# Preface

Diabetes mellitus (DM) is a chronic disorder (an excess of glucose levels in blood) because insulin is no longer produced in the pancreas (type I DM) or the body is unable to utilize produced insulin in the body properly (type II DM). DM is the world's most endemic and mortality causing disease affecting more than 6% of the adult population. The growth rate of DM patients has been increasing rapidly due to different factors such as genetic, environmental, lifestyle, increased calorie intake, and less body exercise. But the development of medication is not as much as the growth rate of DM and its complications. Type I DM has no preventive medicine, but type II can be prevented and controlled by maintaining a healthy lifestyle. However, their complications can be delayed by taking insulin therapy.

The complications of DM have more impact on different metabolisms in the body and are not specific to any particular disease, because insulin is the principal hormone responsible for the uptake of glucose from blood to different cells of the body. DM mainly damages the blood vessels and leads to the preliminary complications in the eyes, kidneys, and nerves. All these complications are interlinked to each other because glucose is the principal fuel for cellular functions. The damage of nerves due to DM is known as diabetic neuropathy (DN); its main symptoms are numbness and tingling that lead to skin damage.

Skin damage due to DM is because of peripheral arterial damage, i.e., lower blood circulation. Diabetic foot ulceration/diabetic foot ulcer (DFU) is one of the foremost DM complications associated with it and sometimes may cause amputation.

The availability of information on DFU prevalence, major symptoms, pathogenesis, complications, treatments, and management was very less. This book provides updated knowledge on the prevalence of DFU around different parts of the world, its development, pathophysiology, major complications, and new methodologies in its treatment. The editors sincerely acknowledge the efforts of authors in manifesting their perspectives about DFU.

*Shamina Begum* et al. describe the occurrence of DM, its complications, and the current scenario about prevalence, risk factors, and different strategies and policies to control DFU around Asia and European continents.

*Zulfiqarali G. Abbas* explains the common causes of DFU, in relation to peripheral neuropathy, and analyzes over the last two decades conditions of DFU complications and prevention and control programs in Africa and Antarctica.

*Kanakamani Jeyaraman* presents the implications of DFU in relation to clinical, social, and economic problems because of endemic type II DM and the annual outlay on DM and its complications including DFU in American and Australian continents.

*Ayman Faisal Foad* explains the pathophysiology of wound healing with respect to different control factors and importance of proteins and vitamin C in wound healing.

*Hyder O. Mirghani* describes the different approaches for image (scanning) models to differentiate harm at various tissue levels for providing the remedial approaches to different foot inflammation including DFU due to DM.

*Mohammad Zubair and Farha Fatima* demonstrates the various complications due to DM, mainly focused on development of DFU, and explains the risk factors for DFU development and approaches for timely diagnosis to overcome complications of DFU.

*Ahmad Faraz* et al. explain the major healthcare challenges in the twenty-first century and how DM and its complications impact the mortality rate around the globe and also elucidate the association of diabetic neuropathy with the diabetic foot abnormalities.

*Tarek Kabil* describes the association of inflammation wounds with different microbes (aerobic and anaerobic) and their involvement in DFU and its complications.

*Fohad Mabood Husain* et al. illustrate the DFU and DN contribution for the development of different pathogenic microorganisms at infectious sites and how these microbial infections lead to tissue and bone injury.

*M. Oves* et al. illustrate the hidden role of fungus in infection management.

*Thomas Thanyath* demonstrates the risk factors for DFU, and evaluation of DFU at appropriate stages in different diabetic patients using various identification methods.

*Hamid Ashraf* et al. explain the management of different microbial infections associated with DFU using different antibiotics.

*Vijay Viswanathan and Sai Prathiba A.* explain the recent circumstances about the DFU and its treatments in the Indian subcontinent.

*Zulfiqarali G. Abbas* elucidates complications, its prevalence, and management strategies to control and prevent DFU in developing countries.

*Deepti Singh and Hifzur R. Siddique* discuss about the role of different growth factors, their usage in control and prevention, and future prospects in DFU management.

*Rashid Mir* et al. expound the current approaches in the control, prevention, and treatment of DFU and also explain the role of stem cell therapy in different wound healing infections including DFU management.

*M. Ahmed Mesaik* et al. explain the importance of alternative medicine (AM) against the rising of global DM patients and the management of AM in the DM and its complications including DFU and diabetic foot infections (DFIs).

*Mohamed Ali-Seyed and Ayesha Siddiqua* enlighten the role of phytomedicine (traditional medicine) and herbal formulations in the treatment of DM and

DFU. They also explain the possible mechanism of action of important medicinal plants against DM and their future scope in identification of different phytocompounds against DM, DFU, and other complications.

*Sumbul Rehman* explains the common complications including DFU due to prolonged high blood glucose levels and the management of bloodletting by leeching therapy using *Hirudo medicinalis.*

*Mohammad Azam Ansari* et al. describe the prevalence of DM and DFU complications and emphasize the delayed wound healing because of DFU, possibly employing nanotechnology in the management of DM and DFU treatment using nanoformulations.

# About the Editors

**Mohammad Zubair** is an Assistant Professor at the Department of Medical Microbiology, Faculty of Medicine, University of Tabuk, Kingdom of Saudi Arabia. He completed his PhD and post-doctorate research on diabetic foot infections and has extensive teaching and research experience in the field of medical science. His research focuses on the extended spectrum beta-lactamase gene (CTX, TEM & SHV), pro and anti-inflammatory cytokines, healing proteins and their clinical correlations. He has published more than 35 papers in international, peer-reviewed journals, and has presented his work at various international conferences. He is also the recipient of the prestigious "Marvil Levin" research awards presented by the American Diabetes Association (ADA) at the 72nd Scientific Session held at Philadelphia, USA.

**Jamal Ahmad** is a former Professor of Endocrinology; ex Dean of the Faculty of Medicine, J.N. Medical College; and ex Director of the Rajiv Gandhi Centre for Diabetes & Endocrinology, Faculty of Medicine, Aligarh Muslim University, India. He has made a significant contribution toward determining the role of protein glycation in diabetes and its associated complications. He has published more than 240 research articles in various international and national journals, was Principal Investigator or Co-Investigator in a number of research projects, and has completed 9 phase III international, multi-centre, multicounty new drug trials in diabetes mellitus. He is a former President of the Endocrine Society of India, and the recipient of the prestigious RSSDI fellowship-2015 and a Lifetime Achievement Award by Diabetes India 2019.

