–572.5 mg of tomatine per kg of FW of green tomatoes was reported (Bushway et al. 1994). Other sources indicate that dehydrotomatine and α-tomatine content of tomatoes varied from 42 to 1498 and 521 to 16,285 mg/kg of FW, respectively. The ratio of α-tomatine to dehydrotomatine ranged from 10.9 to 12.5 in tomatoes, and from 2.3 to 7.8 in the other plant tissues. This variation can also be explained by variety and developmental stages. Tomatine is almost nonexistent in red tomatoes, because it has been widely demonstrated that tomatine is degraded during ripening.

32.3 Bioactivities, Bioavailability, and Metabolism

Biological activities of saponins are structure dependent. Both in steroidal, as well as between triterpene saponins, there are compounds showing high biological activities and glycosides lacking any proven activity. It seems that the most important factor determining activity is the structure of aglycone, in particular, the number and the location of functional groups. For example, between triterpene saponins, those having soyasapogenols as the aglycone show limited activity, while those having more -OH or COOH groups, e.g., medicagenic acid, hederagenin, oleanolic acid, etc., show substantial biological activity. For those active compounds, the level of activity is strongly dependent on the number and the structure of the sugar chains. Generally, monodesmosides show much higher activities than bi- or tridesmosides (Table 3).

The most important feature of saponins, determining their activity, is the sterol affinity of some of them. Saponin molecule possesses hydrophobic aglycone and very polar sugar chain. Hydrophobic part may react with sterols of membranes, changing their permeability. When saponin binds the erythrocyte cell membrane, it causes membrane disruption and lysis of the cell. Such hemolytic effect eliminates some saponins to be used as pharmaceutical or as food additive.

Sterol affinity was the basis for application of some saponins as cholesterol-lowering agents. Alfalfa saponins supplemented diet lowered total plasma

Table 3 Biological activity of saponins from different food plant species

Plant source	Activity
Allium	Cytotoxic, antifungal, enzyme inhibitory, cardioprotective, antispasmodic, anti-inflammatory, gastroprotective
Oat	Antioxidant, antifungal, increase intestinal permeability, inhibition of lactase activity
Beta vulgaris	Inhibition of glucose absorption, increase motor activity and blood serum α-lipoproteins, decrease blood serum pre-β-lipoproteins and erythrocyte osmotic resistance, inhibition of *Streptococcus mutans*, hemolytic
Chickpea	Antimicrobial
Soybean	Reduce growth performance and feed efficiency in fish, antioxidant activity, decrease of blood pressure, antiproliferative activity, modulate nutrient sensing pathways and metabolism, induce intestinal inflammation
Lentil	Inhibition of digestive enzymes
Tomato, potato	Antiprotozoal, anticancerogenic, antimalarial, liver cancer inhibition
Beans and peas	Inhibition of digestive enzymes, antitumor promoters in carcinogenesis, cytotoxic against cancer cells, regulation of cell proliferation, inhibitory effects against digestive enzymes, pancreatic lipase, and α-glycosidase
Alfalfa	Hemolytic, antifungal, antimicrobial, cholesterol reducing
Tea	Antimicrobial, active for gastrointestinal tumor, anti-inflammatory, anti-acne, preventing hemorrhoid, insecticidal, antialcoholic function, antioxidant
Garden balsam	Anti-hepatic fibrosis
Tiger's tail	Antidiabetic
Ginseng	Anti-inflammatory, anticancer, treatment of hypertension, vertigo and acute faucitis, cardiac remodeling induced by simulated microgravity, inhibiting platelet adhesion to injured endothelial cells, reduce all-cause mortality, myocardial infarction (MI), revascularization, rehospitalization for unstable angina, neuroprotective
Teas	Modulation of gastrointestinal system, anti-cancer, anti-inflammation, anti-microorganism, antioxidation, neuroprotection, hypolipidemic effects, foaming and detergence
Balloon lower	Enhances exercise function, skeletal muscle protein synthesis, and mitochondrial function
Quillaja saponaria	Immunomodulatory activity
Akebia	Reverses corticosterone hypersecretion in AD
Wild vegetable *Aralia elata*	Neuroprotective
Licorice	Anti-inflammatory
Amaranth vegetable	Hemolytic

cholesterol. The effect being prominent, when cholesterol was absent in the diet. But saponins supplementation did not exert any significant effect on the total liver lipids. Several possible mechanisms have been suggested to explain the hypocholesterolemic activity of saponins. However,

the exact mechanism of this activity remains unclear. The hypocholesterolemic effect of saponins could be directly correlated with their ability to decrease intestinal

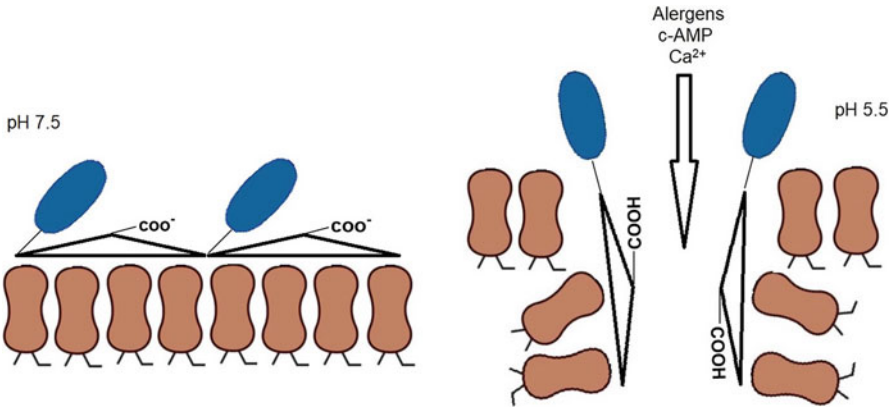

Fig. 15 Configuration of saponins at intestine membrane at pH 7.5 (left) and pH 5.5 (right). Triangles represent aglycone part, blue ellipse represent sugar chain. Brown parts represent hydrophobic intestine bilayer

cholesterol absorption and the increase the fecal excretion of bile acids. However, after ingestion, the nature and extent of the gastrointestinal microbial metabolism of saponins, i.e., the bioaccessibility and bioavailability of dietary saponin components are still lacking (Zhao 2016). Sterol affinity is also responsible for the moderation of the permeability of intestinal mucosa cells and change the absorption and excretion in the small intestine. Sterol binding and permeation of the epithelial barrier may have nutritional consequences. It may cause disorders in the absorption of important microelements or enhance the absorption of allergens (Fig. 15). The effect is strongly pH dependent. At neutral or slightly alkaline conditions, the aglycone (hydrophobic part) is bound to the epithelial cell layer, while in acidic condition, the aglycone penetrates the layer and disrupts the regular structure, making permeable holes in the intestine.

Similar mechanisms are most probably responsible for antimicrobial activity of saponins (Oleszek 2000). The general principle of the action of saponins on microorganism is their interaction with membrane sterols. Thus, the bacteria should not be sensitive to saponins, as their membranes are low in cholesterol. However, recent report on the saponin-sensitive and insensitive *Trichoderma viride* strains indicates that fatty acid composition of membranes may equally be important in this respect. The major effect of saponins on bacteria is the leakage of protein and certain enzymes from their cells.

Antifungal activity is generally demonstrated by saponins with triterpene and spirostanol skeleton. Furostanol saponins, which have bidesmosidic nature, do not complex with sterols and do not exhibit bacteriostatic or antifungal activity. Thus, the mechanism of antifungal activity seems to be dependent also on sterol affinity. Complexing with membrane sterols, proteins, and phospholipids seems to be a major mechanism that predisposes sensitivity of a microbe to saponins, but the effect is relatively nonspecific. Examples of antimicrobial, antifungal, antiviral, and cytotoxic activities of food plants, but also some medicinal plants, are presented in Tables 4, 5, 6, and 7.

Table 4 Antimicrobial activity of saponins from different plant sources. (modified after Oleszek 2000)

Plant source	Type of saponin	Microbe sp.	MIC

It has been proven that saponins exert positive influence on ruminants. *Y. schidigera* plant extract has been found to improve growth, feed efficiency, and health in ruminants. Similarly, *Quillaja* and lucerne saponins have been investigated as agents increasing the efficiency of in vitro rumen-microbial protein synthesis, significantly reducing the total protozoa count in the rumen and decreasing feed protein degradability. The influence of saponins on protozoa resulted from their binding with sterols present on the protozoa surface, which lead to the destruction of the cell (Szumacher-Strabel and Cieślak 2010).

Beneficial effect of saponins on ruminants is associated also with their ability to bind ruminal NH_4 at its high concentration, and release NH_4 again, when it is at low concentration. It provides a continuous, adequate supply of NH_4 for microbial protein synthesis (Francis et al. 2002).

Saponins in animal feed are very helpful in mitigation of methane emission from animal excretes. This emission is very harmful for environment, because methane is one of the main greenhouse gases (GHG). Moreover, loss of methane from the fermentation processes occurring in the rumen, deteriorates feed utilization, and thus

decreases the economic effect of animal maintenance (Szumacher-Strabel and Cieślak 2010). Many studies proved that supplementation of feed with saponins reduced the methane production in the rumen, due to the negative effect on protozoa population, providing hydrogen for methanogens. Mitigation of methanogenesis results from a decreased methanogenic activity, without changing the total methanogen numbers, because methanogens cells do not include cholesterol (Cieślak et al. 2013).

Dietary saponins, particularly from lucerne, were often suspected of causing ruminant bloat, though clear experimental proof for this is lacking in the literature. There were some literature data showing bloating in animals fed with alfalfa, but there is not hard proof that saponins are responsible for that. However, in experiment with hamsters, where alfalfa saponin solutions were orally introduced, the production of gases in the intestine was observed, causing discomfort for experimental animals.

Table 7 Cytotoxic activity of saponins. (modified after Oleszek 2000)

Saponin	Plant species	Cytotoxicity	Concentration
Arginine C	*Palaquium formosanum*	prostate	13.8 mmol
Diosgenin, dihydrodiosgenin	*Dracena afromontana*	KB cells	10 μg/ml
Diosgenin glycosides	*Paris polyphylla*	KB cells	0.16–0.29 μg/ml
		P-388	0.22–0.44 μg/ml
		L-1210	0.14–043 μg/ml
Diosgenin glycosides	*Balanites aegyptiaca*	P-388	0.21–2.4 μg/ml
Echinocystic acid octaglyc.	*Entada phaseoloides*	L-5178 Y	0.83 μg/ml
Ginsenoside R_{b2}	*Panax ginseng*	RLE, B16	Not effective
		HRA	10–100 μmol
α-Hederin	*Hedera helix*	B 16	5 mg/ml
Holestane glycosides	*Holothuria forskalii*	P-388	0.38–0.46 μg/ml
Oleanolic acid diglycoside	*Panax zingiberensis*	MT-4	46.2 μmol
Pectiniosides A-F	*Asterina pectinifera*	L 1210	8.8–11 μg/ml
		KB	10–11.5 μg/ml
Saikosaponins	*Buphlerum wenchuanese*	PLC/PRF/5	20–50 μg/ml
"Sho-saiko-to" medicine		Hep-G2	
Saikosaponi-acetylglycosyl		P-388	<5 μg/ml
Sarasinoside A1	*Asteropus sarasinosum*	P-388	2.8 μg/ml
Sarasinosides D-G		A-549	7.4 μg/ml
		HT-29	4.55 μg/ml
		P-388	3.62 μg/ml
		B 16-F 10	9.62 μg/ml
Solamargine	*Solanum* spp.	PLC/PRF/5	1.53 μg/ml
Khasianine		PLC/PRF/5	8.60 μg/ml
Spirostanol glycosides	*Chamaedorea linearis*	L 1210	32 μmol
Trillin	*Dracaena afromontana*	KB cells	100 μg/ml
Triterpene glycosides	*Dysoxylum cumingianum*	MOLT-4	0.0045–0.0062 μg/ml
Triterpene glycosides	*Myrsine australis*	P-388	0.85 μg/ml
Tubeimoside 1	*Bobolstemma paniculatum*	GOTO	0.24 μmol/l
		A-172	0.15 μmol/l
		PANC-1	0.27 μmol/l
		COLO 320 DM	0.43 μmol/l
Yamogenin glycosides	*Balanites aegyptiaca*	P-388	0.21–2.40 μg/ml
Zingiberoside R1	*Panax zingiberensis*	MT-4	84.4 μmol

Some saponins may influence on activity of different enzymes involved in digestion or other metabolic processes. Total saponins of radix and flower of ginseng, which have high content of saponins, were able to inhibit the

inflammatory-related transcriptional activities and the related mRNA expression of IFNα, TNFα, il-6 and TGFβ, as well as induce anti-oxygen NrF2 activities.

The research on commonly consumed food legumes produced in China proved their inhibitory effects against digestive enzymes, pancreatic lipase, and α-glycosidase. Saponin extracts from the adzuki bean and rock bean exhibited inhibitory effects against α-lycosidase. The results indicate that adzuki bean is one of the best target beans for further study on their anti-obesity and antidiabetic effects.

The avenacosides present in *Avena sativa* seeds inhibited the lactase activity significantly in vitro. However, in vivo studies showed no or small effects due to the low avenacosides concentration found in oats. The in vitro hydrolysis of starch by α-amylase was increased in the presence of saponins, probably due to their detergent effect. Thus, the in vitro studies showed that the avenacosides could influence the enzyme activities.

Saponins may show some features discouraging feed intake by animal. Some of them are recognized as bitter compounds, while the others, e.g., zanhic acid glycosides from alfalfa show strong throat-irritating activity. However, since the concentration of saponins in most food and feedstuffs is low, these effects are not of great importance in their acceptance. Inclusion of purified alfalfa saponin in Bengalgram diet, showed no interference with food intake and food efficiency ratio during 47 days of feeding experiment. Saponin supplemented diet lowered total plasma cholesterol. This effect was prominent when cholesterol was absent in the diet. The hypocholesterolemic effect of saponin could be directly correlated with their ability to decrease intestinal cholesterol absorption and the increase of the fecal excretion of bile acids.

Most of research performed on the influence of saponins on animal performance can be question. The reason for that is poor characterization of feedstuff. Instead of pure saponins, rather poorly characterized plant material is being used in experiments and, in fact, it is difficult to precisely say which plant component is responsible for the observed effect.

Many research data show that saponins generally are not absorbed from the digestive tract into blood stream. In the chamber experiment with segments of proximal rats' small intestine, it was found that avenacosides from oats do not pass across intestinal epithelium. No saponins were, however, detected in feces collected from rats given avenacosides. In experiments with chicken, rats, and mice fed soybean saponins, no saponins or sapogenins were detected in the blood indicating they were not absorbed. At the same time, saponins in all three animal species were detected in small intestine, but in the cecum and colon, only sapogenins were found. This indicated that saponins were hydrolyzed by colonic microflora or by enzymes in the lower part of intestine.

In experiments with zebrafish fed soybean saponins, some metabolic disturbances and growth reduction were observed. Saponins fed at the concentration of 5 and 10 g/kg of diet significantly reduced growth performance and feed efficiency, and damaged the morphology of intestinal mucosa. Saponins also increased the expressions of key metabolic enzymes involved in glutamine synthetase, glutamate

dehydrogenase and lipolysis, hormone-sensitive lipase, and lipoprotein lipase. This documented that saponins modulate nutrient sensing pathways and metabolism.

In experiment with hypertensive rats, feeding with soybean saponins 80 mg/kg of body weight per day for 8 weeks significantly decreased blood pressure. The mechanism of this activity remains unclear.

However, more epidemiological and clinical studies are required for the proper validation of these activities. For better understanding of these effects, more precise saponin products should be used and more sophisticated methods of evaluation of intact saponins, as well as their metabolites and degradation products, are required.

32.4 Benefits for Humans

As discussed above, saponins may exert differential biological activities depending on their structures. It is also quite evident that, when consumed in human diet, they show no toxicity at the doses present in foodstuffs. This is mostly due to the fact that their concertation in foodstuffs is rather low. Besides, their high molecular weight, poor stability under stomach condition and poor membrane permeability make them low bioavailable. It was suggested by recent research that the bioavailability can be enhanced by the application of different "absorption enhancers," which act as opener of cellular pathways of absorption. Bio-adhesive preparative containing saponins extend the time of preparation effects on target sites, increase the contact with the absorption membrane, change membrane fluidity, and increase saponin penetration to the intestinal epithelial cell, promoting absorption and oral availability (Li et al. 2017). These enhancers can be natural components of some foodstuffs such as fatty acids, phospholipids, as well as calcium chelators, surfactants, bile salts, and chitosan derivatives. Some other means of enhancing saponin absorption were also suggested. That includes usage of liposomes and nanoparticles as physical vehicles or esterification of saponins with fatty acids to increase their hydrophobicity. This may suggest that evaluation of the absorption level from the food matrix can be different from those observed with pure saponins. It should be also mentioned that bioavailability of saponins can be different for individuals. The paracellular permeability of intestinal epithelium can be individual characteristic or can be modified by some health disorders, e.g., diabetes. The bioavailability of saponins in different animals is also different. Some of the observed values were as low as 0.1% for saponins from ginseng (ginsenosides) in rats, or 3% in dogs, and as high as 90% for the sapogenin from licorice (glycyrrhetic acid), also in rats.

The bioavailabity of saponins may also be changed by the processing of saponin-bearing foodstuffs. It was documented that bioavailability of soybean saponins present in bread was in the range of 30–91%, depending on the structure.

The seeds of legumes, which are rich in saponins, are usually presoaked and cooked, which is accompanied by leaching of saponins. The level of leaching is dependent on the time of the process and on the seed to water ratio. Pre-soaking enhanced subsequent thermally induced degradation of the saponins and caused a high loss of the contents during the cooking processes. It was shown that in the

cooked lentils, bioaccessibility of soyasaponins was in the range of 9–10%. Another research showed that accessibility of saponin from lentil, soybean, fenugreek, and quinoa ranged between 30% and 100%. Several factors can influence this accessibility including concertation of saponins in the extract, presence of other food components, type of saponin, as well as the ratio of saponin to sapogenin in the matrix (Hierro et al. 2018).

The stability of saponins in vegetarian, broccoli-based bars incorporating chickpea, soy, and faba beans as protein sources after being subjected to different cooking methods were studied. Commonly domestic ways of bars preparation were microwaving, frying, frying and microwaving, steaming, and baking. It was shown that soaking and peeling of checkpeas and faba bean reduced saponin content by 8% and 35%, respectively. Particularly, DDMP saponins were affected (Barakat et al. 2015).

The major benefit of saponins in human nutrition seems to be their cardioprotective activity. Thus, it seems reasonable to introduce saponin-bearing plants such as alfalfa, onion, garlic, soybean, beans, and ginseng to inhibit the intestinal absorption of cholesterol and reduce serum cholesterol level. High saponin extracts from these plant species, as well as from some medicinal plants (*Terminalia arjuna*, *Clematis species*, *Glycyrrhiza glabra*, *Ilex cornuta*, *Crataegus oxyacantha*, *Astragalus membranaceus*), enriched with "absorption enhancers," may be a good solution for food supplements in routine intake for cardiac protection. Semisynthetic "designer saponins" with high saponin content have been of interest, and several patents were received.

Another possible feature benefit for consumer is vasorelaxant activity of saponins. The ginsenosides Rg1, Re, Rb, Rc, and Rg3 showed vasorelaxant activity by inhibiting Ca^{2+} influx via receptor-operated Ca^{2+} channels in vascular smooth muscle cells. Out of these, the ginsenoside Rg3 emerges as the most potent vasodilatory agent to open the Ca^{2+} activated K^{+} channel. Other activities of saponins in the prevention of human diseases are presented in Table 3.

32.5 Safety: Toxicity and Side Effects

Despite many beneficial effects of saponins on the human and animal health, the problem of their toxicity is still considered and important. As with all others substances, also in the case of saponins, the toxicity depends on the dose and the route of entry of chemicals into organism. Moreover, it should be mentioned that saponins, as the large group of compounds, varied much in the toxicity (George 1965).

It is commonly known that saponins are poison for fish. Nonetheless, the results of many studies proved that they are practically nontoxic to man upon oral ingestion, because they normally remain within the digestive tract (Oakenfull 1981). The problem with safety of saponins can occur, for example, in the case of severe poisoning of gastrointestinal lesions or irritation of the gastrointestinal tract by some causes, allowing saponins to enter into the blood stream. At that time, the intravenous lethal dose can be one thousandth of the lethal oral dose (George 1965).

The result of penetration of saponins into the blood may be liver damage, hemolysis of red blood cells, respiratory failure, convulsions, and coma. Therefore, it is recommended that people using drastic purgatives or having inflamed intestines or cirrhotic livers should avoid all foods containing saponins. Moreover, saponins can moderate the permeability of intestinal mucosa cells and change the absorption and excretion in the small intestine. It may cause disorders in the absorption of important microelements or enhance the absorption of allergens (Lásztity et al. 1998). Simultaneously, it is claimed that the saponins from soybeans, lucerne, or *Quillaia* are safe for short-term human-feeding trials at levels of below 50 mg kg^{-1} body weight per day (Oakenfull 1981; Lásztity et al. 1998).

Many saponins exhibit cytotoxic activity, which is a promising property for their anticancer application. Unfortunately, the hemolysis of red blood cells is a major drawback for the clinical development of saponins as antitumor agents (Gauthier et al. 2009). Structure–activity relationship (SAR) studies have recently been undertaken in order to explain the differences in the action between particular saponins and to select the most favorable compounds devoided of undesirable toxicity. It has been proven that both the nature of the aglycone and the osidic part are important for biological activity of saponins. Moreover, bidesmosidic saponins, bearing sugar moieties at both C-3 and C-28 positions, were generally less hemolytic toward erythrocytes than C-3 monodesmosides. Furthermore, the presence of nonnatural linkages (1,2-cis-glycosides) have detrimental effects both for the hemolytic and cytotoxic activities of saponins. However, there is no evident correlation between the hemolysis of red blood cells and cytotoxicity of saponins (Gauthier et al. 2009).

32.6 Marketed Products

The beneficial physicochemical and biological properties of saponins have been successfully exploited in a numerous commercial applications in food (Güçlü-Üstündağ and Mazza 2007). In some countries there are regulations describing the level and the source of saponins allowed to be used in food products. The two major commercial sources of saponins are *Quillaja saponaria* and *Yucca schidigera* extracts. As early as 1962, Quillaya saponins have been approved to be used as emulsifiers and foaming agents at maximal concentrations of 20 ppm in the UK. *Quillaja* extract is classified also by the European Union as a foaming agent for use in water-based, flavored nonalcoholic drinks. Its symbol on the list of ingredients is E999. Similarly, *Quillaja* and *Yucca* extracts rich in saponins received Generally Recognized as Safe (GRAS label) issued by Food and Drug Administration in the USA. *Quillaja*, *Yucca*, soybean, and enju saponins are accepted in food products also in Japan.

As natural nonionic surfactants, saponins find widespread use in food as emulsifiers (Oleszek and Hamed 2010). The ability of a saponin to foam is caused by the combination of the nonpolar sapogenin and water-soluble side chain. Hydrophilic part of saponins is built from a sugar chain, which can differ in the length, branching, substitution, and composition (glucose, galactose, rhamnose, arabinose, xylose,

apiose, and uronic acid), while the lipophiles may have a steroidal or triterpene structure. This is why saponins are recognized as nonionic surfactants. The strongest surfactant activity is showed by saponin with one sugar chain. An increase in the number and length of sugar chains decreases foaming characteristics, or sometimes, no foaming effect is observed. A great advantage of saponins, as emulsifiers over other synthetic emulsifiers, is their salt-free nature, which makes them less likely to be affected by alkaline or acid conditions (Zhu et al. 2019). Thus, saponins from different sources are being used in following food processing technologies:

- As emulsifiers of oil-based flavors for candy
- As substances preventing precipitation in a protein containing liquid composition
- As substances helping to prevent oil separation in mayonnaise
- As a leavening agent in the bakery industry
- As compounds increasing stability of cream when added to coffee
- As a natural dispersing agent for waxes used in food coatings

Application of *Yucca* extract to sugar-candy foam at the saponin concentration equivalent to 50 and 100 ppm proved its better foaming parameters that eggs whites. This extract had a beneficial effect on dry matter content, density, and porosity of sugar-candy foam products. Moreover, since *Yucca* extract contains also strong antioxidants, the shelf life of sugar-candy foams were substantially prolonged (Sucharzewska et al. 2003).

The main food products providing saponins to human and animal diet are vegetables containing these compounds such as beans and legumes, garlic, asparagus, spinach, oats, quinoa, and amaranth and lucerne sprouts. Despite the fresh vegetables available in the market, there are also products of their processing. The most popular prepared products containing saponins are tofu, falafels, and tempe. Saponins are present also in protein concentrates prepared from saponin-containing plants, mainly soya protein isolates, and leaf protein from lucerne.

According to the newest reports of Patra et al. (2018), the species *Panax ginseng* is the most widely cultivated and marketed species among phytochemicals-rich plants all over the world. This plant is distributed across approx. 35 countries, where market is subdivided based on its application in food products and dietary supplements, but also in pharmaceuticals, personal and oral care products. The worldwide ginseng production is estimated at more than 80,000 t. In 2015, the ginseng's global market of dietary supplements was valued at over US$ 123 billion. Moreover, it is assumed that the market's demand for ginseng will continue to remain strong throughout the 2016–2026 forecast period (Patra et al. 2018). Nowadays, there is the highest demand for the powdered form of ginseng, due to its extensive consumption as an energy booster.

Some saponins from non-food plants find application as food supplements. A good example is *Tribulus terrestris*, which is used in the folk medicine against sexual impotence, edemas, abdominal distention, and cardiovascular diseases (Kostova et al. 2002). Many pharmaceutical preparations and food supplements based on the saponin fraction from this plant are on sale worldwide. Another widely

Table 8 Plant sources for industrially utilized saponins (Böttcher and Drusch 2017)

Plant source	Common name	Use
Agave sisalana	Sisal, Henequen	Hecogenin source
Balanites aegyptiaca		Diosgenin source
Chlorogalum pomeridianum	Soaproot, California soap plant	Amolonin source surfactant
Costus speciosus		Diosgegnin source
Digitalis lanata	Purple Foxglove	Digitonin source
Digitalis purpurea	Digitalis	
Dioscorea composita	Yams, Barbasco	Diosgenin source
Dioscorea terpinapensis		
Dioscorea spp.		
Glycine max	Soybean	Soyasaponin source
Quillaya saponaria	Quillaya	Soaps, foaming agents
Chenopodium quinoa	Quinoa	Brewing, cosmetics, and detergent production
Smillax spp.		Smilagenin and sarsapogenin source
Solanum spp.		Solasodine source
Trigonella faenum-graecum	Fenugreek	Diosgenin source
Yucca schidigera	Mohave Yucca	Soaps, foaming agents
Avena sativa	Oats	Emulsifier

known food supplement for sexual potency and for body builders is produced from Bucher's broom (*Ruscus aculeatus)*, a plant containing ruscogenin and some other saponins.

Number of saponin containing plant species is being widely used for the production of saponin raw materials for pharmacy, cosmetic, and food industries. These are presented in Table 8.

32.7 Patents

The presence of saponins in food, as natural components and as additives, brings benefits both for consumers and for producers of food. The growing interest in their beneficial properties is manifested by the issuance of more and more patents in this sector. Two hundred eighteen patents, published in the last 5 years, have been recorded. The most patented plant was *Panax ginseng* and other species from this genus. Moreover, many patents concerned also *Camelia* sp. (Fig. 16). As regards the country, the greatest activity in patenting was recorded in China, South Korea, the USA, Russian Federation, and Japan (Table 9) (ISI Web of Knowledge, Derwent Innovations Index Database 2018).

Many patents on saponins concern manners of their extraction and isolation in the context of subsequent usage in food, as well as the methods of their determination

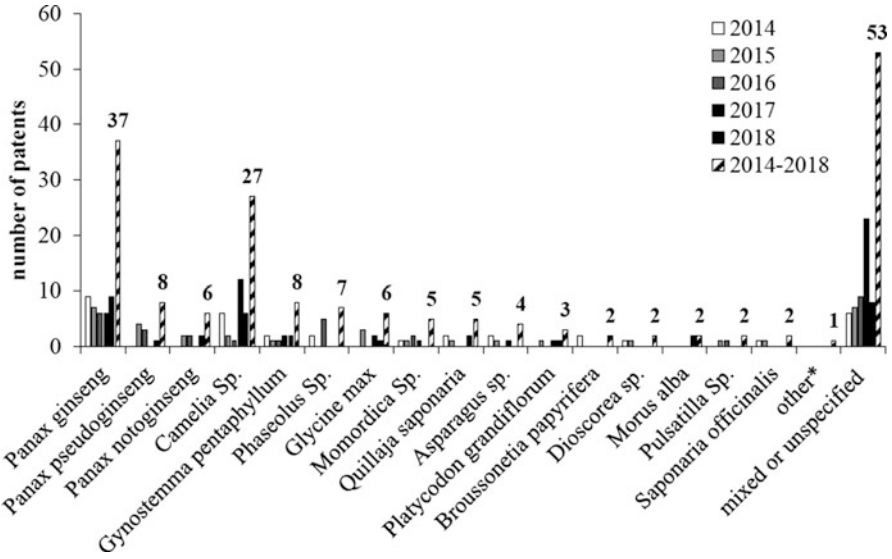

Fig. 16 The number of patents depending on the plant species in 2014–2018 based on ISI Web of Knowledge, Derwent Innovations Index Database (2018). Other plant, for which only one patent during the period of 2014–2018 was recorded: *Alopecurus myosuroides*, *Akebia* sp., *Beta vulgaris*, *Bupleurum* sp., *Cannabis sativa*, *Cicer arietinum*, *Cistanche salsa*, *Cucurbita* sp., *Derris eriocarpa*, *Epimedium* sp., *Ganoderma* sp., *Gossypium* sp., *Hedychium flavescens*, *Hosta* sp., *Ipomoea batatas*, *Kosteletzkya virginica*, *Lilium* sp., *Monascus* sp., *Myriopteron extensum*, *Pandanus* sp., *Polygonatum odoratum*, *Polygonatum officinalis*, *Sarcodon imbricatus*, *Siraitia grosvenorii*, *Solanum lycopersicum*, *Spartina alterniflora*, *Tupistra chinensis*, *Vaccaria pyramidata*, *Vitis* sp., *Yucca* sp., *Ziziphus jujube*

Table 9 Countries of inventors of saponins' application in food (2014–2018) (ISI Web of Knowledge, Derwent Innovations Index Database 2018)

Country	Number of patents	Share in total (%)
China	154	70.6
South Korea	45	20.6
United States of America	7	3.2
Russian Federation	7	3.2
Japan	5	2.3

and quantification in food and feed. Nonetheless, the vast majority patents published in recent years presented the way of application of saponins as food ingredients and additives. The most frequently patented was the usage of saponins as emulsifiers in food and beverages. Moreover, a lot of inventions related to saponins in food, were based on their beneficial effect on humans and animals health.

Panax ginseng saponin are useful in beverages and emulsified food but also in the production of healthcare and functional food. Such food containing ginseng saponins is recommended for preventing and treating cancer, cardiovascular and liver

diseases, as well as overcoming physical fatigue. Moreover, ginsenosides are patented as ingredients of food for improving and restoring skin appearance and elasticity, preventing skin aging, providing beautifying effect, as well as treating depression and anxiety.

Saponins from *Panax notoginseng* were used for preparing plant salt useful for promoting digestion, and as the ingredients of functional food for treating Parkinson's disease, reducing blood pressure and lowering blood fat.

The patents of tea saponins concern their use as emulsifiers in production of beverages and food but also in preparation of fertilizers and organic insecticides. A huge number of patents concern the application of tea saponins as components of animal feed. Feed enriched in tea saponins increases animal immunity, preventing diseases and promoting appetite.

Next, the most frequently patented plant being the source of saponins for composition of livestock feed is *Gynostemma pentaphyllum*. The *Gynostemma* saponins fed to chicken improve their immunity. Other patented applications of this plant concerned the production of healthcare food used for treating the obesity, diabetes type II, and hyperlipidemia. *Gynostemma* saponins are useful also for preparing composition for improving intestinal flora and promoting characteristic microbial colonization.

Popular food plant rich in saponins is also soybean. According to one of the latest patents, food and feed enriched in soybean saponins can prevent and treat osteoporosis, due to the improvement of formation and differentiation of osteoblasts. Moreover, soybean extract containing saponins was patented as an agent enhancing taste of food, e.g., sauce and soup. There are few patents, concerning food composition with saponins of other plants belonging to *Fabaceae* family, such as adzuki bean, mung bean, kidney bean, etc. Such food exhibits anticancer and antioxidant activity, prevents osteoporosis, enhances immunity, reduces blood cholesterol, induces appetite, and improves functioning of pancreas.

Saponins are important components of various compositions of food and drinks for treating hyperglycemia and other diseases associated with the sugar metabolism. Tomato saponins were used for preparation of oral liquid or healthcare food for treating of insulin resistance and sugar tolerance, reducing blood sugar, and increasing insulin sensibility. Moreover, there are patents providing the usage of *Derris eriocarpa* and samara saponins in sweetening composition for food or drink.

Among other, the most interesting patented applications of saponins, the usage of *Yucca* saponins as components of sausage and ham, should be mentioned. The inventors claimed that these products have unique taste and flavor, antimicrobial activity, antioxidant activity, inhibit growth of spoilage bacteria. Moreover, saponin component is easily consumed by consumers and promotes health of people, as well as is effective for prevention and treatment of multiple cancers.

One of the worth mentioning patents is also application of lily saponins for production of sleep-aiding honey bread. Thanks to synergic effect of lily saponins, the fructus gardeniae oil and the liensinine, the honey bread is fresh and sweet, delicious, and convenient to eat and has effects of shortening fall-asleep time, prolonging sleep time, and resisting convulsion. Moreover, the bread can effectively

improve the sleep quality of an insomnia patient; it is eaten for a long time. Similar properties were exhibited by saponins of *Ziziphus jujube* (spina date). Extract from its seeds was the component of patented healthcare food composition, useful for improving sleep.

Many inventors did not precise the origin of saponins, or used the mix of saponins from various species. It makes up one fourth of patents from the years of 2014–2018. Apart from functional healthy food, mixed or unspecified saponins were applied mainly for preparing high strength food bag, membranes useful, e.g., for coating on fried foods, degradable films for packaging of food products, or coating composition useful for preserving foodstuffs. Furthermore, mixture of various saponins was applied also in the composition of natural food preservatives.

32.8 Perspectives

Saponins due to their wide range of biological activities are interesting compounds with high potential to be applied in food supplement, medicinal food, and food processing industries. The last function seems to be connected to emulsifying abilities of most of these compounds. As they are generally not toxic to humans, their application as natural emulsifiers should be explored. Many researches have been conducted during last decades on these aspects.

In regard to their health-promoting activities, it has been very important to established best practices of food preparation to increase their accessibility. As the food matrix of individual foodstuffs containing saponins is different, each plant species should be treated separately or in the mixture with other accompanying food components.

Important issue in saponin health-promoting activity is their bioavailability, which is a consequence of many processes the saponin molecules are undergoing when enter digestive tract. It is known that hydrolytic enzymes present in gut or microbiota enzymes hydrolyse glycosidic forms to hydrophobic aglycones. Nonetheless, it still remains not clear which form is better absorbed and active. The cloned BlBG3, a GH3 β-glucosidase from *Bifidobacterium longum*, was proved to be microbiota enzyme processing ginseng saponin. However, structurally divergent saponins may undergo different mechanisms of these conversions and should be research in detail separately. Further studies on understanding factors modulating gastric transformations of saponins seem necessary.

Interesting option for increasing saponins bioavailability is the application of different kinds of absorption enhancers. Development of easy and practical enhancers is of high priority.

Abstract

Phytoecdysteroids are polyhydroxylated steroids which are widely distributed in the plant world and are present in significant amounts in 5–6% of plant species. Their major role in the plant is probably to deter invertebrate predators, but ecdysteroids also have many beneficial effects in mammals and are attracting attention as therapeutic and nutraceutical agents. Four hundred analogues have been identified so far from plant sources, but 20-hydroxyecdysone is the most frequently encountered and is often the major analogue present. Here we consider the occurrence of phytoecdysteroids in food plants and the human diet and how this might change in the future against the backdrop of what we currently know about biosynthesis of these compounds in plants and their bioavailability, metabolism, and biological activities in mammals. Finally, we discuss the medical and pharmaceutical potential of these molecules, particularly in the area of muscle wasting diseases and diabetes, and indicate which areas of fundamental research require focused study.

33.1 Introduction

There are believed to be 50,000 edible plant species among the estimated 300,000 terrestrial plant species, but only a few hundred contribute significantly to the human diet. Further, fewer than 20 account for 90% of the plant food intake of humans, with just 3, maize, rice, and wheat, accounting for >50% of the calorific intake (https://www.worldatlas.com/articles/most-important-staple-foods). While this perhaps makes the plant secondary compounds of those staple foods particularly relevant, it should not be allowed to obscure the contribution that the secondary compounds present in the minor food species might contribute to the diet, since their phytochemical contents and geographical preponderance vary enormously, and relatively small intakes of particular secondary compounds can have a marked impact on the physiological status of the human body.

Ecdysteroids are a family of steroid hormones, which were initially identified in insects and crustacea as hormones regulating molting, development, and reproduction (Koolman 1989). These zooecdysteroids have since been found to be present in other arthropods and invertebrates, but their roles are not so clearly elucidated. Shortly after the characterization of the structures of ecdysone (previously known as α-ecdysone) and 20-hydroxyecdysone (formerly known as β-ecdysone, ecdysterone, or crustecdysone) in the mid-1960s (Fig. 1), four research groups almost simultaneously discovered that ecdysteroids were also present in certain plant species (summarized in Nakanishi 2006), where they are referred to as phytoecdysteroids, in far higher concentrations than those found in invertebrates. To date, ca. 500 ecdysteroid analogues have been identified (Ecdybase; Lafont et al. 2002) from invertebrates, plants, and fungi (mycoecdysteroids), although the vast majority of these have been isolated from plants, reflecting the much higher concentrations found in ecdysteroid-containing plants (typically 0.1–1% of the dry weight but reaching 3.2% of the dry weight in the case of bark of *Diploclisia glaucescens*; Bandara et al. 1989). 20-Hydroxyecdysone is the most frequently encountered and major ecdysteroid analogue in arthropods and plants. Accumulating evidence supports the role of phytoecdysteroids in the reduction of invertebrate predation on the plants containing them either by endocrine disruption on ingestion

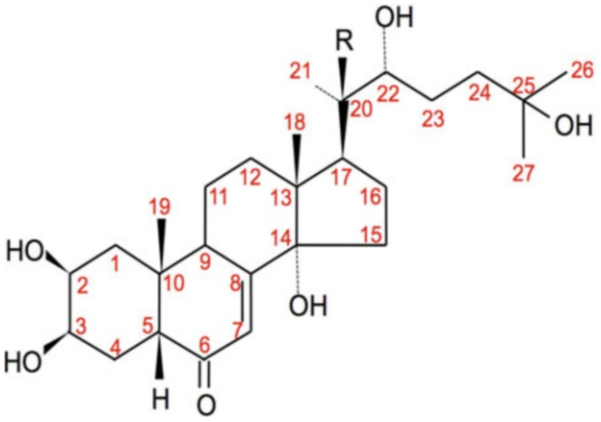

Fig. 1 Structures of ecdysone (R = H) and 20-hydroxyecdysone (R = OH), showing the stereochemistry and the standard numbering system

of the plant material or by deterrence following contact or ingestion of a small sample of the plant. This has led to the suggestion that phytoecdysteroids might be used to enhance the protection of crop species against predation. Indeed, it appears that most, if not all, plant species retain the genetic capacity to produce ecdysteroids, but that differential regulation of the as yet not fully elucidated biosynthetic pathway determines whether a particular species will accumulate ecdysteroids, at what levels within different parts of the plant and what the mix and proportions of various ecdysteroid analogues (the ecdysteroid profile) will be (Dinan et al. 2001).

The attractiveness of this idea is considerably enhanced by the lack of toxicity of ecdysteroids to mammals and by a plethora of essentially beneficial pharmacological and physiological effects in mammals which have been ascribed to phytoecdysteroids on ingestion or injection (reviewed Dinan and Lafont 2006). Mammals do not have the capacity to synthesise ecdysteroids de novo, nor do they possess homologues of the arthropod ecdysteroid receptor proteins (EcR and USP/RXR). Also, ecdysteroids, which differ significantly from vertebrate steroid hormones in polarity, bulk and shape, do not appear to interact with the vertebrate steroid hormone nuclear receptors (Báthori et al. 2008). However, exogenous ecdysteroids, like other dietary xenobiotics, are absorbed, distributed, metabolized, and excreted by mammals. In vivo and in vitro studies indicate that ecdysteroids modulate mammalian cell activities rapidly (in seconds to minutes) by interaction with membrane receptors and/or ion channels, which are in distinct contrast to the direct genomic regulation via nuclear receptors in arthropod cells (over hours to days). In view of the diversity of potential pharmacological benefits of ecdysteroids in mammals, there is a rapidly growing interest in assessing these compounds for use in a variety of medical conditions, especially those which involve muscle wasting (sarcopenia, cachexia, Duchenne muscular dystrophy, etc.).

In this review we shall consider the occurrence and identity of ecdysteroids in major and minor dietary plants; summarize the currently available data on the bioavailability, metabolism, activities, and modes of action of ecdysteroids, mainly

20E, in mammalian systems; and discuss the current and potential impact of this class of compound on the human diet.

For those readers who are not already acquainted with it, the website "Ecdybase" (Lafont et al. 2002), which incorporates several updatable databases associated with various aspects of the ecdysteroid literature, provides a good companion reference to this chapter. Ecdybase grew out of *The Ecdysone Handbook* (Lafont and Wilson 1996). It provides structures, spectral data, and references for all the published phyto-, zoo-, and mycoecdysteroid analogues, biological activity data, and literature surveys of the occurrence of ecdysteroids in plant and non-arthropod species and the effects and uses of exogenous ecdysteroids in animals and plants. To save space in this chapter, rather than referencing many original articles in the primary literature, Ecdybase will be cited, and the original literature can be found there.

33.2 Dietary Phytoecdysteroids

33.2.1 Bioactive Constituents

33.2.1.1 Distribution of Ecdysteroids in the Plant World

Somewhere in the region of 6000 species of plants have been assessed for the presence or absence of ecdysteroids, which accounts for about only 2% of the total number of terrestrial plant species. Additionally, one must bear in mind that studies have used different methods (ranging from bioassays detecting positive extracts to unambiguous spectroscopic identification of specific analogues by NMR or crystallography) differing in their selectivity and sensitivity. Also, different portions of the plants at different stages of development have been assessed. However, the most extensive study has been the Exeter Survey which assessed whether ecdysteroids are present in dormant seeds of ca. 5000 plant species by means of standardized microextraction methodology followed by an ecdysteroid-responsive cell-based bioassay (testing for 20E-like biological activity) and sensitive ecdysteroid-specific radioimmunoassays (testing for chemical similarity to E) (Dinan 1995b). Phytoecdysteroids have been detected in specific members of the ferns, gymnosperms, monocots, and dicots (Lafont 1998). Although phytoecdysteroid-containing species are more common in some genera than in others, where enough species in a genus have been examined, positive species have been found. Also, there is no correlation between species which contain high levels of ecdysteroids and the occurrence of ecdysteroids in other members of the same genus or family, as demonstrated by the rarity of ecdysteroid-containing species in the Asteraceae in general, but the presence of species like *Serratula coronata* and *Leuzea carthamoides*, which contain significantly high levels, in this family. However, if enough species within a family (e.g., the former Chenopodiaceae [now included in the Amaranthaceae]: Dinan et al. 1998) or large genus (e.g., *Silene*; Zibareva et al. 2003) are examined, a pattern in relation to taxonomic structure does begin to emerge, suggesting that the presence and profile of ecdysteroids have chemotaxonomic significance.

33.2.1.2 Distribution of Ecdysteroids Within Plants

Phytoecdysteroids are dynamic molecules within plants; they are not necessarily accumulated where they are biosynthesized; and they demonstrated seasonal variations in where they are located in the plant and how they are metabolized, sometimes resulting in different profiles in different organs at different stages of development. As would be expected of secondary compounds which represent a considerable investment of the plant's resources, phytoecdysteroids seem to be judiciously distributed to enhance the survival of the plant from one year to the next or from one generation to the next in the case of annual plants. Thus, annual cycling of ecdysteroids has been observed in herbaceous biennials or perennials (Lafont et al. 1991), and the association of high levels of ecdysteroids with new growth and/or flower- and seed-producing structures has been observed in several species. Thus, in spinach and quinoa, two annual species of dietary significance, the highest ecdysteroid levels are associated with young shoots, young leaves, flowers, and seeds (Dinan 1992a, b, 1995b).

33.2.1.3 Ecdysteroid Profiles

Ecdysteroid profiles in phytoecdysteroid-containing plants vary from simple, where one analogue prevails (Fig. 2), through moderate, where one to three major analogues are present alongside a "cocktail" of minor analogues, to complex where a mixture of analogues is present and none dominates or where the mixture varies considerably in composition and total ecdysteroid content depending on the ecotype,

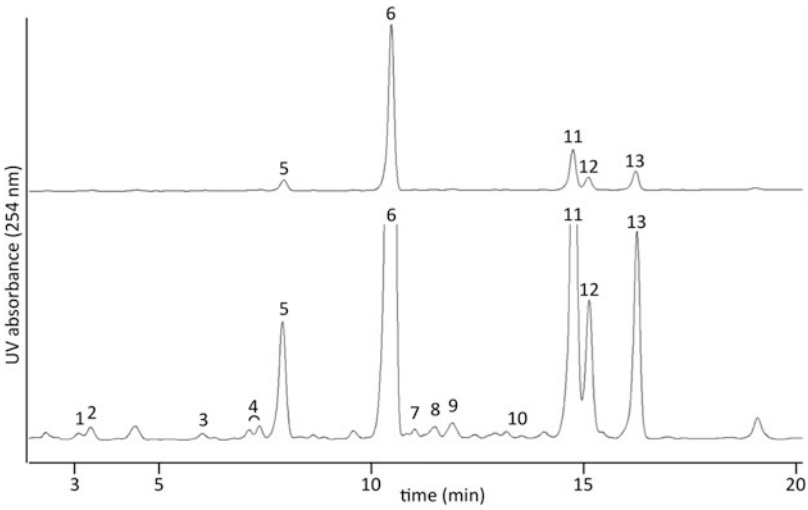

Fig. 2 Chromatograms showing the ecdysteroid cocktail present in a crude extract of *Cyanotis* sp. roots. (1) Dihydrorubrosterone (17β-OH); (2) dihydrorubrosterone (17α-OH); (3) turkesterone; (4) 20,26-dihydroxyecdysone (25*R* + 25*S* isomers); (5) rubrosterone; (6) 20E; (7) inokosterone; (8) 2-deoxy-20,26-dihydroxyecdyone; (9) poststerone; (10) stachysterone B; (11) 20E 3-acetate; (12) ajugasterone C; (13) 20E 2-acetate. The lower panel was recorded with a tenfold increase in sensitivity when compared to the upper panel

growing conditions, or even the individual plant. One presumes that these various profiles are linked to the "strategy" that helps the plant to defend itself from invertebrate predation, but there is no conclusive proof for this. Whatever the distribution and profile of secondary compounds within a plant, it is relatively easy to speculate on a rationale for it, but obtaining substantiating evidence for it requires painstaking study of phytoecdysteroid levels, the generation of plant lines accumulating high and low levels of ecdysteroids, and observations of the effects on the appropriate predator species.

33.2.1.4 Major Analogues

Ecdysteroids are polyhydroxylated steroids which can exist in the free steroid form or as polar or nonpolar conjugates. The structural limits of what constitutes an ecdysteroid are not fully defined, but the majority possesses a 14α-hydroxy-6-keto-7-ene functional group (giving rise to a characteristic UV absorption at 242 nm [ε = 12,400 L/mol/cm] in methanol) with A/B-*cis* ring fusion and *trans* B/C- and C/D junctions. The number of C atoms in unconjugated ecdysteroids depends on which phytosterol they are derived from (C_{27}, C_{28}, or C_{29}; see below) or the extent of side-chain cleavage during biosynthesis (C_{24}, C_{21}, C_{19}). Hydroxyl groups may be located at various positions around the molecule and vary in their stereochemistry, but the most frequently encountered locations are 2β, 3β, 14α, 20*R*, 22*R*, and 25, as found in 20E, the natural arthropod steroid hormone. 20E is the most commonly encountered phytoecdysteroid as it is present in the vast majority of phytoecdysteroid-containing species. 20E is normally also the most predominant ecdysteroid present in a species, frequently accounting for >50% of the total ecdysteroid. Other commonly encountered analogues are polypodine B, pterosterone, turkesterone, and makisterone A (Fig. 3).

33.2.1.5 Range of Analogues and Potential Number

The structural features which categorize a molecule as an ecdysteroid have not been definitively defined, and the approach currently used by most workers in the field is that a molecule should possess several of the chemical features of the archetypal ecdysteroid 20E, i.e., steroid nucleus, polyhydroxylation, 7-en-6-one functional group, A/B-*cis*-ring junction, and C/D-*trans*-ring junction. However, it has been proposed that the spectrum of ecdysteroid analogues can be divided into "true ecdysteroids," which possess a 5β-H, a 14α-hydroxyl group, and a 7-en-6-one chromophore (regardless of whether they possess ecdysteroid biological activity), and "ecdysteroid-related compounds," which do not fulfill all these criteria (Lafont and Horn 1989). A standardized system of abbreviations has been proposed for common ecdysteroids (Lafont et al. 1993).

As more analogues were identified, it became apparent that the range of analogues result from a combination of a number of biochemical changes (hydroxylations, oxidations, reductions, isomerizations, conjugation reactions, etc.) on a basic structure ([5β-H]14α-hydroxy-6-oxo-7-ene cholestane). Over 500 ecdysteroid analogues have been identified, of which 400 have been identified in plants, and more are continuing to be isolated; considering the possible permutations of the possible

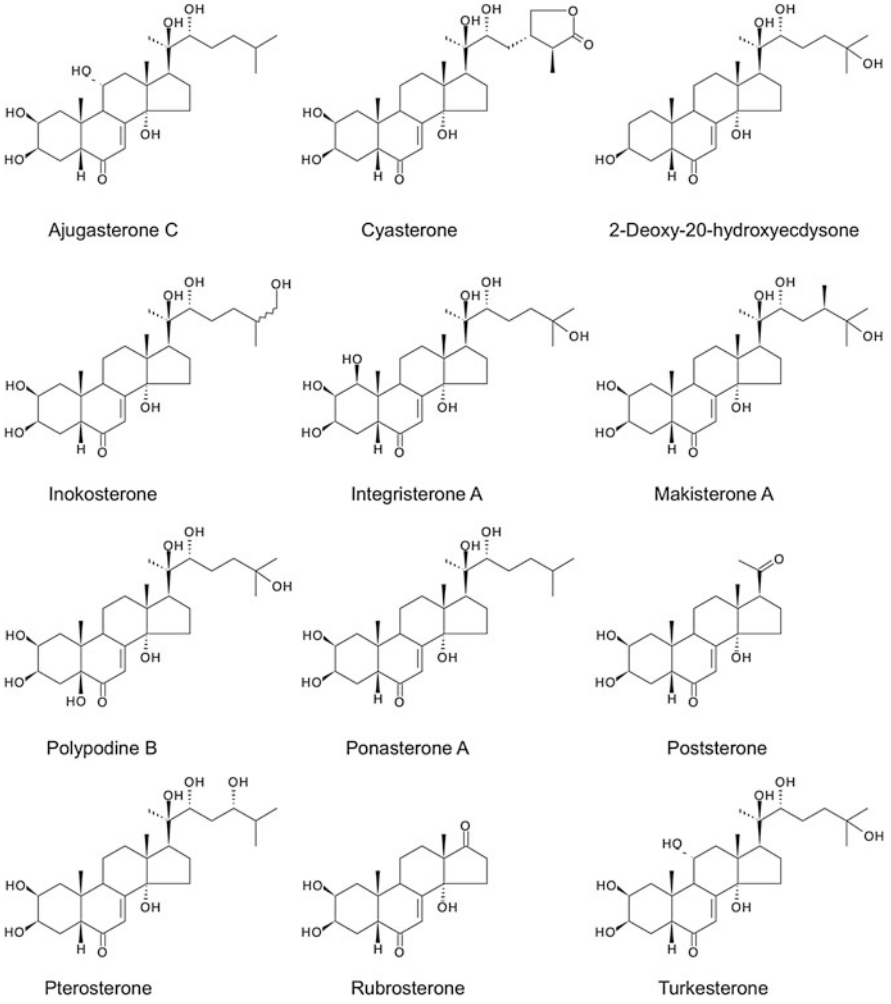

Fig. 3 Structures of significant phytoecdysteroids. See Ecdybase for structures of all published ecdysteroids

biochemical changes involved allows a theoretical calculation that over 1000 analogues could ultimately be identified (Dinan 2001).

33.2.1.6 Biosynthesis in Plants

While considerable progress has recently been made in elucidating the later stages of ecdysteroid biosynthesis from dietary cholesterol or a related sterol in insects and other arthropods, understanding of the biosynthetic pathway(s) and the regulation in plants is still largely unknown. The current state of knowledge has been reviewed (Fujimoto et al. 2000, 2015; Dinan 2001). Very briefly, plants are capable of

generating sterols and steroids de novo by the cytosolic mevalonic acid (MVA) or plastidial methylerythritol phosphate (MEP) routes, although the mevalonate pathway seems to predominate in the biosynthesis of ecdysteroids. Synthesis from cholesterol gives rise to C_{27}-ecdysteroids, while the presence of an alkyl (methyl, methenyl, ethyl, ethenyl) group at C-24 of the sterol gives rise to the corresponding C_{28} and C_{29} ecdysteroids. The wide structural diversity of phytoecdysteroids and the existence of complex cocktails of analogues in many species of phytoecdysteroid-containing plants suggest that there is a lower specificity of the terminal steps (hydroxylases, etc.) of the pathway (after a common intermediate which already contains the 14α-hydroxy-6-oxo-7-ene group) which enables the production of multiple ecdysteroid analogues through permutations in the sequence of the various possible modifications. Thus, the later stages of phytoecdysteroid biosynthesis are probably not a linear pathway but rather a network of steps where differential regulation of the amounts and activities of particular enzymes determines which analogues are generated and their relative amounts in the profile. This would be advantageous for the plant in avoiding a lot of genetic redundancy associated with many specific enzymes and also providing a flexibility to redirect synthesis through differential regulation to new analogues should phytophagous predators become tolerant to previously predominant analogues. The wide taxonomic diversity of plants which accumulate significant amounts of ecdysteroids (see Ecdybase) and the presence of individual plants which accumulate albeit low levels of ecdysteroids in species which are regarded as ecdysteroid-negative (Dinan et al. 2001) imply that most, if not all, plants retain the genetic capacity to generate ecdysteroids, but that the activity of the biosynthetic pathway(s) is downregulated in ecdysteroid-negative plants.

33.2.2 Bioavailability and Metabolism in Mammals

Studies on the pharmacokinetics and metabolism of ecdysteroids in mammals have been sporadic, and our understanding of this important area is far from complete. The early studies (Hikino et al. 1972; Lafont et al. 1988) demonstrated that, in mice, 20E and E were excreted rapidly (within 24 h) and faster after i.p. injection than after ingestion, with the main excretion route being the feces. Ecdysteroids transiently increase in the plasma and liver after administration and then accumulate in the intestine within 1–2 h. Metabolism is initially very limited until the ecdysteroid reaches the large intestine, where gut bacteria dehydroxylate the molecule at C-14, reduce the 6-keto group and bring about C-20/C-22-side-chain cleavage and an enterohepatic cycle (as for bile acids) results in glucuronide conjugation in the liver, transport in the bile and deconjugation in the large intestine. The enterohepatic cycle results in an increasingly complex pattern of metabolites of the administered ecdysteroid and also helps to maintain low but biologically significant levels of ecdysteroids in the plasma. The metabolism of E is simpler, since the absence of a C-20/C-22 diol precludes side-chain cleavage, such that 14-deoxyecdysone is the major metabolite (Girault et al. 1988). 20E is metabolized to 14-deoxy-20-

hydroxyecdysone, 6α-hydroxy-20E, 6α-hydroxy-14-deoxy-20E, poststerone, 14-deoxy-poststerone and 20,26-dihydroxyecdysone as major metabolites (Foucault et al., in preparation). Further metabolites can occur by relocation of the B-ring double bond (Kumpun et al. 2011b) Fig. 4). It is currently not clear if observed biological effects are attributable only to the administered ecdysteroid or, in part, to the metabolites which are generated. Some of the metabolic transformations mentioned above have also been observed in calf urine after the oral administration of 20E (Destrez et al. 2009).

Studies on the pharmacokinetics and metabolism in humans are restricted as it is not possible to use radioactively labelled tracer molecules. Four pharmacokinetic studies have been carried out. Simon and Koolman (1989) used an ecdysteroid-specific immunoassay to monitor urinary excretion after oral ingestion of 15 mg 20E and found that significant immunoreactive material (peaking at ca. 0.5 μM) was excreted in the first 8 h but continues to be excreted at low levels until 24 h (Simon 1988). Brandt (2003) used RIA and HPLC-MS to monitor the excretion of a single oral dose of 20 mg 20E which showed a urinary peak after 3–4 h with a total of 1–2 mg ecdysteroid being recovered in the urine. One of the metabolites was tentatively identified as 14-deoxy-20-hydroxyecdysone. Bolduc (2008) found that only 5 mg 20E was recovered in the urine after the ingestion of 434 mg 20E.

The bioavailability of 20E in mammals is low (<1%), while that of poststerone is somewhat higher (19%). This is in accord with the druggability scores (ADMET Traffic Light Scores; Lobell et al. 2006) for these compounds based on features dependent on their structures and polarities (MW, LogP, polar surface area, number

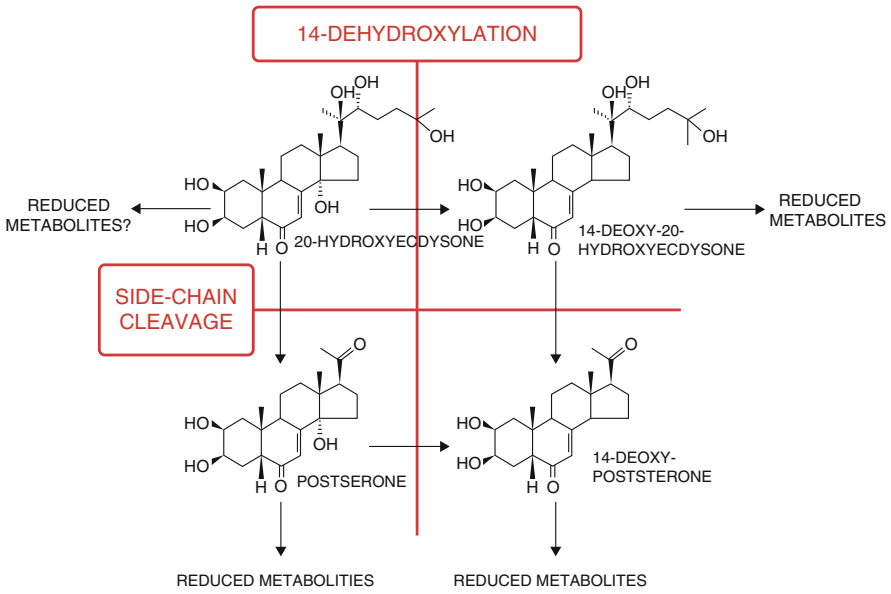

Fig. 4 Metabolism of 20E in mice. (Modified after Kumpun et al. 2011b)

of rotatable bonds, numbers of H-bond donors and acceptors), which gives 20E a score of 3 ("amber"; poor to moderate bioavailability), while Post has a score of 0 ("green"; good bioavailability). This is an aspect requiring attention since the consumption of relatively large amounts of 20E is required to bring about the necessary plasma concentrations required for the induction of biological responses in mammals.

33.2.3 Bioactivities of Ecdysteroids in Mammalian Systems

33.2.3.1 General

The literature up to 2009 has been extensively reviewed previously (Sláma and Lafont 1995; Lafont 1997; Lafont and Dinan 2003, 2009; Dinan and Lafont 2006; Báthori et al. 2008; Dinan 2009). Briefly, in the period after the initial identification of ecdysone and 20-hydroxyecdysone in the mid-1960s, it was considered that ecdysteroids might be used as insect pest control agents, and as a consequence studies were undertaken to obtain toxicological and safety data for mammals exposed to these agents, revealing that they are nontoxic and that they stimulated protein synthesis (summarized below). The next phase, up to about 1984, involved important studies indicating a wide diversity of essentially positive biological activities (anabolic, adaptogenic, wound healing, antidiabetic, hepatoprotective, anti-inflammatory activities, etc.), which were largely published in Russian and unfortunately mainly ignored in the USA and Europe. It was when it became apparent in the mid-1980s that ecdysteroids, in the form of the "Russian Secret," were being used in the belief that they improved the performances of sportsmen and women by increasing muscle mass, stamina, recovery from injury, and mental attitude that the pharmaceutical and medical interest in these molecules started to rapidly increase, such that it is now fair to say that this is now the main focus of ecdysteroid research around the world. Another important factor has made a significant contribution to these advances, and that is the current availability of large amounts of 20E at reasonable cost; in the mid-1970s, 20E was available only in limited amounts and costs at least USD 2000/g, whereas it can now be purchased for USD 1000/kg, which has made clinical trials with this compound feasible.

Since 2010, investigations of the effects of ecdysteroids (essentially 20E) on mammals have concentrated on four main areas: increase of muscle mass, reduction of body fat, antidiabetic effect, and adaptogenic effects.

33.2.3.2 Diabetes

Several plant species (*Ajuga iva*, *A. turkestanica*, *Achyranthes bidentata*) used in traditional medicines for diabetes contain significant levels of ecdysteroids (Lafont 2012). It has been shown that pure 20E significantly reduces hyperglycemia in three rodent models of diabetes at doses of 0.1–10 mg/kg and modifies enzyme levels in the liver such that less glucose would be released from glycogen and more glucose would be converted to lipids. 20E increases glucose consumption by insulin-resistant HepG2 (hepatocyte) cells in a dose- and time-dependent way with a maximal

effect being reached at 5 μM (Chen et al. 2006), which appears to be mediated by an increase in the Glut-4 glucose transporter activity (summarized in Lafont 2012). Kizelsztein et al. (2009) showed, using rat H4IIE hepatoma cells, that 20E stimulates PI3K to phosphorylate/activate Akt, which in turn stimulates the translocation of Glut-4 to cell membranes and thereby facilitating glucose uptake. Further, 20E reduces transcription of glucose-6-phosphatase and phosphoenolpyruvate carboxykinase, thus reducing the formation of glucose by release from glycogen and by gluconeogenesis, respectively. 20E also stimulates glucose use by peripheral tissues and increases glycogen content (Syrov et al. 1997), not only of the liver but also in the heart and skeletal muscle (Syrov et al. 1975).

33.2.3.3 Adaptogens

Adaptogens are metabolic regulators present in extracts of certain plants (e.g., *Bryonia alba*, *Eleutherococcus senticosus*, *Rhodiola rosea*, *Schisandra chinensis*) which increase the ability of an organism to adapt to physical, chemical, or biological environmental factors ("stressors") and to avoid damage from such factors by favoring maintenance of homeostasis. Thus, adaptogens help an organism to survive and cope with situations of intense or prolonged stress and to enhance work capacity/mental performance over a longer period, in contrast to stimulants which provide a short-term increase in capacity followed by a rapid decline in performance to below that of the pre-stimulated state (Panossian et al. 1999). The difference seems to derive from adaptogens providing a more general metabolic stimulation of the cells and organs of the organism (involving stimulation of RNA and protein synthesis and ATP production) involving non-specific and specific mechanisms, whereas stimulants act on more specific sites in the CNS which, after a short time, results in exhaustion of the supply of stimulatory neurotransmitter substances. Extracts of the active plants are more effective than pure compounds isolated from the same species, which is in accord with general stimulation through multiple mechanisms, rather than a mode of action involving a single biochemical target. Progress is starting to be made in the elucidation of the complex biochemical modes of action of adaptogens (Panossian 2017), but much remains to be clarified. Some of the plants proposed as adaptogens (*Leuzea carthamoides*, *Tinospora cordifolia*; Panossian and Wikman 2005) are known to be ecdysteroid-containing. *L. carthamoides* is known as maral root, after the maral deer, which has been observed to dig out and consume the rhizomes (containing ca. 1% of the dry weight as 20E) of the plant at the beginning of spring, which improves their overwintered condition remarkably. Consequently, in Eastern Europe, the roots are harvested, dried, and powdered to prepare an adaptogenic tonic for humans.

33.2.3.4 Body Fat

Foucault et al. (2012, 2014) conducted experiments using a diet-induced mouse obesity model, where feeding a high-fat diet rapidly results in the mice becoming obese, but when simultaneously fed 20E at 5 or 10 mg/kg, there was a much lower fat increase which was not a consequence of lower food intake. Adipocytes from treated mice were reduced in size, but not in number and tissue inflammation, and the

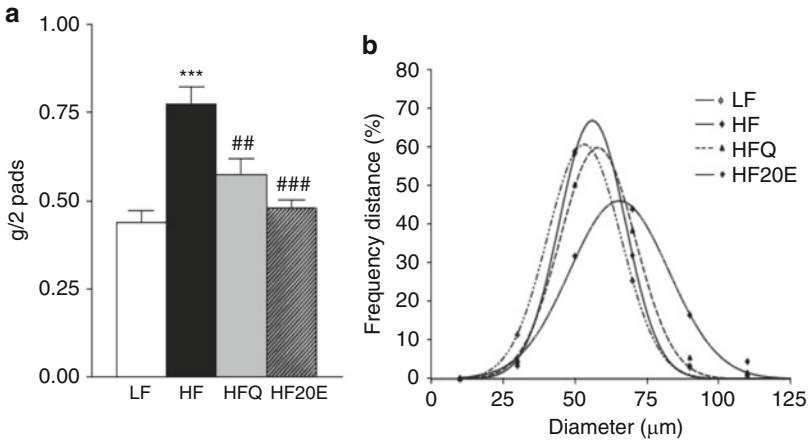

Fig. 5 Body growth and adipose tissue cellularity. Data are expressed as mean ± s.e.m. ($n = 12$ per group). (**a**) Epididymal adipose tissue weight; (**b**) distribution of epididymal adipose cell diameters. $***P < 0.001$, when compared to LF group; $\#P < 0.05$, $\#\#P < 0.01$ and $\#\#\#P < 0.001$, when compared to HF group. *20E* 20-hydroxyecdysone, *HF* high-fat diet, *LF* low-fat diet, *Q* quinoa extract enriched in 20E. (After Foucault et al. 2012, reproduced with permission)

levels of cytokines involved in adipocyte growth and differentiation were reduced (Fig. 5). Adiposity was also reduced in ovariectomized rats treated with 20E (Seidlova-Wuttke et al. 2010a). The mechanism of action of this response has not yet been investigated.

33.2.3.5 Muscle Mass

The mouse C_2C_{12} myocyte cell line, when stimulated with 20E or turkesterone, increases the incorporation of [^{3}H]leucine into protein rapidly (maximum incorporation after 2 h) and in a dose-dependent manner. The mechanism of action involves the PI3K/Akt system and an influx of Ca^{2+} ions. The effects of 20E were suppressed by inhibitors of GPCRs, phospholipase C, and PI3K. In parallel in vivo experiments, it was shown that treatment of rats with 20E for 28 days significantly increased their grip strength (Gorelick-Feldman et al. 2008; 2010). Male Wistar rats receiving 20E (5 mg/kg body weight) by subcutaneous injection into the left thigh for 8 days showed a significant increase in body mass, and the *soleus* and *extensor digitorum longus* muscles were significantly enlarged on both sides with increases in the number of muscle fiber nuclei, implying activation of the satellite cells (Tóth et al. 2008). In conjunction with the effect on adipocytes described above, 20E enhances lean body mass.

Previous studies had shown that insulin and IGF-1 stimulation of muscle protein is mediated by PI3K/Akt activation of mTORC1 assembly and signal transduction (Fig. 6). Anthony et al. (2015) could find no evidence for enhanced phosphorylation of Akt, mTOR, or 4E-BP1 in rat muscle or liver after oral administration of 20E. Bioavailability of the 20E was poor in the rats, and even using an excipient

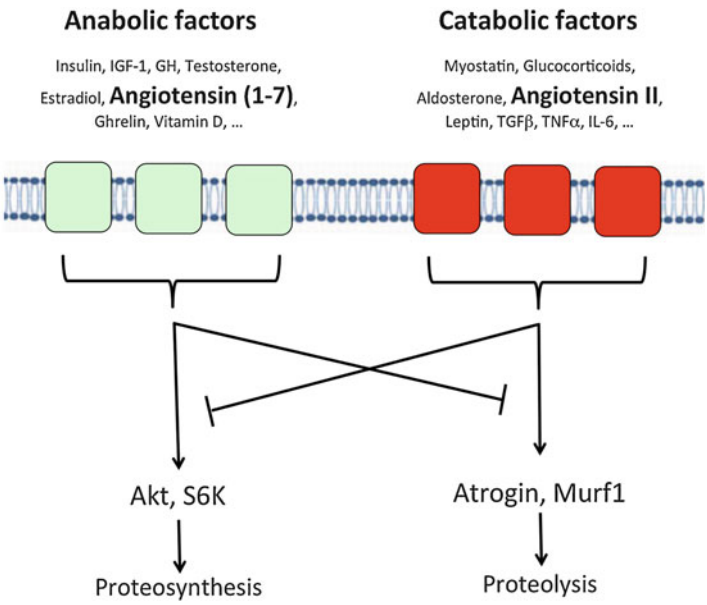

Fig. 6 Major actors and signalling pathways coordinating muscle protein balance. Red and green square represent various membrane receptors

(Labrasol) to enhance 20E bioavailability did not result in increased phosphorylation of the signalling components. These data appear to be in conflict with those of Gorelick-Feldman et al. (2008, 2010), but the route of 20E application was different. Unfortunately, it is not known if the rats used by Anthony et al. (2015) would have demonstrated muscular hypertrophy, as the animals were sacrificed after 4 h or less after gavage with 20E.

33.2.3.6 The Nutritional and Medical Applications of Phytoecdysteroids

In view of the broad spectrum of positive biological activities of ecdysteroids in mammals and their low toxicity, ecdysteroids have nutritional and pharmaceutical potential as food supplements and medicines. While these two areas possess some aspects in common, they do differ fundamentally in several important ways:

Food supplements: Preparations sold as food supplements normally consist of an extract enriched in the active component(s) in a largely undefined matrix which should be nontoxic; the registration procedure is considerably facilitated if the concentrated extract derives from a recognized food plant. The daily intake of the active substances is low (<100 mg/day), although the amount of the plant extract may be considerably higher (1–2 g), depending on the concentration of the active compound in the plant matrix. The activity may be a result of the active components alone, or derive from additive or synergistic interactions between the identified active substances and components of the matrix. The claimed activities of food supplements should be supported by scientific evidence, but it is not necessary that

the mode of action should be fully understood. Food supplements are made available to the general public (i.e., to a more or less healthy population), to improve/maintain general well-being, improve diet and digestion, and enhance the ability to cope with stress. Nutritional clinical trials may be performed on potential food supplements based on dietary plants, but there is no legal requirement for this.

Quinoa, an extract of *Chenopodium quinoa* seed enriched in ecdysteroids, was investigated as a food supplement to promote muscle mass and fat loss. It is perhaps instructive to briefly describe the developments in this area as a fairly typical example of its kind. Initially, certain ecdysteroid-containing food plant species (*Ajuga iva*, *Chenopodium quinoa*, *Spinacia oleracea*; Bakrim et al. 2008, 2014; Kumpun et al. 2011a) were assessed for their ecdysteroid distributions, levels, and profiles, which led to quinoa seed being selected for further development. The initial studies had investigated the ecdysteroid contents of seeds from various sources and also the ecdysteroid contents in bran and flour after various milling techniques, which identified quinoa bran as a more concentrated source of 20E (Kumpun et al. 2011a). The next stage was to develop a simple and cost-effective extraction procedure which was amenable to scale-up. Quinoa bran (450 kg; ca. 0.08% w/w 20E) was mixed with water (4500 L) and shaken for 2 h at room temperature and then filtered. The filtrate was heated to coagulate protein, filtered again, and then concentrated tenfold, before being applied to an Amberlite FPX66 resin column, to which the ecdysteroids adhere and were eluted with ethanol. The eluate was spray-dried to yield a preparation which contained 2.4% (w/w) 20E (Foucault 2012). An alternative approach based on leaching ecdysteroids from quinoa seeds has also been described (Graf et al. 2014).

The 20E-enriched extract (quinoa) when fed to mice prevented significantly the development of obesity in the same way as an equivalent amount of 20E, which could be attributed to effects on energy metabolism such that more glucose was oxidized, lipogenesis decreased, and less dietary lipid uptake was observed (Fig. 5: Foucault et al. 2012, 2014). On the basis of these very encouraging results, a clinical trial of quinoa, involving 118 overweight and obese adult humans, compared the effects of 1.6 g quinoa/day (containing 40 mg 20E) to 1.6 g of placebo in a 12-week controlled double-blind trial separated into two 6-week periods, a weight-loss phase (restricted calorific intake) followed by a weight-loss maintenance phase. Patients were monitored for body weight, obesity parameters, dietary intake, and various relevant biochemical parameters at 0, 6, and 12 weeks. Although the data indicated a tendency to prevent body weight and fat mass regain when compared to placebo, the differences were not statistically significant to the required degree, which may be attributable to the relatively low dosage of 20E in the quinoa and reflect one of the difficulties in preparing food supplements: the balance between the amount of active ingredient (20E) and the daily amount of the preparation (quinoa) that the patient can be expected/is willing to take. However, a statistically significant improvement of insulin sensitivity could be observed in this study.

Medications: The regulatory regime is much stricter for compounds intended as medicines. These are aimed for use by a smaller population suffering from a recognized and defined medical condition. The preparation consists of an essentially

pure active compound in a fully defined formulation, and the dosage is normally considerably higher than those encountered in food supplements, and this dosage has to be defined and shown to be effective and safe in relation to the age and gender of the target group. With regard to plant-derived active compounds, the source of the compound, its purification, its formulation, and its route of application must be fully defined. The drug will also have to successfully undergo preclinical and clinical trials before it receives authorization from the national regulatory agency:

Preclinical: In vitro and in vivo (nonhuman animal) studies to obtain information about efficacy, toxicity, pharmacokinetics, and mode of action.
Phase 0: Studies performed on a small number [10–15] people to obtain preliminary information on the bioavailability and half-life of the drug in humans.
Phase I: The drug is tested on healthy volunteers (20–100) with ascending doses to assess safety. Pharmacokinetics and pharmacodynamics are also determined.
Phase II: Tested on patients (100–300) suffering from the specific disease at the therapeutic dose to assess efficacy and identify side effects.
Phase III: The therapeutic dose is tested in a large-scale, multicenter trial (300–3000 patients) to assess efficacy, effectiveness, and safety.

The sequence of clinical trials are increasingly costly, and only a relatively low percentage of drugs entering Phase I trials successfully complete Phase III and obtain regulatory approval. There is also a Phase IV trial which monitors the performance of the drug once it becomes available for prescription. It used to be the case that large pharmaceutical companies funded the necessary research and development from initial lead compound to marketed medicine, but increasingly the identification of leads and initial trials are being undertaken by smaller innovative companies specializing in particular therapeutic areas or approaches, with the larger companies becoming involved, through licensing or purchase, to guide and finance a promising drug through the Phase III trial.

Although many patents attest to the pharmaceutical potential of ecdysteroids in human medicine, no drugs based on ecdysteroids have yet received regulatory approval.

33.2.3.7 Mode(s) of Action

The modes of action of 20E at responding mammalian cells have not been fully clarified, and several models are being pursued. The models are not mutually exclusive, and it is possible that they could operate simultaneously or in different tissues. Given the pleiotropic effects described for 20E on mammalian cells, it seems possible that it operates through several signalling pathways, which could be more or less tissue-specific.

Gorelick-Feldman et al. (2010) clearly established that 20E acts through a membrane GPCR receptor, and this has been confirmed using albumin-bound 20E which cannot cross cell membranes (Raynal et al. 2015).

The renin-angiotensin system (RAS) is strongly implicated in maintaining muscle function, and one of the peptide products of this system, angiotensin II, targets

skeletal muscle cells via the AT1R receptor and has been implicated in the development of sarcopenia (Yoshida et al. 2013), both directly through AT1R which results in increased resistance to insulin and IGF-1 and indirectly by increased production of myostatin, glucocorticoids, TNF-α, and IL-6. Consequently, ACE inhibitors (which inhibit the production of angiotensin II) have found some application in the treatment of sarcopenia. Another actor of the RAS is angiotensin 1-7 which has been identified as the natural ligand for another GPCR, Mas, activation of which has been hypothesized to enhance protein synthesis in muscle cells. Thus, RAS would have a "harmful arm" acting through AT1R where activation of the receptor enhances proteolysis, but this can be counteracted by a "protective arm," acting through Mas, where activation of the receptor enhances protein synthesis. Thus, according to this hypothesis, protection against muscle wasting can be achieved by reducing activation of AT1R, or activation of Mas, or a combination of the two. There are reasons to believe that activation of Mas would be more effective at stimulating muscle anabolism and reducing adipose tissue than an ATIR antagonist, and has fewer side effects than ACE inhibitors.

Mas receptor is expressed in many tissues, and its activation in different tissues (e.g., heart, kidney, CNS) may evoke protective effects (Höcht et al. 2009) (Fig. 7). Activation of Mas by 20E could explain the anabolic effects of 20E on muscle cells (Raynal et al. 2015).

Parr et al. (2014) have put forward an alternative model for the mode of action of 20E in bringing about the hypertrophy of mammalian skeletal muscle cells which involves interaction of the steroid with nuclear estrogen receptor-β (ERβ). Using C_2C_{12} cells, they observed that both 20E (1 μM) and E2 (1nM) enhanced myotube diameter. Co-treatment with the antiestrogen ZK antagonized the hypertrophy

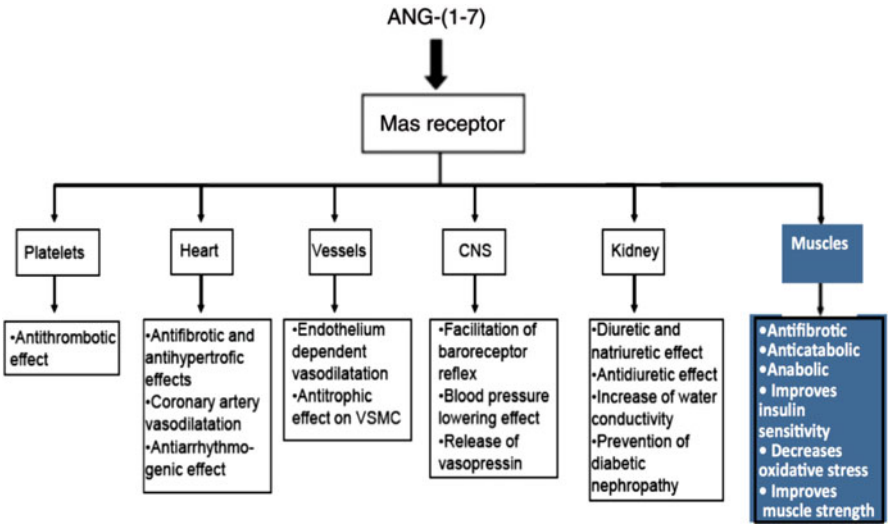

Fig. 7 The multiple targets of Mas receptor. (Adapted from Höcht et al. 2009)

brought about not only by E2 but also by 20E, indicating that E2 and 20E share a common mode of action. The authors next showed that a reporter gene under the control of an estrogen response element could be activated dose dependently by E2 or 20E interacting with ERα or ERβ and that this activation could be prevented if ZK was also present. Use of the estrogen receptor-specific agonists, ALPHA (for ERα) and BETA (for ERβ), indicated that ERβ mediated the hypertrophy of the C_2C_{12} myotubes, but a note of caution is required because these agonists are only selective at low concentrations and the beta dose-response curve was bell-shaped. Finally, the selective ERβ-antagonist (ANTIBETA) antagonized the effects of E2 and 20E in the C_2C_{12} cells. The authors suggest that, as it had previously been shown that ERβ can modulate Akt phosphorylation, this could be the link by which 20E brings about hypertrophy in the C_2C_{12} cells. In silico docking studies suggest that 20E can interact with the ligand-binding domains of ERα and ERβ but has the potential for stronger interaction with ERβ (Parr et al. 2015). However, we may question the exact nature of the receptor involved in the observed effects, because all binding studies performed with nuclear receptors ERα and ERβ were negative (Báthori et al. 2008), and truncated membrane-bound forms of ER receptors have been described that may display different ligand specificity (Schreihofer et al. 2018). Finally, we wish to mention the recent article by Sobrino et al. (2017). These authors provide evidence that in primary human umbilical vein endothelial cells (HUVEC) cultures, E2 acts via membrane-bound ER to bring about NO-dependent vasodilation and they show that this effect also requires Mas activation, as it is abolished by a Mas inhibitor. Although this a different system to the muscle cells above, it might perhaps give an indication of how both 20E and E2 can bring about muscle hypertrophy.

33.2.3.8 Potency and Structure-Activity Relationships

The availability of so many ecdysteroid analogues, which often differ by just one biochemical change from other known analogues, is a considerable resource for SAR studies and has been used to advantage to characterize the ecdysteroid nuclear receptor in insects (Dinan and Hormann 2005). However, no such comparable extensive study has yet been performed for an ecdysteroid-induced effect in a mammalian system. There are several reasons for this, but most are related to the fact that the biological systems are not yet well characterized enough. The potency of a molecule depends on its affinity for its target, rates of metabolism and excretion, sequestration, and the nature of the cellular response. Most responses to ecdysteroids in mammalian systems appear to require concentrations of 20E in the 0.1–10 μM range, but this does not mean very much unless one has a good understanding of the mode of action and metabolism, both of which might vary from system to system and are only now starting to be elucidated.

The earliest SAR for ecdysteroids in a mammalian system was for the stimulation of protein synthesis in mouse liver (Uchiyama and Otaka 1974), where 11 ecdysteroids were compared at 50 μg/100 g body weight. Nine of the ecdysteroids (20E, inokosterone, cyasterone, ponasterone A, pterosterone, shidasterone, lemmasterone, ponasteroside A, and polypodine B), all possessing a C-20/C-22-diol, were active in a time-dependent manner, as was rubrosterone, which is a C19 ecdysteroid lacking the side chain. Ecdysone (E), however, showed no activity.

When four of the ecdysteroids (20E, Ino, Cyast, and Rub) were tested at 5 μg/100 g body weight, only cyasterone remained active. Rubrosterone may have a different mode of action to the other ecdysteroids, as it has been suggested that its structure is close to the androgenic compound androsta-4-en-3,17-dione (Báthori et al. 2008).

Gorelick-Feldman et al. (2008) compared four ecdysteroids (20E, Turk, PolB, and PoA) for their ability to stimulate the incorporation of [^{3}H]leucine into protein in mouse C_2C_{12} cells in culture which had been differentiated into muscle myotubes. All four were active in a dose-dependent manner, with 20E and Turk appearing to be more active (EC_{50} = ca. 0.04 μM) than PolB and PoA (EC_{50} = ca. 0.1 μM).

Báthori et al. (2008) laudably collated the diverse findings in the early literature (published in Russian) on the anabolic activities of 23 ecdysteroid analogues in 6 types of rodent-based assays (not all analogues had been assessed in all of the assays). This brought out the importance of the hydroxyls at 2β, 3β, 11α, and 20*R* for the stimulation of amino acid incorporation into mouse liver proteins, such that turkesterone and its tetra-acetylated derivative had the highest activity. However, the relative potencies of 20E and Turk depend on the biological system used (cf. Gorelick-Feldman et al. 2008), indicating that factors other than target sensitivity (e.g., bioavailability, metabolism, sequestration, clearance) also affect overall potency.

An initial investigation of the relationship between ecdysteroid structure and the promotion of stamina has been assessed for swimming duration until exhaustion in mice (Mamadalieva et al. 2008; Table 1). Notably, all ten pure ecdysteroid analogues tested promoted the duration of swimming by 10–40% after receiving 5 mg/kg body weight per os 1 h before the test, while siverinol (a mixture of ecdysteroids extracted from aerial portions of *Silene viridiflora*), also at 5 mg/kg body weight, enhanced swimming duration by just under 50%, implying synergistic interaction between the ecdysteroids in the mixture. The most active pure analogues were 20E, Turk, silenoside A, and silenoside D, but not enough analogues were tested to develop a meaningful SAR. The ecdysteroids were more effective than a couple of adaptogenic plant extracts and some synthetic compounds (an androgenic compound and a psychotropic substance) used in higher amounts. Only Fenamin (an anti-inflammatory agent) prolonged swimming duration more than the ecdysteroids (Table 1).

While these studies provide amenable assays and demonstrate the fundamental characteristics of time and dose dependency, they are too preliminary in terms of validation, reproducibility of the response, and range of tested analogues to provide anything other than a glimpse of what the SAR might be.

33.2.4 Potential Benefits

33.2.4.1 Aging

Loss of muscle mass and strength is a normal aspect of aging, starting from about the age of 40 and with a loss of ca. 1% per annum, rising to 2% beyond the age of 70. Although inevitable for the vast majority of people, individuals can slow down the process by regular exercise and a good, balanced diet. Unfortunately, the decline can

Table 1 Influence of ecdysteroids (and other substances) on swimming duration until exhaustion of mice bearing a load (5% of body weight). Animals were treated 1 h before starting the swimming period. Male mice (18–20 g) received treatments per os; pure ecdysteroids or siverinol (5 mg/kg b.w.), natural product mixtures as *Eleutherococcus* (Siberian ginseng) extract containing a complex mixture of phenolic compounds (0.2 mL/20 g b.w) or Saparal (a mixture of triterpene glycosides extracted from the roots of *Aralia manchurica*; 20 mg/kg b.w.), and synthetic compounds as Nerobol (methandrostenolone, a non-aromatizable anabolic androgen, 10 mg/kg b.w.), Bemithyl (2-ethylthiobenzimidazole hydrobromide, a psychotropic substance, 50 mg/kg b.w.) and Fenamin (mefenamic acid, a non-steroidal anti-inflammatory analgesic, 10 mg/kg b.w.). Data from Mamadalieva et al. (2008)

Experimental conditions	Duration of swimming (min)	% relative to control
Control	34.0 ± 1.2	100
Ecdysone	38.7 ± 0.7	114
2-Deoxyecdysone	37.0 ± 1.2	109
Integristerone A	39.3 ± 0.4	116
Polypodine B	41.0 ± 0.6	121
20-Hydroxyecdysone	45.6 ± 0.9	134
Turkesterone	46.5 ± 0.6	137
Silenoside A	48.8 ± 1.0	143
Silenoside C	43.0 ± 0.8	126
Silenoside D	46.7 ± 0.9	137
Silenoside E	41.3 ± 0.8	121
Siverinol[a]	50.7 ± 0.8	149
Eleutherococcus extract	39.3 ± 1.0	116
Saparal	41.2 ± 1.3	121
Bemithyl	44.7 ± 1.8	131
Nerobol	40.0 ± 0.9	118
Fenamin	64.8 ± 2.5	191

[a]A partially purified ecdysteroid-containing methanol extract of *Silene viridiflora* (Caryophyllaceae)

become a vicious circle, since declining muscle strength results in ever less inclination to remain active, with many only recognizing the problem once it has become established, and it is perhaps too late to pursue a more active lifestyle. Biochemically, the rate of skeletal muscle protein synthesis declines with aging, owing largely to decreased activation of the PI3K/Akt/mTORC1 signalling pathway (Zwetsloot et al. 2014). Hence, the potential attractiveness of mild anabolic agents, such as the ecdysteroids, which activate this signalling pathway through a G-protein-coupled receptor, and, unlike the androgenic anabolic steroids, and does not require a concomitant exercise regime for effect and does not produce unpleasant physical and psychological side effects. However promising ecdysteroids may seem as "exercise mimetics," they need yet to be thoroughly tested by means of double-blind, placebo-controlled clinical trials to assess for efficacy and safety, especially as it is a medication which will need to be taken for the rest of life. Also, it cannot be expected that agents like ecdysteroids would be able to reverse age-related muscle loss, but they could slow the progress of the decline.

33.2.4.2 Sarcopenia

Under certain circumstances in a proportion of the aging population, the rate of muscle mass and function loss is greater and causes a general deterioration of physical state. Muscle fibers atrophy and the muscles become fibrotic (contain regions of collagen). This process is accompanied by motoneuron death. Obesity can aggravate sarcopenia, by decreasing functional capacities further. Sarcopenia enhances the risk of falls and fractures and is associated with greater incidence of dementia. Once muscle mass/strength is lost past the age of ca. 60, it is increasingly difficult to reverse the process, and beyond the age of 70, it is virtually impossible to do so, hence the importance of a healthy, active life from at least middle age and preferably throughout life. It is estimated that 30% of the US population between 65 and 79 is affected by sarcopenia, rising to 50% among the over 80s. This translates as 14.8 million sufferers among a population of 308 million (Baumgartner et al. 1998).

33.2.4.3 Cachexia

Cachexia is the rapid muscle and adipose tissue wasting associated with loss of weight, fatigue, weakness, and loss of appetite occurring in conjunction with certain conditions, e.g., cancer, multiple sclerosis, rheumatoid arthritis, tuberculosis, or anorexia nervosa. Loss of >5% of body weight over 6 months indicates that cachexia may be present. Ca. 50% of cancer patients suffer from cachexia, and it significantly increases the risk of mortality. The mechanism(s) by which the above diseases cause cachexia are not well understood, and control of the condition is currently poor. It is plausible that ecdysteroids might help to slow loss of body mass associated with cachexia, but there is no current proof of this. A recent study has implicated activation of the Mas receptor (see Sect. 2.3.7 above) in the attenuation of muscle wasting in cachexia (Murphy et al. 2018).

33.2.4.4 Duchenne Muscular Dystrophy

DMD is a rare recessive X-linked inherited genetic disorder which affects about 1 in 3,500 boys (ca. 30,000 afflicted in Europe). It involves mutations of various degrees of severity which affect the expression of the dystrophin gene, the product of which is a major component of the cytoskeleton in muscle cells and is important in maintaining muscle cell structure and providing resistance to damage. Those affected undergo a gradual physical decline from about the age of 5, becoming increasingly weaker and less independently mobile, with death normally ensuing by the age of 30–40. A number of therapeutic strategies are currently being assessed for DMD, but no cure is presently available. It is envisaged that ecdysteroids might slow down the muscular decline or support the maintenance of muscle mass after gene therapy.

33.2.4.5 Type 2 Diabetes (Metabolic Syndrome)

The inexorable rise of the incidence of type 2 diabetes around the world (rising from 108 million sufferers in 1980 to 422 million in 2014, corresponding to 8.5% of the adult population; www.who.int/news-room/fact-sheets/detail/diabetes) is a major health and social problem. The characteristic symptom is elevated and imperfectly

regulated blood glucose levels, but this can arise by a number of mechanisms (reduced/inadequate insulin production, reduced sensitivity to insulin, etc.), so that in reality there is a syndrome of metabolic diseases of differing severity (Ahlqvist et al. 2018). Although genetic predisposition plays a role, it is the modern lifestyle which combines poor diet (excessive calories, processed foods, low amounts of fresh fruit and vegetables) with limited regular exercise, resulting in large sections of the population becoming overweight or even obese, which is strongly associated with the development of type 2 diabetes, which normally begins with lethargy or the need to drink larger volumes of water, but, if not adequately treated, can go on, after two to three decades, to result in blindness, loss of sensory feeling and poor blood flow in extremities (especially the feet), amputations, and early death. The onset used to be in late middle age, but in addition to the rapidly increasing incidence, the age of onset is dropping, such that the incidence among children is now very concerning. Early detection, before nerve and blood vessel damage has become too established, coupled with lifestyle/dietary changes and medication (if appropriate) is paramount to controlling blood glucose levels and prolonging the patient's active life. The effects of ecdysteroids on carbohydrate, protein, and lipid metabolism in mammals are particularly interesting in this respect. Many studies have now shown that ecdysteroids, while not affecting blood glucose levels in healthy subjects (Uchiyama and Yoshida 1974), reduce hyperglycemia. Again, these promising preclinical studies need to be supported by thorough double-blind clinical studies.

33.2.4.6 Anabolic Activity

Ecdysteroids (mainly 20E, but also turkesterone) are already extensively used by certain sportsmen, bodybuilders, bouncers, etc. to increase muscle mass and stamina. 11α-Hydroxy ecdysteroids, such as turkesterone, are claimed to have higher anabolic activity than 20E (Syrov 2000). The absence of the side effects (long-term muscle degeneration, virilization, roid (as it is a contraction of steroid) rage, etc.) characteristic of androgenic-anabolic steroids is an attractive feature of ecdysteroids for these user groups. Further, the anti-inflammatory effects may aid recovery from injuries. Many unregulated products are sold largely through the Internet, and they contain purified ecdysteroids or partially purified plant extracts (mainly from *Pfaffia glomerata* or *Cyanotis arachnoidea* [for 20E] and *Ajuga turkestanica* [for Turk]), often combined with other supposedly anabolic substances (protein, essential amino acids, creatine, etc.), but the composition and batch-to-batch reproducibility are uncertain. Their consumption is not supervised and does not follow a scientifically verified regimen; rather the users tend to follow the empirical advice of other users. As with all other unregulated pharmaceuticals, the safety of such preparations can be questioned. Regulation and standardization would benefit all.

33.2.4.7 Osteoporosis

Menopause in women is often accompanied by osteoporosis, where bone strength is lost and the incidence of fractures increases. Ecdysteroid-containing plants (*Achyranthes bidentata*, *Tinospora cordifolia*) have been traditionally used in Chinese and Indian medicines for the treatment of osteoporosis. Ecdysteroid-

containing plant extracts or pure 20E have an osteoprotective effect in ovariectomized rats without any effect on the uterus or mammary glands (Seidlova-Wuttke et al. 2010b). 20E stimulates the proliferation and osteogenic differentiation of bone marrow mesenchymal stem cells (Lafont 2012). Ecdysteroids also show promise to counteract secondary osteoporosis brought about when glucocorticoids are used in medication (Dai et al. 2017).