**Abida Malik** is a former Professor and Chairperson of the Department of Microbiology, and the former Dean of the Faculty of Medicine, Jawaharlal Nehru Medical College, Aligarh Muslim University. A leading Indian microbiologist, she has over 41 years of teaching and research experience and authored more that 185 publications. She established the Virology Lab in 1976, Mycology lab in 1980 and was founded and responsible for the AIDS Surveillance Centre for 20 years. She is the former president of the Indian Association of Microbiologists, and received the Dr U. C. Chaturvedi Life Time achievement Award for her services to microbiology in 2011.

**Mallikarjuna Rao Talluri** is currently a Research Associate at AXIS Clinicals Limited, Hyderabad, India, where his work focuses on development methods and the quantification of new drugs and their bioavailability and bioequivalence. He is an expert on the evaluation of the biological activities of natural products (bio-guided extraction), and scientific writing, and has experience in instrumental handling, such as LC-MS/MS, HPLC, column chromatography, and TLC. He has worked extensively in the field of phytopharmacology, and has published more than 50 papers in peer-reviewed, international and national journals.

# Diabetic Foot Complications in Asia and European Continents

1

Shamina Begum, Mohammad Zubair, Marai M. Alamri, Fohad Mabood Husain, Farha Fatima, Mohammad Oves, Mohammad Azam Ansari, and Iftekhar Hassan

## 1.1 Introduction

Diabetic Foot Ulcer (DFU) is a major global concern accounting for costly complications. Its prevalence is gaining momentum particularly in Asia and European Continents. The intent of this chapter is to provide an overview of diabetic foot ulcer both globally and regionally. It also provides insights on the social and economic burden along with the factors that cause it. Different ways of diagnosis of DFU are also described followed by the management strategy which can be implemented for achieving improved health outcomes. This chapter focuses on the regional wise

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_1

comparison of Asia and European Continents concerning the adequate treatment and prevention of DFU. As per the International Diabetes Federation [1], the annual estimation of the foot ulcer ranged from 9.1 million to 26.1 million people, globally. The diabetic proportion and the foot ulcer history are understandably higher as compared to the individual ratio of an active ulcer, i.e., 3.1–11.8%. This percentage accounts for the global population of about 12.9 million to 49 million [2]. The foot ulcer lifetime incidence is predicted to be 15–25% among diabetes. The complication of diabetic food includes Charcot neuroarthropathy (CN), amputation, and ulceration. The complications of the foot are substantially increasing, which is predicted to be more than 5% of the diabetic patients will have foot ulcer history, while the overall lifetime concerning the risk of foot ulceration might exceed 25%. Given that the overall amputation ratio is preceded by foot ulcers, it can be safely presumed that the success in the mitigation of the incidence concerning foot ulcers would reduce the occurrence of amputation.

### 1.1.1 Foot Ulceration Pathogenesis

The ulcer of the foot occurs rarely due to a single pathology, instead, its major occurrence is due to its interaction with either two or more contributory causes that cause a high-risk foot breakdown. For instance, the neuropathic foot ulceration does not lead to spontaneous ulceration. It occurs due to insensitivity combination including in either extrinsic (such as barefoot walking, step on the sharp object, and inadequate fit of the shoes) or intrinsic factors (such as insensitivity and callus among the patients, who walks and which leads to the ulcer development), leading to ulceration [3]. The most significant contributory cause in the ulceration pathway is neuropathy.

### 1.1.2 Neuropathy

For the past many years, the link between the autonomic and somatic neuropathy as well as foot ulceration has been identified. The prospective follow-up researches in the previous decades have confirmed the somatic neuropathy causative role. The risk is sevenfold among the patients that suffer from a loss in the sensory ability, leading to the development of the ulcer in the foot in contrast to the patients with non-neuropathic diabetes. The inadequate balance, as well as instability, are substantially recognized as the challenging peripheral neuropathy, which is presumably secondary for the proprioceptive loss [4].

The dysfunction of the peripheral autonomic (sympathetic) makes the skin dry along. It, in the peripheral vascular disease, results in a warm foot with distended dorsal foot veins. This increases the difficulties concerning the education of the patient given the recognized fact that each foot problem develops as a result of vascular disease. This makes it challenging for the patients to identify that their warm feet, which is pain-free are at an increasing unperceived trauma risk, which subsequently results in foot ulceration [5]. In case, the preventive programs concerning the

education of being planned, it is necessary to dedicate substantial attention to the effective and careful neuropathy development, leading to understandable terms.

Practically, the simple clinical examination can lead to easy documentation of the peripheral neuropathy for obtaining the neuropathy evidence. In it, the most significant process is to remove the socks and shoes of the patients and examine the feet closely. The tools, for instance, the neuropathy disability scorecard or the monofilament can be used to assists in the identification of the neuropathic foot [3] that can be used for the neuropathic evidence. Also, to identify the increased risk of the foot, there is no need to conduct comprehensive testing through a survey or using electrophysiology.

### 1.1.3 Peripheral Vascular Disease

The peripheral ischemia, which occurs from the disease of proximal arterial, is identified as a component that occurs in the pathway for the foot ulceration, accounts for the third in all patients [3]. Whereas, the details concerning the ischemic foot are that the feet are dry, red, as well as neuropathic. These characteristics further increase its susceptibility to its pressure resulting from the footwear type.

### 1.1.4 Other Risk Factors

The deformity of the foot, primarily the claw toes and the prominent metatarsal heads, which is a well-recognized ulceration risk factor. Likewise, the accumulation of the plantar callus is linked with the sevenfold risk increase in a cross-sectional study, while the patients' follow-up increase showed it occurrence for only callus sites for the neuropathic feet, leading to an infinite increase in the risk. The other risk factors concerning the complication of the diabetic feet include microvascular complications that increase the diabetes duration, plantar foot pressure, peripheral edema, as well as the foot ulcer history or the amputation [3].

The foot ulcer prevention for the identified risk factors is integral, in case, a decrease in the ulcer incidence is required. It is suggested that enhancement of the educational programs and provision of podiatric care on a regular basis can improve early diagnosis of the patients and helps provide the treatment at an initial level. Accordingly, different psychosocial factors are also identified to lead to ulceration incidence. The patient's behavior concerning the ulceration and its risk factors are not based on the risk abstraction definition, but on the risk, a perception held by the patients. Thereby, in case, the patient does not believe that the foot ulcer lies in the neuropathy path to amputation, there lie low prospects concerning following their educational device, leading to an increased risk of developing a foot ulcer. This necessitates introducing different interventions for ensuring adequate care as well as preventive measures. This includes a proper examination of the patient's feet and collecting information concerning neuropathy, vascular disease, deformities, edema, and more.