33.2.4.8 Anti-stress

The adaptogenic properties of ecdysteroids have been recognized in Eastern Europe and Russia for several decades (Panossian and Wikman 2005), and there is scope to expand this knowledge to increase resilience to the modern lifestyle by reducing the impacts of physical and mental stress, increase stamina, and increase resistance to infections. In this sense preparations of the water-soluble ecdysteroid might be consumed on an occasional basis as tonics and as components of teas or infusions. It seems that adaptogens cease to be effective if they are consumed on a daily basis for too long a period (a week to a few months, depending on the adaptogen and the performance required; Panossian and Wikman 2005), so it is to be expected that the ecdysteroid preparations would be consumed when fatigued and stressed, rather than as a "daily tonic." Thus, such preparations might help in people with seasonal affective disorder (SAD), loss of libido, loss of appetite, chronic fatigue, age-associated lethargy, sport-associated weariness, poor sleep patterns, and alcohol or narcotic withdrawal (Panossian et al. 1999)

33.2.4.9 Alzheimer's Disease

There are numerous reports indicating that ecdysteroids have potential as neuroprotective agents, in the treatment of neurological diseases, and the improvement of memory and learning. Thus, it is perhaps not surprising that their effects in model systems for Alzheimer's disease are beginning to be assessed. Alzheimer's disease is a neurodegenerative disease and is believed to account for 60–70% of cases of dementia. As humans are living longer, the incidence of Alzheimer's is increasing, such that there were 30 million sufferers worldwide in 2015. In the USA, in 2000, the incidence was 1.6% in the 64–74 age group, 19% in the 75–84 age group, and 42% in the >84 year olds, at a cost of $100 billion per year (Wikipedia: Alzheimer's disease). The risk factors are predominantly (70%) genetic, but environmental factors also play a role (e.g., smoking, pollution, poor diet, lack of physical or mental exercise). There is currently no cure, but certain treatments and lifestyle choices may delay onset or the development of symptoms. Progress in the search for effective medication has been hampered by the first symptoms (usually short-term memory loss) becoming apparent many years (perhaps decades) after the biochemical defects have been initiated, with the result that clinical trials of possible treatments have been performed on patients at a too advanced stage of the disease. Several hypotheses have been proposed for the underlying cause of the disease, of which the two major ones are the amyloid and tau hypotheses, which are, respectively, associated with the deposition and accumulation of insoluble extracellular amyloid-β plaques and the hyperphosphorylation of tau protein, which normally

stabilizes microtubules, resulting in neurofibrillary tangles in nerve cell bodies, bringing about cell death. Studies involving ecdysteroids have concerned the amyloid hypothesis. The N-terminal fragment of amyloid precursor protein (N-APP) and the adjacent amyloid-β proteins (Aβ; 39–42 amino acids in length) are aberrantly cleaved from the large amyloid precursor proteins (APP; several isoforms) by β-secretase 1 and γ-secretase (Chakraborty and Basu 2017). According to one version of the hypothesis, $A\beta_{1-42}$ initiates the plaques seen in the brains of Alzheimer's patients, and soluble forms bind to neuron cell-surface receptors and disrupt neuronal communication, while, according to a more recent version of the hypothesis, N-APP binds to neuronal receptor DR6 inducing self-destruction of the cell by apoptosis. An initial study (Yang et al. 2003) considered the ability of 20E to prevent aggregation of $A\beta_{1-42}$ into fibrils (precursors of the plaques) and found that 100 μM 20E prevented fibril formation in PBS and that neuronal cell viability consequent on treatment with $A\beta_{1-42}$ was increased in a dose-dependent manner by 20–100 μM 20E. In an independent study (Yang et al. 2010), involving six ecdysteroid analogues isolated from *Klaseopsis chinensis*, five of the analogues were found to enhance or decrease fibril formation, but, oddly, 20E was without effect at 50 μM. In a more recent study (Chakraborty and Basu 2017), 20E (20 μM) was found to prevent $A\beta_{25-35}$ (an analogue of $A\beta_{1-42}$, which also forms fibrils, but perhaps not with the same kinetics or affinity) aggregation in vitro. This study also looked at the effect of 20E on β-secretase 1 (BACE 1) and provides experimental evidence that 20E both binds to BACE 1 with a relatively high affinity (Kd = 1.75 μM) and prevents its catalytical activity, which were supported by in silico molecular docking studies which indicated that 20E binds to the active cavity of the enzyme, but does not interact directly with the amino acid residues responsible for catalysis. 20E also prevents Aβ-induced mitochondrial-dependent apoptosis in cultured human neuroblastoma cells (Xu et al. 2018). Thus, ecdysteroids appear to have potential to target several possible sites in the early development of Alzheimer's disease. However, studies on rats after i.p. injections of ecdysteroids show that although 20E diacetonide will cross the blood-brain barrier, 20E itself does not (Kalász et al. 2017).

33.2.5 Application in Food

33.2.5.1 Dietary Intake

Findeisen (2004) undertook a survey of 115 food items for the presence of ecdysteroids as detected by enzyme immunoassay, using the ecdysteroid-specific DBL2 antiserum. In addition to various fruits, vegetables, and nuts, she also tested a selection of meats, fish, ready meals, herbs and spices, dairy products, and drinks. Although low levels of immune-positive material were detected in most food samples, only fresh spinach (*Spinacia oleracea*; Amaranthaceae) contained a significant level (2210 μg 20E eq./g dw [0.22%]; 185 μg/g fw), with the next highest concentration being found in a sample of common mushrooms (*Agaricus bisporus*) at only 95 μg 20E eq./g dw; 8.5 μg/g fw. On the basis of the data obtained, it was

possible to estimate the intake of ecdysteroids associated with four main courses with meat or fish, or fast food, or vegetarian, all of which were calculated to contain between 10 and 66 μg 20E equivalents/meal, although none of these meals contained spinach and any losses during preparation were not allowed for. However, the data clearly indicate that the average dietary intake of ecdysteroids, at least in the Western European diet, is rather low, probably only very occasionally exceeding 100 μg/day. Also, these approximate calculations do not allow for the effects of cooking. Thus, Simon (1988) found that cooked spinach contained low levels of immunoreactive ecdysteroids (0.7 nmol ecdysone eq./kg = 0.3 ng E eq./g wet weight), indicating that most is leached out or destroyed during cooking of the leaves and stalks.

Around the world, the diversity of food plants is considerably greater than the range customarily consumed in the current Western diet. It is estimated that in total 20,000 species of plants are consumed to a greater or lesser extent by humans (https://pfaf.org/user/edibleuses.aspx). Most of these correspond to wild plants, and not to cultivars which have been optimized for yield and uniformity, but may also have reduced resistance to predators and diseases owing to lower levels of secondary compounds. However, 90% of the calorific intake from plant sources across the world is accounted for by just 33 crops (Table 2). Where these plants have been assessed for ecdysteroid content (not necessarily the consumed part), these major crop plants appear to contain little or no detectable ecdysteroids.

In certain parts of the world, the so-called pseudocereals have contributed significantly to the diets of the local populations over many centuries, and several of these have recently been "discovered" by Western societies and valued for their nutritional properties and even regarded as "super foods." Significantly, a high proportion of these crops are members of the Amaranthaceae (Table 3) and contain levels of ecdysteroids similar to those found in spinach; most of the other pseudocereals have not yet been adequately assessed to be able to say whether or not they contain ecdysteroids. A 100 g portion of quinoa would contain ca. 50 mg ecdysteroids (mainly 20E) before preparation and cooking. The extent of retention of ecdysteroids in quinoa grain during the usual preparation and cooking procedures has not been extensively studied, but it is known that immersion in water even at 25 °C results in leaching of about 20% of the ecdysteroid in 24 h (Graf et al. 2014). However, Kumpun et al. (2011a) found that, under normal cooking conditions (boiling for 20 min), >70% of the 20E was retained within the grain after cooking. These two findings together imply that ecdysteroids are present in quinoa grain in two forms, a readily leachable form and a more strongly retained form.

As part of the preparation for this chapter, a database was compiled of the major and minor food plants and the parts of the plant consumed, combined with information on whether any part of the plant had yet been examined for the presence of ecdysteroids and the levels detected (derived from the literature/Ecdybase and the Exeter Survey of ecdysteroid levels in plant seeds). Of the 746 edible plants included, 294 have been in any way examined for the presence of ecdysteroids, and only 17 (5.8%) contained more than 10 μg/g dw (>0.001%): *Amaranthus* spp. (Saeng-ngam et al. 2004; Bespayeva et al. 2012), *Atriplex* spp. (Dinan et al. 1998), *Chenopodium* spp. (Rastrelli et al. 1996; Dinan et al. 1998), *Dioscorea dumetorum*

Table 2 The 33 major world plant crops. (Modified from http://oregonstate.edu/instruct/ccs/330/two/Unit4Notes.htm) and their content of ecdysteroids: (a) sourced from Ecdybase (+ relevant reference); (b) sourced from Exeter Survey

(Sautour et al. 2008), *Halimione portulacoides* (Dinan et al. 1998), *Lamium* spp. (Savchenko et al. 2001), *Silene acaulis* (Zibareva et al. 2003), *Spinacia oleracea* (Dinan et al. 1998), and *Vitex donania* (Ochieng et al. 2013). Further, where plants have been assessed, it is often not the portions of the plant which are consumed which have been assessed for ecdysteroids. The database will be added to the Ecdybase website to provide access to the information and in a format which can be updated as further information becomes available.

In view of the limited nature of the data concerning the presence and quantification of ecdysteroids in food plants, it seemed worthwhile to assess a range of staple foods and a wide variety of fruits and vegetables with a specific HPLC-MS/MS method for the quantification of 20E (the most frequently encountered phytoecdysteroid in the plant world) and targeting those parts of the plants which are typically consumed. Of the plant food sources assessed, only spinach leaves/petioles and quinoa grain contained significant amounts of 20E, while virtually all other samples (Table 4) contained no detectable 20E. The spinach sample was found to contain 236 μg 20E/g dw, while a sample of commercial quinoa grain contained 138 μg 20E/g dw, which was reduced to 98 μg/g dw after heating at 100 °C in 10 volumes of water for 15 min (i.e., 32% of the 20E was lost to, and recovered in, the cooking water). The only other sample found to be positive was lemon (*Citrus limon*) fruit at 1.04 μg/g dw, which was at the limit of detection. However, this is interesting in the light of the report of the presence of ecdysteroids in *Citrus medica* (citron; Yin et al. 2015), which is a wild progenitor from which modern lemon and some lime hybrid cultivars are derived (summarized in Velasco and Licciardello 2014). Assessment of fruits of *C. medica* var. *sarcodactylis* (hand of Buddha), *C. maxima* (pomelo), *C. x clementina* (clementine), *C. hystrix* (kaffir lime), or *C. japonica* (kumquat) by HPLC-MS/MS did not detect 20E at or above the limit of detection (Table 4).

A further database has been prepared for the occurrence of ecdysteroids and ecdysteroid-related molecules in edible fungi. The world production of edible mushrooms is not insignificant, being 7,700,000 tonnes in 2011, of which 65%

Table 4 Plant foods (vegetables, fruits, herbs, and spices) tested for the presence of 20-hydroxyecdysone by means of a sensitive and specific HPLC-MS/MS method. Plant materials were purchased from supermarkets, freeze-dried, and powdered, and samples (ca. 100 mg) were extracted with 50% aq. ethanol (1.5 mL) at 75 °C for 2 h. An aliquot (1 mL) was diluted with water (4 mL) and partially purified on a pre-activated RP-SPE (SEPAK; Waters) cartridge, washed with 10% aq. methanol (5 mL), and eluted with 100% methanol (5 mL). Aliquots (5 μL) were subjected to RP-HPLC-MS for quantification of 20E (limit of detection = 50 ng/mL). See the text for a summary of the results

Latin binomial	Family[a]	Common name	Plant parts assessed
Abelmoschus esculentum	Malvaceae	Okra	Fruit

Zingiber officinale	Zingiberaceae	Ginger	Rhizome

[a]Family name according to APGIV (2016)
[b]Positive for 20E at the LOD (see text)
[c]Positive for 20E (see text)

were produced in China followed by 10% in Italy and 5% in the USA (Wikipedia: edible mushrooms). Mycoecdysteroids (reviewed in Kovganko 1999) have been much less extensively investigated than phytoecdysteroids, but it appears from the

data currently available that the levels found in fruiting bodies are generally low in comparison to those in phytoecdysteroid-containing plants and that a different range of structural modifications are found in fungi than in plants, such that 20E is often not the predominant ecdysteroid in a mycoecdysteroid profile and the ergostane-type ecdysteroid analogues are often related to cerevisterol ([22*E*,24*R*]-3β,5α,6β-trihydroxyergosta-7,22-diene). Since mushroom fruiting bodies are susceptible to attack by invertebrate pests (predominantly, but not exclusively, soil nematodes and dipteran sciarid [fungus gnats], phorid [humpbacked flies], and cedid [midges] flies; Singh and Sharma 2016), it is possible that mycoecdysteroids also serve a defensive function. No studies have been performed on the biosynthesis of mycoecdysteroids, so it is currently not possible to say if they are endogenously synthesized and taken up from the substrate or a precursor is taken up and modified by the fungus. An extract of the database, focusing on the edible mushrooms which have been investigated for ecdysteroids and ecdysteroid-related compounds, is presented in Table 5. It is clear that currently very few species of edible mushrooms have been examined for the presence of ecdysteroids and ecdysteroid-related compounds. The most extensively studies species is Polyporus umbellatus, which is not only edible but it is used extensively in traditional Chinese, Japanese and Indian medicines, primarily to treat oedema and as a diuretic, but also for other conditions, and without toxicity or side-effects (Zhao 2013).

33.2.5.2 Dietary Supplements

At the present time, 20E or extracts of ecdysteroid-containing plants (particularly *Pfaffia glomerata*; Brazilian ginseng) are incorporated into protein supplements aimed at body builders and sportsmen with the stated claim of enhancing the anabolic effect. With the growing interest in the potential of ecdysteroids to delay or reduce the impacts of age-related or genetically determined muscle wasting conditions or, more generally, to counteract various stresses as adaptogens, it is to be expected that range of ecdysteroid-supplemented foods will increase significantly in the near future and that they will be of interest to wider sections of society.

33.2.6 Safety: Toxicity and Side Effects

33.2.6.1 Data on Low Toxicity and Absence of Negative Side Effects

Ogawa et al. (1974) determined LD_{50}s for ingested 20E or inokosterone in mice of >9 g/kg and an LD_{50}s of 6.4 g/kg and 7.8 g/kg for i.p.-injected 20E and inokosterone, respectively. Thus, ecdysteroids are regarded as nontoxic to mammals. Also, no effects were seen after the administration of these two ecdysteroids to bullfrogs or rabbits. The two ecdysteroids did not have sex hormonal or, interestingly in the context of more recent studies, anti-inflammatory or anabolic effects in rats.

33.2.6.2 Ecdysteroids and Cancer

El Mofty et al. (1987, 1994) have claimed that E is carcinogenic to toads and mice, but the certainty of these findings has been questioned (Sláma and Lafont 1995;

Table 5 Edible fungal species for which the fruiting bodies have been assessed for the presence or absence of ecdysteroids or ecdysteroid-related compounds. Where possible, the quantities determined and the methods used are also given. This table summarizes and expands the information provided in the reviews by Kovganko (1999) and Mamadalieva (2013)

Latin name	Family	Common name	Category	Ecdysteroids and ecdysteroid-related compounds	Reference & Method
Agaricus blazei (A. subrufescens)	Agaricaceae	Almond mushroom, himematsutake	Commercially cultivated	Cerevisterol (2.3 mg from 5 kg fw), 3β,5α-dihydroxy-6β-methoxyergosta-7,22-diene (3.4 mg), 3β,5α,6β,9α-tetrahydroxyergosta-7,22-diene (6.3 mg), 3β,5α,9α-trihydroxyergosta-7,22-diene-6-one (5.7 mg)	Kawagishi et al. (1988); isolation and spectroscopic identification
Agaricus bisporus	Agaricaceae	Common mushroom	Commercially cultivated	Chestnut: 0.32 μg 20E eq./g dw	Findeisen (2004); ecdysteroid EIA (DBL2 antiserum)
				White 1: 20.1 20E eq. μg/g dw	
				White 2: 95.2 20E eq. μg/g dw	
				–	Biophytis (unpublished); HPLC-MS/MS for 20E
Amanita muscaria	Amanitaceae	Fly agaric	Edible only after cooking	–	Dinan (unpublished); RIA for ecdysteroids (DBL1 antiserum)

Amanita rubescens	Amanitaceae	Blusher	Edible only after cooking	–	Dinan (unpublished); RIA for ecdysteroids (DBL1 antiserum)
Boletus edulis	Boletaceae	Edible boletus	Commercially harvested from the wild	–	Dinan (unpublished); RIA for ecdysteroids (DBL1 antiserum)
Calvatia cyathiformis	Lycoperdaceae	Purple-spored puffball	Edible wild species	Calvasterone ([6,6′*R*]-biergosta-4,4′,7,7′,22,22′-hexaene-3,3′-dione)	Kawahara et al. (1993); isolation and spectroscopic identification
				Cyathisterone (ergosta-7,22-diene-3,6-dione; 30 mg from 4 kg fw)), cyathisterol (8β-hydroxyergost-4,6,22-trien-3-one; 80 mg), ergosta-4,7,22-triene-3,6-dione (300 mg), ergosta-4,6,8(14),22-tetraen-3-one (200 mg)	Kawahara et al. (1994); isolation and spectroscopic identification
				Calvasterol A (14α-hydroxyergosta-4,7,9,22-teraen-3,6-dione; 10 mg from 4 kg fw), calvasterol B (9α,14α-dihydroxyergosta-4,7,22-trien-3,6-dione; 15 mg from 4 kg fw),	Kawahara et al. (1995); isolation and spectroscopic identification

Tapinella atrotomentosa (Paxillus atrotomentosus)	Tapinellaceae	Velvet roll-rim, velvet-footed pax	Only young fruiting bodies are edible	Paxillosterone (356 mg from 6.65 kg fw), paxillosterone 20,22-p-hydroxybenzylidene acetal (5.5 mg), atrotosterones A (41 mg), B (3.9 mg) &C (5.5 mg), 25-hydroxyatotosterones A (11.9 mg) & B (4.2 mg), 20E (41 mg)	Vokáč et al. (1998); isolation and spectroscopic identification

Lafont and Dinan 2009) on the basis of the low doses used, relative to the amounts of ecdysteroids expected in the animals' normal diets. Neves et al. (2016) believe that 20-hydroxyecdyonse is genotoxic in a rat bone marrow micronuclei assay and an *Allium cepa* (onion) cell abnormality assay. However, other reports have claimed that ecdysteroids have no effects on tumor cell growth or even possess antitumor activity either alone (Hirono et al. 1969; Lagova and Valueva 1981; Takasaki et al. 1999) or in conjunction with known anticancer agents (Konovalova et al. 2002; Martins et al. 2012, 2015). Studies of this sort should be conducted with ecdysteroids of the highest degree of purity, which may not always have been the case.

33.2.6.3 Ecdysone and Effects on the Kidney

Recently (Lu et al. 2018a, b), it has been suggested that ecdysone (E, which is rarely a major phytoecdysteroid) has detrimental effects on renal function in mice at a dose of 6 μg/g/d, bringing about glomerular injury and proteinuria. The authors propose that E acts as a mimic of aldosterone, activating the mineralocorticoid nuclear receptor (MR), and that the detrimental effects can largely be blocked by spironolactone, an antagonist of MR. As yet, it is not known if these effects are common to other ecdysteroids, e.g., 20E.

33.2.6.4 Potential for Environmental Endocrine Disruption

As indicated above, the toxicity and safety data for 20E and the few other ecdysteroid analogues which have been in any way assessed do not indicate that dietary or environmental contact would have negative impacts on mammals. However, significant releases of ecdysteroids into the environment, either as a by-product of the isolation of large amounts of 20E for pharmaceutical/nutraceutical purposes or as the consequence of excretion of 20E or its metabolites by those taking doses (probably 0.5–5 g/person/day) for medical, health, or aesthetic reasons, might have serious detrimental effects on arthropods and other invertebrates, with aquatic insects and crustaceans being particularly susceptible if waste water and sewage are not appropriately treated before it enters natural water courses (Lafont and Dinan 2009). It will be necessary to determine the extent to which ecdysteroids are subjected to microbial degradation in passing through a sewage works and whether they can be readily removed from purified water by adsorption onto charcoal or reverse-phase materials. One can also envisage that signal invertebrate species (e.g., Asada et al. 2014) or cell-based bioassays (Dinan 1995a; Pounds et al. 2002) could be used to detect and monitor for the release of ecdysteroid agonists into the environment and thereby avoid serious environmental impacts.

33.2.7 Marketed Products

The Verde Vital series of commercial supplements (www.verdevital.de) contain spinach powder in preparations with other plant extracts, vitamins, minerals, fatty acids, creatine, resveratrol, etc. with designations for osteoporosis, muscle, joint, heart, and circulation problems and for improved stamina. The website indicates that

the daily dose for most of the supplements in the series contains 400–900 mg of "ecdysone," but this seems questionable since E is a minor ecdysteroid in spinach, and it may be that the amounts refer to the mass of spinach powder, in which case the amount of 20E would be ca.0.5–1 mg/day. Additionally, it has been questioned whether the ecdysteroid profile of these products is compatible with spinach alone, and evidence has been provided that ecdysteroids from another plant species (*Cyanotis arachnoidea*) have been added; quantification of 20E revealed 2–24 mg in daily doses of the various preparations (Hunyadi et al. 2016).

33.2.8 Relevant Patents

Over 275 separate patents concerning phytoecdysteroid preparations and their pharmaceutical, medical, and nutraceutical applications have been published over the last 50 years, with the number per annum increasing exponentially over the period. It is not possible to review all these patents in the context of this chapter, so we shall add the list of relevant patents to Ecdybase. Also, it is possible to access most patents on Google Patents, searching by criteria (key terms, year, inventor, etc.), and often the patent can be read in several languages.

33.2.9 Perspectives

Present evidence indicates that ecdysteroids are currently rare, nontoxic components of the human diet, with only those relatively small population groups (Andean Indians etc.) which consume a significant proportion of amaranth crops (quinoa, etc.) potentially receiving significant amounts of ecdysteroids, mainly 20E. It should be determined how much ecdysteroid those for whom quinoa or other amaranths are staple foods really do consume once it has been cooked, whether the pharmacokinetics of ecdysteroids are different in these people through genetic selection or induction of enzymes or other relevant biological processes and whether they are less susceptible to conditions which the consumption of ecdysteroids is believed to counteract (e.g., sarcopenia, type 2 diabetes).

One can expect the Western diet to undergo major changes over the next few decades, driven by two major factors: climate change and the need to reverse the spread of metabolic syndrome. Reduction in the consumption of meat, together with greater proportion and diversity of vegetables in the diet, the medicinal use of ecdysteroids, social health uses as adaptogens, anabolics, etc., can all be expected to increase the intake of phytoecdysteroids. Enhanced levels of ecdysteroid in crop plants could arise from increasing the levels of these compounds by GM or non-GM means for crop protection purposes or for health/nutraceutical reasons (e.g., using the diet to help counteract the effects of aging and/or inactivity).

Clearly, for this to become feasible, we need fundamental data on the elucidation and characterization of the biosynthetic pathway(s) for ecdysteroids in plants and a thorough understanding of how their synthesis and metabolism are regulated. Only then will it be possible to devise rational strategies for enhancing ecdysteroid levels

in other crop species and also for controlling the regulation so that the desired analogues are produced at the desired concentrations, at the right time, and in the correct parts of the plant to optimize crop protection or nutraceutical value.

On the other side of the equation is our currently incomplete understanding of the mode(s) of action, pharmacokinetics, and metabolism of ecdysteroids in mammals and particularly in humans. The low toxicity and plethora of beneficial effects which have been ascribed to ecdysteroids are encouraging for their future development, but the low bioavailability means that ingested doses of 20E have to be relatively large, which increases cost and raises supply problems (especially as 20E can only be realistically obtained by isolation from a rich plant source; 20E is chemically too complicated for efficient commercial chemical synthesis) and the potential release of an invertebrate endocrine disruptor into the environment.

In theory, bioavailability might be increased by improved formulation, modified routes of application (e.g., sublingual or dermal implants; Dittrich et al. 2000), or the use of new analogues with greater potency (improved bioavailability, reduced metabolism and/or rate of excretion, enhanced biological activity), but since 20E is currently the only ecdysteroid which can be isolated economically in adequate amounts and semisynthetic routes from this analogue would have to be high yield, the options are presently restricted.

The mode(s) of action of ecdysteroids in mammalian systems needs to be fully established. It is clear that it is very different from the main modes of action of ecdysteroids in insects or crustaceans and that it involves signalling from the plasma membrane, but the precise nature and whether the same or different signalling systems operate in different mammalian target tissues need to be determined. As for vertebrate steroid hormones, membrane-, as well as nuclear-, receptors for ecdysteroids have relatively recently been detected in invertebrate systems (e.g., Elmogy et al. 2004; Srivastava et al. 2005), and thus research on ecdysteroid membrane receptors in mammals and invertebrates can be expected to cross-fertilize each other.

Only after concerted effort to understand the bioavailability, mode of action, metabolism, and excretion of ecdysteroids in specific mammalian systems will it be possible to fully exploit the extensive range of analogues which already exist to identify more active analogues and more potent analogues which possess better bioavailability or resistance to metabolism and excretion.

The historical and continuing traditional medicinal uses of ecdysteroid-containing plants and the large number of scientific publications attesting to a plethora of essentially beneficial pharmacological effects in mammals, including humans, attest to the great promise and strong potential of ecdysteroids for the development of a new class of drug for the treatment or at least slowing the progress of several currently intractable muscle wasting diseases and modern societal syndromes, such as obesity or type 2 diabetes. The way to reach this goal is long and demanding, as it requires companies to invest much time, effort, and money into the identification of a good plant source of 20E, secure a reliable supply of the compound, develop an economically viable industrial-scale procedure for the preparation of pharmaceutical grade drug; obtain thorough evidence for the effectiveness, efficacy, pharmacokinetics, and mode of action in animals and humans; and successfully complete all the necessary clinical trials. Preclinical and clinical trials of 20E have recently been initiated for a

number of designated disease conditions (sarcopenia, Duchenne muscular dystrophy) and can be expected to be completed within the next year. This is reassuring because although the first data on the effects of ecdysteroids on mammals goes back almost 50 years, the area had been very deficient in thorough clinical trials because enough pure 20E simply was not available.

33.3 Conclusions

Phytoecdysteroids accumulate in a wide range of plant species where they serve to deter invertebrate predation. In this context, ecdysteroids are currently natural components of a limited number of natural food plants, with quinoa and spinach being responsible for the largest amounts of ecdysteroids in the human diet. 20E, at least, is nontoxic and appears to have many positive biological effects in mammalian systems. Thus, one could envisage the amount of dietary ecdysteroids significantly increasing in the near future, if (i) ecdysteroid levels are elevated in other crop species either to enhance their resistance to predation or to take advantage of the promising biological activities of the ecdysteroids, (ii) phytoecdysteroids become established as therapeutic agents for muscle wasting diseases or type 2 diabetes, and (iii) phytoecdysteroid-containing preparations become more popular as anabolic and adaptogenic dietary supplements among specific groups (sportsmen, body builders, etc.) or as tonics for the general public. There remains a strong need to elucidate biosynthesis and regulation of phytoecdysteroid biosynthesis and to clarify the pharmacokinetics and mode of action in responding mammalian cells, but ecdysteroids are showing considerable promise and potential as therapeutic agents of the future.

Abstract

Food is one of the three basic requirements of mankind, supplying six kinds of nutrients including water, carbohydrate, protein, lipid, vitamins, and minerals. Alkaloid-containing foods are an intrinsic part of the human diet, such as tea, coffee, and tomato. These food-oriented alkaloid constituents possess diverse effects on the human body, either wanted or unwanted. A large variety of food-produced alkaloids exhibit potent bioactivities, such as caffeine, atropine, and cocaine, whereas, lots of other alkaloids are toxic to human, such as pyrrolizidine alkaloids. This chapter focuses on the alkaloids in human diet and their mode of action and possible toxic effects. To organize this chapter, the alkaloids were categorized into nine groups based on their structures: pyrrolizidine alkaloids, tropane alkaloids, quinolizidine alkaloids, isoquinoline alkaloids, quinoline alkaloids, glycoalkaloids, purine alkaloids, pyridine alkaloids, and amide alkaloids. The structures of food-derived alkaloids are described, and their pharmacological activities, bioavailability, metabolism, and toxicological effects are discussed. Moreover, the application of alkaloids in medicines and food supplement, patents, as well as a conclusion about their current impact on food safety are reviewed. The main purpose of this chapter is to provide a comprehensive and up-to-date state of knowledge from phytochemical, pharmacological, and toxicological studies performed on alkaloids in human food.

Keywords

Alkaloids · Bioactive constituents · Toxicity · Bioavailability · Safety

34.1 Introduction

Alkaloids are a class of nitrogen-bearing organic compounds, which are produced by a large variety of organisms, including bacteria, fungi, plants, and animals. More than 13,000 alkaloids have been isolated and structurally elucidated. Plants are the major sources of alkaloids, especially certain families of flowering plants, including Papaveraceae (poppy), Amaryllidaceae (amaryllis), Ranunculaceae (buttercups), Solanaceae (nightshades), and Stemonaceae. Commonly, a given species contains only a few alkaloids with the same core structure, such as the opium poppy (*Papaver somniferum*) and the ergot fungus (*Claviceps*) each containing about 30 different morphine and ergoline alkaloids, respectively. Animal-produced alkaloids are seldom reported, such as the New World beaver (*Castor canadensis*) and poison-dart frogs (*Phyllobates*). Interestingly, alkaloids are widely existed in regular human diet, either intrinsic constituents of vegetables and drinks or food contaminants and flavorings from food processing.

The function of alkaloids in plant is largely unknown. Alkaloids were originally considered as the by-products of plants' metabolic processes, such as the biosynthesis of amino acids. More and more evidence has suggested that some alkaloids serve specific physiological function in plants, such as to protect some plants against certain microorganisms, insects, or animals, to mediate signaling transduction in plants, and to stimulate seed formation and ripeness.

Alkaloids exist in plant tissues as water-soluble salts of organic acids and esters or combined with tannins or sugars rather than as free bases. In their pure form, most alkaloids are colorless, nonodorous, nonvolatile, and crystalline solids. The free bases of alkaloids are prone to dissolve in nonpolar organic solvents, such as chloroform and ether. On the contrary, the salts of alkaloids are soluble in water or dilute acids. The differences in the solubility of alkaloids, depending on their forms, are used in laboratory and industry for the extraction and production of pharmaceutically acceptable products. They also tend to have a bitter taste, such as quinine which is used as a bitter principle in tonic water.

The structural diversity of alkaloids is extremely significant. Most alkaloids have one or more of their nitrogen atoms as part of a ring structure. Biosynthetic precursors of most alkaloids are amino acids, including ornithine, lysine, phenylalanine, tyrosine, tryptophan, histidine, aspartic acid, and anthranilic acid. The biosynthetic pathways of alkaloids are too numerous and mostly remained unknown at the current stage.

Alkaloids possess diverse and significant physiological effects on humans and other animals (both wanted and unwanted); thus they have been used for thousands of years as medicines, poisons, stimulants, insecticides, aphrodisiacs, and narcotics. Morphine is the first alkaloid to be isolated and crystallized in 1804, as the active constituent of the opium poppy, which is a powerful narcotic used for the relief of pain. Codeine, the methyl ether derivative of morphine from the opium poppy, is an excellent analgesic. Ergonovine (from the fungus *Claviceps purpurea*) and ephedrine (from *Ephedra* species) function as blood vessel constrictors. Ergonovine is used to reduce uterine hemorrhage after childbirth, and ephedrine is used to relieve discomfort from common colds, sinusitis, hay fever, and bronchial asthma. Quinidine, widely distributed in plants of the genus *Cinchona*, has been used to treat arrhythmias and irregular rhythms of heartbeat; quinine (from *Cinchona* species) is used to treat malaria. The alkaloid curare (from *Chondrodendron tomentosum*) is used as a muscle relaxant in surgery. Two alkaloids, vincristine and vinblastine (from *Vinca rosea*), are widely used as chemotherapeutic agents in the treatment of many types of cancer.

Alkaloids are often classified on the basis of their chemical structures. To organize this chapter, the common alkaloids in human diet were classified into nine groups based on their core structures: pyrrolizidine alkaloids (PA), tropane alkaloids (TA), quinolizidine alkaloids (QA), isoquinoline alkaloids, quinoline alkaloids, glycoalkaloids (GA), purine alkaloids, pyridine alkaloids, and amide alkaloids. The core structures of the nine types of alkaloids were shown in Fig. 1. For each type of alkaloids, the occurrence in food and their chemical structures are described, their pharmacological activities, bioavailability, metabolism, and the

application in food (including correctly cooking foods rich in phytochemicals) are introduced, and the marketed products, toxicological effects, and existing safety assessments are discussed.

34.2 Pyrrolizidine Alkaloids

PAs, also called as necine bases, are a group of naturally occurring alkaloids with a core structure of pyrrolizidine (Fig. 1). More than 660 PAs and their N-oxides have been identified in around 6,000 plants, and more than half of them exhibit hepatotoxicity. PAs are produced by plants as a defense mechanism against insect and herbivores. They are found frequently in plants from the families Boraginaceae, Asteraceae (Senecioneae and Eupatorieae), Orchidaceae, and Fabaceae (*Crotalaria*), less frequently in the families Convolvulaceae and Poaceae.

Many kinds of foods have been reported to produce PAs, including borage (*Borago officinalis*), comfrey (*Symphytum officinale*), *Gynura bicolor*, and *Emilia sonchifolia*, to possess PA contamination, such as honey. Food-containing PAs are mostly esters of 1-hydroxymethyl-1,2-dehydro-pyrrolizidine, which always bear a hydroxyl group on carbon 7. Some examples of PAs in food were shown in Fig. 2. In grain commodities, the PAs are considered to originate from seeds or plant fragments of PA-containing weeds (ranging from 50 to 6,000 mg/kg). The consumption of PA-contaminated grains causes acute or chronic liver toxicity. Symptoms of acute PA poisoning include abdominal pain, ascites, nausea, vomiting, diarrhea, dropsy, and very rare, jaundice and fever. PA poisoning is associated with hepatic vein occlusive disease (HVOD) involving obstruction of the small veins with sudden hepatomegaly (enlarged liver) and ascites and may end with death (Dharmananda 2004). According to the World Health Organization (WHO), the lowest daily intake of PAs that causes adverse effects in a human is 0.015 mg/kg body weight,

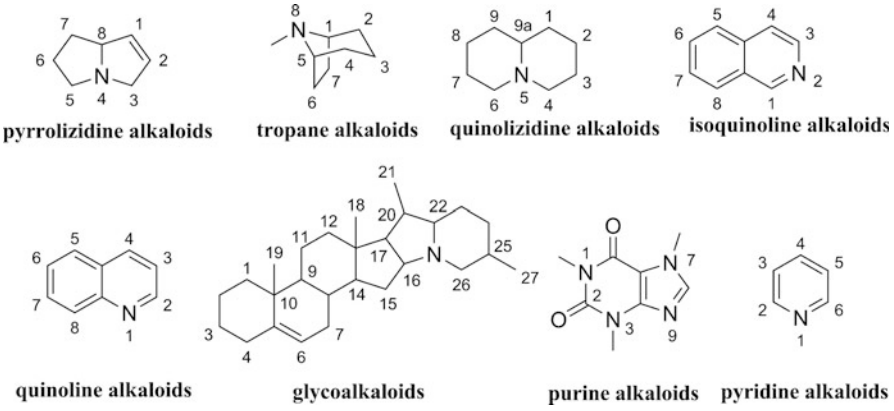

Fig. 1 The core structures of pyrrolizidine alkaloids, tropane alkaloids, quinolizidine alkaloids, isoquinoline alkaloids, quinoline alkaloids, glycoalkaloids, purine alkaloids, and pyridine alkaloids

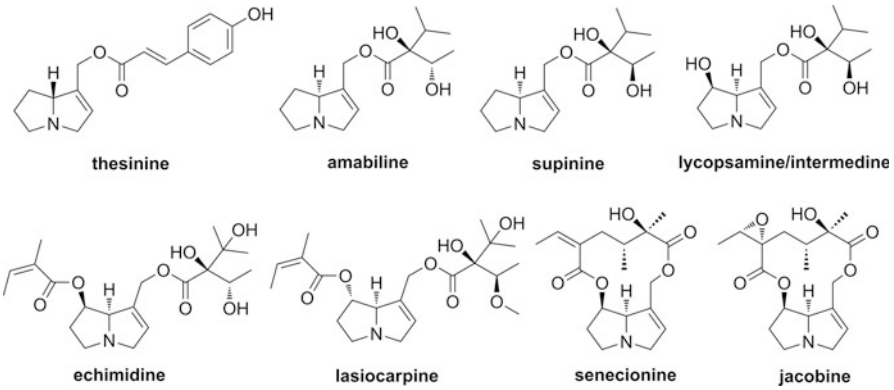

Fig. 2 Some representative PAs in the plant-derived food

corresponding to 0.9 mg/day for a 60 kg person, based on the use of comfrey over a period of 4–6 months (Dharmananda 2004). PAs exert fetotoxic and teratogenic effects at higher doses (Wiedenfeld et al. 2008).

PAs are metabolically activated within the liver, and they can alkylate both proteins and DNA molecules; they are therefore hepatotoxic causing liver damage, as well as mutagenic and carcinogenic. The major metabolic pathways of PAs in human are described as follows: Ester hydrolysis and N-oxidation of PAs represent detoxification processes (Prakash et al. 1999). Toxicity occurs via dehydrogenation of the pyrrolizidine nucleus to generate dehydro-pyrrolizidine moiety (pyrrolic derivatives), followed by acid-catalyzed cleavage of the C7-O bond, resulting in the formation of a carbocation. Then, carbocation may react with available nucleophiles like DNA, leading ultimately to liver necrosis and tumor formation (Prakash et al. 1999).

34.2.1 Borage (*Borago officinalis*)

Borago officinalis (Boraginaceae) is known as starflower, borage, burrage, bourrache, and bugloss. Borage is a plant being widely used in pharmaceutical, industrial, and forage fields and is also being used to make drinks and salads. Borage is native to Europe, North Africa, and Asia Minor and is now being cultivated worldwide. Historical documents showed that borage was firstly cultivated in North Africa and then spread to Spain and other regions.

Borage is a common vegetable in Germany, the Spanish regions of Aragon and Navarre, the Greek island of Crete, and the northern Italian region of Liguria. The plant parts of borage are used in the following ways: leaves made into tea, washes, and poultices; flowers eaten; seeds pressed for oil; and tinctures made from leaves and flowering tops. One of the well-known German borage recipes is the green sauce (grüne soße) made in Frankfurt. In Italian Liguria, borage is commonly used as a filling of the traditional pasta ravioli and pansoti. The flowers or petals of borage are

edible and often used as a garnish on salads and soups and used to flavor pickled gherkins in Poland.

Borage leaves have been used in European herbal medicine since the Middle Ages and are mentioned by Pliny, Dioscorides, and Galen. The name "borage" derives from the Medieval Latin "burra," meaning rough-coated, which refers to the hairs. An alternative explanation suggests it is a corruption of the Latin "corago" (courage). This is in line with its reputation as an herb to dispel melancholy. Borage leaves also have been used to treat rheumatism, cold, and bronchitis, as well as to increase lactation in women. Infusions of the leaves were used to induce sweating and diuresis. Before the invention of ice, borage was used in a cooling drink called a "cool tankard" or "claret cup" consisting of wine, water, lemon, sugar, and borage leaves and flowers. Borage is still widely used in British herbalism, but its use has been waned in North America.

Pliny the Elder believed borage to be antidepressant, and it has long been thought to give courage and comfort to the heart. One old wives' tale states that if a woman slipped a bit of borage into a promising man's drink, it would give him the courage to propose. In European traditional medicine, the heart was believed to store the vital spirit and circulate it around the body via the arteries. Thus "heart medicines" were usually medicines for the spirit – for depression and confusion. Lemon balm (*Melissa officinalis*), lily of the valley (*Convallaria majalis*), motherwort (*Leonurus cardiaca*), and borage are specifics for matters of the heart. These remedies were used to protect the heart from excess heat in high fevers, and borage was much favored for this. Motherwort and borage are a useful combination in thyrotoxicosis, which is a modern version of "excess heat attacks the heart."

The leaves of borage were found to contain a high amount of PAs (10 mg/kg) (Dharmananda 2004). Thesinine (Fig. 2) is one of the few nontoxic PAs produced by plants and is responsible for the deep blue color of the flowers of borage. It tastes sweet, honey-like, and is one of the few blue but edible compounds. Borage also produces small amounts of the poisonous PAs, including amabiline, supinine, intermedine and its enantiomorph lycopsamine, and their 7-acetyl derivatives (Fig. 2). Amabiline and supinine are structural analogues of indicine, a predominant PA in the seeds from plants of the *Heliotropium* species, which might contaminate cereals and grains intended for human and animal consumption. It is not recommended that borage leaves be taken long term internally because of the concentration of PAs that can damage the liver. Some recommend limiting its use to 4–6 weeks, others say 2–3 months at a time. Most sources specify low doses and limited use. Young leaves of borage have been shown to contain less PAs than older ones. Do not take borage if the persons are taking anticoagulants. Borage can cause nausea, cramping, bloating, and headache, although they are relatively mild. Currently, borage is not recommended during pregnancy or lactation, but it has been traditionally used as a galactagogue. Additionally, the hairs on the fresh leaves can irritate the skin.

PAs are also present in borage seeds oil but may be removed by processing. Analysis of borage seed oil showed the possible existence of PAs to induce side effects. Borage seed oil is used for chronic skin inflammatory disease, skin itch, and stimulation problems.

34.2.2 Comfrey (*Symphytum officinale*)

Comfrey (*Symphytum officinale*) is commonly found throughout Europe and parts of Asia and North America, which has been used as a herbal medicine for the treatment of painful muscle and joint complaints for more than 2,000 years. Comfrey is commonly called knitbone because of its amazing ability to heal broken bones and "knit" them back together again. The botanical name, *Symphytum*, means "to unite." Comfrey is used to treat upset stomach, ulcers, heavy menstrual periods, diarrhea, bloody urine, persistent cough, and chest pain as well as is applied to the skin for wounds, joint inflammation, bruises, and rheumatoid arthritis. The leaves and roots of comfrey are also used as herbal teas and vegetable (e.g., in salads).

Several PAs, including echimidine and lasiocarpine (Fig. 2), have been isolated from comfrey. The PA content in comfrey leaves varies from 20 to 1,800 mg/kg. Comfrey root contains PAs with 1,2-unsaturated necine ring structures, almost entirely in the form of their N-oxides, the main ones being 7-acetylintermedine and 7-acetyllycopsamine together with smaller amounts of intermedine and symphytine (Fig. 2). The total amount of PAs given by different authors varies from 0.013% to 1.2% based on the analytical methods.

The major hepatotoxic manifestation in humans ingesting comfrey is hepatic VOD, also called sinusoidal obstruction syndrome (SOS). Several cases of VOD/SOS associated with comfrey ingestion were reported in humans, as well as in experimental animals. Comfrey-induced dose-dependent hepatic VOD was found in rats that were gavaged with a single dose of 200 mg/kg of the mixed PA or 50 and 100 mg/kg thrice a week for 3 weeks. The mechanisms underlying comfrey-induced genotoxicity and carcinogenicity are still not fully understood. The available evidence suggests that the active metabolites of PAs in comfrey interact with DNA in liver endothelial cells and hepatocytes, resulting in DNA damage, mutation induction, and cancer development.

In 2001, the US Food and Drug Administration issued a ban on comfrey products marketed for internal use and a warning label for those intended for external use (FDA/CFSAN 2007). Nowadays, only pyrrolizidine-depleted or pyrrolizidine-free extracts are used in proprietary medicinal products. Comfrey should not be used during pregnancy and lactation, in infants, and in people having liver, kidney, or vascular diseases. To date, the activity-determining constituents and mechanisms of action of comfrey are only partly known. In accordance with the modern approach of evidence-based medicine, comfrey extract creams have been demonstrated their efficacy and tolerability in a number of muscle and joint injuries, such as acute myalgia in the back area, and in blunt injuries. Comfrey herb has also been shown to be efficacious in wound healing. Comfrey root has also been proven to be efficacious in activated osteoarthritis and equivalent or more efficacious in distortions compared with topical diclofenac. It could therefore be promising to investigate topical comfrey preparations in further indications related to muscle or joint pain, for instance, chronic forms of back pain.

34.2.3 Honey

Honey is a sweet, viscous food substance produced by bees and some related insects. Bees produce honey from the sugary secretions of plants (floral nectar) or from secretions of other insects (such as honeydew). Honey production and use have a long history, depicted in Valencia, Spain, by a cave painting of humans foraging for honey at least 8,000 years ago. Over its history as a food, honey is used as a spread on bread; an addition to various beverages, such as tea; and a sweetener in some commercial beverages. Honey barbecue and honey mustard are other common flavors used in sauces. Honey is also used to make mead beer, called "braggot."

Honey made by bees foraging on *Senecio jacobaea* (tansy ragwort) contain senecionine and jacobine, with the total PA content ranging from 0.3 to 3.9 mg/kg (Fig. 2). The highest level of PAs is 3.9 mg/kg in honey from *Senecio jacobaea*; because this value was not corrected for extraction efficiency, the amount of PAs might be higher.

Plant genera-producing PAs are important contributors to honey production in many countries. Honey made by bees foraging mainly on *Echium* spp. contains echimidine as the major alkaloid (Fig. 2). Analysis of honey available on the German/European market revealed that 19 samples (9%) contained PAs within the 216 samples, in the range of 0.019–0.120 mg/kg, calculated as retronecine equivalents (Kempf et al. 2008).

Levels of PAs present in honey from PA-containing plants are well above that considered by the German Federal Health Bureau. Long-term consumption of PA-containing honey is capable of causing progressive chronic toxicity, especially in infants and fetuses. Although no incidents of PA poisoning have been reported due to consumption of honey, a report issued by the International Programme on Chemical Safety (IPCS) concluded that the level of PAs in honey may contribute to chronic liver disease or liver tumors (Edgar et al. 2002).

34.3 Tropane Alkaloids (TAs)

TAs are a class of bicyclic [3.2.1] alkaloids and secondary metabolites that contain a tropane ring in their chemical structure. TAs are found in plants of numerous families, especially Solanaceae, Erythroxylaceae, Convolvulaceae, Brassicaceae, and Euphorbiaceae, and they comprise mono-, di-, and tri-esters and carboxylated and benzoylated tropanes. More than 200 TAs have been isolated and identified. Several of these alkaloids occur as chiral structures due to the presence of a tropic acid residue attached to the ecgonine nucleus as an ester. The former occurs naturally in its *R* form; however, racemic mixtures may appear, especially during alkaline extraction (e.g., the formation of (+)-atropine from (−)-hyoscyamine). Several acids are distinguished as being present in the TAs, including tropic, tiglic, acetic, isovaleric, isobutyric, benzoic, or anisic acids.

TA-containing plants have been used medicinally and for folkloric purposes in many countries. Atropine, hyoscyamine, and scopolamine are used therapeutically

for different medical indications. TAs are commonly used as anti- colic and spasmolytic drugs (scopolamine) in both digestive and urinary tract spastic conditions. Especially, atropine is commonly used in ophthalmological eyedrops to enlarge pupils, paralyze the accommodation reflex, and enable the ophthalmic examination. The juice from *Atropa belladonna* was extensively used by women in the time of the Renaissance to enlarge the pupils of the eyes so as to improve their looks. The bioactivities of TAs are relied on the antagonistic action on muscarinic acetylcholine receptors (Brown and Taylor 2006). Several TAs are hallucinogenic agents and some are powerful anticholinergic drugs.

Plants synthesize and store TAs as a protection against being eaten (e.g., by insects). Most TAs are toxic to humans. However, TAs are characterized by numerous contraindications and side effects. The effects of TA administration are characterized by dryness of the mucosa of the upper digestive and respiratory tract, constipation, pupil dilatation, disturbance of vision, photophobia, dose-dependent occurrence of hyper- or hypotension, bradycardia, tachycardia, arrhythmias, nervousness, restlessness, irritability, disorientation, ataxia, seizures, and respiratory depression (EFSA 2008b). Oral administration of atropine in single doses of 0.5–1 mg up to three times daily is used to treat smooth muscle spasms in the gastrointestinal tract, which causes side effects including slight cardiac slowing and dryness of mouth (Brown and Taylor 2006). A single oral dose of atropine in the range of 2–5 mg is associated with rapid heart rate, dilated pupils, blurring of vision, difficulties of speaking and swallowing, and dry and hot skin (Meletis and Wagner 2002). Oral doses of 10 mg or more atropine lead to rapid and weak pulse, ataxia, restlessness, excitement, hallucinations, delirium, and coma (Brown and Taylor 2006). Hyoscyamine is used in the treatment of visceral spasm in oral single doses of 0.15–0.3 mg up to four times daily, showing the same adverse effects as atropine (Martindale 2010). Scopolamine is administered orally in single doses of 0.15–0.3 mg up to four times daily in the prevention of postoperative dizziness and motion sickness. Typical adverse effects for anticholinergic drugs such as dryness of the mouth, changes in heart rate, and disturbance of vision are reported within the range of the therapeutically dosage (Martindale 2010). TAs should be avoided in patients with glaucoma, prostatic hypertrophy, and urinary tract diseases and also during pregnancy.

TA intoxications for humans result mainly from abuse (because of the hallucinogenic effects), consumption with TA-containing plants, or accidental exposure (EFSA 2008b). Cocaine is a drug of abuse in many countries. It is the second most popular psychostimulant (after cannabis), temporarily improving mental and physical functions. Cocaine inhibits serotonin, norepinephrine, and dopamine reuptake. In higher doses, cocaine may evoke the blockage of sodium channels resulting in cardiac death. Chronic intake may cause serious transmitter level disorders leading to depressions, suicide attempts, insomnia, or psychomotor retardation. Its abuse resulted in more than 4,000 deaths in 2013. It has local anesthetic properties which are largely forbidden nowadays. After absorption, hydrolysis of TAs inactivates their bioactivities and reduces their toxicity in certain animal species (EFSA 2008b).

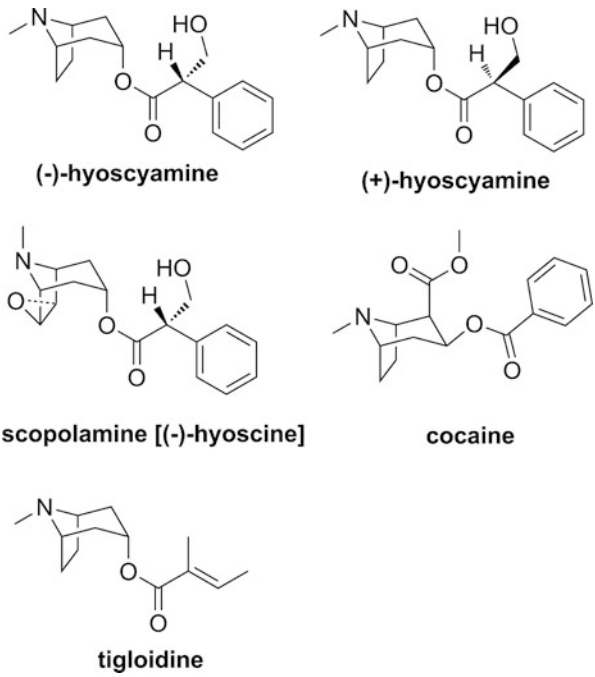

Fig. 3 Structures of some representative TAs in the plant-derived food

The TA-containing foods include wolfberry (*Lycium barbarum* L.), buckwheat (*Fagopyrum esculentum*), soybean (*Glycine max*), flax (*Linum usitatissimum*), Cape gooseberry (*Physalis peruviana*), and coca (*Erythroxylum coca*). The structures of some food-producing TAs were shown in Fig. 3, such as (−)- and (+)-hyoscyamine (a racemic mixture of these two alkaloids is known as atropine), (−)-scopolamine (also known as (−)-hyoscine), and cocaine.

34.3.1 Wolfberry (*Lycium barbarum* L.)

Lycium barbarum L. and *Lycium chinense* Miller (wolfberry, belonging to Solanaceae family) are two closely related species with congruent uses as food and medicinal plants in East Asia. The berries of both species are a very popular ingredient in Chinese cuisine. They are consumed in soups and porridges and added to different meat and vegetable dishes. The young leaves of both species are a valued vegetable.

Wolfberries are not only a vegetable but also a traditional Chinese herbal medicine. Although only *L. barbarum* is officinal in the China Pharmacopoeia, both species, *L. barbarum* and *L. chinense*, have been used medically for more than 2,000 years. In traditional Chinese medicine, wolfberries are used as a mild Yin tonic, enriching Yin in the liver and kidney and moistening lung Yin. Wolfberries are prescribed to treat blurry vision and diminished visual acuity, infertility, abdominal

pain, dry cough, fatigue, and headache. The berries are also praised in the folk medicine to increase longevity and against prematurely gray hair. In a representative study with 42 elderly participants, consumption of 50 mg of wolfberry extract twice a day over 2 months decreased dizziness, fatigue, chest distress, sleep problems, and anorexia. Besides China, wolfberry is also used as herbal drug in other Asian countries, including Vietnam, Korea, and Japan.

Wolfberry is commonly designated as "Himalayan goji berry" or "Tibetan goji berry" on the global functional food market. The variety of commercialized products is considerable. Besides juices, beers, and wines, wolfberry is found in cookies, crispy bars, chocolate, muesli, sausages, and soaps. Wolfberry products are increasingly available in drugstores, "Reformhäuser," and organic food shops. Wolfberries and its related products are legally sold as food or food supplements in USA and Europe. However, these products cannot be promoted as drugs, and therapeutic claims are prohibited.

There have been some controversial reports about the atropine content in the fruits of *L. barbarum*. In 1989, a report showed around 0.95% atropine in the fruits of *L. barbarum* collected in India. In a systematic investigation of wolfberries from various provenances, only trace amount of atropine was detected with high-performance liquid chromatography-mass spectrometry (HPLC-MS) method, maximally 19 ppb (w/w) among the analyzed samples (Adams et al. 2006). The presence of atropine in the roots of wolfberry was reported, which is much higher than that in the fruits. In 2006, the US Food and Drug Administration sent warning letters to two wolfberry juice distributors in violation of marketing their product as a drug intended for the prevention or cure of disease, when wolfberry juice is not generally recognized as safe and effective for various health benefits.

The LD_{50} value of a water extract of wolfberries is 8.32 g/kg by subcutaneous application in mice (Potterat 2010), which confirms the virtual absence of toxicity of wolfberry. Although there is no risk with cultivated plants, some caution is advised with samples of unknown origin.

34.3.2 Buckwheat (*Fagopyrum esculentum*)

Buckwheat (*Fagopyrum esculentum*), also known as common buckwheat, Japanese buckwheat, and silver hull buckwheat, is a plant cultivated for its grain-like seeds and as a cover crop. The crop was originated from China, and nowadays, it is widely cultivated over the world. Buckwheat noodles have been consumed by people from Tibet and Northern China for centuries, as wheat cannot be grown in the mountain regions. Nowadays, buckwheat noodles are very popular in the cuisines of Japan (soba), Korea (naengmyeon, mak-guksu, and memil guksu), buckwheat fresh pasta (pasta di grano saraceno) are commonly consumed in Apulia region of Southern Italy and the Valtellina region of Northern Italy (pizzoccheri), and buckwheat groats are commonly used in Western Asia and Eastern Europe. Dehulled seeds (raw groats) are principally used for human consumption as breakfast cereals or as processed flour for making different bakery products and buckwheat-enhanced

nonbakery products (tea, honey, tarhana, and sprouts). Buckwheat is a gluten-free pseudocereal; these products may be included in gluten-free diets for patients suffering from gluten intolerance.

Buckwheat is an important raw material used for functional food because it exhibits a broad range of bioactivities, such as antidiabetic, hypotension, hypocholesterolemic, and hypoglycemic effects. Buckwheat becomes a dietary source of bioactive compounds, such as nutritionally valuable protein, phenolic compounds, starch and dietary fiber, essential minerals, and trace elements. However, TAs are found in buckwheat and its related matrices at concentrations higher than 100 μg/kg. The major source of TA contamination in buckwheat is stramonium (*Datura stramonium*), which produces high concentration of TAs, including atropine and scopolamine. In most temperate climates, stramonium can easily thrive as weeds in buckwheat fields. Despite an adequate management, postharvest handling, and control, some seeds may go undetected to subsequent stages of the food chain making a certain degree of contamination by these TAs unavoidable. Both *Datura* and *Fagopyrum* species in fact produce, and maturate almost simultaneously, a dehiscent fruit-harboring seeds with similar size and weight. It may be particularly relevant for organic agriculture, as a less strict weed management may allow an increased in-field presence of potentially dangerous plants alongside with crops.

34.3.3 Soybean and Flax

Soybean is a species of legume native to East Asia. Soybean is a significant and cheap source of protein for animal feeds and many packaged meals. Soybean products, such as textured vegetable protein (TVP), are ingredients in many meat and dairy substitutes. Approximately 85% of the world's soybean crop is processed into soybean meal and soybean oil. Tofu, soy milk, and soy sauce are among the top edible commodities made from soybeans.

Flax (*Linum usitatissimum*), also known as common flax or linseed, is a species from the family Linaceae. It is a food and fiber crop cultivated in cooler regions of the world. Flax is grown for its seeds, which can be ground into a meal or linseed oil, a product used as a nutritional supplement.

TA contamination has been found in soybean and flax (animal feed). In surveys conducted in Germany, up to 31.1% of soybean and flax products were contaminated with *Datura* seeds; and 65 of the 66 samples contained scopolamine at levels between 0.1 and 33 mg/kg (Bucher and Meszaros 1989).

34.3.4 Cape Gooseberry (*Physalis peruviana*)

The genus *Physalis*, of the family Solanaceae, includes annual and perennial herbs bearing globular fruits, each enclosed in a bladderlike husk which becomes papery on maturity. Of the more than 70 species, only a very few are of economic value. A

species which bears a superior fruit and has become widely known is the Cape gooseberry (*Physalis peruviana* L.), which is used for sauce, pies, and preserves in mild-temperate climates. Reportedly native to Peru and Chile, where the fruits are casually eaten and occasionally sold in markets but is still not an important crop, it has been widely introduced into cultivation in other tropical, subtropical, and even temperate areas.

In addition to being canned whole and preserved as jam, the Cape gooseberry is made into sauce; used in pies, puddings, chutneys, and ice cream; and eaten fresh in fruit salads and fruit cocktails. Because of the fruit's decorative appearance in its showy husk, it is popular in restaurants as an exotic garnish for desserts. To enhance its food uses, hot air drying improved qualities of dietary fiber content, texture, and appearance. In Colombia, the fruits are stewed with honey and eaten as dessert. The British use the husk as a handle for dipping the fruit in icing.

In Colombia, the leaf decoction is taken as a diuretic and an antiasthmatic. In South Africa, the heated leaves of Cape gooseberry are applied as poultices on inflammations, and the Zulus administer the leaf infusion as an enema to relieve abdominal ailments in children. The aerial parts and roots of Cape gooseberry have been shown to contain tigloidine and other secotropane alkaloids (Fig. 3).

34.3.5 Coca

Coca is the leaves of the four cultivated plants in the family Erythroxylaceae, (*Erythroxylum coca* var. *coca*, *Erythroxylum coca* var. *ipadu*, *Erythroxylum novogranatense* var. *novogranatense*, and *Erythroxylum novogranatense* var. *truxillense*) native to western South America. Coca is grown as a cash crop in Argentina, Bolivia, Colombia, Ecuador, and Peru and even in areas where its cultivation is illegal.

Coca is known for its psychoactive alkaloid, cocaine (Fig. 3). The alkaloid content of coca leaves is relatively low. The native people use it as a stimulant, like coffee, or an energy source. Although only the indigenous populations directly chew coca leaves, the consumption of coca tea (Mate de coca) is common among all sectors of society in the Andean countries and is considered to be beneficial to health, mood, and energy. Coca leaf is packaged into tea bags and sold in most grocery stores in the region. Coca-Cola used coca leaf extract from 1885 to 1903. Extraction of cocaine from coca requires several solvents and a chemical process called acid-base extraction.

Traditional medical uses of coca are foremost as a stimulant to overcome fatigue, hunger, and thirst. It is considered particularly effective against altitude sickness. Coca is also used as an anesthetic and analgesic to alleviate pain from headache, rheumatism, wounds, and sores. The high calcium content in coca explains why people used it for bone fractures. Because coca constricts blood vessels, it's also used to stop bleeding. Indigenous use of coca has also been reported to treat malaria, ulcers, and asthma, to improve digestion, to guard against bowel laxity, and to extend

life span. Modern studies have verified a number of these medical applications (Biondich and Joslin 2016).

The major pharmacologically active ingredient of coca is cocaine, with the amount ranging from 0.3% to 1.5% in fresh leaves. Besides cocaine, the coca leaves contain a number of other alkaloids, including methylecgonine cinnamate, benzoylecgonine, truxilline, hydroxytropacocaine, tropacocaine, ecgonine, cuscohygrine, dihydrocuscohygrine, nicotine, and hygrine. When chewed, coca acts as a mild stimulant to suppress hunger, thirst, pain, and fatigue. Almost all of the coca alkaloids are absorbed within 20 min of nasal application, while it takes 2–12 h after ingestion of the raw coca leaves for alkaloid concentrations to peak. When the raw leaf is consumed in tea, around 59–90% of the coca alkaloids are absorbed. The direct consumption of coca leaves does not induce a physiological or psychological dependence or symptoms typical to substance addiction. Due to its alkaloid content and nonaddictive properties, coca has been suggested as a method to help recovering cocaine addicts to withdraw the drug.

Coca is used in the cosmetics and food industries. A de-cocainized extract of coca leaves is one of the flavoring ingredients in Coca-Cola. Coca tea is produced industrially from coca leaves in South America. Coca leaves are also found in a brand of herbal liqueur called "Agwa de Bolivia" (grown in Bolivia and de-cocainized in Amsterdam) and a natural flavoring ingredient in Red Bull Cola. Coca-Cola is an energy drink which is produced in Bolivia from the coca extract.

A health risk assessment of coca leaf extract-containing soft drink concluded that no health risk is to be expected from consumption of this product because of low cocaine content. The lowest dose of cocaine that can cause adverse effect is 4,800 mg per day for an adult. Assuming a high daily consumption of 1.7 L, the margin of safety (MOS) between the consumed amount of cocaine and the amount upward of which adverse effects may occur is a factor of approximately 7,000. The prohibition of the use of the coca leaf was established by the United Nations in 1961, except for medical or scientific purposes. The coca leaf is listed on Schedule I of the 1961 Single Convention together with cocaine and heroin.

34.4 Quinolizidine Alkaloids (QAs)

QAs (norlupinane, octahydro-2H-quinolizine) are nitrogen-containing heterocyclic compounds. The most common QAs include sparteine and lupanine, α-isolupanine, 13α-hydroxylupanine, and anagyrine (Fig. 4). QAs exist in many species of the genus *Lupinus*, commonly known as lupin or lupine. *Lupinus* is a diverse genus; only four species have been domesticated and are agriculturally significant: *Lupinus angustifolius* (NLL), *Lupinus albus* (white lupin), *Lupinus luteus* (yellow lupin), and *Lupinus mutabilis*. Plants from the genus *Lupinus* have been traditionally used as an animal feed and gained recognition as a healthy food. They contain high amount of protein and fiber and possesses certain beneficial nutraceutical properties.

QAs are nontoxic to the legumes that produce them but toxic and in some cases very toxic to other organisms. The toxicity of alkaloids is considered to be connected

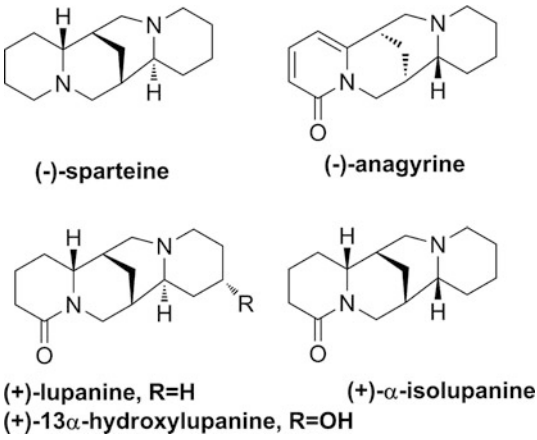

Fig. 4 Structures of some representative QAs in the plant-derived food

with their bitter taste. The QAs are certainly bitter in taste to humans. The most toxic QAs are tetracyclic with a pyridone nucleus. One of these is anagyrine. One case mentions anagyrine being passed into the human body via milk from goats foraging on *Lupinus latifolius*. The anagyrine caused severe bilateral deformities of the distal thoracic limbs in a baby boy. Both sparteine and lupanine display moderate acute toxicity, the former being the more toxic one. The acute oral LD_{50} (lethal dose for 50% of the population) value in rats for the extract of *Lupinus angustifolius* L. is 2,279 mg/kg body weight and for lupanine is 1,464 mg/kg body weight. There are some cases of acute toxicity in humans. According to some results, the LD_{50} value for sparteine is 60 mg/kg, lupanine 159 mg/kg, 13-hydroxylupanine 189 mg/kg, 17-hydroxylupanine 177 mg/kg, and oxolupanine 190 mg/kg. When humans ate lupin beans, which had not been de-bittered, they suffered from blurry vision, dry mouth, facial flushing, and confusion. A young man who drank 0.5 L of water that had been used for the de-bittering of lupin seeds suffered from sudden weakness, palpitations, extra systoles, and different anticholinergic symptoms. In another study, accidental ingestion of unripe lupin seeds resulted in nausea, migraine, abdominal pain, bradycardia, and respiratory depression.

Sparteine is especially present in European *Lupinus* species, whereas lupanine is typical for Australian species. The Australian varieties developed by plant-breeding programs are called "sweet lupins" as they contain a strongly reduced amount of total alkaloids. The mean total alkaloid content of the marketed Australian sweet lupin (*Lupinus angustifolius*) seeds is on average 130–150 mg/kg, of which 70% is lupanine. European lupins, which are predominantly consumed in Southern Europe as seeds (beans), have a high alkaloid content of 10–20 g/kg. The alkaloid level can be reduced through a de-bittering process involving soaking and washing with water. Lupin flour is used to replace a small percentage of wheat flour and soybean flour. It is further used in food formulations to replace soy flour in food commodities and also in lupin-based meals, pastas, pastries, cakes, biscuits, snacks, tempe, bread, miso, soy sauce, dairy/tofu product, and coffee substitutes. For example, a coffee surrogate, made of roasted lupin beans, has an alkaloid content of 200 mg/kg of

product. Lupins can be used to make a variety of foods, both sweet and savory. The European white lupin beans are commonly sold in a salty solution in jars (like olives and pickles) and can be eaten with or without the skin.

QAs are potent antagonists on the nicotinic cholinergic receptor but weak antagonists on the muscarinic cholinergic receptor. Neurological (weakness, dizziness, mydriasis, anxiety, confusion, malaise, loss of coordination, visual disturbances, and dry mouth), cardiovascular (dysrhythmias), and gastrointestinal (nausea, vomiting) symptoms are due to their anticholinergic effects. QAs act via inhibition of ganglionic impulse transmissions of the sympathetic nervous system. It is evident that each QA has its own effect. On the other hand, some QAs are used as folk medicines. They probably have chronic toxicity. However, adequate knowledge about the chronic toxicity of these alkaloids and especially of chronic toxicity across generations is not available. The premise that QAs have not produced hereditary symptoms has not been checked with total reliability.

A risk of lupine allergy exists in patients allergic to peanuts. Indeed, most lupin reactions reported are in people with peanut allergy. Because of the cross-allergenicity of peanut and lupin, the European Commission has required that food labels indicate the presence of "lupin and products thereof" in food.

34.5 Isoquinoline Alkaloids

Isoquinoline alkaloids constitute one of the largest groups of natural substances. These compounds are biogenetically derived from phenylalanine and tyrosine and include an isoquinoline or a tetrahydroisoquinoline ring as a basic structural feature in their skeleton. Isoquinoline alkaloids are widely distributed in plants of the families Papaveraceae, Berberidaceae, Ranunculaceae, Menispermaceae, Fumariaceae, Rutaceae, and Annonaceae. Poppy alkaloids, derived from *Papaver somniferum*, belong to the isoquinoline alkaloids. Isoquinoline alkaloids have a variety of biological activities, including antitumor, antibacterial, analgesic, immune regulation, antiplatelet aggregation, anti-arrhythmia, and antihypertensive effect.

Foods containing isoquinoline alkaloids include opium poppy (*Papaver somniferum*) and lotus (*Nelumbo nucifera*).

34.5.1 Opium Poppy (*Papaver somniferum*)

Papaver somniferum, commonly known as the opium poppy or bread seed poppy, is a species of flowering plant in the family Papaveraceae. In 2016, the worldwide production of poppy seeds was 92,610 tons. The Czech Republic occupied 31% of the total, followed by Turkey and Spain.

Isoquinoline alkaloids occur in the latex of opium poppy. The latex of immature capsules is called opium, which is released by incisions and dried on the capsule surface. Opium contains approximately 20–25% alkaloids. Till now, around 50 isoquinoline alkaloids have been isolated from opium. The main alkaloids of

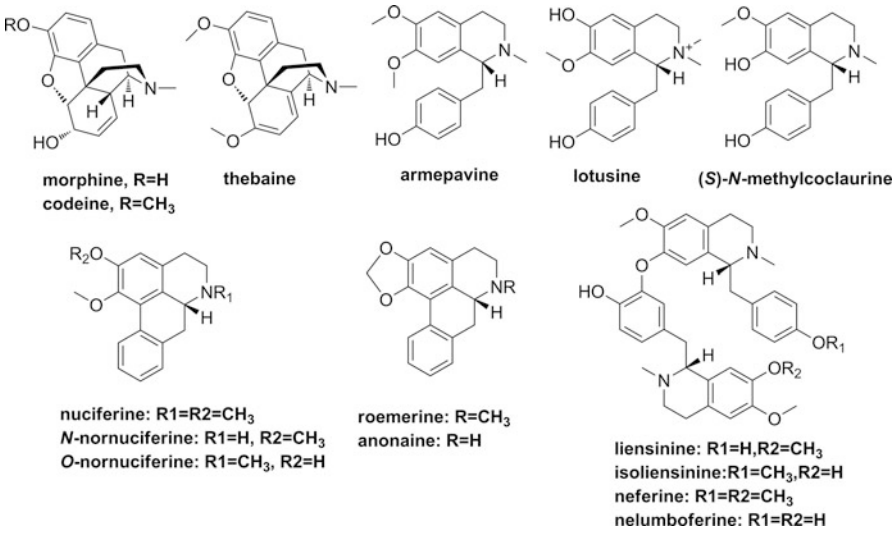

Fig. 5 Structures of some representative isoquinoline alkaloids in the plant-derived food

opium are morphine (depending on origin 7–20%), codeine (0.3–6%), and thebaine (0.2–1%) (Fig. 5).

The seeds of opium poppy are the only part of the plant used as food. The alkaloid content in seeds varies greatly. Morphine (<0.1–620 mg/kg) and codeine (0.1–57 mg/kg) are usually detected in the seeds probably due to contamination with the latex or other parts of the plants. The differences of the alkaloid content in the seeds depend on the geographical origin, soil type, climate, year of harvest, and the cultivar. Washing the seeds prior to use removes as much as 45.6% of free morphine. 10–50% and 98–100% of the morphine content in the seeds can be removed by baking and washing combined with subsequent heating, respectively. The small black, brown, white, or blue seeds are common garnish on bagels, rolls, muffins, and breads in some countries and also used to produce edible oil and jams.

Morphine acts through binding to opioid receptors in the central and peripheral nervous system and the gastrointestinal tract. Activation of the opioid receptors in these organs mediates both the beneficial and the adverse effects of opium alkaloids. Acute morphine intoxication exhibits three symptoms: miosis, respiratory depression, and unconsciousness (coma). Respiratory depression is the most important risk after an opioid overdose. The direct cause of death is respiratory arrest. In individuals who do not show any tolerance development, serious toxic symptoms may occur after the oral administration of 40–60 mg of morphine. For adults, a dose of 200 mg morphine may be acutely lethal. Other studies give a range of 230–1,140 mg of morphine for the oral lethal doses in the case of non-opiate-dependent adults, whereas babies and infants are far more sensitive (Arzneibuch 2004). In animal experiments, morphine had a negative impact on development and reproduction. It has been reported that the consumption of commercially available

poppy seeds, e.g., in the form of desserts with approximately 10–20% poppy seeds or poppy seed cakes, led to light-headedness and enteroparesis in sensitive individuals.

Manufacturers and consumers should be advised to use some methods (e.g., washing, heating, baking) to reduce the contamination of poppy seeds with opium alkaloids. In the case of ingestion of small amounts of poppy seeds used for decoration of pastries, the effects of morphine on human health seem to be negligible.

34.5.2 Lotus (*Nelumbo nucifera*)

Nelumbo nucifera (Nymphaeaceae), which is commonly known as lotus, is a large aquatic herb. The genus *Nelumbo* consists of two species, Asian lotus (*Nelumbo nucifera* Gaertn.), distributed in Asia and the northern parts of Oceania, and American lotus (*Nelumbo lutea* Wild.), distributed in eastern North America. All parts of *Nelumbo nucifera*, including root, leaf, petioles, seeds, lotus core, and lotus house (torus), are edible, with the rhizomes and seeds being the main consumption parts. The rhizomes, leaves, and seeds of *Nelumbo nucifera* have been used as folk medicines, Ayurveda, traditional Chinese medicine, and oriental medicine. The leaves are used for hematemesis, epistaxis, and hematuria; the seeds are used for diarrhea, cholera, fever, and hyperdipsia; and the rhizomes have diuretic, antidiabetic, and anti-inflammatory properties.

The alkaloids are mainly accumulated in lotus leaves and lotus hearts, and their content is as high as 0.6% of their fresh weight (Deng et al. 2016). On the basis of their structures, the alkaloids from lotus can be divided into three categories: monobenzylisoquinolines, aporphines, and bisbenzylisoquinolines. The aporphine-type alkaloids, such as nuciferine, *O*-nornuciferine, *N*-nornuciferine, anonaine, roemerine, dehydronuciferine, and pronuciferine, are mainly distributed in lotus lamina, whereas the bisbenzylisoquinoline-type alkaloids, including liensinine, isoliensinine, and neferineare, predominantly accumulate in the embryo of the seeds (Fig. 5).

These alkaloids have shown a wide range of bioactivities. In the area of neurological disorders, the alkaloids from lotus seeds possess strong inhibitory activities against β-site amyloid precursor protein-cleaving enzyme 1 (BACE1) and butyrylcholinesterase (BChE), suggesting the potential use of *Nelumbo nucifera* in the prevention and treatment of Alzheimer's disease. Further studies showed that the active constituents of *Nelumbo nucifera* that possessed inhibitory effects against BChE and BACE1 are neferine, liensinine, vitexin, quercetin 3-*O*-glucoside, and northalifoline (Je and Lee 2015). Nuciferine has been reported to have a receptor profile similar to aripiprazole-like antipsychotic drugs. Administration of nuciferine blocks head-switch responses and enhances amphetamine-induced locomotor activity, suggesting the potential of nuciferine as antipsychotic drug. Moreover, the lotus leaf alkaloid extract displayed sedative hypnotic and anxiolytic effects via binding to the γ-amino butyric acid (GABA) receptor and activating the monoaminergic system

(Ye et al. 2014). In addition, the total alkaloids from lotus leaf showed sedative hypnotic effect by increasing the brain level of GABA (Yan et al. 2015). Liensinine, isoliensinine, and neferine, isolated from the embryo of *Nelumbo nucifera* seeds, elicit antidepressant-like effects in mice after the forced swimming test.

The alkaloid-rich fraction and neferine possess the potent effect on inhibition of vascular smooth muscle cell (VSMC) proliferation and migration. In addition, neferine and liensinine are effective in preventing the onset of reentrant ventricular tachyarrhythmia. Neferine inhibits angiotensin II-stimulated VSMC proliferation through induction of heme oxygenase-1 and downregulation of fractalkine gene expression (Zheng et al. 2014). Nuciferine increases the phosphorylation of endothelial nitric oxide synthase (eNOS) at Ser(1177), thereby increasing the cytosolic NO level to promote vasorelaxation in human umbilical vein endothelial cells (HUVECs). Under endothelium-free conditions, nuciferine attenuates calcium-induced contraction, suggesting that nuciferine may have a therapeutic effect on vascular diseases associated with aberrant vasoconstriction (Wang et al. 2015b). In addition, the treatment of the *Nelumbo nucifera* extracts significantly suppresses VEGF-induced angiogenesis (Lee et al. 2015). Furthermore, the hydroalcoholic extract of *Nelumbo nucifera* seeds showed antiestrogenic effect without altering the general physiology of reproductive system.

The potential benefit of (*S*)-armepavine on systemic lupus erythematosus was studied on MRL/MpJ-lpr/lpr mice, a model to study human systemic lupus erythematosus. (+)-(*R*)-coclaurine and (−)-(*S*)-norcoclaurine, quercetin 3-*O*-β-D-glucoside, aporphine, liensinine, neferine, and isoliensinine from *Nelumbo nucifera* leaves possess potent anti-HIV activity. Nuciferine decreases hyperuricemia in potassium oxonate-induced rats (Wang et al. 2015a).

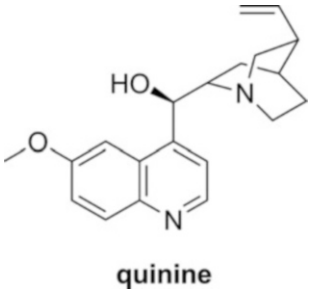
Nuciferine inhibits nicotine-induced non-small cell lung cancer via inhibiting proliferative Wnt/B-catenin signaling pathway and its downstream targets including c-myc, cyclin D, and VEGFA (Liu et al. 2015). Similarly, three major bisbenzylisoquinoline alkaloids, isoliensinine, liensinine, and neferine, show anti-cancer activity in triple-negative breast cancer cells (Zhang et al. 2015).

34.6 Quinoline Alkaloids

The best-known quinoline alkaloid is quinine (Fig. 6). Quinine occurs in considerable amounts in the bark of *Cinchona* species, e.g., *C. pubescens* and *C. officinalis*, from which it is isolated for pharmaceutical and food uses. It is applied to treat malaria (650 mg of quinine sulfate every 8 h for 3–7 days) and nocturnal leg cramps (200–400 mg of quinine sulfate dihydrate/day for a maximum of 5 weeks). *Cinchona* is a genus of flowering plants in the family Rubiaceae, containing at least 23 species of trees and shrubs. *Cinchona* is the only economically practical source of quinine, a drug that is still recommended for the treatment of falciparum malaria.

The main dietary exposure to quinoline alkaloids is through beverages. Quinine is a flavor component of tonic water, bitter lemon, and vermouth because of its pleasant bitter taste. In some countries like USA and Germany, nonmedical use of quinine is

Fig. 6 Structure of quinine



regulated. The latest version of the German Flavorings Ordinance of May 2, 2006 (Annexes 4 and 5), gives the following maximum levels in drinks, calculated as quinine: total 300 mg/kg in spirits and 85 mg/kg in nonalcoholic beverages. In USA, the quantity in soft drinks is limited to 83 mg/L (Ballestero et al. 2005).

Quinine exerts physiological effects on skeletal muscles, which has clinical implications. Quinine increases the tension response to a single maximal stimulus delivered to the muscle directly or through the nerves, but it also increases the refractory period of the muscle. The excitability of the motor endplate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. It may produce alarming respiratory distress and dysphagia in patients with myasthenia gravis. Because of easy placental accessibility, oxytocic action, and embryotoxicity at high doses, pregnancy is a contraindication as are hypersensitivity to *Cinchona* alkaloids, bradycardia, and other cardiac dysrhythmias of clinical relevance, tinnitus, prior damage to the optic nerve, glucose-6-phosphate-dehydrogenase deficiency (symptom: hemolytic anemia), and myasthenia gravis. Quinine may enhance the effects of cardiac glycosides, muscle relaxants, and anticoagulants.

Based on the data available and for the purposes of health protection, the Bundesinstitut für Risikobewertung (BfR) advises against consuming quinine-containing beverages during pregnancy (EFSA 2005). BfR also recommends that people who have existing contraindications should also refrain from consuming quinine-containing drinks. Patients having cardiac arrhythmia and people who take medications that interact with quinine should only drink quinine-containing drinks after consulting their doctors. This applies in particular to medications that inhibit blood coagulation (Dusemund et al. 2010). In view of warnings having been issued about persons who may be particularly sensitive to quinine, the European Food Safety Authority (EFSA) recommends that the toxicological database on quinine should be reconsidered (EFSA 2008a).

34.7 Glycoalkaloids (GAs)

GAs are a group of nitrogen-containing compounds that are naturally produced in various cultivated and ornamental plant species of the Solanaceae family. This large family of plants includes commonly consumed vegetables such as potatoes,

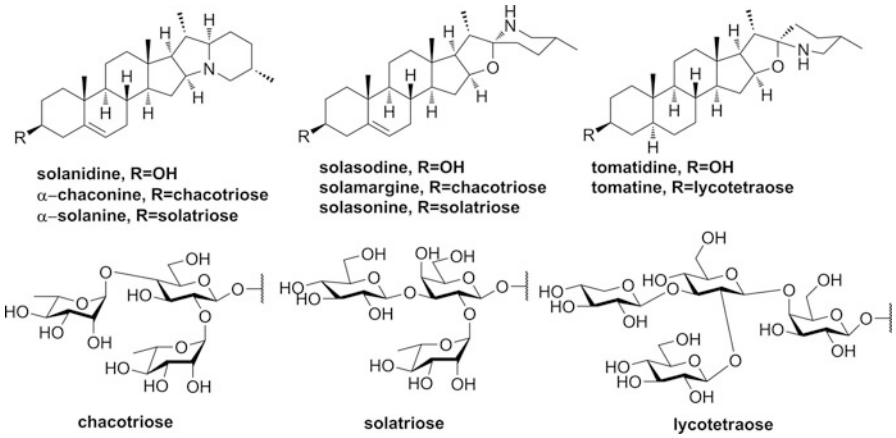


Fig. 7 Structures of GAs in the plant-derived food

tomatoes, eggplants, and peppers. A GA consists of a C27-steroidal alkaloid (aglycone) and a sugar moiety, usually a tri- or tetrasaccharide attached to the 3-OH position. Synonyms for GAs are solanins, *Solanum* alkaloids, steroidal GAs, or basic saponins. Some aglycones, such as solanidine, tomatidine, and solasodine, can form GAs, such as α-solanine and α-chaconine (from potatoes), tomatine (from tomatoes), and solasonine (from eggplant), respectively, when combined with the corresponding glycosides (Fig. 7).

GAs are hardly affected by food processing (baking, cooking, frying), but their content is influenced by the type of cultivar, original total GA content, light, mechanical injury, and storage. GAs (α-solanine, α-chaconine, tomatine, and solasonine) are less toxic than non-glycosylated alkaloids, because the sugar moiety hampers absorption, thereby reducing bioavailability. In vivo hydrolysis results in the formation of aglycones, solanidine, tomatidine, and solasodine, which occurs either by hydrochloric acid in the stomach or bacterial glycosidases in the gastrointestinal tract (Friedman et al. 2003).

34.7.1 Potatoes

Potato is a starchy, tuberous crop from the perennial nightshade *Solanum tuberosum*. Today potato is a staple food in many parts of the world. Potatoes are the world's fourth largest food crop after maize (corn), wheat, and rice. The vegetative and fruiting parts of the potato contain the toxic GAs, including α-solanine and α-chaconine, and are not fit for human consumption. Normal potato tubers that have been grown and stored properly produce small amount of GAs, which are negligible to human health. If the sprouts and skins are exposed to light, the tuber can accumulate a high amount of GAs that can affect human health. Additionally, physical damage and age increase GA content within the tubers.

α-Solanine and α-chaconine poisoning results in gastrointestinal disturbances when consumed at low doses, e.g., vomiting, diarrhea, and usually severe abdominal pain. When consumed at high doses of α-solanine and α-chaconine, neurological disorders occur, including drowsiness, apathy, confusion, weakness, and visual disturbances. The other adverse effects include fever, rapid and weak pulse, low blood pressure, and rapid respiration. GAs from potato cause liver damage, destroy cell membranes, harm the digestive system, and affect metabolism. Breeders try to keep GA levels below 200 mg/kg (200 ppm). McMillan and Thompson reported an epidemic of potato poisoning among 78 school boys after having eaten a lunch with prepared potatoes containing 250–300 mg/kg GAs.

The potato GAs adversely affect intestinal permeability and aggravate inflammatory bowel disease. They are potent irritants of the intestinal mucosa (lytic effect) and cholinesterase (acetyl- and butyrylcholinesterase) inhibitors (Korpan et al. 2004). Based on mice studies, potatoes containing more than 200 mg/kg GAs are considered to cause acute poisoning, but little is known about long-term effects of repeated ingestion of small amounts of potato GAs. This value of 200 mg/kg GAs being of concern with respect to acute poisoning is somewhat different. The results from a limited study in humans cited by Joint FAO (Food and Agriculture Organization)/WHO Expert Committee on Food Additives (JECFA) indicated that the daily consumption of 200–300 g potato tubers containing approximately 240 mg/kg GAs, giving a daily intake of approximately 1 mg/kg body weight/day, did not result in any signs of acute toxicity in humans (JECFA 1993). JECFA also refers to another study where intake of 1–1.5 kg cooked potatoes containing 240 mg/kg GAs, equivalent to about 3.4–5.1 mg/kg body weight, resulted in typical "solanine" poisoning (JECFA 1993).

Control measures should be maintained, especially for potatoes that have been exposed to light and mechanical injury and started to green, which may accumulate 1,000 mg/kg or more GAs. Other applications of potatoes in food such as fried potato skin, potato chips, and baked jacked potatoes may result in increased GA levels than that in boiled potatoes.

34.7.2 Tomatoes

Tomato is the edible, red berry of the nightshade *Solanum lycopersicum*. The species is originated from Western South America. Tomato is consumed in diverse ways, raw in salads or in slices, stewed, incorporated into a wide variety of dishes or sauces, or processed into ketchup or tomato soup. Unripe green tomatoes can also be breaded and fried and used to make salsa or pickled. Tomato juice is sold as a drink and is used in cocktails. Tomatoes are botanically classified as berries, which are commonly used as a vegetable ingredient or side dish.

Tomato contains α-tomatine and a small amount of α-solanine, a toxic alkaloid found in potato leaves and other plants in the nightshade family (Fig. 7). Thus, the application of tomato leaves in herbal tea has been responsible for at least one death. Immature green tomatoes contain up to 500 mg of α-tomatine/kg of fresh fruit

weight. The compound is largely degraded as the tomato ripens until, at maturity, it reaches levels in red tomatoes of around 5 mg/kg of fresh fruit weight. α-Tomatine is a biologically active molecule, as shown by its ability to disrupt cell membranes, bind cholesterol, inhibit acetylcholinesterase, and perturb acid-base equilibria in vivo.

GAs have evolved in nature to protect tomatoes against bacteria, fungi, insects, and animals. It is striking that both green tomatoes and tomato leaves have a very high GA content, which makes them undesirable to eat because the green fruit and leaves not only taste bitter to animals but may not be safe to phytopathogens. Observations that the absence of a 5,6-double bond in the B-ring of tomatidine results in a much less toxic molecule in both pregnant and nonpregnant mice as compared to the structurally similar solasodine (which contains such a double bond) confirm related findings that GAs without such a double bond such as tomatine are less toxic than those which have them such as the potato GAs α-chaconine and α-solanine. It may benefit food safety to create, through plant breeding and/or plant molecular biology methods, plant foods with modified GAs that lack the double bond.

34.7.3 Eggplants

Eggplants (*Solanum melongena* L.), known as aubergine, brinjal, berenjena, or Guinea, is an agronomically and economically important non-tuberous species of the nightshade Solanaceae family. Eggplant has been cultivated for centuries in Asia, Africa, Europe, and the Near East. The fruits of the eggplant are one of the most widely consumed vegetables in the world; however, it is not advisable to eat it raw. In Chinese cuisine, eggplants are often deep-fried. Eggplant supplies low contents of macronutrients and micronutrients. The capability of the fruit to absorb oils and flavors into its flesh through cooking is well-known in the culinary arts.

Eggplants contain several classes of bioactive compounds, including anthocyanidins, flavonoids, saponins, and GAs. Individual or combinations of the bioactive compounds are probably responsible for the reported analgesic, antianaphylactic, anti-inflammatory, antioxidant, antipyretic, intraocular pressure reducing, central nervous system depressing, hypolipidemic, and hypotensive properties of eggplants. Two main GAs found in eggplant are α-solamargine and α-solasonine (Fig. 7). It is well-known that GAs are effective inhibitors of cancer cells due to their toxic effects. Using liquid chromatography-mass spectrometry methods, the contents of the major eggplant GAs (solamargine and solasonine) of *S. melongena* to the allied accession of the Africa-cultivated *Solanum aethiopicum* and *Solanum macrocarpon* were compared. The results show that (a) fruits of *Solanum aethiopicum* and *Solanum melongena* contained (in mg/100 g fresh weight) 0.58–4.56 α-solamargine and 0.17–1.0 α-solasonine and (b) the corresponding much higher values for *S. macrocarpon* are 124–197 and 16–23, respectively, suggesting that this accession might not be safe for consumption. A related study of ten eggplant lines and three allied species (*Solanum aethiopicum*, *Solanum integrifolium*, and

Solanum sodomaeum) confirmed that the allied species had higher GA content than the widely consumed eggplants and that the GA content generally increased during fruit development and ripening. A British study used colorimetry to determine the average GA content of two eggplant samples of about 8 mg/100 g fresh weight. For the adults, 400 mg α-solasonine would be life-threatening. Vegetables in the nightshade family contain a variety amount of solanine, from 2 to 13 mg, and eggplants are found to contain up to 11 mg solanine. Grilling or boiling of eggplants did not result in significant changes in the total GA (solamargine plus solasonine) content.

34.8 Purine Alkaloids

Purine is a heterocyclic aromatic organic compound that consists of a pyrimidine ring fused to an imidazole ring. They are the most widely occurring nitrogen-containing heterocycles in nature. Purines are found in high concentration in meat and meat products, especially internal organs such as the liver and kidney. In general, plant-based diets are low in purines. The food-containing purine alkaloids include caffeine, theobromine, 7-methylxanthine, and theophylline (Fig. 8). Purine alkaloids are bitter-tasting alkaloids found in coffee, tea, kola nuts, and cocoa beans. Purine alkaloids, in particular caffeine, exert various effects on metabolic targets (e.g., satiety, thermogenesis, and fat oxidation). The thermogenesis involves inhibiting the phosphodiesterase-induced intracellular degradation of cyclic adenosine monophosphate and antagonizing adenosine receptors that have a negative effect on increased noradrenaline release.

Caffeine is the most consumed psychoactive substance worldwide. It can cause behavior changes in adults (mood, sleep pattern). Caffeine consumption at doses of 50–200 mg/day causes a reduction in drowsiness and fatigue. Consumption of over 200 mg/day caffeine can provoke headache; nervousness; irritability; tremors; central convulsions; negative effects on premenstrual syndrome, fertility, and pregnancy; and cardiovascular effects. Above 400 mg/day caffeine may cause general toxicity like tremor; gastrointestinal problems; cardiovascular problems, including cardiac arrhythmias; and high blood pressure. Oral doses between 5 and 10 g of caffeine are lethal to man (Arzneibuch 2007). Studies on the overall health risks of coffee or caffeine suggested the probability of cancer, including pancreatic,

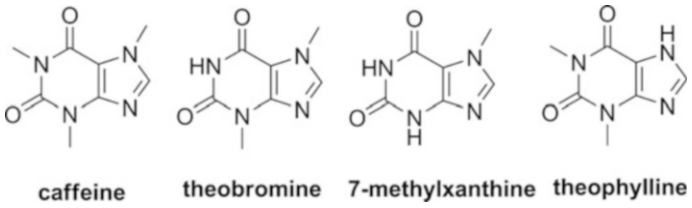

Fig. 8 Structures of purine alkaloids in the plant-derived food

bladder, stomach and ovarian cancers, or leukemia, fibrocystic breast disease, and gallbladder disease (Kotsopoulos et al. 2009). However, no risks of coffee, including decaffeinated coffee and tea for colorectal cancer, were established in epidemiological studies (Michels et al. 2005). Patients with a nonfatal first myocardial infarction taking at least five cups/day have been reported to be prone to increase the risk of a second incidence.

In contrast to the other methylxanthines, the action of theobromine on the central nervous system is weak. The only report about adverse effects showed intake of high doses of theobromine causes nausea and anorexia in humans.

Theophylline is medically used to treat asthma due to its bronchodilating effect. Theophylline toxicity symptoms range from seizures, tachycardia, nausea and vomiting, hypokalemia, headache, and tremors. Cardiac arrest and arrhythmias and hypotension were also frequently recorded in patients or healthy subjects taking theophylline.

34.8.1 Coffee

Coffee is a brewed drink prepared from roasted coffee beans, the seeds of berries from certain *Coffea* species (Rubiaceae). The genus *Coffea* is native to tropical Africa (specifically having its origin in Ethiopia and Sudan), Madagascar, the Comoros, Mauritius, and Réunion in the Indian Ocean. *Coffea* plants are now cultivated in over 70 countries, primarily in the equatorial regions of the Americas, Southeast Asia, Indian subcontinent, and Africa. The two most economically important varieties of *Coffea* plant are the Arabica and the Robusta, which occupy 60% and 40% of the coffee produced worldwide, respectively. In 2016, the worldwide production of green coffee beans was 9.2 million tons, around 33% from Brazil.

Coffee is darkly colored, bitter, and slightly acidic and has a stimulating effect in humans, primarily due to caffeine. Coffee is one of the most popular drinks in the world, and it can be prepared and presented in a variety of ways. Coffee seeds contain 10–20 g/kg caffeine and trace amount of theophylline and theobromine. Brewed coffee and instant coffee contain 360 mg/L and 118–316 mg/L caffeine, respectively, while decaffeinated coffee contains less than 20 mg/L caffeine. A review of clinical trials found that drinking coffee at doses of 3 or 4 cups daily is generally safe and is more likely to improve health outcomes than to cause harm. Exceptions include possible increased risk in women having bone fractures and a possible increased risk in pregnant women of fetal loss or decreased birth weight. Meta-analyses have consistently found that long-term coffee consumption is associated with a lower risk of Parkinson's disease. In a systematic review and meta-analysis of 28 prospective observational studies, representing over one million participants, every additional cup of caffeinated and decaffeinated coffee consumed in a day was associated, respectively, with a 9% and 6% lower risk of type 2 diabetes.

In a healthy liver, caffeine is mostly broken down by the hepatic microsomal enzymatic system. The excreted metabolites are mostly paraxanthines, theobromine

and theophylline, and a small amount of unchanged caffeine. Therefore, the metabolism of caffeine depends on the state of the enzymatic system in the liver.

In 2012, the National Institutes of Health–America Association of Retired Persons (AARP) Diet and Health Study analyzed the relationship between coffee drinking and mortality. They found that higher coffee consumption was associated with lower risk of death and that those who drank coffee lived longer than those who did not. However, the authors noted, "whether this was a causal or associational finding cannot be determined from our data." A meta-analysis found that coffee consumption (4 cups/day) was inversely associated with all-cause mortality (a 16% lower risk), as well as cardiovascular disease mortality specifically (a 21% lower risk from drinking 3 cups/day), but not with cancer mortality (Crippa et al. 2014). Additional meta-analysis studies showed that higher coffee consumption (2–4 cups per day) was associated with a reduced risk of death by all disease causes.

34.8.2 Tea

Tea is an aromatic beverage commonly prepared by pouring hot or boiling water over cured leaves of *Camellia sinensis* (the family Theaceae), an evergreen shrub (bush) native to East Asia. Tea is the most widely consumed drink in the world. There are many different types of tea. Darjeeling and Chinese greens have a cooling, slightly bitter, and astringent flavor, while others have vastly different profiles that include sweet, nutty, floral, or grassy notes. Tea originated in Southwest China, where it was used as a medicinal drink. It was popularized as a recreational drink during the Chinese Tang dynasty, and tea drinking spread to other East Asian countries. Tea was introduced to Europe during the sixteenth century.

Caffeine occupies about 1–3% of tea's dry weight, equal to 30–90 mg per 8-oz (250 ml) cup depending on different type, brand, and brewing method. A study found that the caffeine content ranges from 22 to 28 mg in 1 g black tea, while ranged from 11 to 20 mg in 1 g green tea, reflecting a significant difference. Tea also contains small amounts of theobromine and theophylline, which are xanthines similar to caffeine.

It has been suggested that green and black tea can protect against cancer or other diseases such as obesity and Alzheimer's disease, but the compounds found in green tea have not been conclusively demonstrated to have any effect on human diseases. One clinical study demonstrated that regular consumption of black tea over 4 weeks had no beneficial effect in lowering blood cholesterol levels in human.

34.8.3 Kola Nuts

The kola nut is a caffeine-containing nut of evergreen trees of the genus *Cola*, primarily of the species *Cola acuminata* and *Cola nitida*. In folk medicine, kola nuts are used for aiding digestion when ground and mixed with honey and are used for anti-coughs. Kola nuts are perhaps the best known to Western culture as a flavoring

ingredient and one of the sources of caffeine in cola and other similarly flavored beverages, although the use of kola (or kola flavoring) in commercial cola drinks has become uncommon. The kola nut contains up to 3% (30 g/kg) of caffeine, partly bound to tannins. Caffeine-containing drinks including cola drinks and energy drinks contain normally 65–250 mg/L caffeine, which is added to some soft drinks as a flavoring ingredient and to increase the basal metabolic rate.

34.8.4 Cocoa Beans

The cocoa bean, which is also called the cacao bean, is the dried and fully fermented seeds of *Theobroma cacao*, from which cocoa solids (a mixture of nonfat substances) and cocoa butter (the fat) can be extracted. Cocoa beans are the basis of the sweet food preparation chocolate and of the Mesoamerican foods tejate and a pre-Hispanic drink maize.

Cocoa bean contains 35–50% (350–500 g/kg) oil (cocoa butter or theobroma oil), 1–4% (10–40 g/kg) theobromine, and 0.2–0.5% (2–5 g/kg) caffeine, plus tannins and volatile oils. Theobromine is the major alkaloid found in cocoa plants. Due to fermentation and processing, theobromine is hardly found in different cocoa products. Chocolate/cocoa drinks contain 21 mg/L caffeine.

34.9 Pyridine Alkaloids

Pyridine alkaloids are a class of pyridine ring-containing compounds widely found in plants. Foods containing pyridine alkaloids include pepper (*Piper nigrum*), kava (*Piper methysticum*), areca nuts, and *Nicotiana tabacum*.

34.9.1 *Piper nigrum*

Piper nigrum is a flowering vine in the family Piperaceae, cultivated for its fruit, which is usually dried and used as a spice and seasoning, known as a peppercorn. Peppercorns are described simply as pepper or more precisely as black pepper (cooked and dried unripe fruit), green pepper (dried unripe fruit), and white pepper (ripe fruit seeds). Dried ground pepper has been used both for its flavor and as a traditional medicine. Its spiciness is due to the presence of piperine, which is different from the capsaicin characteristic of chili peppers. It is ubiquitous in the modern world as a seasoning and is often paired with salt.

Piperine (Fig. 9) is responsible for the biting, pungent taste of peppers and is used as a spice. The main human dietary exposure comes from this source. Another possible source is brandy to which pepper is added to impart a pungent taste. Black pepper (*Piper nigrum*) contains 5–9% piperine. A daily consumption of 0.33 g of black pepper by a 60 kg person is equal to an intake of 16.5–29.7 mg piperine/person/day.

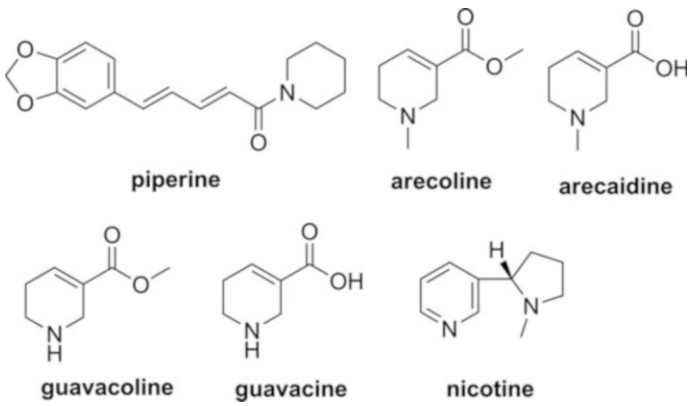

Fig. 9 Structures of pyridine alkaloids in the plant-derived foods

Chronic consumption of black pepper might cause gastric mucosal injury. In a double-blind clinical trial, intragastric administration of the spice (1.5 g) to healthy human volunteers caused severe bleeding in one subject after intake of black pepper. Several cases of fatal pepper administration have been reported in the literature. Mechanical obstruction and mucosal edema were identified as mechanisms of death. However, the observed effects cannot clearly be linked to piperine since piperine was not administered as such. Fatalities/severe side effects might have been caused by mechanical means because exposure was via (accidental) aspiration. Oral intake of large amounts of black and white peppers is regarded as likely unsafe for children and pregnant women. There are insufficient data on possible abortifacient effects in large amounts (Jellin and Gregory 2007). Piperine was found to inhibit human cytochrome P450 3A4(CYP3A4) and P-glycoprotein in vitro, the proteins that are important for the metabolism and transport of xenobiotics and their metabolites (Bhardwaj et al. 2002). By inhibiting drug metabolism, piperine may increase the bioavailability of other compounds (Reen et al. 1993).

Consuming a lower amount of piperine-containing white and black peppers does not represent risks for human health. However, when consumed at higher doses, these peppers might induce unfavorable effects including gastric mucosal injury, and extreme consumers of black pepper may be at increased risk. Due to its effects on drug metabolism, piperine-containing spices should be taken cautiously by individuals taking other medications.

34.9.2 Areca Nuts

The areca nut is the fruit of the areca palm (*Areca catechu*), which grows in the tropical Pacific (Melanesia and Micronesia), Southeast and South Asia, and parts of East Africa. In parts of India, Sri Lanka, and southern China, areca nuts are not only chewed along with betel leaf but also used in the preparation of Ayurvedic and

traditional Chinese medicines. Powdered areca nut is used as a constituent in some dentifrices (Bhat et al. 2013). Other traditional uses include the removal of tapeworms and other intestinal parasites by swallowing a few teaspoons of powdered areca nut, by drinking as a decoction, or by taking tablets containing the extracted alkaloids (Bhat et al. 2013).

Arecoline (methyl-1,2,5,6-tetrahydro-1-methyl-nicotinate) (Fig. 9) is an alkaloid isolated from *A. catechu*, which is considered as the major effective constituent of *A. catechu*. Additionally, arecoline has a wide spectrum of pharmacological activities including effects on nervous, cardiovascular, digestive, and endocrine systems.

For chewing areca nut, a few slices of the nut are wrapped in a betel leaf along with calcium hydroxide (slaked lime) and may include clove, cardamom, catechu (kattha), or other spices for extra flavoring. Arecoline is used in medical treatment for glaucoma. Habitual chewers of betel leaf and areca nut have a greatly increased risk of developing a range of serious diseases, including cancers of the mouth and esophagus (Jain et al. 2017). Chewing areca nut alone has been linked to oral submucous fibrosis. According to MedlinePlus, "Long-term use of betel-areca preparations has been associated with oral submucosal fibrosis, pre-cancerous oral lesions and squamous cell carcinoma. Acute effects of betel chewing include asthma exacerbation, hypertension, and tachycardia. There may additionally be a higher risk of cancers of the liver, mouth, esophagus, stomach, prostate, cervix, and lung with regular betel use. Other effects can include altered blood sugar levels, which may in turn increase the risk of developing type 2 diabetes" (Peng et al. 2015).

34.9.3 *Nicotiana tabacum*

Nicotiana tabacum is an annually grown herbaceous plant. Actually, all plants in the genus *Nicotiana* have been widely cultivated. The leaves are commercially grown in many countries to be processed into tobacco. In their first voyage to the New World, Christopher Columbus and his expedition were introduced to a plant whose smoke was called tobacco by the natives of Hispaniola. In 1560, Jean Nicot de Villemain, the Ambassador of France in Portugal, brought tobacco seeds and leaves as a "wonder drug" to the French court. In 1586, the botanist Jacques Dalechamps gave the plant the name Herba nicotiana, which was also adopted by Linné. It was considered as decorative plant at first, then a panacea, before it became a common snuff and tobacco plant. Tobacco arrived in Africa at the beginning of the seventeenth century. The leaf extract was a popular pest control method up to the beginning of the twentieth century. In 1851, the Belgian chemist Jean Stas documented the use of tobacco extract as a murder poison. The Belgian count Hippolyte Visart de Bocarmé had poisoned his brother-in-law with tobacco leaf extract in order to acquire some urgently needed money. This was the first exact proof of alkaloids in forensic medicine (Wennig 2009).

Pyridine alkaloids are present in tobacco as free bases and salts. Nicotine (Fig. 9) accounts for 90–95% of the tobacco pyridine alkaloids, and nornicotine and anatabine account for roughly 2.5% each. Other pyridine alkaloids are present in

trace amounts including anabasine, myosmine, cotinine, and 2,3′-bipyridyl. *S*(−)-Nn icotine, a major alkaloid in tobacco, is accepted generally as being responsible for maintaining smoking behavior. The reinforcing properties of *S*(−)-nicotine have been demonstrated in laboratory animals using the intravenous self-administration paradigm.

Nicotine's mood-altering effects vary in different reports, both a stimulant and a relaxant. Nicotine stimulates a release of glucose from the liver and epinephrine (adrenaline) from the adrenal medulla, which, in turn, causes stimulation. Users report feelings of relaxation, sharpness, calmness, and alertness (Benowitz 1988). When a cigarette is smoked, nicotine-rich blood passes from the lungs to the brain within 7 s and immediately stimulates nicotinic acetylcholine receptors (Vivekanandarajah et al. 2019); this indirectly promotes the release of many chemical messengers such as acetylcholine, norepinephrine, epinephrine, arginine vasopressin, serotonin, dopamine, and beta-endorphin in parts of the brain (Vivekanandarajah et al. 2019; Pomerleau and Pomerleau 1984). Nicotine also increases the sensitivity of the brain's reward system to rewarding stimuli. At very high doses, nicotine dampens neuronal activity (Kenny and Markou 2006).

A protein of the white-brown complex subfamily can be extracted from the tobacco leaves. It is an odorless, tasteless white powder and can be added to cereal grains, vegetables, soft drinks, and other foods. It can be whipped like egg whites, liquefied, or gelled and can take on the flavor and texture of a variety of foods. It contains 99.5% protein, no salt, fat, or cholesterol. It is currently being tested as a low calorie substitute for mayonnaise and whipped cream.

Nicotine is highly addictive. It is one of the most commonly abused drugs. Generally, a cigarette yields about 2 mg absorbed nicotine. High amounts of nicotine (30–60 mg) are harmful. Nicotine induces both behavioral stimulation and anxiety in animals. Nicotine addiction involves drug-reinforced behavior, compulsive use, and relapse following abstinence. Nicotine withdrawal symptoms include depressed mood, stress, anxiety, irritability, difficulty concentrating, and sleep disturbances. Mild nicotine withdrawal symptoms are measurable in unrestricted smokers, who experience normal moods only as their blood nicotine levels peak, with each cigarette. The withdrawal symptoms worsen sharply and then gradually improve to a normal state. The evidence suggests that exposure to nicotine between the ages of 10 and 25 years causes lasting harm to the brain and cognitive ability (U.S. Department of Health and Human Services 2016). Nicotine use during pregnancy increases the child's risk of type 2 diabetes, obesity, hypertension, neurobehavioral defects, respiratory problems, and infertility (Schraufnagel et al. 2014).

All parts of the plant contain nicotine, which can be extracted and used as an insecticide. The dried leaves can also be used; they remain effective for 6 months after drying. The juice of the leaves can be rubbed on the body as an insect repellent. The leaves can be dried and chewed as an intoxicant. The dried leaves are also used as snuff or are smoked. This is the main species that is used to make cigarettes, cigars, and other products for smokers.

34.10 Amide Alkaloids

The chili pepper, also called chile, chile pepper, chilli pepper, or chilli, is the fruit of plants from the genus *Capsicum*, which are members of the nightshade family, Solanaceae. Chili peppers are widely used in many cuisines as a spice to add heat to dishes, usually in the form of spices such as chili powder and paprika. In high amount, chili pepper will cause a burning effect on other sensitive areas, such as the skin or eyes. Because people enjoy the heat, there has long been a demand for chili pepper products like curry, chili con carne, and hot sauces such as Tabasco sauce and salsa. Chili peppers originated in Mexico. After the Columbian exchange, many cultivars of chili pepper spread across the world, used for both food and traditional medicine. *Capsicum* cultivars belong to the five major species of cultivated peppers: *Capsicum annuum*, *Capsicum chinense*, *Capsicum baccatum*, *Capsicum frutescens*, and *Capsicum pubescens*. Cultivars grown in North America and Europe are believed to all derive from *Capsicum annuum* and have white, yellow, red, or purple to black fruits. In 2016, world production of raw green chili peppers was 34.5 million tons, with China producing half of the world's total production.

Capsaicinoids are the active components of chili peppers. The most commonly occurring capsaicinoids are capsaicin (69%), dihydrocapsaicin (22%), nordihydrocapsaicin (7%), homocapsaicin (1%), and homodihydrocapsaicin (1%) (Fig. 10). Capsaicinoids are irritants for mammals, including humans, and produce a sensation of burning in any tissue with which they come into contact. Capsaicinoids function as deterrents against certain mammals and fungi. Pure capsaicin is a hydrophobic, colorless, highly pungent, and crystalline to waxy solid compound. Capsaicin and dihydrocapsaicin are the most pungent capsaicinoids; nordihydrocapsaicin, homocapsaicin, and homodihydrocapsaicin are about half as hot.

Capsaicin is used as an analgesic in topical ointments and dermal patches to relieve pain, typically in concentrations between 0.025% and 0.1%. It may be applied in cream form for the temporary relief of minor aches and pains of

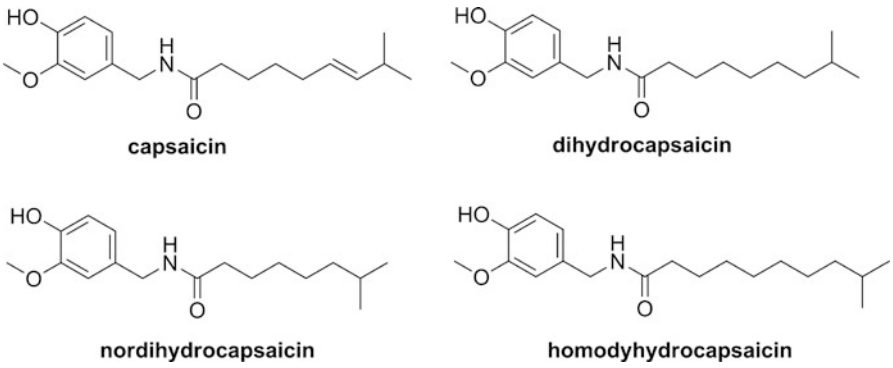

Fig. 10 Structure of representative capsaicinoids

muscles and joints associated with arthritis, backache, strains, and sprains, often in compounds with other rubefacients.

Capsaicin is also used to reduce the symptoms of peripheral neuropathy, such as postherpetic neuralgia caused by shingles. Capsaicin transdermal patch (Qutenza) for the management of this particular therapeutic indication (pain due to postherpetic neuralgia) was approved as a therapeutic by the US Food and Drug Administration, but a subsequent application for Qutenza to be used as an analgesic in HIV neuralgia was refused. It is common for people to experience pleasurable and even euphoric effects from ingesting capsaicin. Folklore among self-described "chiliheads" attributes this to pain-stimulated release of endorphins, a different mechanism from the local receptor overload that makes capsaicin effective as a topical analgesic.

The burning and painful sensations associated with capsaicin result from its chemical interaction with sensory neurons. Capsaicin binds to a receptor called the vanilloid receptor subtype 1 (TRPV1). By binding to the TRPV1 receptor, the capsaicin molecule produces similar sensations to those of excessive heat or abrasive damage, explaining why the spiciness of capsaicin is described as a burning sensation.

Capsaicin is a strong irritant requiring proper protective goggles, respirators, and proper hazardous material handling procedures. Capsaicin takes effect upon skin contact (irritant, sensitizer), eye contact (irritant), ingestion, and inhalation (lung irritant, lung sensitizer). LD_{50} in mice is 47.2 mg/kg. Painful exposures to capsaicin-containing peppers are among the most common plant-related exposures presented to poison centers. They cause burning or stinging pain to the skin and, if ingested in large amounts by adults or small amounts by children, can produce nausea, vomiting, abdominal pain, and burning diarrhea. Eye exposure produces intense tearing, pain, conjunctivitis, and blepharospasm. The primary treatment is removal from exposure. For external exposure, bathing the mucous membrane surfaces that have contacted capsaicin with oily compounds such as vegetable oil, paraffin oil, petroleum jelly (Vaseline), creams, or polyethylene glycol is the most effective way to attenuate the associated discomfort. Capsaicin can also be washed off the skin using soap, shampoo, or other detergents. When capsaicin is ingested, cold milk is an effective way to relieve the burning sensation; and room-temperature sugar solution (10%) at 20 °C (68 °F) is almost as effective. The burning sensation will slowly fade away over several hours if no actions are taken. Capsaicin-induced asthma might be treated with oral antihistamines or corticosteroids.

34.11 Conclusions

Many alkaloid-containing foods have certain physiological activities, such as the anti-pressure effect of lotus root, the anticancer effect of solanine, and the antibacterial effect of broccoli. Further chemical and pharmacological studies are definitely needed to elucidate the chemical principles of these foods and underlying mechanisms. Moreover, investigations to determine alkaloid amount in foods are of importance of controlling food safety, and quality has a decisive influence. For

example, morphine in poppy shells, nicotine in tobacco, total alkaloids in lotus leaves, and solanine in potatoes are all safe as food. The alkaloids in food have great potential for development as food supplements or drugs. For example, the alkaloids in tomatoes can be developed as natural food preservatives, and the caffeine in tea can replace some additives and drugs. A small amount of edible alkaloids is good for human health, and excessive amounts are harmful. A closer understanding of the alkaloids in food can lead to a healthier diet and better benefit for human beings.

J. Xiao et al. (eds.), *Handbook of Dietary Phytochemicals*,
https://doi.org/10.1007/978-981-15-4148-3_37

Abstract

Dietary phytochemicals are bioactive components of plant-based foods (phyto-foods), e.g., fruits, vegetables, grains, and tea. Their regular and adequate intake may offer protection from major chronic diseases, including cardiovascular diseases, cancer, and neurodegenerative diseases. Phyto-foods like apples, blueberries, broccoli, cherries, soybeans, and walnuts contain bioactive phytochemicals of various chemical classes, in addition to usual micronutrients and fibers. One of such major groups of phytochemicals found in plant-based food items are naturally occurring coumarins, which belong to the chemical class of 1-benzopyran derivatives. Plants from the families Apiaceae, Asteraceae, and Rutaceae are three major sources of naturally occurring coumarins. Some commonly consumed coumarin-containing phyto-foods include carrots, celery, parsnip, strawberries, citrus fruits, apricots, and cherries, as well as spices like cinnamon and fennels. This chapter presents a coverage primarily on most common coumarins that occur in food plants and their contributions to human health and wellbeing.

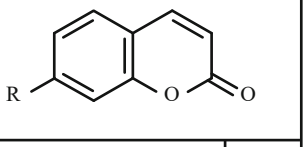
35.1 Introduction

Dietary phytochemicals are usually biologically active components of plant-based foods (sometimes referred to as "phyto-food"), e.g., fruits, vegetables, grains, and tea. Their regular and adequate intake often offers protection from major chronic diseases, including cardiovascular diseases, cancer, and neurodegenerative diseases (Krzyzanowska et al. 2010; Probst et al. 2017; Bansal et al. 2018). Phyto-foods like apples, blueberries, broccoli, cherries, soybeans, and walnuts contain bioactive phytochemicals of various chemical classes, in addition to usual micronutrients and fibers (Dillard and German 2000). One of such major groups of phytochemicals found in plant-based food items is naturally occurring coumarins.

Coumarins are the largest class of 1-benzopyran derivatives ubiquitously distributed in the plant kingdom (Sarker and Nahar 2017). There are about 4000 naturally occurring coumarins identified to date. Coumarin (**1**) (2*H*-1-benzopyran-2-one) (Fig. 1), a fragrant colorless compound isolated from the tonka bean (*Dipteryx odorata*, family Fabaceae) in 1820, is the first member of the coumarin class. The



Coumarins	R
Coumarin (**1**)	H
Umbelliferone (**2**)	OH

Fig. 1 Structures of coumarin (**1**) and 7-hydroxycoumarin (umbelliferone, **2**)

name coumarin comes from a French term for the tonka bean, *coumarou*. The families Apiaceae, Asteraceae, and Rutaceae are three major sources of naturally occurring coumarins (Sarker and Nahar 2007). Some commonly consumed coumarin-containing phyto-foods include apricots (*Prunus armeniaca*), carrots (*Daucus carota*), celery (*Apium graveolens*), cherries (*Prunus avium*), citrus fruits (*Citrus* spp.), parsnip (*Pastinaca sativa*), and strawberries *(Fragaria* × *ananassa)*, as well as spices like aniseed (*Pimpinella anisum*), caraway (*Carum carvi*), cinnamon (*Cassia cinnamon*), coriander (*Coriandrum sativum*), dill (*Anethum graveolens*), and fennel (*Foeniculum vulgare*) (Table 1).

Most natural coumarins possess oxygenation at C-7. Umbelliferone (7-hydroxycoumarin, **2**), first isolated from the family Umbelliferae (*alt.* Apiaceae), is the first member of the 7-oxygenated coumarins. It is the parent compound for the biosynthesis of all other highly oxygenated, prenylated, geranylated, farnesylated, and more complex forms of natural coumarin derivatives (Sarker and Nahar 2017).

The biosynthesis of natural coumarins often begins from *para*-coumaric acid (**3**, also known as *trans*-4-hydroxycinnamic acid) following the phenylpropanoid pathway (Fig. 2), and proceeds through an enzyme-mediated oxidation leading to the formation of 2-hydroxy-*para*-coumaric acid (**4**), which is then glycosylated to form its 2-glucoside (**5**) (Sarker and Nahar 2007, 2017). Intermediate **5** undergoes isomerization to form its *cis*-isomer (**7**), which finally produces umbelliferone (**2**) through ring closure.

Usually, the classification of natural coumarins is based on structural diversities that exist in this group of compounds and can be classified into simple, simple prenylated, simple geranylated, furano, pyrano, sesquiterpenyl, and oligomeric coumarins (Table 2) (Sarker and Nahar 2007).

In plants, coumarins contribute to the defense against phytopathogens, response to abiotic stresses, and regulation of oxidative stress and act as signaling molecules; they also possess considerable medicinal values, and many of these bioactive coumarins are found in dietary plants and plant components (Sarker and Nahar 2007). The major therapeutic applications of coumarins stem from their antimicrobial, antiviral, anti-inflammatory, antidiabetic, antioxidant, and various enzyme inhibitory activities. In addition to their therapeutic properties, the aromatic properties of coumarins, especially in spices, are exploited extensively in culinary, cosmetic, and tobacco industries. This chapter will restrict its coverage primarily to the

Coumarin classes	Core structures	Examples
Simple prenylated coumarins	One or more prenyl (C_5) or modified prenyl group on the core simple coumarin structure	 Osthol (**10**)
Simple geranylated coumarins	One or more geranyl (C_{10}) or modified geranyl group on the core simple coumarin structure	 Auraptene (**11**)
Furanocoumarins	One or more furan or dihydrofuran ring fused with the simple coumarin skeleton (angular or linear)	 Angelicin (**12**);  psoralen (**13**)
Pyranocoumarins	One or more pyran or dihydropyran ring fused with the simple coumarin skeleton (angular or linear)	 Seselin (**14**);  xanthyletin (**15**)
Sesquiterpenyl coumarins	One or more farnesyl (C_{15}), modified farnesyl, or a sesquiterpenyl group linked to the core simple coumarin structure	 Umbelliprenin (**16**)
Olegomeric coumarins	Two or more coumarin units linked or fused together	 Daphnoretin (**17**)

most common coumarins that occur in food plants and can be placed broadly under the category of dietary phytochemicals.

35.2 Bioactive Dietary Coumarins

Many coumarins found in food plants are bioactive, and they, being part of human diets, contribute to human health and well-being. Table 3 lists most commonly available dietary coumarins, their sources, and summarizes their reported bioactivities (mainly based on *in vitro* studies), and Figs. 3 and 4 show the structures of those coumarins.

Table 3 Most common dietary coumarins, their sources, and reported *in vitro* bioactivities

Dietary coumarins	Dietary sources	Bioactivities	References
Angelicin (**12**)	Parsnip	Anticancer, antioxidant, and antiviral	Wagstaff (1991), Cho et al. (2013), Wang et al. (2017a)

Most of these dietary coumarins are furanocoumarins, and mainly from the food plants of the family Apiaceae. For example, grapefruit furanocoumarins, e.g., 6′,7′-dihydroxybergamottin (**36**), bergamottin, (**29**) and bergapten (**27**), possess antioxidant, anti-inflammatory, anticancer, and bone health-promoting properties. They also exert antiproliferative activities against cancer cell growth through modulation of several molecular pathways, such as regulation of the

signal transducer and activator of transcription 3, nuclear factor-κB (NF-κB), phosphatidylinositol-3-kinase/protein kinase B (AKt), and mitogen-activated protein kinase expression (Hung et al. 2017). However, several reports on *in vitro* bioactivities of various *Citrus* coumarins (family: Rutaceae) are also available. For example, bergamottin (**29**), and 5-geranyloxy-7-methoxycoumarin (**26**) and 8-geranyloxypsolaren (**26**) from *Citrus limon* were reported to possess

antitumor activity (Miyake et al. 1999). Similarly, 5-geranyloxy-7-methoxycoumarin (**26**), limettin (**25**), and isopimpinellin (**31**), from *Citrus aurantifolia* (lime), were shown to inhibit human colon cancer (SW-480) cell proliferation, with 5-geranyloxy-7-methoxycoumarin (**26**) being the most active (Patil et al. 2013).

As the discussion on *in vitro* bioactivity of dietary coumarins is not really within the remit of this chapter, the focus will be on the *in vivo* studies involving either animal models or human trials.

35.3 Bioavailability and Metabolism

Bioavailability refers to the degree and rate at which an administered drug is absorbed by the body's circulatory system, the systemic circulation. Thus, the effectiveness of any medication administered through the oral route depends on how quickly and how much of it is available in the blood circulation and whether the amount is at the therapeutic concentration. Bioavailability is an essential measurement tool, as it determines the correct dosage for non-intravenous administration of a drug. In clinical trials, the bioavailability of a drug is a key factor to be measured in Phase 1 and Phase 2 trials. Solubility and effective absorption are two major factors that control bioavailability of any oral dosage form. There are several studies on bioavailability and metabolism of some of the dietary coumarins, mainly in animal models, available to date.

The absorption and distribution of coumarin (**1**) is rather rapid through the gastrointestinal (GI) tract, despite poor water solubility of both coumarin (**1**) and umbelliferone (**2**) (Lacy and O'Kennedy 2004). However, because of high partition coefficients of these compounds, 21.5% for coumarin (**1**) and 10.4% for umbelliferone (**2**), the compounds are rapidly and almost completely absorbed once they are in aqueous solution, and owing to their non-polarity, they cross lipid bilayers easily by passive diffusion.

Pharmacokinetic studies involving humans confirmed that coumarin (**1**) is fully absorbed from the GI tract after oral administration and metabolized by the liver in the first pass with only 2–6% reaching the systemic circulation intact. The low bioavailability of coumarin (**1**), in addition to its short half-life (1.02 h per oral vs. 0.8 h intravenous), indicated that it is actually a prodrug, with its metabolite umbelliferone (**2**) being the compound of main pharmacological relevance. Note that a prodrug is a biologically inactive compound that can be metabolized in the body to produce a drug.

The metabolism of coumarin (**1**) itself has been studied quite extensively in various *in vitro* and *in vivo* models. Coumarin (**1**) is metabolized through hydroxylation primarily by specific cytochrome P450-linked monooxygenase enzyme (CYP2A6) system in the liver microsomes leading to the formation of **2**, which then undergoes Phase 2 conjugation reaction that produces glucuronide conjugate of **2**. Although hydroxylation is possible at all six positions (carbon atoms 3, 4, 5, 6, 7, and 8) in coumarin (**1**), the most common routes of hydroxylation are at C-7 and C-3,

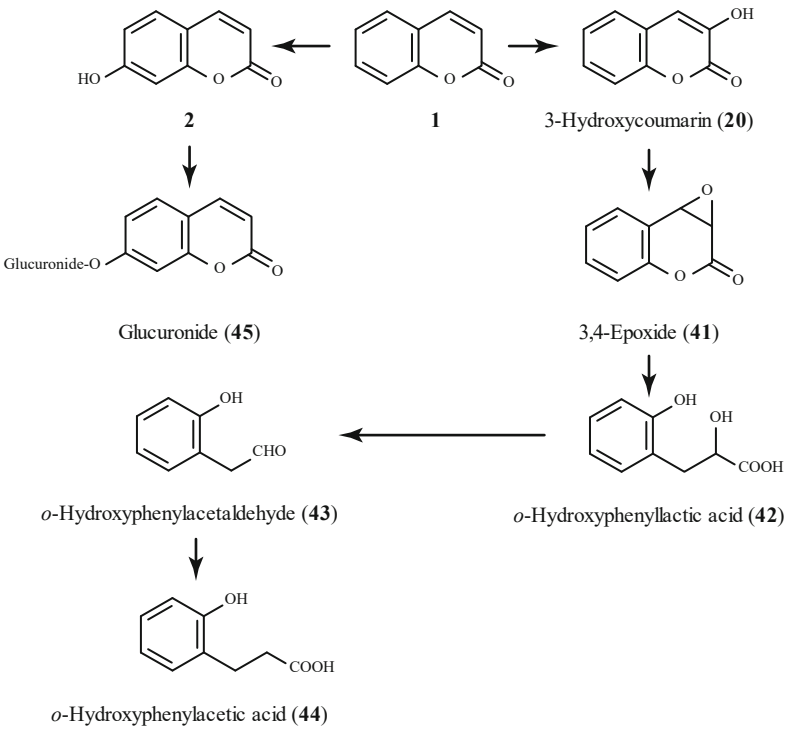

Fig. 5 Common routes of metabolism of coumarin (**1**). (Adapted from Lacy and O'Kennedy 2004)

yielding umbelliferone (**2**) and 3-hydroxycoumarin (**20**), respectively (Lacy and O'Kennedy 2004) (Fig. 5). 3-Hydroxylation leads to further metabolism *via* ring opening, producing two further products, *o*-hydroxyphenyllactic acid (*o*-HPLA, **42**) and *o*-hydroxyphenylacetic acid (*o*-HPAA, **44**). In humans, coumarin (**1**) is extensively and almost exclusively metabolized to umbelliferone (**2**). However, some individuals can metabolize a significant amount of coumarin (**1**) utilizing pathways other than 7-hydroxylation, e.g., the 3,4-epoxidation pathway to *o*-HPAA.

The absorption and metabolism of dietary furanocoumarins are well studied. Ingestion of, or dermal contact with, furanocoumarin-containing plants enable their absorption into the bloodstream (Melough et al. 2018). However, the kinetics and bioavailability of furanocoumarins can be quite variable depending on the dietary sources, as the matrix dictates dissolution, stability, gastric emptying, and intestinal absorption. In both humans and animals, ingested dietary furanocoumarins are rapidly absorbed in the GI tract; they go to systemic circulation and are taken up in the tissues in addition to the brain, the spleen, adipose, the kidneys, and the testis following an oral administration. Furanocoumarins could undergo extensive metabolism in the body; it was shown that the metabolism of these compounds began in the GI tract through the activity of intestinal bacteria or in the liver by cytochrome P450-dependent monooxygenases. It was suggested that 6′,7′-dihydroxybergamottin

(**36**) might be partially metabolized to bergaptol (**28**) before excretion in the urine (Melough et al. 2018). Although the exact pathways of furanocoumarin metabolism in humans have not yet been established conclusively, a few studies demonstrated that furanocoumarin metabolites were excreted in urine as hydroxylated products or in the form of glucuronides.

Bioavailability and metabolism of scopoletin (**9**) was studied in a dog model after intravenous (1 mg/kg) and oral (10, 25 and 50 mg/kg) administrations (Zhao et al. 2018a); it had short elimination half-life, its oral bioavailability was low (~6–7%), and glucuronidation was the predominant metabolic pathway. A similar study was performed with three simple coumarins, scopolin (**23**), scopoletin (**9**), and isofraxidin (**19**), in a mice model (Zhang et al. 2018a), where it was observed that the metabolism of these coumarins involved multiple *in vivo* metabolic reactions including glucuronidation, sulfonation, isomerism, and reduction. Glucuronidation was found to be the major route for xanthotoxol (**33**) metabolism in human (He et al. 2018).

The oral bioavailability of auraptene (**11**) was observed to be 8.5% after oral administration in rats, as measured by an LC-MS/MS method (Ye et al. 2016). After auraptene (100 mg/kg, p.o.) administration, the maximum plasma concentration and the time taken to reach maximum concentration were 1719.5 ± 384.3 g/mL and 108.0 ± 25.3 min, respectively, and the elimination half-life was 108.0 ± 25.3 for the dose 100 mg/kg, p.o., and 3.0 ± 0 min for 2 mg/kg, i.v.

The bioavailability and metabolism of bergapten (**27**), a well-known anti-inflammatory and antitumour natural furanocoumarin, was studied after oral administration (15 mg/kg) in a rat model (Yu et al. 2016). The absolute oral bioavailability (F) were 80.1 ± 29.6%, 94.0 ± 40.3%, and 69.5 ± 44.2% for low, medium, and high concentrations using the formula F = (AUC oral/AUC intravenous) × 100%, based on the AUC(0–∞) obtained after i.v. and oral administrations. The AUC of the medium and high concentration were similar, which meant that the absorption of **27** reached its peak within the range of 10–15 mg/kg. Bergapten (**27**) might be well absorbed from the GI tract in rat, and an oral administration of this coumarin might be the better route for clinical use.

35.4 Bioactivities (Animal Studies)

Although various chemical, cell line, and enzymatic *in vitro* assays dominate the bioactivity assessment arena, there are significant amounts of bioactivity data from various *in vivo* studies involving several animal models available on dietary coumarins. Some major bioactivities of dietary coumarins as evident from *in vivo* studies include analgesic, anti-allergy, anti-asthma, anticancer, anticolitis, antidepressant, antidiabetic, antidermatitis, antihypertensive, anti-inflammatory, anti-obesity, anti-osteoporotic, anti-pruritic, antipsoriatic, antipsychotic, antitumor, cardioprotective, gastroprotective, hepatoprotective, nephroprotective, and neuroprotective activities, and they are discussed below.

35.4.1 Analgesic

An analgesic or painkiller is a substance that produces analgesia (relief from pain). Analgesic agents act in several ways on the peripheral and central nervous systems (CNS). Among the most common dietary coumarins, imperatorin (**34**), osthol (**10**), seselin (**14**), and xanthotoxol (**33**) possess considerable analgesic property. The analgesic potential of **10** was shown in acetic acid and formalin-induced hyperalgesia in mice (Singh et al. 2018). Osthol (**10**), administered epidurally in the early stage of pain in rats, could alleviate the pain for a long time, which might be attributed by the inhibition of p38 mitogen-activated protein kinase signaling-related pathways (Zhang et al. 2018c). Analgesic activity of **14** was studied in a mice model (Lima et al. 2006). This coumarin could inhibit inflammatory hyperalgesia, suggesting that seselin (**14**) might possesses both important peripheral anti-inflammatory and antinociceptive properties. Imperatorin (**34**) and xanthotoxol (**33**) displayed analgesic property, mediated through the central opioidergic system, in an *in vivo* study involving rats (Kumatia et al. 2017).

35.4.2 Anticolitis

Colitis is the inflammation of the inner lining of the colon, often caused by infection, inflammatory bowel disease (Crohn's disease, ulcerative colitis), and allergic reactions. Coumarins **10** and **34** possess anticolitis property. The therapeutic potential of **10** in the treatment of colitis was reported in dinitrobenzene sulfonic acid-induced colitis in rats through its anti-inflammatory and antioxidant properties (Khairy et al. 2018). This coumarin improved the loss in body weight, accompanied with betterment of the disruption of the colonic architecture as well as improvement in the antioxidant defense system. Treatment with osthol (**10**) could suppress activities on pro-inflammatory Th2-related cytokines and upregulation of anti-inflammatory Th2-related cytokines. Previously, Sun et al. (2017) demonstrated the anticolitis potential of **10**. Pretreatment with this compound could alleviate trinitrobenzenesulfonic acid (TNBS)-induced colitis in mice by reducing the expression of inflammatory mediators and attenuating p38 phosphorylation *via* both cAMP/PKA (cyclic AMP/protein kinase A)-dependent and independent pathways, among which the cAMP/PKA-independent pathway played a major role. Pretreatment with **10** also ameliorated the clinical scores, colon length shortening, colonic histopathological changes, the expression of inflammatory mediators in TNBS-induced colitis, and increased serum cAMP levels. The anticolitis property of imperatorin (**34**) was shown in a study in a dextran sulphate sodium-induced colitis mouse model Liu et al. (2018d); coumarin **34** could activate CYP3A4 promoter activity, recruit steroid receptor ac-activator 1 to the ligand binding domain of pregnane X receptor, and increase the expression and activity of CYP3A4.

35.4.3 Antidermatitis, Antipruritic, and Antipsoriatic

Psoriasis is a skin condition that causes red, flaky, crusty patches of skin covered with silvery scales. These patches normally appear on elbows, knees, scalp, and lower back but can appear anywhere on the body. Most people are only affected with small patches, and in some cases, the patches can be itchy or sore. Chen et al. (2018a) investigated the effects of esculetin (**8**) on psoriatic skin inflammation in a mice model and studied its plausible molecular mechanisms of action to conclude that coumarin **8** could attenuate psoriasis-like skin lesion in mice and might possess clinical significance. Jeong et al. (2018) reported a similar observation, where compound **8** attenuated atopic skin inflammation by inhibiting the expression of inflammatory cytokines, suggesting its potential therapeutic applications in the treatment of atopic dermatitis.

The antidermatitis and antipruritic potential of osthol (**10**) is well documented. Sun et al. (2018) established that the antipruritic effect of **10** could be mediated by selective inhibition of thermosensitive transient receptor potential vanilloid 3 channel in the skin in mice model.

Psoralen (**13**) and its derivatives together with ultraviolet (UV) lights could be useful in reducing psoriatic response, both in murine and human models. The effect of bergapten (**27**), which is actually 8-methoxypsoralen, plus UV A or UV B alone on imiquimod-induced psoriasis was examined in a mice model (Shirsath et al. 2018). Mouse skin was treated with repetitive sub-phototoxic doses of **27** plus UV A or UV B alone before or during the induction of toll-like receptor 7/8 activation and psoriasis through the application of imiquimod. Bergapten (**27**) plus ultraviolet A suppressed the established imiquimod-induced psoriatic phenotype to a greater degree than UV B alone, but pretreatment with the former, prior to administration of imiquimod, also reduced the susceptibility of murine skin to respond to imiquimod to a greater degree than did pretreatment with UV B alone.

35.4.4 Antidiabetic

Diabetes is a lifelong condition that causes an extremely high blood sugar level. There are two main types of diabetes: type 1 diabetes, where the body's immune system attacks and destroys the cells that produce insulin, whereas in type 2 diabetes, the body does not produce enough insulin or the body's cells do not react to insulin. However, between these two types, type 2 diabetes is far more common in the human populations. Dietary coumarins auraptene (**11**), esculetin (**8**), esculin (**18**), osthol (**10**), scopoletin (**9**), phellopterin (**35**), and umbelliferone (**2**) possess antidiabetic potential, mainly because of their antioxidative property. Coumarins **10** and **18** could improve type 2 diabetes in high-fat-diet- and streptozotocin-induced diabetic mice through antioxidative mechanisms (Yao et al. 2018a). Both coumarins lowered fasting blood glucose and blood lipid levels while increasing insulin levels. They exhibited antioxidant effects in the pancreas through elevating the activities of the enzymes glutathione peroxidase, catalase, and superoxide dismutase. Osthol (**10**) attenuated cellular imbalance, blurry fringes of hepatic sinusoid and extensive

vacuolization due to hepatocellular lipid accumulation, and reduced inflammatory infiltration in the pancreas.

Esculin (**18**) ameliorated cognitive improvement in experimental diabetic nephropathy, mediated through its anti-inflammatory and antioxidant actions (Song et al. 2018). Earlier, Kang et al. (2014) reported the protective effect of this compound on streptozotocin-induced renal damage in diabetic mice. Similarly, umbelliferone (**2**) was shown to protect liver injury in diabetic mice (Yin et al. 2018) and renal injury in type 1 diabetic rats (Garud and Kulkarni 2017) and to attenuate unpredictable chronic mild stress induced-insulin resistance in rats (Su et al. 2016). Although antihyperglycemic property of **2** is well known, Naowaboot et al. (2015) demonstrated that **2** could also improve impaired metabolism of glucose and lipid in high-fat-diet-/streptozotocin-induced type 2 diabetic rats. This action is mediated through inducing expression of adiponectin, which is a protein hormone involved in regulating glucose levels as well as fatty acid breakdown, glucose transporter type 4 (GLUT4, the insulin-regulated glucose transporter found primarily in adipose tissues and striated muscle), peroxisome proliferator-activated receptors (PPARs), and PPAR-protein expressions.

Esculetin (**8**) is equally effective against type 2 diabetes. Kadakol et al. (2017b) showed that **8** could ameliorate insulin resistance and type 2 diabetic nephropathy through reversal of histone H3 acetylation and H2A lysine 119 monoubiquitination. Choi et al. (2016) reported the effects and mechanism of **8** on nonalcoholic fatty liver in diabetic mice fed with high-fat diet and suggested that compound **8** could protect against development of nonalcoholic fatty liver in diabetes via regulation of lipids, glucose, and inflammation. The antidiabetic effect of scopoletin (**9**), which regulates glucose metabolism, was confirmed in a streptozotocin-induced mice model, particularly focusing on its effect on carbohydrate metabolizing enzymes, and postprandial hyperglycemia. This coumarin lowered postprandial hyperglycemia through inhibition of carbohydrate digestive enzymes, e.g., α-glucosidase and α-amylase (Jang et al. 2018). Kalaivanan et al. (2018a) exhibited that **9** intervention could suppress pancreatic endoplasmic reticulum stress (normally observed in type 2 diabetes sufferers) induced by lipotoxicity and revealed its potential in delaying the progression of insulin resistance. The same group also showed that supplementation of **9** could improve insulin sensitivity in rats by attenuating the imbalance of insulin signaling through 5′-adenosine-monophosphate-activated protein kinase (Kalaivanan et al. 2018b). Choi et al. (2017) investigated the effects of **9** on hepatic steatosis and inflammation in a high-fat-diet-fed type 1 diabetic mice in comparison with antidiabetic drug metformin. Both scopoletin (**9**) and metformin lowered blood glucose and hemoglobin A1c (HbA1c), serum alanine aminotransferase (ALT), tumor necrosis factor α (TNF-α) and interleukin-6 (IL-6) levels, glucose intolerance, and hepatic lipid accumulation compared with the diabetic control group. Both compounds downregulated hepatic gene expression of triglyceride and cholesterol synthesis as well as inflammation and upregulated cholesterol 7α-monooxygenase (CYP7A1) gene. They downregulated hepatic PPAR and diacylglycerol-*O*-acyltransferase 2 (DGAT2) protein levels and inhibited hepatic fatty acid synthase and phosphatidate phosphohydrolase activities suggesting that **9** could protect against diabetes-induced steatosis and inflammation by inhibiting lipid biosynthesis

and myeloid differentiation primary response 88 (TLR4-MyD88) pathways. Coumarin **9** could also protect against methylglyoxal-induced hyperglycaemia and insulin resistance mediated by suppression of advanced glycation end product generation and antiglycation (Chang et al. 2015). It can be noted that glycation is a non-enzymatic condensation reaction between reducing sugars and amino groups of proteins that undergo rearrangements to stable ketoamines, leading to the formation of advanced glycation end products.

Auraptene (**11**) regulates gene expression involved in lipid metabolism through PPAR-α activation in diabetic obese mice (Takahashi et al. 2011). In high-fat-diet-fed diabetic obese mice, this compound suppressed hyperlipidemia and triglyceride accumulation in the liver and skeletal muscle and increased the mRNA expression levels of the PPAR-α target genes involved in fatty acid oxidation in the liver and skeletal muscle. Furthermore, in the auraptene-treated mice, the adipocyte size was considerably smaller than that in the control high-fat-diet-fed mice rendering the improvement of high-fat-diet-induced hyperglycaemia and abnormalities in glucose tolerance.

The antidiabetic potential of phellopterin (**35**) was demonstrated *in vivo* using a diabetic mouse model (Han et al. 2018), where diabetes was induced by high-fat diets and streptozotocin. Treatment with **35**, at the doses of 1 mg/kg and 2 mg/kg, reduced the levels of blood glucose, triglycerides, and total cholesterol. It also enhanced adipocyte differentiation in preadipocytes. The study concluded that this coumarin might be a valuable therapeutic alternative for enhancing insulin sensitivity through promotion of adipocyte differentiation and by increasing mRNA expression levels of PPAR-γ, which is a major mediator of insulin sensitivity.

35.4.5 Antifertility

Two furanocoumarins, bergaptol (**28**) and xanthotoxin (**32**), showed antifertility activity in rodents (Ulubelen et al. 1994). About 70% of the test animals developed cystic and atretic follicles in their ovaries, and glomerulocapsular adhesion and segmental fusion were noticed in the kidneys. However, no adverse effect was observed in the brain.

35.4.6 Antihypertensive

Hypertension or high blood pressure is a long-term medical condition in which the blood pressure in the arteries is persistently elevated. High blood pressure typically does not cause symptoms, but it puts extra strain on blood vessels, the heart, and other organs, such as the brain, the kidneys, and the eyes. Persistent high blood pressure can increase the risk of various serious and potentially life-threatening conditions, e.g., heart disease. Auraptene (**11**), imperatorin (**34**), osthol (**10**), and scopoletin (**9**) have antihypertensive property. Scopoletin (**9**), which is 6-methyl ether of esculetin (**8**), showed antihypertensive effect in an acute hypertension

animal model (Lagunas-Herrera et al. 2019). Antihypertensive effect of osthol (**10**) was demonstrated against pulmonary arterial hypertension, which is a progressive cardiovascular disease with high mortality (Yao et al. 2018c). Auraptene (**11**) displayed antihypertensive effect in a hypertensive rat model (Razavi et al. 2015); this compound reduced mean systolic blood pressure in hypertensive rats, but not in normotensive rats. The antihypertensive potential of imperatorin (**34**) was demonstrated in rats (Cao et al. 2013), where the 2-kidney, 1-chip (2 K,1C) model of hypertension was utilized.

35.4.7 Anti-inflammatory

An inflammation is a localized physical condition or state where part of the body becomes reddened, swollen, hot, and often painful, especially as a reaction to injury or infection. Generally, diets containing high levels of antioxidants can minimize inflammation and somewhat act as anti-inflammatory agents. Several dietary coumarins possess anti-inflammatory property, which has been shown in various animal studies. The *in vivo* anti-inflammatory activity of umbelliferone (**2**), the most common natural coumarin, has recently been reported by Wang et al. (2019b), showing the protective effect and underlying mechanism of action of **2** against lipopolysaccharide (LPS)-induced acute lung injury, following the similar mechanism as stated earlier. However, in fact, several researchers previously demonstrated the *in vivo* anti-inflammatory and antioxidant effects of **2**, and associated mechanisms of actions were also studied quite extensively in various animal models (Rauf et al. 2014; Anwar et al. 2015; Sim et al. 2015; Germoush et al. 2018).

The role of esculin (**18**) against macrophages and endotoxin shock induced by LPS in mice was analyzed by Li et al. (2016a), where they showed that this glycoside could suppress inflammatory reactions in macrophages and protected mice from LPS-induced endotoxin shock. Pretreatment with **18** improved the survival rate of mice. It inhibited LPS-induced increase of TNF-α and IL-6 in serum, the lungs, the liver, and the kidneys and upregulated IL-10, an anti-inflammatory cytokine. Esculin (**18**) attenuated the tissue injury of the lungs, the liver, and the kidneys in endotoxic mice. It diminished the protein expression of NF-κB p65 in the lungs, the liver, and the kidneys, resulting in lowering of levels of inflammatory mediators. Earlier, Zhang and Wang (2015) reported anti-inflammatory effects of this coumarin on LPS-induced acute lung injury in a rat model. The protective effect of **18**, mediated though anti-inflammatory and antioxidant mechanisms, on hyperoxia-induced lung injury model in newly born rats was established (Qi and Yu 2016). Niu et al. (2015a) reported the anti-inflammatory activity of **18** in xylene-induced mouse ear edema, carrageenan-induced rat paw edema, and carrageenan-induced mouse pleurisy models, while in the same year, Zheng et al. (2015) highlighted the anti-inflammatory effects of **18** on the adjuvant-induced arthritis in adult female Sprague Dawley rats. In the latter study, the treatment with **18** improved the body weight of rats accompanied with a reduction of paw volume in comparison to arthritic control.

Esculetin (**8**), the aglycone of the coumarin glycoside esculin (**18**), could attenuate LPS-induced neuro-inflammatory processes and depressive-like behaviour in mice (Zhu et al. 2016). It could reduce LPS-induced elevated levels of pro-inflammatory cytokines including IL-6, interleukin-1β (IL-1β), and TNF-α in serum and hippocampus. It also attenuated nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) protein expressions by inhibiting NF-kappa B (NF-κB) pathway in hippocampus. Rzodkiewicz et al. (2016) showed that **8** could reduce leukotriene B4 level in plasma of rats with adjuvant-induced arthritis, indicating its potential as a drug candidate for the treatment of rheumatoid arthritis. In a rat experimental model of inflammatory bowel disease induced by trinitrobenzenesulfonic acid, coumarin **8** at the dose of 5 mg/Kg exhibited intestinal anti-inflammatory activity (Witaicenis et al. 2014).

Another simple coumarin, scopoletin (**9**), could offer protection against cerulein-induced acute pancreatitis and associated lung injury in mice; the effect was because of its anti-inflammatory effect mediated through downregulation of pre-protachykinin A expression (encodes neuropeptide substance P) in the pancreas and the lungs and hydrogen sulfide signaling *via* nuclear factor B pathway (Leema and Tamizhselvi 2018). The anti-inflammatory property of **9** was shown *in vivo* in various other animal studies (Choi et al. 2017; Osman et al. 2017). Almost in all those cases, the anti-inflammatory activity of **9** was mediated through decreasing the myeloperoxidase and adenosine-deaminase activities and nitric oxide, TNF-α, and IL-1β levels and could be attributed to its ability to inhibit the phosphorylation of NF-κB and p38 MAPK (mitogen-activated protein kinases). Earlier, a similar observation was made with isofraxidin (**19**) in a xylene-induced mouse ear edema model (Niu et al. 2012); this coumarin exhibited anti-inflammatory effects *in vivo* and inhibited TNF-α production in LPS-induced mouse peritoneal macrophages *in vitro via* the mitogen-activated protein kinases pathway. Scopolin (**23**), the glucoside of **9**, was shown to suppress adjuvant-induced rat arthritis by inhibiting inflammation and angiogenesis at a dose of 100 mg/kg (Pan et al. 2009).

The anti-inflammatory potential of osthol (**10**) was exhibited in carrageenan-induced paw edema in mice (Singh et al. 2018); involvement of nitric oxide (NO) and cyclooxygenase pathways was investigated, the expression of inducible nitric oxide synthase and cyclooxygenase-2 (COX-2) was determined in spinal sections by immunohistochemical analysis, and LPS-challenge was used to assess *in vivo* effect on inflammatory cytokines. Osthol (**10**) could decrease carrageenan-induced paw edema, the levels of iNOS and COX-2 expression as well as TNF-α and IL-6. While the immunosuppressive effect of **10** is known, its potential as an anti-inflammatory agent was further established by Xu et al. (2018) in a collagen-induced arthritis rat model. This coumarin was effective on uric acid crystal-induced acute gouty arthritis through the inhibition of inflammasome, which is a multi-protein intracellular complex that detects pathogenic microorganisms and sterile stressors and that activates the highly pro-inflammatory cytokines IL-1β and IL-18. It can be mentioned that inflammasomes also induce a form of cell death termed pyroptosis (Yang et al. 2018a). The anti-inflammatory therapeutic potential of osthol (**10**) has been demonstrated in a number of other studies involving various *in vivo* animal models

(Bao et al. 2018; Jin et al. 2018; Khairy et al. 2018; Wu et al. 2018a; Zhang et al. 2018c; Zhao et al. 2018c).

Auraptene (**11**) is known to exert immunomodulatory effect and shows anti-inflammatory effects in peripheral tissues, and this was demonstrated in the brains of a LPS-injected systemic inflammation animal model and a brain ischemic mouse model (Okuyama et al. 2016, 2018). Seselin (**14**), an angular pyranocoumarin found in celery, has recently been shown to exert anti-inflammatory activity in two models of sepsis, cecal ligation and puncture or injection of LPS, in C57BL/6 mice, which is a common inbred strain of laboratory mice (Feng et al. 2019). It can also be noted that the C57BL/6 mouse was the second-ever mammalian species to have its entire genome published. This coumarin ameliorated sepsis induced by cecal ligation and puncture and produced anti-inflammatory activity through its action on Janus kinase 2 (JAK2), which is a kinase that is mutated in a number of myeloproliferative diseases and cancers. Earlier, the anti-inflammatory activity of imperatorin (**34**), psoralen (**13**), and seselin (**14**) was investigated using an ear edema model in mice (Garcia-Argaez et al. 2000). The anti-inflammatory potential of the sesquiterpenyl coumarin, umbelliprenin (**16**), was demonstrated in C57/BL6 mice (Khaghanzadeh et al. 2017), and its effect on the acute, chronic, and neuropathic pain was shown in albino mice (Hashemzaei et al. 2015).

Bergapten (**27**) possesses anti-inflammatory property, and this was supported by an *in vivo* study conducted using a zebrafish model (Yang et al. 2018b). Coumarin **27** could effectively inhibit the tail cutting-induced production of reactive oxygen species (ROS) and NO in zebrafish larvae, suggesting **27** could be a potential candidate for inflammation therapy. Zhou et al. (2017) provided further evidence for anti-inflammatory potential of **27** through *in vivo* study; this compound prevented LPS-induced inflammation in RAW264.7 cells through suppressing Janus kinase/signal transducers and activators of transcription (JAK/STAT) activation and ROS production as well as decreased mortality rate of mice after LPS challenge. Two other furanocoumarins, xanthotoxol (**33**) and imperatorin (**34**), were found to possess anti-inflammatory property in an *in vivo* study involving rats (Kumatia et al. 2017; Zhang et al. 2017b).

35.4.8 Anti-obesity

Obesity is a medical condition where excess body fat is accumulated to an extent that it may have a negative effect on health. Obesity has become a global health problem, mainly caused by eating too much (especially fat and sugar) and moving too little (no exercise or physical activities). Some plant-based diets can help treat and manage obesity, and many of those diets contain anti-obesity coumarins. For example, the anti-obesity potential of the geranyloxy furanocoumarin, bergamottin (**29**), a major a component of grapefruit juice, was demonstrated *in vivo* in a diet-induced obese mice model (Ko et al. 2018). The regulatory role of coumarin **29** in lipolysis is well known. Bergamottin (**29**) administration in a high-fat diet-induced obese mice model could reduce the weight and sizes of white adipose tissue as well as the weight gain

of mice fed with high-fat diet. The expressions of the brown adipocyte marker genes, uncoupling protein 1 (UCP1) and peroxisome proliferator-activated receptor-γ coactivator 1 (PGC1) alpha, were higher in the bergamottin-treated high-fat diet mice than that in the high-fat-diet-induced obese mice. Antihyperlipidemic activity of umbelliferone (**2**) and xanthotoxin (**32**) was shown in a mouse model (Iyer and Patil 2014); a considerable reduction in total cholesterol, triglycerides, and low-density lipoproteins and a significant increase in high-density lipoprotein were observed after the treatment with **2** and **32**.

35.4.9 Antipsychotic and Antidepressant

Simply, psychosis can be defined as an impaired relationship with reality, often manifested by serious mental disorders. People who are experiencing psychosis may have either hallucinations or delusions. Hallucinations are sensory experiences that take place within the absence of an actual stimulus. Pandy and Vijeepallam (2017) reported the antipsychotic-like activity of scopoletin (**9**) in a mice model, assessing apomorphine-induced climbing behavior and methamphetamine-induced stereotypy, and concluded that **9** could alleviate positive symptoms of schizophrenia only at a specific dose. Cao et al. (2017) used prenatally stressed offspring rats to investigate the potential antidepressant-like effects of imperatorin (**34**). After 4 weeks of treatment, coumarin **34** exhibited antidepressant-like effects and increased 5-hydroxytryptanin (serotonin) concentration in male prenatally stressed offspring, providing some evidence for the therapeutic use of **34** in prevention of depression-like behavior in adolescents.

35.4.10 Antitumour and Anticancer

Auraptene (**11**), a geranylated simple coumarin, widely occurs in the edible fruits of the genus *Citrus* (Murakami et al. 1997). This compound possesses antitumour property as evident from an *in vivo* animal experimentation; topical application of auraptene (at 160 nmol) could reduce tumor incidence and the numbers of tumors per mouse by 27% ($P < 0.01$) and 23% ($P < 0.05$), respectively (Murakami et al. 1997). Coumarin **11** possesses anticancer potential as evident from numerous *in vitro* studies, but its effectiveness in suppressing renal carcinoma progression in a mouse model was reported by Jang et al. (2015).

Administration of angelicin (**12**), an angular furanocoumarin, to mice bearing liver tumor xenografts inhibited tumor growth, without producing noticeable secondary side effects, suggesting its potential as a novel therapeutic agent for the treatment of patients with liver cancer (Wang et al. 2017a). Angelicin (**12**) and its isomer, psoralen (**13**), were equally effective in treating osteosarcoma in nude rats, in both low- and high-dose groups (Lu et al. 2014). They could induce apoptosis or necrosis of osteosarcoma.

Anticancer property of umbelliferone (**2**) was shown in a chemically induced renal carcinoma model in rats (Anwar et al. 2015). Kim et al. (2018b) reported that esculetin (**8**) could suppress tumor growth and metastasis by targeting Axin2/E-cadherin axis in colorectal cancer *in vivo* using an HCT116-implanted orthotopic mouse model. Zhu et al. (2018a) showed the inhibitory effect of compound **8** on the growth of lung cancer xenograft, possibly mediated by downregulating the expression of the oncogene C-myc, Cyclin D1 (a protein required for progression through the G1 phase of the cell cycle) and NF-κB. Esculetin (**8**) was shown to possess cancer chemopreventive potential *in vivo* using the 7,12-dimethylbenz(a)anthracene-induced hamster buccal pouch carcinogenesis model (Selvasundaram et al. 2018). A supplementation with coumarin **8** could modulate C-myc-induced energy metabolism and attenuate neoplastic changes in rats challenged with the procarcinogen 1,2-dimethylhydrazine (Sharma et al. 2017). Esculetin 3-methyl ether, also known as scopoletin (**9**), inhibited human tumor vascularization in xenograft models (Tabana et al. 2016); it (100 and 200 mg/kg) strongly inhibited (59.72 and 89.4%, respectively) vascularization in matrigel plugs implanted in nude mice.

Antitumour activity of the prenylated coumarin, osthol (**10**), is well documented, and its effectiveness in inhibiting tumour growth in hepatocellular carcinoma through the induction of apoptosis and enhancement of antitumor immune responses in mice was established (Yao et al. 2018b). Furthermore, the role of angiogenesis in the proliferation, invasion, and metastasis of tumour cells in hepatocellular carcinoma was evident in several animal studies. Yao et al. (2018b), using an orthotopic mouse model of hepatocellular carcinoma, proved that **10** could inhibit angiogenesis, which might be one of the mechanisms underlying its antihepatocellular carcinoma activity, possibly mediated by the NF-B/VEGF (vascular endothelial growth factor) signaling pathway. This coumarin was also shown to increase the sensitivity of nasopharyngeal carcinoma in nude mice to radiotherapy by a possible mechanism of downregulation of expressions of vascular endothelial growth factor and hypoxia-inducible factor-l alpha (HIF-1α) and inhibition of angiogenesis (Chen et al. 2018b). Osthol (**10**) is able to inhibit bone metastasis of breast cancer, as demonstrated by Wu et al. (2017) in a mice model of breast cancer osseous metastasis. Mice treated with **10** developed considerably less bone metastases and displayed decreased tumor burden; it inhibited breast cancer cell growth, migration, and invasion and induced apoptosis of breast cancer cells. Furthermore, osthol (**10**) regulated OPG (osteoprotegerin)/RANKL (receptor activator of NF-κB ligand) signals in the interactions between bone cells (osteoblasts and osteoclasts) and cancer cells and inhibited TGFβ (transforming growth factor β)/Smads signaling in breast cancer metastasis to bone in MDA-231BO cells. Note that Smad transcription factors lie at the core of one of the most versatile cytokine signaling pathways in metazoan biology – the TGFβ pathway.

Umbelliprenin (**16**), a farnesyloxy coumarin constituent of *Citrus* fruits, was shown to possess antineoplastic and immunostimulatory effects in 4 T1 mammary tumour-bearing mice, when 12.5 mg/mL of 16 was intraperitoneally administrated to healthy and tumour-bearing mice for 18 days (Rashidi et al. 2018). Coumarin **16** decreased tumour size, augmented serum interferon gamma, and reduced IL-4,

suggesting that this compound could inhibit tumor growth, angiogenesis, metastasis, and inflammation and potentiate an antitumor immune response *in vivo*. The same group also reported its effectiveness against colorectal cancer, developed in mice by intradermal injection of CT26 cell line (Alizadeh et al. 2018). Earlier, Khaghanzadeh et al. (2014) provided *in vivo* evidence in support of the cytotoxic effect of **16** on predominance of the responses of the T helper cells, Th1 and Th2 responses, in Lewis lung cancer mouse model. The cancer chemopreventive activity of **16** *in vivo* by using a two-stage carcinogenesis assay of mouse skin tumours induced by peroxynitrite as an initiator and 12-*O*-tetradecanoylphorbol-13-acetate as a promoter was reported by Iranshahi et al. (2009). This coumarin reduced the number of tumours, and the pattern of tumour promotion was slower in mice treated with **16**.

It is well known that many naturally occurring coumarins, especially *Citrus* coumarins, exert anticarcinogenic effect partly by inducing carcinogen-detoxifying enzymes glutathione S-transferase (GST) and/or NAD(P)H quinone oxidoreductase (NQO1). A comparison of such coumarins, auraptene (**11**), imperatorin (**34**), and limettin (**25**), on carcinogen-detoxifying enzymes in Nrf2 knockout mice was carried out by Prince et al. (2009). It was observed that coumarins **11** and **34** induced murine liver cytosolic GST activities via the Nrf2/ARE mechanism.

Bergapten (**27**) possesses anticancer potential as evident from various animal studies (Pattanayak et al. 2018). It was shown in an *in vivo* study that **27** could ameliorate the cancer-induced alterations in body weight and liver weight and significant restoration of the changes in mRNA and protein expressions of liver X receptor (LXR) (α, β). It could reduce the lipid droplets level in liver cancer cells. Pattanayak et al. (2018) provided evidence and validated the critical role of **27** in maintaining the lipid homeostasis justifying its anticancer potential against NDEA-induced hepatocellular carcinoma. The antitumour potential of umbelliferone (**2**) and xanthotoxin (**32**) was demonstrated in an *in vivo* murine mouse melanoma model (Iyer and Patil 2014).

The antitumour potential of another *Citrus* furanocoumarin, bergamottin (**29**), was shown *in vivo* using a nude mouse model (Wu et al. 2016); an intraperitoneal injection of **29** induced dose-dependent as well as time-dependent cytotoxic effects and inhibition of colony formation in the A549 cancer cells. It also suppressed cancer cell invasion and migration. The doses of 25, 50, and 100 mg/kg bergamottin (**29**) injection reduced the tumour weight from 1.61 g in the phosphate-buffered saline (PBS)-treated group (control) to 1.21, 0.42, and 0.15 g in the bergamottin-treated groups, respectively. It was established that **29** could inhibit lung cancer cell growth in both a cell model and a xenograft mouse model by inducing apoptosis, mitochondrial membrane potential loss, and G2/M cell cycle arrest as well as inhibiting cell migration and invasion.

Anti-skin tumour potential of another furanocoumarin, isopimpinellin (**31**), was reported by Kleiner et al. (2002), who studied the effect of an oral administration of **31** on skin tumour initiation by topically applied benzo[1]pyrene and 7.12-dimethylbenz [a]anthracene. The anticancer potential of imperatorin (**34**), isoimperatorin (**38**), oxypeucedanin (**39**), and oxypeucedanin hydrate (**40**) was established *in vivo* using a melanin possessing hairless mice implanted with B16F10 cells under UV radiation

(Kimura et al. 2013). UV radiation together with these coumarins could reduce tumor growth and final tumor weight in B16F10-bearing mice.

Dong et al. (2018) reported the antileukemic potential of the dihydrofuranocoumarin, marmesin (**41**). In addition to *in vitro* studies, they showed that marmesin (**41**) could prevent the tumour growth at a dose of 30 mg/kg *in vivo* using a rat model.

35.4.11 Asthma and Anti-allergic

The protective effects of angelicin (**12**) on allergic asthma induced by ovalbumin (abbreviated OVA) was studied in mice by Wei et al. (2016); this angular furanocoumarin inhibited inflammatory cells' infiltration into the lungs, attenuated ovalbumin-induced lung injury, and inhibited airway hyperresponsiveness and NF-κB activation. Note that OVA is the main protein found in egg white, making up approximately 55% of the total protein, and it displays sequence and three-dimensional homology to the serpin superfamily. However, unlike most serpins, it is not a serine protease inhibitor.

Potential anti-asthmatic effect of esculetin (**8**) and its plausible mechanism were evaluated by Long (2016) in a mouse model of allergic asthma, which was developed with the sensitization and challenge of OVA. Coumarin **8** could inhibit OVA-induced eosinophil count and recover IL-4, IL-5, IL-13, and IL-17A levels in bronchoalveolar lavage fluid. It was suggested that **8** might effectively ameliorate the progression of asthma and have therapeutic potential in patients with allergic asthma.

The anti-allergic effects of osthol (**10**) in asthmatic mice and its immunomodulatory actions on dendritic cells and T cells were studied by Chiang et al. (2017); an oral administration of 10 to BALB/c mice after OVA sensitization ameliorated all of the cardinal features of T helper 2 (Th2)-mediated allergic asthma. This study provided evidence for the potential therapeutic application of **10** to treat allergic asthma. Anti-asthmatic property of **10** in an OVA-induced asthma model in murine was also reported in the same year (Wang et al. 2017c). Osthol treatment reduced the OVA-induced increase in serum immunoglobulin E (IgE) and inflammatory cytokines, IL-4, IL-5, and IL-13, in bronchoalveolar lavage fluid, and decreased the recruitment of inflammatory cells in lavage fluid and the lung. It also attenuated goblet cell hyperplasia and mucus overproduction in lung tissue. All these findings supported potential pharmaceutical applications of osthol (**10**) in the treatment for asthma and other airway inflammation disorders.

Scoparone (**22**) was reported to inhibit inflammation by lowering the contents of IL-5 in serum and bronchial alveolar lavage fluid and polylactic acid in pulmonary tissues in an asthmatic guinea pig model (Fan et al. 2006). Allergic rhinitis is inflammation of the inside of the nose caused by an allergen, such as pollen, dust, mold, or flakes of skin from certain animals, and a study conducted by Cheng et al. (2013) demonstrated the effectiveness of **22** against this condition in a rat model. Scoparone was highly effective in treating allergic rhinitis by regulating the expression of Th1/Th2 cytokines and IgE.

The anti-allergic property, manifested by antihistaminic effect, of several dietary coumarins, e.g., bergapten (**27**), byakangelicol (**37**), imperatorin (**34**), isoimperatorin (**38**), isopimpinellin (**31**) oxypeucedanin (**39**), oxypeucedanin hydrate (**40**), phellopterin (**35**), scopoletin (**9**), xanthotoxin (**32**), and xanthotoxol (**33**), was reported by Li and Wu (2017). Among these compounds, **27** and **40** were the most effective coumarins. Xian et al. (2018) evaluated the inhibitory effect of imperatorin **34** on airway remodeling model of asthmatic mice and established its possible mechanisms. In an earlier study conducted by Li et al. (2016b), **34** was shown to inhibit allergic airway inflammatory reaction and mucin secretion in OVA-induced asthmatic rats *via* suppressing IgE, histamine, inflammatory cells, and cytokines and also through downregulating the protein coding gene MUC5AC (mucin 5 AC, oligomeric mucus/gel forming). A similar effect was observed with **38** (Wijerathne et al. 2017); this coumarin could attenuate airway inflammation and mucus hypersecretion in an OVA-induced murine model of asthma. Coumarin **38** inhibited OVA-induced inflammatory cell infiltration and mucus production in the respiratory tract, and the pretreatment with **38** suppressed the activation of p38 mitogen-activated protein kinase (p38 MAPK), extracellular-signal-regulated kinases1/2 (ERK1/1) and NF-κB.

35.4.12 Cardioprotection

Cardioprotection comprises several regimens that preserve function and viability of cardiac muscle cell tissue subjected to ischemic insult or re-oxygenation. Umbelliferone (**2**) could provide cardioprotection in coronary artery ligation-induced myocardial ischemia in rats through inflammation and apoptosis pathways (Gan et al. 2018); this effect was also demonstrated by Luo et al. (2018) in a rat model. Jagadeesh et al. (2016) reported the protective effects of **2** in dyslipidemia (abnormal amounts of lipids in blood) and cardiac hypertrophy (abnormal enlargement or thickening of the heart muscle) in isoproterenol-induced myocardial infarction in rats.

Esculetin (**8**) and telmisartan combination could alleviate the pathological features of type 2 diabetic cardiomyopathy including metabolic perturbations, morphometric alterations, altered vascular reactivity, increased Keap1 and fibronectin expression more effectively than their respective monotherapy (Kadakol et al. 2017a). Earlier, the cardioprotective effect of **8** on myocardial ischemia/reperfusion damage in rats was demonstrated (Tao et al. 2016), and potential mechanism was also studied. Coumarin **8** could attenuate myocardial ischemia/reperfusion-induced injury in rats by inhibiting the receptor-interacting protein 140 (RIP140)/nuclear factor kappa B (NF-κB) inflammatory pathway. Another simple coumarin, scoparone (**22**), also known as 3,4-dimethoxycoumarin, was found to possess cardioprotective property in an *in vivo* rat model of ischemia-reperfusion injury and an *in vitro* primary cultured cardiac myocyte model of oxygen-glucose deprivation/re-oxygenation (Wan et al. 2018). The treatment with **22** increased cell viability, superoxide dismutase levels, and B cell lymphoma 2 protein expression

and decreased lactate dehydrogenase release, malondialdehyde production, creatine kinase levels, reactive oxygen species concentration, cell apoptotic rate, myocardial infarct area, and Bcl-2-associated X protein, and caspase-3 and cytochrome c protein expression. Effect of this compound against cardiac fibrosis was reported by Fu et al. (2018), where the possible remedial effect of **22** on angiotensin II-induced extracellular matrix remodeling and its possible mechanism in cardiac fibroblasts was established.

In a recent study, osthol (**10**) was implicated to cardiac protection *in vivo*; this coumarin was observed to decrease collagen I/III contents and their ratio in TGF-β 1-overexpressed mouse cardiac fibroblasts through regulating the TGF-β/Smad signaling pathway (Liu et al. 2018c). It was suggested that **10** might play a beneficial part in the prevention and treatment of myocardial fibrosis. Note that cardiac fibrosis is an abnormal thickening of the heart valves due to inappropriate proliferation of cardiac fibroblasts but more commonly referred to the excess deposition of extracellular matrix in the cardiac muscle. This coumarin was also reported to attenuate right ventricular remodeling via decreased myocardial apoptosis and inflammation in monocrotaline-induced rats (Li et al. 2018a) and to attenuate myocardial ischemia/reperfusion injury in rats by inhibiting apoptosis and inflammation through attenuating pro-inflammatory cytokines, including TNFα and IL-6 and IL-1β, providing evidence for its cardioprotective effect (Wu et al. 2018a).

Another coumarin, imperatorin (**34**), also possesses cardioprotective property. In a study conducted by Zhang et al. (2012), it was observed that coumarin **34** could prevent cardiac hypertrophy and the transition to heart failure via nitric oxide (NO)-dependent mechanisms in mice. Marmesin (**41**), a dihydrofuranocoumarin, was shown to provide protection in myocardial infraction in animal model (Krushna et al. 2017); the findings were also supported by molecular docking studies.

35.4.13 Gastroprotection

Li et al. (2017c) reported the gastroprotective property of esculin (**18**) in a mouse model of ethanol-induced gastric lesion. Pretreatment with this coumarin could reduce macroscopic and histopathological damage and gastric lesion index in a dose-dependent fashion. It could also reduce NO production, inducible NO synthase (iNOS) levels, and NF-κB p65 protein expression in gastric tissues after ethanol challenge and suppress the increased expression of tumour TNF-α and IL-6 in ethanol-treated mice. The underlying mechanism of gastroprotection offered by **18** was assumed to be linked to inhibition of NF-κB activation, which subsequently reduces expression of iNOS, TNF-α, and IL-6. Scoparone (**22**) could offer gastroprotection through its anti-ulcerogenic property as observed on HCl/ethanol-induced gastritis in rats (Choi et al. 2012). In a similar animal model, scopoletin (**9**) and scopolin (**23**) showed anti-ulcerogenic activity at a dose of 50 mg/kg (Awad et al. 2015).

Sekiguchi et al. (2012) reported the gastroprotective effect of auraptene (**11**), a key component of *Citrus* fruit peels; it could suppress *Helicobacter pylori* adhesion

via expression of CD74 (an integral transmembrane molecule), which has been identified as a new receptor for *H. pylori* urease. *Helicobacter pylori* is a major human pathogen that plays central roles in chronic gastritis and gastric cancer. This coumarin inhibited *Helicobacter pylori*-induced expression and/or production of CD74, macrophage migration inhibitory factor, IL-1β, and TNF-α in gastric mucosa, together with serum macrophage inhibitory protein-2. Thus, auraptene (**11**) could be a promising dietary coumarin for reducing the risk of *H. pylori*-induced gastritis and carcinogenesis.

35.4.14 Hepatoprotection

Hepatoprotection or antihepatotoxicity is the ability of a substance to prevent damage to the liver cells and thus the liver. The protection of the liver cells against toxic substances, e.g., drugs, lipid peroxidation, and free radical injury, may decrease inflammation, improve liver blood flow, and ultimately help in reduction of ascites and blood pressure. Hepatoprotecive property of esculin (**18**), a glucoside of the coumarin esculetin (**8**), was evaluated in a mice model (Liu et al. 2018a). Its hepatoprotection is generally mediated through its antioxidant and anti-inflammatory effects. Liu et al. (2018a) showed that this coumarin glucoside (**18**) could reduce the pathological symptoms of induced acute liver injury in mice, as well as serum AST (aspartate aminotransferase) and ALT (alanine aminotransferase) levels. While lipopolysaccharide (LPS)/D-Gal-induced liver myeloperoxidase (MPO) activity and malondialdehyde (MDA) content were suppressed by **18**, LPS/D-Gal-induced liver TNF-α and IL-1β production were attenuated by this compound. Furthermore, **18** inhibited NF-κB activation as well as increased nuclear factor E2-related factor 2 (Nrf2) and heme oxygenase-1 (HO-1) expression.

Hepatoprotective potential of the simple coumarin, umbelliferone (**2**), was evaluated in diabetic mice, and it was suggested that the effect was mediated possibly through inhibition of HMGB1 (*high mobility group box 1* protein)-induced inflammatory response and activation of Nrf2-induced antioxidant property (Yin et al. 2018). Possible involvement of Nrf2 and PPAR-γ (peroxisome proliferator-activated receptor gamma) upregulation in the protective effect of **2** against cyclophosphamide-induced hepatotoxicity was demonstrated by Mahmoud et al. (2017). Hepatoprotective effect of **2** and **8** was demonstrated in *N*-nitrosodiethylamine-induced hepatotoxicity in rats (Subramaniam and Ellis 2016). Earlier, Kim et al. (2014) reported that dietary intake of coumarin **2** could attenuate alcohol-induced fatty liver *via* regulation of PPAR-α and SREBP (*sterol regulatory element-binding proteins*)-1c in rats; this compound could attenuate alcoholic steatosis through downregulation of SREBP-1c-mediated lipogenesis and upregulation of PPAR-α-mediated fatty acid oxidation. While hepatoprotective property of **2** and its associated mechanisms of action were also reported by Mohamed et al. (2014), this effect was demonstrated for **8** on ethanol-induced liver injury in human HepG2 cells and in a mouse model (Lee et al. 2018).

Esculetin (**8**) prevented ethanol-induced liver injury by reducing glutathione depletion, malondialdehyde production, and the lipid contents in the liver. Moreover,

this compound lowered the levels of serum ALT, serum AST, and the content of serum lipids. Hepatoprotective potential of compound **8** was also reported by Pandey et al. (2017) in a high-fat-diet-induced non-alcoholic fatty liver disease mouse model; esculetin (**8**) was effective in improving liver fibrosis. A similar work was carried out by Choi et al. (2016), and they reported that coumarin **8** could protect against development of non-alcoholic fatty liver in diabetes *via* regulation of lipids, glucose, and inflammation. Hepatoprotective effect of scopoletin (**9**) was shown using a high-fat-diet-fed mice model, as part of the investigation looking at the effects of this compound on non-alcoholic fatty liver in obese mice (Ham et al. 2016). It was observed that at the doses of 0.01 and 0.05% w/w for 16 weeks, **9** could reduce body weight, visceral fat, serum levels of leptin, lipid, TNF-α, IL-6, interferon (IFN)-γ and MCP-1 (monocyte chemoattractant protein-1), insulin resistance, and hepatic lipid accumulation. It was postulated that this coumarin could possibly treat high-fat-induced hepatic dysfunction via regulation of lipid metabolic and inflammatory genes. The hepatoprotective effect of scoparone (**22**), which is actually scopoletin methyl ether, was demonstrated by Liu and Zhao (2017). Earlier, Kang et al. (2013) showed that **22** could attenuate D-galactosamine/LPS-induced fulminant hepatic failure through inhibition of toll-like receptor 4 signaling in mice.

Isofraxidin (**19**) is thought to play a protective role against lipid metabolism disorder induced by a high-fat diet *via* inhibition of lipid production and inflammation in the liver. Li et al. (2017a) demonstrated that the treatment with **19** could inhibit the high-fat-diet-induced elevation in body weight, liver weight, lipid metabolism, and hepatic injury in mice. The anti-inflammatory activity in isofraxidin-treated hepatic tissue correlated with downregulation of TLR4 (toll-like receptor 4) expression and NF-κB transcription. Scopolin (**23**), which is the glucoside of scopoletin (**9**), could exhibit beneficial effect on high-fat-diet-induced hepatic steatosis in mice (Yoo et al. 2017). This coumarin glycoside could attenuate hepatic steatosis through activation of sirtuin 1-mediated signaling cascades, a potent regulator of lipid homeostasis, and increase hepatic sirtuin 1 activity and protein expression.

Potential hepatoprotective effects of osthol (**10**) at a dose of 100 mg/kg (i.p.) was shown by Zhou et al. (2018) using a tamoxifen-induced acute liver injury in mice. Pretreatment with **10** could attenuate tamoxifen-induced liver injury evident from dose-dependent reduction of serum ALT and AST activities and could counteract tamoxifen-induced oxidative stress, evident from marked increase of reduced glutathione and reduction of malondialdehyde and hydrogen peroxide. It was concluded that **10** could prevent tamoxifen-induced liver toxicity by suppressing p38 activation and subsequently reduce tamoxifen-induced oxidative damage. Coumarin **10** could ameliorate the hepatic lipid metabolism and inflammatory response in nonalcoholic steatohepatitic rats, and the effects might be mediated by the activation of hepatic peroxisome proliferator-activated receptor alpha/gamma (PPAR-α/ PPAR-γ) (Zhao et al. 2018c). The hepatoprotective potential of **10** and its possible mechanisms of action were studied in several animal models (Cai et al. 2018; Zhao et al. 2018c).

Hepatoprotection of auraptene (**11**), a coumarin found in the peels of *Citrus* fruits such as grapefruits, was evaluated against thioacetamide-induced hepatic fibrosis in

mice (Gao et al. 2018). They showed that **11** could protect against liver injury induced by thioacetamide in mice and maintain the homeostasis of bile acids *via* the regulation of FXR (farnesoid X receptor) target genes, reducing collagen content in the liver and inhibiting the activation of hepatic stellate cells by downregulating the expression of TGF-β1 and α-SMA (smooth muscle actin). Hepatoprotection-related anti-inflammatory effects of **11** were mediated by reducing the expression of NF-κB, TNF-α, and IL-1β. Earlier, the effect of dietary auraptene (**11**) on hepatic lipid metabolism both *in vitro* and *in vivo* was studied. It was shown that this coumarin could normalize lipid abnormalities in HepG2 hepatocytes (Nagao et al. 2010), and administration of **11** alleviated obesity and hepatic triglyceride accumulation in part through lipolysis enhancement in the livers of obese Otsuka Long-Evans Tokushima fatty rats.

Hepatoprotective effect of bergamottin (**29**) was demonstrated in a paracetamol-induced hepatotoxicity model in rats (Baleni et al. 2015). Hepatoprotection mediated through carcinogen-detoxifying effect of furanocoumarins, imperatorin (**34**) and isopimpinellin (**31**), and **11**, was demonstrated by Prince et al. (2009). It was observed that coumarin **31** could increase liver cytosolic NAD(P)H quinone oxidoreductase (NQO1) activities, and its effect was not attenuated in Nrf2(−/−) mice, suggesting that the coumarins **11** and **34** could induce murine liver cytosolic glutathione S-transferase (GST) activities via the Nrf2/ARE mechanism. It was also noted that despite structural similarities, **31** could not activate HepG2-ARE-GFP (green fluorescent protein), and in the Nrf2 knockout mouse, compound **31** induced GST and NQO1 via additional mechanisms.

35.4.15 Immunomodulation

Bergapten (**27**) has immunomodulatory effects, which was shown to be responsible for its ability to attenuate D-galactose-induced aging in mice (Xie et al. 2018). Bergapten-treated group could reverse body weight and spleen index in aging progress, promote T cell proliferation, and upregulate IFN-γ and IL-4 in aging mice. Additionally, this compound could enhance T helper cell (Th) and cytotoxic T cell (Tc) responses, which seemed to participate in the process of eliminating the virus in an old age.

35.4.16 Lung Injury Protection

Umbelliferone (**2**) attenuated LPS-induced acute lung injury in mice, possibly *via* the anti-inflammatory and anti-apoptotic activities (Luo et al. 2016). Like coumarin **2**, esculetin (**8**) was also shown to possess protective effects in lung injury (Chen et al. 2015). It was shown that esculetin (**8**) could resolve lipopolysaccharide (LPS)-induced acute lung injury via regulation of RhoA/Rho kinase/NF-κB pathways *in vivo* and *in vitro*. It can be noted that the Rho A/Rho kinase pathway plays an

important role in the development of hypoxic pulmonary hypertension, which contributes to the pathogenesis of cardiopulmonary diseases.

Similarly, scopoletin (**9**) could offer protection against cerulein-induced acute pancreatitis and associated lung injury in mice (Leema and Tamizhselvi 2018). The protective effects and potential mechanism of action of isofraxidin (**19**) against LPS-induced acute lung injury in mice were reported by Niu et al. (2015b); the pre-treatment of **19** lowered LPS-induced mortality and lung wet-to-dry weight ratio and reduced the levels of TNF-α, IL-6, and prostaglandin E-2 (PGE-2) in serum and bronchoalveolar lavage fluid. The protective effect of **19** appears to be mediated from the inhibition of COX-2 protein expression in the lung, which regulates the production of PGE-2. Another simple coumarin, scoparone (**22**), was found to project LPS-induced acute lung injury in mice *via* suppression of TLR4-mediated NF-κB signaling pathways (Niu et al. 2014).

Osthol (**10**) is able to protect against acute lung injury. In a recent study, it was found that this coumarin could protect against acute lung injury by suppressing NF-κB-dependent inflammation in mouse (Jin et al. 2018). Coumarin **10** treatment inhibited the LPS-induced inflammatory response in mouse peritoneal macrophages through blocking the nuclear translocation of NF-κB. Preventative effect of imperatorin (**34**) on acute lung injury induced by LPS in mice was reported by Sun et al. (2012). BALB/c mice were pretreated with **34** 1 h prior to LPS challenge. The levels of TNF-α, IL-1, and IL-6 in the bronchoalveolar lavage fluid were reduced significantly, and the level of IL-10 was upregulated 10 h after the imperatorin treatment. Pretreatment with **34** decreased lung wet-to-dry ration, the number of inflammatory cells, and myeloperoxidase activities.

35.4.17 Nephroprotection

Nephroprotection by esculin (**18**) in a diabetic animal model, mediated through its established antioxidant and anti-inflammatory routes, was demonstrated by Wang et al. (2015a). This compound could improve dyslipidemia, inflammation responses, and renal damage in streptozotocin-induced diabetic rats. Nephroprotective effect of this compound was also reported by Kang et al. (2014) on streptozotocin-induced diabetic renal damage in mice. Naaz et al. (2014) demonstrated the protective properties of **18** against pro-oxidant aflatoxin B-1-induced nephrotoxicity in mice, which was implicated to its antioxidant and free radical-scavenging activities. Nephroprotection was also shown to be offered by umbelliferone (**2**) in methotrexate-induced renal injury in adult male albino rats (Hassanein et al. 2018). It was concluded that the nephroprotective effect of **2** was through modulation of oxidative stress and inflammation and apoptosis with enhancement of its cytotoxicity. Like umbelliferone (**2**), esculetin (**8**) could also offer nephroprotection in type 2 diabetic rats (Kadakol et al. 2017b).

Osthol (**10**), well known for its inhibitory effects on inflammation, oxidative stress, fibrosis, and tumor progression, could offer nephroprotection by ameliorating renal fibrosis, which is a common pathway of virtually all progressive kidney

diseases, in mice (Zhang et al. 2018b). Coumarin **10** could hinder renal fibrosis in unilateral ureteral obstruction mouse mainly through inhibition of fibroblast activation and epithelial-mesenchymal transition. Earlier, the nephroprotective potential of osthol **10** in a chronic kidney failure rat model was established by. They showed that this compound could protect against inflammation in a rat model of chronic kidney failure *via* suppression of NF-κB and transforming growth factor-beta 1 and activation of phosphoinositide 3-kinase/protein kinase B/nuclear factor (erythroid-derived 2)-like 2 signaling. Osthol (**10**) treatment reversed chronic kidney failure-associated changes in serum creatinine, calcium, phosphorus, and blood urea nitrogen levels in chronic kidney failure rats. It inhibited chronic kidney failure-induced TNF-α, IL-8, and IL-6 expressions and suppressed NF-κB protein expression. Furthermore, it attenuated the protein expression of transforming growth factor-beta 1 (TGF-β1), reduced monocyte chemoattractant protein-1 activity, and increased the phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt) ratio. The nephroprotective activity of imperatorin (**34**), mediated by its antihypertensive and antioxidant property, was demonstrated in a rat model (Cao et al. 2013), where **34** showed antihypertensive and antioxidant effects in the renal injury of renovascular hypertensive rats, providing evidence for its potential therapeutic use in the prevention of renal injury related hypertension.

35.4.18 Neuroprotection

Xanthotoxin (**32**) is one of the most common furanocoumarins present in food plants, especially from the family Apiaceae (Table 1), and it has been implicated to many bioactivities. In a recent study (Skalicka-Wozniak et al. 2018), the effect of **32** was investigated on the scopolamine-induced cognitive deficits in male Swiss mice using the passive avoidance test. Either single (2.5 and 5 mg/kg) or repeated (1 mg/kg) administration of this coumarin could increase index of latency in both acquisition and consolidation of memory processes linking to some procognitive effects. An acute (2.5 mg/kg) and subchronic (1 mg/kg) administration of **32** could prevent memory impairment induced by the injection of scopolamine (1 mg/kg). Based on these findings, it was suggested that **32** might possess neuroprotective effect in scopolamine-induced cognitive impairment connected to cholinergic neurotransmission and oxidative stress in the brain structures. Earlier, the same group showed that **32**, its isomer bergapten (**27**), and the simple coumarin umbelliferone (**2**), which are known as CYP2A6 inhibitors, could prolong the antidepressive and procognitive effects of nicotine as demonstrated by the forced swimming test (animal models of depression) and passive avoidance test (memory and learning paradigm model) (Budzynska et al. 2016). The same group also reported the anticonvulsant potential of **27**, **32**, imperatorin (**34**), and oxypeucedanin (**39**), using mouse model (Luszczki et al. 2010; Skalicka-Wozniak et al. 2014). Li et al. (2017b) reported estrogen-like neuroprotection of angelicin (**12**) in an animal model of spinal cord injury; intraperitoneal injections (5 and 10 mg/kg per day for 2 weeks) enhanced the hind limb locomotor functions of mice with spinal cord injury.

Antidepressant effect, mediated though associating signaling with neuroinflammation and neurogenesis, of the simple coumarins esculetin (**8**) and its glucoside (esculin, **18**) in a mouse model of chronic stress-induced depression was reported (Kim et al. 2018a). Umbelliferone (**2**) was shown to reverse depression-like behaviour in chronic unpredictable mild stress-induced rats (Qin et al. 2017). It was suggested that the neuroprotective effects on chronic unpredictable mild stress-induced model of depression could be associated with the inhibition of neuronal apoptosis. Umbelliferone (**2**) is known to cross blood-brain barrier (Subramaniam and Ellis 2013) and to protect neuronal cells from death. This fact was further reinforced by Wang et al. (2015b); the effects of **2** in a rat model of focal cerebral ischemia induced by middle cerebral artery occlusion/reperfusion were studied. They concluded that the possible neuroprotection was offered by **2** against focal cerebral ischemic partly through the inhibition of TXNIP (thioredoxin-interacting protein)/NLRP3 (NOD-like receptor protein 3) inflammasome and activation of PPAR-γ. Neuroprotective effects of coumarins **2** and **8** were reported using a mouse model of Parkinson's disease, where 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine-induced neurotoxicity was utilized (Subramaniam and Ellis 2013).

Esculetin (**8**) is a potent antioxidant and anti-inflammatory compound, and it has been shown to possess neuroprotective potentials in various animal models of neurodegeneration (Lin et al. 2017), one of those is the study by Lin et al. (2017), where they elucidated the neuroprotective potential of **8** against streptozotocin-induced experimental dementia of Alzheimer's type in rats. Zhu et al. (2016) provided evidence from *in vivo* experimentation using a rat model to support that neuroprotection of **8** could be attributed to the upregulations of brain-derived neurotrophic factor (BDNF) and phosphorylated tyrosine kinase B (p-TrkB) protein expression in hippocampus. The antidepressant-like effects might be related to the inhibition of NF-κB pathway and the activation of BDNF/TrkB signaling. Dietary antioxidants, like **8**, play an important role in the aging process by relieving oxidative damage, a likely cause of age-associated brain dysfunctions (Martin-Aragon et al. 2016). Esculetin treatment could attenuate the increased immobility time and enhance the diminished climbing time in the forced swim task elicited by acute restraint stress in the 11- and 17-month-old mice versus their counterpart controls (Martin-Aragon et al. 2016). It could also partially reverse the acute restraint stress generated impairment of contextual memory in the step-through passive avoidance both in mature adults. It was postulated that **8** could be useful in preventing the acute restraint stress-induced oxidative stress mostly in mature adult mice by restoring antioxidant enzyme activities.

Scopoletin (**9**) and scopolin (**23**) at the doses of 2.5, 5, 10, and 15 mg/kg, p.o., were evaluated for memory-enhancing activity against scopolamine-induced amnesia using elevated plus maze and step-down paradigms, and the effect on acetylcholinesterase activity in mice brain (Malik et al. 2016). Both coumarins, **9** and **23**, dose-dependently attenuated the scopolamine-induced amnesic effect. In addition, compounds **9** and **23** at the doses of 10 and 15 mg/kg showed activity comparable to that of donepezil, and they also exhibited significant cetylcholinesterase inhibitory activity.

Osthol (**10**), sometimes also spelt as osthole, is a prenylated simple coumarin and could be effective against neurodegenerative diseases, e.g., Alzheimer's disease. Yao et al. (2019) have recently investigated the possible role of **10** in decreasing hyperphosphorylated tau protein in Alzheimer's disease and studied the underlying mechanism in a mice model. Osthol (**10**) improved learning and memory dysfunction and ameliorated the histology structure of damaged neural cells in hippocampal area. It could decrease tau protein phosphorylation as well as inhibit cells apoptosis. Neuroprotection, offered by **10**, was demonstrated in a recent study, where this compound promoted endogenous neural stem cell proliferation and improved neurological function through Notch signaling pathway in mice acute mechanical brain injury (Yan et al. 2018), establishing its potential in neural restoration. Note that the Notch signaling pathway is a highly conserved cell signaling system present in most multicellular organisms, and mammals possess four different notch receptors, i.e., NOTCH1, NOTCH2, NOTCH3, and NOTCH4. The *notch* receptor is a single-pass transmembrane receptor protein. Coumarin **10** was particularly useful in enhancing the therapeutic efficiency of stem cell transplantation in neuroendoscopy caused traumatic brain injury (Tao et al. 2017), and in stimulating neural stem cells differentiation into neurons in an Alzheimer's disease cell model via upregulation of microRNA-9 and rescued the functional impairment of hippocampal neurons in transgenic mice (Li et al. 2017d).

Several other dietary coumarins, e.g., auraptene (**11**) (Okuyama et al. 2016, 2018), also offer neuroprotection. Using an animal model, it was shown that **11** could suppress inflammatory responses including the hyperactivation of microglia in the ischemic brain and inflamed brain, thereby inhibiting neuronal cell death (Okuyama et al. 2016). Ghanbarabadi et al. (2016) also reported the neuroprotective and memory-enhancing effects of **11** in a rat model of vascular dementia. Xanthotoxol (**33**) could offer neuroprotection through suppression of the inflammatory response in a rat model of focal cerebral ischemia as evident from alleviation of brain edema, inhibition of the neutrophil filtration, and reduction of intercellular adhesion molecule-1 and E-selectin (He et al. 2013). It was concluded that the neuroprotection might be linked to xanthotoxol's ability to attenuate the expression of pro-inflammatory mediators and to inhibit the inflammatory response after cerebral ischemia. Neuroprotective effect of imperatorin (**34**) was shown in a LPS-induced memory loss in mice (Chowdhury et al. 2018). Coumarin **34** could ameliorate LPS-induced memory deficit by mitigating pro-inflammatory cytokines and oxidative stress and modulating brain-derived neurotrophic factor. Imperatorin (**34**) pretreatment reversed LPS-induced behavioral and memory disturbances and decreased oxidative stress and acetylcholinesterase levels. It also reduced TNF-α and IL-6 levels and upregulated brain-derived neurotrophic factor in hippocampus and cortex of the brain.

35.4.19 Osteoporosis and Osteoarthritis

Osteoporosis is a condition that weakens bones, making them fragile and more likely to break. Coumarins from *Citrus aurantifolia* and *C. sinensis*, e.g., xanthotoxin (**32**)

and marmesin (**41**), were assessed for the osteoporosis-preventing property of the crude extracts using an ovariectomized rat model (Shalaby et al. 2011), suggesting the potential of these *Citrus* extracts to be developed as clinically useful anti-osteoporotic agents. Earlier, Dou et al. (2016) exhibited that coumarin **32** could prevent bone loss in ovariectomized mice through the inhibition of NF-κB ligand (RANKL)-induced osteoclastogenesis and also could decrease osteoclast number, prevent bone loss, and restore bone strength in mice. Thus, xanthotoxin (**32**), a common coumarin in *Citrus* fruits, might be a new therapeutic candidate for the treatment of osteoporosis.

Bergapten (**27**), another major component of *Citrus* fruits, was also found to exert similar effects in animal models (Chen et al. 2019). In a recent study, this furanocoumarin was shown to suppress receptor activator of NF-κB ligand-induced osteoclastogenesis and ovariectomy-induced osteoporosis *via* suppression of NF-κB and JNK (c-Jun N-terminal kinases) signaling pathways (Chen et al. 2019). Earlier, this compound was shown to inhibit diabetes-related osteoporosis *via* the regulation of the PI3K/AKT, JNK/MAPK, and NF-κB signaling pathways in osteoprotegerin knockout mice and thus to protect trabecular structure and decrease osteoclastogenic differentiation (Li et al. 2016b). This coumarin could also promote bone marrow stromal cell differentiation into osteoblasts *in vitro* and *in vivo* using a mouse model (Xiao et al. 2015). The protective effect of **27** against ovariectomy-induced bone loss was found by distal femur micro-CT scanning, with improvements of bone metabolism parameters such as bone mineral density, trabecular number, and trabecular separation.

Using a similar rat model, Liu et al. (2018b) reported the effect of esculetin (**8**) on bone metabolism. Esculetin-treated group had greater femoral bone mineral density and tibial trabecular bone volume and much smaller trabecular resorption surface, suggesting that coumarin **8** could increase bone mass by upregulating receptor activator of NF-κB ligand (RANKL) expression in osteoblasts and bone marrow stromal cells, and decreasing serum IL-6 concentration, and thus offer its therapeutic effect *via* a decrease in bone resorption.

Angelicin (**12**), also known as isopsoralen, could increase bone strength and trabecular bone microstructure in a sex hormone deficiency-induced osteoporosis model (Ge et al. 2018). This angular furanocoumarin promoted osteoblast differentiation and mineralization, increased calcium nodule levels and alkaline phosphatase (ALP) activity, and upregulated osteoblast markers, including ALP, runt-related transcription factor 2 (RUNX2), and collagen type I alpha 1 chain (COL1A1). It was suggested that **12** could act as an AhR antagonist and promote osteoblast differentiation via the AhR/ER alpha axis. In a similar study involving rats, **12** was shown to inhibit oxidative stress in osteoporosis (Wang et al. 2018a).