### 1.1.5 Ulceration Pathway

The ulceration pathway refers to the combination of one or two risk factors that lead to the development of the foot ulcer among the diabetic patients. Various studies have accounted for the commonest triad of components leading to the diabetic foot breakdown such as trauma (footwear), peripheral neuropathy (insensitivity), deformity (toes clawing, metatarsal head prominence), and more. Mechanical trauma (standing on the nail), as well as neuropathy or the thermal trauma (insensate feet of the patient who use a heating pack), are the common examples of the two-component pathway leading to the ulceration among the diabetic patients [6]. Another common example includes "corn cures" which refers to inadequate chemical use.

### 1.1.6 Sensory Loss Among the Patients

The neuropathy foot problems can only be reduced, when the clinicians give consideration to the fact that patients who have insensitive feet have lost their ulcer warning signs, such as pain, which requires the patient to make a visit to the doctor [6]. The sensitivity to the pain is integral for the patient to lead to various medical consultations, including the training and healthcare-oriented toward the deliverance of relief from the foot ulcer. Therefore, the training should be integrated for the clinicians to help assist in providing treatment to the patient with no pain sensation.

### 1.1.7 Charcot Neuroarthropathy

The occurrence of Charcot neuroarthropathy (CN) is reported for the patients who are at a loss concerning the sensation, autonomic dysfunction (i.e., increase in the blood flow as well as the dry skins) following by the trauma (unperceived by the patient) [6, 7]. The common risk factor indicated CN is the warm foot which has bounding pulses though there exists sensation loss. The patient presents with a swollen foot, unilateral warm, either with or without pain symptoms, as well as discomfort with proper circulation, is required to be assessed for Charcot neuroarthropathy. Its risk can be reduced with proper care and instigation of educational interventions.

## 1.2 Overview of the Diabetic Foot Ulcer (DFU)

Primarily, diabetic foot ulcer is identified as the most prevalent problem among the diabetic patients, with an annual incidence percentage of 2.2% on average [8]. Despite taking all the corrective measures for preventing the DFU, the occurrence of DFU can cause substantial complications in the form of infection, amputations, as well as death. Prompers [9] stated that the occurrence of infection among the diabetic foot ulcer is present among the 58% of the patients who present a new foot

ulcer. An earlier European study of Prompers [10] showed that about 5% of the diabetic patients had DFU, where a major amputation was required in 1 year. Another research on the European states presents that the mortality rates for the next 5 years concerning the diabetic foot ulcer, which is 45% high for the neuropathic ulcers, along with 55% high for the ischemic ulcers [8].

The predicted and actual percentage concerning the diabetic foot ulcer showed similar and at times worst statistics for various common tumor types, which include the breast, prostate, and colon [11–13]. The incidence of the diabetic foot ulcer is prevalent across the world, leading to severe economic consequences for not only patients but their families as well as the society at large. Boulton et al. [14] presented The Lancet article and wrote that the occurrence of the diabetic foot ulcer is probably of neuropathic origin. Since a major part of the occurred foot ulcer is the potential of neuropathic origin, these are extremely preventable for the developing regions, which frequently report the incidence of Type 2 diabetes for the next 20 years. Boulton et al. [14], in his paper, stated that "*Individuals that are at an increasing ulceration risk could be identified easily through the instigation of careful examination, education as well as the frequent follow-up.*" It is stated that the foot care problem continues to prevail for the former Soviet countries, though the development of the multidisciplinary foot clinic is becoming more commonplace. Figure 1.1 presents the pathway concerning the physical foot ulcers and the different factors associated with it.

Understanding the economic impact and burden of the diabetic foot ulcer, it is necessary to study the recurrence rates of foot ulcers. The present recurrent rates, as presented by Boulton et al. [14], are less than 50% subsequent to 3 years. This recurrence rate is substantial for the determination of the economic impact posed by the foot ulcer [15]. The cost associated with the diabetic foot disease does not only comprise of the immediate cost but also cost in the form of home care and ulcers (subsequently). For understanding the total resource required, a broader view should