Earlier, the same group demonstrated angelicin-mediated suppression of bone marrow adiposity and attenuation of the adipogenic commitment of bone marrow-derived mesenchymal stem cells (Wang et al. 2017b). Yuan et al. (2016) studied the preventative effect of psoralen (**13**) and its isomer (angelicin, **12**) in a mice model and exhibited that these coumarins could ameliorate sex hormone deficiency-induced osteoporosis in female and male mice. After administration of these compounds for 8 weeks, osteoporosis was ameliorated with increasing bone strength and

improving trabecular bone microstructure, suggesting that coumarins **12** and **13** could be good natural compounds for the treatment of osteoporosis in males and females. In a similar study, Zhao et al. (2017) showed that esculin (**18**) could modulate bone metabolism by suppressing receptor activator of NF-κB ligand-induced osteoclastogenesis and transduction signals. They demonstrated that this coumarin could protect against bone mass loss in the ovariectomized and dexamethasone-treated rat osteoporosis model. Psoralen (**13**) has recently been shown to be effective in the treatment of steroid-induced avascular necrosis of femoral head in a rabbit model (Li et al. 2019). Wang et al. (2019c) have demonstrated that **13** could protect and activate chondrocytes, antagonizing the expression of matrix metalloproteinases and interleukins secreted by synovial cells, and effectively attenuates monosodium iodoacetate-induced osteoarthritis. The effect of combination therapy with bone morphogenetic protein (BMP)-2 and **13** on fracture repair in ovariectomized mice was evaluated by Huang et al. (2018), where it was observed that the systematically administered combination therapy could improve bone healing compared with BMP-2 alone. Efficacy of **13** and its derivatives in the treatment of osteoporosis and their possible mechanisms have been demonstrated in various animal models quite extensively (An et al. 2016; Li et al. 2017e).

The effect of scopoletin (**9**)-standardized *Morinda elliptica* leaf extract against osteoarthritis was investigated in *ex vivo* explant culture and preclinical rodent model (Osman et al. 2017). The scopoletin-rich extract dose-dependently reduced serum inflammation biomarkers, increased bone formation biomarkers to near-normal levels in the osteoarthritis-induced rats, and alleviated osteoarthritis progression and articular cartilage structure, by ameliorating cartilage degradation, nitric oxide levels, inflammation, bone/cartilage homeostasis, collagenase/aggrecanase activities, chondrocytes survival, subchondral bone structure, and integrity.

Osthol (**10**) is well known for its osteogenic and anti-osteoporotic properties, as demonstrated in various animal models. Osthol (**10**) could inhibit osteoclastogenesis and thus prevent ovariectomy-induced bone loss in mice at a dose of 10 mg/kg/d for 7 days (Zhao et al. 2018b); the inhibitory effects of **10** on receptor activator of NF-κB ligand (RANKL)-activated osteoclastogenesis were responsible for its bone protective effects in ovariectomized mice. Based on this study, it could be suggested that **10** might be a potential new drug for treating postmenopausal osteoporosis. Zheng et al. (2018) also showed that **10** could be effective in the treatment of osteoporosis in rats and eventually a potential anti-osteoporosis medicine for humans. They investigated the effect of **10** on proliferation and differentiation of osteoblast and observed that the effect of **10** on inhibition of proliferation was relevant with activation of endoplasmic reticulum stress, and activation of Wnt/beta-catenin signaling pathway could be one of the mechanisms how this coumarin could promote osteoblast differentiation. Osthol (**10**) was shown to improve collagen-induced arthritis in a rat model through inhibiting inflammation and cellular stress (Xu et al. 2018). Zhang et al. (2017a) demonstrated the osteopromotive action of coumarin **10** on mouse osteoblastic MC3T3-E1 cells and on mouse femoral fracture repair, and the interaction between osthol-induced osteopromotive effect and cyclic adenosine monophosphate (cAMP) elevating effect. Osthol treatment could promote osteogenesis in osteoblasts by enhancing alkaline

phosphatase activity and mineralization. Oral gavage of osthol (**10**) enhanced fracture repair and increased bone strength. It was concluded that osthol-mediated osteogenesis was related to activation of the cAMP/CREB signaling pathway and downstream osterix expression. Coumarin **10** is able to enhance bone formation and improve fracture healing. Wang et al. (2017d) showed that this compound could promote bone fractures through activation of BMP (bone morphogenetic protein) signaling in chondrocytes and suggested that coumarin **10** could be used as an alternative approach in the orthopedic clinic for the treatment of fracture healing.

Ouyang et al. (2017) reported the potential therapeutic efficacy of isoimperatorin (**38**). In their study using a mouse model for osteoarthritis, it was observed that this compound could ameliorate osteoarthritis by downregulating the mammalian target of rapamycin C1 signaling. Isoimperatorin (**38**) ameliorated osteoarthritis-induced pathological changes by delaying chondrocyte deterioration, activating autophagy, and inhibiting mTORC1.

35.4.20 Periodontitis and Orthodontic Tooth Movement

Periodontitis is inflammation of the gums and supporting structures of the teeth. Periodontitis is caused by certain bacteria (known as periodontal bacteria) and by the local inflammation triggered by those bacteria. Li et al. (2018b) demonstrated the effectiveness of angelicin (**12**) and psoralen (**13**) in the treatment of periodontitis in a mouse model. Orthodontic tooth movement occurs as a result of a force being placed on a tooth and is dependent on efficient remodeling of the bone. Orthodontic treatment is often based on the premise that when force is delivered to a tooth and thereby transmitted to the adjacent investing tissues, certain mechanical, chemical, and cellular events take place within these tissues, resulting in structural alterations and contributing to the movement of that tooth. Wu et al. (2018b) investigated the effects of **13** on relapse after orthodontic tooth movement and its possible molecular mechanism, using a rat model. They found that compound **13** could act as a bone-modifying agent to prevent relapse after orthodontic tooth movement through activating GPR30 and upregulating BMP2 (bone morphogenic protein 2) and BMP4 (bone morphogenic protein 4) expressions.

35.5 Benefits (Human Studies)

The benefits of dietary coumarins for humans have been explored quite considerably. Various reported physiological, bacteriostatic, and antitumor activities of coumarins, mostly based on *in vitro* findings, have put these compounds in the forefront of further backbone derivatization and screening as novel therapeutic agents. For example, it was shown that coumarin (**1**) and umbelliferone (**2**) had antitumor activity against several human tumor cell lines, and coumarins could have potential as inhibitors of cellular proliferation in various carcinoma cell lines (Lacy and O'Kennedy 2004). It was demonstrated that 4-hydroxycoumarin (**21**) and

umbelliferone (**2**) inhibited cell proliferation in a gastric carcinoma cell line (Budzisz et al. 2003). However, subsequently several reports on *in vivo* studies of various coumarins in animal models opened up the opportunities for coumarins to be used in clinical medicine. It had been evaluated for the treatment of various clinical conditions, resulting in the use of a variety of dosing regimens. Recommended doses range from 8 mg for the treatment of venous constriction to 7000 mg/day in anticancer therapies. Auraptene (**11**), isolated from the peels of *Citrus kawachiensis* (Kawachi Bankan) fruits, was shown to contribute to the preservation of cognitive function in a randomized, placebo-controlled, double-blind study in healthy volunteers (Igase et al. 2018). It was observed that coumarin **11** did not improve cognitive function after 24 weeks compared with baseline data, but there was a significant difference in the percentage change in cognitive function between the test and placebo orange juice groups.

Psoralen plus UVA (PUVA) is an effective therapy for mycosis fungoides, which is the skin-limited variant of cutaneous T cell lymphoma (Vieyra-Garcia et al. 2019). In low-burden patients, this therapy reduced or eradicated malignant T cells and induced clonal expansion of CD8+ T cells associated with malignant T cell depletion. Whereas the high-burden patients clinically improved, large numbers of malignant T cells persisted in the skin. Boix-Vilanova et al. (2018) presented a rather rare case of a folliculotropic mycosis fungoides in a 13-year-old boy, which initially presented as a plaque on his face and was treated with local psoralen plus UVA therapy. When the lesions did spread, the treatment was changed to systemic PUVA with good response.

Brass et al. (2018) carried out an observer-blinded randomized controlled pilot study using validated scoring criteria to compare immersion PUVA with narrowband-UVB for the treatment of chronic hand eczema unresponsive to topical steroids and found that both PUVA and narrowband-UVB could reduce the severity of chronic palmar hand eczema. "Turban PUVAsol," which is a modification of topical PUVA used as localized immunotherapy using psoralen (**13**) solution followed by sun exposure, especially for the treatment of alopecia areata, an autoimmune characterized by nonscarring loss of scalp and/or body hairs (Majumdar et al. 2018). This modified psoralen-based therapy was found to be cost-effective and a safer treatment option for alopecia. Mateeva et al. (2018) demonstrated the efficacy of systemic PUVA treatment in Bulgarian patients with mycosis fungoides, especially at the early stage of this disease. It was observed that PUVA therapy alone or in combination with interferon alpha-2a or chemotherapy led to clinical improvement and reduction of the burden of disease in mycosis fungoides in all clinical stages. Earlier, the efficiency of PUVA bath therapy in psoriatic patients was demonstrated by Volnukhin et al. (2006). PUVA bath therapy, which incorporates bergapten (**27**), isopimpinellin (**31**), and xanthotoxin (**32**), was found to be highly effective in psoriatic patients and could be used as an alternative to other forms of PUVA therapies (Volnukhin et al. 2006). In fact, bergapten (**27**) is under investigation in clinical trial NCY00533195 (comparison of UVA1 phototherapy versus photochemotherapy for patients with severe generalized atopic dermatitis). Table 4 summarizes the clinical uses and human benefits of some dietary coumarins.

Table 4 Clinical uses and human benefits of various dietary coumarins

Clinical conditions	Recommended coumarins	References
High protein edema	Coumarin (**1**)	Lacy and O'Kennedy (2004)
Chronic infections	Coumarin (**1**)	Lacy and O'Kennedy (2004)
Malaria	Coumarin derivative from *Toddalia asiatica*	Oketch-Rabah et al. (2000)
Cancer (malignant melanoma, renal cell carcinoma, prostate cancer, leukemia, cervical carcinoma)	Angelicin (**12**), coumarin (**1**), esculetin (**8**), 4-hydroxycoumarin (**21**), psoralen (**13**), and umbelliferone (**2**)	Lacy and O'Kennedy (2004)
Skin disorders (mycosis fungoides, psoriasis, and vitiligo)	Psoralen (**13**)	Lacy and O'Kennedy (2004)
Cognitive decline	Auraptene (**11**)	Igase et al. (2018)
Mycosis fungoides	Psoralen	Mateeva et al. (2018), Vieyra-Garcia et al. (2019)
Psoriasis	Bergapten (**27**), isopimpinellin (**31**), and xanthotoxin (**32**)	Volnukhin et al. (2006)

35.6 Safety: Toxicity and Side Effects

Coumarin (**1**) itself is moderately toxic to the liver and kidneys ($LD_{50} = 275$ mg/kg) in humans but is highly hepatotoxic in rats, but less so in mice. Rodents metabolize it mostly to 3,4-coumarin epoxide, which on further differential metabolism may cause liver cancer in rats and lung tumours in mice. Humans metabolize coumarin mainly to umbelliferone (**2**), which is much less toxic than coumarin (**1**). According to the German Federal Institute for Risk Assessment the tolerable daily intake (TDI) of coumarin (**1**) is 0.1 mg/kg body weight. However, it was suggested that a higher intake for a short period might not be dangerous. However, it has been shown that even a small quantity of coumarin may cause reversible liver damage in humans. Therefore, isolated coumarins must not be added to foods. To flavor foods, coumarin-containing plant parts may be used. For cinnamon-containing foods, new maximum permissible coumarin levels have been in place in the European Union since 2011. There are no limit values for cinnamon (*Cassia cinnamon*) as a spice. Cinnamon-based food supplements may contain high quantities of *Cassia cinnamon*, and the consumers should always limit their consumption to moderate levels. In the case of frequent use of large amounts of cinnamon as a spice in cooking, one should use Ceylon cinnamon that has low levels of coumarins.

Phototoxicity of several furanocoumarins, e.g., psoralen (**13**), bergapten (**27**), and xanthotoxin (**32**), found in the food plants, mainly from the families Apiaceae and Rutaceae, is well documented (Wagstaff 1991). Photoallergic contact dermatitis to xanthotoxin (**32**), isolated from fig, was demonstrated in a human trial using positive

patch test reactions observed in 12 of 47 patients. However, interestingly, **27** was negative in that trial. Histopathological findings on biopsies from positive photopatch tests to **32** confirmed dermatitis (Bonamonte et al. 2010).

Efficacy, safety, and toxicity of coumarins present in diets, like any other compounds, depend on their type and the amounts consumed. Yordi et al. (2017) utilized the in silico technology to study the genotoxicity of the major dietary coumarins and to identify the structure-activity relationships and genotoxic structural alerts. They carried out a virtual screening using a clastogenic model and different software, e.g., MODESLAB, ChemDraw, and STATISTIC. Simple coumarins and furanocoumarins, e.g., xanthotoxin (**32**), isopimpinellin (**31**), esculin (**18**), scopoletin (**9**), scopolin (**23**), and bergapten (**27**), were classified as active in this screening. In silico genotoxicity was mainly predicted for coumarins found in beer, sherry, dried parsley, fresh parsley, and raw celery stalks.

Furanocoumarins, mainly psoralen derivatives, are the major components of grapefruit juice, and these compounds are mainly responsible for the interactions with conventional drugs (Fuhr 1998). Simultaneous intake with grapefruit juice is known to increase the concentrations of many drugs in humans, e.g., felodipine, nitrendipine, nisoldipine and saquinavir. The effect is thought to be mediated by suppression of the cytochrome P450 enzyme CYP3A4 in the small intestinal wall, which leads to diminished first-pass metabolism with higher bioavailability and increased maximal plasma concentrations of substrates of this enzyme. Therefore, it is advisable that patients should not drink grapefruit juice when taking a drug that is extensively metabolized the cytochrome P450 enzyme CYP3A4.

As a part of the investigation focusing on the inhibitory effects of angelicin (**12**) and psoralen (**13**), Lu et al. (2014) also studied their toxicity and side effects. After administration of high doses of these coumarins, toxic reactions such as writhing, lassitude, and hypoactivity were observed. Kidney histopathology demonstrated tubulointerstitial dilatation and congestion and inflammatory cell aggregation in the renal intercellular space. However, none of these compounds caused any significant toxic side effects to the bone marrow or other organs such as the heart, the lung, the liver, and the spleen. Hepatotoxicity of both **12** and **13** in rat and mice models was reported by Wang et al. (2018b); these compounds could induce the toxic reactions of liver and other organs in rats, while mice were not sensitive to these compounds. It was suggested that these compounds could cause liver injury, possibly through inhibiting bile acid excretion in the liver, leading to the accumulation of toxin in hepatocytes. It was also shown that **13** could induce developmental toxicity in zebrafish embryos/larvae mediated by oxidative stress, apoptosis, and energy metabolism disorder (Xia et al. 2018).

Singh et al. (2018) found no toxicity symptoms in osthol (**10**)-treated mice while studying its analgesic and anti-inflammatory properties. However, in a study conducted by Shokoohinia et al. (2017), it was shown that this coumarin was a moderately toxic substance when administered intraperitoneally (i.p.), and renal function impairment was caused by this compound in a rodent model. In that study, for acute toxicity, single doses

of osthol (100, 500, and 1000 mg/kg) were administered i.p. to mice, and the mice were then monitored for 14 days, whereas for subchronic toxicity, it was administered orally to rats at doses of 5, 25, and 50 mg/kg/day for 45 days.

The safety of oral administration of auraptene (**11**) was evaluated in rats in acute and subacute toxicity by evaluating clinical signs, hematology, biochemical factors, pathological changes, and immunotoxicity (Vakili et al. 2017). Acute administration of **11** in doses of 125–2000 mg/kg body weight had no mortality or clinical signs in a period of 2 days. To assess subacute toxicity, coumarin **11** was administrated for 28 days by oral gavage in doses of 125 and 250 mg/kg. Considerable differences in the hematological and biochemical data of the treated and untreated groups were observed, albeit almost all hematological differences were within normal reference ranges. While subacute administration of **11** exhibited no toxic histopathological effects on organ tissue, the assessment of immunotoxicity revealed no significant differences between treatment and untreated groups.

Kleiner et al. (2002) studied the probable systemic toxicity of imperatorin (**34**) and isopimpinellin (**31**) in a mouse model following oral administration and did not find any significant changes in blood clotting, renal or liver functions, and histopathology of the lungs and the kidneys. Nonetheless, a considerable increase in liver weight accompanied by cytoplasmic vacuolation of hepatocytes.

35.7 Marketed Products

The major marketed coumarin-containing food plant product is cinnamon, which is marketed as ground cinnamon, cinnamon sticks, spice mixes (such as pumpkin pie spice, curry mixes, Chinese five spice), breakfast cereals, baking mixes (muffin and cake mixes), baked goods (cookies, granola/breakfast bars), baby foods (such as infant cereals and purées) and dried tea (Ballin and Sorensen 2014).

There are also several medicinal products where the main active ingredient is dietary coumarin(s), available in the market. For example, psoralen plus UVA (PUVA) is an effective therapy for mycosis fungoides, and a modified formulation, "Turban PUVAsol," is for the treatment of alopecia areata. Similarly, Wenshen Zhuanggu Formula (WSZG), which contains a cocktail of psoralen (**13**), isopsoralen (**12**), bergapten (**27**), xanthotoxin (**32**), osthol (**10**), and imperatorin (**34**), is a traditional Chinese medicine (TCM) prescription used in clinics for adjuvant treatment of breast cancer bone metastases in China (Chen et al. 2018c). A similar therapy, called PUVA bath therapy, which incorporates a mixture of three coumarins, bergapten (**27**), isopimpinellin (**31**), and xanthotoxin (**32**), is available in the market for the treatment of psoriasis (Volnukhin et al. 2006), and Yuanhu Zhitong tablet, where imperatorin (**34**) and isoimperatorin (**38**) are the main active ingredients, is prescribed for various types of pain management. There are several xanthotoxin (32)-containing prescription products/formulations available in the market, and some of those are presented below (Table 5).

Table 5 Examples of some commercially available xanthotoxin (**32**)-containing prescription products (source: DrugBank at https://www.drugbank.ca/drugs/DB00553)

Products	Dosage forms	Quantity (Each unit)	Routes of administration	Providers
Methoxsalen	Liquid-filled capsule	10 mg	Oral	Actavis Pharma Inc.
8-Mop	Gelatin coated capsule	10 mg	Oral	Valeant Pharmaceuticals North America
Oxsoralen	Lotion	10 mg/mL	Topical	Valeant Pharmaceuticals North America
Oxsoralen-Ultra	Liquid filled capsule	10 mg	Oral	Valeant Pharmaceuticals North America
Uvadex	Injectable solution	10 μg/mL	Extracorporeal injection	Therakos
Ultra Mop Lotion 1%	Liquid	1%	Topical	Canderm GP

35.8 Patents

Patent publications (2015–2016) describing coumarins and their derivatives have been reviewed by Detsi et al. (2017), which included synthesis, biological evaluations *in vitro/in vivo*, e.g., antiviral, anticancer, cytotoxic, antioxidant, and anti-inflammatory protocols, and a discussion on several pharmaceutical applications and pharmaceutical compositions of coumarins. However, most of the coumarins covered in that review are synthetic analogues, most often inspired by natural coumarins, e.g., angelicin (**12**), bergapten (**27**), psoralen (**13**), scopoletin (**9**), scoparone (**22**), and umbelliferone (**2**), which are major components of various dietary plants (Detsi et al. 2017). For example, Bianchi et al. (2009) patented (US patent no. US 07572827) the use of angelicin (**12**) and of its structural analogues for the treatment of thalassemia. Similarly, pharmaceutical product (patent number: US 08518460) containing osthol (**10**), and several furanocoumarins, e.g., bergapten (**27**), imperatorin (**34**), isopimpinellin (**31**), xanthotoxin (**32**), and xanthotoxol (**33**), to treat psoriasis was patented in 2013 (Yang 2013). However, the major active ingredient in this product is osthol (**10**) accounting for about 90% by weight of the active ingredients.

35.9 Perspectives

Coumarins have been reported from a variety of edible plants, fruits, and vegetables, and reports related to economically and commercially important dietary plant materials that contain high amounts of various coumarins are also available. While a vast majority of bioactivity data on dietary coumarins are based on *in vitro* studies, and a good number of publications are available reporting *in vivo* studies involving animal models, human trial reports are rather limited. Thus, further well-designed human studies involving coumarins present in dietary plants are needed. In recent years, in

silico pharmacology has progressed significantly with the phenomenal progress in computing and artificial intelligence (AI) (Sarker and Nahar 2018); this can help better understand various mechanisms involved in relation to several pharmacological properties of dietary coumarins discerned from *in vitro* and *in vivo* studies carried out to date and to establish their role in human health benefits.

Abstract

Lignans are a large group of natural products consisting of dimers of phenyl propane units. They are found in diverse forms distributed in a variety of plants. Owing to their biological activities ranging from antioxidant, antitumor, anti-estrogenic, antivirus, anti-inflammatory to antiviral properties, they have been used for a long time both in ethnic and in conventional medicine. In particular, it may prevent hormone-dependent diseases, such as breast cancer, prostate cancer, and benign prostatic hyperplasia. However, many important scientific problems have not been constrained. This chapter has systematically reviewed the bioactive constituent, classification, distribution, bioavailability, metabolism, bioactivities, human health, application, and safety aspects of lignans. And lastly, a prospective of future studies on lignans is elucidated.

Keywords

Lignan · Bioactivity · Bioavailability · Metabolism · Human health

36.1 Introduction

Lignans are a family of secondary metabolites widely distributed in plants and human food sources. The term lignan was coined by Haworth in 1936 to describe a group of phenylpropanoid dimers in which C6-C3 units are linked by the central carbon of their propyl side chains (Stasevich et al. 2009). These compounds show dimeric structures formed by a β, β′-linkage between two phenyl propane units with a different degree of oxidation in the side chain and a different substitution pattern in the aromatic moieties. Similar to the ecological functions of several other secondary metabolites, lignans represent a means of protection against herbivores and microorganisms for the plants that synthesize them. For nomenclature purposes, the C6-C3 unit is treated as propylbenzene and numbered from 1 to 6 in the ring, starting from the propyl group, and with the propyl group numbered from 7 to 9, starting from the benzene ring. With the second C6-C3 unit, the numbers are primed. When the two C6-C3 units are linked by a bond between positions 8 and 8′, the compound is named as a "lignan" (Teponno et al. 2016).

Lignans are bioactive, non-nutrient, non-caloric, phenolic plant compounds that are found in diverse species in the plant kingdom including members of pteridophytes, gymnosperms, and angiosperms (Fuss 2003). In angiosperms, lignans have been isolated from members belonging to Asterales, Scrophulariales, Lamiales, Solanales, Apiales, Sapindales, Aristolochiales, Piperales, Laurales, Malvales, Malpighiales, and Magnoliales orders in the division Magnoliophyta (Stasevich et al. 2009). The enterolignans (sometimes referred to as mammalian lignans) are metabolites of food lignans produced by human intestinal bacteria. They have been identified in human urine and plasma. It is known that lignans have remarkable ecological functions in plants, providing protection against herbivores and

microorganisms. The consumption of foods rich in lignans has potential to decrease the risk of cancers. During its long research history, this family has exhibited attractive pharmacological activities, such as antibacterial, antiviral, antitumor, antiplatelet, phosphodiesterase inhibition, 5-lipoxygenase inhibition, HIV reverse transcription inhibition, cytotoxic, antioxidant, immunosuppressive, and antiasthmatic properties (Fang and Hu 2018).

The following is an overview on the current status of research on lignans in terms of bioactive constituents, bioavailability, metabolism, bioactivities, application, toxicity, and side effects.

36.2 Bioactive Constituents of Lignans

Lignans are one of the largest groups of naturally occurring phenols in the plants. The lignans are derived from the shikimic acid biosynthetic pathway. Traditionally, lignans are divided into two classes: classical lignans and neolignans. It should be noted that the term lignan in the literature refers to classical lignans in most cases. Regarding the classification of classical lignans, four different types are reported. The first one arranged classical lignans into three subgroups: acyclic lignan derivatives, arylnaphthalene derivatives, and dibenzocyclooctadiene derivatives (Chang et al. 2005). The second type includes six subgroups: dibenzylbutanes, dibenzylbutyrolactones, arylnaphthalenes, dibenzocyclooctadienes, substituted tetrahydrofurans, and 2,6-diarylfurofurans (Pan et al. 2009). The third one includes seven subgroups of lignan scaffolds: cyclobutanes, tetrahydrofurans, furofurans, dibenzylbutanes, aryltetralins, cycloheptenes, and dibenzocyclooctadienes (Albertson and Lumb 2015). The fourth one is comprised of eight subgroups: furofuran, furan, dibenzylbutane, dibenzylbutyrolactone, aryltetralin, arylnaphthalene, dibenzocyclooctadiene, and dibenzylbutyrolactol (Fig. 1) (Satake et al. 2015).

In a recent review, Teponno et al. (2016) clearly described the plant source, isolation, structure, bioactivities, and synthesis of bioactive lignans. At present, 131 dibenzocyclooctadiene-type lignans have been isolated, especially from different species of *Schisandra* and *Kadsura,* such as marlignans A–L and M–S from *S. wilsoniana*; tiegusanins A–M from *S. propinqua*; neglignans A, B, and E–G, neglectalignans A–D, and neglschisandrins B, E, and F from *S. neglecta*; arisanschinins F–L from *S. arisanensis*; schilancifolignans A–C from *S. lancifolia*; kadsuphilols I–M from *Kadsura philippinensis*; and 14-*O*-demethyl polysperlignan D from *K. coccinea* (Teponno et al. 2016).

There are 16 types of lignans isolated from sesame. Most of them are fat-soluble aglycones and therefore elute into the oil on extraction. The remaining are glycosylated and have been isolated from the oil-free meal. The major aglycone lignans are sesamin and sesamolin (Dar and Arumugam 2013). Sesamol, sesaminol, sesamolinol, pinoresinol, matairesinol (MAT), lariciresinol, and episesamin form minor aglycones of sesame oil (Liu et al. 2006). The lignan glycosides include mono-, di-, and triglucosides of sesaminol, sesamolinol, and pinoresinol (Moazzami

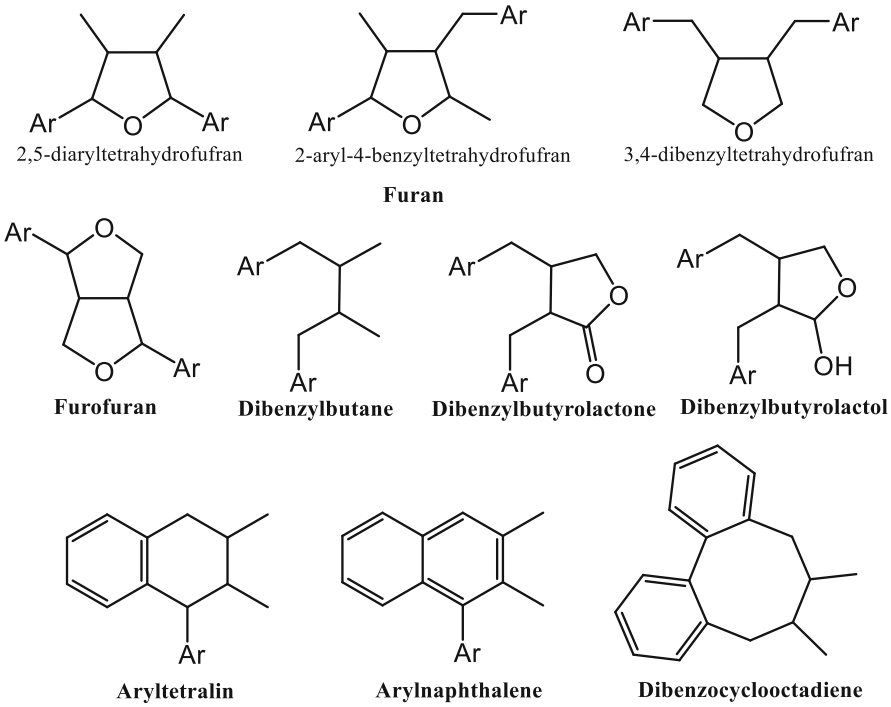

Fig. 1 Subtypes of classical lignans (Ar = aryl)

et al. 2006). Sesaminol triglucoside, sesaminol diglucoside, and sesaminol monoglucoside are the most abundant lignan glycosides in sesame. *Sesamum alatum*, a species with winged seeds, is said to be devoid of both sesamin and sesamolin but has a novel furofuran lignan, 2-episesalatin (Kamaleldin and Yousif 1992). Three additional lignans, namely, saminol, episesaminone-9-*O*-β-D-sophoroside, and semamolactol, have been detected in the perisperm of *Sesamum indicum* (Grougnet et al. 2012). Episesaminone, a furanoketone, was characterized in part via hemisynthesis from sesamolin. Recently these authors have isolated two new lignans, namely, sesamolinol-4′-*O*-β-D-glucoside and disaminyl ether (samin dimer), from sesame seeds (Grougnet et al. 2012).

36.3 Bioavailability and Metabolism of Lignan

36.3.1 Lignan Bioavailability

A prerequisite for investigating lignan bioavailability is to accurately determine their occurrence in foods and to estimate their intake in human populations. Although flaxseed is the main source of lignans (approximately 4 mg/g dried mass), a variety of cereals, fruits, vegetables, legumes, and beverages also contain

lignans in substantial concentrations (10 ng to 400 μg/g) (Milder et al. 2005). Thus, lignans are found in a wide range of foods consumed daily in Western countries. Secoisolariciresinol diglucoside (SDG), its aglycone secoisolariciresinol (SECO), and MAT are the most frequently studied dietary lignans.

A recent study reported that the absolute oral bioavailability of schisandrin B in male and female rats was about 55.0% and 19.3%, respectively. Further, micronization technology effectively improved the bioavailability of schisandrin B (two-fold) when compared with the untreated preparation (Wang et al. 2017). Sa et al. (2015) reported that the absolute bioavailability of schisantherin A in nanoemulsion formulation was significantly enhanced from 4.3% to 47.3%. Among the various *Schisandra* lignans, schisandrol A, schisandrin B, and schisandrin C appeared to be poorly absorbed in intestinal cells. Previous studies reported that schisandrin A appears to be one of the most relatively absorbed lignans (Wang et al. 2011). In a self-emulsifying drug delivery system using oleic acid, Polysorbate 20, and Transcutol P, the bioavailability of schisandrin and schisandrin B was 292.2% and 205.8%, respectively (Shao et al. 2010).

36.3.2 Lignan Metabolism

Absorption of plant lignans and bioconversion of plant lignans to enterolignans and their subsequent absorption vary greatly from person to person. Lignans are present in plants both as aglycones (without sugars) and as glycosides (with sugars) (Julia et al. 2010). At present, only in flaxseed has SECO been found as a lignan oligomer. Lignan glycosides are absorbed in the gastrointestinal tract after metabolism by intestinal bacteria to lignan aglycones and the enterolignans (enterolactone (EL) and enterodiol (ED)), which are formed from them. The extent of hydrolysis to release the lignans from the sugars (and in flax from the oligomer), the formation of enterolignans, and the bioavailability of these compounds vary quite significantly from person to person. Due to these differences in metabolism in the gastrointestinal tract, lignan intake is an imperfect measure of tissue exposure (Clavel et al. 2006).

36.3.2.1 Lignan Metabolism in the Gut

Lignans originate from cinnamic acid derivatives which are related biochemically to the metabolism of phenylalanine. Chorismic acid is transformed into prephenic acid via a Claisen rearrangement, which transfers the phosphoenolpyruvate-derived side chain so that it becomes directly bonded to the carbocycle, and thus builds up the basic carbon skeleton of phenylalanine. Decarboxylative aromatization of prephenic acid yields phenylpyruvic acid, and pyridoxal phosphate-dependent transamination leads to L-phenylalanine (Dar and Arumugam 2013). The biosynthesis of coniferyl alcohols is initiated with deamination of phenylalanine by phenylalanine ammonia lyase to form cinnamic acid, which is then hydroxylated by a P450 enzyme, cinnamate-4-hydroxylase, to form *p*-coumaric acid. Coniferyl alcohol is derived from the reduction of coumaric acid via coenzyme A ester to an aldehyde, which is further reduced in the presence of a NADPH molecule. Formation of the

coenzyme A ester facilitates the first reduction step by introducing a better leaving group ($CoAS^{-}$) for the NADPH-dependent reaction (Vogt 2010).

Lignan glycosides, such as the flax SDG ester-linked complex and the sesame seed sesamolin triglucoside, are hydrolyzed by some of the anaerobic microbes in the gut to lignan aglycones (Jan et al. 2009; Kim et al. 2006). The free lignans are then converted into enterolignans through a series of metabolic reactions by various gut bacteria (Clavel et al. 2006). The efficiency of conversion depends on many factors and differs considerably from one individual to another. The metabolism of the lignans in the tissues is influenced by genetic factors, but as yet these are not well understood (Dagmar et al. 2010; Low et al. 2007).

The predominant plant lignan compound in foods, SDG, is metabolized in the gut to SECO, then to the enterolignan ED, and finally to EL, but the conversion is never 100%. The plant lignan MAT is metabolized directly in the gut to the enterolignan EL. In an in vitro fecal microflora metabolism system, lariciresinol was completely converted in 24 h into the enterolignans EL (46%) and ED (54%), whereas other plant lignans were incompletely converted, i.e., MAT (62%), SDG (72%), and pinoresinol diglucoside (55%). All four were metabolized to EL, in part, but SECO and pinoresinol diglucosides were converted to ED (50% of the SECO and 32% of the pinoresinol total doses) and then in small amounts to EL (21% of the SECO and 19% of the pinoresinol total doses) (Heinonen et al. 2001). Other lignans that are metabolized to EL include arctigenin, 7-hydroxymatairesinol, sesamin, and syringaresinol (Heinonen et al. 2001; Peñalvo et al. 2005). Smeds et al. (2006) found cyclolariciresinol, lariciresinol, and MAT but not SECO in serum samples from a Finnish population. Peñalvo et al. (2004) determined the presence of cyclolariciresinol, lariciresinol, MAT, pinoresinol, as well as anhydrosecoisolariciresinol, 7′-hydroxymatairesinol, SECO, and sesamin in plasma of Finns after the ingestion of sesame seeds (50 g).

The enterolignans ED and EL have been detected in the blood and urine of both humans and animals, but only small amounts of the plant lignans cyclolariciresinol, lariciresinol, MAT, pinoresinol, SECO, and syringaresinol have been found in human urine (Tarja et al. 2003). In contrast, lignins are thought to be largely inert and not absorbed in the human gut due to their polymeric nature. It is possible that they are dietary precursors of enterolignans, but the ability of gut bacteria to transform and metabolize lignins into enterolignans has yet to be demonstrated in human studies (Begum et al. 2004). This possibility is worth pursuing since conversion of food lignins to lignans might explain the relatively high concentrations of enterolignans in biofluids compared to lignan intakes (Horner et al. 2002).

EL is the main circulating enterolignan; therefore, serum EL levels and urinary EL excretion are used as biomarkers for plant lignan intakes. However, these are imperfect surrogates. Differences between lignan intakes and EL production may arise because of variations in the composition of the gut microflora, conversion of some lignans into other compounds, intestinal transit time, the metabolic half-life of EL, the redox state of the colon, the types of lignans present in the diet, and the use of antibiotics (Kilkkinen et al. 2001; Clavel et al. 2006).

36.3.2.2 Systemic Metabolism

Once they are formed from the parent plant lignans by gut microbiota, the enterolignans ED and EL are absorbed through the colonic barrier (Jansen et al. 2005), and most are conjugated to glucuronides in the tissues. They are usually detectable in the blood 8–10 h after dietary intake (Clavel et al. 2006). In a recent study, some plant lignans (anhydrosecoisolariciresinol, 7′-hydroxymatairesinol, cyclolariciresinol, lariciresinol, MAT, pinoresinol, SECO, and sesamin) were rapidly absorbed in the small intestine and appeared in the systemic circulation within an hour after the ingestion of sesame seeds (Peñalvo et al. 2005). The mechanisms responsible for the uptake of plant lignans in the small intestine are still unknown (Lampe et al. 2006). The pharmacokinetic characterization of lignans is an under-researched area that must be pursued if further insights are to be gained about the actual lignan compounds providing putative health benefits.

The enterolignans either enter enterohepatic circulation or are excreted in the urine, usually as glucuronides and sulfate esters (Knust et al. 2006). Some free lignans and aliphatic or aromatic hydroxylated metabolites from hepatic metabolism may also be excreted (Knust et al. 2006; Lampe et al. 2006). One study found that the total amount of EL and ED detected in the urine was up to 40% of the ingested dose (0.9 mg/kg body wt, average 60–66 mg) of SDG and the majority of it was excreted within 2 days (Kuijsten et al. 2005).

The enterohepatic recirculation of SECO, sesame lignans, and enterolignans is significant. In general, lignans permeating the gastrointestinal mucosa are likely to undergo extensive first-pass metabolism by phase II enzymes, resulting in glucuronidation or sulfation, either in the mucosa or in the liver prior to their appearance in the systemic circulation. Glucuronides and sulfates of SECO, EL, and ED may undergo enterohepatic recirculation or simply be eliminated in the bile or urine (Jan et al. 2010; Liu et al. 2006).

Lignan intakes, as evaluated with available food composition data and dietary records or even with biomarkers, are such imperfect estimates of exposure that they may obscure diet-disease relationships. In the lignan food frequency questionnaire validation study, conducted by Horn-Ross et al. (2006) using only MAT and SECO, the correlations with urinary total ED and EL were only 0.16. In the food frequency questionnaire validation study of Bhakta et al., the correlation of MAT and SECO "true intake" with plasma EL was only 0.11. Since several other lignans are present in the diet and can be converted to EL or ED at varying rates, and some lignans are absorbed without conversion, such low correlations are not surprising. However, these problems do point to the need to improve dietary assessment methodology for these compounds.

36.4 Lignan Bioactivities

Lignans individually as well as in combination have been found to exhibit varied biological activities. What mechanisms underlie the activity of either the naturally occurring lignans or their derived metabolites? The antioxidant activity and the

estrogenic and antiestrogenic functions of lignans, as well as the influence of lignans on hormone metabolism and availability and on gene expression and/or enzyme activity, could all explain the effects of lignans. Some examples are provided in this section. Mainly ED and EL are responsible for these functions; thus the transformation of plant lignans by intestinal microbiota might be essential for these functions to be manifested (Landete 2012).

36.4.1 Antioxidant Activity

Some authors described the structure-activity relationships of lignans from *S. chinensis* in connection with antioxidant activity. Lee et al. (1999) studied the structure-activity relationships of lignans and their derivatives from *S. chinensis* as platelet-activating factor antagonists. In their study, 6,7- dehydroschisandrol A, a dibenzocyclooctadiene lignan, showed the strongest activity. The higher activity of lignans was observed in the absence of an ester group at C-6, a hydroxyl group at C-7, or a methylenedioxy moiety and the presence of an R-biphenyl configuration. Yim and Ko (1999) examined the protective effects of schisandrin A, schisandrin B, and schisandrin C against myocardial ischemia-reperfusion injury. The authors found that methylenedioxy group and the cyclooctadiene ring of the schisandrin molecule play as important structural determinants in the protection against myocardial ischemia-reperfusion injury. Choi et al. (2006) investigated the structure-activity relationships of the dibenzocyclooctadiene lignans in relation to their antioxidant activity. The study showed that the exocyclic methylene functionality was important for antioxidant activity of lignans. In addition, the presence of benzoyloxy group possibly improves such effects.

In some cases, antioxidant activity appears to be responsible for the bioactivity of plant and mammalian lignans. For example, beneficial effects of SDG in cancer and lupus nephritis revealed that these beneficial effects could be due to the ability of SDG to scavenge hydroxyl radicals (Prasad 1997), showing SDG to exert powerful antioxidant activity.

The antioxidant activity of flaxseed lignans and derived metabolites is because they exert protective effects against AAPH (2, 2′, azobis (2-amidinopropane) dihydrochloride), a compound used extensively as a free radical generator (Hosseinian et al. 2007; Hu et al. 2007). The flaxseed lignan SDG and mammalian lignans ED and EL act as antioxidants against DNA damage and lipid peroxidation. Plant lignan antioxidant activity has been attributed to the 3-methoxy-4-hydroxyl substituents of SDG and SECO, versus the meta mono-phenol structures of ED and EL. Benzylic hydrogen abstraction and potential resonance stabilization of phenoxyl radicals in an aqueous environment are likely to contribute to the antioxidant activity of the mammalian lignans. These probably represent extra- and intracellular antioxidant activities of flax-derived lignans at concentrations that are potentially achievable in vivo (Hu et al. 2007).

36.4.2 Estrogenic and Antiestrogenic Functions

Lignans and their derived metabolites ED and EL act either as estrogen agonists or antagonists. The chemical structures of these bi-phenolic compounds closely resemble that of endogenous 17β-estradiol, and they exert biphasic agonistic (estrogenic) and antagonistic (antiestrogenic) activities in vitro (Sathyamoorthy et al. 1994) and in vivo (Pauliina et al. 2011; Tou et al. 1999).

Research shows that physiologically relevant EL concentrations lead to in vitro and in vivo activation of estrogen receptor (ER)-mediated events and this has generated interest because of their potential use in hormone replacement therapy and cancer prevention (Hébert-Croteau 1998).

Because of their structural similarity to 17β-estradiol, enterolignans are natural ligands of ERs and are believed to be naturally existing selective estrogen receptor modulators. They might therefore act as anticarcinogens, either through antiestrogenic actions (e.g., by competing with estradiol to bind ERs) or by initiating their own anticarcinogenic effects (e.g., by recruiting specific transcriptional coregulators to phytoestrogen-activated ERs).

The mechanism of action of enterolignans on ER has been studied, and there is evidence from human observational studies that phytoestrogens may modulate hormone levels and ER expression (Touillaud et al. 2005). It is assumed that the biological action of phytoestrogen is mediated by ERα and ERβ. The ER is a ligand-dependent transcription factor belonging to the nuclear receptor superfamily. The ER binds estrogen response elements, a 13-bp inverted repeat, through its conserved DNA-binding domain. The ER contains two transcriptional activation domains: the autonomous transcriptional activation domain, AF-1, located at the N-terminus, and the ligand-dependent activation domain, AF-2, located at the C-terminus (Green and Chambon 1988); the primary sequence of AF-2 differs significantly between ERα and ERβ. This causes different agonist/antagonist characteristics for various chemicals containing phytoestrogens, depending on their affinity for the receptors (Barkhem et al. 1998). Carreau et al. (2008) examined and compared the ability of ED, EL, and 17β-estradiol to induce the transactivation of ERα and ERβ, to modulate ERα target genes. This study indicates that enterolignans have distinct properties for the transactivation of ERα and ERβ. ED, like 17β-estradiol, induces ERα transcriptional activation through transactivation functions AF-1 and AF-2, while EL is less efficient in inducing AF-1, acting mainly through AF-2. Furthermore, ED and EL modulate ERα mRNA and protein contents as well as MCF-7 cell proliferation.

EL, at physiological concentrations, activates ER-mediated transcription in vitro with preference for ERα. The effects of EL are mediated by the ER ligand-binding domain and are susceptible to antiestrogen treatment. Penttinen et al. (2007) demonstrated that EL exerts estrogenic activity in vivo. In transgenic estrogen-sensitive reporter mice, EL induces tissue-specific estrogen-responsive reporter gene expression as well as promotes uterine stromal edema and expression of estrogen-responsive endogenous genes (Cyclin D1 and Ki67). Taken together, these data show that

EL is a selective ER agonist inducing ER-mediated transcription both in vitro in different cell lines and in vivo in the mouse uterus.

Therefore, the transformation of plant lignans by intestinal microbiota might be essential for the estrogenic and antiestrogenic activity to manifest. Lignans and their derived metabolites have also been associated with a reduction in the risk of breast cancer through estrogenic and antiestrogenic effects. As above mentioned, the estrogen agonistic effect of ED and EL may be useful for conventional hormone replacement therapy in postmenopausal women. However, Pianjing et al. (2011) suggested that due to a potential tumor growth stimulation of lignans and their ability to induce certain estrogen-related genes, oral supplementation of enterolignans should be prescribed with caution, particularly in postmenopausal women and hormone-dependent breast cancer patients.

36.5 Health Benefits

Lignans are polyphenolic compounds with a wide spectrum of biological functions including antioxidant, anti-inflammatory, and anticarcinogenic activities; therefore, there is an increasing interest in promoting the inclusion of lignan-rich foods in humans' diets. The lignans consumed by human are in fact digested by the microflora present in the intestine. The weak and antiestrogenic effects of lignans are caused by distinct transactivation activities of estrogen receptors between the enterolignans ED and EL (Brito and Zang 2018). Previous researches indicate that certain conditions including breast, colon, and prostate cancer can be reduced by dietary lignan intake and/or increased levels of EL and/or ED. Clearly, more research is needed to determine causality and to evaluate the potential role of lignans and their metabolites in metabolic profiles.

36.5.1 Colon Cancer

ERs, especially the β-type receptors, are abundant in colon cells (Konstantinopoulos et al. 2003), where they play a role in normal colon functioning (Wada-Hiraike et al. 2006); however, cancer progression is associated with a loss of ER β (Castiglione et al. 2008; Jassam et al. 2005). This, together with data from epidemiological studies showing that hormone replacement therapy protects against colon cancer (Nelson et al. 1997), would indicate that EL has the potential to protect against colon cancer. EL may exert these potential effects both during absorption from the colon lumen and when passing the intestinal cells during systemic circulation.

Treatment of human colon cancer SW480 cells with EL and ED, either alone or in combination, resulted in dose- and time-dependent decreases in cell numbers (Qu et al. 2005). Cell growth inhibition by lignan metabolites seems to be mediated by cytostatic and apoptotic mechanisms (Ayella et al. 2010).

In a case-cohort study of Danish middle-aged men and women, which gathered detailed information on diet and lifestyle factors, Kuijsten et al. (2006) investigated

the association between plasma enterolignans and the incidence of colon and rectal cancer. The authors observed a substantial reduction in colorectal adenoma risk among subjects with high plasma concentrations of enterolignans, in particular, ED. Recently, Johnsen et al. (2010) examined the association between plasma EL concentration and incidence of colon and rectal cancer in 57,053 participants aged 50–64. They concluded that higher EL levels are associated with lower risk of colon cancer among women and higher risk of rectal cancer among men.

36.5.2 Breast Cancer

Some studies show that the administration of plant lignans, which are further metabolized to EL or EL as such, inhibit or delay the growth of experimental mammary cancer (Saarinen et al. 2010). The mechanisms underlying the anti-carcinogenic action of EL are not yet fully understood, but there is intriguing evidence for EL as a modulator of estrogen signalling. Sesamin is converted to the phytoestrogens and ELs. The phytoestrogens are known to play protective role against breast cancer (Peñalvo et al. 2005). Therefore, lignans and their derived metabolites have been also associated with a reduction in the risk of breast cancer through an estrogenic and antiestrogenic effect.

The results of the large prospective study of French women done by Touillaud et al. (2007) showed that higher dietary intakes of lignans were associated with a reduction in the risk of postmenopausal breast cancers. However, epidemiological studies that examined whether lignans protect against breast cancer have yielded inconsistent results. In this respect, Buck et al. (2010) conducted meta-analyses on the association between lignans and breast cancer risk. The meta-analyses included 21 studies (11 prospective cohort studies and 10 case-control studies), in which high lignan intake was associated with a significant reduction in breast cancer risk in postmenopausal women. Breast cancer risk was also inversely associated with enterolignan exposure but not with blood or urine EL concentrations.

36.5.3 Prostate Cancer

Lignans and their derived metabolites are believed to be partly responsible for growth inhibition of human prostate cancer cell lines (Demark-Wahnefried 2001). Morton et al. (2015) associated higher EL levels in prostatic fluid with a low risk of prostate cancer. In a small clinical study, prostate cancer cell proliferation decreased and apoptosis increased in men fed 30 g of flaxseed per day (Demark-Wahnefried et al. 2001). Other work by these authors further supports the role of flaxseed in combination with a low-fat diet as a means to control prostate growth (Demark-Wahnefried et al. 2004). In the study, prostate-specific antigen levels and cell proliferation both decreased from baseline after only 6 month on the dietary regime.

EL has been shown to inhibit prostate cancer growth and development, but the mechanistic basis for its anticancer activity remains largely unknown. Activation

of insulin-like growth factor-1 receptor signalling is critical for prostate cancer cell growth and progression (Chen et al. 2009).

36.5.4 Intestinal Cancer

Results by Pajari et al. (2006) demonstrate that MAT or SECO do not prevent intestinal carcinogenesis in MIN mice and that MAT may have adverse effects on intestinal carcinogenesis. The number of intestinal adenomas in the MIN mouse model is not related to plasma EL levels nor is it associated with the levels of intestinal lignans (Oikarinen et al. 2005).

36.5.5 Menopausal Symptoms

Phytoestrogens may be of use in ameliorating some menopausal symptoms. Results by Wu et al. (2006) suggest that sesame ingestion benefits postmenopausal women by improving blood lipids, antioxidant status, and possibly sex hormone status. On the other hand, epidemiological and pharmacological studies have shown that ED, and particularly its oxidation product EL, have preventive effects on osteoporosis and menopausal syndrome (Lemay et al. 2002).

36.5.6 Cardiovascular Disease

Flaxseed can protect against atherosclerotic plaque deposition in carotid arteries and shows anti-atherosclerotic effects in the aorta. The aforementioned authors show that dietary flaxseed can improve endothelium-dependent vascular relaxation in the presence of a high-cholesterol diet. Lignan intake may have an important protective effect against human vascular disease. Later, Dupasquier et al. (2007) demonstrated how dietary flaxseed can inhibit the atherogenic effects of a high-cholesterol diet in the LDLrKO mouse. However, the results by Kuijsten et al. (2009) do not support the hypothesis that high plasma ED or EL concentrations are associated with a reduced risk of nonfatal myocardial infarction. On the other hand, sesamin inhibits intestinal absorption of cholesterol and reduces the activity of acylCoA:cholesterol acyltransferase and 3-hydroxy-3-methylglutaryl CoA reductase in rats (Wu et al. 2006). Sesamin, at a rather low dose (65 mg/day or approximately equivalent to consuming 13 g of sesame seeds), lowers plasma cholesterol in subjects with hypercholesterolemia (Hirata et al. 1996).

36.5.7 Hepatoprotective Effects

Platelet-activating factor (PAF) has been linked to aggregation and degranulation of platelets and is an important mediator in inflammation and asthma. Plant lignans have been reported to exert anti-PAF activity (Tibiriçá 2010). Flaxseed

potentially inhibits several mechanisms associated with renal disease in lupus nephritis. Incorporating flaxseed into the diet of either an experimental mouse model of lupus, MRL/PR, or human lupus nephritis subjects demonstrated significant changes in renal and neutrophil function and plasma lipids (Westcott and Muir 2003). Doses above 30 g/day were not well tolerated mainly due to increased laxation. Use of purified SDG in the mouse model (MRL/lpr) showed that lignan was well tolerated and provided reno-protection similar to whole flaxseed (Clark et al. 2001). Ogborn et al. (2002) administered purified SDG and found that cystic change, epithelial proliferation, interstitial fibrosis, macrophage infiltration, and oxidant injury were all reduced (Ogborn et al. 2002). Recently, Moneim et al. (2014) have demonstrated how flaxseed oil may play a protective role against kidney injury.

Hepatoprotective effects have also been associated to lignans in a flaxseed supplemented diet. Hemmings and Barker (2010) found a hepatobeneficial effect of increased levels of γ-glutamyltranspeptidase (γGT) in the livers of both male and female rats. In addition, they reported that a diet with 10% flaxseed lacks long-term effects on growth, development, and behavior, is nontoxic, and may be hepatoprotective. SDG from flaxseed has been shown effective in preventing/delaying the development of type 1 and type 2 diabetes (Prasad 2002).

36.5.8 Neuroprotection

In regard to neuroprotective actions, Qin et al. (2014) reported that schisantherin A, schisandrin C, and schisandrol B were found to possess remarkable neuroprotective effects against serum and glucose deprivation injury in SH-SY5Y cells than schisandrin A, schisandrin B, and schisanhenol. The authors suggested that the number and position of a hydroxyl group and a methylenedioxy may be responsible for the neuroprotective effects of these lignans. Out of five dibenzocyclooctadiene lignans (deoxyschisandrin, gomisin N, gomisin A, schisandrin, and wuweizisu C) isolated from the methanolic extract of *S. chinensis*, deoxyschisandrin, gomisin N, and wuweizisu C markedly protected the glutamate-induced neurotoxicity in rat cortical cells (Kim et al. 2004). Song et al. (2015) studied the protective effects of schisandrin, schisantherin A, schisandrin B, and schisandrin C on amyloid-β_{25-35}- and homocysteine-induced neurotoxicity in PC12 cells. Among the four lignans, schisandrin B and schisandrin C effectively protected amyloid-β-induced neurotoxicity in PC12 cells by inhibiting the production of reactive oxygen species (ROS) and modulating the apoptotic signal pathway via Bax and caspase-3. Further, gomisins A, G, J, and N (schisandrin B) are strong inhibitors of toll-like receptor 2/4 (TLR 2/4) agonist-induced hyperneuroinflammatory responses (Young et al. 2014).

36.5.9 Anti-inflammatory Activity

Sesamin exhibited anti-inflammatory activity by inhibiting delta-5 desaturase, a key enzyme in arachidonic acid biosynthesis that leads to a reduction in the formation of

pro-inflammatory mediators (Chavali et al. 1998). An unusual tetrahydrofuran lignan from the roots of *Zanthoxylum planispinum* has also the potential anti-inflammatory effects (Su et al. 2016).

36.6 Application of Lignans in Food

36.6.1 Food Sources of Lignans

The lignan content of foods is generally low and usually does not exceed 2 mg/100 g. The exceptions are flaxseed (335 mg/100 g) and sesame seeds (373 mg/100 g), which have a lignan content a hundred times higher than other dietary sources (Julia et al. 2010). They are present in many plant families, although the types and amounts vary from one family to another. Lignans are found in whole grains (especially in the bran layer) and seeds (in the seed coat). Barley, buckwheat, flax, millet, oats, rye, sesame seeds, and wheat contain fairly high levels of lignans. Nuts and legumes are also reasonably good sources. Although in lesser amounts than in grains, lignans are present in fruits and vegetables such as asparagus, grapes, kiwi fruit, lemons, oranges, pineapples, wine, and even in coffee and tea (Kuhnle et al. 2009; Smeds et al. 2007).

In contrast to plants, there are virtually no lignans in animal foods. Minute amounts of the enterolignans ED and EL are sometimes found in animal foods (milk products) as a result of their production by bacterial metabolism in the animals' guts, but these are exceptions. Little has been done to investigate the effects of storage and processing on lignans in most foods (Kuhnle et al. 2009; Brenes et al. 2002), although it is known that the lignan content is apparently not changed considerably during the processing of flaxseed and sesame seed (Strandås et al. 2008; Wu 2007). Furofuran-type lignans are widely distributed in edible plants (flaxseed, sesame, seeds, cereal products, and *Brassica* vegetables). Sesame lignans in particular are obtained from *Sesamum indicum*, a highly prized oilseed crop cultivated widely in many countries in the east. The plant is the main source of clinically important antioxidant lignans such as sesamin, sesamolin, sesaminol, and sesamol.

36.6.2 Effect of Cooking on Lignans in Food

Plant foods or oils are used for preparing various foods like bakery products, chips, or blanched and cooked vegetables. During their production, the raw materials are heated to a lesser or greater extent, and the stability of lignans occurring in different conjugation patterns is influenced.

Roasting of sesame seeds at 200 °C for 60 min cleaved and liberated phenolic compounds (Jeong et al. 2010), and sesamolin could be degraded into sesamol (Lee et al. 2010). Infrared roasting of sesame seeds at 200 °C for 30 min also degraded sesamolin to sesamol (Kumar et al. 2010). In sesame oil the content of sesamol increased under heating conditions, while that of sesamolin decreased slightly, and

the sesamin content changed only little. For pinoresinol a high stability to thermal treatments below 180 °C was observed in olive oil (Brenes et al. 2002). However, a short microwave treatment already resulted in a small decrease (Cerretani et al. 2009). Kotsiou et al. (2009) reported that lignans like 1-acetoxypinoresinol remained unchanged during boiling or frying in olive oil. In pumpkin seeds, SECO was degraded by thermal heating with increasing roasting time (Murkovic et al. 2004). Hyvarinen et al. (2006) reported that the complex ester of SDG and SDG itself are stable in various bakery products. In flaxseeds, isolariciresinol, SECO, lariciresinol, and pinoresinol which were mainly present as esterified compounds were stable even if heated to 250 °C for 3.5 min. In contrast, pinoresinol aglycone in olive oil was degraded even at 180 °C (Carrasco-Pancorbo et al. 2010). This finding demonstrates that the type of conjugation and the matrix influence the thermal stability of lignans. To conserve a relatively high content of lignans during production of commercial foods, the raw product, the water content, and the applied temperatures have to be considered and optimized.

Moderate heating at 100 °C did not degrade the lignan aglycones and glycosides in dry foods. In contrast, heating was responsible for the better extractability of the lignans. If samples with high moisture content were heated, the degradation of the lignans in sesame seeds and rye was observed already at 100 °C. Higher roasting temperatures caused degradation of aglycones and glycosides.

36.7 Safety: Toxicity and Side Effects

A single-blind, placebo-controlled, parallel-group, and multiple oral dose study was conducted in 48 healthy subjects to investigate the pharmacokinetics and safety of multiple oral doses of sesame lignans (sesamin and episesamin). The results showed that sesamin was absorbed with a peak plasma concentration at 5.0 h. The plasma concentration of the main metabolite, SC-1, reached a peak at 5.0 h and decreased rapidly with a terminal half-life of 2.4 h. Episesamin was also absorbed with a peak plasma concentration at 5.0 h and decreased with a terminal half-life of 7.1 h. The plasma concentration of the main metabolite, EC-1, reached a peak at 5.0 h and decreased rapidly with a terminal half-life of 3.4 h. The plasma concentrations of sesamin and episesamin reached a steady state by day 7. Sesame lignans were confirmed to be safe and tolerable in healthy subjects (Namino et al. 2013). Niemeyer and Metzler (2002) reported that lignans resembled the isoflavone daidzein and differed from genistein and coumestrol, which exhibited clastogenic and gene mutagenic activity in V79 cells.

36.8 Marketed Products

Flaxseed can be incorporated into various food products to increase the intake of lignans. Traditionally, this has been done by adding flaxseed to bread either as whole seeds or in the form of ground flaxseed meal. However, the characteristic flavor of

flaxseed may limit its other applications in foods. More recently, the development of dehulling techniques has made it possible to separate a lignan-rich hull fraction from flaxseed (Hyvarinen et al. 2006), and several hull preparations are now commercially available. On the other hand, the possible presence of harmful substances such as cyanogenic glycosides and cadmium in flax has to be taken into account if the use of flaxseed in our diet is to be increased. Supplementation of bakery products with SDG isolated or enriched from flaxseed, thus, offers an attractive approach to be investigated.

36.9 Patents

Lignan Flax Seed Cakes offers consumers a delicious and simple way to consume ground flaxseed. This product combines multiple healthy ingredients, such as fruit, oats, and walnuts, with ground flaxseed to produce a well-textured and desirable food item. This comestible food product enables individuals to receive a known (controlled) quantity of flaxseed while simultaneously consuming other beneficial ingredients. The enjoyable taste makes it easy to obtain the health benefits provided by flaxseed within a consumer's diet.

The invention provides an enzyme having the lignan glycosidation activity by identifying an enzyme involved in the production of lignan glycosides, identifying an amino acid sequence of the enzyme polypeptide, and a base sequence encoding the polypeptide. Based on the information of these sequences, transformants capable of producing the lignan glycosides were prepared (Hyvarinen et al. 2006).

36.10 Perspectives

Although many of the studies reviewed suggest possible associations with dietary or biomarker measures of lignan exposure, several limitations are worth noting. More research on the food content of lignans and on food sources in relation to health outcomes in epidemiologic studies is needed. It may be that a certain threshold of intake is required and many Western populations either do not reach those levels or the appropriate foods are not assessed on research questionnaires. If possible, repeated measures of these biomarkers would benefit studies of the association between EL and chronic disease outcomes. Finally, it is of interest that most studies of lignan intake were of women, whereas all but one of the EL studies were of men. Because associations with lignans may vary by gender, more research including both men and women is needed. Future studies should employ both complete dietary intakes of lignans and serum (or plasma) enterolignan markers in high-risk groups.

The application of sesamin in auguring human health is one of the main themes of current research in medical science. Focus is required on validating the biological activities of furofuran lignans other than sesamin. Another point of concern at this juncture is to ensure the availability of sesamin in reasonable quantity for medical application, as sesame is the only major source of these lignans. Therefore, it may

be concluded that there is potential of a tremendous research on qualitative and quantitative improvement of the sesame crop for sesamin production. High-throughput analytical methods based on cell culture techniques would be a way out in advancing our knowledge on biosynthesis of sesamin both for productivity and human health.

Public acceptance of dietary products derived from transgenic organisms is limited. Nevertheless, lignans produced by transgenic hosts are chemically identical to natural ones and free from any recombinant genes or proteins. Thus, their public acceptance is expected to be more easily garnered than that of transgenic foods. Accordingly, more attention should be paid to the establishment of scaling-up and following industrialization of the lignan production systems (Satake et al. 2015). Large-scale lignan production by transgenic plants requires a closed cultivation system to prevent contamination of the environment by transgenic plants. Recently, various closed plant factories have been emerging, which completely shut off a gene flow into the outer environment and enable the transgenic plant-based molecular breeding of genes or compounds of interest under optimal and sterile conditions. Such advances in the metabolic engineering of lignan biosynthesis will surely pave the way for the conversion of conventional agricultural lignan production to innovative industrial lignan production.

Abstract

Gingerols and shogaols belong to the secondary metabolites of the representatives of Zingiberaceae family. These phenolic compounds are responsible for the pungent taste of ginger and also for a wide range of pharmacological properties of the plants. The aim of this chapter is to collate the information on their chemical structure, bioavailability, toxicity, pharmacological properties, and application as food products, nutraceutics, and drugs.

Keywords

Zingiberaceae · Ginger · *Zingiber officinale* · Gingerols · Shogaols · Pharmacological activity · Food products

37.1 Introduction

Gingerols and shogaols belong to plant-derived secondary metabolites, known to be synthesized by the representatives of the Zingiberaceae family (see Table 1), mainly by the genus *Zingiber*.

The composition of ginger varies depending on the collection area, time of collection, and condition of the rhizomes; however, generally it can be concluded that the odor of ginger rhizomes is affected by terpenes abundantly present in its tissues (e.g., β-sesquiphellandrene, α-zingiberene, β-bisabolene, (E,E)-α-farnesene, or ar-curcumene) whereas their pungent taste by the presence of gingerols and their dehydration products, namely, shogaols – all of which belong to the class of polyphenols (Koch et al. 2017; Ali et al. 2008; Semwal et al. 2015; Villaflores et al. 2010).

Metabolites of ginger and their impact on human health are of particular interest to a wide group of researchers around the world. Numerous studies have been performed on ginger extracts and on their isolates, which prove broad and comprehensive properties of this plant used extensively as a spice first in the Asian traditional medicine.

Ginger species originate from Asia, where they have been growing in mild climate zones with high humidity rate, like Indo-Malayan area or Japan. Now they

Table 1 The natural sources of gingerols and shogaols (Koch et al. 2017; Ali et al. 2008; Semwal et al. 2015; Villaflores et al. 2010)

5	Gingerols, shogaols	*Lycianthes marlipoensis*	Solanaceae

Table 2 Ginger-producing countries of the world (Dhanik et al. 2017; FAO Statistical Database http://www-fao.org)

	1999		2013
Years	Area (ha)	Production (tonnes)	Production (tonnes)
India	70,000	235,000	683,000
China	13,450	157,018	425,000
Nigeria	145,000	80,000	160,000
Bangladesh	7,700	39,000	69,000
Jamaica	180	620	–
Nepal	1,200	3,200	235,033
Indonesia	9,900	80,351	232,669
Thailand	–	–	140,000

are widely distributed around the world and are collected in Africa, Australia, and America (Yeh et al. 2014). These days India and China are the top producers of ginger rhizomes (see Table 2).

The application of the most widely cultivated species of ginger – *Zingiber officinale* Roscoe – in foods and medicine exceeds 2000 years. Within this time much research have been done in the field of cultivation, identification of the major constituents of its extracts, and, finally, its pharmacological activity. Ginger was proven to exhibit numerous effects on human health in traditional medicine formulations, including digestive, antimicrobial, bile production-enhancing, anti-emetic, anti-inflammatory, antirheumatic, laxative, anti-colic, rubefacient, and warming-up properties (Yeh et al. 2014; Ali et al. 2008). The aim of this chapter is to review the currently available scientific literature and to present the results of the in vivo studies on gingerols and shogaols properties on both animals and humans, the marketed products, and patents.

37.2 Bioactive Constituents

A number of pharmacological properties of ginger are responsible for its bioactive phytochemical compounds: essential oils, phenolic compounds, proteins, carbohydrates, glycosides, alkaloids, saponins, steroids, and tannins. Ingredients of ginger are numerous and differ in qualitative and quantitative content in the rhizome, depending on the place of origin and whether the raw material was dried or fresh. Terpenes are responsible for the characteristic aroma of ginger rhizomes: monoterpenes (camphene, β-phellandrene, cineole, geraniol, curcumene, citral, terpineol, borneol) and sesquiterpenes (α-zingiberene, β-sesquiphellandrene, β-bisabolene, α-farnesene, ar-curcumene). Also, an important group of secondary metabolites of ginger are polyphenolic compounds: gingerols and compounds similar to gingerols such as shogaol, paradoles, gingerdiony, and gingerdiols (Ali et al. 2008; Koch et al. 2017).

Gingerols predominate in fresh ginger rootstocks; they are homologues of 1-(3-methoxy-4-hydroxyphenyl) 3-oxo-5-hydroxyhexane, and individual compounds differ in the length of unbranched alkyl side chains; the highest number is 6-gingerol ((5S))-5-hydroxy-1-(4-hydroxy-3-methoxyphenyl) decan-3-one), 10-gingerol ((5S)-5-hydroxy-1- (4-hydroxy-3-methoxyphenyl) tetradecan-3-one), and 8-gingerol ((5S)-5-hydroxy-1-(4-hydroxy-3-methoxyphenyl) dodecan-3-one), respectively. Gingerols are thermally unstable due to the presence of the β-hydroxy keto group and are easily dehydrated during drying and storage processes, forming shogaols. Among the latter compounds, which are the dehydration products of the respective gingerols, 6-shogaol ((E)-1-(4-hydroxy-3-methoxyphenyl) dec-4-en-3-one), 8-shogaol ((E)-1-(4-hydroxy-3-methoxyphenyl) dodec-4-en-3-one), 10-shogaol ((E)-1-(4-hydroxy-3-methoxyphenyl) tetradec-4-ene-3-one), and 12-shogaol predominate in the dried rhizome. In turn, the paradols are structurally similar to gingerols; they are unsaturated ketones produced as a result of shogaols' biotransformation. Gingerdions, another constituent of ginger extracts, are the dehydrogenation products of hydroxylated β-ketones of gingerols and include the subgroup of 1-dehydro-gingerdiones and gingerdiols, which are ketone reduction products of gingerols (Ali et al. 2008; Dhanik et al. 2017; Tao et al. 2009). Diarylheptanoids are also present in ginger extracts. They are characterized by a backbone of the structure of 1,7-diphenylheptanes, comprising the compounds of linear or macrocyclic structures (Wei et al. 2005) (see Fig. 1).

37.3 Bioavailability and Metabolism

Despite the widespread use of ginger, there is little information on the bioavailability of its compounds, especially for human use. Existing studies relate to intravenous or oral administration of the entire extract or isolated compounds on rodents and to in vitro tests in conditions similar to those existing in the human gastrointestinal tract. The poor solubility of 6-gingerol causes its weaker absorption after oral administration and rapid metabolism. There are studies suggesting the use of special solutions that deliver ginger compounds in a more efficient way (Ogino et al. 2018; Sato et al. 2017; Wang et al. 2018; Xu et al. 2016).

Based on studies by Jiang et al. 2008 in rats, after oral administration at a dose of 240 mg/kg of ginger extract (containing 53% (w/w) 6-gingerol), rapid absorption of 6-gingerols into the plasma, and its the maximum concentration was 4.23ug/ mL and was reached 10 min after administration. The remaining parameters were 1.77 h elimination half-life, 40.8 L/h of apparent total plasma clearance of 6-gingerol, and 18.4 L of apparent volume of distribution. Studies have shown that 6-gingerol was distributed to tissues in the brain, lungs, heart, kidneys, and liver and the highest concentration was determined in the gastrointestinal tract. Work of Arablou and Aryaeian 2018 suggests that after oral administration to rats, 6-gingerol was converted into glucuronide conjugates and was excreted in the bile and its polar metabolites in a small amount into the urine. In the same work, one study on healthy

Fig. 1 Chemical structures of the various gingerol and shogaol analogues isolated from ginger rhizome

people, receiving various doses of 100 mg to 2 g of ginger, was described. The results of this experiment showed that the main ginger compounds, 6-, 8-, and 10-gingerol and 6-shogaol, were quickly absorbed, but they were present in the serum in the forms of glucuronide and sulfate conjugates – not their free forms.

After intravenous administration of 6-gingerol into rats at a dose of 3 mg/ kg, the compound was rapidly removed from the plasma, and its total half-life was 7.23 min, the total clearance 16.8 mL/min /kg, and the binding to serum proteins 92.4%. The elimination half-life of 6-gingerol in rats with damaged liver was significantly increased, thus indicating that 6-gingerol is mainly excreted by the liver. The major 6-gingerol metabolites have been identified as 6-gingerol diastereomers by means of GC-MS. In other studies using high-performance liquid chromatography (HPLC), the main compound gingerols administration was (S)-[6]-gingerol-40-*O*-*β*-glucuronide, and the metabolites in the urine were vanillic acid, ferulic acid (S)-(+)-

4-hydroxy-6-oxo-8-(4-hydroxy-3-methoxyphenyl)-acetanoic acid, 4-(4-hydroxy-3 methoxyphenyl) butanoic acid, 9-hydroxy-[6]-gingerol, and (S)-(+)-[6]-gingerol (Ali et al. 2008). Research by Nakazawa and Ohsawa (2002) suggests that both intestinal flora and enzymes in the liver play an important role in the metabolism of [6]-gingerol (Arablou and Aryaeian 2018; Semwal et al. 2015; Ali et al. 2008; Jiang et al. 2008; Mukkavilli et al. 2017; Xu et al. 2016; Tao et al. 2009).

6-Shogaol similar to 6-gingerol is rapidly absorbed and eliminated after oral administration in rats, and in blood it is transformed into glucuronide forms, which significantly reduces its bioactivity. Currently, 28 metabolites of 6-shogaol were identified in mouse feces and urine, including the following structures: (1E, 4E)-1-(4′-hydroxy-3′-methoxyphenyl)-deca-1,4-dienes-3-one (6-dehydroshogene), (E)-1-(4′-hydroxy-3′-methoxyphenyl)-dec-1-en-3-one (6-dehydroparadol), 1-(4′-hydroxy)-3′-methoxy-phenyl)-decan-3-one (6-paradol), 1-(4′-hydroxy-3′-methoxy)-decan-3-ol, and 1-(4′-hydroxy-3′-methoxyphenyl)-deca-4-ene-3-ol (Kou et al. 2018).

37.3.1 Biosynthesis

The basic synthesis pathway of 6-gingerol proposed and explained by Denniff et al. (1981) and Denniff et al. (1980) starts from dihydroferulic acid and hexanoic acid. The authors of this theory described the conversion of phenylalanine to dihydroferulic acid, which participates in the biological reaction of Claisen with malonate and hexanoate to form 6-dehydrogingerdione, further transformed into 6-gingerol.

Ramirez-Ahumada et al. (2006) proposed an alternative route of 6-gingerol synthesis in which the following enzymes have a significant contribution: ammonia lyase, p-coumaroyl shikimate transferase, p-coumaroyl quinate transferase, caffeic acid O-methyltransferase, and caffeoyl-CoA-O-methyltransferase (Fig. 2).

37.4 Bioactivities (Animal Aspects)

Ginger in Hindu mythology has been described as a plant helping people, plants, and animals. It belongs to one of the oldest spices and medicinal herbs. The latest and more frequent studies confirm the possibility of using ginger in many diseases. Here below the activity of polar extracts of ginger and of its single phenolic compounds are presented as drug candidates targeting a wide range of therapeutical application.

37.4.1 Antiemetic Properties

The mechanism of antiemetic action of ginger extracts remains uncertain and not fully understood. There are many theories explaining this direction of *Z. officinale* activity. One of them performed in vivo on animal models (guinea pig) suggests that the ginger extract and its single constituents (6-gingerol, 6-shogaol, and

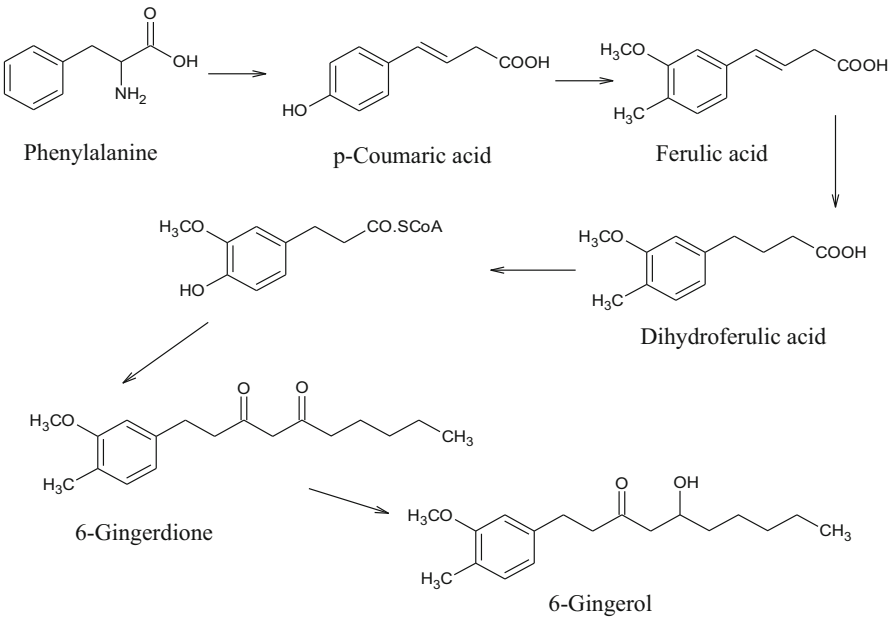

Fig. 2 Biosynthesis of 6-gingerol as proposed by Denniff et al. (1980)

galanolactone) have antiserotonin properties due to their antagonistic effect on the 5-HT3 receptors. The ability of these compounds to cross the blood-brain barrier might be achieved due to their small molecular masses (Mishra et al. 2012). Similar molecular observations resulted from the research of Yamahara and co-workers (1989), who tested 6, 8-, and 10-gingerol on an isolated ileum of guinea pig and observed the ability of all compounds to block the 5-HT3 receptors. In another study conducted on the house musk shrew animals (*Suncus murinus*), it has been shown that ginger acetone (150 mg/kg p.o.) extract and 6-gingerol (25 mg/kg p.o.) administered 60 min prior to cyclophosphamide successfully prevented the tested animals from emesis (Yamahara et al. 1989a). Further studies of Yamahara and co-workers (1990) in mice revealed that ginger acetone extract (75 mg/kg) and its metabolites (6-gingerol at 2.5 mg/kg, 6-, 8-, and 10-gingerol at 5 mg/kg) supported the transport of charcoal meal travel along the digestive system, leading to a conclusion that ginger extracts and its metabolites have significantly increased the speed of gastric emptying and the intestinal transit. On the other hand, according to Ali et al. (2008), ginger phenolic compounds are capable of gastric motility reduction (they inhibit the development of slow-wave stomach cramps) and therefore act as antiemetics. These effects were observed in dogs and rats protected from cisplatin-evoked vomiting by 50% ethanolic extract rich in gingerols and shogaols.

In consideration to the above-described examples of research, ginger extracts and phenolic compounds thereof are capable to influence the motility of

gastrointestinal tract by influencing the muscle contraction and blocking the functions of serotoninergic receptors in the digestive system.

In traditional medicine, ginger has been recommended in the morning nausea occurring in pregnancy, especially in the first trimester, but caution is required when taking the drug. The daily dose of powdered ginger should not exceed 2 g (Grys et al. 2010). Studies on pregnant ginger-fed rats by Wilkinson (2000) showed that their fetuses have higher weight and a better developed skeleton; however, the miscarriages may occur more often among these animals.

37.4.2 Antibacterial, Antifungal, and Anthelmintic Effects

The antimicrobial properties of ginger have been widely studied. Its water-ethanol extract was found to possess antibacterial properties against Gram-positive and Gram-negative (Chrubasik et al. 2005) bacteria, which is quite rare for the plant extracts. Several strains susceptible to ginger polar extracts were described by different authors and included the data on the inhibitory properties of ginger against *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, *Salmonella typhimurium*, and *Escherichia coli* (Ali et al. 2008). Boiled ginger rhizomes were found effective against *Escherichia coli*, *Vibrio parahaemolyticus*, *Pseudomonas aeruginosa*, *Mycobacterium phlei*, *Streptococcus faecalis*, and *Bacillus cereus* (Chrubasik et al. 2005). Unfortunately gingerols and shogaols have not yet been enough investigated for their antimicrobial properties so far.

In one study the methanolic extract of raw ginger powder and the isolated compounds 6-, 8-, and 10-gingerol and 6-shogaol inhibited the growth of some *Helicobacter pylori* strains. Still, in this case, the total extract was found more effective in comparison with the isolates, whose MIC's ranged from 1.6 to 25 μg/mL with 10-gingerol as the strongest component (Mahady et al. 2003). According to the study of Park and co-investigators (2008), the derivatives of gingerol (10- and 12-gingerol) inhibited the growth of oral bacteria: the pathogens like *Porphyromonas gingivalis*, *P. endodontalis*, *and Prevotella intermedia* with the MIC values calculated from 6 to 30 μg/mL. 10-Gingerol was found active against *Bacillus cereus* (MIC = 250 ppm) (Cetin-Karaca and Newman 2018). Also, the growth of two strains of *Mycobacterium*, *M. avium* and *M. tuberculosis*, was restricted by 6-gingerol (Semwal et al. 2015).

The phenolic compounds from ginger were found to increase the activity of some antibiotics, like aminoglycosides, against vancomycin-resistant strains of *Enterococcus*. For *E. faecalis* the MIC of an antibiotic arbekacin was decreased from 64 to 4 μg/mL, when joined with 10-gingerol (Semwal et al. 2015).

Only a few studies report the inhibitory properties of ginger against fungi. Hydroalcoholic extracts of *Zingiber officinale* inhibited the growth of *Candida albicans* in the study of Jagetia and co-investigators (2003). Another study performed by Ficker and co-workers (2003) on the African ginger phenolics showed that three gingerols and gingerdiol exhibited the antifungal effect against 13 strains

at the concentration lower than 1 mg/mL. 8-Gingerol was found to be more active from 6-gingerol and gingerdiol according to this study. Even if these compounds exhibited antifungal potential, still their activity was calculated as more than 10 times weaker from the antifungal drug: amphotericin B.

37.4.3 Anthelmintic Properties

Anthelmintic activity of ginger extracts was tested on several species of parasites. Its antiparasitic properties were confirmed, e.g., against *Angiostrongylus cantonensis*, *Anisakis simplex* larvae present in fish, *Aedes aegypti*, *Schistosoma mansoni* (Aly and Mantawy 2013), and *Culex quinquefasciatus* (Lin et al. 2010; Ali et al. 2008).

Raw, aqueous ginger extract was administered to sheep infected with nematodes, and depending on the dose of ginger and the duration of treatment, anthelmintic activity was noted (Ali et al. 2008).

The studies on single metabolites of ginger are less abundant. In the scientific paper of Lin and co-investigators (2014) among 11 single constituents obtained from ginger extracts, the cestocidal activity and/or the ability to inhibit the movements of *Hymenolepis nana*, 10-shogaol, and 10-gingerol exhibited the biggest potential in a dose- and time-dependent manner. The parasite exposed to the action of the former compound at the concentration of 200 μM had died within 12 h. Similar results were presented in case of *Anisakis simplex*. The maximum lethal efficiency and larvicidal action were obtained for both 10-shogaol and 10-gingerol; however, in this case the latter compound was found preferable and stronger (Lin et al. 2010).

37.4.4 Effects on the Digestive System

Powdered rhizome ginger has a long history of use in traditional medicine as a remedy alleviating the symptoms of diseases of the digestive system. Acetone extract from ginger improves gastric motility and has a diastolic effect on the smooth muscle of the gastrointestinal tract, so it can be used to relieve indigestion, bloating, and general symptoms of irritable bowel syndrome (Ali et al. 2008). Among the metabolites of ginger, according to Yamahara and collaborators, 6-shogaol gave a more visible anticathartic effect than 8- and 10-gingerol and 6-dehydrogingerdione. 6-, 8-, and 10-gingerol and 6-shogol administered orally enhanced the transport across the digestive system and the emptying of the stomach, in a similar manner than that of metoclopramide (Chrubasik et al. 2005).

The protective role of ginger compounds has been demonstrated to inhibit the development of *Helicobacter pylori* in vitro, which is responsible for indigestion, stomach ulcers, and the development of colorectal cancer (Ali et al. 2008; Mishra et al. 2012).

In contrast to oral administration, intravenous injection of 6-shogaol inhibited the transport through the digestive tract. According to these studies, 6-gingerol and

10-gingerol caused an increase in bile secretion and increased the activity of pancreatic and intestinal lipases (Chrubasik et al. 2005).

In addition, ginger enhanced the appetite, eliminated the feeling of fullness after eating fatty foods, and protected the animals against the formation of ulcers after ingestion of alcohol or drugs (Ali et al. 2008). The rhizomes were found to possess a protective effect on the mucous layer of the stomach, by increasing its resistance to harmful factors (including alcohol, acetylsalicylic acid, and other drugs) (Shukla and Singh 2007). In the studies of Weng and collaborators, an oral dose of 1.5–50 mg/kg of 6-gingerol inhibited the secretion of basal acid, also in conjunction with capsaicin (Semwal et al. 2015).

Oral administration of unpolar constituents of ginger (e.g., zingiberene) and 6-gingerol (at a dose of 100 mg/kg) inhibited the occurrence of gastric lesions in mice by 54%, each, according to the study of Yamahara cited by Chrubasik and co-workers (2005). This particular activity was strictly correlated with the prevention of gastric ulcer at a similar level to nonsteroidal anti-inflammatory drugs.

Furthermore, 6-shogaol and some ginger terpenes (*ar*-curcumene, *b*-sesquiphellandrene, *b*-bisabolene) (Yamahara and co-investigators), 6-gingesulfonic acid, and 6-gingerol (Yoshikawa and co-workers) were found to exhibit anti-ulcer properties in rats. Interestingly, the process of rhizome roasting enhanced the protective activity (an active dose of 170.6 g/kg).

Ginger extract, 6-gingerol and 10-gingerol, administered in rats exhibited cholagogue properties (Yamahara and co-investigators) and, at a dose of 50 mg% within 8 weeks, an enhanced pancreatic lipase activity (Platel and Srinivasan) (Chrubasik et al. 2005). Also, its effect on the stimulation of pancreatic lipase, amylase, and proteinases (chymotrypsin, trypsin, carboxypeptidase) was described in rats (Srinivasan 2017).

6-Gingerol was responsible for the lowering of the total bilirubin content and hepatic marker enzymes (phosphatase, aminotransferases) in a similar manner as silymarin, which was described in the studies of Sabina and collaborators (Semwal et al. 2015). In the studies on rats, both 6-gingerol and 6-shogaol protected liver from the toxic effects of diclofenac at a dose of 10 mg/kg (i.p.), when administered for 6 days (studies of Alquasoumi and collaborators) (Semwal et al. 2015).

37.4.5 Effects on the Cardiovascular System

Ginger extracts and its constituents due to their highly described anti-inflammatory, antioxidant, hypotensive, antiplatelet, and hypolipidemic effects supported by the results of numerous in vivo studies are perceived to play a significant protective role in cardiovascular diseases.

In the conducted studies on rats, the indirect and direct influence of ginger components on the value of arterial blood pressure and heart rate was suggested (Mishra et al. 2012). The studies describe the effect of raw ginger extract on lowering arterial blood pressure in anesthetized rats and reducing heart rate and contractility, heart rate reduction, and spontaneous contraction force in guinea pigs. The ginger pressure-lowering effect can be caused indirectly by blocking voltage-dependent

calcium channels (Nicoll and Henein 2007). Interestingly, it has been noticed that some active ingredients of ginger may have opposite properties (Chrubasik et al. 2005; Ali et al. 2008). In smaller doses these compounds possess cardio-depressant properties, whereas at higher doses, the cardiotonic properties were observed (Mishra et al. 2012). 8-Gingerol in the studies of Kobayashi and co-workers at the concentrations of $1 \times 10–6$ to $3 \times 10–5$ M resulted in a positive inotropic effect on a left atrium of guinea pig (Semwal et al. 2015).

According to the Suekawa and collaborators, who studied the effects of single ginger compounds, likewise to capsaicin, 6-shogaol caused a rapid decrease in the blood pressure and induced bradycardia in rats. This particular activity was reversed by the administration of calcium antagonists and α-adrenoreceptor blockage. Also, 6-gingerol at lower doses evoked the response of the depressor on the blood pressure, when injected to the bloodstream (Chrubasik et al. 2005). In the study of Liu and co-workers, 6-gingerol was proven to be an inhibitor of the angiotensin II type 1 receptor with IC50 value of 8.2 μM (IC50 of angiotensin = 1 μM) and could be therefore treated as a blood pressure regulator. Other studies confirm its additional anti-atherosclerotic activity related to the inhibition of the incorporation of [35S]-Met/Cys into the vascular proteoglycans, leading to a decreased protein synthesis and protein synthesis (Semwal et al. 2015).

Gingerols and especially 6-gingerol were able to increase the thermogenesis in animal studies in a stronger manner than the respective shogaols. Considering this, the authors of the study (Eldershaw and collaborators) observed vasoconstriction effects. Another manuscript described the occurrence of an increased intestinal blood flow with no effect on the arterial blood pressure (assessed by Doppler flowmetry) upon the intraduodenal administration of dried ginger with high concentration (2 mg/kg) of 6-shogaol (Chrubasik et al. 2005), which could support an increased digestion upon the ginger intake.

6-Gingerol, 6-shogaol, and gingerdiones were reported to possess inhibitory properties against thromboxane, leukotriene, and prostaglandin biosynthesis (Mishra et al. 2012). 6-Gingerol administered at a dose of 10 mg/kg ameliorated the elevation heart enzymes induced by doxorubicin in rats, such as NF-KB, sRAGE, and cardiac caspase-3, so it may be helpful as a cardioprotecting agent (Semwal et al. 2015). In fact, the cardioprotective properties of ginger were studied also concerning its eventual prevention of myocardial infarction. In Wistar rats pretreated with ginger extract for 4 weeks prior to the induced infarction, significantly lower levels of cardiac markers were noted. Those included alanine transaminase, lactate dehydrogenase, aspartate transaminase, and creatine kinase-MB isoenzyme. Furthermore, an improved concentration of antioxidant enzymes was seen for those pretreated rats in relation to a control group (Srinivasan 2017).

37.4.6 Impact on the Metabolism of Lipids

Treatment with methanolic extract from the dried ginger rhizome resulted in a significant reduction of the level of triglycerides, phospholipids, and LDL cholesterol resulting in the decrease of body weight and decreased levels of

hypercholesterolemia, hyperglycemia, and hyperinsulinemia, in animal models. A reduction in urinary protein and a decrease in urine output were also observed. In mice deficient in apolipoprotein E after ginger supplementation, the LDL oxidation was inhibited, and the development of atherosclerosis was slowed down (Mishra et al. 2012) in a similar manner to the activity of ascorbic acid (Ahmed et al. 2000). Moreover, ginger reduced the synthesis of cholesterol in the liver and had an accelerating effect on its conversion to bile acids, their excretion in the feces (Nicoll and Henein 2007), and activation of pancreatic lipase (Srinivasan 2017). In the studies on rats fed with 0.5% ginger oleoresin for 20 days, fecal cholesterol levels were higher compared to the control group, together with a decreased serum and liver levels of cholesterol (Srinivasan 2017).

According to the studies, the metabolite responsible for the above listed properties in the highest extent is 6-gingerol as it is involved in the metabolism of lipids (Ghosh et al. 2011).

In the studies of Okamoto and collaborators, 6-gingerol reduced fat accumulation in mice as, according to Tzeng and Liu, it was able to suppress the accumulation of oil droplets by decreasing their size in the 3 T3-L1 cells (Semwal et al. 2015). The anti-obesogenic properties evaluated in various in vivo studies were related to the stimulation of PPAR δ (peroxisome proliferator-activated receptor δ), to the regulation of PPARγ pathway in adipocytes, and to the inhibition of inflammatory markers, by ginger and its metabolites. These properties were visible in a catabolic action toward lipids by 6-gingerol and 6-shogaol observed without high lipid food intake being affected (Srinivasan 2017).

Also, a significant decrease in obesity, glucose, and insulin levels was described in diabetic rats, where ginger treatment (mainly due to the presence of 6-gingerol) lowered serum glucose, cholesterol, and triglycerides' levels (Ali et al. 2008; Semwal et al. 2015). Its mechanism of action could be related to the ability to inhibit the HMG-CoA reductase and the subsequent activation of LDL receptors in diabetic rats. The administration of ginger ethanolic extract at a dose of 800 mg/kg noticeably decreased the blood sugar level after 1 h, with a maximum effect recorded after 4 h (Srinivasan 2017). An enhanced glucose uptake was proven to be related to the presence of 6- and 8-gingerols as demonstrated by Li and collaborators upon the analysis of L6 myotubes. Stronger activity was attributed to 8-gingerol who stimulated an increased surface distribution of the GLUT4 protein in the myotube membranes (Semwal et al. 2015). Antidiabetic properties were also observed in diabetic rodents through an increase in insulin sensitivity and the protective effects toward β-pancreatic cells reflected in a lowered antioxidative stress (6-gingerol stimulated catalase, GSH, superoxide dismutase, and glutathione peroxidase), higher glucose uptake by the peripheral cells, and reduced accumulation of fat. Gingerols and shogaols treatment (administered in the form of polar extracts rich in phenolic metabolites) appeared to reconstruct the kidney tubules by their antiglycation activity, to reduce the fatty infiltrations, and to inhibit diabetes-related formation of cataract (Srinivasan 2017; Semwal et al. 2015).

37.4.7 Anti-inflammatory, Anticoagulant, and Analgesic Properties

Ginger has long been known as an anti-inflammatory, anticoagulant, and analgesic agent (Ross 2005). It inhibits prostaglandin biosynthesis, disrupts the arachidonic acid cascade, and blocks vanilloid receptors (associated with the chemical and thermal nociceptive stimuli) (Ali et al. 2008).

It has similar properties to nonsteroidal anti-inflammatory drugs (NSAIDs) because it suppresses prostaglandin synthesis by inhibiting the COX-2 enzyme (cyclooxygenase-2) and leukotriene biosynthesis by affecting the 5-lipoxygenase enzyme (LOX-5) (Ali et al. 2008). According to some various studies, it does not inhibit COX-1 (Cisowski et al. 2004; van Breemen et al. 2011). Thanks to these properties, ginger has a better therapeutic profile and fewer side effects than drugs belonging to the NSAID group.

The extract obtained from *Zingiber officinale* was proven to inhibit the activity of several genes involved in the formation of inflammatory response, as well as genes encoding cytokines and chemokines and inducing the COX-2 enzyme (Grzanna et al. 2005; Ali et al. 2008).

Attention is also paid to the effect of ginger and its compounds on the transcription factors that regulate the expression of genes responsible for inflammation. These factors include NF-κB and AP-1, which under the influence of, for example, lipopolysaccharides from G (−) bacteria lead to an increased expression of genes and proteins for TNF-α, IL-1, IL-12, iNOS, and COX-2 (Lantz et al. 2007).

In one of the studies performed on rats, an oral or intraperitoneal intake of ginger extract at a dose of 50 mg/kg triggered a statistically significant reduction in serum PGE 2 levels. Higher dose of 500 mg/kg administered orally reduced TXB2 level, and the same dose administered orally and intraperitoneally decreased the level of PGE2. In addition, when using a higher dose of ginger, a reduction in serum cholesterol was observed (Ali et al. 2008). Other experiments indicate that ethanolic ginger extract reduces rat swelling caused by carrageenan and also reduces yeast-induced fever (Ali et al. 2008).

In the presence of phenolic compounds with a long side alkyl chain such as [6]-gingerol, [6]-shogaol, [4]-shogaol, or [12]-shogaol, stronger inhibitory properties were observed toward the synthesis of leukotrienes than toward prostaglandins as proven for ginger extracts. The length of the chain also affected the efficiency of COX-2 inhibition in the study of Kiuchi and collaborators. The compounds lower than 8-gingerol, 8-shogaol, and 8-paradol were less active from the remaining components with a longer chain. Higher than 10-gingerol and its derivatives, a plateau in the pharmacological potential was observed (Kiuchi et al. 1992).

Ginger extract containing a mixture of compounds 6-gingerol, 8-gingerol, 10-gingerol, and 6-shogaol showed in subsequent tests more inhibitory activity against PGE2 than each of them separately. The obtained results allowed to arrange phenolic compounds in terms of their ability to inhibit the production of PGE2 in the following order: 10-gingerol <8-gingerol <6-gingerol <6-shogaol. These phenolic compounds not only inhibited COX-2 enzyme activity but also reduced the level of

COX-2 mRNA (Lantz et al. 2007). In terms of a low toxicity ratio of ginger metabolites toward the digestive system, they were found preferable from the NSAIDs (Ali et al. 2008). Besides the above-described effects, ginger metabolites were also found to inhibit the antigen presentation (6-gingerol), the NOS, IL-1β, IL-6, NO synthase and TNF-α expression (by suppressing the 1-κBα phosphorylation and PKC-α translocation), NF-κB activation by inhibiting intracellular adhesion molecule-1 (10-gingerol, 6- and 8-shogaol), and the radical processes (Semwal et al. 2015). Also, some in vivo models on animals were applied to determine ginger's anti-inflammatory potential. According to these tests, 6-gingerol was proven to block the paw edema effects at a dose of 100 mg/kg in mice, to inhibit the iNOS and COX-2 protein expression, and to influence the transcriptional properties of NF-κB by phosphorylation blockage (Semwal et al. 2015). A possible anti-inflammatory mechanism of ginger's activity may be related to its affinity to calcium channels by stimulating its influx and an intracellular release of calcium. According to different studies, shogaols are more potent than gingerols, and they were successfully used in the treatment of arthritis or swelling (Bode and Dong 2011).

Ginger extracts were proven to exhibit **anticoagulant** properties due to the inhibition of platelet aggregation and thromboxane-B2 production in the animal studies on rats (Srinivasan 2017; Thomson et al. 2002; Ali et al. 2008). Ginger metabolites were suggested as new inhibitors of platelet activation, with no side effects of acetylsalicylic acid (Bode and Dong 2011). These properties could be affected by the presence of 6-gingerol in the extract. According to the studies of Guh and collaborators, the release of arachidonic acid cascade was inhibited by 6-gingerol at the concentrations of 0.5–20 μM whereas the inhibition of thromboxane B2 formation at a dose of 0.5–10 μM (Semwal et al. 2015). Even if some results of this particular pharmacological activity have been published, the anticoagulant properties of ginger are still doubtful due to a number of tests on human with no effect observed (see Sect. 5).

6-Shogaol was proven to deliver **antinociceptive** properties and was perceived as a substance P inhibitor in the tests on rats (Mishra et al. 2012).