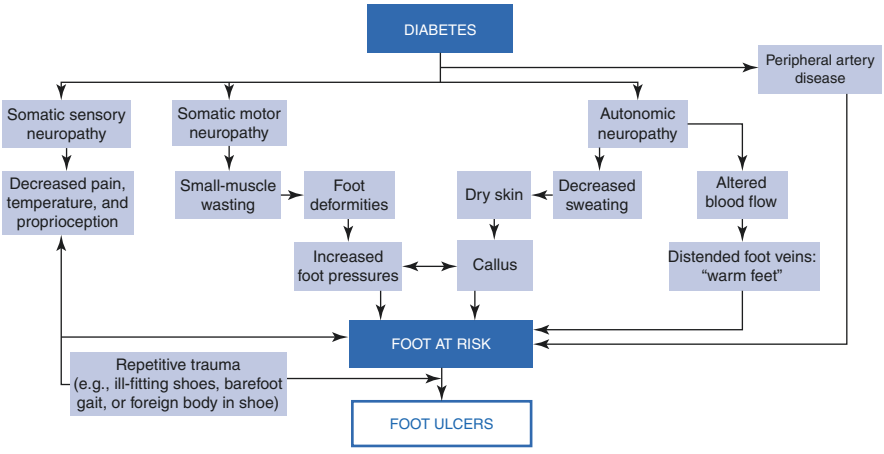

**Fig. 1.1** Pathways to diabetic foot ulceration [15]

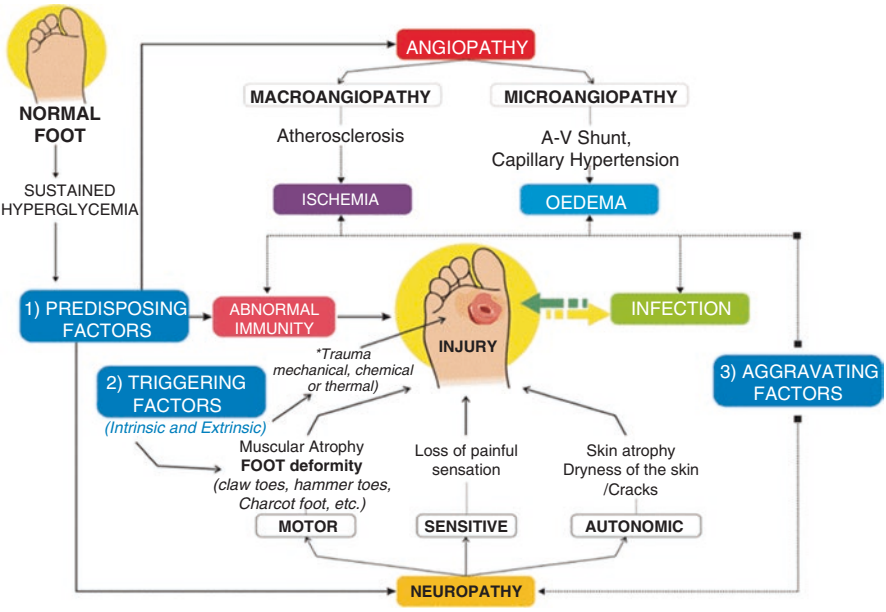

**Fig. 1.2 Diabetic foot ulcer common pathway for occurrence and recurrence**: *Risk factors and predisposing factors for the development of diabetic foot ulcers (DFUs). There are two main protagonists among the risk factors and/or predisposing factors of DFUs: angiopathy and neuropathy, whose presence, together with intrinsic (foot deformity) and/or extrinsic triggers, such as trauma (mechanical, chemical, or thermal), causes the loss of skin integrity. Aggravating factors, such as ischemia, abnormal immunity, and neuropathy, favor the development of DFU infections* [16]

be gathered comprising of the increasing quality of life and the ultimate outcome. This recurrence rate can be reduced through the instigation of the frequent screening as well as patient education which leads to a decrease in the expenditure and the screening healthcare costs. Figure 1.2 presents the overall procedure involved in the occurrence and reoccurrence of the diabetic foot ulcer. Majorly, the occurrence of the diabetic foot ulcer is based on the different factors that lead to the breakdown of the skin. The factors comprise of the sequelae related to sensory, autonomic, as well as motor neuropathies.

### 1.2.1 Diabetic Foot Ulcer (DFU) Burden in Asia

The data concerning the problems of diabetic foot ulcers in Asia are scarce. Such as the report of the International Working Group on the footcare clinics in China show that there are only five specialist foot care clinics in the region, where none offers podiatry services. The increase in the amputations remains a major and interesting area in the diabetic foot ulcer. Accordingly, another country such as India comprises of the more diabetic population as compared to other countries, where the

occurrence of amputations is quite frequent [14]. The most primary cause of foot ulceration is its late diagnosis and is generally associated with gross infection and neuropathy. Concerning a wide overview of the continent, diabetic foot problems are substantially scared. Other causes related to the increasing cost of diabetic patients is related to the barefoot gait, which is quite frequent, where the traditional healer or the elders in the village are contacted for help.

In contrast to the other Asian countries that have a link with the Europeans, a small degree of inclination is observed for education and training. For instance, the Netherland team comprising the podiatrist's teams, surgeons, and diabetologists help deliver information as well as care concerning the diabetic foot ulcer patients in Jakarta. Another study in Canada, which used the diabetes population risk tool showed that diabetes development is at a higher risk in South Asia as compared to any other region. Another research further showed that the diabetic disease rate of prevalence for the South Asian patients is predicted to be four times high as compared to any other ethnic group [17]. Similarly, across the globe, the number of patients with diabetes is estimated to have escalated from 171 million in the year 2000 to 366 million until the year 2030 [18]. These figures are further expected to increase by 2030, which for India is expected to be 46 million, for Pakistan it is 14 million, whereas, for Bangladesh, it is 11.1 million [19].

### 1.2.2 Diabetic Foot Ulcer (DFU) Burden in European Continents

Despite the implementation of various international guidelines for the prevention of diabetic foot ulcers along with the establishment of the substantial multidisciplinary foot clinics, the disparity in clinical care is evident [4]. For instance, there are only a few countries in East Europe which have foot clinics or podiatry services. Also, in the UK, a community-based study showed that its patients that are at risk of ulceration are predicted to be further diagnosed as a result of a simple clinical test, which includes screening strategies implication for the developing countries. In the Soviet countries, difficulties related to the care are also present, although the multidisciplinary foot clinic is further becoming a common part of the large cities across different European countries. Boulton et al. [14] have reported that the provision of the best foot care is available at the Baltic state.

The provision of adequate care for the European countries is also integral given the increasing cases of diabetes with about 55 million people, where the risk of developing diabetic ulcers prevails in about eight million people. The burden of the diabetic ulcer on the European countries because of the unsuccessful DFU treatment which causes about 450,000 lower limb amputations that account for health authorities' costs of about EUR 2–2.5 billion [20]. The diabetic foot ulcer management is substantially costly for the countries. For instance, Marion Kerr carried out a detailed investigation concerning the care cost associated with the foot complication in diabetic patients. The report findings stated that diabetic patients with low risk of ulcers require the regular change in the dressing as well as visits to the orthotics, podiatry, as well as the hospital in case the condition becomes worst. The

cost computed in England for managing such conditions is found to be £325 million. In case, the condition becomes worst, and patient's hospitalization is required then the annual cost is about £213 million, where the cost of amputation is more, which ultimately leads to the total cost of management to vary across £639 to £662 million in England.

Various collaborative studies in the European countries such as one from Manchester, Athens, Antwerp, and Rome have shown no substantial difference for the patients at the hospitals and diabetic clinics concerning the determination of the foot lesion risk factors including neuropathy prevalence as well as of the peripheral vascular disease [15]. These findings highlight that foot prevention similar strategies should be instigated for the delivery of effective care across the European countries. Likewise, another research on the three districts of the UK supported that active foot ulcer is found among type 2 diabetic patients along with 5% of the population that have had an ulcer. Another research on the large community-based report endorsed that incidence rate concerning the foot ulcer is 2% on an annual basis, which is comparable to the primary care delivery of the foot ulcer in the Netherlands. A significant finding of the community study is that the simple tests help identify the ulceration risk, where the modified neuropathy disability score, i.e., a dichotomous variable composite score, is the best for prediction of the ulcer risk.

Concerning the ethnic minority in the region, the data is found to be interesting. For instance, the risks for the diabetic foot ulcer among the Asian and African Caribbean's is much lower as compared to the other minorities [15]. The findings in France also report an increase for the diabetic foot ulcer, where the clinic in Paris reported the inpatient's stays of the patients decline following the multidisciplinary foot care team establishment. The difference in the amputation rates is observed to vary across Europe, which generally shows a reduction in the success of the amputation rates. Despite the unchanged increase in Germany, the diabetic foot ulcer reports provide an optimistic result for the Netherland as well as Italy. This amputation reduction might be associated with the International Consensus implementation consequences for the diabetic foot in Tuscany. The podiatry service increase might also be linked to the amputation reduction in the Netherlands.

## 1.3 Factors for Diabetic Foot Diseases in Asia and European Continents

### 1.3.1 Poverty and Hygiene

Another factor that leads to the occurrence of diabetic foot ulcer is poverty. Most studies reported that the link of poverty with the unhygienic conditions lead to infectious sequelae. The other primary factors include the occurrence of diabetic foot ulcers which comprise walking barefoot or late diagnosis of the diabetic foot for initial clinical assessment. For the developing countries such as Asia, the difference in urban–rural life continues to prevail, where the Western lifestyle is being deployed along with the change in the behavior concerning the rural conditions.

Such as reflecting on the Asian countries, for instance, Sri Lanka, Nepal, India, Samoa, Thailand, the Solomon Islands, and more, where more than 50% of the national population in the rural areas has diabetes [21]. Accordingly, recent statistics, for instance, in India and China [22–24] the prevalence of diabetes is found to be greater for the rural area as compared to the urban area. Another research concerning the Hwang et al. [25] through its multiple surveys has shown that the diabetes prevalence was fivefold more from 1985 to 2010, among the developing countries' rural population [26].

Barefoot walking is a common practice across different rural areas in Asia. Such as in the rural areas, the outhouses are located at a substantially considerable distance at the dwelling places, leading to foot injuries due to walking barefoot. Similarly, the lack of hygiene leads to other factors which cause diabetic foot ulcer. For instance, these individuals have a lack of awareness concerning the risk factor or the preventive measures which can be achieved through a better education level. Precisely, in the rural areas of the region, foot injuries often occur due to the house rate and other rodents [14]. For the peripheral neuropathy diabetic patients, these injuries are often not noticed until the patient starts observing symptoms [27]. These patients then present such injuries to the clinics for foot care with the injury or ulcer that has been progressed to fulminating foot sepsis.

Another care that must be taken care of includes occlusive footwear, which causes sweating and can lead to the occurrence of the fungal infection [28], especially for tropical countries. Dorresteijn et al. [29] writes that to prevent foot ulcer occurrence, the individuals must wear the prescribed footwear which does not usually wear at home, where these individuals are more active. Messenger et al. [30] report that the mortality ratio for the low-income countries is substantially high with increased hospitalization ratio. Therefore, in order to reduce the occurrence ratio, it is integral that caregivers must provide the patients with the information necessary for meeting the adequate level of hygiene along with the proper procedure for ensuring its adequate care. One primary thing that the diabetic patients need to ensure, in the words of Boulton et al. [14], is:

*The two golden rules of prevention are regular foot inspection and not walking barefoot.*

### 1.3.2 Sociocultural Practices

Different sociocultural practices continue to affect the foot ulceration prevalence across different countries. For instance, the sociocultural practices, i.e., walking barefoot, religious practices, improper use of footwear, and inadequate knowledge concerning foot care can lead to an increase in the foot complications prevalence across Asia [31]. Other causes of the foot ulcer include stress, smell leading social isolation, as well as decreased mobility of the patients. Accordingly, the awareness concerning adequate foot care is also lacking among the Asian countries, with incomplete information of the foot care, including foot protection, and limited self-care practices. Various Asian studies have expressed that most of the patients do not

refer to healthcare due to fear and related healthcare factors. This includes the fear of contact with the healthcare nurses and professionals who are consulted for determining the glucose level in the blood, dressing of the wounds, and procedure for collecting the data. These fairs could be overcome through the provision of a better and organized diabetic clinic focused on providing adequate health education, availability of cheap drugs, as well as accessibility and opening hours [32].

Other sociocultural factors that serve as a risk include believes which the people hold, generally in the developing countries, toward illness and health. These beliefs are generally related to individual as well as nature-related factors infused together with the social factors, and few cases related to the supernatural factors. Whereas, in the European countries, the healthcare sectors were referred to when required. This indicates the stark difference among the population of the two regions [33, 34]. Studies suggest that the focus of the non-westerners is mainly on the social and supernatural spheres, where the first contact point includes family, friends, relatives, and traditional healers. Whereas, in comparison to the western countries, particularly Europeans, the focus is on the individual characteristics as well as nature, following the consultation with the profession [33, 34].

### 1.3.3 Ignorance

Lack of awareness of the diabetic foot ulcer refers to another factor for its occurrence. Particularly in the developing countries of Asia, various diabetic foot burden is observed, where the prevalence of other socioeconomic factors leads to its hindrance. This also includes the lack of integration of their foot care into their lives. Such as the finding of the earlier study showed that diabetic patients who do not practice foot care are at a 2.52% increased risk of developing foot ulcers as compared to those who do. Similar findings are observed across different countries in Asia, including Kenya, Ethiopia, Arbaminch, India, Mekele, and more [35, 36]. The self-care practice can also lead to a reduction in diabetic foot ulcer development because of the benefits it provides. This includes washing of the feet on the regular basis, following by the drying of feet appropriately, status evaluation of the foot on a regular basis, adequate circulation as well as proper management of the abnormality at an earlier age that can occur on the foot. Thereby, for the prevention of the diabetic patient foot ulcer, preventive measures, and proper care of the feet should be maintained.

### 1.3.4 Environment and Other Related Factors

There are various environments as well as other related risk factors that can lead to the development of foot ulcers among diabetic patients. Different factors are found to be associated with the increase in the ulceration risk, which are generally linked to the economic development in the region, along with urbanization [37]. Different

dietary patterns, individuals' sedentary behavior, as genetic background, epigenetic susceptibility, as well as obesity, are found to increase the prospects of foot complications among the diabetic patients. Concerning the history of the Asians and the studies conducted on them, it is found that the majority had undergone some sort of nutritional transition, increase in the refined carbohydrates consumption, animal fats, meats, as well as low intake of the dietary fibers as well as vegetables [38]. Similar practices are observed in terms of intake of the sugar-sweetened beverages in China as well as European countries, as provided by the recent statistics and behavior [39]. Various risk factors concerning the diet can be significantly related to Asians. For instance, the diet of the South Asians, substantially depends on the increased carbohydrate consumptions, along with saturated fats and Trans fats [40], which is substantially conducive to the development of the foot complications. For instance, early studies in China have shown that the people who consume the extensive amount of white rice have increased level of glycemic load, linked with the diabetes risks [40, 41]. The similar findings are noted for the diabetic care of the patients who consume white rice in India [41]. Despite rice being recognized as the staple food item for centuries, however, the shift is observed to occur among the traditional rice types (such as polished rice), which increase the glycemic excursion as compared to the offering of a traditional rice type. Conclusively, it is found that increased glycemic excursion exists for Asians as compared to other population groups.