37.4.8 Antioxidant Properties

Ginger is one of the stronger natural antioxidants. The rhizomes themselves, as well as extracts obtained from them, contain a significant amount of polyphenolic compounds. The activity of ginger and its metabolites is based not only on the radical scavenging properties but also on the stimulation of natural antioxidant enzymes, on the inhibition of inflammatory processes related to the arachidonate metabolism, on the inhibition of lipids' oxidation, and on the inhibition of nitric oxide synthase (Srinivasan 2017).

Recently, numerous tests were carried out to determine the scavenging power of ginger metabolites against free radicals, which include the reactions with DPPH reagent, linoleic acid, Fe3+ ions, xanthine oxidase, and others (Peng et al. 2012; Stoilova et al. 2007). In in vitro (butylated hydroxytoluene), ginger extract showed a

similar antioxidant strength (Stoilova et al. 2007). Most often its potential was studied spectrophotometrically, in reaction mixtures with radicals or in cell homogenates (e.g., the studies on the ability to chelate iron (III) ions, inhibit xanthine oxidase, inactivate H_2O_2 and lipid peroxidation in rat brain homogenates) (Peng et al. 2012; Nicoll and Henein 2007). Studies performed on single metabolites proved a marked potential of 6-shogaol, which was found to be the strongest component (IC50 = 8.05 μM), possibly to the presence of α, β-unsaturated ketones in its structure, opposed to the weakest scavenger: 6-gingerol (IC50 = 27 μM). 10-gingerol with a long carbon chain was found effective, too (Dugasania et al. 2010). These properties in turn may lead to a reduction or inhibition of damage caused by radicals in cell membranes and in DNA (Stoilova et al. 2007; Dugasania et al. 2010).

Studies in rats have demonstrated a significant effect of ginger on the reduction of lipid peroxidation and an increase in serum antioxidant and glutathione levels (Nicoll and Henein 2007), which was helpful in the cardiac disorders. On the other hand, diabetic animals were also benefiting from these particular properties of ginger metabolites. In a study on diabetic rodents, Akash and collaborators denoted protective effects toward the B cells in the pancreas, Ahmadi et al. described the antioxidant properties impeding glycation upon the administration of 200 mg/kg ginger extract for 30 days in diabetic rats, and Shanmugam et al. described a neuroprotective effect caused by the acceleration of antioxidant mechanisms in the brain. The latter properties were visible in the hippocampus, hypothalamus, and cerebellum of diabetic rats, which also confirms a satisfactory permeability of ginger phenols through the brain-blood barrier (Srinivasan 2017). Even if some effects of ginger antioxidant activity are described, detailed mechanisms and specific targets are still missing in the scientific reports.

37.4.9 Effect on Cancer Prevention

The anticancer activity assessment of both ginger extracts and ginger metabolites has been widely discussed and published. The researchers underline a marked anticancer activity of the extract itself but also of single metabolites, like zingerone, 6-gingerol, and 6-paradol in their tests. The authors mention their proapoptic properties related to mitochondrial and the bcl-2 family mediation (increase in the Bax/Bcl-2 ratio), by the disturbances in the cell cycle progression (cell cycle arrest at the G2/M phase with only little impact on the sub-G1 phase), and disturbed reproductive capacity with no influence on the healthy host cells (Srinivasan 2017; Lima et al. 2018).

The anticancer properties of 6-gingerol and zerumbone were associated with their high antioxidant capacity, which played a crucial role in the reduction of peroxide levels (Bode and Dong 2011). As mentioned in the subsection on the anti-inflammatory properties of ginger, its compounds exhibit a downregulating effect on the transcription factors and signalling molecules (NF-κB, TNF-α, COX-1, Bcl-2, Mcl-1, AP-1 survivin, cyclin D1, CDS-4, proto-oncogene proteins – c-Myc, hTERT, and caspases), which influence the formation of tumors

(Srinivasan 2017; Lima et al. 2018). Among caspases influenced by the presence of ginger extracts or their metabolites, caspase-3 and caspase-9 are the most frequently indicated. Also, ginger administration led to an upregulated IκB-α and protein p21 level. The inhibition of proto-oncogene proteins like previously mentioned c-Myc or hTERT speaks for the specificity of ginger extracts against certain types of tumors, e.g., breast cancer (Lima et al. 2018).

Ginger metabolites were proven to directly inhibit the AP-1 DNA-binding activity (6-gingerol) or to directly induce apoptosis (6-paradol) as described by Bode and co-workers (2011). According to Lin and collaborators, the proapoptic properties of 6-gingerol could be related to the enhanced levels of negative cell cycle regulators (p21Cip1 and p27Kip1), phosphorylation of p53 protein, and enhanced ROS levels inside the tumor (Lima et al. 2018). Gingerol is perceived as a tumor necrosis sensitizing drug, as it clearly induces a ligand (TRAIL)-mediated apoptosis, e.g., in glioblastoma cells, being normally resistant to TRAIL signalling. These properties were observed based on the elevated levels of survivin, Bcl-2, XIAP (X-linked chromosome to apoptosis inhibitor), or cFLIP. According to Lee and coinvestigators, these compounds could be administered in patients with TRAIL-resistant glioblastoma incidence (Lima et al 2018). Rastogi et al. underlined that the triggered generation of ROS in the tumor by ginger metabolites inhibited the mitochondrial inhibitory complex I and led to the induction of cell death by an increased miR-27b expression and the following DNA damage (Lima et al. 2018).

Interestingly, synergistic effects of action were observed upon the administration of ginger total extract with an isolated 6-gingerol. In the studies of Brahmbhatt and co-workers, the combination resulted in a marked increase in the antiproliferative effect of ginger extract (Srinivasan 2017). 10-Gingerol was proven to increase an intracellular calcium level and induce cytotoxic effects in colorectal cancer cell lines (Bode and Dong 2011).

Another interesting remark was published by the research group of Cheng et al. (2011), who discovered differences in the antiproliferative effect of cooked ginger in comparison with the unprocessed one. According to the researchers, the anticancer potential of the former was about twice as high as of fresh and dried ginger rhizomes. Chromatographic analysis confirmed that a 4-h-long boiling at 120 °C changed the composition of the extracts toward a higher content of shogaols in relation to gingerols.

Interestingly, in the studies performed on a cellular level, ginger phenols and ginger extract were found to decrease the toxicity of chemotherapeutics administered to patients with tumors. In a study of Hosseini et al., the cardiac toxicity of doxorubicin was reversed upon the administration of ginger capable to induce marked antioxidant potential. These properties were confirmed by the suppression of apoptosis and by the reduction in lipid peroxidation (Lima et al. 2018).

The reports are mainly based on the in vitro studies on cell lines, as they offer fast protocols for the assessment of chemopreventive properties in various types of cancer. However, Table 3 lists the results of in vivo studies performed on animal models for a better clarity of the presented data.

Table 3 Selected anticancer studies of ginger and its metabolites

Material tested	Animal model	Type of cancer	Observed activity	Research group/ reference
6-Gingerol (6-GN)	Mice	Skin cancer	Topical application of 6-GN, 6-paradol, and 6-dehydroparadol suppressed the stimulated skin irritation and inflammation, TNF-α production	Surh et al., Chung et al./ Srinivasan 2017, almighty ginger Nigam et al./ Semwal et al. 2015
	Mice	Colon carcinoma 3 μg/mL p.o.	Increase in the infiltration of tumors by lymphocytes (CD4, CD8 T cells, B220 + B cells) and a reduction in the number of CD4 + Foxp3 + regulatory T cells	Ju et al./Semwal et al. 2015
	Mice	B16F1 (mouse skin melanoma)	Increase in the infiltration of tumors by lymphocytes (CD4, CD8 T cells, B220 + B cells) and a reduction in the number of CD4 + Foxp3 + regulatory T cells	Ju et al./Semwal et al. 2015
	Mice	Benzo[a] pyrene-induced skin tumor 2.5 μM/mouse	Reduced the number of tumors and their volume (increased p53 levels)	Nigam et al./ Semwal et al. 2015
	Mice	TPA-induced skin tumor 25 μM/mouse	Inhibition of COX-2 expression, suppression of NF-κB DNA-binding properties and of p38 phosphorylation	Kim et al./ Semwal et al. 2015
	Mice	Murine renal cell carcinoma Topical administration 1 and 2.5 μM	Increase in the infiltration of tumors by lymphocytes (CD4, CD8 T cells, B220 + B cells) and a reduction in the number of CD4 + Foxp3 + regulatory T cells	Ju et al./Semwal et al. 2015
	Mice	Prostate cancer 10 mg/kg p.o. 15 days	Modulation of proteins engaged in the apoptosis pathway	Shukla et al./ Semwal et al. 2015
	Male mice	Pancreatic cancer i.p.	Decreased tumor incidence	Akimoto et al./Li et al. 2018
	Nude mice	Tumor induction 2.5 and 5 mg/kg i.p. 45 days	Induction of apoptosis and upregulation of p53 protein	Rastogi et al./ Lima et al. 2018

(continued)

Table 3 (continued)

Material tested	Animal model	Type of cancer	Observed activity	Research group/ reference
Ginger extract	Nude mice	Prostate cancer 100 mg/kg p.o.	Inhibited progression of cancer by the perturbed cell cycle progression and proapoptic properties	Karna et al./ Srinivasan 2017
	Rats	Colon cancer 50 mg/kg	Suppressive activity against tumor by a decreased oxidative damage (enhanced superoxide dismutase, catalase, glutathione peroxidase, and transferase) and inhibition of β-glucuronidase and mucinase microbial enzymes	Yoshimi et al.; Manju and Nalini/almighty ginger
	Nude mice	Induced prostate cancer 100 mg/kg 8 weeks p.o.	Decreased Ki67, cyclin B, D, and E levels	Karna et al./Li et al. 2018
6-Shogaol	Xenograft mouse model	Colon cancer 15 mg/kg i.p.	Inhibition of HCT-116 (arrested at the G2/M phase by the regulation of p53/p21 pathway) and SW-480 cell proliferation (IC50 = 7.5 and 10 μM, respectively)	Qi et al./ Srinivasan 2017
	Mice	TPA-induced skin tumor 3 μM/mL, 60 days	Inhibition of TPA evoked iNOS and COX-2 mRNA expression (suppressed nuclear translocation of NF-κ B subunits)	Kim et al./ Semwal et al. 2015

37.4.10 Varia

Rodent tests confirmed a reduction in mortality of gamma-prone mice as well as the ability of ginger extracts to inhibit the **radiotherapy**-induced emesis. Therefore, ginger can reduce the damage that occurred during irradiation (Ali et al. 2008) and also because of these can be successfully used in sunscreens, due to its effectiveness in protecting the skin against UV-B radiation (Mishra et al. 2012).

Several **central nervous system** activities of ginger extract and single metabolites were described. Powdered ginger at a dose of 500–600 mg given early enough before the onset of migraine brings relief during its attack (Ghosh et al. 2011). Ginger has the ability to inhibit monoamine oxidase A (MAO-A). Its increased activity and expression of MAO mRNA occurs in people with Alzheimer's and depression. The MAO-A inhibition is indicative of neuroprotective and

antidepressant properties and slowing down the progression of Parkinson's disease (Peng et al. 2012).

Both terpenes and phenols were found to exhibit these properties; however, possibly a higher antidepressant potential was related to the presence of lipophilic components, as described in the study of Kukula-Koch and collaborators (2018).

The statistics show a significant effect of the ginger extract on the reduction of symptoms of knee degenerative diseases (Ghosh et al. 2011). Ginger extracts were found promising in the rheumatoid arthritis, edema, and inflammation, as shown in animal studies (Mishra et al. 2012). In some animal tests, ginger compounds were proven to milden the effects of induced rheumatoid arthritis and streptococcal cell wall-induced arthritis. Funk and collaborators concluded that dichloromethane extract rich in unpolar compounds was more effective from the one rich in phenolic fractions, mainly 6-gingerol (Mishra et al. 2012).

The hepatoprotective effects of ethanolic extracts administered orally were confirmed in the studies on rats with CCl_4- and paracetamol-induced hepatotoxicity described by Ezenou et al. and Abdullah et al. The levels of superoxide dismutase (SOD), malondialdehyde (MDA), and aspartic transaminase (AST) were significantly reduced upon the administration of 200 mg/kg (for SOD) and 300 mg/kg (for the remaining levels) of extract. Also serum levels of serum glutamate pyruvate transaminase (SGPT) and serum glutamate oxaloacetate transaminase (SGOT) were influenced but at higher doses of extract, namely, 1000 mg/kg.

6-Gingerol was proven to exhibit an **immune-stimulating** effect. It is believed that it eliminates cough, has a warming effect on the body, and protects against small infections of the respiratory system (Mishra et al. 2012).

Oral and intravenous administration of 6-gingerol and 6-shogaol at the doses of 1.8–3.5 mg/kg for the former compound and 70–140 mg/kg for the latter showed visible **analgesic** and **antipyretic** effects; however, the researchers noted its cumulative sleep-inducing effect with hexobarbital. Similarly, in the studies of Young and collaborators, 6-gingerol administered in the form of intraperitoneal injection at the dosage of 25 and 50 mg/kg showed analgesic properties (Semwal et al. 2015).

8-Gingerol inhibited **melanogenesis** in the assays on mouse skin cells through downregulation of the MAPK and PKA signal pathways. Therefore, this compound may be used as a skin whitening agent (Huang et al. 2013).

37.5 Benefits (Human Studies)

Zingiber officinale belongs to the most studied herbal drugs. A variety of clinical studies performed on the groups of patients or volunteers are available in the scientific literature. This chapter intends to collect some selected ones, which deliver crucial information on the applicability of this plant in health disorders in which ginger is the most frequently used.

37.5.1 Influence on the Digestive System

37.5.1.1 Antiemetic Properties

The highest quantity of clinical studies was found for these particular properties. Among them there are voices confirming the antiemetic activity of ginger, but also those, which negate these findings. Nevertheless, the conducted studies were mainly considering the groups of pregnant women, as nausea and vomiting affect up to 80% of females at their first trimester of pregnancy (Bodagh et al. 2019). Clinical trials proved that ginger at a dose of 1–2 g per day is effective in pregnancy vomiting or nausea.

Other studies described the postoperative nausea in both sexes, which occurs in 30–70% of patients within 24 h after the operation. The administration of ginger at similar doses to the previously described protocols results in the lesser severity of mild stomach discomfort or diarrhea (Ball et al. 2015).

Also the behavior of tumor patients during chemotherapy was studied. Nausea is often evoked by cisplatin or cyclophosphamide, which is normally limited by serotonin receptor (5-HT3) inhibitors and glucocorticoids (e.g., dexamethasone). These drugs are bearing serious side effects, and their activity is often not sufficient enough, which gives way to the ginger trials. Various researchers describe positive effect of ginger therapy rather in acute than delayed nausea and after 6 h from the administration (Bodagh et al. 2019).

Ernst and Pittler (2000) in their review set together the outcomes of different clinical trials describing the influence of ginger on nausea and vomiting. Two out of three examples concerning postoperative nausea and vomiting confirmed a noticeable antiemetic activity of ginger in relation to placebo and its equal strength as metoclopramide. Divergent results leave this activity still debatable (1 g of ginger taken before operation obtained an absolute risk reduction of 0.052, which includes the possibility of no profit).

Other, newer and better planned trials (double-blind, well-controlled, randomized tests) confirm the influence of ginger on emesis in 30 hospitalized women before their 20 weeks gestational age. The patients were given 1 g of ginger or placebo every 4 days, followed by a 2-day washout before crossover. As a result 70% of group members responded positively to the treatment (placebo response: 15% only) with a statistical significance of $p = 0.035$ and a mean relief score of 3.7 to 4.1 (placebo: 0.1 to 0.9). Among the study outcomes, the patients described a reduced nausea and more rare incidence of vomiting (Bryer 2005). Smith and co-investigators intended to compare the strength of ginger with vitamin B6 in treating vomiting and nausea in 291 outpatient women at the beginning of their pregnancy (before 16th week of gestational age). The women were self-administered with 25 mg of vitamin B6 and 350 mg of ginger, three times a day and for 3 following weeks. In consequence both drugs were perceived as similarly effective in reducing vomiting (mean difference of 0.5), nausea (of 0.2), and dry retching (of 0.3). Neither of drugs had influence on the pregnancy course (Bryer 2005).

The antiemetic properties of ginger in motion sickness were demonstrated by testing 36 volunteers aged about 19 years who were given ginger and induced nausea

using a rotating chair. A reduction in the frequency of vomiting and nausea was observed after the administration of ginger (Chrubasik et al. 2005; Grys et al. 2010).

Malfunctions in the gastric emptying contribute to gastrointestinal problems, like nausea or dyspepsia. Their symptoms are often related to the feeling of fullness, epigastric burning, early satiety, discomfort in the upper abdomen, or gastroesophageal reflux, which frequently appear in correlation with meals (Bodagh et al. 2019). Several clinical trials studied the effect of ginger rhizome administered together with artichoke on dyspepsia and gastric emptying. Lazzini and colleagues determined the gastric volume by ultrasonography – before and after the meal. They proved that the administered herbs helped the patients by increasing the volume of 24%, compared with placebo. These effects, according to Giacosa et al., might have been influenced by the ability of ginger and its phenolic constituents (6-gingerol, 8-gingerol, 10-gingerol, and 6-shogaol) to stimulate the cholinergic M3 and serotoninergic 5-HT3/5-HT4 receptors (Bodagh et al. 2019).

To elucidate the mechanism of ginger's action, Micklefield et al. in their trial on a group of 16 healthy volunteers who took 1 g of ginger per day, orally, proved that the rhizome had no effect on the emptying of the stomach, as it was previously believed, but increased antral motility in the phase III of the migrating motor complex (MMC). As a result of this action, an increased motor response of the body was noted with no effect on duodenal contractions (Mishra et al. 2012) (see Table 4).

37.5.2 Analgesic and Anti-inflammatory Properties

In humans, one study of Bliddal and colleagues did not provide significant differences between ginger and placebo in the group of osteoarthritis of the knee or hip. On the other hand, the study of Altman and Marcussen delivered suitable data to confirm a greater response from the knee osteoarthritis patients in comparison with placebo (Bode and Dong 2011). In another double-blind randomized study on 67 healthy adults in a postsurgical pain model described by Rayati and colleagues (2017), ginger anti-inflammatory and analgesic properties were of similar intensity as those of ibuprofen.

The researchers confirm the analgesic properties of ginger in various clinical trials. A relief from swelling and pain was reported by Ozgoli and collaborators in the trial on the patients with osteoarthritis, rheumatoid arthritis, or other muscular discomfort upon the administration of 250-mg capsules from powdered ginger for the period of 3 months to 2 years. The results of this double-blind clinical trial showed a similar strength of ginger as of ibuprofen administered at the quantity of 400 mg or mefenamic acid (250 mg) (Srivastava and Mustava).

The anti-inflammatory properties of ginger were not confirmed in a study of Black and Oconnor, who administered 2 g of ginger to patients 30 min prior to cycling exercise. As a result, the studied group did deliver quadriceps muscle pain, higher work rate, and heart rate (Bode and Dong 2011). However, Black et al., who administered 2 g of ginger for 11 days on a group of 36 participants, to cure muscle pain, proved moderate-to-large reductions (Mashhadi et al. 2013).

Table 4 Selected examples of clinical trials lead in the direction of anti-nausea and anti-vomiting properties of ginger

	Study group	Dosage	Reference	Comments	Reference
Vomiting and nausea	291 outpatient women <16 weeks' gestational age	350 mg of ginger rhizome 25 mg of vitamin B6 3 times a day 3 weeks	Ginger versus vitamin B6	Ginger was equivalent to vitamin B6 in nausea, vomiting, and dry retching reduction	Smith et al./in Bryer 2005
	26 outpatient women 7–11 weeks' gestational age	250 mg ginger syrup 4 times a day 1 week	Double-blind, randomized study: ginger versus placebo	67% patients stopped vomiting and nausea	Keating and Chez/in Bryer 2005
	70 outpatient pregnant women	1 g of ginger for 4 days	Double-blind randomized study Ginger versus placebo	Milder nausea in ginger group ($p = 0.014$) Reduction of 62% for ginger and 34% for placebo group	Vutayavanich et al./in Bryer 2005
	30 pregnant women	1 g of ginger 1 time a day for 4 days, followed by a 2-day washout	Double-blind randomized crossover study with 2-day washout before crossover Ginger versus placebo	Significant preference for ginger (70%) versus placebo (15%), $p = 0.035$ Reduced incidence of vomiting and decreased nausea	Fischer-Rasmussen et al./in Bryer 2005
	16 volunteers	1 g of ginger orally	–	Increased antral motility during phase III of the MMC – migrating motor complex	Micklefield et al./in Mishra et al. 2012
	120 women after gynecological surgery	1 g of powdered ginger 1 h prior to anesthesia	Ginger versus placebo or metoclopramide (10 mg)	Incidence of nausea: 21% ginger, 27% metoclopramide, 41% placebo, no side effects observed	Phillips et al./ in Mishra et al. 2012
	80 cadets	1 g of powdered ginger, 1 dose	Placebo 2 parallel groups	Significant relief after 4 h past administration, superior to placebo	Grontved/in Mishra et al. 2012
	34 patients during chemotherapy	500 mg Twice a day Orally 5 days	Placebo and crossover with antiemetics	No significant differences between the placebo and ginger	Thamlikitkul et al. (2017)/ in Bodagh et al. 2019

(continued)

Table 4 (continued)

	Study group	Dosage	Reference	Comments	Reference
	36 patients during chemotherapy	0.5 or 1.5 g of extract a day + antiemetic drug Consumption 2 × 6 day, evaluation 3 × 4 day	Placebo + antiemetic drug	Reduced incidence of acute but not delayed nausea in chemotherapy with cisplatin	Fahimi et al./ in Bodagh et al. 2019

To conclude, even if the results confirming the efficacy of using ginger preparations as anti-inflammatory and nociceptive agents are not unified, the positive voices still seem encouraging.

37.5.3 Other Activities

The results obtained from animal tests were confirmed in several human trials. In a study of Verma and colleagues, 5 g of ginger consumed by the studied group **inhibited the platelet aggregation** and, according to Verma and Bordia, induced fibrinolytic activity. In the studies on human blood cells among several single ginger constituents, 8-gingerol, 8-shogaol, and 8-paradol, the latter exhibited the strongest antiplatelet properties expressed as COX-1 inhibition with an IC50 value of ca 20 μM (Bode and Dong 2011).

On the other hand, ex vivo studies by Janssen and co-workers gave no effect of ginger oral consumption on thromboxane B2 levels on human blood samples (Srinivasan 2017).

The **antioxidant potential** of *Zingiber officinale* extract and 6-gingerol was confirmed in a clinical trial with the presence of 43 patients diagnosed with cancer. In this trial 19 patients were given 2 g of standardized ginger extract with an addition of 5 mg 6-gingerol a day and 24 placebo for a period of 3 consecutive days before the first cycle and during chemotherapy until the fourth cycle. According to Danwilai and colleagues, increased level of antioxidant enzymes, like SOD, CAT, and GSH/GSSG, was noted, together with decreased MDA and $NO2^{-}/NO3^{-}$ levels (Lima et al. 2018).

Good penetration of ginger and its metabolites was confirmed by Martins et al. in their double-blind randomized clinical trial in 60 participants suffering from **episodic migraines** with no aura who consumed 400 mg of ginger extract or placebo in addition to an intravenous ketoprofen, to treat the attack of migraine. The patients who supplemented ginger showed better response after 1, 1.5, and 2 h ($p < 0.04$) (Martins et al. 2019).

Ginger rhizomes and ginger extracts have been traditionally used in the treatment of hypercholesterolemia and hypertension. However, scientific studies conducted in many research centers provide inconclusive results, and the overall effect of ginger administration on the lipid profile still seems to be unclear.

In a detailed meta-analysis of the published clinical trials on this topic, Pourmasoumi and colleagues concluded that the supplementation with ginger at a dose higher than 2 g per day was successful in the reduction of triacylglycerol (TAG) and low-density cholesterol (LDL) levels, with no impact on the total cholesterol or the high-density lipoprotein cholesterol (HDL-C) (Pourmasoumi et al. 2018).

37.6 Application in Food (Including Correctly Cooking Foods Rich in Phytochemicals)

Ginger (*Zingiber officinale)* is widely used in folk medicine, but also because of its characteristic taste and smell, it is popular in gastronomy. Several food products contain ginger, and it is used, e.g., in the production of beverages and cakes and as an addition to sushi. The hot and spicy taste of rhizomes can cause irritation to the throat and larynx, which reduces the consumed quantities. Several methods have been developed to reduce the sharp taste of ginger, and some processing procedures were evaluated to extend the shelf-life, increase the content of active compounds, and improve its consumption. The ginger rhizome can be heat-treated by drying, cooking, and baking as well as fermenting to deliver marinated ginger (Choiv 2019). In marinated form it is used as an additive to various types of sushi in order to clean the taste buds. The first mention of the use of ginger in foods was connected with its addition to beer and traditional gingerbread. Cooked or baked it is an excellent additive to meats, raising the health benefits of dishes and increasing antioxidant properties. Ginger in food can affect an increase in the antioxidant activity, demonstrate the protective effect on the liver, exhibit antiaging properties, and work in the prevention of stomach ulcers and cancer. Thanks to its antibacterial properties, it can prolong food durability (Chrubasik et al. 2005).

37.7 Safety: Toxicity and Side Effects

Ginger is recognized by the FDA (US Food and Drug Administration) as a food additive that is "generally recognized as safe."

However, the occurrence of adverse reactions after ingestion of ginger has been demonstrated in some studies after administration of 1 g of raw material. The most commonly described symptoms were gastrointestinal discomfort: diarrhea, heartburn, abdominal discomfort, indigestion, and nausea. The symptoms were of mild to moderate severity, and the serious effects were not recorded. There are cases describing the occurrence of asthma after inhalation of ginger by an increase in the level of IgE antibodies – in people working in the production of ginger in the form of

a spice. In ginger toxicity studies, there were no changes in blood counts, hemoglobin, liver function tests, or creatinine.

Pillai et al. (2011), investigating the use of ginger in nausea and vomiting caused by chemotherapy in children and adolescents, did not report any side effects.

In order to investigate the safety of ginger administration in pregnant women, studies were carried out on a group of women in the first trimester of pregnancy. Ginger was given to the pregnant women in the form of capsules, teas, ginger cakes, or candies; the results of the tests in comparison with the comparative group did not differ significantly. Unfavorable symptoms described were limited to abdominal discomfort, reflux, and drowsiness. However, it should be emphasized that the duration of the study was short and the number of patients small (Portnoi et al. 2003).

37.7.1 Interactions

Ginger has antiplatelet aggregation properties; in the literature, a case of interaction of ginger compounds with anticoagulants – warfarin – was described. It led to an increase in the international normalized ratio (INR) and nasal bleeding (Krüth et al. 2004). On the other hand, the studies performed by Jiang et al. (2008) did not confirm the effect of ginger combined with anticoagulants on the results of blood analysis and on the pharmacokinetics of warfarin. Ambiguous results suggest the need for further research to clearly determine the safety of ginger in patients with an increased risk of bleeding.

According to in vitro studies, extracts of ginger affected cytochrome p450 and P-glycoprotein, which can cause potential interactions with many commonly used drugs (Nabekura et al. 2005).

37.8 Patents

Ginger rhizome extracts, its single metabolites, and powdered ginger rhizome are subjects of numerous patent submissions around the world. The search engine for patents by Google showed more than 196,000 of items. Most of them describe the use of ginger extracts, as a source of gingerols and shogaols and as health-promoting food products. Some of them relate to their medical applications or the methodology describing the acquisition of high value of plant material (e.g., summer and autumn cultivation method – CN101283655A), plant extracts (JP2002047195A), or ginger preparations, e.g., teas or herbal compositions. Several submissions are related to the utility of powdered rhizome for industrial applications, e.g., as an ingredient of a stop-leak composition for automobile coolers (US4348235A), as a special purpose fertilizer (CN1463951A), as detergent (CN103351957A), or in the cosmetics industry (shampoo, CN102451128A, CN1513436A; soap, JP2004002517A; liquid soap, CN102008414A; plant hair dye, CN101559030A).

The addition of ginger to food preparations was intended to achieve the reduction of gastroesophageal reflux in infants (US6051235A); to promote liver and intestinal

health and reduce inflammation (US20010046523A1, US6387416B1); to support cardiovascular functions (US20010046523A1, CN1730094A); to reduce pain, swelling, and decreased mobility of limbs (WO2014188214A1); to protect the stem cells (EP2772245A1); to prevent from cancer (CN1337243A, WO2002098399A2), from chronic obstructive pulmonary disease, or from Parkinson's disease (CN101862312A); to induce analgesic and anti-inflammatory action in the mouth (JP2007169247A); to warm the body during cold or flu conditions (CN103385323A); and others.

Often ginger-enriched various compositions in combination with other plant species or metabolites are described. The patents apply the combinations with long pepper (CN102166335A), dark plum fruits (CN102091315A), clove (CN102145158A), or orange peel (CN102133384A) to increase the efficacy of medicaments for radiotherapy- and chemotherapy-induced emesis and with bisabolol (US20090238905A1) to intensify the anti-inflammatory potential in the gastrointestinal and respiratory tracts, to keep out cold and tonify the organism (CN102406013A), and to support the healthy swallowing (US6596313B2) and hair growth (CN1130056A), in sleep- (US6391346B1), hormonal balance- (US6242012B1), and prostate health- (US6261607B1) promoting compositions.

Ginger rhizomes or extracts are introduced to teas (CN102669332A, CN102406013A, CN1149404A; brown sugar ginger tea, CN102696805A; ginkgo and ginger tea, CN101627790A), beverages (kvass drink, CH694314A5; ginger-haw beverage, CN101066152A; ginger brown sugar beverage, CN102266108A), flour confectionery products (gingerbread RU2450525C1, RU2388229C1, CN102461621A; ginger cakes CN101617790A, CN1210679A), porridges (CN103478551A), jams (CN1234983A), noodles (CN103621895A), milk (CN1398530A), yoghurt (CN101530132A), wine (CN102559428A), honey (CN101779714A), ginger pastes (CN1246293A, CN1176069A), syrup (FR2609870A1), candies (CN103039677A), and sausages (DE3247166A1) and manufactured as fermented rhizomes (CN101273783A, KR101254740B1, CN101675781A) or beverages containing fermented ginger (KR100880127B1).

The patents list a wide range of extraction protocols of *Zingiber rhizoma* (ginger oil – CN1065782A), which in their optimized operation conditions provide enriched extracts of high pharmacological potential (e.g., anti-inflammatory, anti-fungal, antiplatelet aggregation, antiemetic properties) and longer stability (US20050031772A1, DE19859499A1, JP2012050377A). Among them supercritical carbon dioxide extraction (JP20020047195A, CN1692924A, CN1144102A), reflux extraction (CN102293997A), and steam distillation (JP2002047195A) play the most important role. Also, granulation method was elaborated for ginger (CN103609991A). Some patents (e.g., JP2012249553A) describe the constructed protocols applied to enrich the extracts in particular metabolites, e.g., increase the content of shogaols (JP2008079562A) and gingerols (JP2012050377A, CN104447259A), or decrease the presence of gingerols known from their skin-irritating properties (water-soluble ginger extract EP1281402B1), and isolate 6-gingerol from ginger extract (CN104397660A, CN1616391A) also by means of high-speed countercurrent chromatography (CN101781184A) or 6- and 8-gingerol by reflux, liquid-liquid extraction, and column chromatography (CN101085727A).

The preservation of ginger extracts properties has been also widely patented. Temperature- and humidity-controlled storage boxes were constructed to preserve the rhizomes from deterioration (CN102344019A). Moreover, its oleoresin was microencapsulated with cyclodextrin (CN101473954A) or maltodextrin and arabic gum (CN1488290A).

37.9 Perspectives

Plentiful pharmacological effects of gingerols and shogaols presented in this chapter but also denoted in numerous studies performed on in vitro models, which were not described herein, shed light on the application of ginger rhizome as a nutraceutical and a natural remedy. Ginger rhizomes, as the major source of gingerols and shogaols, were traditionally used as digestives and antimicrobials. Together with the development of the scientific instruments and assays, further precious properties of this plant were revealed. Its administration in human seems to be an interesting and precious alternative to synthetic drugs, which often bear serious side effects. Low toxicity of single metabolites of ginger extracts and often appearing synergistic actions of its metabolites with synthetic drugs encourages the use of ginger metabolites in various therapeutic strategies. Thanks to a wide spectrum of pharmacological studies on ginger, it may be concluded that the spice has a value of functional foods.

Among health benefits of ginger, its value in the cancer treatment should be underlined. The oleoresin constituents are also effective in the antiobesity, antidiabetic, antisclerotic, and antiamnestic treatment and also as antioxidants, chemopreventives, and anti-inflammatory agents.

Therefore, it is of the highest importance to collect funds on the structure-activity studies, reveal the potential of minor gingerols and shogaols present in the extracts, and collect funds and volunteers on the clinical trials on ginger extracts and metabolites.

This still underestimated spice will certainly draw attention of researchers in the nearest future, as further trials are necessary to confirm its therapeutic benefits already revealed in in vitro tests.

Ming Ming Zhao, Shi Hang Xiong, Guan Ding Zhao, and Hua Yu

Contents

Abstract

Sulfur is one of the essential macronutrients and plays critical role in overall health maintenance. Plant-derived organosulfur compounds (OSCs) are the important source of dietary sulfur. Garlic is one of the OSCs-enriched vegetables with long history of cultivation and has been widely applied in nutritional, healthcare, and medicinal applications. The potential functions of garlic and garlic derivatives in health beneficial and disease prevention have been well accepted by the people worldwide. In this chapter, taking garlic as a case, the research progress (up-to-date 2019) on the investigations of phytochemistry,

bioavailability and metabolism, pharmacology, and safety for garlic OSCs were systemically reviewed and discussed. Moreover, the information on marketed products and granted patent (2009–2018) for garlic derivative products were also summarized.

Keywords

Organosulfur compounds · Garlic · Phytochemistry · Pharmacology · Safety

38.1 Introduction

Sulfur is one of the essential macronutrients (the seventh most abundant) to human, and widely distributed in nearly all human proteins, in building blocks of the body's tissues and organs (Jalilehvand 2006). Sulfur is also an important part of some biological coenzymes (e.g., *S*-adenosyl methionine; protease, ATP carboxylase; and acetyl coenzyme A), several amino acids (e.g., methionine, cysteine, homocysteine, and taurine), peptides (e.g., glutathione), and vitamins (e.g., vitamin B, vitamin H, and carotene) and plays numerous critical roles in metabolism and overall health maintenance (Dong et al. 2018; Ingenbleek and Kimura 2013). Although poorly studied, deficiency of sufficient amount of sulfur has been considered to be one of the potential factors responsible for increasing risk of obesity, chronic fatigue, cardiovascular disorders, dermatological problems, allergies, and even neurodegenerative Alzheimer's disease (Seneff 2010). Therefore, daily uptake of certain amount of sulfur element is considered to be necessary and benefit to maintain good health.

In nature, sulfur presents as various forms (inorganic and/or organic) in different foods. High-protein foods, such as meats, poultry, fish, legumes, cheese, eggs, and nuts, are the primary source of sulfur-containing amino acids (SAAs). Moreover, because of the fact that biosynthesis of organosulfur compounds (OSCs) takes place only in plants and bacteria, plant-sourced OSC is another important source of sulfur both to human and animals (Prasad 2014). The OSC-enriched plant foods include allium vegetables (e.g., garlic, onion, chive, scallion, shallots, and leek) and cruciferous vegetables (e.g., turnip, broccoli, cabbage, and cauliflower), other vegetables (e.g., spinach, tomatoes, carrot, mustard, and potatoes), fruits (e.g., avocados, bananas, watermelon, and pineapple), as well as cereals (e.g., brown rice and wheat flour) (Petropoulos et al. 2017).

Garlic (*Allium sativum* L.) is one of the worldwide-distributed and historically cultivated allium vegetables and has been widely applied in the fields of nutrition, healthcare, and medicines (Santhosha et al. 2013). In chemistry, garlic contains an abundance of OSCs; carbohydrates, proteins, and fiber; trace elements; and compounds of phenolic and steroidal origin (Santhosha et al. 2013). Among them, OSCs have been identified to be closely associated to various bioactivities of garlic, including antimicrobial (Goncagul and Ayaz 2010), anticancer (Ariga and Seki 2006), antioxidant (Capasso 2013), antidiabetic (Hosseini and Hosseinzadeh 2015), hepatoprotective (Guan et al. 2018), immune boosting (Arreola et al. 2015),

as well as potentials in preventing cardiovascular diseases (Zhu et al. 2018). In this chapter, we mostly deal with OSCs that are found in garlic (*Allium sativum* L.) for their phytochemistry, bioavailability and metabolism, pharmacology, safety, and applications.

38.2 Bioactive Constituents

Alliin (*S*-alk(en)yl cysteine sulfoxide) is an important natural ingredient which separately exists with alliinase in fresh garlic. When the garlic was chopped or crushed, alliin will be quickly converted to allicin (γ-glutamyl-*S*-alkenyl-L-cysteine) by alliinase. Thereafter, allicin is converted readily to some more stable alk(en)yl sulfides, vinyldithiins, ajoenes, and some others (Fig. 1) (Guan et al. 2018; Amagase 2006).

Currently, various organosulfur compounds (OSCs) have been isolated and identified from fresh and/or processed garlic. Based on their physicochemical properties, the garlic OSCs could be divided into lipid-soluble (essential oil) and water-soluble compounds. The mostly investigated lipid-soluble compounds include alliin, allicin, such as diallyl sulfide (DAS), diallyl disulfide (DADS), diallyl trisulfide (DATS), and ajoene, while the most investigated water-soluble compounds include *S*-allyl-L-cysteine (SAC), *S*-allylmercaptocysteine (SAMC), and allyl mercaptan (AM). The chemical structures of some representative OSCs from garlic were illustrated in Table 1.

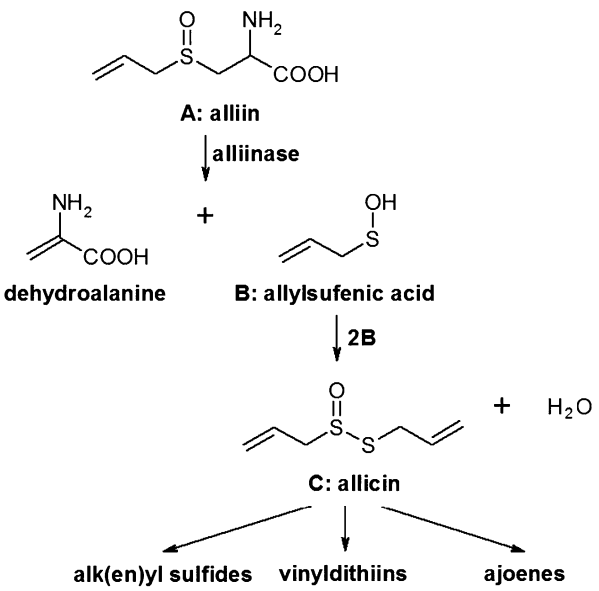

Fig. 1 The enzymatic reaction of alliin (*S*-allyl cysteine sulfoxide) and further reaction of allicin (γ-glutamyl-*S*-alkenyl-L-cysteine)

38.3 Bioavailability and Metabolism

The biopharmaceutical properties of garlic OSCs are limitedly investigated and reported because most of OSCs could not be directly determined in biological samples, which are due to their metabolic instability after administration.

In one early study in human, breath acetone and breath allyl methyl sulfide (AMS) were used as makers to evaluate the oral bioavailability of allicin. The AMS was further identified to be the main active metabolite of allicin and allicin-derived compounds in vivo (Lawson and Wang 2005; Lawson and Gardner 2005). In addition, in a mice model, allixin was detected to be quickly metabolized within 2 h and with an oral bioavailability of 31%. The main metabolites of allixin were identified to present a hydroxylated pentyl group in the structure (Kodera et al. 2002a).

Recently, the pharmacokinetic profiles of SAC, one of the most abundant components in garlic OSCs, have been widely investigated and reported in animals (mice, rat, and dog) (Park et al. 2017; Amano et al. 2015, 2016; Lee et al. 2015). SAC was detected to be fast and completely absorbed from the gastrointestinal tract (bioavailability >90%) (Amano et al. 2015) and extensively reabsorbed from the kidneys. The main metabolites of SAC were determined to be *N*-acetyl-(*S*)-allyl-L-cysteine (80%) and *N*-acetyl-(*S*)-allyl-L-cysteine sulfoxide (11%), which were excreted with SAC (2.9%) in urine (Amano et al. 2016). In addition, another study compared the bioavailability and bioequivalence of allicin after oral administration

of different garlic supplements and garlic foods (Lawson and Hunsaker 2018). The obtained results provided a new guideline for developing of the quality standard for manufacturers of garlic products.

38.4 Bioactivities

The OSCs have been investigated to present various pharmacological activities. The main biological properties of garlic OSCs include antimicrobial, anti-inflammatory, antioxidant and immunomodulatory, anticancer activities, as well as cardiovascular protection.

38.4.1 Antimicrobial Activity

The antimicrobial activity of garlic has long been recognized and investigated (Goncagul and Ayaz 2010). Garlic juice was considered to be "natural antibiotic" and ever used as disinfectant to prevent wound infections during the World Wars. The antimicrobial activities of garlic are closely related to its high contents of OSCs (Kyung 2012). Some garlic-derived OSCs have been reported to present broad-spectrum activities against bacterial, viral, mycotic, and parasitic infections (Goncagul and Ayaz 2010).

In some researches, the volatile oil and/or alcohol extracts have been investigated to present much higher antimicrobial activities than those of the water extracts for garlic. Further studies indicated that garlic OSCs played important roles in inhibiting bacteria (gram-positive and gram-negative), fungus, parasites, and viruses (Kshirsagar et al. 2018; Foroutan-Rad et al. 2017; Borlinghaus et al. 2014; Ankri and Mirelman 1999; Naganawa et al. 1996; Weber et al. 1992). The relationship of the main garlic OSCs and their antimicrobial properties are summarized in Table 2.

Recently, allicin was reported to be more potent against pathogens of certain drug-resistant bacteria such as methicillin-resistant *S. aureus* than some traditional antibiotics (Petropoulos et al. 2017). The potential mechanisms might be related to the combined approaches by decreasing glutathione levels, unfolding stress, and inactivation of crucial metabolic enzymes via S-allylmercapto modification of cysteines (Müller et al. 2016).

Except for the direct actions, garlic OSCs were also observed to enhance the antifungal activity of some other antimicrobials. It was reported that allicin could synergistically enhance the fungicidal activity of amphotericin B against *S. cerevisiae* through effecting on the intracellular ergosterol trafficking (Ogita et al. 2009). In addition, allyl sulfide significantly increased the sensitivity of microbial to multiple antimicrobial agents through modulating multidrug efflux pump EmrD-3 as well as in synergy with multiple antimicrobial agents (Bruns et al. 2017).

Table 2 Antimicrobial activities of main OSCs from garlic

Antimicrobial activity	Garlic-derived compound	References
Antibacterial		
Gram-positive bacteria		
Staphylococcus aureus	Allicin, allistain I, allistain II, ajoene	Goncagul and Ayaz (2010), Ankri and Mirelman (1999), Naganawa et al. (1996)
Streptococcus spp.	Allicin, ajoene	Borlinghaus et al. (2014), Ankri and Mirelman (1999), Naganawa et al. (1996)
Bacillus spp.	Allicin, ajoene, DADS	Borlinghaus et al. (2014), Naganawa et al. (1996)
Mycobacterium spp.	Ajoene	Naganawa et al. (1996)
Lactobacillus spp.	Allicin, ajoene	Naganawa et al. (1996)
Gram-negative bacteria		
Vibrio cholerae	Allicin	Borlinghaus et al. (2014)
Escherichia coli (E. coli)	Allicin, allistain I, allistain II, ajoene	Goncagul and Ayaz (2010), Borlinghaus et al. (2014), Ankri and Mirelman (1999), Naganawa et al. (1996)
Salmonella typhimurium	Allicin	Borlinghaus et al. (2014)
Pseudomonas aeruginosa	Allicin, ajoene	Ankri and Mirelman (1999), Naganawa et al. (1996)
Proteus mirabilis	Allicin	Ankri and Mirelman (1999)
Acinetobacter baumannii	Allicin	Ankri and Mirelman (1999)
Helicobacter pylori	Allicin	Goncagul and Ayaz (2010)
Agrobacterium tumefaciens	Allicin	Borlinghaus et al. (2014)
Pseudomonas syringae	Allicin	Borlinghaus et al. (2014)
Klebsiella pneumoniae	Allicin, ajoene	Ankri and Mirelman (1999), Naganawa et al. (1996)
Antifungal		
Candida albicans	Allicin, ajoene, DADS	Goncagul and Ayaz (2010), Ankri and Mirelman (1999), Naganawa et al. (1996)
Histoplasma capsulatum	Allicin	Goncagul and Ayaz (2010)
Aspergillus	Allicin	Goncagul and Ayaz (2010)
Trichophyton spp.	Allicin, ajoene	Goncagul and Ayaz (2010)
Cryptococci spp.	Allicin	Goncagul and Ayaz (2010)
Penicillium	Allicin	Goncagul and Ayaz (2010)
Torulopsis glabrata	Allicin	Ankri and Mirelman (1999)
Candida spp.	Allicin, ajoene	Goncagul and Ayaz (2010)
Saccharomyces cerevisiae	Ajoene	Naganawa et al. (1996)

Vesicular stomatitis virus	Ajoene, allicin, allyl methyl thiosulfinate, methyl allyl thiosulfinate	Ankri and Mirelman (1999), Weber et al. (1992)
Human rhinovirus type 2	Ajoene, allicin, allyl methyl thiosulfinate, methyl allyl thiosulfinate	Ankri and Mirelman (1999), Weber et al. (1992)
Antiparasitic		
Entamoeba histolytica	Allicin	Ankri and Mirelman (1999)
Giardia lamblia	Allicin	Ankri and Mirelman (1999)
Leishmania major	Allicin	Ankri and Mirelman (1999)
Leptomonas colosoma	Allicin	Ankri and Mirelman (1999)
Crithidia fasciculata	Allicin	Ankri and Mirelman (1999)

38.4.2 Anti-inflammatory, Antioxidant, and Immunomodulatory Activities

Oxidative stress-induced inflammatory reactions are always occurring in many chronic autoimmune diseases (Lingappan 2018; Sies et al. 2017; Lugrin et al. 2014). Effective suppression of inflammatory cytokines and scavenge of reactive oxygen species (ROS) are helpful for improving the clinical symptoms and progression of such diseases. In many studies, the anti-inflammatory, antioxidant, and immunomodulatory activities of garlic OSCs have been investigated and reported (Colín-González et al. 2015). The most investigated compounds include DAS

(Suman and Shukla 2016), DADS (Liu et al. 2018), DATS (Zhang et al. 2016), allicin (Zhang et al. 2017), alliin (Shi et al. 2017), *S*-allyl cysteine (Colín-González et al. 2015), as well as some others.

In vitro, OSCs were observed to effectively suppress the release of nitric oxide (NO) (Liu et al. 2014), secretion of various proinflammatory cytokines (e.g., TNF-α, IL-6, IL-8, IL-1β, etc.) (Liang et al. 2019), and generation of ROS (Zhang et al. 2016) in various inflammatory cell models. In vivo, OSCs exhibited potentials in improving clinical symptoms and diseases progression for chronic inflammatory diseases (including arthritis, colitis, diabetic nephropathy, liver injures, neuroinflammations, cardiovascular inflammations, as well as some infectious inflammations) both in animals and humans. Biologically, the underlying pharmacological mechanisms of such activities were demonstrated to be related to their modulations on endothelial nitric oxide synthase (Liu et al. 2014), nuclear factor kappa-B (NF-κB) pathway (Liang et al. 2019), mitogen-activated protein kinases (MAPKs) pathway (Shi et al. 2017), and oxidative stress (Nrf2) pathway (Zhang et al. 2017). All these studies suggested great potentials of OSCs for their further development and application as on autoimmune inflammatory diseases.

38.4.3 Anticancer Activity

In the past decades, the anticancer activity of garlic extracts and OSCs has been widely investigated by many researchers. A numerous cell and animal studies reported that garlic and garlic-derived OSCs presented anticancer activity against various cancers (e.g., breast, gastric, colorectal, liver, glioma, lung, and some other cancers) (Nohara et al. 2017; Puccinelli and Stan 2017; Nicastro et al. 2015). In clinical trials, although several inverse reports, garlic intake was still considered to be potentially associated to the reduction on the risk of some cancers (Wu et al. 2019; Guercio et al. 2014; Kim and Kwon 2009). Furthermore, OSCs were identified to be the most important bioactive compounds to be responsible for the anticancer activity for garlic (Lugrin et al. 2014; Schäfer and Kaschula 2014; Cao et al. 2014; Tsubura et al. 2011).

38.4.3.1 Breast Cancer

To be a most common cancer among females worldwide, breast cancer is estimated to impact more than 2.1 million women each year. In 2018, reported by WHO, about 627,000 women died from breast cancer (approximately 15% of all cancer deaths among women). In some studies, garlic OSCs were demonstrated to affect the development and progression of breast cancer both in vitro and in vivo (Tsubura et al. 2011). Diallyl disulfide (DADS), one of the most important OCSs in garlic, was reported to regulate multiple cancer hallmark pathways involved in cell cycle, apoptosis, invasion, and metastasis in ER-positive and/or ER-negative breast cancers (Xiong et al. 2018). In addition, some other OSCs such as DATS (Puccinelli and Stan 2017), alliin (Izdebska et al. 2016), and SAMC (Zhang et al. 2014) were also reported to present multiple antitumor activities by inducing cell apoptosis and inhibiting cancer metastasis.

38.4.3.2 Digestive (Gastric, Colorectal, and Liver) Cancers

The preventive and therapeutic activities of garlic on digestive cancers have been widely investigated and reported. Garlic OSCs presented satisfied effects on management of various gastric, colorectal, and liver cancers through multiple biological mechanisms. Antioxidative, anti-inflammatory, antiproliferative, and apoptotic effects were demonstrated to be involved in the pharmacological and biological properties of garlic for digestive cancers (Nohara et al. 2017; Nicastro et al. 2015; Fukushima et al. 1997). In recent years, however, the relationship between garlic consumption and reduced risk of gastric and/or colorectal cancers was controversially reported by many studies (Wu et al. 2019; Guercio et al. 2014; Kim and Kwon 2009). Although long-term intake of OSC-enriched garlic products is considered to be beneficial for managements of digestive tract cancers, further epidemiological evidence needs to be conducted to better clarify the relationship between garlic intake and risk of digestive tract cancer occurrence.

38.4.3.3 Brain Cancers

The anticancer effects of garlic OSCs on brain cancers were investigated using various brain cancer models. Garlic OSCs (DAS, DADS, DATS, allicin, and *Z*-ajoene) were investigated to exhibit good effects to promote apoptosis of human glioblastoma cells (T98G, U87MG, SH-SY5Y, and U251) in vitro (Jurkowska et al. 2017) and prevent tumor progression in U87MG-xenografted mice in vivo (Wallace et al. 2013) through antiproliferation, apoptosis, anti-inflammation, and antioxidation. Moreover, for the high liposolubility in physiological fluid, some OSCs might easily cross through the blood-brain barrier and enter into the brain for treatment of brain cancers.

38.4.3.4 Lung Cancer

The anticancer effects of garlic OSCs were also investigated in lung cancer, using various lung cancer models (Nohara et al. 2017; Nicastro et al. 2015). The isolated sulfur-containing compounds of DADS, DATS, SAMC, and ajoene from garlic were found to be effective on lung cancers both in vitro and in vivo. Moreover, because of the volatile properties, OSCs might be pharmaceutically inhaled to be topically delivered to lung tissue thus presenting direct actions in treating lung cancers.

38.4.3.5 Other Cancers

Moreover, the garlic OSCs have been reported to present anticancer activities against some other cancers. DADS and DATS were observed to inhibit differentiation and induce apoptotic death of leukemia both in vitro and in vivo (Sun et al. 2019; Hung et al. 2015). Allicin, SAC, and SAMC were determined to suppress cell proliferation and differential responses of ovarian cancer (Wu et al. 2016).

38.4.4 Cardiovascular Protection

Cardiovascular protection is one of the most important functions for garlic-derived products. The protective effects of garlic on cardiovascular health have been long time investigated and reported (Zhu et al. 2018; Varshney and Budoff 2016). Numerous studies indicated that OSCs play pivotal role regarding the beneficial effects in reducing the risk of cardiovascular diseases (CVD) (Schwingshackl et al. 2016; Seki and Hosono 2015). Pharmacologically, OSCs could effectively prevent or improve CVD through multiple approaches, mainly including antihyperlipidemia (Ried 2016), antihypertension (Ried 2016), and antiplatelet aggregation and antithrombosis (Ariga and Seki 2006).

38.4.4.1 Antihyperlipidemia

Hyperlipidemia is a latent dangerous pathological factor to the development of atherosclerosis. Elevated serum total cholesterol (TC) and/or triglyceride (TG) and reduced high-density lipoprotein cholesterol (HDL-C) are the important clinical indicators for hyperlipidemia (Jain et al. 2007).

The lipid-lowering effects of garlic have long been focused by experimental and clinical attentions. Various in vitro (Chang et al. 2015; Lii et al. 2012) and in vivo (Yang et al. 2018; Annamalai et al. 2017) investigations indicated that garlic oil (high content of OSCs) could effectively improve hyperlipidemia through regulating serum TC and TG as well as HDL-C. However, in clinical trials, although some data are inconsistent (which might be duo to the lower doses of garlic used), the antihyperlipidemic effects of garlic were observed according to the results obtained from some meta-analyses. Compared to garlic, garlic powder and aged garlic extract were found to be more effective in reducing serum TC levels, while garlic oil was more effective in lowering serum TG levels (Zeng et al. 2012).

38.4.4.2 Antihypertension

Hypertension (HTN), high blood pressure, is a major modifiable risk factor for CVD. Unmanaged HTN might result to heart attack, stroke, chronic heart failure, renal failure, and some other problems (Drozdz and Kawecka-Jaszcz 2014). Since the bioactive properties of garlic on anti-HTN have been investigated to be analogous to those of certain standard drugs, garlic derivative (powder, extracts, oil, and/or OSCs) becomes one of the most studied functional food and is being widely used as dietary supplements by people worldwide for ameliorating HTN (Ried and Fakler 2014).

Based on numerous studies, multiple mechanisms underlying have been identified to be involved in the antihypertensive activities of garlic bioactive ingredients (Ushijima et al. 2018). The main mechanisms include (1) improvement of redox balance and cellular homeostasis; (2) suppression of NF-κB expression in endothelial cells; (3) lowering cytosolic and mitochondrial ROS concentration; (4) increasing H_2S production by modulating cystathionine c-lyase (CSE) activity; (5) stimulation of NO production in blood vessels to relax and improve elasticity of

vascular smooth muscle; (6) inactivation of renin-angiotensin-aldosterone (RAA) system by inhibiting angiotensin-converting enzyme (ACE) activity; and (7) prevention of excessive growth of vascular smooth muscle cells (VSMCs). Moreover, sulfur-containing compounds such as allicin, DADS, DATS, and S-allyl cysteine have been attributed to the antihypertensive activities of garlic (Ried and Fakler 2014; Shouk et al. 2014).

38.4.4.3 Antithrombosis and Antiplatelet Aggregation

Garlic has been reported to inhibit platelet aggregation through various mechanisms such as inhibition of cyclooxygenase activity thus leading to thromboxane A2 formation; suppression of calcium mobilizing into the platelets; and increase messenger (cAMP and cGMP) levels within platelets (Bradley et al. 2016; Qidwai and Ashfaq 2013). Moreover, garlic extract could also inhibit the aggregation of platelets by improving dissolution of clots and thrombi via fibrinolysis (Qidwai and Ashfaq 2013).

For example, simultaneously facilitated extracellular ATP and extracellular/intracellular TXB2, as well as suppressed collagen-induced ERK, p38, and JNK phosphorylation, were observed in aged garlic extract (AGE)-treated platelets, which suggested that AGE could suppress platelet aggregation by changing the functional property of platelets (Morihara and Hino 2017). Among the compounds of garlic, allicin and its self-condensation product (ajoene) were considered to be the primary substances responsible for the functions of antithrombosis and antiplatelet aggregation (Chan et al. 2013; Teranishi et al. 2003). All the evidence suggested the effects of OSCs on thrombosis and platelet aggregation for their potentials in preventing cardiovascular diseases.

38.4.5 Others

Except for the abovementioned biological activities, other pharmacological activities of garlic and garlic OSC products are also investigated and reported. The neuroprotection of aged garlic extract and SAC on improving inflammation-induced cognitive dysfunction was identified by in vivo examinations (Nillert et al. 2017; Zarezadeh et al. 2017). In addition, garlic extracts and OSCs (alliin, allicin, DADS, DATS, DAS, SAC, ajoene, and allyl mercaptan) presented great potentials to be developed as promising agents for the management of diabetics and its complications (Padiya and Banerjee 2013).

38.5 Benefits (Human Studies)

Due to the multiple bioactivities, the benefits of garlic and garlic OSCs to human health have been long-term investigated and observed. Among these studies, the benefits of garlic derivative products for preventive and therapeutic effects on cardiovascular diseases (CVD) and cancers are mostly concerned.

The association between uptake of garlic and reduction of CVD risks has been widely investigated and assessed by numerous clinical trials in humans (Zhu

et al. 2018; Varshney and Budoff 2016). Most studies demonstrated the main responsibility and importance of garlic OSCs in cardiovascular protection (Schwingshackl et al. 2016; Seki and Hosono 2015). The pharmacological effects of OSCs for treatment or prevention of CVD have been established to be closely related to its multiple bioactivities including antioxidation, anti-inflammation, immunomodulation, antihyperlipidemia, antihypertension, antiplatelet aggregation, and antithrombosis (Ried 2016; Zeng et al. 2012). In recent years, some emerging evidence indicated the cardioprotective and cytoprotective properties for hydrogen sulfide (H_2S) (Bradley et al. 2016). Since some garlic OSCs could be readily degraded into organic diallyl polysulfides (the potent donors for H_2S) in the presence of thiols, H_2S-dependent hypothesis might provide a new insight for garlic OSCs in preventing myocardial injury and dysfunction (Bradley et al. 2016).

The relationship between garlic consumption and reduced cancer risk is a subject of considerable controversy. Some studies reported the positive relevance between them (Wu et al. 2019; Guercio et al. 2014; Kim and Kwon 2009), while some results suggested the irrelevance. Whatever, the chemopreventive properties (inhibition of the processes of carcinogenesis through anti-inflammation, anti-transformation, and antiproliferation; effects on the final phase of carcinogenesis through inhibiting angiogenesis and metastasis) of garlic have attracted considerable attention in some adjuvant therapies for cancer control (Schäfer and Kaschula 2014). Currently, various garlic and garlic OSC products have been developed as adjuvant agents with immunomodulatory effects for decreasing the side effects and/or enhancing the therapeutic effects of some anticancer agents.

38.6 Application in Food

Garlic is an OSC-enriched dietary vegetable which is widely distributed worldwide. Various flavor foods of garlic could be found in the market of different countries. The most popular garlic foods include spicy pickled garlic, savory garlic, garlic spread, garlic rub, garlic powder, roasted garlic pieces, fried garlic clove, and fried minced garlic. The compositions and contents of OSCs in each product depend on the techniques during individual manufacturing process.

Garlic is widely used as food additive because of its aromatic smell and taste derived from OSCs. Garlic salt, spicy garlic mustard, garlic-infused white balsamic vinegar, various garlic pickles, and garlic-pickled mixed vegetables are the most representative garlic-containing foods sold in supermarkets. Moreover, garlic essential oil is also a commonly used flavoring in cooking.

38.7 Safety: Toxicity and Side Effects

To be a dietary vegetable, garlic is considered to be very safe. Currently, the available toxicological data about garlic and garlic-derived compounds are rather limited.

Reported by Kodera et al. (2002b), SAC presented very minor acute and subacute toxicities in mice and rats (LD_{50} value >54.7 mM/kg, po; and > 20 mM/kg, ip). In another toxicological study, propyl propane thiosulfinate was determined to be not mutagenic or genotoxic in vitro (Mellado-García et al. 2017). In a subacute study in rats, oral administration of high OSCs contained allium extract (0, 25, 100, 400 mg/kg/d) for 90 days, and no treatment-related clinical signs, mortality, or effects (biochemical, hematological, and histopathology parameters) were observed for all animals (Mellado-García et al. 2016).

In a clinical study, gastric administration of garlic powder was observed to induce immediate epigastric symptoms of pressure, stinging, and warmth, as well as fundic relaxation, but does not influence mechanosensitivity or compliance. This might be due to the presence of allicin in the powder (Führer et al. 2019).

38.8 Marketed Products

The OSC-enriched garlic derivatives (garlic powder, garlic oil, garlic water extract, and garlic alcohol extracts) are important raw or supplementary materials for nutritional, healthcare, and medicinal applications. Various garlic organosulfur-contained products have been commercialized in marketing. Some representative products as well as their chemical compositions, functions, and manufactures are listed in Table 3.

38.9 Patents

In the past years, numerous patents about the preparation methods and pharmacological and functional applications for organosulfur compounds have been applied and granted worldwide. Most of them are related to garlic and/or garlic derivatives. Up-to-date, over 20,000 patents for garlic and garlic derivative products have been granted in different countries and regions. Most of which are mainly distributed in China, the USA, Japan, and Europe (Table 4). The trends of the approved patents in different applications (2009.01.01–2018.12.31) in China, the USA, Japan, and Europe are illustrated in Fig. 2.

38.10 Perspectives

Plant-derived organosulfur compound (OSC) is one of the main sources of dietary sulfur and has been investigated to play important role in maintenance of human health. Garlic and its derivates are highly concerned and widely applied as the raw or supplementary materials in various nutritional, functional, and medicinal products because of their high contents of OSCs. The most investigated biological functions for garlic OSCs are mainly focused on antimicrobial, anti-inflammatory, antioxidant and immunomodulatory, and anticancer activities as well as cardiovascular protection. Although the current experimental evidence on the pharmacological activities

Table 3 Representative OSC-enriched garlic products in market

Products	Active ingredient	Functions	Manufacture
Doppelherz Garlic Capsules with Hawthorn	60 mg garlic essence,54 mg hawthorn extract	Clear blood, prevent cancer, improve immunity, prevent Alzheimer's disease	Doppelherz® (GERMAN)
Nutrilite® Garlic and Licorice	Three tablets per day provide 1000 mg of garlic bulb powder and 21 mg of licorice extract	Provides phytonutrient plant compounds for additional nutritional benefits; garlic and licorice are traditionally used to promote well-being	Nutrilite® (AMERICAN)
Nature Made® Odor Controlled Garlic Tablets	Each tablet contains 500 mg of concentrated garlic bulb	Help support normal blood cholesterol levels already within the normal range. The gentle release of garlic in the body results in virtually no after odor on the breath or on the skin	Nature Made® (AMERICAN)
The soft capsule of garlic essential oil of Tomson Beijian®	Takes garlic essential oil as the main raw material and contains 100 g of allicin, 1 g of which each contains 5 mg of allicin	Enhancing immune	Tomson Beijian® (CHINESE)
Mega Garlic Plus	Garlic powder extract 600 mg	Supports healthy circulation and heart health	Herbalife® (AMERICAN)
Odorless Super Garlic	Deodorized garlic bulb Powder (*Allium sativum*) 1000 mg, aged garlic bulb extract (*Allium sativum*), 100 mg	Supports cardiovascular health	GNC Herbal Plus® (AMERICAN)
Puritan's Pride Odorless Garlic & Parsley	500 mg/100 mg	Used for heart and cardiovascular function, respiratory health, contains breath-freshening parsley and the plant nutrient chlorophyll	Puritan's Pride
Pure Garlic	1,500 mg per softgel	Boost the immune system, supports cardiovascular health, promotes healthy cholesterol levels	NaturaLife Labs (AMERICAN)
Sundown Naturals Odorless Garlic	1000 mg, 250 odorless softgels	Facilitating better circulation and promotes good functioning of heart	Sundown Naturals (AMERICAN)
Nature's Bounty Garlic Extract	1000 mg, 100 rapid release softgels	Supports circulatory function	Nature's Bounty (AMERICAN)
Himalaya Garlic	Organic garlic powder (aerial parts) 750 mg, organic garlic extract (bulb) 650 mg	Garlic offers a broad range of body supportive mechanisms, supports normal cardiovascular	Himalaya (AMERICAN)

(continued)

Table 3 (continued)

Products	Active ingredient	Functions	Manufacture
		function, supports normal serum cholesterol levels	
Garlic (organically grown)	Proprietary blend 580 mg (garlic +parsley)	Supports healthy circulatory, liver, lung, and immune system function, provides antioxidant activity	Standard Process (AMERICAN)
The Garlic Lover	Organic canola oil, garlic essential oil	One spray while cooking, perhaps a second before you serve, will unleash the full flavor of herbs that will take your meals simply beyond	Eco-friendly (AMERICAN)
Odorless Garlic	1200 mg (250 softgels)	Support cardiovascular health, healthy circulation support and heart health support, also helps support healthy cholesterol levels within a normal range	Horbaach (AMERICAN)
Odorless Garlic	1000 mg Odorless garlic, 200 mg parsley seed oil, 56mcg chlorophyll	Support heart and cardiovascular health and may nutritionally help support cholesterol levels	BRI Nutrition (AMERICAN)
Garlic Complex	Garlic powder 1 g, spearmint oil 3 mg, rosemary extract 50mgs	Help retain normal cholesterol levels	Shaklee (AMERICAN)

Table 4 Distribution of the granted patents (2009.01.01-2018.12.31) for garlic and garlic-derived compounds in China, the USA, Japan, and Europe

	China	USA	Japan	Europe
Preparation methods	15,649	113	49	39
Medicinal applications	5227	379	313	105
Healthcare products	3647	98	222	12

on garlic OSCs is still limited, the potential functions of garlic derivatives on healthcare and disease prevention are well accepted for their long history in cultivation and traditional applications.

In chemistry, *S*-alk(en)yl cysteine sulfoxides (SACSs) are the precursor OCSs mainly presented in raw intact garlic and could be quickly degraded by enzyme alliinase into various stable small OCSs in chopped or crushed garlic. The compositions and contents of individual OCS in different garlic products were significantly different depending on the process of manufacturing. Therefore, development of the standardized processing methods for garlic derivative products and establishment of the internationally recognized standard for their quality control are necessary and urgent.

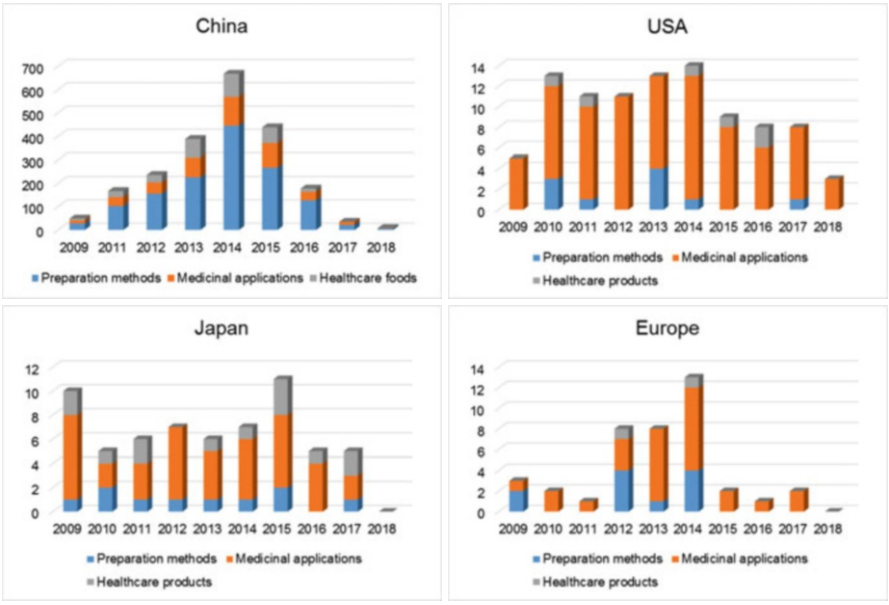

Fig. 2 The trends of the approved patents for different applications (2009.01.01–2018.12.31) in China, the USA, Japan, and Europe

On the other hand, although garlic is a traditional vegetable with good safety, some potential adverse reactions of garlic OSCs were observed and reported both in animals and in humans. The underlying toxicological mechanisms for the side effects and toxicities of garlic OSCs need to be further investigated and assessed thus ensuring the safety for their different applications.

Abstract

Ginseng and its active ingredient ginsenosides are valued for their medicinal properties. More than 100 ginsenosides have been identified from the different parts of the plants in the genus *Panax* and during the processing of the plants. Ginsenosides can increase longevity, reduce blood pressure, alleviate diabetes and cardiovascular diseases, and inhibit cancers. Ginseng is widely used to prepare porridge, soup, and tea. Ginseng products range from neutraceuticals and cosmoceuticals to functional food. No adverse effects of consuming *Panax ginseng* or its extract were observed.

Keywords

Ginseng · Ginsenosides · Anticancer · Anti-inflammatory · Functional food · Cosmoceuticals

39.1 Introduction

Ginseng is well-known to be beneficial to human health: reducing pathological symptoms and protecting against potential diseases. The term ginseng usually refers to the species *Panax ginseng* or more specifically to its root. Ginsenosides are the main active ingredients contributing to the health-promoting effects and are commonly used as a marker for the quality control of ginseng products.

39.2 Bioactive Constituents

Ginsenosides, also known as steroid-like saponins, are the major active pharmacological ingredients in ginseng species which include 14 plants (Table 1) in the genus *Panax*. There have been more than 100 ginsenosides identified, where ginsenosides Rb1, Rb2, Rc, Rd, Re, Rf, and Rg1 are the most abundant ones found in the roots of raw ginseng, while others are formed by chemical reactions during the processing of ginseng including by oxidation, hydrolysis, and dehydration as well as by the action of bacteria in the gastrointestinal tract on the orally administered ginseng (Shin et al. 2015). Table 2 lists the chemical formula and plant part of the ginsenosides isolated from *Panax ginseng*. Ginsenosides have a four-ring structure with carbohydrate moieties attached. Each ginsenoside has at least two or three hydroxyl (—OH) groups attached to carbon (C)-3, C-6, and/or C-20, which are free or bound to monomeric, dimeric, or trimeric carbohydrates. Stereoisomers exist, characterized by the position of —OH group on C-20.

Based on the chemical structures, ginsenosides can be classified into two groups: protopanaxadiols (PPD; 3b,12b,20-trihydroxydammar-24-ene) and protopanaxatriols (PPT; 3b,6a,12b,20-tetrahydroxydammar-24-ene). PPD-type ginsenosides such as Rb1, Rb2, Rc, Rd, Rg3, and Rh2 have carbohydrate moieties

Table 1 Plants in the genus *Panax*. Scientific name and common name for the plants in the genus *Panax*

Scientific name	Common name
Panax bipinnatifidus Seem	
Panax bipinnatifidus var. *angustifolius*	
Panax bipinnatifidus var. *bipinnatifidus*	
Panax ginseng C. A. Mey.	Asian ginseng, Chinese ginseng, Korean ginseng
Panax japonicus (T. Nees) C. A. Mey.	Japanese ginseng
Panax notoginseng (Burkill) F. H. Chen	Sanchi
Panax pseudoginseng Wall.	
Panax quinquefolius L.	American ginseng
Panax sokpayensis Shiva K. Sharma & Pandit	
Panax stipuleanatus H. T. Tsai & K. M. Feng	
Panax trifolius L.	
Panax vietnamensis Ha & Grushv.	
Panax wangianus S. C. Sun	
Panax zingiberensis C. Y. Wu & Feng	

attached to C-3, while PPT-type ginsenosides including Re, Rf, Rg1, Rg2, and Rh1 have carbohydrate moieties attached to C-6 belonging to PPT group (Fuzzati 2004). Pseudoginsenoside F11, a ginsenoside isolated from the roots and leaves of *P. quinquefolius* but not found in *P. ginseng*, also belongs to PPT group even though the carbon chain at the 20-position is replaced by a tetrahydrofuran ring. Figure 1 shows the structures of PPD- and PPT-type ginsenosides from *Panax ginseng*.

39.3 Bioavailability and Metabolism

Most ginsenosides are biosynthesized from 2,3-oxidosqualene which forms cycloartenol, dammarenediol-II, and β-amyrin through three different pathways and then transformed into β-sitosterol, dammarane-type saponins, and oleanane-type saponins, respectively. Dammarenediol-II is hydroxylated to generate PPD and is further converted to various saponins by O-glycosylation of PPD that involves the attachment of saccharides to C-3 and/or C-20. On the other hand, PPD may be further hydroxylated to form PPT and biotransformed to various saponins through O-glycosylation of PPT that involves the attachment of saccharides to C-6 and/or C-20. Ginsenosides Rb1, Rb2, Rc, and Rd are typical PPD found in the roots, flower buds, and leaves of *P. ginseng*, whereas Re and Rg1 are typical PPT. Dammarane-type saponins account for a significant portion of saponins in ginseng species; nevertheless, oleanane-type saponins except for ginsenoside Ro are rare.

Comparing *P. ginseng* and *P. quinquefolius*, the contents of ginsenosides Rb2, Rc and Rg1 are higher in *P. ginseng* than in *P. quinquefolius* while Rb1, Rd, and Re are higher in *P. quinquefolius* than in *P. ginseng*. Both Rb1 and Rg1 promote

Table 2 Ginsenosides from *Panax ginseng*. Chemical formula and plant part of the ginsenosides isolated from *Panax ginseng*

No.	Ginsenoside	Formula	Plant part/process

central nervous system (CNS) activities, but the effect of Rg1 is more potent. Therefore, *P. ginseng* with higher amount of Rg1 is a stimulant, while *P. quinquefolius* with more Rb1 is calming to CNS (Chen et al. 2008).

Some ginsenosides are formed from the peroxidation of PPD or PPT, mostly at or around the double bond between C-24 and C-25 with a hydroperoxyl group at C-26 or C-27, which can be reduced to hydroxyl group (Niki et al. 2005). Besides, some ginsenosides have a hydroperoxyl or hydroxyl group at C-24 and a double bond between C-25 and C-26. Some ginsenosides with a double bond between C-23 and C-24 have a hydroperoxyl or hydroxyl group at C-25. Regarding the possible geometric isomerism in compounds with a double bond between C-23 and C-24, the (*E*)-form isomers are more common than the (*Z*)-form.

The oxidative cleavage of the double bond of PPD, 23-hydroxyprotopanaxadiol, and PPT leads to the formation of an aldehyde with three fewer C atoms, yielding 3β,12β,20-trihydroxy-25,26,27-trinordammar-24-al (floralginsenoside Kb), 3β,12β,20,23-tetrahydroxy-25,26,27-trinordammar-24-al (floralginsenoside Kc), and 3β,6α,12β,20-tetrahydroxy-25,26,27-trinordammar-24-al (floralginsenoside Tb), respectively. The hydration of the double bond of PPD and PPT generates 25-hydroxyprotopanaxadiol and 25-hydroxyprotopanaxatriol, respectively. Steamed or heat processed, PPD- and PPT-type ginsenosides are deglycosylated and dehydrated at C-20 to form double bond either between C-20 and C-21 or between C-20 and C-22, where geometric isomerism presents in the latter case. The acid hydrolysis of PPD- and PPT-type ginsenosides result in the production of a six-membered ring containing oxygen, forming 3β,12β-dihydroxy-20,25-epoxydammarane (panaxadiol) and 3β,6α,12β-trihydroxy-20,25-epoxydammarane (panaxatriol). In addition, there are derivatives of 3β,6α,20-dihydroxy-12,23-epoxydrammar-24-ene or 6α,25-dihydroxy-20,24-epoxydammar-3,12-dione with the epoxy group present between C-12 and C-23 and between C-20 and C-24, respectively.

Ginsenosides are mostly metabolized by intestinal bacteria including *Bacteroides*, *Eubacterium*, *Fusobacterium*, and *Prevotella* when taken orally. PPD-type ginsenosides are deglycosylated at C-3 and PPD or compound K may

result, while PPT-type ginsenosides are deglycosylated at C-6 or C-20 and transformed to PPT or ginsenoside F1 (Fig. 2).

39.4 Bioactivities

39.4.1 Anti-inflammatory Effects

A number of ginsenosides have been demonstrated to exhibit anti-inflammatory effects. Ginsenoside Rb1 and its bacterial metabolite compound K also suppress the activations of nuclear factor-kappa B (NF-κB), IL-1 receptor-associated kinase

(IRAK)-1, IκB kinase-α (IKK-α), and mitogen-activated protein kinases (MAPKs) in lipopolysaccharide (LPS)-induced murine peritoneal macrophages and in 2,4,6-trinitrobenzene sulfuric acid (TNBS)-induced colitis animal model (Joh et al. 2011). Likewise, compound K inhibits intestinal inflammation by negatively regulating NF-κB signaling in dextran sulfate sodium-induced colitis animal model (Li et al. 2014a). Ginsenosides Rb2 and Rd inhibit NF-κB activation and tumor necrosis factor-alpha (TNF-α) expression, having neuroprotective effects in LPS-induced N9 microglial cells (Wu et al. 2007). Furthermore, ginsenoside Rd exerts neuroprotective effects in rats with transient focal cerebral ischemia through suppression of oxidative stress and inflammatory responses (Ye et al. 2011b). Ginsenosides Rb2 exhibits anti-inflammatory effects by decreasing the expressions of inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) and NF-κB activity in LPS-stimulated RAW264.7 cells and mouse liver (Kim et al. 2013a).

Ginsenoside Re lowers the expressions of interleukin-1β (IL-1β) and TNF-α, as well as NF-κB activation to protect against LPS-induced inflammation on macrophages and in TNBS-induced colitis mouse model (Lee et al. 2012). Ginsenoside Rg1 decreases the expressions of iNOS, COX-2, TNF-α, IL-1β, and NF-κB in LPS-treated BV-2 microglial cells (Zong et al. 2012) and suppresses NF-κB signal pathway in both LPS-stimulated RAW264.7 cells and mouse peritoneal macrophages (Wang et al. 2014b). Consistent with the in vitro results, ginsenoside Rg1 ameliorates alcoholic hepatitis (Gao et al. 2015) and TNBS-induced colitis (Lee et al. 2015) in animal models through suppressing NF-κB activation. Modulating inflammatory response and apoptosis, ginsenoside Rb1 protects from ischemia/reperfusion (IR) injury in livers from mice (Guo et al. 2011; Tao et al. 2014). Daily administration of ginsenoside Rg3 for 3 weeks alleviates LPS-triggered learning and memory impairments by inhibiting the inflammation in the rat hippocampus (Lee et al. 2013). Ginsenoside Rg5 has been shown to attenuate lung inflammation by suppressing NF-κB, TNF-α, IL-1β, iNOS, and COX-2 in LPS-stimulated alveolar macrophages and in the bronchoalveolar lavage fluid from LPS-injected mice (Kim et al. 2012).

Ginsenoside Rh1 has been demonstrated to exert anti-inflammatory effects: downregulating the expressions of COX-2 and iNOS in IFN-γ-treated BV2 microglial cells (Jung et al. 2010) and diminishing the serum levels of IgE and IL-6 in mice with atopic dermatitis (Zheng et al. 2011). In addition, ginsenoside Rh2 inhibits the activation of NF-κB and p38 MAPK in murine asthma model (Li et al. 2015).

39.4.2 Antidiabetic and Cardiovascular Effects

Ginsenoside Rb1 ameliorates homocysteine (Hcy)-induced endothelial dysfunction and oxidative stress in porcine coronary arteries (Zhou et al. 2005) and suppresses H_2O_2-induced senescence of human endothelial cells through eNOS-dependent mechanism (Liu et al. 2012). Ginsenoside Rb3 ameliorates isoproterenol-induced myocardial injury and heart function impairment in Sprague-Dawley (SD) rats through inhibition of oxidative stress (Wang et al. 2010a) and protects

cardiomyocytes against ischemia/reperfusion injury by suppressing JNK-mediated NF-κB pathway (Ma et al. 2014). Moreover, ginsenoside Rb3 decreases angiotensin (Ang) II-induced vascular smooth muscle cell (VSMC) proliferation (Wang et al. 2010b). Ginsenoside Rb3 exerted antidiabetic effects in alloxan-induced diabetic mice (Bu et al. 2012). Ginsenoside Rb3 also restores impaired endothelial function in renal arteries from spontaneously hypertensive rats ex vivo through suppression of oxidative stress and improvement of NO bioavailability (Wang et al. 2014a).

Ginsenosides Rb1 and Rg1 induce vasodilatation in mouse coronary arteries (Pan et al. 2012). Ginsenoside Rg3 administration improves islet function before islet transplantation and ameliorates both cytokine-induced damage and apoptosis in Balb/c mice (Kim et al. 2014). Ginsenosides Rg6, F4, Rk3, and Rh4 inhibit U46619-induced platelet aggregation (Lee et al. 2010a). Ginsenoside Re triggers NO production in human endothelial cells (Leung et al. 2007). Saponin extract from *Panax japonicus* alleviates myocardial infarction in SD rats through inhibition of NF-κB and MAPK signaling pathways with increased SIRT1 expression (Wei et al. 2014). Notoginsenoside R1, a ginsenoside found in *P. notoginseng*, inhibits hypoxia- and hypercapnia-induced vasoconstriction in isolated rat pulmonary arteries by decreasing ERK expression (Xu et al. 2014).

39.4.3 Anticancer Effects

Ginsenoside Rg3 exerts inhibitory effects to different cancer cells, for example, inhibiting the proliferation of prostate cancer cells (Peng et al. 2019) and suppressing the migration and invasion of liver cancer cells (Sun et al. 2019). Ginsenoside Rg5 suppresses cell proliferation and triggers apoptosis in retinoblastoma cells through inactivation of AKT pathway and downregulation of BCL2 expression (Cui et al. 2018) and protects against breast cancer by inducing apoptosis and autophagy in mice (Liu and Fan 2018). Ginsenoside Rh2 inhibits proliferation in lung cancer cells (Ge et al. 2017) as prostate cancer cell growth (Gao and Zheng 2018). Ginsenoside Rk3 has been shown to possess anti-esophageal cancer activity in the KYSE150 xenograft model (Liu et al. 2019). 25-Hydroxyprotopanaxadiol (25-OH-PPD) found in the ginseng fruit inhibits cell growth and proliferation in human prostate cancer cells (LNCaP and PC3 cells) as well as the tumor growth in a mouse PC3 xenograft tumor model (Wang et al. 2008). Ginsenoside compound reduces growth of lung cancer cells (Chen et al. 2019). Other ginsenosides like Rb2, Rd, Rh4, and Rk1 exert anticancer effects.

39.4.4 Potential Role in Neurodegenerative Disorders

Ginsenoside Rb1 inhibits local inflammation after cerebral ischemia in Sprague-Dawley rats (Zhu et al. 2012). Ginsenoside Rb1 also ameliorates cerebral IR injury by activating peroxisome proliferator-activated receptor-γ (PPARγ)/heme

oxygenase-1 (HO-1) (Yang et al. 2015) or by suppressing protease-activated receptor-1 (PAR-1) expression in rats (Xie et al. 2015). Ginsenoside Rd improves neuronal function in aged mice with transient middle cerebral artery occlusion (MCAO) (Ye et al. 2011a). Ginsenoside Rg1 induces neuroprotection in transgenic Alzheimer's disease mice (Fang et al. 2012). Furthermore, ginsenoside Rg5 suppresses acetylcholinesterase (AChE) activity and the expressions of COX-2 and iNOS while upregulates the expressions of insulin-like growth factor-1 (IGF-1) and brain-derived neurotrophic factor (BDNF) to improve cognitive function in streptozotocin (STZ)-induced Alzheimer's disease (AD) rats (Chu et al. 2014). Likewise, ginsenoside Rg5 and its metabolite ginsenoside Rh3 inhibit AChE activity and elevate BDNF expression and cAMP response element-binding protein (CREB) phosphorylation, reversing scopolamine-induced memory deficit in mice (Kim et al. 2013b).

39.4.5 Antioxidant Treatment and Alcoholism

Ginsenoside Rg1 exerts protective action against hepatic fibrosis induced by alcohol and CCl4 and antioxidant and anti-inflammatory effects in rat through upregulating Nrf2 expression (Li et al. 2014b). Ginsenosides Rg3 and Rh2 from Korean red ginseng (*P. ginseng*) suppress alcohol-induced oxidative injury through inhibition of MAPK pathway in mouse hepatocytes in vitro (Park et al. 2012).

39.5 Benefits

The PPT-rich ginseng extract (Ginseol K-g1) from *P. ginseng* is composed of ginsenosides Rb1, Rb2, Rc, Rd, Re, and Rg1 and is shown to decrease blood pressure after 4 weeks of treatment in a clinical study involving 90 subjects of age $>$ 20 years old with prehypertension or stage I hypertension (Rhee et al. 2014). Likewise, ginsenoside Rg3-enriched Korean red ginseng reduces central and peripheral arterial pressures in healthy individuals (Jovanovski et al. 2014a). In a randomized controlled trial including 16 healthy individual, the ginsenoside extract of Korean red ginseng (steamed *P. ginseng*) improves flow-mediated dilatation (Jovanovski et al. 2014b). North American ginseng extract lowers the DNA damage in lymphocytes obtained from healthy individuals at 90 min postirradiation (Lee et al. 2010b).

39.6 Application in Food (Inc. Correctly Cooking Food Rich in Phytochemicals)

As ginseng is valued for health benefits in various cultures globally, preparation and right cooking techniques play an important role in preserving the active phytochemical to be consumed. The Koreans has associated ginseng for centuries

to restore stamina; to increase longevity; to treat high blood pressure, diabetes, and cholesterol; and to be used as aphrodisiac. Being one of the largest producers of ginseng, Koreans enjoys the ginseng root as spice in food and tea.

The Samgye-tang, the Korean ginseng porridge, is prepared traditionally by soaking the glutinous rice in water for 2 h while cleaning the chicken by rubbing kosher salt before being rinsed under running water. Approximately, 5 cm of fresh ginseng should be silted to release its pungent flavor during cooking. Then, the ginseng root, red dates, garlic, cloves, and the soaked rice are stuffed into the chicken cavity. The feet of the chicken is tied with kitchen twine and placed in a soup pot filled with water. All these ingredients were left to simmer up to an hour before being enjoyed.

As Samgye-tang is widely enjoyed as Korean ginseng cuisine, in the west, ginseng chicken soup is famous among these traditional herb lovers. It is believed ginseng stores energy and promotes vitality. The ginseng chicken soup is prepared by blanching the chicken pieces in boiling hot water for 5 min and drained. Then, about 40 g of American ginseng, red dates, and the blanched chicken are placed in a pot and boiled over high heat for 10 min. The heat temperature is then lowered to reduce flame and to simmer for 40 min before wolfberries are being added. All these ingredients have to be cooked for another 20 min and then salt is added to taste.

Besides cuisine, ginseng is also made into beverages, being enjoyed mainly by the Chinese community. The ginseng chrysanthemum tea is prepared by boiling 50 g of chrysanthemum flower in a pot at reduced heat and by simmering for less than a minute. The flower is then strained. About 5 g of ginseng is added and simmered for another 5 min before the remainder of the ginseng is being strained. Rock sugar is added to taste and slowly heated until the sugar is dissolved. The tea is then cold to be served.

Insam-cha is another famous ginseng-based tea from Korea. This tea is prepared by peeling and slicing the ginseng into 7–8 thin slices. The ginseng is then coated with a generous amount of honey and let to rest for 15 min. Hot water is then poured over the prepared ginseng and let to steep for 10 min. The ginseng slices are then strained and highly aromatic tea is served at room temperature.

Moreover, the Canadian ginseng tea is prepared by adding 20 g of Canadian ginseng slices and then cleaned and placed in tea bag. In 1.5 liters of water, 20 g of chrysanthemum and the Canadian ginseng is simmered for 30 min before adding 1 tablespoon of soaked wolfberries. These ingredients are then simmered for 5 min before rock sugar is added to taste. The tea is enjoyed chilled or at room temperature.

39.7 Safety: Toxicity and Side Effects

The safety of ginseng consumption had been a topic of research interest since the 1970. For years, researchers had executed the in vivo and in vitro studies pertaining to toxicity and safety of ginseng around the world. Siegel (1979) had coined on “ginseng abuse syndrome.” He reported the undesired effect of ginseng

consumption on 133 patients with constant ginseng consumption up to 2 years. Majority of the correspondent experienced morning diarrhea (35%), skin eruption (25%), nervousness (25%), sleeplessness (20%), hypertension (17%), edema, decreased appetite, depression, and hypotension (10%). His research also concluded that the undesirable side effects manifested in prolonged consumption of high dose of ginseng. It is known that ginsenosides especially ginsenoside Rb1 and ginsenoside Rg1 from *Panax ginseng* display a variety of pharmacological and therapeutic effects on central nervous system (CNS) disorders and metabolic-related diseases such as cardiovascular disease, endocrine secretions, aging, and immune functions (Park et al. 2013; Ernst 2010). Through animal-based assay, Chan and co-workers (2011) had assessed the carcinogenic potential of *Panax ginseng* for 2 years under the US National Toxicology Program (NTP) which revealed that consumption of *Panax ginseng* is neither toxic nor tumorigenic. Park and co-workers (2013) had also studied the pharmacokinetics and bioavailability of ginsenosides based on animal model. Groups of male and female Sprague-Dawley rats were fed with extract of Korean red ginseng and *Panax ginseng* at various concentrations (0, 500, 1000, and 2000 mg/kg/day) for 4 weeks. This experiment revealed that there is no death or clinical abnormalities observed on experimental animal at highest dose of ginseng extracts administered.

Park and co-workers (2013) conducted 4 weeks of oral toxicity studies in rats to observe whether consumptions of Korean red ginseng could induce toxicity to humans. Groups of male and female Sprague-Dawley rats were fed with *Panax ginseng* extract with dose levels of 0, 500, 1,000, and 2,000 mg/kg/day for 4 weeks, orally. Overall, there were no deaths or clinical abnormalities observed among the experimental animal, and the results revealed that no observed adverse effect level of Korean red ginseng extract was established at 2,000 mg/day.

39.8 Marketed Products

As treasure for many reasons, products developed based on ginseng range from neutraceuticals and cosmoceuticals to functional food. As ginseng is rich in phytochemicals and antioxidant, it is believed to elevate mental and physical activities, to combat fatigue, to stimulate alertness, and to reduce signs of skin aging.

39.8.1 Ginseng-Based Beverages

Many organic energy booster formula incorporated *Panax ginseng*, to name a few, Ginseng Energy™ drink from Pakistan, Monster Taurine™ and ginseng energy drink from the United States, Orka Icelandic Ginseng Energy™ drink from Iceland, Elcro Red Ginseng Plus™, and Root9™ red ginseng drink from Korea. Variety of ginseng-based tea infused with lavender, chrysanthemum, and chamomile is enjoyed in many Asian countries as “vitality drink,” which is an alternative to energy drink.

39.8.2 Ginseng-Based Supplements

As ginseng is believed to elevate immune system, boost memory power, promote relaxation, and manage sexual dysfunction in men, various products were formulated to meet this demand, globally in many forms, from powder, capsules, and even droplets. To name a few brands, Yours Nutrition Korean Red Ginseng™ is formulated with concentrated ginsenosides in capsule form at 10% to boost immunity and energy and significantly reduce levels of stress. The Auragin Korean Ginseng™ is a supplement produced in Korea with each capsule containing 300 mg of 8% ginsenosides as active ingredient. The NuSci Panax Ginseng™ is formulated in powder form with recommended serving containing 12% of ginsenosides. Nature's Answer American Ginseng™ is formulated in liquid form and to be used as droplets. It is potent as it contains 2000 mg of ginseng extract constituting 75% of ginsenosides. It is recommended that a few drops of this liquid are needed to be diluted in a glass of water before consuming. The Solgar Korean Ginseng™ comes in capsule form containing 250 mg of Korean ginseng extract (8% ginsenosides).

39.8.3 Ginseng-Based Cosmoceuticals

The range of cosmoceutical products formulated based on ginseng roots are on rise globally. The *Panax ginseng* root extract contains high concentrations of phytonutrients that help to fight the effects of free radicals due to sun exposure and environmental pollution. As the science develop which can fight the effects of sun-induced free radicals from exposure to sunlight and environmental pollution. Ginseng root extract has anti-aging properties, helps to reduce the appearance of wrinkles, reduces collagen degradation induced by stress and environmental factors, brightens skin complexion, reduces dark spots, and protects the skin from solar UVB radiation (Kang et al. 2009; Hwang et al. 2017). This property is treasured as agents for modern age skincare products.

Among famous ginseng-based skincare brand is Sulwhasoo™, the Korean skincare brand had created the world first ginseng-based cosmetics, "The ABC Ginseng Cream" as early as 1966 followed by Dr. Pierre™ catering ginseng based exfoliating gel to lotions. While ORIGINS™ had formulated GinZing™, the refreshing ginseng-based eye cream. The NutraChamps Korean Panax Ginseng™ is a vegetable-based capsule with rice flour as filler containing 5% of ginsenosides. This product is formulated for stress-calming and acne-clearing purposes. The aSquared Nutrition™ capsules are formulated using *Panax ginseng* which comes in a capsule of 500 mg. It is believed that aSquared Nutrition™ capsules could prevent common cold and improve mental arithmetic and are a top quality ginseng supplement for acne.

39.9 Patents

According to the World Intellectual Property Organization (WIPO), a patent is an exclusive right granted for an invention of a product or a process that provides a new way of doing something or offers a new technical solution to a problem. The patent

is granted when the technical information pertaining to the invention is disclosed to the public upon patent application. Currently, the application patent rights regarding ginseng-based products or methods pertaining to ginsenoside extraction from various ginseng species is widely available and on increasing trend. Among the registered patent rights found globally is stated in the Table 3.

Table 3 Patent application on ginseng-based products or ginsenoside extraction methods

Year	Patent ID	Country issued	Product or method patented
1979	US4157894A	United States	Production and analysis of ginseng root extract
1987	US5071839A	United States	Safe pharmaceutical composition for decreasing side effects of antiviral drugs and increasing the immune function (SDI) II
1993	US5230889A	United States	Enriched nutritious food product comprising powder of ginseng and method for producing powder of ginseng
2001	EP0831864A1	Korea	Processed ginseng having enhanced pharmacological effect
2001	US6326202B1	United States	Stable high ginsenoside-yielding callus line of *Panax quinquefolius* (American ginseng) and a method for developing such stable high ginsenoside-yielding callus line
2003	US20030077341A1	United States	Processes of making North American ginseng fractions, products containing them, and use as immunomodulators
2004	WO2005070235A1	Korea	A drink containing ultrafine powder of ginseng and the method thereof
2005	WO2005120535A1	Korea	Composition comprising ginsenosides for treating or preventing angiostenosis and restenosis
2007	CN1656949A	China	Five-ginseng health-care cigarette
2000	WO2000064278A1	Japan	Ginseng berry health products
2008	US7824716B1	United States	Herbal women's health formula.
2010	US8337821B2	United States	Composition for treatment of hyperhidrosis
2010	CN102139013A	China	Health-care tonic wine for strengthening yang
2010	US20110045129A1	United States	Plant extracts (ginseng species) as additives for yeast-raised baked good
2011	CN102139013ACN102302078A	China	Ginseng soft sweets and production process thereof

(continued)

Table 3 (continued)

Year	Patent ID	Country issued	Product or method patented
2011	WO2011062332A1	Korea	A method for extracting ginsenoside-abundant extract from ginseng by using weak alkali water
2011	CA2480438C	Canada	Novel use of the extract of processed ginseng and saponin isolated therefrom
2011	WO2011043564A2	Korea	Composition containing black ginseng extracts for preventing or treating liver cancer
2012	CN102948750A	China	Stranded *Radix puerariae* pseudo-ginseng *Lilium brownii* capsule
2013	WO2013012180A2	Korea	Production method for a red ginseng liquid concentrate having boosted levels of ginsenoside rg3 and rh2
2013	WO2015029134A1	Japan	Ginsenoide composition is derived from ginseng and particulary useful as a concoction for oral use
2013	CN103082261A	China	Ginseng root condiment manufacturing method
2015	EP2152281B1	Korea	Cosmetic use of ginseng berry extract for skin whitening
2016	CN105815717A	China	*Vaccinium bracteatum* Thunb. fruit flavor red ginseng fruit jam
2017	CN103565679A	China	Fresh ginseng extract preparation method and application of fresh ginseng extract in cosmetics
2017	CN107518401A	China	Red ginseng and blueberry cream and preparation method thereof
2017	CN104593178A	China	Multifunctional handmade soap containing rare ginseng saponins
2019	CN100452995C	China	Active American ginseng health-care beverage and fruit tea

39.10 Perspectives

Ginseng is a one of the key medicinal ingredients in traditional Chinese medicine. Belonging to the family Araliaceae, the name *Panax* was derived from a Greek word meaning “all-healing.” The *Panax* family constitute of various species known species, *Panax ginseng*, *Panax quinquefolius* (American ginseng), *Panax notoginseng*, and *Panax japonicus* (Japanese ginseng). Mainly valued for its roots, these species of ginseng have economic values reaching US$ 300 million globally. Although there is a wide debate and skeptical views on usage and consumption of ginseng, this traditional herb will be treasured for many generations.

Abstract

Proanthocyanidins (PAs) found in fruits, cereals, beans, nuts, and spices, are colorless, oligomeric, and polymeric plant secondary metabolites formed from flavan-3-ol molecules. The complexity of final structures depends on the hydroxylation pattern, and location and stereochemistry of the interflavan linkage between extension and end units. PAs exert a wide range of biological activities (antidiabetic, anticancer, antithrombotic, beneficial in cardiovascular disorders, urinary tract infections, or ADHD) which were well documented in in vitro assays and in in vivo animal models, but also were verified in clinical studies involving human subjects. Interestingly, only 5–10% of the total ingested PAs are absorbed in the small intestine, the majority undergoing microbiota modifications. Hence, the beneficial effects proved for PAs consumption should be rather attributed to metabolites formed by the colonic microbiota. PAs can be recovered as added value products from food industry wastes like cocoa beans, grapes, tea, strawberries, raspberries, nuts, cranberries, cocoa beans, cinnamon, apples, and apricots being produced in millions of tons each year worldwide. The abundance of PAs and their common occurrence in food products make this group of plant secondary metabolites a very valuable reservoir of active principles which contribute to human wellbeing and health.

40.1 Introduction

Proanthocyanidins (PAs, also termed condensed tannins) are colorless, oligomeric, and polymeric plant secondary metabolites formed from flavan-3-ol molecules (Khanbabaee and Van Ree 2001; Santos-Buelga and Scalbert 2000), which can be also substituted by methyl, acyl, galloyl, or glycosyl moieties (He et al. 2008). PAs, being considered the second most abundant group of natural phenolics after lignin (He et al. 2008), were discovered in 1947 by French doctor Jacques Masquelier (Masquelier 1987; Passwater 1991). Masquelier's research on PAs was inspired by finding that crew of famous explorer Cartiers was cured from scurvy with tea made from needles and bark of pine, served by native Canadians (Carper 1998). During his work for PhD thesis, Masquelier extracted a colorless fraction from the red-brown

skin of peanuts and confirmed its biological activity as vitamin P. He also proposed that major components of this fraction are oligomers of flavan-3-ol units (oligomeric procyanidins, OPCs) (Weseler and Bast 2017). OPCs derived from peanut skins were then successfully marketed as a blood vessel protectant, and in 1969, Masquelier obtained a US patent for the extraction of OPCs from pine bark and grape seeds and for its medical application (Masquelier 1987; Passwater 1991). Since that time, PAs were extensively studied in terms of structure elucidation and biological activities and over 200 oligomers with degree of polymerization (DP) up to 5 have been described (He et al. 2008). In plant material OPCs are accompanied by PAs with higher DPs reaching even 30 building blocks in grape seeds or black soybean seed coat (Takahata et al. 2001).

Proanthocyanidins are widely distributed in roots, wood, bark, leaves, fruits, and seeds of many herbaceous and woody plants and, most importantly, in variety of edible plants consumed in a daily diet (Engström et al. 2014). Fruits (apples, apricots, avocado, banana, berries, cherries, dates, grapes, kiwi, mango, pears, plums), cereals and beans (barley, beans, cocoa, sorghum, pea), and nuts and spices (cinnamon and curry) contribute to the everyday intake of PAs. Also, snacks and beverages (chocolate, fruit juices, red wine, and beer) are good sources, especially, of OPCs (Prior and Gu 2005). The most important plant species containing PAs are presented below.

40.1.1 *Pinus pinaster* Aiton (syn. *Pinus maritima* Lam)

Pinus radicata D.Don (syn. *Pinus insignis* Douglas ex Loudon) *Pinus massoniana* Lamb

The bark and leaves of pine species and also of other conifers were used as a natural remedy since ancient times. Pine bark served as a food source in emergencies, while its decoction cured scurvy indicating that some of active ingredients correspond to the action of vitamin C. Application of the bark of spruce, pine, and juniper for wound healing was also known at that time (Li et al. 2015). The bark, needles, pollen, and turpentine of *P. massoniana* have been used in traditional Chinese medicine as a remedy for a treatment of hemorrhages, rheumatism, arthralgia, inflammation, and cancer (Cui et al. 2005). Due to the presence of flavonoids, catechins, phenolic acids, but mainly proanthocyanidins (non-conjugated procyanidins B1 and M1 (formed in vivo from catechin polymer by gut microbiota)) (Jerez et al. 2007), the extract of pine bark has found wide application in the fields of nutrition and health. Over the past few decades, it has been used in poor blood vessel conditions (Li et al. 2015). The procedure of preparation of standardized water extract from pine bark was patented and product obtained from *P. pinaster* was marketed worldwide under the trademark Pycnogenol®, while extract from *P. radiate* was named Enzogenol®. The variety of properties (antioxidant, anti-inflammatory, anticarcinogenic, cardioprotective and neuroprotective) was studied for these marketed extracts and strong synergistic activity of a mixture was observed

comparing to individual components (Yoshida et al. 2011) underlining beneficial properties of OPCs.

40.1.2 *Theobroma cacao* L.

Theobroma cacao L. is the most widely cultivated among over 20 species in genus Theobroma. It is a source of cacao beans, which were of historical importance in Mesoamerican culture. Cacao drinks were known and popular in Aztec royalty, while beans were used as currency well into the nineteenth century in remote parts of Mesoamerica (Steinberg 2002). Cacao drinks served as a primary remedy or as a vehicle to deliver other medicines. Among over hundred documented traditional uses of cacao, the application for improvement of digestion and elimination, for stimulation of nervous system and induction of weight gain in emaciated patients was the most common (Dillinger et al. 2000). Lower rates of hypertension, cardiovascular disease, obesity, diabetes mellitus, myocardial infarction, stroke, and cancer were observed among native people drinking daily higher amounts of cacao (Katz et al. 2011). The beneficial effects of cacao consumption are related to the action of OPCs (e.g., dimeric procyanidins B1 to B7, trimeric procyanidin C1, tetrameric procyanidin (cinnamtannin A2), and pentameric procyanidin (cinnamtannin A3)) (Esatbeyoglu et al. 2015), which were proved to be more potent than monomeric and polymeric cocoa procyanidins (Dorenkott et al. 2014). The astringent and bitter taste of cacao is also related to the high content of PAs.

40.1.3 *Vitis vinifera* L.

The primary and traditional use of *Vitis vinifera* is wine-making. During this process the pomace containing grape seeds and skin is produced. As being a side product pomace usually was discarded, however, it is a rich source of PAs. Pomace major fraction constitute polymeric procyanidins (PPCs) (65% and 83% in grape seeds and skins, respectively) which are accompanied by lower content of monomeric and OPCs (35% and 17% in grape seeds and skins, respectively) (Luo et al. 2018). The medicinal uses of *V. vinifera* date back to ancient times. European folk treated sore throats with unripe grapes, while dried fruits were used to heal constipation. For such complaints like cholera, smallpox, nausea, eye infections, skin, kidney, and liver diseases, fresh, ripe grapes were used (Badet 2011). Nowadays grape seed extract composes the majority of dietary supplements in the market containing phenolics. It is usually added in the quantity from 50 to 100 mg per capsule, tablet, or granule. Grape seed extract also found application in cosmetics dedicated to skin care and is widely added into different kinds of foods. The pharmacological effects exerted by grape seed extract such as antidiabetic, anti-inflammatory, lowering blood pressure, or reducing plasma cholesterol are related to the presence PPCs and OPCs with B-type linkages (Ashraf et al. 2015; Choy et al. 2013).

40.1.4 *Vaccinium macrocarpon* Aiton

Wild cranberries were discovered by Native Americans, who used its fruits as a food, fabric dye, and a traditional medicine. The primary medical application of cranberries was treatment of bladder and kidney ailments by American Indians (Boon and Smith 2004). Sailors used berries to prevent scurvy. Wounds and blood poisoning were also cured with cranberry fruits poultice (McKay and Blumberg 2007). Till now, cranberries are commercially grown in Canada, the USA, South America, and Europe. The fruits are usually processed before consumption due to low content of sugar and high amount of organic acids and PAs giving berries characteristic tart and astringent taste. Dried cranberries are popular snack and can be found as an ingredient in baked goods, bars, smoothies, trail mixes, cereals, and juice blends. Fresh berries are used for production of juices, jams, and sauces. The folk knowledge about *V. macrocarpon* usefulness in the treatment and prevention of urinary tract infections has been supported by numerous scientific evidence. The bioactive compounds found in cranberry juice are A-type proanthocyanidins, which were proved to inhibit the adhesion of *Escherichia coli* to the epithelium in urinary tract. The direct consequence of the interaction between bacteria and PAs is the inhibition of bacterial biofilm formation (Howell et al. 2005).

40.1.5 *Cinnamomum verum* J.Presl (syn. *Cinnamomum zeylanicum* Blume)

Cinnamomi cortex (the inner bark of Ceylon cinnamon) is known as a spice since the Middle Ages. Earlier, in ancient Egypt, it was used to embalm mummies and to burn in temples and during funerals. In the Middle Ages, cinnamon and other spices were transported by Arabs to Alexandria, Egypt, and then shipped to Europe (Gunawardena et al. 2014). In that time, cinnamon powder was an ingredient of medicines for sore throats and coughs. It was traditionally applied to heal toothaches, dental problems, and bad breath. The known folk application of cinnamon was intestinal spasms, nausea, stomach cramps, indigestion, loss of appetite, or diarrhea (Gunawardena et al. 2014). The effectiveness of cinnamon in prevention and treatment of type 2 diabetes, cancer, and inflammation has recently been shown. Its hypotensive and cholesterol-lowering effects were also promising (Mateos-Martín et al. 2012). Besides its medicinal usefulness, essence and aroma industries use cinnamon in cosmetics and perfumes and in different varieties of foodstuffs due to its characteristic fragrance and flavor. Some activities of cinnamon are attributed to volatile compounds present in the bark; however, majority of studied health benefits was associated with proanthocyanidins, which are main polyphenolic fraction found in commercial cinnamon. Cinnamon PAs are polymers with a degree of polymerization up to 11 and with a high proportion of A-type linkages (Mateos-Martín et al. 2012).

40.1.6 *Sorghum bicolor* (L.) Moench

Sorghum is a drought-tolerant crop, nowadays commonly produced in semi-arid regions of Africa, Asia, Australia, and North and South America. The earliest findings of wild examples of sorghum grains comes from circa 800–600 BCE from Qasr Ibrim in Egyptian Nubia. It was domesticated no earlier than CE 100 (Zohary and Hopf 2000). Traditionally sorghum was grown for grain; however, besides this primary need of food, now sorghum is also used for forage and sugar (sweet stalk) production. The bioactive compounds (polyphenols and lipids) are mainly located in the bran fraction of sorghum grains. These compounds are accompanied with the abundant cell wall polysaccharides and contribute significantly to the health benefits attributed to whole grain intake (Girard and Awika 2018). Consumption of sorghum grains is related to reduction of oxidative stress and chronic inflammation, prevention of cancer, improvement of glucose metabolism, prevention of insulin resistance, and improvement of lipid metabolism (Girard and Awika 2018). The PAs fraction in sorghum constitutes up to 5%, what is tenfold higher than in other grains. It is composed of catechin/epicatechin oligomers and polymers with the degree of polymerization up to 20 (Girard and Awika 2018).

40.2 Bioactive Constituents

PAs present a wide structure variability which is determined by stereochemistry at the chiral centers and the hydroxylation pattern of flavan-3-ol units. 2*R*-type flavan-3-ols are predominantly produced by plants whereas S*R*-type flavan-3-ols can rarely be found in monocotyledons and in selected dicotyledonous families like *Rhus*, *Uncaria*, *Polygonum*, *Raphiolepis*, and *Schinopsis* (He et al. 2008). The location and stereochemistry of the interflavan linkage between extension and end units as well as degree of polymerization (DP) also influences the complexity of final oligomeric and polymeric structures (He et al. 2008). Two main types of linkages between monomer units can be observed: A-type, when C2 position of the upper unit is linked to the oxygen at C7 or C5 position of the lower unit and C4 position of the upper unit is linked to the C8 or C6 of the lower unit (Fig. 1), and B-type, when C4 position of the upper unit is linked to the C8 or C6 of the lower unit (Fig. 2). Mixed-type PAs combine both kinds of linkages, which can be either α or β (Fig. 3) (He et al. 2008). The clear nomenclature of PAs includes corresponding flavan-3-ol monomers and indicates the configuration (described as α or β), location, and direction of interflavan linkage using parentheses with an arrow (→). The examples of names of oligomers are presented on Figs. 1, 2, and 3.

The chemical term proanthocyanidins suggests they can produce anthocyanins. Indeed, catechin- and epicatechin-based oligomers or polymers are known as procyanidins because upon acid hydrolysis they yield anthocyanin aglycon cyanidin. Similarly, gallocatechin- and epigallocatechin-based polymers (prodelphinidins) are the source of anthocyanin aglycon delphinidin. The other subgroups of PAs classified according to the hydroxylation pattern are presented in the Table 1. Among these

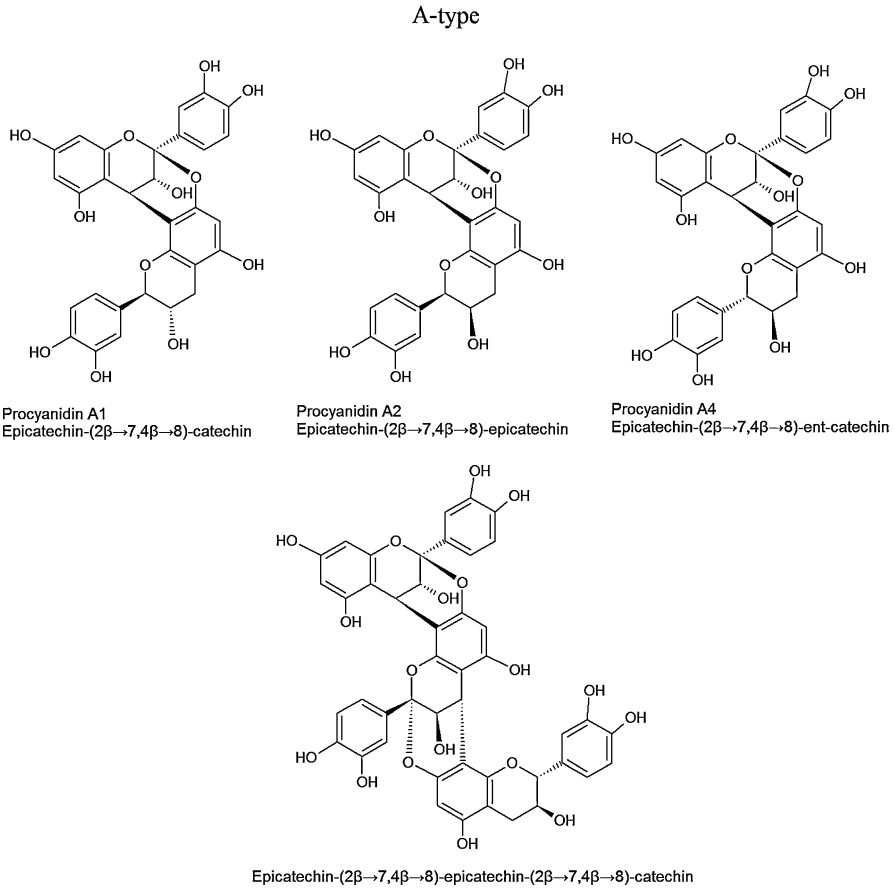

Fig. 1 The structures of A-type proanthocyanidins

subgroups, procyanidins are the most common one. Mixed polymers composed of several types of units can also be found in nature (He et al. 2008; Sieniawska and Baj 2016; Wallace 2010). The main bioactive constituents of plants rich in PAs are presented in the Table 2.

40.3 Bioavailability and Metabolism

Although the beneficial effects have been observed as a result of dietary PAs intake, a more in-depth knowledge of their metabolic pathways in human and animals is still necessary. The low absorption rate of PAs is well-known and can lead to favorable direct activity in the gastrointestinal tract. PAs are found in both forms of oligomers and polymers, but polymers are the most abundant in foods. While oligomers are absorbable *in vivo*, the high molecular weight of the polymers determines their poor absorbability in the gastrointestinal tract.

After ingestion procyanidins undergo metabolic modifications in the gastrointestinal tract. These modifications take place from mouth to colon and result in smaller oligomeric molecules or metabolites with higher bioavailability and thus higher *in vivo* bioactivity.

40.3.1 Influence of Saliva and Gastric Juice

It is known that the first organ involved in the modification and digestion of PAs is the small intestine. However, the role of the two fluids encountered before reaching the small intestine (saliva and gastric juice) must be investigated.

Even though PAs are not metabolized in the oral cavity, however, studies on the role of saliva in altering their structure have been conducted (Zanotti et al. 2015). PAs interactions with salivary proteins were investigated in a study using synthesized procyanidin dimers, C1 trimer, (−)-epicatechin O-gallate, and B2-3″-O-gallate from grape seeds. The results showed a higher tannin-specific affinity to saliva proteins of (+)-catechin, as well as of procyanidin dimers linked through a C4–C8 interflavan bond (de Freitas and Mateus 2001).

In a study conducted on green tea extracts of 5.0 mg/ml administrated as mouth rinse solution for caries prevention, it was found that, eight catechins were retained in saliva at μg/ml levels after 1 h (Tsuchiya et al. 1997).

Because the pH of the gastric juice generally varies between 1 and 3, it is necessary to know the behavior and stability of PAs in such an environment. Two hypotheses may be taken into account: acidic conditions lead to the degradation of PAs to monomers, and as a result, they would not get intact in the small intestine, or PAs are stable under acidic conditions, and in this case, they can be absorbed into the small intestine and detected in the plasma (Zhang et al. 2016). *In vitro* studies have been initiated to simulate the conditions encountered in the stomach, thus constituting a good indicator of the potential bioavailability of procyanidins *in vivo* (Spencer et al. 2001). The results showed that at pH ranging from 1.8 to 2, (−)-epicatechin

was stable, while B2 dimer and procyanidins oligomers degraded into (−)-epicatechin, and dimers and monomers, respectively; on the contrary, while procyanidins oligomers were stable at alkaline pH, (−)-epicatechin and B2 dimer were unstable, and at nearly neutral pH, the latter was stable (Zhu et al. 2002; Kahle et al. 2011; Spencer et al. 2000; Zhang et al. 2016).

The results obtained in *in vitro* studies have not been completely confirmed *in vivo*. On the one hand, the number of such studies is still very small, and on the other hand, besides pH influence, the food matrix may play an important role in PAs digestion as well. In a study conducted by Rios et al. (2002), six human subjects consumed 500 ml of cocoa beverage containing 733 mg of OPCs. At pH of 6.5 monomers, dimers B2 and B5, C1 trimer, as well as oligomers had similar HPLC profiles in the gastric content extracts and in the cocoa beverage indicating that most of the ingested procyanidins reached the small intestine as intact molecules. This could be explained by the higher pH value (5.4) determined by the food bolus.

40.3.2 Metabolism in Small Intestine and Colon

The pathways of PAs absorption can be through the stomach or intestine. However if not absorbed at this level, PAs reach colon and undergo the modification by the microbiota. During this process, PAs come under catabolic or conjugation reactions, then pass into blood, and are subsequently eliminated either through the urinary bladder or through the bile; some unabsorbed ones are eliminated through feces.

Although the small intestine is considered the first organ involved in PAs digestion, there is no evidence of mammalian enzymes that can degrade this type of high molecular weight molecules. It has been estimated that only 5–10% of the total ingested polyphenols are absorbed in the small intestine. The rest is accumulated almost intact in the large intestine (Zanotti et al. 2015). In fact, only procyanidin B2 was found to be absorbed intact. In a study investigating the possibility of quantifying the plasma levels of procyanidins after consumption of a flavanol-rich cocoa, Holt et al. (2002) detected procyanidin dimer in the plasma of human subjects after 0.5 h. The concentration reached a maximum at 2 h after consumption (16 ± 5 nmol/L, 41 ± 4 nmol/L, respectively). The other oligomers, with higher polymerization degree, reached colon and were metabolized by the colonic microbiota (Williamson and Clifford 2017).

Because PAs are absorbed in the small intestine in small proportions, a massive accumulation of several hundred micromoles/l is obtained in the colon (Choy and Waterhouse 2014). The behavior of procyanidins oligomers and polymers in the colon is not fully elucidated, and the results of the studies are sometimes contradictory. However, it has been demonstrated that metabolites with lower molecular weight, such as phenyl valerolactone, phenylacetic acids, and phenylpropionic acids, result after procyanidins are catabolized by colonic microflora (Zhang et al. 2016). The potential biological effects of procyanidins are attributed to these gut

Table 3 Metabolites produced by colonic bacteria

PA source	Compound	Metabolites	References
Grape seed	PAs	Hydroxyphenyl acetic acid, Hydroxyphenyl valeric acid	Zhang et al. 2016
Litchi chinensis	PAs dimer A2 Cinnamtannin B1	3,4-Dihydroxyphenylacetic acid and 3-hydroxyphenylpropionic acid, 4-hydroxyphenylacetic acid, 3-hydroxyphenylpropionic acid, and 3,4-dihydroxyphenylacetic acid.	Zhang et al. 2016
Cocoa	(−)-Epicatechin	(−)-Epicatechin-3′-O-glucuronide	Zanotti et al. 2015

Cocoa	Dimers and other procyanidin oligomers	Epicatechin monomers	Holt et al. 2002
Green tea	Monomeric or dimeric flavan3-ols	Glucuronide, hydroxybenzoic acid, hydroxyphenylacetic acid, hydroxyphenylpropinoic acid, hyrdroxyphenylvaleric acid, hydroxycinnamic acids	Choy and Waterhouse 2014

microbiota metabolites, rather than parent compounds. The metabolites described are presented in Table 3.

In a study conducted on rats by Baba et al. (2001), urine absorption and excretion of (−)-epicatechin was monitored. After administration of both, cocoa powder (in different doses) and equivalent doses of the (−)-epicatechin, the sum of metabolites of (−)-epicatechin in plasma and urine, excreted after 18 h postadministration, was measured. The results showed a linear dose increase and, moreover, an equal level of the amount of (−) epicatechin metabolites in the urine for both types of administration.

Opposite results have been obtained by Donovan et al. (2002), in a study in which the rats were fed with catechins, procyanidin B3 dimer, and grape seed extract containing catechin, epicatechin, and a procyanidin mixture at a single meal. The results showed the presence of catechin and epicatechin conjugated forms, but the absence of procyanidins or their conjugates in plasma and urine. Also, the mixture present in the grape seed extract showed no bioavailable monomers or any effects on plasma levels or urinary excretion.

The microbial metabolism of two A-type procyanidins, procyanidin A2 and cinnamtannin B1, was studied by incubation in a pig cecum model. It was found that both A-type procyanidins were degraded by the microbiota; the procyanidin A2 was degraded by about 80%, while cinnamtannin B1 about 40% after 8 h of incubation. The main identified metabolites were 3,4-dihydroxyphenylacetic acid and 3-hydroxyphenylpropionic acid and 4-hydroxyphenylacetic acid, 3- hydroxyphenylpropionic acid,

and 3,4-dihydroxyphenylacetic acid, respectively (Zhang et al. 2016; Engemann et al. 2012).

In a comparative study conducted *in vitro* and *in vivo*, Serra et al. (2011) investigated colonic metabolism for catechin, epicatechin, B2 dimer, epicatechin gallate (EGC), and epigallocatechin gallate (EGCG) by incubating each individual standard with rat fecal suspension for 48 h, by fermenting a cocoa cream with high-procyanidins content, previously digested by *in vitro* digestion, and also by *in vivo* analysis of rat large intestine and intestinal content after a single intake of the same nuts – cocoa cream. The results allowed the assumption of the existence of two metabolic pathways – dehydroxylation and rupture of the 1–2 bond of the C ring – considering the presence of diarylpropan-2-ol and 5-(3,4-dihydroxyphenyl)-c-valerolactone in the catechin and epicatechin fermentation mediums. The metabolism of ECG and EGCG did not yield the equivalent valerolactone with three hydroxylations, and the metabolites of dimer B2 differed from the ones of epicatechin, phenylacetic, and 4-hydroxyphenylacetic acids being the only common metabolites. *In vivo* verification of the metabolic pathways led to the quantification of phenylacetic acid, 3-hydroxyphenylacetic acid, and 4-hydroxyphenylacetic acid as main metabolites and of two valerolactones 5-(hydroxyphenyl)-c-valerolactone and 5-(3,4-dihydroxyphenyl)-c-valerolactone in lower levels.

Several *in vivo* studies were conducted in order to detect the microbial-derived metabolites in urine, after intake of procyanidins-rich diets. As a result, an increase in 3,4-dihydroxyphenylacetic acid and 3,4-dihydroxyphenyl-γ-valerolactone was found in rats' urine after being fed with procyanidin B3, but neither parent compound nor catechin derivatives could be detected (Choy and Waterhouse 2014; Gonthier et al. 2003). In case of procyanidin trimer C2 intake, the main metabolites found in urine were 3- hydroxyphenylvaleric, 3-hydroxyphenylpropionic acid, and m- coumaric acids (Gonthier et al. 2003). In another study, the absorption of procyanidins was investigated, after apple peel extract was administrated to rats catechin, epicatechin, procyanidin B1 and B2, and procyanidin C1 were detected in rat's plasma, with a maximum level registered at 2 h after administration, and decreasing after until 24 h (Shoji et al. 2006).

In a study investigating the structurally related –(−) epicatechin metabolites present in human systemic circulation, after the consumption of a cocoa dairy-based drink containing –(−) epicatechin, Ottaviani et al. (2012) identified –(−)epicatechin –glucuronide, –(−)epicatechin sulfates as the main metabolites in humans, reaching a maximal plasma levels at 2 h after consumption of the test drink (589 ± 85 nM, and 331 ± 26 nM, respectively). Also unmetabolized –(−)epicatechin was detected in circulation but at low concentration of about 4 nM at 1 h after drink consumption.

Having complicated structures and high molecular weight, the absorption of procyanidins in the small intestine is very ineffective, and therefore the colon remains the main organ responsible for the bioavailability of the dietary procyanidins.

40.4 Bioactivities (Animal Aspects)

40.4.1 Extracts Rich in Procyanidins

The activity of procyanidins present in such plants as cocoa, grape, maritime bark, etc. is intensively studied in animal models (usually rats). Researches in this field are mainly focused on study of diabetes, coronary, or gastrointestinal diseases. Some other effects of procyanidins on other affections are less studied.

The activity of extracts and the main isolated compounds discussed in this chapter is presented in Table 4.

Table 4 Extracts and plants sources with the main compounds

Plant source/ extract	Compounds	Activity	References
Commercially available Pycnogenol	Mixture of procyanidins	Antidiabetic	Maritim et al. 2003

Grape seeds	Procyanidin dimer, tetramer, pentamer, heptamer oligomers	Anticataract activity	Yamakoshi et al. (2002b)

40.4.1.1 Antidiabetic Activity

Pinent et al. (2012), in their review article *Procyanidins Improve some Disrupted Glucose Homoeostatic Situations: An Analysis of Doses and Treatments According to Different Animal Model*, analyzed the potential beneficial effects of PAs, in situations in which glucose homeostasis is disrupted. They observed that several authors have assayed the ability of procyanidin-enriched extracts to ameliorate the physiological state caused by inability to synthesize and/or secrete functional insulin (hyperglycemia in type 1 diabetes). Maritim et al. (2003) used the commercially available Pycnogenol product (at a dose of 10 mg/kg) for the treatment of streptozotocin-induced diabetes in female Sprague Dawley rats (14 days treatment). A decrease of serum glucose level at day 15 was observed. At the same time the safety of tested product was confirmed on normal or diabetic rats. The results obtained by the authors (elevated levels of reduced glutathione and glutathione redox enzyme activities) demonstrated the ability of Pycnogenol (standardized extract of *Pinus maritima* consisting of a mixture of procyanidins) to scavenge free radicals altered oxidative stress and to increase the activity of hepatic-glutamyl-transpeptidase, which normally hydrolyzes glutathione and thiol derivatives and conserves cysteine levels.

Lee et al. (2007) evaluated the antidiabetic and antioxidant potential of PAs obtained from persimmon peel on male Wistar STZ-diabetic rats. At 24 h from the last dose, the decrease in serum glucose and glycosylated protein was observed.

The probable mechanisms involved in beneficial effects of PAs in diabetes mellitus are limitation of post-prandial glycemia increases, inhibition of α-glucosidases and α-amylases, and inhibition of transporters involved in glucose uptake (e.g., glucose transporter type 2 – Glut2) (Kwon et al. 2007).

In long-term treatments, procyanidins which are administered in a daily treatment are more effective than when given with food, which indicates the presence of mechanisms of action other than those inhibiting carbohydrate digestions and/or glucose absorption. Thus these compounds are acting as an insulin-mimetics (Pinent et al. 2012).

Other authors suggest that procyanidins have insulin-mimetic effects in adipose tissue and muscle. Montagut et al. (2009) proved that oligomeric PAs of a grape seed extract interact and induce the autophosphorylation of the insulin receptor in order to stimulate the uptake of glucose, however, in different manner than insulin. It was found that Akt (protein kinase B) and MAPK proteins are essential for PAs signaling mechanisms. The ability of PAs to mimic insulin effects in insulin sensitive targets was demonstrated also in healthy animal models when insulin is scarce or absent. Wistar rats and Zucker lean rats used as healthy model simultaneously with diabetic animals demonstrated no changes in glucose level after 8 and 24 weeks of treatment, respectively (Agouni et al. 2009; Li et al. 2009).

40.4.1.2 Anticancer Activity

Yamagishi et al. (2002) observed that cacao liquor procyanidins inhibit *in vitro* mutagenicity of 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine and rat pancreatic carcinogenesis in the initiation stage. However such promising results were not

confirmed in rat mammary carcinogenesis induced by PhIP model. The same authors evaluated also chemopreventive properties of cacao liquor proanthocyanidins against lung carcinogenesis in F344 male rat multi-organ carcinogenesis model. PAs were effective as chemopreventive agents in the lung cancer; however, none protecting influence in other major organs was observed (Yamagishi et al. 2003).

Mittal et al. (2003) studied how grape seeds procyanidins can prevent UVB radiation-induced photocarcinogenesis and malignant conversion of benign papilloma to carcinomas in SKH-1 hairless mouse model. They introduced PAs into the diet of hairless mice in order to demonstrate the effect of the compounds on different stages of photocarcinogenesis, such as UVB-induced tumor initiation stage, UVB-induced tumor promotion stage and UVB-induced complete carcinogenesis. The used composition was based on dimers (containing procyanidin B1, procyanidin B2, procyanidin B3, procyanidin B4, and procyanidin B5) - 6.6% of total grape seed procyanidins, trimers (containing procyanidin B5-3′-gallate and procyanidin C1) – 5.0%, tetramers – 2.9%, and oligomers – 74.8%. The results presented by the research group showed that this diet prevented photocarcinogenesis, in terms of tumor incidence, tumor multiplicity, and tumor size. PAs showed also protective action against UVB-induced skin tumorigenesis in all the three stages of multi-stage carcinogenesis. These compounds have inhibitory effect on malignant conversion of benign skin papilloma to carcinomas in SKH-1 hairless mice. The observed positive effects were explained by probable antioxidant activity of PAs (Mittal et al. 2003).

40.4.1.3 Neurological Diseases

The administration of procyanidins in neurological diseases was also studied. PAs were showed to effectively protect ischemic neurons, but the mechanism remains poorly understood. The intraperitoneal administration of ginkgo proanthocyanidins in Sprague Dawley rats mitigated neurological disorders, shortened infarct volume, increased superoxide dismutase activity, and decreased malondialdehyde and nitric oxide contents. PAs inhibited inflammatory reaction and activated survival pathways after ischemia/reperfusion injury (Cao et al. 2016).

40.4.1.4 Metabolic Syndrome

Ibars et al. (2017) studied the effects of procyanidins from grape seeds on rats with diet-induced obesity. Dietary obesity is usually linked with hypothalamic leptin resistance, and the authors presented the role of proanthocyanidins on hypothalamic leptin/STAT3 (signal transducer and activator of transcription 3) signaling and pro-opiomelanocortin gene expression on male Wistar rats fed either a standard chow diet or a cafeteria diet for 13 weeks, followed by treatment with grape seed proanthocyanidin extract. The treatment activated the hypothalamic leptin receptor-STAT3 pathway, ameliorated food intake but did not reverse the obesity and hyperleptinemia. Rats treated with procyanidins did not display a significant body weight reduction indicating that the doses were not sufficient to totally reverse leptin dysfunction induced by a high-fat diet.

Osakabe and Yamagishi (2009) investigated cacao procyanidins (CP) effects on plasma lipid levels in high cholesterol-fed rats. The experiments were developed on

9-week-old male Sprague Dawley rats. They demonstrated that ingestion of cocoa procyanidins reduced plasma total cholesterol levels in rats fed with high cholesterol diet, and the accumulation of cholesterol and triglyceride in liver was significantly decreased. The PAs precipitated micellar cholesterol, and this ability was dependent on the molecular weight of the compounds (monomers to tetramers).

The effect of an extract enriched in the flavan-3-ols procyanidin dimmers on obesity-related disorders via estrogen receptor alpha (ERα) was investigated by Leonetti et al. (2018). The investigated obesity-related cardiovascular and metabolic disorders with a particular interest in the role/contribution of ERα revealed that procyanidins reduced adiposity, plasma triglycerides, and oxidative stress in the heart, liver, adipose, and skeletal tissues, but did not improve the vascular dysfunction in a 2-week treatment. The heart structure and function were not affected by the diet, nor the grape seed extract supplementation and reactive oxygen species production in aorta was not significantly modified. The treatment improved muscle function by activating β-oxidation and by increasing mitochondrial functionality. ERα was identified as an important target involved in the reduction of fat accumulation.

40.4.1.5 Antithrombotic Activity

Zhang et al. (2011) studied antithrombotic effect of grape seed proanthocyanidins. Deep vein thrombosis was induced in rats, and a recipe based on 400 mg/kg procyanidins was applied. The authors observed that active compounds reduced thrombus length and weight and protected the integrity of the endothelium, inhibited thrombogenesis-promoting factors, and promoted thrombogenesis-demoting factors CD34, vascular endothelial growth factor receptor-2, and ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type one motif, member 13). The antithrombotic properties of proanthocyanidins were associated with endothelial protection and regeneration, platelet aggregation, and inhibition of inflammatory cell and thrombus adhesion.

40.4.1.6 Other Activities

Schizophrenia is mental disorder with disturbances in emotion, perception, cognition, and social function. Although this illness affects 1% of the population worldwide, fundamental neuropathology of schizophrenia remains unexplained. Tian et al. (2018) demonstrated how procyanidin B2 protects myelin integrity in cuprizone-induced schizophrenia in mice. They evaluated the effects of procyanidin B2 widely available in food on behavioral impairment in mice exposed to cuprizone for 5 weeks. Behavioral impairment tests, myelin integrity assay, and myelin basic protein (MBP) expression revealed that procyanidin B2 could mitigate behavioral impairment and protect myelin integrity via regulating oxidative stress by activating nuclear factor (erythroid-derived 2)-like 2 (Nrf2) signaling.

Yamakoshi et al. (2002b) studied the effect of PAs from grape seeds on cataract formation on a 39 male ICR/f group of rats. The diet was based on mixture of procyanidin oligomers (DP between 2 and 10) but also polymers in total concentration of 38.5% and 2.4% monomeric flavanols such as (+)-catechin. PAs were found

to significantly prevent and postpone the development of cataract formation in rats. The comparison of effectiveness of procyanidin structures with different degrees of polymerization resulted in conclusion that procyanidin pentamer to heptamer and procyanidin oligomers more than decamer groups were significantly more efficient in lowering plasma cholesteryl ester hydroperoxide levels comparing to the procyanidin dimer to tetramer group. The antioxidant properties of PAs and their metabolites were suggested to contribute to the inhibition of progression of cataract formation.

40.5 Benefits (Human Studies)

The 67 clinical trials involving PAs can be found in *Cochrane Database of Systematic Reviews.* Some of them are exemplified in the next subchapters, being classified according to the treated diseases.

Additionally, a summary of clinical trials investigating procyanidins and meta-analysis of these is presented in Table 5. An important source of PAs used in such cases are fruits and berries (blueberries, cranberries, and black currant), some legumes (peas and beans), hazelnuts, pistachios, almonds, walnuts and cocoa, and spices as cinnamon. From the fruits we can mention apples, chokeberries, strawberries, and green and red grapes (especially grape seeds) and the product obtained from grapes: the wine.

40.5.1 Cancer

As a disease of the century with a particular severity, cancer is considered the second leading cause of death worldwide. The major concerns of the scientific and medical world are to find cures for this disease, due to the fact that conventional cancer therapies result in serious side effects and, at best, merely extend the patient's life span by a few years. Formulations based on natural products can be considered good alternatives to traditional treatments.

Procyanidins obtained from grapes and grape seeds are considered good candidates for the anticancer formulations. Santos-Buelga and González-Manzano (2011) considered that excessive alcohol consumption increases the risk of liver cirrhosis and cancers; however, low to moderate red wine consumption has been associated to health-promoting properties. Among the wine phenolics, the authors assign the claimed health effects to procyanidins (such as oligo- and polymeric flavan-3-ols) and to resveratrol.

Colorectal cancer (CRC) is a major cause of morbidity and mortality throughout the world, with a high percent of incidence among all types of cancers. Jin et al. (2012) have studied the effect of dietary flavonoids on the incidence of colorectal adenoma and CRC. At the start of Jin's study, only few researchers investigated the association between procyanidins and colorectal neoplasms, while others reported the effects of six flavonoid subclasses (flavonols, flavones, flavan-3-ols,

Table 5 Summary of clinical trials investigating procyanidins

Compound	Clinical trial/ meta-analysis	Effects	Reference
PAs	Analysis of metadata	Decreasing risk of colorectal cancer (CRC)	Theodoratou et al. 2007
PAs from commercially available standardized cranberry capsules	Clinical trial	Potential to attenuate the adverse effects of cancer radiotherapy	Hamilton et al. 2015
Dietary biologic active compounds from wine, apples, pears, peaches, apricots, prunes, vegetables/ bean soups, chocolate, pulses, and grapes	Analysis of metadata	Reduce endometrial cancer risk	Rossi et al. 2013
Cocoa procyanidins	Clinical trial	Increase of flow-mediated vasodilation Decrease of the pulse wave velocity and blood pressure Decrease of total cholesterol	Heiss and Kelm 2016
Cocoa procyanidins: procyanidin dimers and trimers to decamers	Clinical trial	Improving cardiac function in chronic heart failure, changing blood pressure, decreasing flow-mediated dilatation	De Palma et al. 2016
Apple procyanidins	Clinical trial	Changes in systolic or diastolic BP (peripheral and aortic), plasma nitric oxide (NO) reaction products	Kroon 2016
Enovita®, grape seeds	Clinical trial	Decrease of blood pressure, decrease of the diastolic pressure, oxidation of membrane lipids, endothelial dysfunction, formation of oxidized LDL, and activation of phagocytic cells	Belcaro et al. 2013
Oligopin®	Clinical trial	Improve lipid cardiovascular profile and one of the scarce ways to increase HDL-c in stage-1-hypertensive subjects, improve systolic BP and LDL oxidation	Valls et al. 2016
PAs from cinnamon	Clinical trial	Moderate decrease of fasting plasma glucose, but no effect on glycated hemoglobin A1c, serum lipids, or blood coagulation parameters	Mang et al. 2006
Cinnamon	Clinical trial	Significant reduction in blood pressure, fasting plasma glucose, body mass index	Akilen et al. 2010

(continued)

Table 5 (continued)

Compound	Clinical trial/ meta-analysis	Effects	Reference
PAs from cinnamon	Clinical trial	No significant reduction in glucose values; No changes in the blood lipid profile	Vanschoonbeek et al. 2006
PAs from cinnamon	Clinical trial	Significant decrease of fasting insulin, glucose, total cholesterol and LDL cholesterol The increase of insulin sensitivity	Anderson et al. 2015
Cranberry-lingonberry juice	Clinical trial	Reduction of urinary infection risk	Kontiokari et al. 2001
Cranberry juice capsules	Clinical trial	Preventing urinary tract infections (UTI) after surgery	Foxman et al. 2015
Cranberry juice	Clinical trial	Reduction of bacteriuria incidence (especially *E. coli*) in urinary infections	Wan et al. 2016
Oligomeric and polymeric proanthocyanidins from *Rumex acetosa* L.	Clinical trial	Prophylactic potential on periodontitis	Beikler 2014
Pycnogenol®	One-patient study	Decrease the hyperactivity and impulsivity (in attention deficit hyperactivity disorder (ADHD))	Heimann 1999
Pycnogenol®	Clinical trial	Significant reduction of hyperactivity, improvement of attention and visual-motoric coordination and concentration of children with ADHD	Trebaticka et al. 2006

procyanidins, flavanones, and phytoestrogens) (Theodoratou et al. 2007). Theodoratou's results showed a statistically significant decreased risk of CRC with a high intake of procyanidins (22% reduction in CRC risk associated with the highest quartiles of intake versus the lowest quartile, odds ratio 0.78, $P_{trend} = 0.031$). Their research method was based on the analysis of metadata up to July 2011 in the Cochrane Library, PubMed, EMBASE, and other CINAHL databases and reference lists of previous reviews. Eight studies with 390,769 participants were included. Five studies used a prospective cohort design, two case-control studies, and one a randomized controlled trial (RCT). The methodological quality was measured using the Newcastle Ottawa scale (NOS).

In the clinical trial developed by Hamilton et al. (2015), PAs were evaluated for their potential to attenuate the adverse effects of cancer radiotherapy. The authors used commercially available standardized cranberry capsules, containing 72 mg of

proanthocyanidins, for the evaluation of their effect in prevention and treatment of radiation cystitis in prostate cancer patients. The authors reported decrease in cystitis incidence in treated patients compared with control group, recommending the use of cranberry capsules as a support treatment in prostate cancer patients experiencing common side effects, such as radiation cystitis and inflammation of the bladder.

Rossi et al. (2013) examined the relation between dietary biologic active compounds and endometrial cancer, from an Italian case-control study including 454 incidents, histologically confirmed endometrial cancers, and 908 hospital-based controls. They estimated the intake in proanthocyanidins from fruits and vegetables through statistical tests and concluded that high consumption of proanthocyanidins may reduce endometrial cancer risk. In their study, the authors identified, for the Italian population, as major source of proanthocyanidins monomers and dimers the wine, apples, pears, peaches, apricots, and prunes while for trimers and superior proanthocyanidins the apples, pears, wine, vegetables/bean soups, chocolate, pulses, and grapes.

40.5.2 Cardiovascular Disorders

The use of biologic compounds from plants and fruits offers potential benefices in human health. In the literature there are many papers which describe the role of dietary food, also clinical trials which prove an improvement of health. In the comprehensive review paper, Schroeter et al. (2010) listed several studies on the potential health benefits of dietary flavanols and procyanidins, especially in the context of cardiovascular health. The work was revisited 8 years later (Ottaviani et al. 2018) by authors describing significant developments in understanding of dietary flavanols and procyanidins in the human health and nutrition. In spite of these findings, the recent progress was considered by the authors insufficient for the development of dietary guidance on the flavanols and procyanidins intake or for the establishment of a minimum intake necessary to achieve health benefits.

The effects of cocoa procyanidins on vascular function were investigated in the trial NCT02728466 (Heiss and Kelm 2016). The study started in 2014 involved group of 45 participants. The tests were performed with cocoa-based supplement containing flavanols (monomers) and procyanidins (dimers to decamers) and a placebo comparator (flavanol and procyanidin deprived supplement). The study evaluated the influence of the sustained intake (2x daily over 1 month) of the macro- and micronutrient matched supplement over the baseline endothelial function. Post-consumption, endothelial function, plasma flavanol metabolites, urinary flavanol metabolites, urinary valerolactone metabolites, pulse wave velocity, blood pressure, and high- and low-density lipoproteins were measured at different times. The obtained results showed that the consumption of cocoa extract containing 130 mg (−)-epicatechin and 560 mg procyanidins led to the increase of flow-mediated vasodilation and of the concentration of (−)-epicatechin metabolites in the circulatory system and to a decrease of the pulse wave velocity and blood

pressure. The total cholesterol decreased for both the above described recipe and for another extract (containing 20 mg (−)-epicatechin and 540 mg procyanidins).

De Palma et al. (2016) assessed the potential therapeutic value of a high dose of cocoa flavanols in patients with chronic heart failure. The reductions in N-terminal pro-B-type natriuretic peptide (NT-proBNP) were used as an index of improved cardiac function. The study was a single-center randomized double-blind placebo-controlled investigation with a crossover design with exclusion criteria: age <45 years, diabetes mellitus; LV (left ventricular) dysfunction not related to systolic HF (heart failure) or ischemic heart disease; exertional angina; atrial fibrillation; cardiac surgery, percutaneous coronary intervention, acute coronary syndrome, or stroke within 6 months of the study; active psychiatric or psychological illness; and life expectancy. The patients' diet was rich in flavanols, especially procyanidin dimers and trimers to decamers. This study indicates that combining cocoa flavanols with guideline-directed medical therapy has potential for improving cardiac function in chronic heart failure, changing blood pressure, decreasing flow-mediated dilatation, using reductions in N-terminal pro-B-type natriuretic peptide (NT-proBNP) as an index of improved cardiac function.

Another clinical trial indicates apples as a source of compounds which can be associated with source of reducing risk of cardiovascular disease (CVD) (Kroon 2016). The effect of the ingestion of epicatechin-rich flavanol extract and isolated apple procyanidins on systolic blood pressure (BP) and other cardiometabolic biomarkers was studied in the cited paper. Low epicatechin and procyanidin doses, high epicatechin and procyanidin doses, high procyanidin only and as control, no epicatechin, and procyanidin were administrated for a group of 42 participants. The results of the study showed that none of the isolated flavanol treatments significantly changed systolic or diastolic BP (peripheral and aortic), plasma nitric oxide (NO) reaction products, or measures of arterial stiffness, suggesting that, in isolation, neither monomeric flavanols nor PCs affect BP, blood lipid profiles, endothelial function, or glucose control.

Some studies demonstrated that moderate daily consumption of wine is associated with a lower risk of coronary heart disease. Khan et al. (2015) described the effects of oligomeric procyanidins (OPCs) on vascular endothelial function. They provided an explanation for the reduced incidence of coronary heart disease in red wine drinkers. OPCs were proved to induce atheroprotective changes in vascular function through oxidant signaling mechanisms originating from the mitochondrial electron transport chain.

The efficacy of procyanidins obtained from grape seed extract to decrease blood pressure was investigated by Belcaro et al. (2013). In this study, a controlled group formed by 119 healthy pre- and mildly hypertensive subjects were involved. After 4 months of treatment with two dosages of procyanidins (150 and 300 mg/day), microcirculation state and plasma oxidative status were evaluated. The treatment had beneficial cardiovascular effects that complement current intervention strategies in the hypertension area. The effect on blood pressure (decrease of blood pressure, decrease of the diastolic pressure) and oxidation of membrane lipids (endothelial dysfunction, formation of oxidized LDL, and activation of phagocytic cells) were

observed. The compounds improved endothelial function and promoted microcirculation decreasing the plasma oxidative status.

Valls et al. (2016) reported the effects of Oligopin® (extract from French maritime pine bark with low molecular weight procyanidins) in a clinical trial formed by 24 participants on cardioprotective effects. The randomized patients received a placebo 2 times a day or Oligopin® quantified extract also 2 times a day for 5 weeks each. The measured parameters were blood pressure, lipid profile, anthropometric variables, and other CVD risk biomarkers. The consumption of Oligopin® improved lipid cardiovascular profile and represents one of the scarce ways to increase HDL-c in stage-1-hypertensive subjects. In addition, it also tends to improve systolic BP and LDL oxidation.

40.5.3 Diabetes

Diabetes is a disease characterized by the increase of blood glucose levels. Gonzales-Abuin et al. (2015) suggested that procyanidins help in the hemostasis of glucose in various tissues, reducing the lipogenesis and modulating the secretion of insulin in pancreatic cells. Sun et al. (2016) reported proanthocyanidins as retina protector against early diabetic injury by activating the Nrf2 pathway. Even though the exact mechanisms involved remained unclear, the authors present several previous studies suggesting mechanisms responsible for the protective effect of grape seed procyanidin extracts.

Vanschoonbeek et al. (2006) showed no significant reduction in glucose values using cinnamon diet in postmenopausal type 2 diabetes patients, finding no time × treatment interactions for whole-body insulin sensitivity or oral glucose tolerance, nor changes in the blood lipid profile of fasting subjects following cinnamon supplementation. At the same time, the study of Mang et al. (2006) on the effects of cinnamon aqueous extract in adult diabetes patients on oral hypoglycemic treatment revealed a moderate decrease of fasting plasma glucose, but no effect on glycated hemoglobin A1c, serum lipids, or blood coagulation parameters.

Akilen et al. (2010) studied the effect of cinnamon administered daily (2 g) over a period of 12 weeks in a placebo-controlled double-blind clinical trial. The study demonstrated a significant reduction in blood pressure, fasting plasma glucose, and body mass index, suggesting the potential of cinnamon supplementation in a daily diet to regulate blood glucose and blood pressure levels.

Anderson et al. (2015) demonstrated a significant decrease of fasting insulin, glucose, total cholesterol, and LDL cholesterol and the increase of insulin sensitivity at the end of a 2 months trial after treatment with 500 mg cinnamon water extract daily.

40.5.4 Urinary Infections

Several clinical trials describe the effect of procyanidins on urinary infections. In a randomized controlled 12-month follow-up trial, Kontiokari et al. (2001) described

the effect of administration of 50 ml of cranberry-lingonberry juice concentrate daily for the reduction of urinary tract infection recurrence. The results showed a 20% reduction in absolute risk in the cranberry group compared with the control group (16% recurrence in the cranberry group, compared with 36% recurrence in the control group).

The study of Foxman et al. (2015) evaluated the therapeutic effect of cranberry juice capsules in preventing urinary tract infections (UTI) after surgery. The results showed a decrease by half of the UTI for women undergoing elective benign gynecological surgery involving urinary catheterization (19% vs. 38% for the control group).

The trial developed by Wan et al. (2016) studied the protective effect of highly concentrated cranberry juice against urinary tract infections, using 55 uncircumcised boys and 12 circumcised boys, from 6 to 18 years old, with histories of urinary tract infections. The results showed that prophylactic treatment with cranberry juice led to the reduction of bacteriuria incidence (especially *E. coli*) to 25%, compared with the negative control group (37%) and positive control group (33.3%). The protective effect of the cranberry juice was assigned to its proanthocyanidins content.

40.5.5 Other Diseases

Rumex acetosa L. (garden sorrel), known as a plant with high content of oligomeric and polymeric proanthocyanidins and flavonoids, was used in the clinical trial NCT02039648 in order to establish the prophylactic potential as mouth rinse on periodontitis (especially on *Porphyromonas gingivalis*, one of the major pathogens associated with the onset and progression of periodontitis) (Beikler 2014). Changes of the intraoral prevalence of *Porphyromonas gingivalis*, Approximal Plaque Index and Sulcular Bleeding Index were observed from baseline to 7 and 14 days; changes of cytopathological appearance of the mucosal tissue were observed from baseline to 7 days.

Heinrich et al. (2006) evaluated the contribution of procyanidins-rich cocoa to endogenous photoprotection. Their results suggested that a 12 weeks diet containing high doses of procyanidins (having as main compounds the monomers epicatechin – 61 mg/day and catechin – 20 mg/day, total procyanidin oligomers – 247 mg) provided photoprotection against UV-induced erythema, significant decrease of skin roughness and scaling.

The procyanidin mixture Pycnogenol® (extracted from pine tree bark) was evaluated for application in treating *attention deficit hyperactivity disorder* (ADHD). The product was reported to decrease the hyperactivity and impulsivity in a one-patient study (Heimann 1999). The study of Trebaticka et al. (2006) on 61 patients with ADHD found beneficial effects of Pycnogenol® at a dose of 1 mg/kg and an administration period of 1 month. A very interesting conclusion of the study of Trebaticka et al. was that the effect was sex-related (being more effective in boys). Administration of Pycnogenol® caused a significant reduction of hyperactivity, improved attention and visual-motoric coordination, and concentration of children

with ADHD. At the same time, addition of Pycnogenol® to the classic ADHD treatment with dextroamphetamine resulted in superior effects.

40.6 Application in Food (Including Correctly Cooking Foods Rich in Phytochemicals)

Proanthocyanidins in general (among which procyanidins are the most common) can be found in a series of foods, such as fruits (avocado, bananas, blackberries, grapes, plums, etc.), vegetables (broad beans, etc.), nuts (almonds, peanuts, pistachios, etc.), grains (barley, buckwheat, red beans, etc.), spices (cinnamon, curry, etc.), and beverages (beer, grape juice, tea, wine, etc.). A very useful database regarding the procyanidin content of different foods is maintained by the United States Department of Agriculture (Haytowitz et al. 2018). Table 6 presents the content of proanthocyanidins in common fruits and vegetables.

Several procyanidin-rich products are also commercially available. Cranberry extract powder is considered as food supplement which can be used in fruit-flavored and isotonic drinks, tea drinks, vitamin-enhanced waters, and yogurts. Grape seed powder also exists on the market. It which can be added to food directly, used in cooking and baking, diluted in water or other drinks, or used as an ingredient in more complex products such as protein powders, dietary supplements, functional foods and drinks, and sports nutrition. Another source rich in procyanidins is cocoa; it can be used as powder in cookies, chocolate, etc., and unheated and untreated at temperatures allow it to keep its nutrient-dense qualities.

Due to their antimicrobial and antioxidant properties, procyanidins could be successfully applied for extending the shelf lives of different meat products (Jeong et al. 2015). The cited study presents the effect of procyanidins (extracted from grape seeds, no further details on composition provided) on samples of pork patties: the samples had higher redness and yellowness values, as well as lower registered values for volatile basic nitrogen, 2-thiobarbituric acid reactive substance, and total bacterial counts assays.

The correct cooking of foods rich in procyanidins represents the subject of only a few research papers. Generally speaking, the processing step reduces the higher procyanidin content. Rodriguez-Mateos et al. (2014) showed that the thermal treatment has more pronounced effect on the higher procyanidins (nonamers and decamers disappeared, in the same time, the dimers and trimers having increasing values), with no significant changes in the total procyanidin content. Similar behavior was observed after extrusion of freeze-dried blueberry pomace at 180 °C or after processing berries into juiced, canned, and pureed products.

The study of Stahl et al. (2009) on the influence of preparation of cocoa-containing food on recovery of PAs revealed that the temperature was not the key factor in procyanidin loss but the leavening agents used. Comparing the effect of

Table 6 Maximum total proanthocyanidins (PAs) content in common foods (monomers not presented) (Gu et al. 2001; Haytowitz et al. 2018)

No	Fruit/vegetable	Max. PAs content (mg/100 g edible portion)

baking soda (sodium bicarbonate) and baking powder (mixture of baking soda and acidic ingredients) used as leavening agents, the authors showed that the key factor in procyanidin loss was represented by the pH level (higher recoveries of procyanidins being recorded at lower pH values reached using baking powder).

The literature data suggests that, due to the reduction of higher procyanidins on processing, the consumption of raw products it is recommended, if possible.

40.7 Safety: Toxicity and Side Effects

The intake of PAs can be beneficial for different diseases, but the most important is to find the optimal doses at which the biologic compounds are safe and have no adverse reactions. Ottaviani et al. (2015) investigated the effects of cocoa flavanols (CF) (including procyanidins) intake amount and intake duration on blood pressure, platelet function, metabolic variables, and potential adverse events. The limitations of their study lie in its duration and the number of volunteers studied; however, due to the lack of the studies on human subjects (up to 2015), the authors suggested that their study provides relevant and needed information for current safety assessments. The intake of cocoa flavanols (including procyanidins) up to 2000 mg/day for 12 weeks was well tolerated in healthy adults; the consumption was not associated with significant changes in blood pressure or platelet function.

Safety assessments of grape seeds extract (rich in procyanidins) have been conducted using animal models by Ray et al. (2001) and Yamakoshi et al. (2002a). Ray et al. (2001) conducted acute oral toxicity, dermal toxicity, dermal irritation, and eye irritation studies administrating doses of PAs from grape seeds extract. LD_{50} was found to be greater than 5000 mg/kg in albino rats via gastric intubation and greater than 2000 mg/kg when administrated dermal. The examination of other organs like the brain, duodenum, heart, kidney, liver, lung, pancreas, and spleen did not reveal any abnormalities. The serum chemistry was also not changed in female mice at chronic administration. The acute and subchronic oral toxicity of PAs from grape seeds extracts was also performed on Fischer 344 rats (Yamakoshi et al. 2002a). The authors evaluated mutagenic potential by the reverse mutation test using *Salmonella typhimurium*, the chromosomal aberration test using CHL cells, and the micronucleus test using ddY mice. No signs of toxicity were found indicating the safety of preparation. Lluís et al. (2001) confirmed the previous results describing LD_{50} of PAs from red grape marcs (variety Syrah) as being higher than 5000 mg/kg.

Due to the lack of consistent data regarding evaluation of the safety and tolerability of continuous intake of oral grape seeds extract, Sano (2017) conducted a 4-week toxicity test with daily doses of 1000–2500 mg proanthocyanidin-rich grape seeds extracts in healthy Japanese volunteers. Measured physical parameters as body weight, blood pressure, and pulse rate showed that tested doses were well tolerated, and subject compliance was 100%.

The potential systemic toxicity of Oligopin® was evaluated by Segal et al. (2018). The preparation was showed to be not acutely toxic via oral administration at up to 2000 mg/kg and was well tolerated following repeated oral administration to

Sprague Dawley rats, with a NOAEL (no-observed-adverse-effect level) of 1000 mg/kg/day.

Cranberry extract powder is considered a food supplement and that's why it was emitted an opinion pursuant to Regulation (EC) No 258/97 of the European Parliament and of the Council. None of the clinical trials conducted on this product indicated adverse reactions. The Panel (Turck et al. 2017) which analyzed the safety of this product took into consideration the studies of Cos et al. (2003), and Prior and Gu (2005), regarding absorption, distribution, metabolism, and excretion of this biologically active compounds, and some clinical studies on human subjects (Valentova et al. 2007).

The no-observed-adverse-effect level (NOAEL) of a chronic toxicity study of procyanidins from edible plant extracts is different according to the study or clinical trial which is reported.

The analytical standards available have safety data sheets, covering some aspects regarding their toxicity. For example, the monomers catechin and epicatechin have oral LD_{50} values (mouse and rats) >10,000 mg/kg and 1000 mg/kg, respectively, while for the dimers, trimers, and higher procyanidins, there are no acute toxicity data available. The GHS (Globally Harmonized System of Classification and Labelling of Chemicals) hazard statements usually presents the hazard statements H315 *Causes skin irritation*, H319 *Causes serious eye irritation*, and H335 *May cause respiratory irritation* and several precautionary statement codes for the monomers and other available procyanidins (e.g., Procyanidin B2, Procyanidin B3, etc.). The hazards and precautionary statements should be read carefully and understood, while the general safety regulations in the laboratory should be respected when working with procyanidins fractions or purified procyanidins.

40.8 Marketed Products

Several products based on PAs are present on the market. These are mainly herbal drugs (containing extracts), herbal products, dietary supplements, and functional foods: Pine Bark Extract 95%®, Enovita®, Oligopin®, Pycnogenol®, Leucoselect®, Endotélon®, Masquelier's®, Anthogenol®, Enzogenol®, etc.

Enovita® is a food-grade grape seed proanthocyanidin extract (seed extract from *Vitis vinifera* L.) specifically designed for the food market, developed by Indena (Milan, Italy), with a content more than 95.0% of proanthocyanidins determined by spectrophotometry, 5.0–15.0% of catechin, and epicatechin determined by high-performance liquid chromatography (declared by the company). Belcaro et al. (2013) developed a registry study on 19 healthy, pre- and mildly hypertensive subjects regarding the efficacy of a standardized grape seed procyanidins extract (GSPE, Enovita®) to decrease blood pressure when associated with nondrug intervention. According to Belcaro report, Enovita contains ca. 8.6% monomeric procyanidins (catechin, epicatechin, and epicatechin gallate) and ca. 91% proanthocyanidins (OPC), of which 9% are of the dimeric type. A decrease of systolic

blood pressure was observed at month 1, but the decrease was significantly higher in the treatment group.

French Maritime Pine Bark extract (FMPBE) rich in procyanidolic oligomers was tested as Oligopin® (PureExtract, DRT, France) in different clinical trials or studies on animals, where the systemic toxicity and mutagenicity were evaluated. Segal et al. (2018) have evaluated systemic toxicity of Oligopin® (obtained from the pine tree *Pinus pinaster*) in an acute oral limit test and a 90-day repeated dose oral toxicity study with Sprague Dawley rats. The researchers assessed potential mutagenicity in a bacterial reverse mutation assay and *in vitro* mammalian chromosome aberration assay with human lymphocyte. The results of their tests indicate that Oligopin® was nongenotoxic in both bacterial and human cell assays, was not acutely toxic via oral administration at up to 2000 mg/kg, and was well tolerated following 90 days of oral administration to rats, with a no observed adverse effect level of 1000 mg/kg/day. The composition of the recipe used is procyanidolic oligomers, out of which dimers constituted 15–20%, trimers 15–20%, and tetramers and higher oligomers 30–40%.

The effect of Oligopin® consumption on blood pressure of randomized group of 24 people with mild/moderate degree of hypertension was evaluated in the clinical trial NCT02063477 conducted by Technological Center of Nutrition and Health, Spain (Valls and Sola 2014). The differences in the time of evolution of blood pressure in both two arms of intervention were observed. Other measured parameters were endothelial function, biomarkers related with endothelial function, and biomarker related with inflammatory processes.

Poussard et al. (2013) reported that heat-shock protein beta-1 (HSPB1) is modulated by Oligopin®. Oligopin® prevented the stress-induced phosphorylation of HSPB1 and its subsequent structural modification. This supports the therapeutic usefulness of preparation for preventing the age-related muscle mass loss and for protecting muscle cells from oxidative stress. Valls et al. (2016) reported Oligopin® as being characterized by a practical absence of other tannins (<1%) and a high content in low molecular weight oligomeric procyanidins (OPCs >70%; dimers about 20%).

Pycnogenol® (Horphag Research Ltd., UK, Geneva, Switzerland) is a standardized extract with many benefices for human health due to its chemical composition. It is a standardized plant extract obtained from the bark of the French maritime pine *Pinus pinaster* Aiton (formerly known as *Pinus maritima*), subspecies *Atlantica des Villar*. With a reach composition in procyanidins comprising of catechin and epicatechin subunits with varying chain lengths, it is now utilized throughout the world as a nutritional supplement and as a phytochemical remedy for various diseases ranging from chronic inflammation to circulatory dysfunction, including several impaired psycho-physiological functions (D'Andrea 2010). This supplement is good in the treatment of attention deficit hyperactivity, osteoarthritis, type 2 diabetes, and cardiovascular diseases. Pycnogenol® can be used to slow the aging process, maintain healthy skin, improve athletic endurance, and improve male fertility. Jessberger et al. (2017) reported cellular pharmacodynamic effects of Pycnogenol® in randomized controlled pilot study with 33 patients with severe osteoarthritis. Grether-Beck et al. (2015) reported Pycnogenol®'s effects on human

skin (photoprotection, reducing hyperpigmentation, improving skin barrier function, as well as extracellular matrix homeostasis).

Leucoselect® is a standardized extract from grape seeds developed by Indena (Milan, Italy) with a content of 95.0–100% of proanthocyanidins, determined by spectrophotometry, and catechin and epicatechin between 13.0 and 19.0% evaluated by HPLC. Nuttall et al. (1998) reported Leucoselect® as a placebo treatment in a clinical trial aiming to evaluate the effects of a capsule formulation of an antioxidant polyphenolic extract of grapes on serum total antioxidant activity and vitamin C and E levels. As results they reported that the extract had no effect on serum vitamins C and E levels but increased total serum antioxidant activity. To further improve their bioavailability, Leucoselect® has been formulated with soy (non-GMO) phospholipids (1:3 w/w), thus generating Leucoselect® Phytosome®.

Several other extracted from lychee fruits and grape seeds rich in PAs are currently commercialized under different names (Oligonol®, Vitaflavan®, MegaNatural™).

Besides those marketed products, several foods and beverages with high PAs content are available (as previously presented in Sect. 6) and could provide the necessary daily intake of PAs for a healthy and equilibrated diet (Bhagwat and Haytowitz 2015).

40.9 Patents

One of the first patented recipes based on PAs was Jack Masquelier patent (patent number 4.698.360 from 1987) "Plant extract with a proanthocyanidins content as therapeutic agent having radical scavenger effect and use thereof," where the author's invention relates to the use of a plant extract with a PAs content as therapeutic agent with radical scavenging effect as well as the use of pharmaceutical compositions containing this extract as active ingredient. The recipe is based on bark conifers (*Pinus maritime* Lam.) rich in biological active compounds.

The invention of Soulier et al. (2012) relates to the process of extraction involving the use of cranberries (*Vaccinium macrocarpon*) as a raw material, crushed fruits, or already pre-purified extracts rich in PAs. This invention allows to obtain extracts containing more than 10% PAs, using hydroalcoholic extraction and absorption on a macroreticular polymeric resin. Venkatramesh et al. (2013) describe in their patent the production and extraction of procyanidins from plant cell cultures of Theobroma or Herrania. Schmitz et al. (2017) patented "Compositions and methods of use of A-type procyanidins." The authors extracted procyanidins from peanut skin and investigated characterized compounds for their effect on nitric oxide (NO) production and vasorelaxation using serum-free human umbilical vein endothelial cell (HUVEC) culture system *in vitro* and rabbit aortic ring *ex vivo* models. Additionally, the effects of A1 dimer on platelet count in whole blood were measured. Hammerstone and Chimel (2003) patented the method of extraction of procyanidins from cocoa. They used defatted, unroasted, or unfermented cocoa beans and optimized extraction parameters (solvent used, extraction temperature, extraction pH) in order to obtain

higher yields of PAs. A preferred extraction technique was countercurrent extraction chromatography. The patent of Howard et al. (2012) described a method of extraction of PAs from any plant pomace (apples, pine bark, cinnamon, cocoa, grapes, bilberry, black currant, green tea, black tea, chokeberry, blueberry, and sorghum) by alkaline hydrolysis. Subsequently the active compounds can be used in dietary supplements or added to products to enhance health benefits. The invention of Rull et al. (2004) related to vegetable extracts containing at least 15 and preferably 20–25% of OPC of A2 type. The authors patented the isolation of the compounds from litchi fruits shell involving extraction with methanol and liquid chromatographic purification step.

Patent describing preparations containing A-type procyanidins and their derivatives for treatment or prevention of certain tumors/cancers (especially tumors/cancers overexpressing cycloxygenase-2 (COX-2)) can also be found (Schmitz and Kwik-Uribe 2007). Rohdewald and Ferrari (2003) patented the use of proanthocyanidins and arginine in the treatment of erectile dysfunction. The patent obtained by Danoux et al. (2002) described the use of procyanidin oligomers in the field of cosmetics for skin treatment products, especially products with the ability to counteract skin aging effects.

Several other patents referring to commercial products are described in Sect. 8.

40.10 Perspectives

In order to cope with an increasing global population and a quantity of wastes obtained from agricultural industry, to conform to the principles of sustainable development and bioeconomy, it is a *must* to find new methods to obtain added value products from plant waste.

This is the case of plants and fruits with a high amount of biological active compounds, as procyanidins. Based on the United Nation Food and Agriculture Organization (FAO) statistics, at the end of the year 2016 (most recent available), huge productions of plants rich in procyanidins, which processed will produce waste, were reported worldwide: cocoa beans, 4,466,575 t; grapes, 92,281,609 t; tea, 8,368,892 t; strawberries, 12,920,201 t; raspberries, 795,249 t; nuts, 1,087,750 t; cranberries, 683,672 t; cocoa beans, 4,466,575 t; cinnamon, 300,630 t (from 13 countries); apples, 133,777,757 t; apricots, 3,955,025 t; etc. The growing demand of green materials and renewable resources is due to the fact that wastes from agroindustry can be recycled into food/feed/regenerable fuels, fertilizers, pharmaceutical, and cosmetic products. All over the world, the pomace remaining after fruits extraction is produced. It is not valued as highly profitable waste, but instead leads to several environmental and waste disposal problems.

Also, in the present *eco* and *bio* rush, materials such as essential oils, pharmaceuticals, supplementary foods, cosmetics, etc., are obtained from plants. From this perspective, the use of active compounds obtained from plant waste is encouraged, especially that agro-horticultural waste is cost-effective natural sources. Initiatives regarding the valorization of plant wastes are developed channeling on different types of compounds or plants pomace. Kolodziejczyk et al. (2007) considered by-

product deriving from apple juice pressing as a source of dietary fiber (about 50% of dry weight) and phenolics (from 1200 to 4000 mg/kg dry weight), including flavanols (catechin, epicatechin, procyanidins), hydroxycinnamates, and dihydrochalcones. Altiok et al. (2007) investigated the possibility of recovering of proanthocyanidin from the by-product of Turkish traditional product (*molasses*). Teixeira et al. (2014) presented in their review paper the types of residues produced by the wine industry and the types of compounds that can be obtained from grape waste. Being one of the most important and widespread agro-economic activity, grape industry produces organic residues (nine million tons/year) and inorganic one (diatomaceous earth, bentonite clay, and perlite).

Nevertheless, implementation of waste management from agro-industry is a challenging task, making the development of innovative and effective capitalization procedures necessary in order to recycle, reuse, and recover these residues. Food wastes should no longer be regarded as a waste to be disposed, but as a renewable source of valuable molecules that should be fully exploited.

Adequate procedures to obtain the target compounds will provide successful achievements for phytochemical recovery and obtaining added value products. At the same time, scientific advances are necessary toward the separation and purification of procyanidin compounds, as well as for the *in vitro* and *in vivo* evaluation of the potential effects of those compounds. Moreover, supplementary scientific data are necessary to support the various claims of beneficial effects of regarding procyanidins arising either from folk medicine or from industrial companies in the area of food supplements and related products.

Abstract

Pyrazines are volatile compounds that share a common chemical structure, including a monocyclic aromatic hydrocarbon with a counterpoint nitrogen atom. Pyrazines can be synthesized chemically or biologically and can be used as flavor additives. Pyrazines are mainly formed during food thermal processing, such as coffee, cocoa, roasted nuts and seeds, cereals and cereal products, meat products, wine, and so on. Pyrazines are key flavors in the development of roasted foods. Their formation is closely related to the Maillard reaction, which involves the reaction between the α-dicarbonyl and amino acid groups to yield an aminoketone.

Keywords

Pyrazines · Roasted food · Thermal processing · Bioactivity

41.1 Introduction

Pyrazines are volatile compounds that share a common chemical structure, including a monocyclic aromatic hydrocarbon with a counterpoint nitrogen atom. Pyrazines can be synthesized chemically or biologically and can be used as flavor additives. Pyrazines are mainly formed during food thermal processing (Asikin et al. 2016). Pyrazines are key flavors in the development of roasted foods. Their formation is closely related to the Maillard reaction, which involves the reaction between the α-dicarbonyl and amino acid groups to yield an aminoketone. It suffers further condensation producing new heterocyclic compounds as the pyrazines. Several factors including the composition of food matrix may affect pyrazine formation. Moreover, heating parameters such as temperature and time are probably the most influential factors. The interests of food industry in pyrazines began in the 1960s and continue nowadays. The continuous increasing numbers of publications about pyrazines were indicated.

41.2 Pyrazines in Foods

41.2.1 Coffee

Coffee is an evergreen shrub or small tree of Rubiaceae. Its production is mainly concentrated in tropical developing countries at Latin America, Africa, and Asia, such as Brazil, Colombia, India, Liberia, Ethiopia, and Vietnam (Zhou and Ren

2016; Zhu and Jiang 2010; Sun and Xiong 2010). Coffee produced around the world has its own characteristics: Brazilian coffee, moderately bitter, with gentle flavor and unrestrained tropical taste, it is an excellent base for mixed coffee; Colombian coffee, smooth sour and sweet flavor, rich and full-bodied; Mandening coffee, the aroma is thick and thick; and Yunnan small grain coffee, strong but not bitter, fragrant but not strong, and slightly sour fruit taste (Zhou and Ren 2016; Zhou and Chen 2010). Aroma components of coffee are mainly produced in the process of coffee roasting. In the process of roasting, Millard and caramelization reactions mainly take place, producing aroma volatile components (Zhou and Ren 2016). The Millard reaction is the reaction of hydroxyl and amino groups. For raw coffee beans, it is mainly the reaction of proteins, amino acids, and sugars (Ren and Zhou 2018; Baggenstoss et al. 2008). There are differences in these ingredients in raw coffee beans, but not much, so there is little difference in the Millard reaction that takes place during the roasting process. The Millard reaction has the same reactants and the same products under the same conditions. The difference in content and composition is mainly due to the degree of baking, that is, the degree of reaction (Moon and Shibamoto 2009; Kumazawa and Masuda 2003; He et al. 2015). Since the beginning of the twentieth century, the chemical composition of coffee, especially for coffee bean flavor chemicals from a lot of studies, has been reported. There are nearly more than 1000 kinds of volatile chemicals have been found in coffee bean extract. It found that about 400 kinds of compounds are heterocyclic compounds, including pyrrole, furan, thiazole, pbo, thiophene, imidazole, and pyrazine compounds (Buffo and Claudio 2004; Lv et al. 2015). As the roasting temperature raises, volatile compounds such as pyrazines, aromatic aldehydes, phenols, furans, pyrrole, and imidazole increase and change the characteristic aroma of coffee (He et al. 2015). Coffee beans with different degrees of roasting contain their own volatile substances, which lead to different degrees of roasting with different characteristics of aroma. Pyrazines are the main volatile substances in extremely shallow, shallow, and moderate roasts, while furans, pyrrole, and ketones play a major role in medium and medium deep roasts, and phenols and pyridines play a major role in deep, extremely deep, and French heavy roasts (Wang et al. 2018). Guaiacol has a smoky flavor, pyridine has a scorch flavor, pyrrole has a nutty and roasted flavor, furans can produce a pleasant scorch flavor, phenols are mainly manifested as pleasant clove flavor, and pyrazines and acids are mainly nutty and sour (Lv et al. 2015).

41.2.2 Cocoa

Cocoa (*Theobroma cacao* L.) is used as a raw material in many products and highly appreciated for its flavor. The compounds involved in the chocolate aroma vary accordingly to the cocoa variety are volatile acids, terpene and non-terpene alcohols, and aldehydes. Esters are detected in higher amounts in Criollo beans, which show a richer and peculiar aroma profile. It has been known that the compounds that have given cocoa and chocolate their flavors are N- and O-containing molecules such as

pyrazines, pyrroles, furans, aldehydes, and amides, which are mainly generated during the Maillard reaction (Ducki et al. 2008). The characteristic aroma of cocoa is mainly the aroma of roasted nuts produced by pyrazines and the aldehyde (Sylvie et al. 2008; Yue et al. 2012; Xiao et al. 2012). Pyrazines, especially 2,5-dimethylpyrazine, 2,3,5-trimethylpyrazine, and 2,3,5,6-tetramethylpyrazine, are the main sources of cocoa aroma (Xiao et al. 2012; Christine et al. 2002; De Brito and Narain 2003). Even though the content of pyrazines in cocoa powder is very low (10^{-5}–10^{-4} g/L), it has an important contribution to the flavor of cocoa due to its extremely low flavor threshold. Flavor formation in cocoa is related, partly to thermal treatment (roasting) during which several modifications occur, including the Maillard reaction, which is mainly responsible for the accentuated decrease in the concentration of reducing sugars and amino acids during roasting. In roasted cocoa, volatile compounds are dominated by alkyl-substituted pyrazines followed by aldehydes and esters (Gill et al. 1984; Oberparlaiter and Ziegleder 1997; Ziegleder 1991). Among the different classes of volatile compounds present in cocoa products, pyrazines are by far the most studied. Due to their pronounced formation during roasting, pyrazines are used as index compounds of the roasting process (Hashim and Chaveron 1994; Jinap et al. 1998). The roasting process is a critical step for the development of the chocolate flavor from the precursors which are already formed during the fermentation and drying phases (Perego et al. 2004; Carro et al. 2015). Pyrazines, the dominant compounds which are responsible for the typical chocolate aroma, are mainly developed during this phase. The roasting process consists of a hot air treatment of the seeds in a temperature range between 110 °C and 140 °C. The higher temperatures lead to the over-roasted products with loss of the pleasant characteristics of cocoa and burnt taste (Perego et al. 2004). The roasting phase causes an increase in the content of alcohols, aldehydes, and pyrazines, while the other chemical compounds have less influence (Crafack et al. 2014).

41.2.3 Roasted Nuts and Seeds

Nuts as one type of non-splitting dried fruit of angiosperms have hard or tough walls and usually contain one seed. The research on the aroma substances of nuts can be traced back to the 1970s. Baking is an important food processing process, which can improve the flavor, color, texture, and appearance of food. The special flavor of nuts can only be obtained after the hot processing. There are the complex series of reactions among nonvolatile flavor precursor substances in tissues, which are mainly Millard reaction and thermal degradation reaction of lipids. Organic compounds such as pyrazine, furan, and pyrrole generated generate unique flavor, while unprocessed plant seeds have little or no fragrance (Li et al. 2011). The aroma of baked nuts is complex, including most volatile organic compounds, such as hydrocarbons, alcohols, aldehydes, ketones, acids, esters, lactones, furans, pyridines, pyrazines, pyrrolids, thiazoles, thiophene, and the other sulfur compounds (Yu et al. 2017). The contribution of nitrogen, oxygen, and sulfur heterocyclic compounds to baking flavor is very important, many of which are formed

through the interaction between Millard reaction and lipid degradation products (Castro-Muñoz 2019). Pyrazines are considered as the main flavor compounds that present the typical roasted nut aroma and can be used as an important index to optimize the roasting conditions of nuts. Among them, 2,5-dimethylpyrazine has malt flavor and chocolate aroma, which may be the best compound to predict the flavor of roasted peanuts, hazelnuts, and so on (Braddock et al. 1995; Yu et al. 2017; Michael et al. 2016). Pyrazines can be detected in roasted hazelnuts, while pyrrolidine is not contained in raw kernels, and 2,5-dimethylpyrazine is the highest content (Alasalvar et al. 2003). Pyrazines provide roast hazelnuts with nutty, roasted, and sweet flavors. Among them, the barbecue-flavored 2-ethyl-3,5-dimethylpyrazine and 2,3-diethyl-5-methylpyrazine have a high dilution factor (Michael et al. 2016). The methoxypyrazine-containing, such as 2-isobutyl-3-methoxypyrazine and 2-butyl-3-methoxypyrazine, can be detected in roasted peanuts and has a strong pea-like odor (Braddock et al. 1995; Sabine et al. 2004; Irene et al. 2008). Shimoda et al. (1997) compared the differences in volatile flavor components of deep-baked and light-baked sesame oil. The degree of baking increases the relative reduction of monoalkylpyrazines and the relative increase of dialkyl- and trialkylpyrazines. 1H-Pyrrole-2-carbaldehyde is the highest content of azoles and is the only reduction in deep baking. 4,5-Dimethylthiazole, 2-propyl-4-methylthiazole, and 2-butyl-5-methylthiazole were relatively increased in deep baking. And the content of guaiacol and 2-furyl mercaptan was significantly increased (Li et al. 2011; Sabine et al. 2004).

41.2.4 Cereals and Cereal Products

In addition to the inherent pyrazines in cereals, the most important source of pyrazines in cereal products is the Millard reaction, especially in thermal processing. Ammonia released from deamination of cereals protein also promoted the generation of pyrazines, such as wheat protein (Eon Lee et al. 2012). Pyrazines in beer, and in baking products, are an important research direction for pyrazines in cereals and cereal products. The contribution of pyrazines to roasted flavor of cereal products is the main reason to study their formation (García-Lomillo and González-SanJosé 2019). The important role of pyrazines in beer flavor led to earlier pyrazines studies focusing on pyrazines in malt and baked barley products (Wang and Sakurai 1969). Plenty of pyrazine compounds were found in the essential oil extracted from caramel malt (Zou et al. 2014). GC-MS and sensory results have shown that pyrazines and aldehydes were the most dominant flavor components in malt and roasted barley (Kim et al. 1998). For different types of malt, different amounts and proportions pyrazines were formatted in kiln-drying. And brewing couleurs had relatively high amount of pyrazines (Wittmann and Eichner 1989). Twenty-one pyrazines and main methylpyrazines, including 2,3-, 2,5-, and 2,6-dimethylpyrazines and trimethylpyrazines, were isolated from roasted barley by Harding et al. (1977, 1978). They indicated that pyrazines contributed to the flavor of beer, and roasted barley has a better performance (Collins 1971; Harding et al. 1978). Acetylpyrazine, 2-methyl-3-ethylpyrazine, and 5-methyl-5H-cyclopenta[b]pyrazine

were contributed significantly to the crust flavor (Schieberle and Grosch 1987). Concentrations of 13 pyrazines were determined in aging bottle beer, and most pyrazines decreased quickly in the first 48 h. 2-Methylpyrazine, 2,6-dimethylpyrazine, and 2-ethyl-5-methylpyrazine have been increased in the latter half of storage. However, there were no significant changes in frozen beer. This may indicate some changes of beer flavor during storage (Qureshi et al. 1979). Isolated from English beer, a result shown that pyrazine, methylpyrazine, dimethylpyrazine, and cyclopentapyrazine were important flavor essence, and there was a similar result in other beer and whisky (Harding et al. 1977; Peppard and Halsey 1981; Viro 1984). Extrusion cooking with HTST method to green malt at 130–160 °C obtained more total pyrazines than conventionally processed malt. 2-Vinyl-5-methylpyrazine and 2-vinyl-6-methylpyrazine only formatted in extruded malt (Fors and Eriksson 1986). Pyrazines deeply influence the aroma of bread and other baking cereal products. 2-Acetyl pyrazine and 2-methyl-3-ethylpyrazine are important to crust bread aroma. 2-Ethyl-3methylpyrazine and methylpyrazine are the 2 most abundant pyrazines of total 13 pyrazines detected in different wheat breads, which significantly affect the flavor of breads (Cochrane et al. 1995; Fadel and Hegazy 1993). The volatile components of rye bread were identified including 2-acetylpyrazine, 2-methyl-3-ethylpyrazine, and 6,7-dihydro-5-methyl-(5H)-cyclopentapyrazine in the crust (Schieberle and Grosch 1983). The formation of pyrazine, 2-ethylpyrazine, 2-methylpyrazine, 2-ethyl-3-methylpyrazine, and 2-vinylpyrazine was promoted in fermentation of wholemeal bread crust with higher temperatures, which may lead to a change of flavor (Qhairul et al. 2015; Qhairul et al. 2016). Thermal processing of cereal products brings lots of benefits, including reducing microbial contamination and promoting positive flavor and improving process properties (Neill et al. 2012). Appropriate heat treatment temperature can promote positive flavor, for malt and barley; dry conditions promoted formation of pyrazines at 180 °C (Channell et al. 2010). Heat treatment at 100 °C can eliminate harmful ingredients in materials, but does not induce the formation of flavor substances. When the temperature reaches above 120 °C, pyrazines and other compounds form quickly and result in roasting flavor (Xu et al. 2017). Heat treatment before baking can improve the formation of pyrazines and lead to a strong flavor of baking (Gu et al. 2015). Besides heat treatment, sourdough also showed effects to 11 pyrazines and resulted in the flavor of bread (Pétel et al. 2017). Gluten-free bread showed a lack of flavor which was due to the lack of pyrazines, but an addition of sugars and amino acids before baking could solve the problem (Pacyński et al. 2015). However, heat treatment is not entirely beneficial, and it will also bring some negative effects. Acrylamide, one of the Maillard-reactions products as a toxic substance, it coupled to pyrazine formation, become a noticeable problem in cereal products processing in industry (García-Lomillo and González-SanJosé 2019). In recent studies, natural antioxidants such as phenolic compounds may prevent their binding, but it also led to a reduction of pyrazines until 81%, resulting in a negative effect to flavor of roasting food (Hedegaard et al. 2008; Jin et al. 2013; Mildner-Szkudlarz et al. 2017). The block of pyrazines is also observed in some processing method, such as vacuum frying potato chips, and some additives can also lead to the formation of unpleasant flavor substances (Belkova et al. 2018; Zhao et al. 2017).

41.2.5 Meat Products

Pyrazines make contributions to flavor notes such as cooked and roasted aromatic notes. This is the main role of pyrazines in meat products (García-Lomillo and González-SanJosé 2019). Different from cereals, there are not many pyrazines in the raw meat, but the thermal processing of the meat produces a lot of pyrazines. Several pyrazines and their derivatives are used in food processing for flavoring purposes or decreasing microbial contaminations (Schöck et al. 2018). Pyrazines derivatives are important flavor substances to meat products. In pork, beef, lamb, chicken, and other meat products, pyrazines are widely detected and confirmed as important odor components (Shahidi 1994). 2-Methyl-3-furanthiol is considered as the most important chemical compound for chicken flavor. Alkylpyrazines are important for fried and roasted chicken flavor, but not chicken broth (Jayasena et al. 2013). After heated at 160 °C for 10 min, methylpyrazines and trimethylpyrazines were identified in pork samples with added carbohydrates (Lauridsen et al. 2006). Thirty-three pyrazines were isolated from beef at 162.7 °C, and 9 alkyl-substituted pyrazines were found in shallow-fried beef as flavor components (Mussinan et al. 1973; Watanabe and Sato 1971). Lamb meat has a stronger flavor profile compared to goat meat because of a higher concentration of volatiles including pyrazines and other lipid-derived components. Besides the quality of raw meat, meat flavors were also influenced by the cooking procedure (Shahidi et al. 1986). Heat treatments, such as roasted and cooked, will produce lots of pyrazines derivatives and forms aroma. Due to different temperature profile, different pyrazines derivatives were formatted in different type of cooking methods. One hundred fifty volatiles were identified in pan-fried pork chops. They are mostly hydrocarbons and only a few nitrogen and sulfur compounds like pyrazines (Meinert et al. 2009). The formation of heterocyclic volatiles was influenced by temperature, compared with roasted pork steaks, and significantly higher (Meinert et al. 2007; Mottram 1985). Among all the cooking methods, the roasting is the one that produces the most variety and quantity of pyrazines. Microwave treatment may induce a rapid surface dehydration that promoted the formation of pyrazines. It produced much more methylpyrazines, 2,3-dimethyl-5-ethylpyrazine, and 2,5-dimethyl-3-ethylpyrazine. And boil will produce much more 2-ethyl-6-methylpyrazine and 2,3,5-trimethylpyrazine (MacLeod and Coppock 1976). Moreover, pyrazines have much higher content in electric oven-cooked pork loin than in oven and air fryer (Yang et al. 2016). For antimicrobial purposes, pyrazines derivatives have been studied and used in the industrial productions. *Paenibacillus polymyxa* could produce alkyl-substituted pyrazines as mediators of antimicrobial effects and works on many plant and human pathogens (Rybakova et al. 2016). In chicken meat processing, 5-isobutyl-2,3-dimethylpyrazine decreased 95% viable bacteria in a maltodextrin carrier, and 2-isobutyl-3-methylpyrazine could improve the antimicrobial effects by surface dehydration to meat (Schöck et al. 2018). The decontamination of eggshells can also be done with specific pyrazine derivatives and shown similar efficiency to traditional methods (Kusstatscher et al. 2017).

41.2.6 Wine

Aroma is very important to wine, influencing the quality of wine directly. As an important flavor substance, pyrazine has been studied for many years, and its role in the aroma of wine has been proved. The naturally occurring and added methoxypyrazines significantly influenced the aroma of wine. To Sauvignon blanc wines, a higher methoxypyrazine concentration was significantly different than the lower in aroma; an addition of 8 ng/L 2-methoxy-3-(2-methylpropyl)pyrazine to the methoxypyrazine-free wine could make a significant contribution to its vegetative aroma (Allen et al. 1991). An analysis of pyrazines in the 22 wines and 16 juice samples from different regions shown that 2-methoxy-3-(2-methylpropyl)pyrazine exist in all the samples and 2-methoxy-3-(1-methylethyl)pyrazine exist in 11 wines and almost all juice samples (Lacey et al. 1991). A quantitative analysis of methoxypyrazines to 18 red wines shown that methoxypyrazine mainly contribute to wine flavor, and 2-methoxy-3-(1-methylpropyl)pyrazine has a very low level in all wines (Allen et al. 1994). The level of 3-isobutyl-2-methoxypyrazine was correlation with vegetable aromas and anticorrelation with fruity aromas (Gracia-Moreno et al. 2014). The growing environment of the fruits used in wine making, including temperature, light, irrigation, and planting density, all affects the content of pyrazine in wine and ultimately contributes to our perception of flavor in finished wines (Lund and Bohlmann 2006). Fruits grown in cooler regions had higher methoxypyrazine levels (Lacey et al. 1991). Irrigated vines had significantly higher level of 3-isobutyl-2-methoxypyrazine than nonirrigated plants, and the average levels of 3-isobutyl-2-methoxypyrazine in vines with the higher plantation density were also higher (Sala et al. 2005). In wine volatiles, isobutyl methoxypyrazine was significantly influenced by harvest date and decreased as ripening progressed (Bindon et al. 2013). The pyrazines in wine are not entirely brought in by the fruits. Some of them are converted during the brewing process. The productions of methoxypyrazines are related to the methylation of nonvolatile hydroxypyrazine precursors. Two *O*-methyltransferases were confirmed to catalyze the methylation of hydroxypyrazines and finally influence the wine flavor (Dunlevy et al. 2010). Besides, Cabernet Franc ice wines were produced with yeast, and the change of yeast strain could lead to a change on the pyrazines concentration (Synos et al. 2015).

41.3 Pyrazine Formation and Main Influencing Factors in Processed Foods

Pyrazines, as the products of thermal food processing, are known to contribute to the unique flavor generation of the food (meat products, roasted products, cereal products). The intermediate product (α-dicarbonyl) of Maillard reaction is the most vital precursor substance of Strecker degradation which leads to the formation of pyrazine. The α-dicarbonyl can be generated by the rearrangement of Amadori or Heyns compounds, which comes from the combination of amino acids and reducing sugars. Then the amine of amino acids is transported to α-dicarbonyl via Strecker

action to form α-aminocarbonyls, which are easy to be dehydrated. After dehydration, the hexatomic ring with two unsaturated bonds is oxidized to form pyrazine (Shu 1998). For instance, the 1,4-^{13}C-labeled L-ascorbic acid and L-glutamic acid was used to investigate the formation mechanism of pyrazine. L-Glutamic acid is found to be able to produce ammonia during heated in aqueous solution. What's more, some intermediates, such as acetol, and carbohyl which are released from the L-ascorbic acid, could interact with ammonia to form α-amino carbonyl or hydroxyl. Then the pyrazines with roasted, nutty smells are synthesized. Recent studies had found that the peptides could also leads to the production of pyrazine (Eric et al. 2014). Traditional Strecker degradation includes imine hydrolysis after decarboxylation, but there is no free carboxyl group exists in dipeptides. A hypothesized synthesis mechanism is exploited to explain the formation of pyrazine. The α-dicarbonyl initially reacts with dipeptides to form an imine. The 1,5-hydride shift brings about the enolization of the α-aminoketones, and 4-hydroxy-2-azadiene is produced and followed by deprotonation. The imino moiety in 4-hydroxy-2-azadiene is hydrolysis to generate α-aminoketone, which finally forms the pyrazine (Van et al. 2012). Many factors affecting the Maillard reaction could also influence the formation of pyrazines, such as temperature, heating time, pH, water activity, amino acids or peptides, sugars, and other compounds in foods.

41.3.1 Temperature and Heating Time

The heating temperature is a curial factor in determining the reaction rates and the production of pyrazine (Zhao et al. 2019). It has been verified that almost no pyrazine is detected in the Maillard reaction with glycine at 100 °C; when the temperature increased by 30 °C, pyrazine and its typical derivatives (2,5(6)-dimethylpyrazine and trimethylpyrazine) are founded. In addition, the various kinds of pyrazines are discovered with high content at 150 °C and 180 °C, which indicates a positive correlation between the content of pyrazine and temperature (Van et al. 2012). What's more, the temperature could influence the types and amount of pyrazine through affecting on pH of the reaction system. The initial pH in Maillard reaction containing the L-cysteine and D-xylose was detected at 7.4 at the temperature for 80 °C. After heating at with at 140 °C for 2 h, the pH was decreased to 5.37. The temperature promotes cysteine to accelerate the formation of some acidic compounds (formic and methylglyoxal), which is able to lower the pH (Eric et al. 2014). The heating time often adjusted with temperature during the thermal process, which the time is set for several minutes for high temperature. For instance, the heating time is set as 4 h at a relative low temperature (120 °C), while it is set as 7 min at a high temperature (300 °C).

41.3.2 pH Values

Pyrazines, as the volatiles with special organoleptic properties, are controlled by the pH values at reaction. In this case, it is necessary to evaluate the influence of pH on

pyrazines to control the flavor of thermally treated food. It has been documented that high pH facilitated the generation of pyrazines (Koehler and Odell 1970). A model Maillard reaction at 140 °C for 2 h with different pH 5.0–9.0 was conducted to measure the influence of pH on the amount of pyrazines. In the reaction between L-ascorbic acid and acidic acids (glutamate and aspartate), the content of pyrazines increased with the upward pH value, and it is nearly impossible to detect pyrazines at pHs 5.0–6.0, even it reached maximum at pH 9.0. Also, it is found that the acidic amino acids are much more sensitive to pH value compared with neural acids, which can produce more pyrazines at same pH values. In addition, the impact of pH values on pyrazine generation of basic amino acids is much smaller in comparison with the neutral amino acids, especially the pH at 8.0–9.0. Besides, the basic condition can contribute to the reset and disintegrate of L-ascorbic acid and promote the amino group existed in amino acids to react with the sugar. In general, high pH value almost has no effect on the formation of pyrazines, but has a deep influence on acidic amino acid. The basic group in basic amino acids could contribute to the formation of pyrazines, and the acidic groups could prevent the formation of pyrazines (Tan and Yu 2012; Yu and Zhang 2010a, b).

41.3.3 Moisture Content

The production of pyrazines has a strict requirement on water activity. The presence or absence of water also is a necessary parameter that influences the odor profiles in foods. A Maillard reaction among glucose, glycine, diglycine, and triglycine was carried out at different water content (0%, 10%, 25%, 50%, 75%, and 100%) for 1 h at 160 °C to explore the impact of water content on volatile (pyrroles and pyrazines) generation. It has observed that the substituted pyrazines occupy a large proportion among volatile in all the reaction systems, and their contents increase along with the increased content of water. Because of the limited mobility and solubility, the production of volatile is slightly restrained. The slight restriction may be related with the formation of water during the Maillard process. Besides, the 2-ethyl-5-methyl-, 2-ethyl-3-methyl-, 2-ethenyl-6-methyl-, 3-ethyl-2,5-dimethyl-, and 2-ethyl-3,5-dimethylpyrazines were detected with the water in low and high levels. In addition, water can dominate the degradation of peptides and the reaction rates (Oliyai and Borchardt 1994; Labuza 1980). It has been pointed out that a maximum yield of pyrazines can be obtained when the water activity is 0.33 in a model system. However, a low pyrazine production can be seen when the water activity exceeds 0.33, which may due to the excessive water produced in several condensation processes of Maillard reaction (Eichner and Karel 1972; Scalone et al. 2015).