Another factor identified includes physical inactivity. In many populations, the risk factor in T2DM is physical inactivity [42]. Specifically, in the occupational setting, the decline has been observed in physical activity because of increasing urbanization [43], along with the sedentary behavior, which has also risen. To prevent diabetes in large communal areas such as Asia and the Pacific, this research highlights the significance of encouraging physical activities and minimizes sedentary behavior. In this study, the researchers examined the multiethnic cohorts and observe the relationship between diabetes and adiposity, researchers comparing with Europids, Asian develop diabetes with lower BMI [22, 44]. In the Asian population, this is assumed to visceral adiposity [45]. As a result, lower BMI cutoffs in Asians are being used to describe obesity [46]. Central obesity is defined by the circumference of the lower waist [46, 47]. According to the two observational studies, there is an association between diabetes with increasing adiposity. This condition does not differ between Asian populations and Europid [48]. Thus, there is a traditional difference in the relationship between adiposity-diabetes is probably characterized as a chance for diabetes at each and every level of BMI (waist circumference) or diabetes with a lower level of BMI.

It is seen that diabetes risk in all ages of Asian populations is quite high. Studies highlighted other factors related to age or obesity that raised the awareness regarding diabetes in Asian Population. Many novel putative risk factors have appeared recently as a significant environmental determinant and behavioral for T2DM. Environmental risk due to toxic waste, other chemical, and sleep disturbance are also included. Many developing countries are suffering from pollution

issues, during adult life it has the potential to contribute to the diabetes epidemic or sometimes in utero exposure.

According to the observations made by Hales and Barker [49] on the association between the metabolic disturbance and risk of diabetes in adult age with the lower birth weight. The essential role of utero environments in physiology and customized developmental trajectory and this is highly appreciated, thereby modifying the obesity's risk, other chronic diseases, and T2DM in adult age [26]. Likewise, a hypothetical study designed for adulthood utero nutritional deprivation may predispose a person to T2DM [26]. During early life, in some parts of China, it exposed to some serious famine, therefore it becomes the cause to increase the risk of diabetes in adults as compared to those who do not face the extreme nutritional deprivation in utero development.

During midlife, the risk of diabetes is higher among the generations unprotected by utero low nutrition and who are later exposed to the richest diet [50]. The phenomena concerning the condition of undernutrition at the early life followed by environmental exposure to a "metabolically challenging" along with a diet that is highly energizing may lead to the high occurrence of diabetic patients [26]. The emergency rate in Cambodia about T2DM is at the same rate as those developed countries [17]. In 1975, Cambodia faced a severe shortage of food because of the upheaval condition of socioeconomic and politics. Nauruans were exposed to famine conditions during World War II on another Pacific Island and on Nauru such as Truk, where they were relocated. After three-decade, the rate of diabetes prevalence was high in Nauru in the entire world [51]. Due to war and famine, these are unexpected health issues, which were later pursued by overnutrition. Moreover, Yajnik study [52] suggested that India is experiencing the burden of diabetes due to the early developed health issues and epigenetic. In addition, according to the epidemiological studies, there is a link between the offspring risks and utero undernutrition, among the Pima Indians specifically. Exposed to maternal obesity and diabetes there is a high risk of T2DM and obesity in offspring [26, 53]. Comparing with USA and Europe, Asia is also having a high risk of prevalence of GDM and young-onset diabetes [54]. In future generations, there is an increase in the risk of diabetes; therefore, Asia may operate the intergenerational cycle [26].

## 1.4 Evaluation of Diabetic Foot Infections (DFI)

The understanding of DFI is significant due to its reporting of 1–5% of the foot ulcer among diabetic patients. Countries across the world dedicate a substantial amount of time as well as resources to reduce its occurrence [8]. This requires the patients to be reviewed on a routine basis along with the community podiatry foot protection to provide primary care and nursing. The evaluation of this care is substantially critical as it helps in prevention against the diabetic foot ulcer patient's emergency admission to the hospital, prevention against avoidable amputations, and care delivery.

### 1.4.1 Evaluation: Physical Examination

The DFI management incepts by examining the medical history of the patients along with their physical examination using laboratory as well as imaging findings. The diabetic patients with foot infection might not integrate the general symptoms and signs of the infection (such as vomiting, nausea, malaise, fever, and anorexia) due to the modifications in the leukocytic immune response [8]. The earliest sign concerning the patient with diabetic foot ulcers is unexplainable hyperglycemia. The physical examination of the patients, either in Asia or Europe, may present the "diabetic flu" symptoms including the anorexia, vomiting, fevers, chills, and nausea, which should prompt close inspection for the ulcer foot or infectious signs. This examination should be closely linked to the ulcer size, its depth, odor, drainage, or the margins. The suspiciousness concerning the osteomyelitis should occur based on a close examination of the erythrocyte sedimentation rate of below 70 mm/h, ulcer >2 $cm^2$, positive probe for testing the bone, and the abnormal radiographic findings including the cortical disruption. The presence of osteomyelitis and its high sensitivity and specificity are based on the bone test probe [8]. The accurate osteomyelitis diagnosis is based on the positive predictive values which range from 53% to 89% along with a positive probe to bone test. Substantially, the probe to bone inability is linked with a negative predictive value of about 98%. The elevation of the extremity should occur for determination of the extremity as to whether the Charcot sets as a base for the erythema stems or the infection. Among the patient's supine for about 5–10 min, the low extremity should be elevated, while simultaneously observing the erythema resolution, which provides the noninfectious injury. The infection can be clinically diagnosed due to the purulent drainage, or at least the presence of two inflammation signs (i.e., warmth, swelling, erythema, induration, pain, or tenderness).

### 1.4.2 Evaluation: Laboratory Testing

The evaluation of the patients through laboratory testing is integral to present the infection severity in the quantifiable form, following a response to the treatment. The laboratory finding is required to include the information concerning the patients' blood count, metabolic panel, C-reactive protein, as well as erythrocyte sedimentation rate. Also, the patient's nutritional status should also be assessed by collecting prealbumin and albumin. The level of the glucose should also be assessed, as the glycemic control loss occurs at the initial stage of the infection. Also, the imaging modalities are used for the characterization of the bony involvement and the degree of soft tissues affected [8]. For the initial workup of the foot infection in diabetic patients, the plain radiographs are also useful. The radiographic abnormalities should be paid special attention, which includes soft tissue gas, radiopaque foreign bodies, cortical erosion, and periosteal reactions. Also, for assessing the progressive signs, the repetition of the plain radiographs can be held. However, these

radiographs are not very sensitive and should be combined with the different modalities for better characterization of the suspected infection [8]. The osteomyelitis evaluation through magnetic resonance imaging (MRI) is found to present good specificity as well as sensitivity. Similarly, in the absence of the MRI, nuclear medicine scans can be used.

### 1.4.3 Evaluation: Microbiology

Following infection identification, antibiotic therapy requires culture. For this, deep tissue cultures should be attained. It is because these will present more reliable detection of the causative organism as compared to the superficial swabs. The use of these tissues is more reliable for deriving the causative organism in comparison to the superficial swabs. Despite bone cultures being ideal, these assessments of deep soft tissue culture might be beneficial in the detection of the osteomyelitis offending organism [8]. Following its proper evaluation, the IDSA system can be used for the classification of the infection which assists in the selection of the best treatment for improving communication among providers.

## 1.5 Strategy for Prevention of Diabetic Foot Management

Preventive strategies concerning the management of the diabetic foot are integral. This requires healthcare financers and decision-makers to optimize the resource allocation in an effective way of delivering adequate care quality. This involves funding as well as investing in different programs that help prevent diabetes as well as prevent foot complications among the diabetic patients. The diabetic patient's organization, as well as other advocating the diabetic care change, need to provide arguments that help devise decision for adequate care of the patients reducing the diabetic foot ulcer occurrence. These strategies should be centered on improving the patient's awareness level, where the diabetic ulceration prevention is prioritized, which serves as a substantial healthcare agenda. The preventive strategies also require the partnership of the different industry players, which is not only linked to their valuable contribution for improvement toward their therapeutic care but also facilitates education, research, as well as diabetes awareness programs. From an epidemic perspective, there exists a need for professionals to find a new way of organizing the delivery of the care program and for managing the extensive workload. These preventive strategies require effective working such as shared responsibility, better work management, and improved team work.

### 1.5.1 Education

For preventing the occurrence of diabetic foot problems, the primary prevention strategy is education. Although this might be particularly targeted for the providers

and the patients, the professionals are initially required to understand the significance which the patient's education holds. Once these professionals are educated and trained, they are able to deliver effective patient education. However, the efficiency of the patient's education concerning the education of the treatment and its condition is found to be controversial for diabetic patients with an ulcer. In order to prevent the below-knee amputation and ulceration, the education provision is found to have a low rate of amputation as compared to the patients who are not provided with the education [55]. Delivering education is found to be substantially involved in end-stage renal failure, with substantial self-knowledge improvement [56]. The deliverance of education to the patients makes them aware of the complications, signs, and symptoms of the patients.

This is found by a randomized controlled trial, where the instigation of education as a part of the intervention provided to be extremely beneficial as compared to the control group that was not provided with any education. The reasons highlighted include that the intervention group was involved in practicing foot care as compared to the control group who did not [57]. However, this intervention is not always effective such as Lincoln et al. [58] study using an observer-blinded randomized control design, showed that no difference exists for the two groups in terms of the ulcer incidence at the 6 months along with the amputation rate. Though the difference or no difference might be based on the patient's education that is being delivered or the pedagogical approaches used [59]. Although Kruger and Guthrie [60] reported that didactic teaching produced better results for the hands-on teaching experience.

Another research by Lam et al. [13] indicated that the teaching following the group discussion pattern is also not ideal. Although, diversified findings continue to prevail for the patient's education, various guidelines have prompted the use of the education as an intervention for providing adequate foot care to the patients and the use of adequate footwear [26]. It has strongly been recommended by the international working group to educate the diabetic patients of the footwear and promote self-foot care practices [26]. Similarly, education is required by the professionals comprising of the general practitioners, nurses, doctors, and allied health professionals in the health care sector. Different education materials can be used for improving the education level of the professionals, which help in providing necessary training to the professionals. Table 1.1 below provides information about the sources that could be used for training and teaching the students. This includes the use of different websites, guidelines, as well as books, which can easily be accessed by professionals. However, the primary focus of this education should be on the patients and their caregivers, who are at risk of developing a foot ulcer. This education can be provided into three domains related to care for the foot, care for diabetes mellitus, and lastly the footwear choice. It is because earlier researches in the same domain have found that the aspect concerning diabetes mellitus is not well understood as well as well managed.

Often, the level of glycated hemoglobin (HbA1c) is high among the patients, i.e., at about 10.0% or more. Previous research in 2014 on the multidisciplinary team effectiveness on its efficiency to treat the diabetic foot found that about 45% of the

**Table 1.1** Materials for professional education

| Professional education | Patients education |

patient among the total of 206 patients found that the HbA1c level of the patients was more than 10.0% [26]. Thus, the education initiatives introduced should first be centered on providing necessary awareness and education to the patients related to the management of diabetes, foot care, exercise, diet as well as medication. This should be followed by foot hygiene awareness and knowledge. Accordingly, patients must be educated on adequate footwear use. These materials generally include online reading material, as well as books [26, 66]. Other materials that could be used for the education of the patient include the offering of the education pamphlets. These pamphlets should include information concerning the "Happy Feet," "Knowing Diabetes," as well as "Patients" Guide for "Footwear."

### 1.5.2 Foot Care and Screening

The basics of care for the good foot in the individuals affected with diabetes include sufficient observation and the chances to apply the messages for the self-care and routine observation of foot [67]. The observation of Foot by physicians must emphasize the existence of peripheral arterial disease (PAD), peripheral neuropathy, former ulceration and unusual anatomy of the foot, all of this can forecast individuals at higher chances to develop the foot ulcers [67]. For instance, the routine checkups of the diabetic foot by an expert and professionally trained person must involve the

following steps, i.e., foot examination, which includes the observation of the sensation of foot by the help of a tuning fork or a10-g monofilament, foot pulses' palpation, assessment of the deformity of foot along with the footwear. It realizes aspects which predispose the complexities of foot complications to offer the knowledge and, if needed, to intervene for the prevention of these issues. Realization of pre-existing complexities that can need the cure. Focus on the significance of observation of the foot and spreading awareness for the examination of your own feet. Identification of common medical issues, for example, the existence of PAD that will highlight more common vascular pathology.