41.3.4 Free Amino Acids or Peptides

The types of free amino acids can result in the different yields of pyrazines. For instance, the reaction with L-serine can produce more pyrazines compared with

L-threonine, which may be related with the melting point of L-serine (222 °C) is lower than that of L-threonine (256 °C) (Shu 1999). The addition of leucine to the traditional Maillard reaction causes the formation of 3-methylbutylpyrazine, while the addition of valine leads to the synthesis of 2-methylpropyl pyrazines. These results demonstrated that the different types of peptides could determine the formation of different pyrazines. In relation to the peptides in food, oligopeptides were regarded as the vital precursors on promoting the flavor of fried or roasted foods. The polymerization extent and composition of amino acids play an important role in controlling the amount and kinds of pyrazine. The content of pyrazine produced by glycine or triglycine was apparently higher than that produced by diglycine or tetraglycine (Oh et al. 1991). And a high-content pyrazine formed by dipeptides was detected, which was more than that formed by free amino acids and dipeptides, and the latter can generate more pyrazines than tripeptides (Van et al. 2010, 2012). In addition, pyrazines were produced by glucose or glyoxal with different dipeptides which with lysine at N-terminus (Lys-Lys, Lys-Gly, Lys-Ala, Lys-Leu, Lys-Ser, Lys-Glu, Lys-Cys, or Lys-Phe). When acted with glyoxal, small amount of unsubstituted pyrazines is formed compared with the reaction to glucose. The content of pyrazine (2,5(6)-dimethylpyrazine and trimethylpyrazine) in the reaction with Lys-Leu dipeptides is higher than that react with corresponding amino acids, which may be related with the higher $K_{O/W}$ value of amino acids. Interestingly, the unsubstituted pyrazines are produced more when acting with amino acids. And it can be seen that the different reactivity of N-terminal peptide-bound lysine and R- and ε-amino group of free lysine can produce different kinds of pyrazine (Van et al. 2010). Proline, valine, or leucine at the N-terminus leads to a high content of 2,5(6)-dimethylpyrazine and trimethylpyrazine than the glycine, alanine, or serine at the N-terminus, which may due to the similar structure of dipeptides of Val-Gly, Val-Lys, and Leu-Gly. At the same time, compared with other dipeptides, the speed of pyrazines forming in the reaction between methyglyoxal and Val-Gly, Val-Lys, and Leu-Gly is slower, which may be linked with the huge side group of valine and leucine and is prevented by the α-position deprotonation on amide moiety (Van et al. 2010).

41.3.5 Carbonyl Compounds

It has been confirmed that the generation of pyrazines is closely associated with the type of sugar which the product of sugar is carbon source of pyrazines. The reaction systems involved the leucine and various sugars (fructose, glucose, rhamnose, and the mixture of glucose and fructose (3:1)) are conducted at 100 °C with 1 h. The results show that the reaction with fructose has the maximum output (approximately 8500 μg) of pyrazines. Besides, the more various types of pyrazines are generated when applied rhamnose; and the yield of 2-isoamyl-6-methylpyrazine is the most one compared with other sugars (Ara et al. 2017). The reaction with rhamnose is able to produce more pyrazines than high-fructose corn syrup. And rhamnose affects not only the composition of pyrazines but also the output of C1, C2, C3, and C4 pyrazines (Coleman and Steichen 2006).

41.3.6 Others

Several new Amadori-type conjugates produced during the Maillard reaction are regarded as the crucial intermediate products influencing the formation of pyrazines. The Amadori-type conjugates generated from the aminoketones was regarded as the promoter of pyrazine formation, which may be caused by the subsequent splitting reaction (Zou et al. 2018). The reagent ratio also impacts the formation of pyrazines. It has been confirmed that the different ratio of hydrolyzed whey protein and glucose leads to different content of pyrazines. The amount of pyrazines is at a low level when the protein/glucose ratios is 1:0.08 or 1:0.16, which may be due to the low content of dicarbonyl compounds produced by glucose. As the ratio reaches to 1:0.5 and 1:0.67, the high yield of pyrazines can be discovered. However, the production of pyrazines turns to a downward trend with the increase of the ratio. The excessive glucose is able to generate more carboxylic acids (acetic acid) to decrease the pH of the reaction system (Scalone et al. 2015). It is estimated that some representative pyrazines with roasted and nutty flavor are not detected when the pork loin is roasted. They are easy to be discovered under the deep-fried treatment, which indicates that the cooking methods can also determine pyrazines formation (Yang et al. 2017). At the same time, the oil can be oxidized to act with Strecker degradation products of amino acids to influence formation of pyrazines. The olive oil could produce the most content of pyrazines and followed by sunflower and canola oil. Interestingly, the yield of 2-methylpyrazine, 2,5-dimethylpyrazine, and 2,3-dimethylpyrazine are produced more compared with other oil (Whitfield and Mottram 1992), which maybe the rich content of linoleic acid in sunflower oil. The phenolic compounds ((+)-catechin, quercetin, gallic, ferulic, and caffeic acids) added or existed in thermal can determine the production of pyrazines. It is concluded that the phenolic compounds can inhibit the formation of N^{ϵ}-(carboxymethyl) lysine and prevent the generation of pyrazines. Also, the phenolic compounds have different inhibition effect on the N^{ϵ}-(carboxymethyl)lysine formation, which due to their special thermal stability (Mildner-Szkudlarz et al. 2017). It also proposed that the phenolic compounds serve as the reactive radical precursors' scavenger to wipe out some precursors such as dialkylpyrazine and thus prevent the formation of pyrazines (Wang and Ho 2013). With the formation of pyrazines as a pH-dependent reaction, the addition of phenolic acids decreases the pH of system which further decreases the levels of pyrazines (Yu and Zhang 2010b). What's more, the epicatechin is found to be able to inhibit the formation of pyrazines via affecting the activity of C2, C3, and C4 sugar fragments (Troise et al. 2015).

41.4 Enrichment and Detection

The concentration of pyrazines in food is low. It is necessary to establish an efficient enrichment method for the analysis of pyrazines in liquor. In the present, the main four enrichment methods are liquid-liquid extraction (LLE) (Bañeras et al. 2013),

solid-phase microextraction (SPME) (Wu and Xu 2013), supercritical CO_2 extraction (Fan et al. 2007), and ion exchange (Tae et al. 2013), respectively.

41.4.1 Liquid-Liquid Extraction

Liquid-liquid extraction is one of the unit operations for separating homogeneous liquid mixtures. Liquid mixtures can be separated in a certain solvent because of the solubility difference of each component in liquid mixture. Liquid-liquid extraction involves at least three substances including solute ***A*** and original solvent ***B*** in the raw material liquid and extractant ***S***. There are three types of three-component systems formed by the added extractant and raw material liquid (***A*** + ***B***) as follows: (1) solute ***A*** is completely soluble, but the extraction agent ***S*** and the original solvent ***B*** are completely insoluble, forming ***A*** pair of completely insoluble mixed liquid; (2) the extraction agent ***S*** is partially miscible with the original solvent ***B*** and completely miscible with the solute ***A***, forming ***A*** pair of partially miscible mixed liquid; (3) extraction agent ***S*** is partially miscible with not only the original solvent ***B*** but also the solute ***A***, forming two pairs of partially miscible mixed liquid. Liquid-liquid extraction method can remove volatile components of water, ethanol and interference, and is a good method for the determination of pyrazines. Many researchers extracted pyrazines by liquid-liquid extraction. It is existed method that 15 g fermented grains were weighted at first. After grinding, 30 mL 12% (v/v) ethanol was added to soak for 10 min, and then ultrasonic treatment was performed for 30 min. After centrifugation or filtration, 5 mL of supernatant liquid was extracted and put into a 15-mL extraction bottle, 1.5 g NaCl was added, and a manual sample injector with 2 cm-50/30 μm fiber head was inserted, and the sample was extracted at 60 °C for 40 min in headspace. The extraction head was quickly removed and immediately inserted into the GC injection port (temperature at 250 °C). The samples were injected by thermal analysis for 3 min for pyrazine detection and analysis (Beck et al. 2003).

41.4.2 Solid-Phase Microextraction

The principle of SPME is to apply a layer of polymer stationary phase, such as polydimethylsiloxane or polyacrylate, with a thickness of 30~100 μm on a fused silica fiber about 1 cm long. The fiber is connected to a stainless steel plunger shaped like a syringe device and contracts into the stainless steel needle. The plunger contacts fiber from the needle and the sample solution or headspace so that the analyte is adsorbed and distributed to the coating layer. The analyte, concentrated on the fibers, is released into the column by thermal desorption at the GC entry. In the case of HPLC, the analyte adsorbed on the fiber is transferred to the column by virtue of SPME-HPLC interface (Spietelun et al. 2010). SPME is characterized by sampling, extraction, enrichment, and injection. General sample pretreatment methods

can only complete one or two steps, while SPME integrates multiple steps to simplify the sample pretreatment process according to its own characteristics. SPME is easy to operate and directly interacts with the solid-phase coating and hardly consumes solvent. It can reduce the cost and protect the environment. The speed of SPME depends on the time required for analyte distribution equilibrium, which can be reached within 2~30 min. The technique is suitable for the enrichment of trace or trace components. Furthermore, SPME-mass coupled technology was proposed for accurate extraction. For GC/MS instrument, the sample mixture was separated through chromatographic column and then moved into the mass spectrometer in the high vacuum environment. Positively charged fragments are accelerated by electric field into the quality analyzer, which can detect the number of ions with different mass quantity (abundance) mapping, which is the mass spectrogram. If the mass spectrogram of the chromatographic peak location matches the mass spectrogram of the standard compound in the spectrum library with a high matching rate and the same retention time, the chemical structure of the component can be identified. Therefore, SPME-GC-MS is a new extraction separation and identification technology. After the substance is pre-treated by SPME, it is separated in the GC. And then the mass spectrogram is obtained in the MS, which is analyzed by mass spectrogram and combined with the retention time of GC to identify the structural formula of the compound (Vas and Vékey 2004). Compared with traditional methods, this technique has the advantages of no solvent, simple and fast, economic and nontoxic, high accuracy and sensitivity, and convenient combination. In the recent years, many of the pyrazines in liquor are extracted through SPME. For example, researchers take 150 mL wine sample in a beaker and adjust its pH value to 1 with 6 mol/L H_2SO_4. The concentrated liquid was collected, and its volume was recorded by evaporation and concentration at 60 °C for 30 min. The concentration pH was 12 with 6 mol/L NaOH. Then the 50/30 μm DVB/CAR extracted fiber was aged at 250 °C for 30 min at the GC inlet. The prepared liquor sample and standard solution 1 mL were respectively added to the empty top bottle, and then sodium chloride was added to the empty top bottle until the solution was saturated, and a magnet was added to stir the rotor and sealed. The magnetic agitator is stable for 15 min at 2800 r/min 40 °C to reach gas-liquid equilibrium. The aged-extracted fiber is inserted into the headspace of the headspace bottle (the extracted fiber does not touch the solution) and continuously stirred and extracted for 20 min at the same temperature. After extraction, the extracted fiber is pulled into the needle sheath, and the SPME device is removed from the headspace bottle. The SPME device was inserted into the injection port of the GC for sample injection, and it was removed after thermal desorption at 260 °C for 5 min. The conditions of GC were as follows: the injection port temperature 260 °C and the splitless mode for injection. The initial column temperature was 60 °C, and the velocity rose to 260 °C within 10 min at 20 °C/min. The carrier gas was nitrogen, and the constant flow rate was 2 mL/min. The mass spectrum conditions were ionization mode EI, electron energy 70 eV, interface temperature 280 °C, threshold 100, scanning/second 2.67, and scanning mass number 15–600 amub (Lojzova et al. 2009).

41.4.3 Supercritical CO_2 Extraction

Ion exchange refers to the unit operation of mass transfer separation process by means of exchange of ions in a solid ion exchanger with ions in a dilute solution for the purpose of extracting or removing certain ions in the solution. Ion exchange is a reversible equivalent exchange reaction (Kazarian et al. 2013). The ion-exchange resin is sandwiched between the anion exchange membranes to form a single processing unit and constitutes a freshwater chamber. The ion exchange rate decreases as the degree of cross-linking of the resin increases and increases as the particle decreases. Ion exchange is a liquid-solid phase reaction process, which involves the diffusion process of substances in liquid and solid phases. Typical ion exchangers are ion-exchange resins (functionalized porous or gel polymer), zeolites, montmorillonite, clay, and soil humus (Traynor and Ahmad 2018). Ion exchangers are either cation exchangers, which exchange positively charged ions (cations), or anion exchangers, which exchange negatively charged ions (anions). There are also amphoteric exchangers that are able to exchange both cations and anions simultaneously. However, the simultaneous exchange of cations and anions can be more efficiently performed in mixed beds, which contain a mixture of anion- and cation-exchange resins, or pass the treated solution through several different ion-exchange materials. Ion exchange is a reversible process, and the ion exchanger can be regenerated or loaded with desirable ions by washing with an excess of these ions. The method of ion exchange of pyrazine is as follows: take 20 g of resin, and wash it repeatedly with 2 N NaOH, water, 4 N HCI, water, and acetone until the final acetone immersion liquid is colorless. Wet method is loaded into the glass column, washed with 20 ml l N NaOH, and then washed with distilled water until neutral for use. The pH value of samples (50 mL) was adjusted to 12.5 by 2 N NaOH, and then the samples were transferred to the exchange column at a flow rate of 5–10 (mL/min). 25 mL of mixture (2 mL 2 N NaOH mixed with 23 mL of methanol) and 25 mL of water were used to remove impurities. Then it was eluted with 25 mL 4 N HCl and 25 mL of water, collected with 3 × 10 mL CH_2Cl_2 extraction, eluted with 50 mL of acetone-water (4:1, V/V), collected and extracted with 3 × 10 mL CH_2Cl_2 Then combined with the extracts were combined and washed with a 10 mL 2% $NaHCO_3$ solution. The organic acid was removed, dried over anhydrous Na_2SO_4, and concentrated to 0.5 mL. Then, 0.5 mL derivatization reagent and several K_2CO_3 were added to the concentrated liquid. Finally, the mixture was refluxed at 60–70 °C for 2.5 h, dried with N_2, and dissolved with 0.5 mL of n-hexane to carry out gas chromatography (Calull et al. 1992; Nagarale et al. 2006).

41.4.4 Other Methods

Worben et al. (2006) have revealed that vacuum distillation could remove most of the ethanol and water in the wine and then extracted with CH_2Cl_2, GC-MS separation, and identification of pyrazines in rum and whiskey. Lu et al. (1989) have

reported that cationic resin enriched nitrogen compounds in white wine and a total of 12 pyrazines were detected. Yu et al. (1992) found that the acidification-extraction method was conducted to analyze nitrogen-containing compounds in liquor and obtained 36 kinds of nitrogen-containing compounds including 27 pyrazines. Xu et al. (2008) have used the liquid-liquid extraction combined with normal phase chromatography to detect 32 kinds of pyrazine compounds in Jiannanchun wine by full two-dimensional gas chromatography-flying gas chromatography-mass spectrometry (GC×GC-TOF/MS).

41.5 Biological Activities

Pure pyrazines are rarely found in nature and mostly in the form of derivatives. There are many substitute pyrazines in nature. These pyrazines carry substituents on one or more of the four ring carbon atoms. These substituents may include oxygen-containing functional groups, such as alkoxy and acyl groups, or sulfur-containing mercaptan or sulfide groups. Alkylpyrazines contain carbon and hydrogen substituents, and 70 different compounds have been identified such as phenazine, pteridines, and tetramethylpyrazine (Rudolf and Sugima 2010; Wagner et al. 1999). Pyrazine is less basic (pKa = 0.7) than pyridine (pKa = 5.2), pyrimidine (pKa = 1.3), or pyrimidine (pKa = 2.3). Studies have shown that pyrazine derivatives are best absorbed at intestinal pHs 5–7. In humans and laboratory rodents, oral replacement pyrazines are rapidly absorbed and excreted from the gastrointestinal tract, which is possible to ingestion of flavorings containing pyrazine derivatives without adverse health effects. Pyrazine sequences are found in many compounds, which are the source of unique flavors and aromas in several foods and wines (Sumoto et al. 1991; Rohovec et al. 2010). Although pyrazines are widely studied as a flavor component of food, its derivatives are widely used in medicine, food, and chemicals. Pteridines are compounds based on a pyrimido[4,5-b]pyrazine ring system. These compounds exhibit different biological functions and have been widely concerned in the medical field. Pteridines derivatives have been synthesized and determined for bioactivity. They showed the great potential for drug development by targeting a variety of human diseases including cancer, chronic inflammatory diseases, and microbial infections (Kompis et al. 2005).

Cancer is the second leading cause of death in the world. The number of cancer cases is expected to double in the next 20 years (Alan Kambiz and Freidoun 2008). In order to reduce the resistance of cancer drugs to cancer cells, pteridines have been widely studied and shown to have many anticancer effects. Over the past half century, methotrexate (pteridines derivative) has been used as an anticancer drug, either alone or in combination with other chemotherapy drugs. It was used to treat breast cancer, cutaneous T-cell lymphoma, lymphoblastic leukemia, lung cancer, and advanced non-Hodgkin's lymphoma Carmona-Martínez et al. (2018). It has been reported that pteridine-based compounds have a variety of biological activities, such as anti-inflammatory (Hoffmann et al. 2003; Li et al. 2015), analgesic (Gomtsyan et al. 2004), anti-nematode, antibacterial (Shen et al. 2007), and antivirus activities.

Inflammation is an immune process triggered by the presence of pathogens or damaged tissues. In the process of inflammation, the production of signaling molecules such as cytokines and the aggregation of immune cells help to eliminate pathogens and restore tissues. However, most mechanisms designed to kill pathogens and/or kill dead cells also damage normal cells. Nonsteroidal anti-inflammatory drugs are commonly used to reduce inflammation. However, they are not recommended to treat chronic diseases because of their side effects. In recent years, the anti-TNF drugs have been used to treat autoimmune inflammatory diseases. Most patients do not respond to these drugs and can have adverse effects, such as immunosuppression or neurological failure. It is of great significance to develop a new type of anti-inflammatory drug. Currently, 88 different types of pteridine derivatives have been studied for this purpose (Li et al. 2017). Most pteridine derivatives can inhibit TNF-α and IL-6 of pro-inflammatory cytokines in vitro and are treated by lipopolysaccharide in the human macrophage like myeloid leukemia cells of the HL-60 cell model without resulting in cytotoxicity.

The Ca^{2+}-activated K^{+} (BKCa) channel or Maxi K is expressed in smooth muscle cells and is an important regulator of vascular tension. The opening of BKCa channels inhibits voltage-dependent Ca^{2+} channels, restricting extracellular Ca^{2+} access to smooth muscle cells and inhibiting vasoconstriction (Ledoux et al. 2006). The BKCa channel is the target area for relaxation factors released by endothelial cells including nitric oxide (Bolotina et al. 1994) and endothelium-derived hyperpolarizing factor (Archer et al. 2003; Weston et al. 2010). Changes in the expression or BKCa channel activity have been found to be associated with vascular dysfunction in various diseases, such as atherosclerosis, hypertension, diabetes, and metabolic syndrome (Amberg and Santana 2003; Borbouse et al. 2009; Sébastien et al. 2003). Tetramethylpyrazine is an alkaloid compound isolated from *Ligusticum*. Its cardioprotective effects are attributed to vasodilation, anti-inflammatory, antioxidant, and Ca^{2+} homeostasis activities (Guo et al. 2016). In a recent study, tetramethylpyrazine was shown to have strong anti-endoplasmic reticulum stress activity. In endoplasmic reticulum stress coronary endothelial cells, tetramethylpyrazine and endoplasmic reticulum stress inhibitors have the similar inhibitory effects on the activation of unfolded protein response sensor. And this inhibitory effect has a significant protective effect on endothelial function in hypertension-related conditions (Mak et al. 2017; Sun et al. 2019). In addition, tetramethylpyrazine has been used in clinical treatment with mild side effects for ischemic, cerebral infarction and central nervous system degenerative diseases, such as Alzheimer's disease, Parkinson's disease, and multiple sclerosis (Tang et al. 2011; Yang and Jiang 2010). Tetramethylpyrazine may significantly prevent lipid peroxidation and necrosis of neurons by eliminating oxygen free radicals (Zhikuan et al. 2008). At present, more and more evidences show that tetramethylpyrazine combined with other treatments can significantly reduce the drug resistance caused by chemotherapy and inhibit the proliferation and metastasis of melanoma cells, lung cancer, gastric cancer, and other cancer cells (Huang et al. 2012; Ji et al. 2014). Interestingly, the recent study showed that tetramethylpyridine significantly protected hippocampal neurons by co-culture of glioma neurons while inhibiting glioma

cell survival in vitro (Fu et al. 2008). It can make glioma subside and prolong the survival of glioma transplanted rats. Tetramethylpyrazine may have the potential to treat glioblastoma (Chen et al. 2013).

Phenazine is a kind of secondary metabolite produced by gram-positive bacteria, gram-negative bacteria or palaeomethane bacteria (Laursen and Nielsen 2004). In addition, it is also a class of nitrogen-containing heterocyclic compounds, which have extensive antibacterial properties. Their properties vary based on the type and location of functional groups (Pierson and Pierson 2010). Natural and synthetic phenazines have many biological activities, such as antihypertensive drugs, antiparasitic drugs, antimalarials, neuroprotectants, free radical scavengers, and anticancer agents (Laursen and Nielsen 2004; Laura et al. 2010; Mavrodi et al. 2006). Krishnaiah et al. (2018) found that 6,9-dichloro-n-(methylsulfonyl)phenazine-1-carboxamide and 9-methyl -*N*-(methylsulfonyl)phenazine-1-carboxamide showed certain effects on drug-resistant *Escherichia coli* and *Staphylococcus aureus*.

Phenylpropanoids (Phenylpropenes) in Diets

42

Sushmita Nath, Lutfun Nahar, and Satyajit D. Sarker

Contents

Abstract

Phenylpropanoids are a large group of phytochemicals that are biosynthesized from the amino acids, phenylalanine, and tyrosine, and they contain at least a phenyl ring linked to a three-carbon alkyl (propyl) group (C_6–C_3 structure). They also form one of the common groups of bioactive phytochemicals that are distributed in plant-based diets. A majority of phenylpropanoids contains

an unsaturated three-carbon alkenyl chain and is commonly known as phenylpropenes, e.g., cinnamic acid and its derivatives. Thus, the main coverage of this chapter is on phenylpropene derivatives found in food plants and their bioactivities that are established from in vivo testing using either animal models or human trials. The chapter also briefly deals with bioavailability and metabolism of these bioactive dietary phytochemicals.

42.1 Introduction

Phenylpropanoids are a large group of phytochemicals that are biosynthesized from the amino acids, phenylalanine, and tyrosine, and they contain at least a phenyl ring linked to a three-carbon alkyl (propyl) group (C_6–C_3 structure). They are the building blocks and/or intermediates for the biosynthesis of more complex natural products, e.g., coumarins, flavonoids, isoflavonoids, and lignans (Sarker et al. 2002; Sarker and Nahar 2007; Koeduka et al. 2014; Atkinson 2016; Marei and Abdelgaleil 2018). These compounds are distributed widely in the plant kingdom but predominantly found in essential oil-producing plants from the families of Apiaceae, Lamiaceae, Lauraceae, Myrtaceae, and Rutaceae, many of those plants are food plants. The vast majority of phytochemicals of this class contain an unsaturated three-carbon alkenyl chain and are commonly known as phenylpropenes, e.g., cinnamic acid and its derivatives; thus, the main coverage of this chapter will be on phenylpropene derivatives. Diversity in the phenylpropene core structure is generally governed by the position of the propenyl double bond position as allyl-phenylpropenes and propenyl-phenylpropenes and various substitutions on the phenyl ring as well as oxidation status on the C_3 side chain, leading to the formation of terminal alcohol, aldehyde, or carboxylic acid (Fig. 1) (Koeduka 2018). Many components of plant essential oils are phenylpropenes, e.g., eugenol, and they often offer distinctive fragrance to the oils. Because of their fragrance, they are used as flavoring agents in processed foodstuffs (Atkinson 2016; Marei and Abdelgaleil 2018). In plants, phenylpropanoids are known

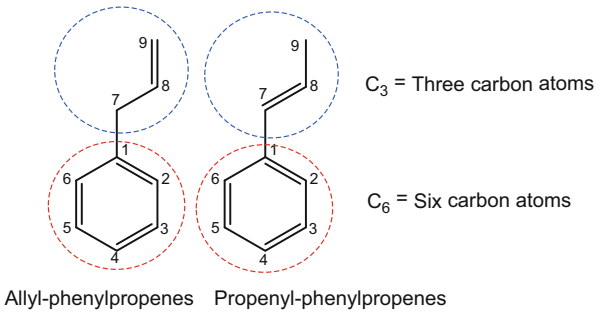

Fig. 1 Core structures of phenylpropenes with different positions of the double bond

to provide protection against biotic and abiotic stresses (Koeduka et al. 2014) and act as chemical defense against various pathogens including microbial attacks (Gang et al. 2002; Özcan and Chalchat 2006; Atkinson 2016).

The tropical and subtropical plants, especially their fruits, contain a high concentration of phenylpropenes, which are biosynthesized through the shikimic acid pathway from their precursor phenylalanine by forming an intermediate cinnamic acid (Fig. 2). Later on, this leads to the biosynthesis of different structural analogs and derivatives incorporating side chain modifications, changes in functional groups, isomeric variation, and oxidation. As these compounds form the major group of phytochemicals within the food plants and often possess culinary significance and medicinal values, they attract food scientists or phytochemists working with food plants for various chemical, pharmacological, and toxicological studies. The traditional medicinal uses of some phenylpropene-containing plants are summarized in Table 1.

42.2 Bioactive Constituents

Aroma of phenylpropenes, especially in edible plants and their folklore medicinal uses, has always intrigued the phytochemists to study their potent bioactive constituents. The amounts of phenylpropenes present in popular culinary species like cloves, fennel, star anise, nutmeg, cinnamon, sweet basil, and rosemary are high. In addition to culinary values, all these plants have significant medicinal value as antimicrobial, antioxidant, anti-inflammatory, anthelmintic, expectorant, and anticancer agents, because of the presence of a variety of phenylpropenes. Notable bioactive phenylpropenes (Fig. 3) isolated from dietary plants include apiole (**1**) from parsley (Parthasarathy et al. 2008), anethole (**2**) from anise (Parthasarathy et al. 2008), caffeic acid (**3**) from coffee (Ross 2005), chavicol (**4**) from allspice (Parthasarathy et al. 2008), cinnamaldehyde (**5**) from cinnamon (Parthasarathy et al. 2008), curcumin (**6**) from turmeric (Parthasarathy et al. 2008), estragole (**7**) from fennel (Gross et al. 2009), eugenol (**8**) from clove (Jirovetz et al. 2006), ferulic acid (**9**) from popcorn (Zhao and Moghadasian 2008), isochavicol (**10**) from apple (Atkinson 2016), isoeugenol (**11**) from apple (Atkinson 2016), methyleugenol (**12**) from apple (Atkinson 2016), methyl isoeugenol (**13**) from strawberry (Atkinson 2016), myristicin (**14**) from nutmeg (Parthasarathy et al. 2008), rosmarinic acid (**15**) from rosemary (Parthasarathy et al. 2008), safrole (**16**) from sassafras (Long et al. 1963), and sinapic acid (**17**) from lemon (Nićiforović and Abramovič 2014).

42.3 Bioavailability and Metabolism

High intake of fruits and vegetables, the key source of phenylpropanoids/phenylpropenes, reduces the chances of degenerative diseases. These dietary sources have different rates of absorption by the systemic circulation followed by the different percentage of bioavailability and metabolism. To make a nutrient bioavailable, it needs to be converted into a bioaccessible chemical from the food matrix so that the gut cells can absorb it. Different phenylpropenes have different rates of

bioavailability and metabolism because of their chemical diversity in presence/absence of certain functionalities contributing to solubility and absorption through GI tract.

For this instance, we can take the example of ferulic acid (FA; ferulic acid, **9**), which in comparison to the other dietary phenylpropenes studied so far, is more bioavailable and has antioxidant efficacy. The bioavailability of FA depends on its absorption in the target tissue. According to pharmacological evidences, FA remains in the blood circulation for a longer period and thus resides in the body for a considerable time to get absorbed. Human can ingest around 80–165 mg of FA per meal, which is present in both conjugated and free forms. Around 56.1% of FA rapidly gets absorbed by the enterocytes as conjugative derivatives. Just within 15–30 min of FA ingestion, its absorption rate remains high. About 50% of FA reaches the liver and enters into the hepatocytes and 6% of that secrete in the bile. An amount of 49.9% of the remaining conjugated FA gets distributed into the bloodstream, gastric mucosa, and peripheral tissues. Around 0.5–0.8% FA is excreted through feces, and the remaining is excreted through urine. Mainly the foregut absorbs free FA and feruloyl monomers (e.g., γ-oryzanol), which further metabolized into FA-glucuronides and FA-sulfates by conjugation in the liver and intestinal mucosa. Furthermore, a part of FA undergoes β-oxidation to metabolize in the liver and produces the metabolites dihydroferulic acid and vanillic acid. These metabolites by concatenating with free FA flow through the circulatory system to reach to the target organs like the intestine, spleen, lungs, and kidneys. In the intestine, the esterases present in the lumen hydrolyze the FA to free FA for immediate absorption. Chiefly, the feruloyl monomers and oligomers of FA are hydrolyzed in the small intestine, whereas the feruloyl polysaccharides and feruloyl oligosaccharides need the assistance of intestinal microflora to be hydrolyzed to produce dihydroferulic acid, hydroxyphenylpropionic acid, and phenylpropionic acid (Fig. 4). This is because of the complex structure of feruloyl polysaccharides, which reduces the interaction between the hydrolyzing enzymes, xylanases and ferulate esterases, and FA polymers. All these products after absorption are further metabolized into benzoic acids and hippuric acids in conjugated form in the liver. Upon completion of this cycle, the metabolites are excreted through urine as

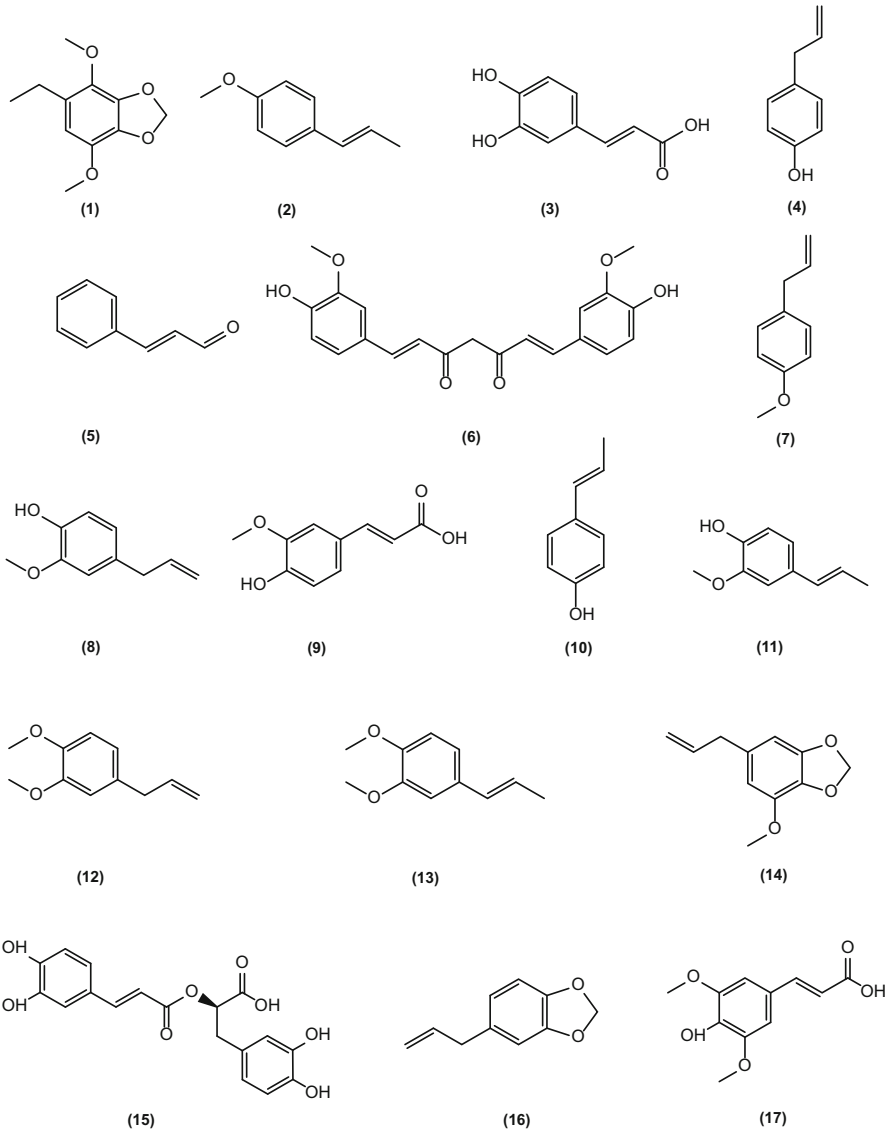

Fig. 3 Bioactive phenylpropenes available in edible plants

3-hydroxyphenyl and 3-methoxy-4-hydroxy phenyl derivatives (Fig. 4). The free or bound forms of dietary FA determine the degree of their absorbability and availability, which has been described in Table 2.

In this process, FA is converted to active form CoA thioester by feruloyl-CoA synthetase, which subsequently is hydrated and catalyzed by β-ketothiolase (Świzdor et al. 2012). The intestinal mucosa and kidney are also involved in this

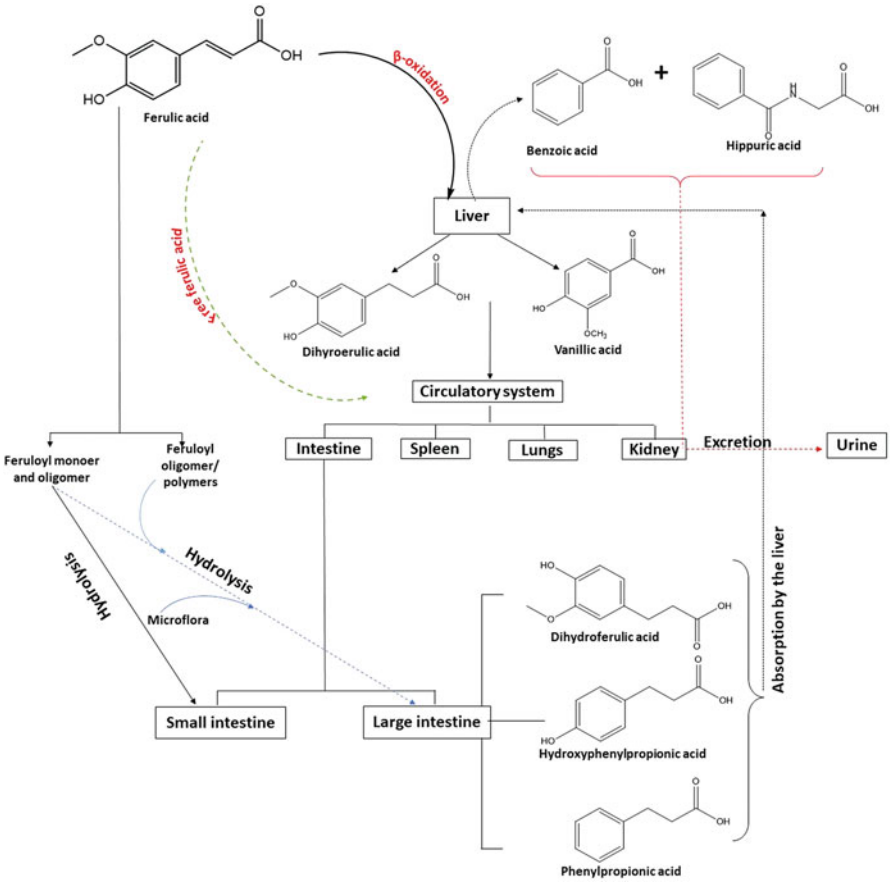

Fig. 4 Diagrammatic representation of ferulic acid metabolism

Table 2 Urinary excretion of dietary FA in human (Zhao and Moghadasian 2008)

Dietary source	Forms of FA	Urinary recovery (%)
Tomatoes	Free and glucuronide FA	25–11
High barn breakfast	Free and conjugated FA	3.13
Pine bark extract	Free and conjugated FA	>92

conjugation process. High intake of FA-rich food (e.g., popcorn) saturates the conjugation enzymes and intensifies the free FA accumulation in plasma and is excreted from the body by a rapid filtration through the kidneys.

Another example can be anethole (**2**), which after oral administration is excreted within 24 h as conjugates of anisic acid and *p*-hydroxybenzoic acid through urine. It follows uniform distribution in the body. Intravenous dose of anethole (**2**) accumulates into the liver, lungs, and brain. It undergoes biotransformation by *N*-oxidation, *O*-demethylation, and epoxidation. The first route is the source of metabolites

like derivatives of cinnamic acid and benzoic acid for ~60–65% dose. The second route is responsible for 40–50% dose. Approximately 30% was excreted as urine metabolites and 0.5% dose excreted as radioactive urea through urine (Tisserand and Young 2014).

Estragole (**7**) is a yet another excellent example. After oral administration of estragole (**7**), it undergoes *O*-methylation and forms chavicol (**4**). It also undergoes oxidation in the allylic side chain and produces the genotoxic metabolites 1′-hydroxyestragole (0.9–8%) and estragole 2′,3′-oxide. 1′-Hydroxyestragole is further converted to its sulfate conjugate 1′-sulfooxyestragole. The liver cells coverts approximately 12.5% of estragole (**7**) into 1′-hydroxyestragole within 24 h and excretes through 0.3–0.4% of ingested estragole (**7**) through urine (Tisserand and Young 2014). Estragole 2′,3′-oxide forms an unstable DNA adduct, which rapidly gets deactivated by detoxification reaction.

Around 75–85% cinnamaldehyde (**5**) is distributed in the gastrointestinal tract, ~2% in blood, ~2% in muscle, ~1% in liver, and ~0.3% in kidneys and other tissues just after 30–60 min of oral administration. It follows the major metabolic pathway of β-oxidation and is excreted through urine in the form of 81.6–84.8% hippuric acid, 3.4–5.1% benzoic acid, and 1.0–1.6% cinnamic acid. The hippuric acid further conjugates with glucuronic acid or glycine (Tisserand and Young 2014). Eugenol (**8**) is rapidly distributed in the blood and kidneys after oral administration. A 70% oral dose is excreted through urine. For an oral dose of 150 mg, 95% is excreted in urine, ~55% as glucuronide and sulfate conjugates and 0.1% as unchanged eugenol (**8**).

42.4 Bioactivities (Animal Aspects)

Phenylpropenes have a wide range of bioactivities like antioxidant, anti-inflammatory, anticarcinogenic, antidiabetic, and so on; many of the bioactivities have been documented through in vivo investigations on various animal models. Some notable bioactivities of some frequently used phenylpropenes, which have been tested on animals for the evaluation of their therapeutic efficacy, are summarized in Table 3.

42.5 Benefits (Human Studies)

Phenylpropenes are an essential part of human diet and are ubiquitous in plants. These key plant metabolites are abundantly present in fruits and vegetables. Studies have shown that their potential therapeutic properties play a major role in human health benefits. Some of such vital benefits of phenylpropenes are outlined in Table 4.

Table 3 Bioactivities of some major dietary phenylpropenes, established from animal studies

Phenylpropenes	Bioactivity	Animal model	References
Apiole (**1**)	Anti-inflammatory	Rat	de Cássia da Silveira e Sá et al. 2014
Anethole (**2**)	Anti-inflammatory, convulsive, antioxidant, reproductive toxicity, secrolytic expectorant, sedative activity, antinociceptive, and gastroprotective	Balb/c mice, Swiss mice, mouse, pig, and rat	Freire et al. 2005; Wang et al. 2011; Kang et al. 2013; de Cássia da Silveira e Sá et al. 2014; Marinov and Valcheva-Kuzmanova 2015
Caffeic acid (**3**) and its derivatives	Antioxidant, anti-inflammatory, and antidiabetic	Rat	Zhang et al. 2014
Chavicol (**4**)	Muscle reluctant, anticonvulsant, and gastroprotective	Guinea pig, mice, and rat	Shojaii and Abdollahi Fard 2012
Cinnamaldehyde (**5**)	Anti-inflammatory, anticancer, antidiabetic, and chemoprotective	Balb/c mice, rat, mice	Bandara et al. 2012; de Cássia da Silveira e Sá et al. 2014; Ashakirin et al. 2017
Curcumin (**6**)	Chemoprotective, hepatoprotective, antioxidant, anti-inflammatory, and antifertility	Rats, pigs	Beevers and Huang 2011; Kádasi et al. 2012
Estragole (**7**)	Muscle reluctant, anticonvulsant, analgesic, laxative, and sedative	Rats, mice	Wang et al. 2011; Shojaii and Abdollahi Fard 2012
Eugenol (**8**)	Antioxidant, anti-inflammatory, hepatoprotective, and DNA-protective	Wistar rats, rabbit, rat, bovine, murine	Yogalakshmi et al. 2010; Bachiega et al. 2012; de Cássia da Silveira e Sá et al. 2014
Ferulic acid (**9**)	Antioxidant, anti-inflammatory, antidiabetic, anticholesterolemic, neuroprotective, antithrombosis, and anti-atherosclerosis	Wistar rats, murine, rabbit	Ou and Kwok 2004; Paiva et al. 2013
Isoeugenol (**10**)	Anti-arthritic	Murine	Kaur and Sultana 2012
Methyleugenol (**11**)	Hepatoprotective	F344 rats	Alhusainy et al. 2014
Methyl isoeugenol (**12**)	Anxiolytic and antidepressant	Swiss mice	Fajemiroye et al. 2014
Myristicin (**13**)	Analgesic, anti-inflammatory, antipyretic, antithrombotic, antidiarrheal, and hepatoprotective	Rats, mice	Olajide et al. 2000; Morita et al. 2003

Antidiabetic	Cinnamaldehyde (**5**) and curcumin (**6**)	Beevers and Huang 2011; Bandara et al. 2012
Anti-inflammatory	Anethole (**2**), cinnamaldehyde (**5**), curcumin (**6**), and eugenol (**8**)	Gupta et al. 2013; de Cássia da Silveira e Sá et al. 2014; Marinov and Valcheva-Kuzmanova 2015
Antimicrobial and antiplasmodial	Anethole (**2**), cinnamaldehyde (**5**), eugenol (**8**), ferulic acid (**9**), isochavicol (**10**), isoeugenol (**11**), methyleugenol (**12**), and safrole (**16**)	Miladi et al. 2010; Nazzaro et al. 2013; Diao et al. 2014; Koeduka et al. 2014; Gharib et al. 2017; Marei and Abdelgaleil 2018
Estrogenic activity	Anethole (**2**), eugenol (**8**), isoeugenol (**11**), and methyleugenol (**12**)	Tisserand and Young 2014
Inhibition of lipid peroxidation	Ferulic acid (**9**) and sinapic acid (**17**)	Nićiforović and Abramovič 2014)
Menopausal hot flash reducer	Anethole (**2**), estragole (**7**), and eugenol (**8**)	Shojaii and Abdollahi Fard 2012
Photoprotection of the skin	Caffeic acid (**3**) and ferulic acid (**9**)	Saija et al. 1999; Chan et al. 2004; Lin et al. 2005

42.6 Application in Food (Including Correctly Cooking Foods Rich in Phytochemicals)

The edible plants are rich in phenylpropenes (Table 1) that have great culinary values. This section of the chapter gives a glimpse of the application of these phenylpropene-rich plants in food. The stems, leaves, flowers, and fruits of these plants are widely used as flavoring spices and food additives. For example, sweet basil leaves are extensively used in salads, meats, and soups for its distinct aroma. EOs from allspice is used as a flavoring agent in meat products. The European Commission (2002/113/EC, 2002; 2004/1935/EC, 2004; 89/1107/EEC, 1989) has accepted phenylpropenes like eugenol (**8**) and cinnamaldehyde (**5**) to be used as food flavoring agents. The phenylpropenes in processed foods, like addition of cinnamaldehyde (**5**), enhance the taste of carrot broth. The use of cinnamaldehyde (**5**) in food in vapor form is a potential way. Sometimes the phenylpropenes are used as food preservatives, for example, ferulic acid (**9**). Due to its low toxicity level, it is used as a popular food additive and a natural antioxidant. Rosmarinic acid (**15**) is favored in meat industry due to its meat quality-enhancing capacity. Additionally, it improves the self-life of meat products (Alagawany et al. 2017). Eugenol (**8**) is another extensively used flavoring and fragrance agent. Typically, at a concentration range of 0.05–0.1% (v/v), eugenol (**8**) is used as a food additive. Strawberries treated with eugenol show delayed fruit deterioration.

Additionally, the fruit like bitter gourd rich in phenylpropene is a favorite culinary ingredient in Asian kitchen. People in Taiwan prepare the welcome beverage by mixing its juice with honey. Another example of this category of fruit is carrot. Carrot has worldwide consumer mainly because of its antioxidant values. It can be eaten as steamed, boiled, stews, soups, and salads to get the benefits of the phytochemicals present in it. Juice, cakes, and puddings are also made from carrot to enhance its taste. Apiole (**1**) is abundantly present in parsley leaves, which is used as a freshly chopped form in foods to enhance the flavor. Costmary leaves, having a high content of caffeic (**3**) and ferulic acid (**9**), are used freshly in salads, minced meat, beverages, and cakes to add spicy flavor (Preedy 2015). The cumin seeds are rich in anethole (**2**), estragole (**7**), and ferulic acid (**9**). They have worldwide usage as a spice in various ethnic cuisines for flavoring foods and beverages. The whole seeds are also used as food preservatives to improve the self-life of the food product. Hyssop is another aromatic plant rich in rosmarinic acid (**15**) and caffeic acid (**3**). This plant is famous for its minty aroma and quite popular in Mediterranean kitchen. The phytochemical content is high in its leaves, and therefore they are used in a limited quantity in green salads. The leaves are also used for baking pita breads, which adds the aroma. The whole herbs are used in the form of soup and tea, whereas the young leaves are used as a seasoning for soft cheeses. The nutmeg is the key source of myristicin (**14**), and safrole (**16**) is extensively used in traditional cooking for the sweets preparation. The seed powder is used as a spice to flavor the baked foods, puddings, meats, soft drinks, and vegetables. Its essential oil is used for

flavoring the processed foods. Its mace in dried form is used for flavoring the sweets and dairy products. Another popular phenylpropene-rich culinary ingredient is star anise, containing anethole (**2**). Its essential oil is produced by steam distillation to use in culinary usage. The oil is extensively used as a flavoring agent for alcohols and soft drinks. The aqueous extracts of its fruits are also taken as tea due to its high antioxidant and antimicrobial efficacy. The safrole (**16**)-rich Tasmanian pepper leaf extracts are used in savory dishes. This extract enhances the flavor of cooked meat (Preedy 2015).

42.7 Safety: Toxicity and Side Effects

The human diet frequently includes plants because of their phytochemicals. As these metabolites are produced naturally, therefore they are thought to be safe to consume. Whereas this is not the actual case, in some cases, these naturally occurring substances may lead to severe toxicity and health issues. Phenylpropenes present in fruits and vegetables sometimes may cause toxic effect if they are not handled carefully within the stipulated dose limit. In this section, a few of such kind of examples have been discussed.

One of the commonly available phenylpropene is apiole (**1**). It causes hepatotoxicity and nephrotoxicity and may lead to abortion if the oral consumption limits exceed 53 mg/kg/day. Intake of apiole (**1**)-rich food/fruits/vegetables during pregnancy is not preferable due to high abortifacient activity. The most common apiole (**1**) poisoning are abdominal pain, vaginal bleeding, vomiting, and diarrhea (Tisserand and Young 2014). Hazardous effects of anethole (**2**) overdose are nausea, vomiting, seizures, pulmonary edema, modulation of reproductive hormones, induction of carcinogenicity, and inhibition of blood coagulation if the oral intake exceeds the limit of 54 mg/kg/day. Precautions should be taken while taking the anethole (**2**)-rich content for a person on diabetes or anticoagulant medication because anethole (**2**) interferes with blood glucose and blood clotting cascades. However, anethole (**2**) as a flavoring agent does not have any safety concern (Tisserand and Young 2014; Marinov and Valcheva-Kuzmanova 2015). As a side effect, cinnamaldehyde (**5**) causes skin sensitization and depletes hepatic glutathione. Patients on antidiabetic drugs are advised to avoid cinnamaldehyde (**5**) content because of its antiplatelet aggregation activity. As per the safety concern, estragole (**7**) is a potential carcinogenic and reproductive hormone modulator. It interferes with diabetic medications as it inhibits platelet aggregation. High exposure of eugenol (**8**) and methyleugenol (**12**) potentially becomes carcinogenic. Its maximum oral dose concentration is 233 mg/kg/day, and for dermal usage, the maximum is 0.02%. As a side effect, it causes skin sensitization, whereas isoeugenol (**11**) is corrosive to tissues and hepatocarcinogenic. In general, myristicin (**14**) does not cause any toxicity or side effects, but it is a monoamine oxidase inhibitor (MAOI) and cytochrome P450 (CYP) enzyme inducer. Therefore, patients on MAOIs or

pethidine drugs should avoid myristicin (**14**). High intake of myristicin (**14**) content may cause neurotoxicity. The maximum exposure level recommended for safrole (**16**) is 0.01%; its high dose causes central nervous system depression.

42.8 Marketed Products

Emerging evidences of abundant use of phenylpropenes as essential oils, perfumes, food additives, and flavoring agents have led to manufacture of various marketed products from them. Some of the products are listed below (Table 5) (Source TOXNET).

42.9 Patents

A patent is one of the intellectual rights, where a government authority or license confers a right or title for a certain period of time and excludes any other from making, using, or selling that particular invention under the mentioned time period. The intellectual property of the inventor for methodologies of phytochemical extractions, their application to obtain functional foods, their biological activities, and their application in disease prevention can be protected by the patent right. Researchers working with phenylpropanoids have produced a number of new inventions with these compounds. Some of them are presented in Table 6.

Table 5 Usage of phenylpropenes in marketed products

Phenylpropenes	Marketed products
Anethole (**2**)	Pharmaceutical aid, flavoring cattle feed, and carminative medicine
Cinnamaldehyde (**5**)	Flavor and perfume industry, rubber reinforcing agent, brightener, pesticide, metal coating, corn rootworm attractant, dog and cat repellent, and soil casing mushroom
Eugenol (**8**)	Insecticide, perfumes, essential oils, analgesic medicine, denaturant for alcohol, zinc oxide-eugenol cements for dentistry, meat preservatives, and manufacture of vanillin
Ferulic acid (**9**)	Food preservatives and food supplements for bodybuilding athletes
Methyleugenol (**12**)	Flavoring agent, insect attractant, and oriental fruit fly attractant
Myristicin (**14**)	Psychopharmacological drugs, food flavoring agents, and insecticides
Safrole (**16**)	In manufacture of piperonyl butoxide, as preservatives in mucilage and library paste, perfumes, denaturing fats in soap, and in manufacture of heliotropin

Table 6 Patents on phenylpropene-related research. (Source PubChem)

Phenylpropenes	PubChem CID	Total number of patents
Apiole (**1**)	10659	109
Anethole (**2**)	637563	4987
Caffeic acid (**3**)	689043	1001
Chavicol (**4**)	68148	741
Cinnamaldehyde (**5**)	637511	2579
Curcumin (**6**)	969516	2556
Estragole (**7**)	8815	381
Eugenol (**8**)	3314	3052
Ferulic acid (**9**)	445858	1384
Isochavicol (**10**)	5474441	19
Isoeugenol (**11**)	853433	11
Methyleugenol (**12**)	7127	404
Methyl isoeugenol (**13**)	637776	24
Myristicin (**14**)	4276	87
Rosmarinic acid (**15**)	5281792	22
Safrole (**16**)	5144	972
Sinapic acid (**17**)	637775	525

42.10 Perspectives

Phenylpropenes are detected in a wide range of edible plants, fruits, and vegetables, but the reports related to economically and commercially important plant materials are fewer in number. Most of the studies on phenylpropenes/phenylpropanoids have been conducted in animals, whereas they have a huge impact on human health also. Studies related to human aspects are yet to meet the epitome. Like the protective effect of eugenol (**8**) in strawberry, the other phenylpropenes are in the queue to get such validations. The biosynthesis and pharamcokinetics of all the available phenylpropenes are in need for much deeper understanding to elucidate their role in human health benefits.

Abstract

So far, more than 1000 polyynes have been identified from nature. Nevertheless, little is known about their function and mechanism in food plants from nutraceutical and/or pharmaceutical perspectives. In this chapter, recent studies on the structure and function of bioactive polyynes in food plants are summarized. In particular, their mechanism, biosynthesis, bioavailability, metabolism, human benefits, safety, patent, and potential applications are discussed whenever the information is available. The information provided here highlights the possible usefulness of the polyynes in food plants for human and animal health, and offers insights into their future research directions.

Polyynes · Food · Bioactivity

43.1 Introduction

Plants are a cornerstone of foods, drinks, and medicines that promote human health (Bartolome et al. 2013). The use of plants and their compounds in traditional/folkloric medicine and as functional foods is still quite prevalent in developing countries. Furthermore, plants and their compounds are an extraordinary source of novel drug which leads for different categories of illnesses. Currently, half of all prescribed medicines are developed from terrestrial plants and microorganisms (Newman and Cragg 2016).

Polyynes represent a group of organic compounds with two or more carbon-carbon triple bonds. Naturally occurring polyynes have been isolated from a variety

of plant species, fungi, bacteria, and invertebrates (Shi Shun and Tykwinski 2006). Since the isolation of the first polyyne from an *Artemisia* plant in 1826, over 1000 polyynes have been identified from nature, mainly from plants. Despite much progress in the identification of polyynes and their derivatives from plants over the past two centuries, information about the function and mechanism of the polyynes in food plants is still fragmented and needs to be updated (Christensen and Brandt 2006; Dembitsky 2006; Negri 2015; Shi Shun and Tykwinski 2006). Extensive pharmacological screening and functional studies have demonstrated that food plant extracts and polyynes display broad biological activities, including anti-metabolic, anticancer, antimicrobial, anti-inflammatory, immunomodulatory, and other activities (Dembitsky 2006). Therefore, they are of great interest, especially in the nutraceutical and/or pharmaceutical industries. However, their safety is poorly studied. In fact, two polyyne-type drugs, neocarzinostatin, and calicheamicin/esperamicin, derived from bacterial compounds, were approved as prescription drugs for cancer therapy despite of their high toxicity (Van Lanen and Shen 2008).

The present chapter focuses on recent studies on the structure and function of bioactive polyynes in food plants. In addition, their mechanism, biosynthesis, bioavailability, metabolism, human benefits, safety, patent, and potential applications will be emphasized whenever the information is available. The information provided here highlights the possible usefulness of the polyynes in food plants and offers insights into their future research directions. The present chapter focuses on recent studies on the structure and function of bioactive polyynes in plants used as foods as examples. Their mechanisms of action, biosynthesis, bioavailability, metabolism, human benefits, safety, patent, and potential applications are outlined whenever the relevant information is available. The information provided here highlights the possible usefulness of the polyynes in food plants and offers insights into future research directions.

43.2 Bioactive Constituents (with Chemical Structures of the Main Bioactive Compounds)

So far, polyynes have been identified from 24 families of higher plants. Among them, six families, Asteraceae, Campanulaceae, Apiaceae, Araliaceae, Torriceliaceae, and Annonaceae, seemed to regularly produce various polyynes (Negri 2015). Vegetable plants (Fig. 1) such as carrot (*Daucus carota*, Apiaceae), celery (*Apium graveolens*, Apiaceae), lettuce (*Lactuca sativa*, Asteraceae), parsley (*Petroselinum crispum*, Apiaceae), parsnip (*Pastinaca sativa*, Apiaceae), fennel (*Foeniculum vulgare*, Apiaceae), aubergine (*Solanum melongena*, Solanaceae), artichoke (*Helianthus tuberosus*, Asteraceae), tomato (*Lycopersicon esculentum*, Solanaceae), caraway (*Carum carvi*, Apiaceae), and *Bidens pilosa* (Asteraceae) are common food plants known to produce polyynes (Bartolome et al. 2013; Crozier et al. 2013). In this chapter, we revisit and discuss the structure and bioactivity of polyynes in the plants of the Asteraceae, Campanulaceae, Apiaceae, Araliaceae, Torriceliaceae, and Annonaceae families. Ninety-four bioactive compounds and their related bioactivities and plant sources are listed in Table 1.

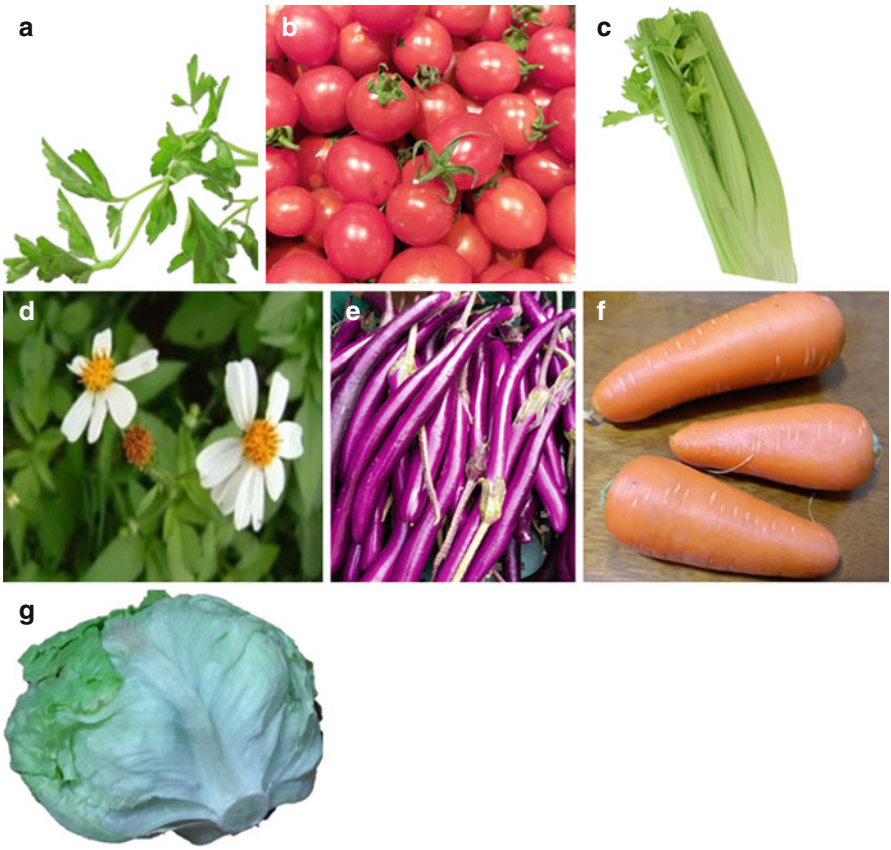

Fig. 1 Some vegetables rich in polyynes: parsley (**a**), tomato (**b**), celery (**c**), *B. pilosa* (**d**), aubergine (**e**), carrot (**f**), and lettuce (**g**)

43.3 Biosynthesis, Bioavailability, and Metabolism

Although the biosynthesis of polyynes in plants and other organisms is not well defined, they are thought to be derived from desaturation and acetylation of fatty acids (Fig. 2) in plants (Yang 2014). Taking *B. pilosa* as an example, polyynes can be found in its various parts including leaves, stems, flowers, and roots (Yang 2014). Polyyne aglycones are normally lipid soluble and absorbed within 30 min via the guts of mice. However, polyyne aglycones are sometimes cytotoxic compared with other phytochemicals such as flavonoids, lignans, terpenoids, coumarins, etc. In addition, polyynes can conjugate with glucose to form their glycosides, which can increase their water solubility, reduce their cytotoxicity, and augment their stability and/or bioactivities. Polyyne glycosides may be degraded by intestinal microbiota in animal guts. Moreover, polyynes are said to be unstable compounds because of their

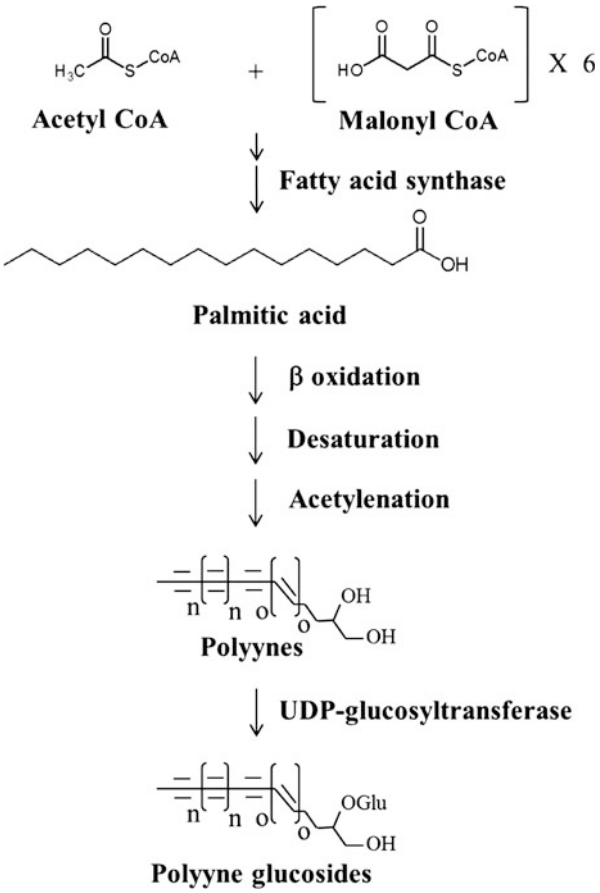

Fig. 2 A putative biosynthetic pathway of polyynes and their glucosides in food plants

carbon-carbon triple bonds. However, the content of polyynes in the Asteraceae plants is high compared to other type of compounds. For instance, the content of *B. pilosa* (Asteraceae) is as high as 0.1–0.3‰ of the dried plant weight (Yang 2014). One argument for their high content in these plants is that they are stable in a milieu of other phytochemicals with high antioxidant activities.

43.4 Bioactivities (in Animals and Humans)

As summarized in Table 1, polyynes from plants used as foods have a variety of bioactivities, such as anticancer, antimetabolic (anti-obese and antidiabetic), antimicrobial (antiviral, antibacterial, antiprotozoan, etc.), anti-inflammatory, immunomodulatory, complement inhibition, diuretic, choleretic, and other activities. Below is an outline of the major bioactivities of the plant extracts and their active polyynes.

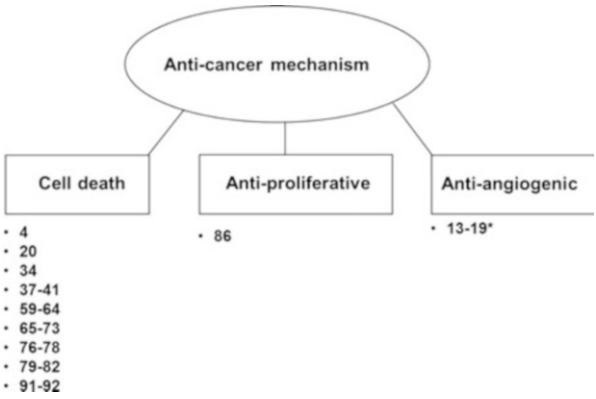

Fig. 3 The underlying mechanisms of the polyynes against cancer. Different polyynes suppress cancer growth via inhibition of cell death, cell proliferation, and angiogenesis. Asterisks (∗) indicate that compounds 13–19∗ promote cell death and inhibit angiogenesis

43.4.1 Anticancer Activity

Plants are an extraordinary source of anticancer drug discovery (Newman and Cragg 2007, 2016; Newman et al. 2003). Over the past 25 years, over 70% of anticancer drugs have been developed from phytochemicals and their derivatives, such as vinblastine, camptothecin, etoposide, paclitaxel, etc. (Newman and Cragg 2016). As delineated in Table 1, the majority of polyynes from edible plants show anticancer properties, i.e., have cytotoxic, antiproliferative, and antiangiogenic bioactivities (Fig. 3). As listed in Table 1, the Asteraceae plants are extremely rich in polyynes. For example, compound **4** isolated from *Conyza albida* (Asteraceae) exhibited cytotoxicity to epithelial (KB) cancer cells (Fukuyama et al. 2012). Compounds **13–19** were initially identified from the edible plant *B. pilosa* (Asteraceae) and identified to have cytotoxic activity against leukemia and carcinoma (Chang et al. 2001; Chiang et al. 2007; Sundararajan et al. 2006; Wu et al. 2004). Moreover, compound **14** promoted apoptosis of endothelial cells and, in turn, suppressed angiogenesis (Wu et al. 2004, 2007a). Further, the antitumor effect and mechanism of compound **14** were able to induce cell apoptosis of cancer cells via induction of caspases 3, 6, and 7 (Kuo et al. 2017). Similarly, phenylhepatriyne (**20**), isolated from *B. pilosa*, was effective against colon and liver cancer cells (Kumari et al. 2009). From the aerial parts of *Artemisia lactiflora* (Asteraceae), Arytemisidyne A (**34**) was identified and shown to be cytotoxic against different cancer cells (Xiao et al. 2014). From the root of *Gymnaster koraiensis* (Asteraceae), compounds **37–40** displayed cytotoxicity against L1210 leukemia cells (Jung et al. 2002). Vernoniyne (**41**) was purified from the leaves and flowers of *Vernonia scorpioides* (Asteraceae). This compound was reported to suppress cancer growth in vitro and in a mouse model of cancer via regulation of caspase activation (Buskuhl et al. 2009). The Apiaceae plants also synthesize polyynes. Vegetables of this family regularly produce common polyynes (Crozier et al. 2013; Lund 1992). Furthermore, related polyynes such as falcarinol (**59**), falcarindiol (**60**), and derivatives (**61–64**) were found in the root of carrot, *D. carota* (Apiaceae). Falcarindiol and its derivatives (**59–64**) were shown to inhibit cancer in vitro and in vivo (Lund 1992). The 8-methyl

ether derivative of falcarindiol (**65–73**) was extracted from the stem of celery, *Apium graveolens* (Apiaceae), and displayed cytotoxicity against leukemia, lymphoma, and myeloma comparable to that of falcarinol and falcarindiol (Zidorn et al. 2005). Other derivatives of falcarindiol, notoethers A-H (**65–73**) of falcarindiol, were identified from the rhizomes and roots of *Notopterygium incisium* (Apiaceae), a Chinese medicinal herb used to treat infection and inflammatory diseases (Liu et al. 2014). Compounds **76–78** from the stem bark of *Mitrephora maingayi* (Apiaceae) were shown to have cytotoxic activity against epithelial, breast, lung, and astrocytoma cancer cells (Zhang et al. 2010). Canangionones A-D (**79–82**) were isolated from the stem bark of *Cananga latifolia* (Annonaceae), a Thai herbal medicine for nasal polyposis and fever (Wongsa et al. 2011). The Araliaceae plants are also rich in polyynes. Araladiol (**86**) was isolated from the leaves of *Aralia cordata* (Araliaceae), a plant that is used as food plant in Asian countries (Cheng et al. 2011). This compound suppressed cell growth of breast cancer cells via inhibition of the cell cycle involving down-modulation of CDK4 and cyclin D and up-modulation of p21 in a p53-independent fashion. In addition, stipudiol (**91**) and stipuol (**92**) were isolated from the rhizomes of *P. stipueantus*, an herb traditionally used in China as a tonic and to treat muscle pain, bleeding, and bruises (Liang et al. 2011).

43.4.2 Antimetabolic Activity

Metabolic syndrome, as known as insulin-resistance syndrome or American syndrome, is a clustering of at least three of the following five medical conditions: central obesity, high blood pressure, high blood sugar, high serum triglycerides, and low serum high-density lipoprotein. Metabolic syndrome increases the risk of heart disease, stroke, and diabetes in humans.

Plants are an extraordinary source of antidiabetic agents. Over 1200 plant species have been claimed to treat diabetes (Habeck 2003; Marles and Farnsworth 1995). One such plant, *B. pilosa* has been shown to treat diabetes (Lin et al. 1994; Marles and Farnsworth 1995; Ubillas et al. 2000), obesity (Liang et al. 2016), and hypertension (Bilanda et al. 2017; Dimo et al. 2002). One seminal study by Ubillas et al. showed that the aqueous ethanol extract of the aerial part of *B. pilosa* at 1 g/kg BW lowered blood glucose in db/db mice, a T2D mouse model (Ubillas et al. 2000). They also used a bioactivity-guided identification strategy to identify two polyynes, compounds **17** and **19**. Moreover, the mixture of the compounds (**17**:**19**) in a 2:3 ratio significantly reduced the blood glucose level and food intake on the second day when administered at doses of 0.25 g/kg twice a day to C5BL/Ks-db/db mice. When evaluated at 0.5 g/kg, a more substantial decrease in blood glucose level as well as more severe anorexia (food intake reduced from 5.8 g/mouse/day to 2.5 g/mouse/day) was observed (Ubillas et al. 2000). This study suggested that compounds **17** and **19** were active ingredients in *B. pilosa* for diabetes (Ubillas et al. 2000). The antidiabetic effect of both polyynes was partially caused by the hunger suppressing effect. However, the anoxic effect of the ethanol extract of *B. pilosa* was not observed in the studies described below. In another study (Hsu et al. 2009), water extracts of *B. pilosa* (BPWE) were tested in diabetic db/db mice, aged

6–8 weeks, with post-meal blood glucose levels of 350–400 mg/dL. Like oral antidiabetic glimepiride, which stimulates insulin release, one single dose of BPWE reduced blood glucose levels from 374 to 144 mg/dL. The anti-hyperglycemic effect of BPWE was relevant to an increase in serum insulin levels, implying that BPWE drops blood glucose concentration through an upregulation of insulin production. However, BPWE showed different insulin secretion kinetics from glimepiride (Hsu et al. 2009). One drawback of current antidiabetic agents is their decreasing efficacy over time. Therefore, the authors investigated the long-term antidiabetic effect of BPWE in db/db mice. BPWE lowered blood glucose, boosted blood insulin, improved glucose tolerance, and reduced the percentage of glycosylated hemoglobulin (HbA1c). Both one-time and long-term experiments strongly support the superior action of BPWE on diabetes (Hsu et al. 2009). Unlike glimepiride which failed to preserve pancreatic islets, BPWE significantly protected against islet atrophy in mouse pancreas. The group also evaluated the antidiabetic effect of three *B. pilosa* varieties, *B. pilosa* var. *radiate* (BPR), *B. pilosa* var. *pilosa* (BPP), and *B. pilosa* var. *minor* (BPM) in db/db mice (Chien et al. 2009). A single oral dose (10, 50, and 250 mg/kg BW) of BPR, BPP, or BPM water extract decreased postprandial blood glucose levels in db/db mice for up to 4 h, and this reduction was dose-dependent. Of note, BPR extract resulted in a higher reduction in blood glucose levels when administered at the same dose as the other two varieties. Further, the BPR extract increased serum insulin levels in db/db mice to a greater extent than the other varieties at the same dose, 50 mg/kg. Three polyynes, cytopiloyne (**15**) and its related polyynes (**17** and **19**), were identified from the three *Bidens* strains though their contents varied. Compound **15** at 0.5 mg/kg exerted better stimulation for insulin production in db/db mice than compounds **17** and **19**. On the contrary, 28-day treatment with the *Bidens* extracts and the three polyynes was then conducted on diabetic mice with postprandial glucose levels from 370 to 420 mg/dL, and glimepiride was used as a positive control. The applied dosages ranged from 10 mg/kg to 250 mg/kg BW. Results showed that the positive control as well as the crude extracts of the three varieties lowered the blood glucose levels in db/db mice. However, only BPR extract, containing a higher content of cytopiloyne (**15**), reduced blood glucose levels and augmented blood insulin levels more than BPP and BPM. The percentage of glycosylated hemoglobin A1c (HbA1c), a long-term indicator of blood homeostasis, was also monitored. HbA1c in the blood of 10- to 12-week-old diabetic mice was 7.9 $\pm$ 0.5%. However, treatment with BPR crude extract (50 mg/kg), glimepiride (1 mg/kg), and compound **15** (0.5 mg/kg) led to HbA1c of 6.6 $\pm$ 0.2%, 6.1 $\pm$ 0.3%, and 6.2 $\pm$ 0.3%, respectively, in the blood of age-matched mice (Chien et al. 2009). Since cytopiloyne (**15**) was the most effective polyyne found in *B. pilosa*, against T2D, it was used for further study of the antidiabetic action and mechanism in another study (Chang et al. 2013b). The data confirmed that cytopiloyne reduced post-meal blood glucose levels, increased blood insulin, improved glucose tolerance, suppressed HbA1c level, and protected pancreatic islets in db/db mice. Nevertheless, cytopiloyne never managed to decrease blood glucose in streptozocin (STZ)-treated mice whose β cells were already destroyed. In addition, cytopiloyne dose-dependently promoted insulin secretion and

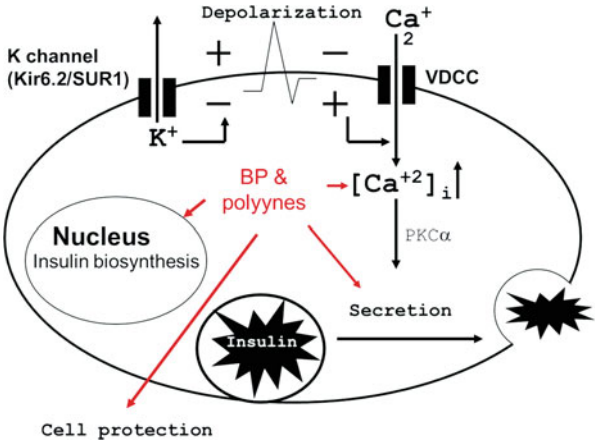

Fig. 4 The mechanism underlying the action of the crude extract of *B. pilosa* and its polyynes (compounds **15**, **17,** and **19**) in T2D. BP and/or its polyynes can treat T2D development via control of β cell function in db/db mice. Their antidiabetic actions are through upregulation of insulin expression/secretion and protection of β cells involving secondary messengers (calcium and diacylglycerol) and their downstream PKCα pathway

expression in β cells as well as calcium influx, diacylglycerol, and activation of protein kinase Cα. Taken together, these mechanistic studies suggest that cytopiloyne acts on T2D via regulation of β cell function (insulin production and β cell preservation) involving the calcium/diacylglycerol/PKCα cascade (Fig. 4). The above studies point to the conclusion that cytopiloyne (**15**) and related polyynes (compounds **17** and **19**) are antidiabetic agents in animal models. The data revealed a new biological action of the polyynes. Similarly, compounds **87** and **88** were isolated from *P. ginseng*, and both inhibited the activity of diacylglycerol acyltransferase (DAGAT) (Lee et al. 2004).

We, for the first time, reported that a standard diet containing 0.5% *B. pilosa* extract dose-dependently decreased fat content, adipocyte size, body weight, and increased protein content in ICR mice and ob/ob mice (Liang et al. 2016). Further, mechanistic studies showed that *B. pilosa* inhibited the expression of peroxisome proliferator-activated receptor γ (PPARγ) and CCAAT/enhancer-binding protein α (C/EBPα) in adipose tissue (Liang et al. 2016). Finally, we examined the effect of cytopiloyne on adipogenesis in adipocytes. We found that *B. pilosa* significantly decreased the adipogenesis and lipid accumulation. This decrease was associated with the down-regulation of expression of PPARγ and C/EBPα and adipocyte Protein 2 (aP2) and adiponectin (Liang et al. 2016). The data suggest that *B. pilosa* and cytopiloyne suppressed adipogenesis and lipid content in adipocytes and/or animals via the down-regulation of the PPARγ and C/EBPα pathways. Mechanistic studies indicated that compound **15** inhibited the adipogenesis in pre-adipose cells (Liang et al. 2016).

Dimo et al. first stated that the methanol and dichloromethane extract of *B. pilosa* leaves at 75 md/kg/day or more reduced blood pressure in fructose-treated rats (Dimo et al. 2002). Further, the same group confirmed that the ethyl acetate extract of *B. pilosa* leaves at 75 md/kg/day or more reduced blood pressure in L-N^G-nitroarginine methyl ester-treated rats (Bilanda et al. 2017). They suggested that *B. pilosa* exerted its hypotensive action via a reduction of NO synthesis (Bilanda et al. 2017). However, the hypotensive compounds of *B. pilosa* need to be characterized.

43.4.3 Antimicrobial Activity

Polyynes have been shown to be effective against viruses, bacteria, and fungi. Compound **5** was identified from *Conyza canadensis* (Asteraceae). This compound exhibited antibacterial activity (Xie et al. 2007). Compounds **14**, **15**, **20**, **21**, and **22** were isolated from *B. pilosa*. Some polyynes show antibacterial and antimalarial activities (Chiang et al. 2007; Chung et al. 2016; Wang et al. 2010; Wu et al. 2007b, 2010). Compounds **35** and **36** were isolated from *Helianthus annuus*; both exhibited antibacterial activity (Seshimoto et al. 2011). Vernoniyne (**41**) and compounds **42–48** were purified from the leaves and flowers of *Vernonia scorpioides* (Asteraceae). These compounds showed antiviral activity (Buskuhl et al. 2009; Klein et al. 2013; Pollo et al. 2013). Compound **49** was isolated from the aerial parts of *Matricaria aurea* (Asteraceae). This compound exhibited inhibitory activity against bacteria and fungi (Ahmed and Elela 1999). Phenylhepatriyne (**20**), isolated from *B. pilosa*, had antimalarial activity (Kumari et al. 2009). Compounds **53–58** were isolated from *Xanthopappus subacaulis* (Asteraceae), used as a Chinese herbal medicine to treat hematemesis, gastroenteral ulcers, and idiopathic thrombocytopenic purpura. These compounds had antibacterial activities (Zhang et al. 2014). Compound **74** from the extract of the roots of *Polyalthia cerasoides* (Annonaceae), which is used as a tonic or febrifuge in China, was shown to have antimalarial and anti-mycobacterial activities (Kanokmedhakul et al. 2007). Mkiluaynoic acid A (**75**) was isolated from the fruits and stem bark of *Mkilua fragrans* (Annonaceae). Mkiluaynoic acid A had antifungal activity against *Candida albicans* (Li et al. 2009). In addition, compounds **76–78** displayed antimicrobial and antifungal activities (Li et al. 2009). Compound **83** was obtained from the roots of *Polyalthia evecta* (Annonaceae) and is used as a galactagogue in Thailand. This compound showed inhibitory activity against malaria and herpes virus (Kanokmedhakul et al. 2006). Compounds **84** and **85** were purified from *P. suberosa*; both showed anti-HIV activity (Tuchinda et al. 2001). In addition, two polyynes (**224** and **228**) from *P. ginseng* had antibacterial and antifungal activities (Fukuyama et al. 2012).

43.4.4 Anti-inflammatory Activity

Inflammation has four signs, redness, heat, swelling, and pain. Phytochemicals including the polyynes and their derivatives are usually assessed for their anti-inflammatory properties. Compound **1** was identified from the hydroalcoholic extract of *B. parviflora* (Asteraceae) and was found to have antipyretic, anti-inflammatory, and anti-rheumatic activities (Li et al. 2008). Compounds **2** and **3** were isolated from the ethanolic extract of the aerial parts of *A. capillaris* (Asteraceae), a Chinese herbal medicine used for anti-inflammatory, hepatoprotective, diuretic, and choleretic purposes (Zhao et al. 2014). Compound **12** was shown to inhibit the activity of lipoxygenase (LOX), an enzyme involved in inflammatory diseases (Stavri et al. 2005). Compounds **24–26** were identified from the cyclohexane extract of the rhizomes of *Atractylodes macrocephala* (Asteraceae), traditionally used to treat splenic asthenia, edema, anorexia, and

hyperhidrosis in Northeastern Asia (Yao and Yang 2014). These compounds were reported to reduce nitrogen oxide (NO) production and inflammatory mediators (Yao and Yang 2014). Compound **30** was identified from the extract of *B. bipinnata* (Asteraceae), and this compound had anti-inflammatory activity (Wang et al. 2014). Compounds **31–33** were obtained from the capitula of *Coreopsis tinctoria* (Asteraceae). All three compounds inhibited the activity of cyclooxygenase-2 (COX-2) in mouse peritoneal macrophage-stimulated lipopolysaccharide (LPS) (Zhang et al. 2013). Compound **50** was isolated from the extract of *Artemisa dracunculus* (Asteraceae). This compound had insecticidal activity (Saadali et al. 2001). Compounds **51–52** were obtained from the roots of *Echinacea atrorubens* and *E. pallida* (Asteraceae). Compound 132 displayed inhibition of macrophage activation stimulated by LPS (Schmiech et al. 2009). Oploxyne A (**93**) and B (**94**) were identified from the stem of *Oplopanax elatus* (Araliaceae), a medicinal medicine for analgesic and anti-inflammatory purposes (Yang et al. 2010).

43.4.5 Immunomodulatory Activity

The immune system is a host defense system that is instrumental in the maintenance of human health. Imbalance in the immune system can result in infection, autoimmunity, inflammatory diseases, and cancer. For instance, T1D is caused by the autoimmune destruction of pancreatic β cells, leading to insulin deficiency, hyperglycemia, and complications. Immunotherapy is a common approach to treat T1D (Chang et al. 2013a).

Plants and their compounds are commonly used to enhance and/or suppress host immunity in an attempt to treat disorders of the immune system. Plants from the genus *Bidens* were reported to treat 41 categories of diseases such as immune regulation (Bartolome et al. 2013). Compounds **6–8** were obtained from the ethanolic extract of the aerial parts of *B. bipinnata* (Li et al. 2004; Wang et al. 2001). All three compounds indicated anti-allergic activity via inhibition of NO and histamine production in mouse macrophages stimulated by LPS and interferon-γ (Wang et al. 2001). In addition, we reported that *B. pilosa* extract and its butanol fraction decreased Th1 cells and cytokines and increased Th2 cells and cytokines (Chang et al. 2004). This study indicated that the IC_{50} value of the butanol fraction was 200 μg/mL. This inhibition was reported to be partially attributed to cytotoxicity because the butanol fraction at 180 μg/mL could cause 50% death of Th1 cells. Using a bioactivity-directed isolation and identification approach (Fig. 5), three active polyynes, compounds **15**, **17,** and **19,** were isolated from the butanol extract using high pressure liquid chromatography (HPLC) and were then structurally identified by nuclear magnetic resonance (NMR) (Chang et al. 2004; Chiang et al. 2007). All the three polyynes had similar effects on Th cell differentiation to the *B. pilosa* butanol fraction. Moreover, compound **15** showed greater activity than compounds **17** and **19** in terms of enhancement (by 277% compared to 34% and 8%) of differentiation of Th0 to Th2 at 10 μg/mL and inhibition (by 60% compared to 17% and 9%) of differentiation to Th1 at the same concentration (Table 2) (Chang et al. 2004; Chiang et al. 2007).

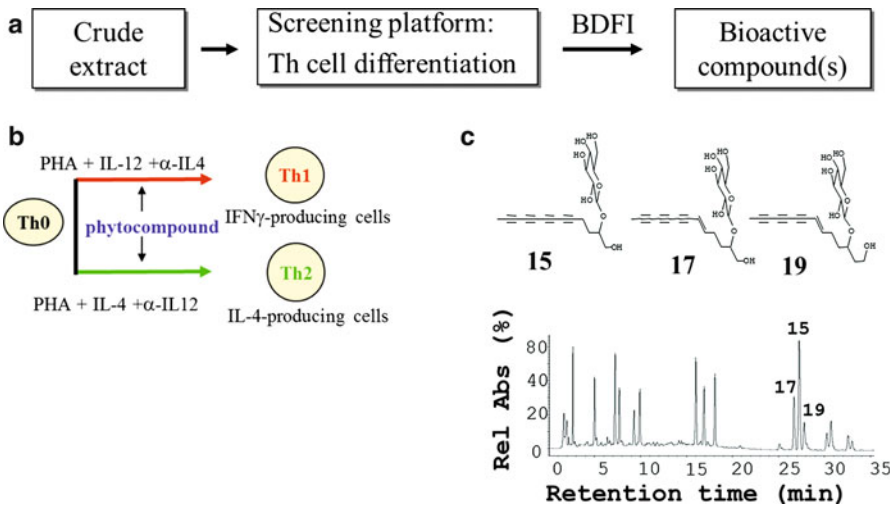

Fig. 5 Bioactivity-directed fractionation and isolation approach to identify three active polyynes that regulate Th cell differentiation. A flowchart of the bioactivity-directed fractionation and isolation (BDFI) strategy describes the use of the screening platform, Th cell differentiation assays to determine bioactive compounds from the crude extract and fractions of *B. pilosa* (A). Bioassays composed of human naïve helper T cells (Th0) can differentiate into type 1 helper T (Th1) cells and type 2 helper T (Th2) cells in the presence of PHA plus IL-12 and anti-IL-4 antibody and PHA with IL-4 and anti-IL-12 antibody, respectively. The crude extract, fractions, and compounds of *B. pilosa* are added to differentiating cells to test the Th cell differentiation (B). Compounds **15**, **17,** and **19** are active compounds that promote Th2 cell differentiation but inhibit Th1 cell differentiation

Table 2 Th1 inhibition and Th2 promotion by the extract (150 μg/ml) and polyynes (10 μg/ml) of *B. pilosa*

	Butanol extract	Compound **15**	Compound **17**	Compound **19**
Reduction of Th1 (%)	32%	75%	9%	17%
Increase of Th2 (%)	103%	277%	6%	31%

The butanol fraction of *B. pilosa* effectively prevented T1D in nonobese diabetic (NOD) mice (Chang et al. 2004). Consistently, this prevention involved down-regulation of Th1 cells or upregulation of Th2 cells. This was proven by intraperitoneal injection of the butanol fraction at a dose of 3 mg/kg body weight (BW), 3 times a week, to NOD mice from 4 to 27 weeks (Chang et al. 2004). This dosage resulted in lower incidence of diabetes (33%). At a dose of 10 mg/kg, the butanol fraction of *B. pilosa* totally stopped (0%) the initiation of the disease (Chang et al. 2004). Th1 cytokine IFNγ and Th2 cytokine IL-4 favor the production of IgG2a and IgE, respectively. To further confirm whether this butanol in vivo regulated Th cell differentiation and Th cytokine profiling, IgG2a and IgE production was measured in the serum of NOD mice. As expected, high levels of IgE and some decline in the levels of IgG2a were observed in the serum (Chang et al. 2004).

Since cytopiloyne (**15**) had the most potent effect on Th cell differentiation among the aforesaid polyynes (Chang et al. 2007), another study used cytopiloyne

to explore the action and molecular mechanism of cytopiloyne on T1D in NOD mice (Chang et al. 2007). NOD mice received intraperitoneal or intramuscular injection of cytopiloyne at 25 μg/kg BW, 3 times per week. Twelve-week-old NOD mice started to develop T1D, and 70% of NOD mice aged 23 weeks and over developed T1D. Remarkably, 12- to 30-week-old NOD mice treated with cytopiloyne showed normal levels of blood glucose (<200 mg/dL) and insulin (1–2 ng/mL). Consistent with T1D incidence, cytopiloyne delayed and reduced the invasion of $CD4^+$ T cells into the pancreatic islets (Chang et al. 2007). Albeit less effectively than cytopiloyne (**15**), 3-ß-D-glucopyranosyl-1-hydroxy-6(*E*)-tetradecene-8,10,12-triyne (**19**), 2-ß-D-glucopyranosyloxy-1-hydroxy-5(*E*)-tridecene-7,9,11-triyne (**17**) also decreased T1D development in NOD mice.

The underlying mechanism by which cytopiloyne and its derivatives inhibited T1D included inactivation of T cells, polarization of Th cell differentiation, and Th cell depletion, leading to islet protection (Chang et al. 2007) as is illustrated in Fig. 6.

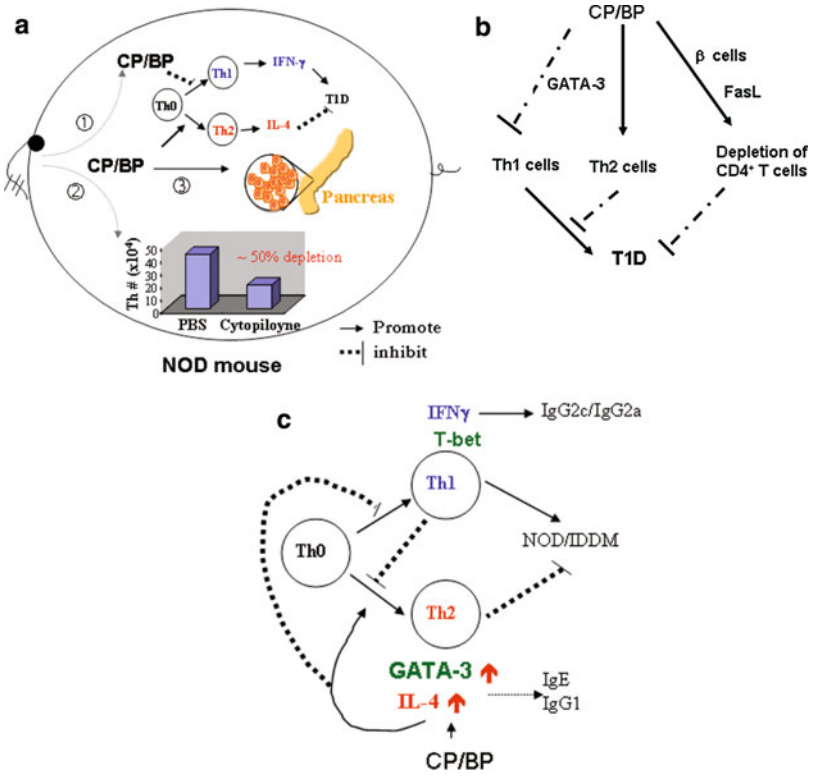

Fig. 6 The underlying mechanism of the crude extract of *B. pilosa* (BP) and its active polyyne, cytopiloyne (CP, **15**), in T1D. BP and/or CP can suppress T1D development via regulation of T cells (① and ②) and β cells (③) in NOD mice (**a**). Their regulation of T cells involves Th cell activation and differentiation (①) and partial depletion of Th0 cells (②) as depicted (**b**). CP and/or BP augment the expression of GATA-3 gene and, in turn, promote the expression of IL-4 and Th2 cell differentiation. In contrast, BP and/or cytopiloyne (CP) do not affect the expression of T-bet (**c**)

First, [^{3}H] thymidine incorporation assay showed that cytopiloyne inhibited ConA/IL-2- and CD3 antibody-mediated T cell proliferation, implying that cytopiloyne could inhibit T cell activation. Second, in vitro study showed that cytopiloyne (**15**) inhibited the differentiation of naïve Th (Th0) cells (i.e., $CD4^+$ T cells) into Th1 cells and promoted differentiation of Th0 cells into Th2 cells (Chiang et al. 2007). The in vitro data are consistent with the in vivo results indicating that cytopiloyne reduced Th1 differentiation and increased Th2 differentiation as shown by intracellular cytokine staining and FACS analysis (Chang et al. 2007). Cytopiloyne also enhanced the expression of GATA-3, a master gene for Th2 cell differentiation, but not the expression of T-bet, a master gene for Th1 cell differentiation, further supporting its role in skewing Th differentiation (Chang et al. 2007). In line with the skewing of Th differentiation, the level of serum IFN-γ and IgG2c decreased while that of serum IL-4 and serum IgE increased compared to the negative controls (PBS-treated mice). Third, cytopiloyne partially depleted $CD4^+$ rather than $CD8^+$ T cells in NOD mice (Chang et al. 2007). Co-culture assays showed that the depletion of $CD4^+$ T cells was mediated through the induction of Fas ligand expression on pancreatic islet cells by cytopiloyne, leading to apoptosis of infiltrating $CD4^+$ T cells in the pancreas via the Fas and Fas ligand pathway. However, cytopiloyne did not induce the expression of TNF-α in pancreatic islet cells and, thus, had no effect on $CD8^+$ T cells (Chang et al. 2007). Collectively speaking, the mechanism of action of cytopiloyne and, probably, its polyyne derivatives, in T1D, includes inhibition of T-cell proliferation, skewing of Th cell differentiation and partial depletion of Th cells and protection of β pancreatic islets (Chang et al. 2007; Chiang et al. 2007).

43.5 Benefits (human studies)

43.5.1 Cancer

C. albida, *G.korsiensis*, *V. scorpioides*, *N. incisium*, *M. maingayi*, *C. latifolia*, *A. cordata*, *P. ginseng*, *B. pilosa*, and *P. stipueantus* have been used as traditional medicines or ethnomedicines to treat cancer and vasculature diseases in humans. Currently, their polyynes are not clinically available for humans. In contrast, falcarindiol, falcarinol, falcarindiol-3-acetate, and falcarinone are rich in plants that are used as food such as carrot, celery, etc. and are considered to be nutraceuticals for patients with cancer. However, falcarindiol, falcarinol, and their derivatives need to be evaluated in clinical trials.

43.5.2 Metabolic Syndrome

Over 1200 plant species have been claimed to treat diabetes (Habeck 2003; Marles and Farnsworth 1995). *B. pilosa* and *P. ginseng* have been used to treat different categories of illness in humans. For example, *B. pilosa* formulation (probetacell) was shown to reduce the level of FBG and HbA1c in patients with diabetes but increased fasting serum insulin in healthy subjects (Lai et al. 2015). Moreover, a combination

of *B. pilosa* formulation with antidiabetic drugs had better glycemic control in diabetics (Lai et al. 2015). The homeostatic model assessment (HOMA) data suggested that the antidiabetic activity of this formulation was via improvement of β-cell function (Lai et al. 2015). Furthermore, the toxicological studies showed that oral administration with the *B. pilosa* formulation at a daily dose of 400 mg per 70 kg body weight, three times a day for 3 months, had no obvious side effects in healthy subjects (Lai et al. 2015). The overall data concluded that *B. pilosa* has potential as an antidiabetic remedy. However, the efficacy of the polyynes from *B. pilosa* and *P. ginseng* in treating metabolic syndrome in human subjects is not clear.

43.5.3 Infectious Diseases

C. Canadensis, *L. nudicaulis*, *H. annuus*, *V. scorpioides*, *M.aurea*, *B. pilosa*, *X. subacaulis*, *P. evecta*, *P. suberoa*, and *Mkilua fragrans* have been used as herbal medicines for human infections. However, the potential of their polyynes to treat viral, bacterial, and fungal infections needs to be investigated.

43.5.4 Immune Diseases

A. dracunculus, *A. capillaris*, *A. macrocephala*, *B. parviflora*, *B. bipinnata, B. pilosa, C. tinctoria*, *E. atrorubens* and *E. pallida*, and *O. elatus* have a long history of human use. Only the *B. pilosa* formulation was clinically evaluated in humans (Lai et al. 2015). However, the potential of their polyynes to treat inflammatory disorders and immune diseases needs to be corroborated.

43.6 Application in Food (Including Correct Cooking of Foods Rich in Phytochemicals)

Dietary polyynes from edible plants might be more heat-labile than the other phytochemicals with different structures. Thus, cooking time needs to be considered.

43.7 Safety: Toxicity and Side Effects

Edible plants of the Asteraceae, Apiaceae, and other families regularly produce polyyne metabolites. Some plants and their polyynes have beneficial functions in humans. For example, carrot, celery, lettuce, parsley, parsnip, fennel, aubergine, artichoke, tomato, caraway, and *Bidens pilosa* are generally recognized as safe (GRAS). However, the others may have adverse effects. Thus, toxicological studies need to be tested for the plants and their polyynes without safety information. Polyynes are sometimes thought to have adverse effects in humans because long polyynes are inherently unstable, albeit very reactive, due to their chemical properties. Two enediynes derived from bacterial compounds, neocarzinostatin, and

calicheamicin/esperamicin, were approved as prescription drugs for cancer (Classes of enediynes, Wikipedia 2016) (Maeda 2001; Maiese et al. 1989; Golik 1987). However, despite good anticancer efficacy, both have fatal toxicity, which limit their clinical use.

In the case of *B. pilosa*, the Food and Agriculture Organization and Taiwanese Ministry of Health and Welfare allow its use as an ingredient in food for human consumption. Despite lack of systemic toxicological studies of *B. pilosa* in humans, some information about acute and/or sub-chronic toxicities has been reported in rodents. Frida and colleagues reported that one single oral dose of the water extract of *B. pilosa* leaves at 10 g/kg BW showed no obvious mortality or changes in the appearance of rats (Frida et al. 2007). The same extract at 0.8 g/kg BW/day, once a day, showed no obvious sub-chronic toxicity in rats over 28 days, as shown by survival rate, body weight, and gross examination of organs (Frida et al. 2007). They also evaluated the acute toxicity of hydroethanol extracts of *B. pilosa* in mice (Frida et al. 2007). Five- to six-week-old mice, weighing between 28 and 35 g, received a peritoneal injection of both extracts at different doses. The LD_{50}, the dose that causes 50% lethality, of the hydroethanol extracts in mice was 12.3 g/kg BW and 6.2 g/kg BW, respectively (Frida et al. 2007). Ezeonwumelu et al. showed that oral delivery of the water extract of the *B. pilosa* whole plant at 1 g/kg BW/day, once a day, seemed nontoxic in rats over 28 days in Wistar rats (Ezeonwumelu et al. 2011), which is in line with our observations in rat (Bartolome et al. 2013). Overall, these data suggest that consumption of *B. pilosa* aqueous extract at up to at 1 g/kg BW/day, once a day, is highly safe in rats. A complete toxicology and drug-drug interaction of *B. pilosa* with other drugs in humans are required prior to its further medical use.

43.8 Marketed Products

Juice and dried products of carrot, celery, lettuce, parsley, parsnip, and tomato are commercialized and consumed worldwide. Moreover, nutraceuticals and/or therapeutics of *P. ginseng* and *B. pilosa* have been already commercialized on the market in the world.

43.9 Patents

Dietary polyynes from *B. pilosa* have been patented for treatment of metabolic syndrome (Patent US2011269702 A1), cancer (Patent US20110280809A1), and protozoan infections (Patent US 9072312B2) in humans and animals.

43.10 Perspectives

Edible plants of the Asteraceae, Apiaceae, and other families regularly produce polyyne metabolites. They are used as foods, drinks, and medicines for human health. Polyynes may have beneficial effects in humans. However, some of them

may have adverse effects. Thus, toxicological studies are needed to test the plants and their polyynes for which there is no safety information to date. Precautions and contraindications in the nutraceutical and/or therapeutic use of the plants and their polyynes are needed.

Abstract

Starch, a common constituent of higher plants, is the major form in which carbohydrates are stored. This chapter first introduces chemistry structure, synthesis, digestion, metabolism, and bioavailability of starch. Based on its digestion rate and extent, starch is classified into rapidly digestible starch, slowly digestible starch, and resistant starch. Resistant starch cannot be digested in the small intestine but can be fermented in the large intestine. This chapter introduces five kinds of resistant starch and commercially manufactured products and describes the fermentation process of resistant starch in detail, including the metabolism pathways, the bacteria involved, and end products. The fermentability of resistant starch depends on its physical and chemical structure. Particularly, short-chain fatty acids, mainly acetate, butyrate, and propionate, are produced during fermentation of resistant starch. These short-chain fatty acids have considerable bioactives. As a result, consumption of resistant starch has many benefits, including the prebiotic effect, decreasing protein fermentation, keeping colon healthy, the hypoglycemic effect, the anti-obesity effect, reducing inflammation and oxidative stress, improving mineral absorption, etc.

Keywords

Starch · Low digestion · Resistant starch · Fermentation · Gut bacteria · Colon health

44.1 Introduction

Starch, a common constituent of higher plants, is the major form in which carbohydrates are stored. It can be deposited in roots, tubers, fruits, seeds, etc. Humans and their ancestors always eat starchy foods derived from roots, tubers, fruits, or seeds (Miao et al. 2018). It is suggested that starch is of great importance for human evolution (Hardy et al. 2015). In addition, starch is widely used in our daily life. The history of starch is well documented by Schwartz and Whistler (2009). The use of starch products may date back to the pre-dynastic period when Egyptians cemented strips of papyrus together using starch adhesive made from wheat. Later, sheets were first coated with a high-fluidity starch to prevent ink penetration and then covered with powdered starch to improve their weight and thickness in China. Nowadays, Chinese people still use the starch paste made form rice gruel to stick the documents such as couplets on the wall, which is a tradition since a very long time ago. In the Middle Ages, several starches and starch-based products, such as wheat starch, potato starch, maize starch, dextrin, and starch syrups, appeared. The starch industry enormously expanded in the nineteenth century, largely due to demands of the textile, paper, and color printing industries and the emerging of dextrin. By the 1930s, numerous starch products were developed by carbohydrate chemists, which greatly expanded the application of starch.

Table 1 Roles starches play in various food systems (Mason 2009)

Functions	Foods
Adhesion	Battered and breaded foods
Binding	Formed meat, snack seasonings
Clouding	Beverages
Crisping	Fried and baked foods, snacks
Dusting	Chewing gum, bakery products
Emulsion stabilization	Beverages, creamers
Encapsulation	Flavors, beverage clouds
Expansion	Snacks, cereals
Fat replacement	Ice cream, salad dressings, spreads
Foam stabilization	Marshmallows
Gelling	Gum drops, jelly gum centers
Glazing	Bakery, snacks
Moisture retention	Cakes, meats
Thickening	Gravies, pie fillings, soups

Due to sustainability, biodegradability, biocompatibility, edibility, and low cost, starch is one of the most widely used raw materials in food, textile, and pharmaceutical industries. Unfortunately, native starches usually have some defects, which restrict their applications. Therefore, starch is usually modified physically, chemically, and/or enzymatically to enhance their positive attributes and/or to minimize their defects (Miao et al. 2018). For instance, pregelatinization achieves rapid dissolving of starch or starchy foods. Dextrinization increases water solubility of starch. Carboxymethyl starch has higher freeze-thaw stability, and cross-linking starches have greater resistance to stress. Therefore, modification extends application of starch. Generally, starch and starch derivatives are widely used in food products and play important roles, such as gelling agents, thickeners, emulsifying agents, and encapsulating agents (Table 1) (Mason 2009). Starch is also used in papermaking as wet-end additives for dry strength, surface sizes, and coating binders and as adhesives for warp sizing of textiles and glass fiber sizing (Chiu and Solarek 2009). Modified starches are the common ingredient in tablets. In recent years, some starch is used to make the plastic product due to its biodegradability. Therefore, the starch production is very large and increasing each year. The global annual production of pure native starch reached 73 MT in 2011 and was expected to reach 133.5 MT in 2018 (Blennow 2018).

44.2 Chemistry

44.2.1 Chemical Structure of Starch

Starch exists in the form of semicrystalline granules that consist of amylose and amylopectin with very small quantities of proteins, minerals, lipids, and ash. Amylose accounts for 20%–30% by weight in most native starches (Hu et al. 2018; Miao

et al. 2018); expect that waxy starches do not contain amylose. In recent years, genetic strategies have been used to enhance the amylose content in some starches. For instance, high-amylose maize starches have been developed, and there are commercial products, such as amylomaize V, VI, and VII, which correspond to the amylose content of approximately 50%, 60%, and 70%, respectively (Vineyard et al. 1958; Jiang et al. 2010). Amylopectin, the major component of most starches, is a complex branched polysaccharide. The degree of polymerization (DP) of amylopectin ranges 3×10^5–3×10^6 (Zobel 1988). The α-D-glucopyranosyl residues of chains are linked mainly by α-1,4-linkages, and these chains are linked together by α-1,6 bonds at the branch points to form branches (Buléo et al. 1998). Approximately 5%–6% of the glucosyl units in amylopectin are joined via (1-6) bonds, which introduce chain branches. The amylopectin chains are classified into A-, B-, and C-chains as defined by Peat et al. (1952). Each amylopectin molecule has one single C-chain (Pérez and Bertoft 2010). The C-chain contains the terminal reducing end oriented towards the center or hilum of the granule and carries other chains as branches. The B-chains are attached to the C-chain by α-1,6-linkages. The A-chains are the outer chains without any branches which are glycosidically linked at their potential reducing group through C6 of a glucose residue to B-chains. The B-chains carry A- or B-chains as branches. A- and B-chains form clusters and B-chains can carry multiple clusters. These chains are always different in DP, which leads to a broad distribution of the chain length. A-chains typically consist of 6–12 glucosyl units, while B-chains usually contain more glucosyl units. It is well-known that the chain length of amylopectin significantly affects the physicochemical properties. Therefore, chain length distribution is one of the key characteristics for amylopectin. Amylopectin structure usually varies between species and even differs in organelles within the same species (Jaiswal and Chibbar 2017). Potato starches carry more long chains than other starches (Semeijn and Buwalda 2018). The chain length distribution is usually analyzed by high-performance anion-exchange chromatography with pulsed amperometric detection and fluorophore-assisted capillary electrophoresis.

Some native starches, particularly potato starch, possess phosphorylation, and the phosphate groups are mostly monoesterified at the C-3 and C-6 positions of the anhydrous glucose residues of amylopectin in the amorphous parts of the starch granules (Hizukuri et al. 1970). The C-6 phosphate esters are in majority and account for approximately 70% of the total phosphorylation (Hizukuri et al. 1970; Tabata and Hizukuri 1971). These phosphate groups generate charge on the starch molecules, providing the starch with low temperature of gelatinization. Moreover, the starch paste is relatively clear with high viscosity.

Amylose was defined as a linear molecule whose α-D-glucopyranosyl units were linked by α-1,4-linkages, but today it is recognized that some amylose molecules are slightly branched by α-1,6-linkages like amylopectin. The DP of amylose ranges 1500–6000, which is much smaller than amylopectin (Zobel 1988). It is generally accepted that the crystalline part of starch granules is composed of double helices formed by side chains of amylopectin, while the branching point of amylopectin and amylose is located in the amorphous region. Both amylopectin and amylose can

interact with I_2 to form complex. The color and intensity of the starch-I_2 complex depend on the chain length of amylopectin or length of amylose (Baldwin et al. 1944). The amylose-I_2 complex is blue, and its maximum absorbance wavelength (λ_{max}) is approximately 620 nm. The color of the amylopectin-I_2 complex shifts to red-purple, and the λ_{max} shifts to lower wavelengths at 530–575 nm, since the chain length of amylopectin is much smaller than the length of amylose. The blue value (BV) which indicates the complex ability of starch and I_2 is defined as the absorbance at 680 nm of 1 mg starch in 100 mL solution containing 2 mg I_2 and 20 mg KI. Absolutely, amylose has higher BV at 1.01–1.63, whereas BV of amylopectin is low, ranking 0.08–0.38 (Bertoft 2018). Besides, amylopectin and amylose display other different properties, such as viscosity and crystallization behavior. Due to the difference of amylopectin and amylose, the amylose content is an important parameter of native starch.

44.2.2 Starch Synthesis

Amylopectin biosynthesis is executed by a coordinated series of enzymes, including ADP-glucose pyrophosphorylase (AGPase), soluble starch synthase (SS, including SSI, SSII, SSIII, and SSIV), and starch branching enzyme (BE, including BEI and BEII), whereas amylose is synthesized by AGPase and granule-bound starch synthase (GBSSI) (James et al. 2003; Jaiswal and Chibbar 2017). The general scheme of starch synthesis is summarized in Fig. 1 (Buléo et al. 1998). Glucose is first phosphorylated into α-glucose-6-P (P represents the phosphate group) via action of hexokinase, and then α-glucose-6-P is converted into α-glucose-1-P via action of phosphoglucomutase. Alternatively, α-glucose-1-P results from phosphorolytic degradation of starch, which is catalyzed by starch phosphorylase. The α-glucose-1-P should be activated into adenosine diphosphate-glucose (ADP-Glu), the glucosyl

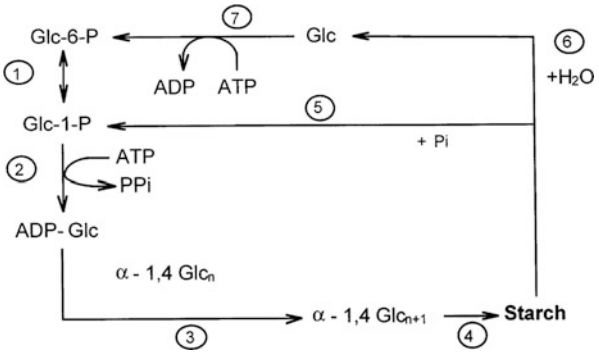

Fig. 1 General scheme for starch biosynthesis: (1) phosphoglucomutase; (2) ADP-glucose pyrophosphorylase; (3) granule-bound and soluble starch synthases; (4) branching enzymes; (5) starch phosphorylase; (6) amylases, branching enzymes, maltases; (7) hexokinase (Buléo et al. 1998). ADP represents adenosine diphosphate and ATP represents adenosine triphosphate

donor. This reaction is catalyzed by AGPase. Then, the glucosyl unit of ADP-glucose is transferred to the nonreducing end of a glucan chain by formation of α-1,4 glycosidic bond for elongation of linear glucan chain, which is catalyzed by SS or GBSS. Studies on roles of SS isoforms in chain length distribution of amylopectin indicate that SSI is primarily responsible for the synthesis of shortest chains (DP $\leq$ 10) (Keeling and Myers 2010). The longer chains of amylopectin are mostly synthesized by SSII and SSIII (Commuri and Keeling 2001). Accordingly, differences in contribution of starch synthases have been observed with respect to species and even different tissues in the same species, which cause variations in fine structure of amylopectin (Smith et al. 1997). The branches of the amylopectin and amylose molecules are produced by SBE, which cleaves internal α-1,4 glycosidic linkage and attaches the released chain through an α-1,6 glycosidic bond to a new site on the glucan molecule. BEI and BEII differ in terms of the lengths of chains transferred in vitro (James et al. 2003). Specifically, BEII transfers shorter chains than BEI. In another study, it was found that BEs might act sequentially during starch synthesis; BEII acted first and produced precursors which further acted as substrate for BEI (Seo et al. 2002). Mutations in many species suggest that starch synthesis also involves debranching enzymes (DBEs) (James et al. 2003). Two DBE families exist in plants, isoamylase type and pullulanase type. They hydrolyze α-1,6 bonds but differ in substrate specificity. Final packaging of starch granules requires trimming of extra branches, and DBEs play this role (Ahuja et al. 2013). Two mechanisms for DBE mode of action have been proposed. According to the preamylopectin-trimming model, the outer branches of preamylopectin molecules are trimmed by DBE to facilitate elongation of chains by SS. This results in amylopectin with an ordered branch structure and allows the molecules to package in starch granules. In addition, the glucan chains released by action of DBE on amylopectin can be used to form the amylose fraction by elongation action of GBSSI. According to the soluble glucan recycling model, DBE participates in degradation of short-chain glucans produced either by SS or SBE action to prevent accumulation of highly branched soluble polymers. This model is supported by the fact that phytoglycogen instead of amylopectin from soluble glucans is formed in endosperms deficient in DBE activity by lesions in DBE genes.

44.2.3 Modification of Starch

Food-grade enzymes, such as α-amylase, β-amylase, amyloglucosidase, and pullulanase, are used to produce maltodextrin, modified starches, or syrups (Jiang et al. 2014; Li et al. 2014; Qi et al. 2017). α-Amylase randomly breaks down the inner α-1,4 glycosidic bonds of starch (Miao et al. 2014d). β-Amylase acts from the nonreducing end of starch and hydrolyzes the second α-1,4 glycosidic bond, cleaving off two glucose units at a time and producing maltose (Miao et al. 2014c). But it cannot pass α-1,6 branch linkage. Therefore, only approximately 40%–60% of amylopectin is converted to maltose, and the remaining part is the β-limit dextrin (Tester and Qi 2011). Amyloglucosidase catalyzes the hydrolysis of both α-1,4 and

α-1,6 bonds, but the rate of hydrolyzing α-1,6 bond is much slower (Miao et al. 2014b). Pullulanase is often used to debranch starch due to its specificity on α-1,6 bond (Miao et al. 2009).

Every α-D-glucopyranosyl unit of starch molecules has three hydroxyl groups, which provides active sites for chemical modification (Lu et al. 2016). Generally, chemical modification of starch involves oxidation, etherification, esterification, or cross-linking of the available hydroxyl groups on the α-D-glucopyranosyl units of starch molecules; thus new groups are introduced to the starch polymer (Miao et al. 2011). Examples of esterified starches include hydroxypropyl starch, hydroxyethyl starch, or carboxymethyl starch, whose hydroxyl groups are partially substituted by hydroxypropyl, hydroxyethyl, or carboxymethyl group through the formation of an ether link (R-O-R), respectively (Masina et al. 2017). Starch octenyl succinate and starch acetate are generally obtained by the esterification of native starch with octenyl succinic anhydride (OSA) and acetic anhydride in the presence of an alkaline catalyst, respectively (Miao et al. 2014a). Cross-linking modification is intended to randomly produce intra- and intermolecular bonds between hydroxyl groups of starch. The commonly used agents to cross-link food-grade starches include sodium trimetaphosphate, sodium tripolyphosphate, monosodium phosphate, phosphoryl chloride, epichlorohydrin, vinyl chloride, and a mixture of adipic acid and acetic anhydride (Singh et al. 2007).

44.3 Metabolism and Bioavailability

44.3.1 Metabolism of Digestible Starch

Starch must be digested into glucose to be absorbed in the small intestine of human beings. Starch is firstly hydrolyzed by salivary α-amylase in oral cavity. Chewing comminutes the food and provides good interaction between salivary α-amylase and starch, which may protect the enzyme inside the bolus and continue to digest starch to some extent in the low-pH environment of the stomach. After the journey through the stomach, starch arrives at the small intestine and is hydrolyzed by pancreatic α-amylase. At this point, starch is hydrolyzed into glucose, maltose, maltotriose, α-limit dextrin, isomaltose, etc. Then these non-glucose molecules are further hydrolyzed into glucose by α-glycosidases at the brush border of the small intestine, including maltase-glucoamylase and sucrase-isomaltase. Maltose, maltotriose, and maltotetraose are hydrolyzed into glucose by maltase-glucoamylase via successive action from their nonreducing end. The α-1,6-linkages of hydrolyzed starch are hydrolyzed by sucrase-isomaltase. Finally, glucose can be actively transported across the enterocyte of the small intestine via the sodium glucose cotransporter 1 (SGLT-1) and enters the blood, thus increasing the blood glucose concentration.

The increasing of the blood glucose concentration leads to secretion of insulin, and the insulin facilitates tissue uptake of glucose to decrease the blood glucose concentration. Some glucose molecules are oxidized immediately to provide energy,

and some are used to synthesize glycogen in liver and muscle tissues. However, the capacity to synthesize glycogen for storing glucose of human body is limited. The maximum storage capacity for storing glucose by glycogen is approximately 700 g (Li 2018). This capacity in muscle is in majority. However, this capacity in the liver is limited, and only a maximum of approximately 150 g glucose can be stored in the liver of a normal 70 kg person. If the glucose intake exceeds both the oxidative and glycogen storage capacities, glucose will be converted into fat. The capacity to convert glucose into fat is much larger, which can explain why eating too much induces obesity. Liver glycogen can be degraded into glucose, and glucose is released to general circulation. Glycogenolysis which means degradation of glycogen into glucose functions according to the body's needs, which plays an important role in maintaining blood glucose levels constant during the intervals between meals (Blanco and Blanco 2017). However, muscle glycogen does not release glucose into the general circulation. Actually, muscle glycogen serves as an energy reserve for this tissue and is intensely utilized when muscle performs work, such as high-intensity exercise. In this case, breakdown of glycogen produces pyruvate and lactate in muscle.

The catabolism of glucose mainly takes place through glycolysis (also known as Embden-Meyerhof pathway), which is fully completed in the cell cytoplasm (Blanco and Blanco 2017). This pathway includes ten reactions (Fig. 2). Phosphorylation is the initial step for the metabolic utilization of glucose (Reaction (1)). The first metabolic transformation is the esterification with phosphate to form glucose-6-P. This reaction is catalyzed by hexokinase, an enzyme present in all cells, or glucokinase. The formation of glucose-6-P is important for converting glucose into a more reactive compound, which is suitable for further transformations. In addition, because glucose-6-P cannot pass through cell membranes, glucose is trapped into the cell via glucose phosphorylation. Moreover, rapid conversion of glucose to glucose-6-P maintains the intracellular glucose concentration at a low level, which facilitates the continual entry of glucose into the cell. In Reaction (2), the aldo sugar, glucose-6-P, is isomerized to the keto sugar, fructose-6-P. This reaction is catalyzed by phosphoglucoisomerase. Then, fructose-6-P is further phosphorylated at the other end by phosphofructokinase to generate fructose-1,6-bisphosphate (fructose-1,6-P_2) (Reaction (3)). This reaction requires the transfer of a phosphoryl group from ATP and is catalyzed by phosphofructokinase. In Reaction (4), fructose-1,6-P_2 is cleaved into two triosephosphate molecules: glyceraldehyde-3-P and dihydroxyacetone-P. Then, dihydroxyacetone-P is transformed into glyceraldehyde-3-P (Reaction (5)). These steps are usually considered as the first or early phase of glycolysis. In Reaction (6), glyceraldehyde-3-P is oxidized and phosphorylated into 1,3-bisphosphoglycerate. This reaction is catalyzed by glyceraldehyde- 3-phosphate dehydrogenase, an oxidoreductase that uses nicotinamide adenine dinucleotide (NAD^+) as coenzyme. Therefore, the acceptor of the reducing equivalents is NAD^+, and it becomes reduced nicotinamide adenine dinucleotide (NADH), while the second hydrogen is released simply as a proton in solution. Substrate-level phosphorylation occurs in Reaction (7). High-energy phosphate is transferred from 1,3-bisphosphoglycerate to ADP, which is catalyzed by phosphoglycerate kinase.

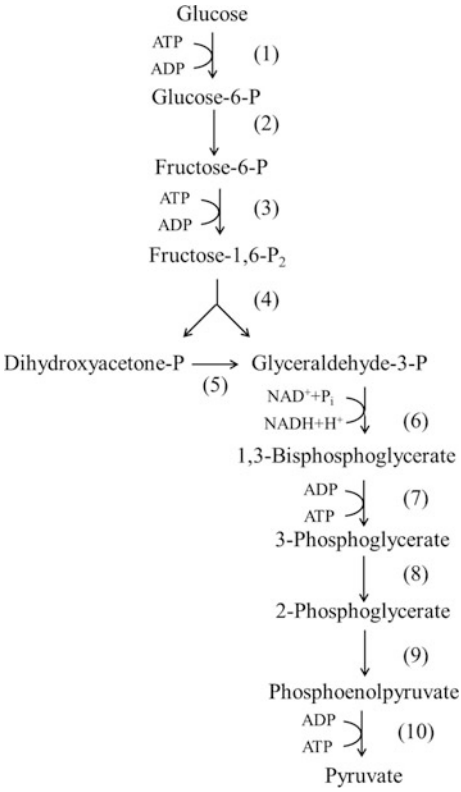

Fig. 2 Reactions of glycolysis

As a result, 3-phosphoglycerate and ATP are produced. Subsequently, 3-phosphoglycerate is converted into 2-phosphoglycerate via an intramolecular phosphoryl transfer (Reaction (8)), which is catalyzed by phosphoglycerate mutase. 2-Phosphoglycerate is dehydrated and intramolecularly redistributed, generating an energy-rich compound, phosphoenolpyruvate (Reaction (9)). The second substrate-level phosphorylation occurs in Reaction (10). The energy-rich phosphoenolpyruvate transfers a phosphate molecule to ADP, forming ATP and pyruvate. This reaction is catalyzed by pyruvate kinase.

The early steps of glycolysis actually consume two ATPs, but four ATPs are produced in the later reactions, resulting in a net production of two ATPs per glucose molecule. Therefore, glucose can quickly provide energy through glycolysis. In this catabolism pathway, two pyruvate molecules are obtained by cleaving a glucose molecule. The fate of pyruvate depends on the oxidative state of the tissue. For glycolysis to proceed, the NADH produced in Reaction (6) must be reoxidized back to NAD^+. Under aerobic conditions, the reducing equivalents from NADH are transferred to the mitochondrial electron transport chain and ultimately to molecular oxygen (Tornheim 2018). In this case, pyruvate produced from glycolysis is completely oxidized to CO_2 and H_2O, which is a complicated process. Pyruvate is first decarboxylated, which produces CO_2 and acetyl-coenzyme A (acetyl-CoA).

Acetyl-CoA moves into the citric acid cycle (also known as tricarboxylic acid (TCA) cycle or Krebs cycle), being completely oxidized to CO_2. The resultant reducing equivalents are transferred to the mitochondrial electron transport chain and ultimately to molecular oxygen, producing H_2O and more ATPs. However, when there is insufficient oxygen or insufficient activity of the electron transport chain, pyruvate must be used to oxidize NADH and regenerate NAD^+ in the lactate dehydrogenase reaction. In this case, pyruvate is reduced to lactate. This is the reason why strong muscular exercise produces lactate. Lactate formation is very important for muscle because it can rapidly use the ATP generated through glycolysis to contract. Increased levels of lactate can be detected in blood and urine after intense exercise, which directly indicates the level of glycolytic activity of muscle. Alternatively, if there is excess use of glucose beyond what would be necessary for energy production, acetyl-CoA can also be used for synthesis of fatty acids, the main constituent of fat (Tornheim 2018). Absolutely, aerobic catabolism of glucose is much more efficient but much slower in energy production than anaerobic catabolism. Particularly, glycolysis is the only pathway for energy production in mature red blood cells due to lack of mitochondria. In addition, the intermediates from glycolysis and citric acid cycle play important roles in supplying the carbon backbone for synthesis of many cell constituents. For instance, 2,3-bisphosphoglycerate which is generated from 1,3-bisphosphoglycerate is an important modulator of hemoglobin. Glycerol-3-P which is formed from dihydroxyacetone participates in the synthesis of triacylglycerols and phospholipids.

In most tissues, 80% or more of glucose catabolism initially enters glycolysis. The rest follows another pathway called the pentose phosphate pathway or the hexose monophosphate pathway. It can be divided into two phases (Fig. 3). The first phase is the oxidative phase. Here glucose-6-P undergoes two oxidations and decarboxylation and is transformed into ribulose-5-P. First, glucose-6-P is dehydrogenated and produces gluconolactone-6-P. This reaction is catalyzed by glucose-6-P dehydrogenase, which depends on nicotinamide adenine dinucleotide phosphate ($NADP^+$) as the hydrogen acceptor. Therefore, reduced nicotinamide adenine dinucleotide phosphate (NADPH) is produced. Then, gluconolactone-6-P is converted into gluconate-6-P. In Step 3, gluconate-6-P is oxidized and transferred into ribulose-5-P and CO_2, which is catalyzed by another $NADP^+$-dependent enzyme, gluconate-6-P dehydrogenase. Thus, NADPH is produced again. The second phase is the nonoxidative phase, which comprises a series of reversible reactions. Firstly, ribulose-5-phosphate produces two isomers: ribose-5-P and xylulose-5-P. They are then transferred into glyceraldehyde-P and sedoheptulose-7-P via action of transketolase, which in turn generate fructose-6-P and erythrose-4-P via action of transaldolase. Erythrose-4-P and xylulose-5-P are redistributed to form glyceraldehyde-3-P and fructose-6-P via action of transketolase. Obviously, glyceraldehyde-3-P and fructose-6-P are intermediates of glycolysis and can enter the glycolysis pathway. In summary, this pathway produces two important substances: pentose phosphate and NADPH (Tornheim 2018). Pentose phosphate is a precursor for synthesis of nucleotides and nucleic acids. On the other hand, NADPH is indispensable to anabolism as a reducing agent, which is used in various

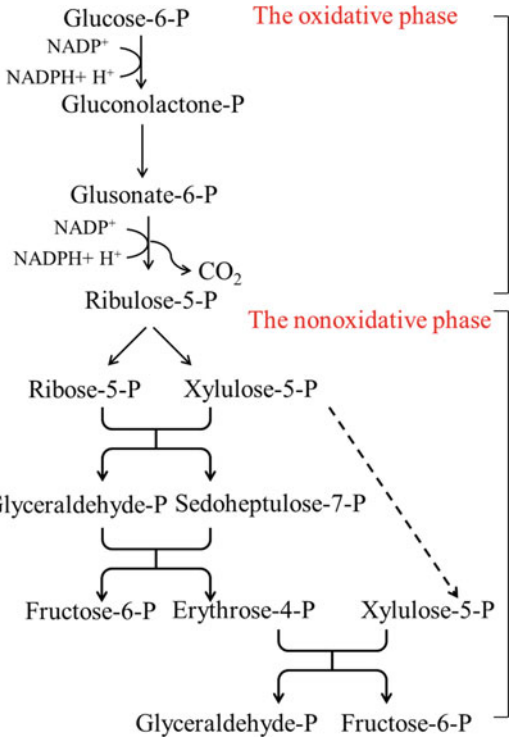

Fig. 3 The pentose phosphate pathway

processes, including fatty acid synthesis, regenerating reduced glutathione, cholesterol and bile acid synthesis, steroid hormone synthesis, and cytochrome P450-dependent biotransformation. Therefore, the pathway is very important for anabolism and is highly active in the tissues where these processes occur, such as liver.

44.3.2 Bioavailability of Starch According to Its Digestion Rate

Digestion of starch is affected by various factors that affect enzyme activity and the susceptibility of the starch substrate to the digestive enzyme (Miao et al. 2013, 2015b). For humans, enzyme activity is mainly affected by the starch structure and enzyme inhibitors either present in the food or generated during digestion of food. As stated above, the main hydrolysis of starch is performed by the α-amylases. Starch digestion by α-amylases requires a series of steps. The enzymes first have to diffuse to the starch matrix, then bind to starch, and finally cleave the α-1,4 glycosidic linkages. Physical entrapment of starch in the food matrix, starch granular structure, and crystallinity may affect the binding of enzymes to the starch substrate (Miao et al. 2015a). For starch granules, one of the limiting factors for the hydrolysis is the penetration of the enzyme into the granules by successive formation of pits and larger pores. On the other hand, the starch has to be properly oriented inside the

active side of the enzyme for the catalytic action of the enzyme to occur (Sun et al. 2019). Only the part of the starch that can fit into the active site cavity of the α-amylase can be hydrolyzed. Structures such as double helices are too big and rigid to fit into the active site cavity, which is another reason for why it is difficult for amylases to hydrolyze starch granules. Thus, the amorphous starch is less resistant to digestive enzymes than the crystalline starch. Similar phenomenon occurs to the starch-lipid complex with a left-handed helix, which is more resistant to enzymes. Molecular structure of starch also influences its digestion. As mentioned above, starch is comprised of amylopectin and amylose. Amylose is a linear polysaccharide whose glucose monomers are linked by α-1,4 glycosidic bonds, whereas the highly branched amylopectin contains α-1,6-linked glucose monomers that create branch points in addition to the linear α-1,4-linkages. The linear regions of the starch molecules are easily digested by human α-amylases. The digestion products of α-amylase, small sugar and oligosaccharide, are then digested further by the intestinal brush border enzymes. Therefore, humans hydrolyze α-1,6 glycosidic bonds more slowly than α-1,4 bonds. A linear portion of the starch chain has to fit in active site of α-amylase to be hydrolyzed. This linear portion must be long enough to favorably bind with the enzyme. Glucose units close to the branch points have less favorable binding with the active site of the enzyme, thus decreasing the hydrolysis efficiency. Thus, no matter what type of linkage that creates the branching of the starch chain, branch points create steric hindrance for α-amylase digestion. Chemical modification of starch usually introduces a bulky side group to the starch chains, which can be viewed as a modification that creates branches on the starch chains and brings steric hindrance to human digestive enzymes. Therefore, chemical modification including etherification, esterification, and cross-linking decreases the digestibility of starch. Particularly, cross-linking links two starch chains, in effect producing a branch on both starch chains.

Therefore, based on its rate and extent of digestion, starch has been classified into rapidly digestible starch (RDS), slowly digestible starch (SDS), and resistant starch (RS) (Englyst et al. 1992). RDS corresponds to the starch fraction digested within 20 min of incubation; SDS is the starch fraction digested within 20–120 min; and the remaining fraction is RS, which cannot be digested further in the small intestine (Miao et al. 2015a). Accordingly, RDS leads to a postprandial fluctuation in blood glucose with the blood glucose peak occurring 30–60 min after consumption (Hendrich 2018). For individuals with normal glucose metabolism, the blood glucose concentration is declined to the fasting state within ~2 h. Ingestion of SDS blunts and slows this pattern of blood glucose response. Ingestion of RS further blunts blood glucose response (Miao et al. 2015a).

44.3.3 Gut Bacterial Metabolism of RS

Generally, RS has been classified into four subtypes named RS1–RS4 (Englyst et al. 1992). RS1 refers to physically inaccessible starch that is enclosed in food matrixes. Starch granules are always surrounded by the protein matrix and cell wall materials.

For instance, it is confirmed that the protein matrix hinder digestion of rice starch (Ye et al. 2018). The whole cereal grains are digested much more slowly than flours, which suggests that the cell wall materials hinder digestion of rice starch. When cooked as whole kernels or coarsely ground seeds, the thick cell wall of legume seeds and the protein matrix in cereal grains prevent water penetration into the starch in the matrix (Birt et al. 2013). Therefore, starch granules do not have adequate moisture to fully swell and gelatinize. Without adequate swelling and gelatinization, starch is not readily susceptible to enzymatic hydrolysis. The cell wall material and the protein matrix also prevent enzymes from reaching and hydrolyzing starch through acting as a physical barrier. Examples of RS1-containing foods in the previous reports include pasta made from durum wheat by extrusion and breads made from whole or coarsely ground kernels of grains (Jenkins et al. 1988; Granfeldt et al. 1991). Durum wheat has a higher protein content and harder texture. Consequently, the postprandial glycemic response after ingesting semolina pasta is substantially lower than white bread. Residual starch that is not digested in the small intestine passes into the colon as RS1. However, these starches may become more accessible and less resistant after milling and chewing. RS2 is composed of native starch granules whose crystallinity makes them resistant to enzymatic hydrolysis. Examples of RS2 include uncooked potato starch, green banana starch, gingko starch, and high-amylose maize starch (Birt et al. 2013). However, after cooking, most of RS2 becomes highly digestible due to starch gelatinization and loss of the crystallites. An exception is high-amylose maize starch. This starch displays a high gelatinization temperature, above the boiling point of water. Therefore, under the common cooking conditions, this type of starch retains its crystalline structure and remains resistant to enzymatic hydrolysis. Retrograded starches formed after cooking belong to RS3. Examples include the starch found in cooked and cooled potatoes, bread crusts, cornflakes, and retrograded high-amylose maize starch. After cooked starchy foods are stored, particularly in a refrigerator, amylose molecules and long-chain branches of amylopectin are prone to forming double helices and lose their water-binding capacity. This process is called retrogradation. The double helices of starch molecules are resistant to amylases. Therefore, those factors which affect retrogradation of starch, such as the amylose content, chain length, and processing conditions, would influence the amount and quality of RS3.The amylose content is positively correlated with the RS3 yield. Several RS3 ingredients are in the market, which are usually derived from cooked and recrystallized maize or tapioca starch. Because amylose molecules have a greater tendency to retrograde than amylopectin molecules, high-amylose starch is often used to prepare RS3. To promote crystallization of starch and formation of RS3, the starch is usually debranched to increase the amount of linear chains (Maningat and Seib 2013). In addition, annealing and heat-moisture treatment can enhance the RS3 content, since more perfect structures are formed, resulting in an increase in enzyme resistance of the starch. RS4 includes chemically modified starches. The introduced groups, such as phosphate groups or octenyl succinic groups, partially inhibit the enzymatic hydrolysis of the starch molecule due to steric hindrance, resulting in RS.

Recently, a new type of RS, RS5, is proposed, which comes from the amylose-lipid complex (Ashwar et al. 2016). When starch interacts with lipids, the hydrocarbon chain of the lipid interacts with the hydrophobic moiety of the amylose chain and fills the central cavity of the amylose. The complex forms amorphous (Form I) or highly crystalline structures (Form II), which both show V-type crystallinity in the X-ray diffraction analysis. This complex occurs in small amounts to native starch, and its production can be enhanced by addition of exogenous fatty acids and heat processing, such as steam jet cooking, wet heat processing, and extrusion cooking (Panyoo and Emmambux 2017). The enzyme resistance of amylose-lipid complex is attributed to the helical conformation of the starch-lipid complex, which prevents amylose molecules from dispersing and interfering with enzymes for hydrolysis (Jane and Robyt 1984). Because the amylose-lipid complex is spontaneously formed during cooling after being heated above its dissociation temperature, RS5 is thermally stable (Panyoo and Emmambux 2017). In addition, the crystalline structure of the complex enhances its enzyme resistance. For instance, the crystalline amylose-lipid complex (Form II) is more resistant to amylolytic enzyme hydrolysis than the amorphous complex counterpart (Form I). The resistance of the complex also depends on the lipid structure. The complex made from longer length fatty acids has greater enzyme resistance, while fatty acids with a greater degree of unsaturation make the amylose-lipid complex with lower enzyme resistance (Hasjim et al. 2013).

Different from RDS and SDS, RS cannot be digested into glucose by the small intestine. Actually, RS passes through the upper digestive part and arrive at the colon where RS is fermented by gut bacteria. The fermentation products of RS by gut bacteria mainly include short-chain fatty acids (SCFAs, mainly acetate, butyrate, and propionate) and gases (methane, hydrogen, and carbon dioxide) (Birt et al. 2013). In addition, few branched-chain fatty acids (isobutyrate and isovalerate), organic acids (lactate, succinate, and formate), and alcohols (methanol and ethanol) are produced. Fermentation of RS is a cooperative process in the lower gut, including (1) degradation of starch polymers into glucose performed by amylolytic gut bacteria; (2) glycolysis with SCFAs or other organic acids as end products which is performed by butyrogenic bacteria; and (3) methane production by *methanogenic Archaea* spp. from formate, hydrogen, and carbon dioxide, the products of bacterial metabolism of RS (Flint et al. 2008).

A range of enzymes is involved in breakdown of RS in the gut, including α-amylases that cleave α-1,4-linkages, type I pullulanases that specifically hydrolyze α-1,6 bonds, and amylopullulanases that cleave both α-1,4 and α-1,6 bonds (Ramsay et al. 2006). By far, the greatest number of starch-degrading enzymes in the gut, including α-amylases, pullulanases, and amylopullulanases, belong to family 13 glycoside hydrolases (MacGregor et al. 2001). It was found that the majority of amylolytic isolates were identified as bifidobacteria (58%) and bacteroides (18%), and fusobacteria and butyrivibrios accounted for about 10% of starch-hydrolyzing bacteria isolated when using fresh feces to ferment soluble starch (Macfarlane and Englyst 1986). In another in vitro fermentation experiment, it was found that *Bifidobacterium* spp., *Bacteroides* spp., *Fusobacterium* spp., and strains

of *Eubacterium*, *Clostridium*, *Streptococcus*, and *Propionibacterium* could hydrolyze the gelatinized amylopectin and high-amylose maize starch, whereas only *Bifidobacterium* spp. and *Clostridium butyricum* could efficiently utilize ungelatinized high-amylose maize starch granules (Wang et al. 1999). Therefore, *Bifidobacterium* spp. and *Clostridium butyricum* would be particularly important to gut bacterial fermentation of insoluble starch. In addition, Ze et al. 2012 found that *Eubacterium rectale* and *Bacteroides thetaiotaomicron* showed limited ability to utilize RS2 and RS3 compared with *Bifidobacterium adolescentis* and *Ruminococcus bromii*. However, only *R. bromii* was proved to be able to stimulate RS2 and RS3 utilization by the other three bacterial species in co-culture, even in a medium that does not permit growth of *R. bromii* itself. These results suggested that *R. bromii* was a keystone species for degradation of RS in the human colon. A recent study in humans also confirmed that the primary degradation of RS2 was largely governed by features linked to *Firmicutes*, including *R. bromii* as a main taxon (Vital et al. 2018).

Bacterial binding to starch is important for fermentation of starch in some bacteria. The enzyme system in *B. thetaiotaomicron* responsible for soluble starch utilization has been well established (Reeves et al. 1996, 1997). The enzyme system is organized by an outer membrane protein complex, including starch-utilization-structure (Sus) gene clusters that bind to and hydrolyze starch. In the complex, these outer membrane Sus proteins regulate the binding and transporting products of starch from partial hydrolysis into the periplasm where they are hydrolyzed and processed further. Specifically, the membrane protein complex contains maltose-inducible outer membrane proteins, SusC, SusD, SusE, SusF, and SusG (Fig. 4) (Flint et al. 2008; Reeves et al. 1996, 1997). SusC and SusD are physically associated and majorly contribute to starch binding. It is likely that SusE and SusF also contribute to binding but not to the same extent as SusD. SusG seems to contribute little to starch binding but is essential for growth on starch. Starch-hydrolyzing activity in *B. thetaiotaomicron* is greatly cell-associated, with much of it being periplasmic. In *E. rectal*e, a complex which contains two glycoside hydrolase13 family enzymes and three ATP-binding cassette transporter solute-binding proteins at the cell surface is responsible for hydrolyzing starch and capturing the released maltooligosaccharides (Cockburn et al. 2015). A multi-domain cell wall-anchored amylase, one of the two enzymes, is tethered to the peptidoglycan layer and may bind the bacterium to starch via its five N-terminal carbohydrate-binding modules and one unknown domain. It preferentially targets starch or maltooligosaccharides longer than maltotriose. The main product is maltotetraose, and significant amounts of maltopentaose are also produced. The other enzyme is a membrane-associated maltogenic amylase, which breaks down maltooligosaccharides with higher DP than maltotriose. The three solute-binding proteins display a range of glycan binding specificities.

Recently, it is found that there is unique organization of extracellular amylases, which is called amylosomes, in the RS-utilizing human colonic *R. bromii* (Ze et al. 2015). Dockerin-cohesin interactions occur among the enzymes in the amylosomes. *R. bromii* is a specialized amylolytic bacterium belonging to the *Ruminococcaceae*, a

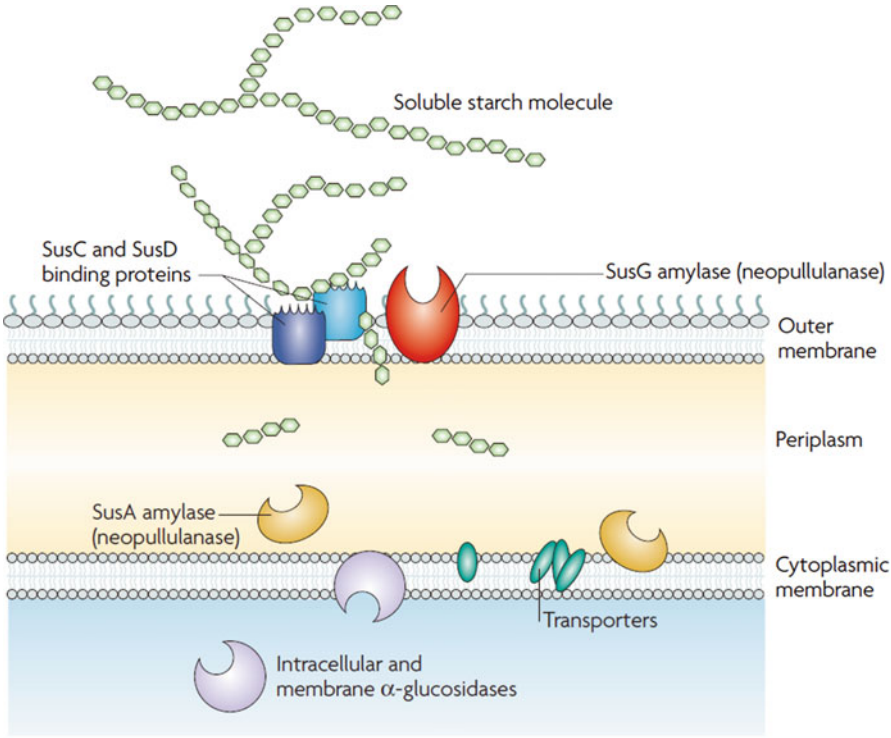

Fig. 4 The sequestration system for soluble starch in *B. thetaiotaomicron.* SusC and SusD are two proteins that have been shown to be essential in binding starch molecules to the cell surface. Limited hydrolysis by SusG is followed by more extensive hydrolysis in the periplasm and the uptake of oligosaccharides across the cytoplasmic membrane (Flint et al. 2008)

family of *Firmicutes* that is better known for the ability of certain rumen species to degrade cellulose. Compared with other amylolytic human intestinal bacteria such as *B. thetaiotaomicron*, *E. rectale*, and *B. adolescentis*, *R. bromii* shows high hydrolyzing activity against raw or boiled RS containing starch granules. It is observed that *R. bromii* cultures mainly have six extracellular GH13 amylases. They are four glycosidases, including Amy4, Amy1, Amy2, and Amy9, and two type I pullulanases, including Amy10 and Amy12. Amy4, Amy9, Amy10, and Amy12 carry dockerin, and Amy4 also carries a cohesin module. It is predicted that Amy4 and Amy9 bind a cohesin present in protein scaffolding. It is also inferred that further complexes are formed between the dockerin-carrying amylases Amy4, Amy9, Amy10, or Amy12 and two other cohesin-carrying proteins. In addition, Amy4 has the ability to autoaggregate, as its dockerin can recognize its own cohesin.

As stated above, glycolysis is the main pathway for glucose catabolism in human cells. Actually, glycolysis is a typical example of the unity of living organisms, since all living organisms have this route (Blanco and Blanco 2017). Many microorganisms metabolize glucose by this pathway through fermentation, but the end products

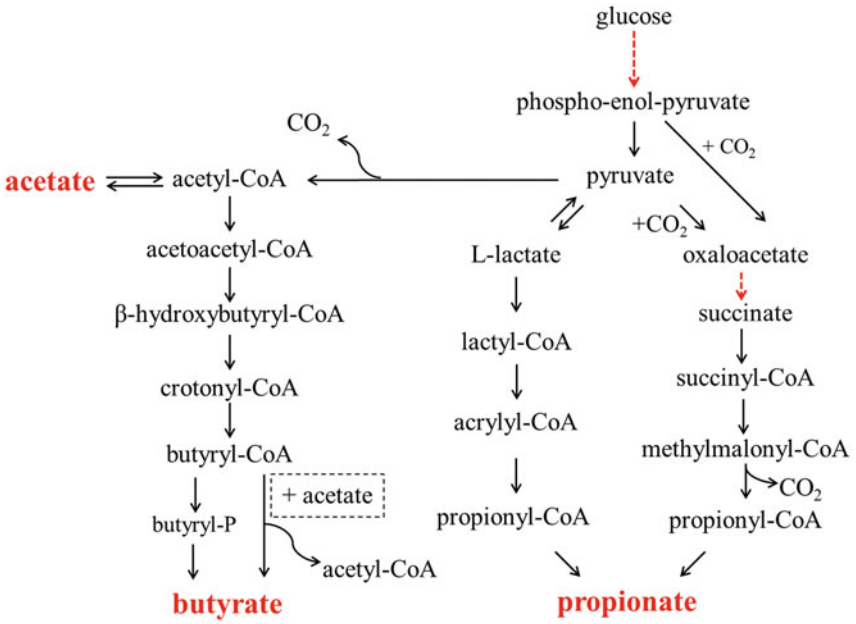

Fig. 5 Fermentation pathways leading to acetate, butyrate, and propionate formation from RS. Dotted arrow indicates several reactions

vary in different organisms. In the gut microorganisms, glycolysis is also the main pathway for glucose catabolism. After glycolysis, different pathways happen to pyruvate, resulting in different SCFAs. According to the previous reports (Pryde et al. 2002; Louis et al. 2007; Zhu et al. 2005), fermentation pathways leading to acetate, butyrate, and propionate are summarized in Fig. 5. Pyruvate is the major precursor of acetate and butyrate. Pyruvate is first decomposed into CO_2, one of the products for RS in gut, and acetyl-CoA. Acetyl-CoA is directly converted into acetate or participates in butyrate synthesis by butyrate kinase through a series of reactions. Acetate can act as a CoA acceptor and react with butyryl-CoA to synthesize butyrate, which is catalyzed by butyryl-CoA: acetate-CoA transferase. There are two routes to form propionate from glucose: the acrylate route from lactate is found in bacteria belonging to the clostridial cluster IX group, while *Bacteroides* species generally employ the succinate route to form propionate (Louis et al. 2007). Acetate accounts for approximately 60%–75% of the total SFCAs detected in feces and is formed by many of the bacteria, with around one-third coming from reductive acetogenesis (Miller and Wolin 1996). Butyrate-producing colonic bacteria generally belong to the clostridial clusters I, IV, XI, XIVa, XV, and XVI (Pryde et al. 2002). Two particularly abundant groups that together constitute 7%–24% of the total gut bacteria in healthy subjects are cluster IV bacteria related to *Faecalibacterium prausnitzii* and cluster XIVa bacteria related to *Eubacterium rectale* and *Roseburia* spp. The pathway employing butyrate kinase seems to widely

exist in different butyrate-producing *Clostridium* species and several clostridia (Zhu et al. 2005; Louis et al. 2007). The pathway employing butyryl-CoA:acetate-CoA transferase has been described in several bacteria, such as *Butyrivibrio fibrisolvens*, *Roseburia* sp., *F. prausnitzii*, and *Coprococcus* sp. (Diez-Gonzalez et al. 1997; Duncan et al. 2002).

Gas production is another fermentation outcome, and particularly the production of methane can be considered as the final end product consuming hydrogen and carbon dioxide (Li 2010). In ruminant animals, methanogens are ubiquitous. However, the distribution of methanogenic *Archaea* in human fecal bacterial populations is a good example of individual variability. Caucasians (48%) and Blacks (45%) had significantly more methane producers than Orientals (24%) and Indians (32%) by measuring breath hydrogen after lactulose intake (Pitt et al. 1980). On the other hand, it was reported that the abundance of methanogenic *Archaea* was negatively correlated to fecal butyrate concentration (Weaver et al. 1992; Belenguer et al. 2006). The production of methane mainly involves two parts as follows:

$$\text{Pyruvate} \rightarrow \text{CO}_2 + \text{H}_2 + \text{Formate}$$

$$\text{CO}_2 + 4\text{H}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$$

The microbial communities of the large intestine are characterized by high cell densities and interspecies cross-feeding of fermentation products. Without exception, metabolic cross-feeding between bacteria plays an important role in metabolism of RS. For instance, the potential for metabolic cross-feeding between *B. adolescentis* and lactate-utilizing, butyrate-producing *Firmicute* bacteria related to *Eubacterium hallii* and *Anaerostipes caccae* was investigated in vitro (Belenguer et al. 2006). *E. hallii* L2-7 and *A. caccae* L1-92 failed to grow on starch in pure culture but produced butyrate when in co-culture with *B. adolescentis* L2-32, which confirmed cross-feeding of metabolites to the lactate utilizers. In summary, the utilization of RS is a complex and cooperative process in the gut. Identifying bacteria or bacterial functions in fermentation of RS is important for predicting health outcomes of ingesting RS (Li 2010).

Obviously, fermentation of RS is affected by many factors. It is generally accepted that the production of SCFAs, particularly butyrate, is considered to be favorable. Therefore, fermentability of RS is often reflected by the total SCFA production and the butyrate production. Obviously, the amount of RS entering the large bowel influenced the total and individual SCFA productions. As RS must be depolymerized by bacterial hydrolytic enzymes prior to fermentation, the rate of depolymerization affected the degree at which RS become available for bacteria. As stated above, only several bacteria can utilize starch granules. Thus, it can be inferred that fermentation of RS containing starch granules may be much slower than that of non-granular RS. In addition, granule dimension and surface area of RS containing starch granules may affect hydrolysis of RS. For example, it was found that hulless barley cultivar CDC Fibar (waxy starch) and CDC McGwire (normal starch) started to ferment sooner (lag time of 0.7 and 0.9 h, respectively) than

SH99250 (high-amylose starch; 1.7 h) (Jha et al. 2011). It was confirmed that total and individual SCFA productions also depended on its composition and physical structure of RS. For instance, Martin et al. (1998) found that luminal total SCFA in the caeco-colon of pigs 7 h after feeding potato starch (RS2), high-amylose maize starch (RS2), and retrograded high-amylose maize starch (RS3) were 33, 78, and 105 mmol, respectively, with potato starch providing the highest production of butyrate. They also demonstrated that in vivo fermentation of diets containing raw potato starch, high-amylose maize starch, or retrograded high-amylose maize starch induced different patterns of SCFAs in the portal blood of pigs during a 14-h test period (Martin et al. 2000). In addition, it was observed that acetate and butyrate molar ratios in the SCFA profile differed in vitro fermentation of eight native purified starches (RS2), which suggested that fermentation of RS was influenced by chemical composition and physical form of RS fermented (Giuberti et al. 2013). Similar results were also reported by Torres et al. (2013), who found that the concentration and composition of SCFAs differed after in vitro fermentation of five tropical legume grains. In summary, both the total SCFA production and the profile of each individual SCFA depended on several factors, including chemical composition, physical form, and availability of RS to ferment as well as the microbial population during fermentation. Different RS sources and types also might affect the site of fermentation in the large intestine (Giuberti et al. 2015). Slowly fermentable RS types in diets may provide substrates generating SCFAs in the more distal parts of the colon. In addition, the mixture of RS with different fermenting rates may provide substrates generating SCFAs in the whole colon.

44.4 Bioactivities (Animal Experiments)

Usually, starch is not considered as the biological active substance. However, RS cannot be digested in the small intestine and serve as a carbon source for bacterial fermentation in the large intestine. Therefore, RS is often considered as dietary fiber and displays important bioactivities. In addition, SCFAs are the major end products of gut bacterial metabolism of RS. A number of animal and human studies found that RS increased fecal excretion of SCFAs, specifically butyrate (Li 2010, 2018). Particularly, esterified or acylated forms of RS such as acetylated, butyrated, or propionylated RS4 confer specificity in the delivery of SCFAs, because these starches already carry specific SCFAs (Li 2018). These SCFAs loaded on the starches are only released in the large intestine, leaving the residual starch available for fermentation. Therefore, RS have the bioactivities resulting from SCFAs.

SCFAs are rapidly absorbed in the cecum and colon with only 5%–10% being excreted in the feces (Topping and Clifton 2001). Butyrate is the preferred energy source of colonocytes where oxidation of butyrate accounts for at least 60% of the cell's energy requirements, while other absorbed SCFAs enter the portal vein. Propionate is metabolized in the liver and thus is only present at low concentration in the periphery. Therefore, acetate is the most abundant SCFA in peripheral

circulation (Cummings et al. 1987). Furthermore, acetate can pass through the blood-brain barrier and decrease appetite via a central homeostatic mechanism (Koh et al. 2016). Among the SCFAs, butyrate particularly attracts considerable scientific interest due to its high efficiency in most bioactivities. For normal colon, butyrate promoted the integrity of the mucosal barrier, modulated the immune and inflammatory response, moderated fluid and electrolyte flux, and regulated colonic motility and cell growth and differentiation (Topping and Clifton 2001; Hamer et al. 2008). Importantly, animal experiments demonstrated that butyrate lowered colorectal oncogenesis, including reducing cell proliferation and inducing apoptosis of colorectal tumor cell lines (Perrin et al. 2001; Clarke et al. 2008; Le Leu et al. 2009). The mechanisms of lowering colorectal oncogenesis were complicated. Firstly, butyrate was able to inhibit histone deacetylases (HDACs) and thus affects gene expression (Gupta et al. 2006). Histone acetylation emerged as a central switch that regulated interconversion between permissive (via acetylation) and repressive chromatin structures (via deacetylation) (Koh et al. 2016). Histone acetylation is thought to increase accessibility of the transcriptional machinery to promote gene transcription. Acetyl groups are introduced to histone tails by histone acetyltransferases (HATs) and are removed by HDACs. As a result, HDAC inhibitors can be used for cancer therapy. Compared with normal colonocytes that consume butyrate, butyrate was accumulated threefold in nuclear extracts of cancer cells that consume glucose, resulting in higher concentrations of butyrate in cancerous epithelial cells (Donohoe et al. 2012). Thus, butyrate might act as an efficient HDAC inhibitor in cancerous cells rather than in normal colonocytes. Secondly, in vitro studies demonstrated that cell cycle arrest and apoptosis were induced in both a p53-dependent and p53-independent manners by butyrate at physiologically relevant concentrations (0.6–5 mmol/L) (Janson et al. 1997). In colorectal cancer cell lines, butyrate downregulated the expression of p53 mRNA and protein and also directly increased the expression of p53 target genes to induce cell cycle arrest (Gope and Gope 1993; Nakano et al. 1997). Thirdly, butyrate also altered gene expression through regulating the expression of micro-RNA rather than inhibiting HDAC (Fung et al. 2012).

In addition to being an antitumor agent, SCFAs have the anti-inflammatory effect in the large bowel. Rectal administration of either SCFA mixtures or butyrate alone was shown to effectively ameliorate the clinical symptoms of the disease in patients with distal ulcerative colitis (Luhrs et al. 2002; Scheppach et al. 1992; Breuer et al. 1991). The molecular mechanisms might be that butyrate reduces the expression of interleukin-8 and inhibits inducible NO synthase expression (Huang et al. 1997; Stempelj et al. 2007). In addition, it was reported that butyrate suppresses pro-inflammatory effectors due to inhibition of HDAC (Chang et al. 2014). Butyrate was also reported to modulate oxidative stress of healthy humans by increasing the level of glutathione in colonic mucosa (Hamer et al. 2009).

Another well-recognized general effect resulting from increased concentrations of SCFAs is to decrease the pH of the proximal colon. The pH in the colon can markedly affect composition of the colonic microbiota. It was reported that the final butyrate concentrations were significantly higher at pH 5.5 than at pH 6.5, which correlated with a change in the composition of the microbiota (Walker et al. 2005).

That is, the lowering of pH in the colon may promote butyrate production and improve populations of butyrate-producing bacteria. Moreover, the lowering of pH curtailed the growth of *Bacteroides* spp., propionate-producing bacteria. The inhibition effect of acidic pH is already recognized as an important factor to restrict the populations of certain pH-sensitive pathogens in the gut (Louis et al. 2007). On the other hand, the mildly acidic pH improved Ca^{2+} reabsorption from the colon (Abrams et al. 2005).

Therefore, the RS has the following health benefits, including the prebiotic effect, decreasing protein fermentation, keeping colon healthy, deducing postprandial glycemic response, inhibiting fat accumulation, reducing inflammation and oxidative stress, and improving mineral absorption.

44.4.1 The Prebiotic Effect

RS is proved to have the prebiotic effect by different methods from pure culture studies to animal experiments. Prebiotics are defined as nondigestible food ingredient that are beneficial to the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon (Gibson and Roberfroid 1995). Therefore, prebiotics improve host health. In vitro tests suggested that the environment was found to be dominated by the probiotic strains of *Bifidobacterium* and *Lactobacillus* in co-cultures of intestinal and probiotic bacteria in the presence of tartaric acid-modified dextrin (RS) (Barczynska et al. 2012). A RS-rich diet significantly increased the *Lactobacilli*, *Bifidobacteria*, and *Streptococci* populations, decreased the enterobacteria population, and altered the microbial enzyme metabolism in the colon of rats (Silvi et al. 1999). In another study, feeding high-amylose maize starch, one kind of RS, increased fecal *Bifidobacterium* numbers in mice (Wang et al. 2002). Pigs consuming high-amylose starch had higher fecal concentrations and excretion of *B. longum* than those consuming a conventional starch (Brown et al. 1997), which confirmed the prebiotic action of RS. In addition, it was reported that fructooligosaccharides (FOS) and RS raised fecal *Bifidobacterium* numbers by approximately equal amounts when they were fed separately (Brown et al. 1998). This result also confirmed the prebiotic effect of RS, since FOS is a well-known prebiotic. Interestingly, when FOS and RS were fed together, the increase of *Bifidobacteria* numbers exceeded the increase induced by individual, which suggested that the combination of FOS and RS resulted in a synergistic prebiotic effect. Their synergistic prebiotic effect was also confirmed by experiments in the rats (Rodriguez-Cabezas et al. 2010).

44.4.2 Decreasing Protein Fermentation

High-protein diet could result in an increase in protein fermentation in the large intestine, leading to an increased production of branched-chain fatty acids (BCFAs) and potentially detrimental metabolites, such as ammonia, amines, *N*-nitroso

compounds, phenols, thiols, and indoles (Cummings et al. 1979). It was reported that the high-RS (39 g/d) diet daily significantly increased fecal nitrogen and reduced excretion of fecal phenols, fecal concentrations of ammonia, and pH of human subjects (Birkett et al. 1996). However, daily output of urinary ammonia, urea, phenols, and total nitrogen did not significantly alter. These results suggested that RS might hinder protein fermentation, thus significantly attenuating accumulation of potentially harmful by-products from protein fermentation in the human colon. In addition, it was reported that a high-protein (25% casein) diet for 4 weeks led to a twofold increase in damage to colonocyte DNA in male Sprague-Dawley rats compared with a low-protein (15% casein) diet, which was associated with thinning of the colonic mucous barrier and increased levels of fecal *p*-cresol (Toden et al. 2005). However, addition of RS to the diet increased cecal SCFA pools and attenuated DNA damage, which confirmed that RS might inhibit protein fermentation and result in less genotoxic agents. Similarly, it was observed that feeding digestion-resistant potato protein increased the protein fermentation products in male Sprague-Dawley rats, which was reduced by adding RS to the diet (Le Leu et al. 2007). In another study, mice were fed 15% or 30% protein using casein or red meat or 30% protein with 10% high-amylose maize starch (equivalent to 5% RS2) (Winter et al. 2011). It was found that high protein diets increased promutagenic adducts (O^6-methyl-2-deoxyguanosine, O^6MeG) in the colon, while addition of 5% RS2 to the high protein diets lowered adduct formation, apoptosis, and fecal products of protein fermentation and increased production of butyrate. It was also found that RS inhibited protein fermentation by inocula from the large intestine of pigs using in vitro cultivation (He et al. 2017). In this study, fermentation patterns were analyzed during a 24-h incubation of cecal and colonic digesta with different RS contents using casein protein as the sole nitrogen source. The results showed that as the corn resistant starch levels increased, the SCFA concentration and cumulative gas production were significantly increased, while ammonia-nitrogen and BCFAs were decreased. The total bacteria, *Bifidobacterium* and *Lactobacillus*, were significantly increased with the increasing of the RS content after incubation. Therefore, it was concluded that addition of RS weakened the protein fermentation by altering microbial population. In summary, RS has the ability to decrease protein fermentation, which may be due to producing SCFAs and altering microbial population.

44.4.3 Keeping Colon Healthy

It is generally accepted that RS is beneficial to keep colon healthy, partially because RS increases fecal excretion of SCFAs, particularly butyrate. In addition, the prebiotic effect of RS may play a role in colon health. Colon health involves maintaining normal function of the colon. Healthy colon has regular bowel movement once a day or more frequently with the feces being relatively soft but non-diarrhetic. Colon health can be reflected in the measurement of laxation. It was observed that the RS supplement increased the fecal bulk by 22 g/day compared with the low-fiber control, while the wheat bran supplement increased fecal bulk 96 g/day (Jenkins

et al. 1998). This result suggested that RS was able to increase the fecal weight, but its ability was much weaker than wheat bran. However, RS and wheat bran significantly increased fecal weight in another study and did not differ from each other when 14 subjects were given 25 g RS (PROMITOR^{TM}, Tate & Lyle Americas, Decatur, IL, USA) or wheat bran fiber per day for 14 days (Maki et al. 2009). The different result might be due to the difference of the RS type used.

The colon health also involves prevention of colon diseases. Several studies have investigated the effect of RS on colon cancer prevention by animal experiments. In most cases, RS has been fed in diets combining treatment by a chemical carcinogen to test its effect on preventing colon cancer. For instance, Sprague-Dawley rats were fed diets containing no RS or digestion-resistant potato protein (PP), 10% raw high-amylose corn starch (HAS, source of RS2), 15% PP, or 10% HAS and 15% PP for 4 weeks prior to treatment by azoxymethane (AOM), and colon cancers were assessed 30 weeks after AOM treatment (Le Leu et al. 2007). The RS inhibited colon tumor development and increased SCFAs including butyrate in the distal colon. In addition, the RS lowered production of potentially toxic protein fermentation products. These suggested that RS not only protected against intestinal tumorigenesis but also ameliorated the tumor-enhancing effects of feeding indigestible protein. They later confirmed that feeding the same RS2 protected against AOM-induced colon carcinogenesis and favorably influenced the colonic luminal environment (Le Leu et al. 2014). In the experiments, male Sprague-Dawley rats were provided with one of three diets, control (without RS), 10% HAS, and 20% HAS for 4 weeks, and then injected with AOM (15 mg/kg) during the 5th and 6th week. Data demonstrated that feeding RS significantly reduced the incidence and multiplicity of adenocarcinomas in the colon compared to the control diet. Both doses of HAS resulted in similar protection against colon tumorigenesis. Similarly, Yuan et al. (2017b) found that RS reduced the numbers of aberrant crypt foci (ACF) and aberrant crypts of mice with AOM-induced early colon cancer. In another study, the RS completely prevented the development of tumors in Sprague-Dawley rats, compared to rats fed control starch, when rates were fed RS for 20 weeks following treatment by 1, 2-dimethylhydrazine (Bauer-Marinovic et al. 2006). It was found that this effect was mediated by enhanced apoptosis of damaged cells accompanied by changes in parameters of dedifferentiation in colonic mucosa. Nakanishi et al. (2003) investigated the inhibitory effects of RS2 and *C. butyricum* strain MIYAIRI 588 (CBM588) on AOM-induced ACF formation in rats. Administering only CBM588 spores increased the concentration of butyrate in the cecum, but did not decrease in the number of ACF. Administering only RS2 or RS2 and CBM588 spores decreased the number of ACF. In these two groups, the concentrations of acetate and propionate in intestinal contents were significantly increased, but the concentration of butyrate did not change. However, the β-glucuronidase activity level of colonic contents was significantly decreased in the two groups of rats fed RS2. These results showed that RS and CBM588 changed metabolism of colonic microbiota and decreased the β-glucuronidase activity, which played a role in the inhibition of ACF formation in the rat colon. In summary, RS can help to prevent colon cancer, but the mechanism is complicated.

RS has been proved to be able to prevent or reduce inflammatory bowel diseases. For rats with colitis induced by trinitrobenzenesulphonate (TNBS), RS accelerated healing via prebiotic and butyrate effects (Jacobasch et al. 1999). Moreau et al. (2003) compared FOS and RS in healing colonic inflammation of dextran sulfate sodium (DSS)-induced colitis rat model and found that intake of RS significantly improved colon histopathology scores compared to control and FOS and also increased SCFA concentrations in cecal contents. Long-term intake of RS showed increased the butyrate content of pigs, reduced damage to colonocytes, improved mucosal integrity, and reduced colonic and systemic immune reactivity, which suggested that RS might help pigs to respond to intestinal inflammation better (Nofrarias et al. 2007).

In addition, long-term intake of RS diet increased crude protein and mucin contents and upregulated the expression of mucin genes MUC4, MUC5AC, and MUC12 in the colons of pigs, suggesting the potential of long-term intake of RS diets to improve colon health by increasing mucin secretion and reducing the harmful fermentation of protein (Zhou et al. 2017).

44.4.4 Reducing Postprandial Glycemic Response

Blood glucose concentration control after consuming a meal is primarily determined by the rate of appearance of glucose from the gastrointestinal tract and its clearance from the circulation (Robertson 2012). Many factors affect blood glucose concentration, but insulin is the most important one. Insulin controls the blood glucose concentration via a classical feedback loop. A rise of blood glucose concentration stimulates the secretion of insulin from β cells of the pancreas, and the resulting insulin stimulates muscle and adipose tissue to increase glucose uptake, thus declining blood glucose concentration. Insulin secretion indicates the ability of a rise in plasma glucose to stimulate insulin secretion, and insulin sensitivity indicates the ability of insulin to stimulate glucose uptake from the blood. Normally, insulin secretion maintains blood glucose concentration within a narrow range. However, insulin resistance, defects in insulin secretion, or both impair both fasting and postprandial glucose regulation of individuals, leading to a rise in the blood glucose concentration. As a result, diabetes may occur. Diabetes has serious complications, including heart disease, kidney disease, eye disease, cerebrovascular disease, and nerve damage. Reducing blood glucose levels can prevent and delay the onset of these complications or reduce the severity for patients with diabetes. It is also known that reducing postprandial glycemic response is beneficial to prevent type 2 diabetes for people with high blood glucose concentration or obesity. Consequently, reducing postprandial glycemic response is important for people with high blood glucose, particularly patients with diabetes and prediabetes.

The ability of RS to decrease blood glucose was confirmed in normal rice model. Male Wistar rats were divided into four groups and fed wheat bread, RS-wheat bread, maize bread, and RS-maize bread (Brites et al. 2011). It was found that the RS-wheat bread group significantly reduced feed intake, fecal pH, postprandial

blood glucose response, and total cholesterol. The RS-maize group significantly reduced body weight gain, fecal pH, and total cholesterol levels; but only a reduction in fasting level was observed in the glycemic response. These results confirmed the effect of RS on glycemic response and suggested that the magnitude of the effect of RS on glycemic response depended on other components of diets. Diabetes rice model was also used to confirm the hypoglycemic effect of RS. In a study, RS2 (Hi-maize starch containing 60% amylose) improved glucose tolerance and reduced body fat in the Goto-Kakizaki rat, a nonobese model of type 2 diabetes (Shen et al. 2011). Specifically, feeding RS greatly improved pancreatic β-cell mass, insulin sensitivity, pancreatic insulin content, total GLP-1 (glucagon-like peptide-1) levels, cecal SCFA concentrations, and butyrate-producing bacteria in cecal contents. In another study, the hypoglycemic effect of low, medium, and high doses of RS2 (Hi-maize 260;100, 150, and 200 g/kg) for 28 days was evaluated, and the potential mechanism of this effect was explored in type 2 diabetic rats treated with high-glucose/high-fat diet and low-dose streptozotocin (STZ) (Sun et al. 2018). Feeding RS induced better regulation of oral glucose tolerance test, insulin, glucose metabolism, lipid in plasma and liver, fructosamine, and pancreatic damage in diabetic rats. Interestingly, the medium-dose RS treatment had the best hypoglycemic activity. These results suggested that RS regulated the blood glucose levels of diabetic rats through altering the expression levels of the genes related to glucose metabolism and ameliorating pancreatic dysfunction.

In addition, studies have been done on the effect of different RS sources on blood glucose in humans. For instance, when patients with impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or newly diagnosed type 2 diabetes ($n = 90$) were randomly assigned to either a group ingesting rice containing 6.51 g RS daily or a control rice group for 4 weeks, the diet containing rice with RS reduced fasting insulin and insulin resistance, postprandial glucose and insulin levels at 30 min, and glucose and insulin areas under the response curve after the standard meal (Kwak et al. 2012). In another study, the test was conducted in 20 subjects (9 men and 11 women with a mean age of 50.5 years) using the crossover method, with a single ingestion of either bread containing RS3 (tapioca maltodextrins were debranched and then retrograded) or the placebo (Yamada et al. 2014). Postprandial increases in blood glucose and blood insulin were significantly decreased in subjects with the blood glucose level before ingestion $\geq$111 mg/dl who took the test food compared with the placebo group. Recently, Mah et al. (2018) designed one experiment in which 21 healthy adults consumed a baked breakfast bar containing tapioca-based RS4 (Actistar 75330; Cargill, Inc.) or a macronutrient-matched control bar and found that compared with the control food, consumption of the RS4 food decreased the incremental area under the curves from 0 to 120 min ($iAUC_{0–120\ min}$) for postprandial capillary glucose and $iAUC_{0–120\ min}$ of insulin by 22% and 37%, respectively. Similarly, it was found that adding a practical dose of RS4 (RSVERSAFIBE™ 2470) in muffin significantly reduced postprandial glucose and insulin responses in healthy adults, which was reflected by reduction in $iAUC_{0–120\ min}$ of glucose, maximum glucose concentration, and $iAUC_{0–120\ min}$ of insulin (Stewart and Zimmer 2018).

In summary, RS consumption has been proved to be able to improve glycemic control in both animal and human studies. Blood glucose level is affected by several factors, including absorption, clearance, and release from internal organs (Wong and Louie 2017). Due to escaping digestion of small intestine, RS absolutely lowers glycaemia when it replaces the available carbohydrate portion of a meal. This effect is reflected by the glycemic index (GI), which indicates glycemic response of different food items upon consumption. RS does not induce indicates glycemic response and belongs to low-GI food. Importantly, RS is able to decrease postprandial glycemic response when the available carbohydrate portion of the diet is not reduced, which suggests RS decreases postprandial glycemic response by other mechanisms. The mechanisms behind are complicated. Particularly, RS is able to improve insulin sensitivity and β-cell function (insulin secretion). Improvements in muscular and hepatic glucose handling may be another mechanism. For instance, it was found that the RS-treated mice expressed more G-protein coupled receptors (GPR) 41 and 43 than with normal rice-treated mice (Yuan et al. 2017a). The GPR 41 and GPR 43, which are SCFA receptors, have been found to lead to an increase in glucose uptake and glycogen storage at muscle tissues (Canfora et al. 2015). In addition, acetate was reported to reduce hyperglycemia in diabetic KK-A(y) mice through activating 5′-AMP-activated protein kinase (AMPK) in the liver, since AMPK played an important role in activating glucose and fatty acid uptake and oxidation (Sakakibara et al. 2006). Another possible mechanism where RS consumption may influence on blood glucose control is that RS upregulates gut hormones, including GLP-1 and peptide YY (PYY) (Zhou et al. 2008; Shen et al. 2011). These two hormones are naturally secreted in response to meal ingestion, but they are rapidly degraded after endogenous secretion or exogenous injection (Zhou et al. 2008). GLP-1, a potent incretin by the enteroendocrine L cells of the distal intestine, is shown to possess multiple effects on glucose metabolism, such as promoting pancreatic β-cell mass, stimulating glucose-dependent insulin secretion, and inhibiting glucagon secretion (Shen et al. 2011). PYY, a 36-amino-acid peptide hormone that is cosecreted from intestinal L cells with GLP-1, is initially found to inhibit appetite, thus lowering energy intake (Manning and Batterham 2014).

44.4.4.1 Inhibition of Fat Accumulation

RS, as one kind of the dietary fiber, was able to lower plasma cholesterol and triglyceride concentrations and reduce fat storage (Higgins 2004; Nugent 2005). Total cholesterol, low-density and very low-density lipoprotein cholesterol, and triglycerides were significantly lowered in serum of hamsters fed on the diet containing extruded cassava starch and RS by 17.87%, 62.92%, and 9.17%, respectively, as compared with the diet of cassava starch without added RS (Martinez-Flores et al. 2004). In another study, the effects of RS and cellulose on blood and liver lipids in hamster were compared, and it was observed that RS and cellulose decreased serum cholesterol level by 16.2% and 13.5%, respectively (Ranhotra et al. 1996a). Recently, the effects of RS on postprandial increases in blood triglyceride levels were investigated in rats using oral fat tolerance/loading tests (Matsuda et al. 2016). After administration of lipid meals, feeding RS evidently declined increases

in serum triglycerides levels of rats. In addition, rats fed corn oil containing 500 mg/mL RS has much greater fecal lipid volumes and wet weights following lipid meals than rats fed only corn oil, which confirmed that fat absorption was inhibited by RS. The RS type also affected its anti-obesity effect. For instance, mice fed the RS4 diet had lower body weight and visceral fat weight than those fed either the unmodified starch or RS2 diet, when male C57BL/6 J mice were fed on a high-fat diet containing unmodified starch, hydroxypropylated distarch phosphate (RS4) or RS2 (high-amylose starch) for 24 weeks (Shimotoyodome et al. 2010). In addition, mice fed the RS4 diet had a higher hepatic fatty acid oxidation capacity and related gene expression and lower blood insulin than the other two groups. When given with fat (trioleate) by gavage, dietary supplementation with RS4 stimulated a lower postprandial glucose-dependent insulinotropic polypeptide (GIP; incretin) response than RS2. The GIP could decrease fat utilization in high-fat diet-fed mice. These results suggested that RS4 attenuated high-fat diet-induced obesity more effectively than RS2, which may be due to lower postprandial GIP and increased fat catabolism in the liver.

As described above, the anti-obesity effect was usually accompanied by the hypoglycemic effect. Several reports have suggested that these effects are partially ascribed to increased SCFAs production in the bowel (Sakakibara et al. 2006; Yamashita et al. 2014; Gao et al. 2009; Arora et al. 2011; Lin et al. 2012). When acetate was orally injected to obesity-linked type 2 diabetic Otsuka Long-Evans Tokushima fatty rats at the dose of 5.2 mg/kg BW, acetate markedly reduced in lipid accumulation in the adipose tissue, protected against accumulation of fat in the liver, and improved glucose tolerance (Yamashita et al. 2014). In another study, supplementation of butyrate enhanced adaptive thermogenesis and fatty acid oxidation, and there is an increased mitochondria function and biogenesis in the skeletal muscle and brown fat when butyrate was administrated in dietary obese C57BL/6 J mice through diet supplementation at 5% w/w in the high-fat diet (Gao et al. 2009). Supplementation of butyrate prevented obesity in C57BL/6 J mice, while fasting blood glucose and insulin tolerance were observed in the mice fed on the high-fat diet. It had been shown that propionate inhibited hepatic cholesterol synthesis in humans and also played a role in regulating food intake in non-ruminants (Arora et al. 2011). In addition, a later study demonstrated that butyrate and propionate suppressed food intake, protected against high-fat diet-induced weight gain and glucose intolerance, and stimulated gut hormone secretion predominantly via free fatty acid receptors 3-independent mechanisms (Lin et al. 2012).

44.4.4.2 Reducing Inflammation and Oxidative Stress

Systemic inflammation and oxidative stress play an important role in the pathogenesis of cardiovascular diseases and complications of chronic kidney disease (Tayebi Khosroshahi et al. 2018). Therefore, it is important to reduce inflammation and oxidative stress. Yuan et al. (2017a) found that after diabetic mice were treated with normal rice, normal rice with RS, or normal rice with RS and Se for 4 weeks, supplementing with RS lowered levels of serum C-reactive protein (CRP), tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), nuclear factor-k-gene binding

(NF-κB), and leptin (LEP) and increased adiponutrin (ADPN) levels. In addition, Se and RS decreased CRP, IL-6, and NF-κB levels much more than RS. These results indicated that RS reduced inflammation and Se and RS might have synergistic effects on chronic inflammation. RS was also proved to reduce inflammation and oxidative stress in humans. For instance, it was found that 4-week dietary treatment with RS also reduced oxidative stress of patients with IFG, IGT, or newly diagnosed type 2 diabetes when this treatment reduced their blood glucose level (Kwak et al. 2012). In another study, 46 stable hemodialysis patients randomly consumed biscuits containing 20 g/day during the first 4 weeks and 25 g/day in the following 4 weeks of either RS2 or wheat flour (Tayebi Khosroshahi et al. 2018). RS2 significantly declined serum levels of TNF-a, IL-6, and malondialdehyde compared with the placebo. In addition, serum urea and creatinine concentrations were significantly decreased, and severity of constipation was improved in RS2-treated patients. These results suggested that administration of RS2 for 8 weeks significantly reduced levels of inflammatory and oxidative markers in hemodialysis patients. Similar results were obtained by Esgalhado et al. (2018). This study evaluated 31 hemodialysis patients assigned to either RS (16 g Hi-maize 260) or placebo (manioc flour) supplementation, which they received for 4 weeks on alternate days through cookies on dialysis days and powder in a sachet on non-dialysis days. It was found that the RS group had lower IL-6, thiobarbituric acid reactive substances plasma (TBARS), and indoxyl sulfate plasma levels, while no significant differences were observed in the placebo group. These reports confirmed that RS had the ability to reduce inflammation and oxidative stress.

44.4.4.3 Improving Mineral Absorption in Large Intestine

As mentioned above, SCFAs produced from fermentation of RS2 decreased the pH, which was beneficial to mineral absorption. Therefore, RS might improve mineral absorption, which was confirmed by several studies. For example, Lopez et al. (2000) investigated the effects of a natural source of phytic acid, wheat bran, in the presence or in the absence of RS on the assimilation of minerals (Ca, Mg, and P) and trace elements (Fe, Mn, Zn, and Cu) in rats adapted to semi-purified diets and found that absorption of Ca, Mg, and P in the cecal was 3.5-fold higher in the RS groups than in the control groups due to the hypertrophy of the cecal wall, low luminal pH, and improved concentrations of soluble minerals. Moreover, the apparent retention of all the above minerals was significantly enhanced by RS ingestion. The disappearance of phytic acid was twofold higher in rats fed the RS diet than those fed the control diet. Thus, it was concluded that the addition of RS into wheat bran diet allowed a greater mineral absorption by increasing the SCFA production and breaking down phytic acid in the large intestine. Likewise, Yonekura et al. (2003) found that RS2 restored Zn and Mg bioavailability suppressed by phytic acid in rats, which was due to that cecal fermentation of RS2 increased SCFA and succinate concentrations and reduced cecal pH. In another study, the effects of RS2 and RS3 on mineral absorption, including Ca, Mg, and Fe, were investigated (Zeng et al. 2017). Specifically, BALB/c male mice were fed five different diets: Diet 1 containing no RS; Diet 2, 3, and 4 containing 5, 10, or 15 g RS3/100 g diet; and

Diet 5 containing 15 g RS2/100 g diet. Data demonstrated that the apparent absorption of Ca was significantly greater in mice fed medium and high levels of RS3, as well as RS2, than in those fed the basal and the low-level RS3 diets. The mice fed high levels of RS3 displayed the greatest apparent absorption of Ca. Similar results were obtained when the effect of RS on Mg absorption was studied. In addition, mice fed on RS3 and RS2 exhibited greater apparent absorption of Fe, and the apparent absorption of Fe was enhanced as the RS3 dose increased. These results might be related to SCFAs by the intestinal microbial fermentation of RS. In addition, it was reported that bread with RS4 and garlic showed a prebiotic effect and increased Ca bioavailability and deposition in bones in male weaning Wistar rats, compared with wheat bread (Weisstaub et al. 2018). However, Schulz et al. (1993) found that apparent absorption of Ca and Mg in rats was improved by RS2 (uncooked high-amylose starch granules) but not by RS3 (cooked and cooled high-amylose starch). Compared with cooked normal starch, RS2 significantly lowered the ileal pH, while RS3 raised it. Cecal pH was lowered by the two kinds of RS. Ca concentrations in the liquid ileal contents were improved by RS2 but were significantly lowered by RS3 relative to control starch. Ma and Ca concentrations in liquid cecal contents were raised by RS2, but RS3 did not change them. These results suggested that RS3 might be not fermented in the ileum since the pH was not decreased. Thus, it was inferred that RS3 might be fermented at a very slow rate, resulting in no increase in Ca and Mg absorption. To summarize, consumption of RS may improve mineral absorption in large intestine. However, this effect may be removed once it is fermented too slowly.

44.5 Function in Human (Human Studies)

The function in human of starch mainly results from metabolism of glucose digested from starch. Glucose, an essential nutrient of living organisms, not only provides the potential energy but also acts as a precursor for metabolic intermediates in biosynthetic pathways (Miao et al. 2015a). Humans require a reliable source of glycemic carbohydrate to support the normal functions of our brain, red blood cells, muscles, kidney medulla, and reproductive tissues. Here, we summarized the function in humans of starch from mental and physical performance like Hendrich (2018).

44.5.1 Function in Mental Performance

Glucose is the main energy source for brain of humans, although brain has the ability to utilize other fuel molecules, such as ketone bodies (Nirmalan and Nirmalan 2017). The adult human brain accounts for only around 2% of body mass but around 20% of whole body resting energy expenditure (Wang et al. 2014; Mergenthaler et al. 2013). Thus, the brain is the main consumer of glucose, approximately consuming 5.6 mg glucose per 100 g human brain tissue per minute. In human newborns, the brain weighs approximately 11% of body weight but consumes >50% of energy (Wang

et al. 2014). Up to the age of 3, when the brain size rapidly increases, it is recommended that at least one-third of dietary energy should be supplied from carbohydrates (Bier et al. 1997). Neuronal computation and information processing, such as the generation of action potentials and postsynaptic potentials generated after synaptic events, consume the largest proportion of energy in the brain (Harris et al. 2012). In addition to providing primary energy of the brain, glucose metabolism plays an important role in physiological brain function through the foundation of neuronal and non-neuronal cellular maintenance and generating neurotransmitters (Mergenthaler et al. 2013). For instance, it seems that astrocytic glycogen is very important for learning, since glycogen selectively supplies carbon and supports de novo synthesis of transmitter glutamate by combined pyruvate dehydrogenation and carboxylation in astrocytes (Hertz and Gibbs 2009). Furthermore, breakdown of astrocytic glycogen and release of lactate from glycolysis are essential for forming long-term memory and for maintaining the long-term potentiation of synaptic strength elicited in vivo (Suzuki et al. 2011). Thus, the brain increases consumption of glucose upon activation (Sokoloff 1999).

In contrast to other tissues, the brain of humans at birth is very immature and undergoes substantial quantitative and qualitative changes during postnatal development, which need substance foundation and energy. Therefore, it seems that glucose metabolism is important for human brain evolution. In addition, abnormal glucose metabolism declines cognition. A meta-analysis of several hundred children with type 1 diabetes (T1D) showed that individuals with T1D had lower scores at overall IQ, executive function, and motor speed than control children without T1D (Tonoli et al. 2014). The same cognitive impairments were seen in adults with T1D, and memory of these adults was also impaired compared with control adults without T1D. In addition, it seemed that the longer the duration of T1D, the more cognition may be impaired. On the other hand, glucose-enhanced cognitive performance is consistently observed in populations who usually have poorer memories and glucose regulation, such as healthy elderly subjects and patients with Alzheimer's disease (Greenwood 2003). This result suggests that glucose can reverse or mask the memory deficits observed in those with poor gluco-regulatory status and/or underlying memory deficits (Greenwood 2003).

44.5.2 Function in Physical Performance

Physical activity requires energy for muscle contraction. As stated above, free glucose from muscle glycogen is not released into the circulation, which indicates that glucose is of great importance as a muscle fuel. Particularly, anaerobic metabolism of glucose can rapidly provide energy during very high-intensity physical activity such as a sprint. It is generally recognized that a decrease in carbohydrate availability can result in fatigue during prolonged exercise in humans (El-Sayed et al. 1997). During prolonged exercise, blood glucose and muscular glycogen are the two major sources of carbohydrate utilization by the active muscles. During exercise, the energy from blood sugar is limited for normal humans. Therefore, long-

term exercise performance may mainly depend on the muscle glycogen stores (Hendrich 2018). It has been shown that administration of glucose or other carbohydrates before or during exercise postpones fatigue, conserves muscle glycogen, and improves performance. Thus, replenishing enough muscle glycogen stores is the main concern for athletes who need extreme endurance.

Particularly, effects of starches on exercise of people with diabetes have been studied. A previous study compared metabolic responses and fuel use of participants with T1D during sub-maximal and high-intensity performance running following pre-exercise ingestion of 0.6 g/kg body mass waxy barley starch or dextrose (Gray et al. 2015). Interestingly, T1D individuals consuming waxy barley starch had a greater carbohydrate oxidation rate at rest and displayed an improved performance at the latter stages of a high-intensity run test, although waxy barley starch and dextrose led to similar hyperglycemic responses. In another study, people with type 2 diabetes (T2D) were fed on a vegetarian diet with 60% carbohydrate or a conventional diet with 50% carbohydrate for 12 weeks at 500 kcal restriction of daily energy requirement and had personalized daily exercise (Veleba et al. 2016). It was observed that the vegetarian diet improved fitness while the conventional diet did not. This suggests that a vegetarian diet higher in complex carbohydrates might benefit people with T2D, as improved physical fitness may help people persist with increased physical activity. Therefore, much work is required to determine what starch types optimize exercise performance for different people and the underlying mechanisms.

44.6 Safety

According to the long-term eating habits of humans, native starches are generally safe and well tolerated. They have little chance for adverse effects except those effects associated with long-term overconsumption (Hendrich 2018). The dose makes the poison, which is a central tenet of toxicology. Therefore, even glucose, the digestion product of safe starches, may be toxic to humans. As stated above, normal people can decline the postprandial blood glucose to the normal level. But some people suffer from hyperglycemia. Therefore, glucose toxicity occurs, and it usually refers to damaging effects of high blood glucose concentrations on body tissues and regulatory processes through several mechanisms (Brownlee 2005). First, the mechanisms involve the polyol pathway, particularly aldose reductase. Normally, aldose reductase reduces toxic aldehydes in the cell to inactive alcohols. However, when the glucose concentration in the cell becomes too high, aldose reductase also reduces glucose to sorbitol. During this process, NADPH is consumed as the cofactor of aldose reductase. But NADPH is also the essential cofactor for regenerating reduced glutathione. Due to the decreasing amount of reduced glutathione, the polyol pathway increases susceptibility to intracellular oxidative stress. Secondly, glucose can interact with free amines in body proteins and form advanced glycation end products (AGEs). AGEs can directly induce cross-linking of long-lived proteins such as collagen (Goh and Cooper 2008). Thus, vascular stiffness is promoted. In addition, AGEs can enhance oxidative stress and elaborate key

proinflammatory and prosclerotic cytokines via interaction with certain receptors (Wautier et al. 2017; Goh and Cooper 2008). Thirdly, the mechanisms involve the protein kinase C (PKC) pathway. In this pathway, hyperglycemia inside the cell increases the synthesis of diacylglycerol, which is a critical activating cofactor for the classic isoforms of protein kinase C, β, δ, and α. Once PKC is activated by intracellular hyperglycemia. It has a variety of effects on gene expression. The pathological effects that may result from activation of PKC include blood flow abnormalities, vascular permeability angiogenesis, capillary occlusion, vascular occlusion, proinflammatory gene expression, etc. Fourthly, some of fructose-6-P resulting from glucose gets diverted into a signaling pathway in which GFAT (glutamine:fructose-6-P amidotransferase) converts the fructose-6-P to glucosamine-6-P and finally to UDP (uridine diphosphate) *N*-acetylglucosamine. Subsequently, the *N*-acetylglucosamine is transferred onto serine and threonine residues of transcription factors, and overmodification by this glucosamine often results in pathologic changes in gene expression. A unified mechanism is that hyperglycemia increases superoxide production and oxidative stress. Therefore, rapidly digestible dietary starches may contribute to such pathologies for those who suffer from hyperglycemia.

Many chemically modified starches made for food use are safe because these modified starches are allowed to contain only small amounts of substituent groups (Singh et al. 2007). When starch octenyl succinates are produced for application in foods, the amount of OSA is limited to 3% based on the dry starch weight (the degree of substitution <0.0231) (Altuna et al. 2018). The maximum permitted amount of substitution groups for starch phosphates, starch acetates, and hydroxypropylated starches are 0.4%, 2.5%, and 10%, respectively (Chen et al. 2018). Similarly, cross-linked food starches are allowed to contain one substituent cross-linking group per 1000 or more anhydroglucose (Singh et al. 2007).

44.7 Products in Market

A vast range of native starches are already at the market, including maize starch, cassava starch, potato starch, wheat starch, rice starch, waxy starches, etc. Physicochemical properties of starches from different sources differ significantly. Worldwide, maize (82%), wheat (8%), potatoes (5%), and cassava (5%) are the main sources of starch (Corre et al. 2010). In the food industry, modified starches mainly include pregelatinized starch, maltodextrin, oxidized starch, hydroxypropyl starch, starch octenyl succinate, starch acetate, starch phosphates, and cross-linked starch.

In addition to natural food sources of RS stated above, increasing commercially manufactured forms of RS are available. Commercial sources of RS2, amylomaize VII (Cerestar Inc., Hammond, IN, USA), Hi-maize 260 (National Starch & Chemical Co, Bridgewater, N.J., USA), and Hylon VII (National Starch & Chemical Co, Bridgewater, NJ) are now available (Ranhotra et al. 1996b; Martínez et al. 2010; Hylla et al. 1998). CrystaLean (Opta Food Ingredients, Inc.), NOVELOSE 330® (National Starch & Chemical Co), Hi-maize 330 (National Starch & Chemical Co),

and Promitor Resistant Starch 60 (Tate & Lyle) are examples of commercially developed RS3 which are derived from high-amylose maize starch (Nugent 2005; Maningat and Seib 2013). To promote formation of RS3, the starch was first hydrolyzed by a debranching enzyme to increase the amount of linear chains, followed by crystallization of the linear chains to (Maningat and Seib 2013). One commercially available example of RS3 produced in this way is Actistar™ (Cargill Inc.), which is produced by debranching and crystallization of tapioca maltodextrin (US6043229) (Kettlitz et al. 2000). To further promote crystallization of starch, Tate & Lyle first treated starch with a glucanotransferase to elongate the external chains of amylopectin, followed by debranching and then crystallization of the linear chains to form RS3 (US7674897B2) (Norman et al. 2010). RS4 products are also commercially available. For example, Fibersym RW (MGP Ingredients, Atchison, Kansas, USA) is a phosphorylated cross-linked wheat starch (Woo and Seib 2002). Actistar 75330 is a phosphorylated RS4 derived from tapioca that is commercially available from Cargill, Inc. (Mah et al. 2018). VERSAFIBE™ 2470 is a newly developed RS4 by Ingredion Incorporated (Bridgewater, NJ) that is derived from high-amylose maize starch modified by acid hydrolysis and heat treatment (Stewart and Zimmer 2018). Dextrinization of starch can lead to the formation of potentially indigestible linkages. Thus, dextrinization is used by several companies to create indigestible dietary fiber ingredients that can be classified as RS4 (Maningat and Seib 2013). Nutriose® soluble fibers are food dextrins derived from wheat or maize starch (US5620871) (Caboche 1997), which are marketed by Roquette (Roquette Frères). Fibersol 2 is a resistant maltodextrin reported in the USA patent (US5358729) (Ohkuma et al. 1995) and is produced by dextrinization of starch followed by heating at 120 to 200 °C. This RS is produced and marketed by a joint venture between Archer Daniels Midland Company and Matsutani (Matsutani LLC). Tate & Lyle's Promitor™ Soluble Corn Fiber ingredients are characterized by a higher concentration of nonlinear saccharide oligomers, which result from treating starch by cooking, hydrolysis, enzyme depolymerization, fractionation, isomerization, etc. (US7608436) (Harrison et al. 2009).

44.8 Perspective

Glucose is an important fuel for humans, particularly brain, muscles, red cells, etc., and starches in human diets are the main providers of glucose. According to the previous results, dietary starch plays an important role in development of the human brain, and tightly regulating blood glucose may be better for cognition. Therefore, it is meaningful to discover, design, and further develop diets and starches that benefit brain development and cognition. Therefore, recommendations for human dietary patterns must include the dietary starch content and type (Hendrich 2018). In addition, there is an additional opportunity to design starches that benefit exercise performance. In summary, starch deserves more attention as a foundation of a healthy diet for cognitively sound and physically active humans (Hendrich 2018). That is, starch ingestion must be optimized and individualized to meet special needs of humans.

On the other hand, effects of RS on gut microbiota and effects of microbiota on RS metabolism are still the focus of scientists. It is possible that different forms of RS are accessible by different groups of colonic microorganisms. Thus, different types of RS may promote different groups of colonic bacteria. This could result in selective effects of RS intake upon the species composition of the colonic microbiota, as well as differential effects on gut metabolism. It highlights the need to consider both primary degraders of RS and specific more-downstream-acting bacterial groups in order to achieve desired intervention outcomes. The gained insights will assist the design of personalized treatment strategies based on an individual's microbiota (Vital et al. 2018). To better interpret the relationship between gut microbiota and RS, new techniques are required to analyze gut microbiota. In addition, new and advanced analytical methods for RS are required, because the analysis of RS still greatly depends on methods developed earlier for dietary fiber (Birt et al. 2013). On the other hand, the previous studies suggest that RS structure determines its rate and site of fermentation in the large intestine. The characteristics of dietary starch, including particle structure, crystallinity, branching, association with other polymers, retrogradation, and modification, are known to affect its digestibility in the small intestine (Miao et al. 2015a, 2018). It is inferred that these characteristics may also affect the rate at which RS is fermented in the colon. Rapid fermentation of RS may lead to complete fermentation in the proximal colon, whereas slower rates support fermentation in more distal regions, with the possibility of incomplete colonic fermentation overall. Fermentation kinetics, combined with information about the transit time, can give an indication about where ingredients are fermented and could therefore be used to select RS sources eliciting fermentation in specific places of the guts. Therefore, it seems possible to control the fermentation rate and site. Accordingly, different RS types in diets may provide enough substrates generating SCFAs in the more distal parts of the colon with more possible reduction in protein fermentation. Recently, imbalances in human gut microbiota are considered to be related to various noncommunicable diseases, such as colon cancer, type 2 diabetes, and obesity. Thus, RS have the potential to prevent these diseases, since RS can modulate gut microbiota. However, considerable research is required to identify the potential effectiveness of RS in preventing or even cure human diseases. Particularly, despite the tremendous diversity of RS in plants and commercial RS products, very few of them have been studied. In conclusion, future integrative research is needed to expand the potential uses of RS in health promotion of humans.