It is controversial to say that the effect of foot screening may reduce the risk of foot wounds in diabetic patients. Lavery et al. [68] the combinations of education and foot screening try to minimize the frequency of amputation by 47.4% ($p < 0.05$), and also minimizes the length of stay of inpatient by 21.7% ($p < 0.05$). however, according to the retrospective case-control study, in which 61 Pima Indians were included with prior amputation, and 183 were included without Prior amputation. Mayfield et al. [69] the risk of amputation cannot be minimized by taking one of more foot care screening ($p = 0.31$), more relevant researches are required. Moreover, outcomes may affect the frequency of foot screening. More researches are required to examine the effect of different occupied frequencies. In our clinic every diabetic patient has to go through the foot and eye screening test on a yearly basis, heart, and kidney screening as well [70]. According to the primary health care level, in Singapore, a strategy is planned by the Ministry of Health about the diagnosis of diabetes as early as possible.

#### 1.5.2.1 Patient Care Pathway for a Screening of Patients for Diabetic Foot Complications

All diabetic patients attending diabetes clinics are referred for screening tests for feet. The nurse who is running the clinic will ensure that the screening takes place and GP is assigned to patients accordingly [6].

##### 1.5.2.1.1 Screening Level 1: Initial Assessment

By podiatrists, all the patients are gone through by vascular and neurological assessments using the Doppler ultrasound and monofilament, in specific form DH 140 findings are recorded. If the patient is clear with diseases and certified normal then the patient has referred again to the diabetes clinic with a yearly appointment.

##### 1.5.2.1.2 Screening Level 2: Further Assessment

In Floriana Health Center, patients who have done their level one screening are having vascular and neuropathic problems, such patients are recommended for further in-depth screening. More tests were done to identify pathological issues with afoot. The follow-up will be continued in Floriana Health center and advise is given to patients by experts. On the other hand, patients are referred for third level screening when they are diagnosed with vascular pathology.

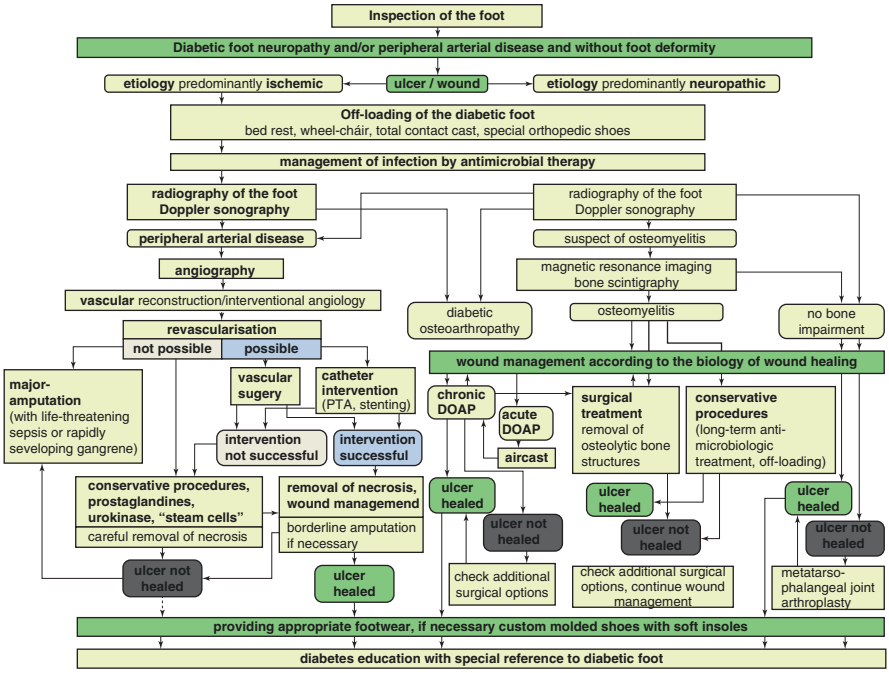

**Fig. 1.3** Clinical pathway of diagnosis and treatment of diabetic foot in the structured health care group [71]

#### 1.5.2.1.3 Screening Level 3: Assessment with Vascular Surgeon

This level of screening is generally held at the hospital where a vascular surgeon is present, who is approached for providing consultation.

The algorithm that is used for the education of the diabetic foot complication is presented in Fig. 1.3.

#### 1.5.2.1.4 Algorithm for Diabetic Foot Complications Screening

This clinical pathway presented in Fig. 1.3 is used for the clinical audit. This pathway is found to be effective for the identification of the early cases concerning the vascular and neuropathic pathology. This accounts for the early treatment of the patients using different intervention tools. This pathway enables the practitioners to improve the patient's quality of life, which also assists them to sustain an adequate glycaemia control.

### 1.5.2.2 Clinical Screening Tests

#### 1.5.2.2.1 Sensation

The two basic methods for the detection of sensory loss linked with foot ulcer risk are the 10-g monofilament, vibration perception having a tuning fork of 128-Hz

and the Ipswich Touch Test. The most commonly used is the 10-g monofilament [72, 73]. By the use of a 128-Hz tuning fork or a 10-g monofilament is not without the restrictions, usually, the error in the operation or poor methods, for example hard hit of the tuning fork, means that it will be heard and will alert the receiving person.

#### 1.5.2.2.2 The 10-g Monofilament

The 10-g monofilament was basically created to test the loss of sensors in the hands of individuals affected by leprosy. Monofilaments friendly in use yet there are a few aspects for the wrong usage; a 10-g monofilament that is inserted against the skin will call up the coarse light touch [67]. It is essential to understand that not all accessible 10-g monofilaments will provide a 10-g force.

### 1.5.3 Government Intervention

The prevention of diabetic foot ulcers can occur across different regulatory channels in both developing and developed countries. For instance, across Asia and Europe, different national campaigns, and funding programs can be introduced for reducing the diabetic foot ulcer. The program DESMOND (Diabetes Education and Self-management for Ongoing and Newly Diagnosed) has been executed in the UK to provide care since 2003 [74]. The instigation of such a program has substantially affected the glycemic control, along with the provision of a better understanding concerning the patient's diabetes mellitus. Several studies have emphasized the significance of government intervention as a national scale preventive tool, which enables improved foot care status among diabetic patients reducing foot complications. For instance, the efforts of the Ministry of Health in Singapore are noteworthy, where they declared war on diabetes [26]. In its efforts, it introduced two different ministerial task forces, where the first task was related to Diabetes Prevention and Care, while the second task was more focused on promoting a healthy lifestyle. These initiatives are required to be long and sustainable. These government interventions are not only required to cater to the diabetes problem but also assist mitigating the complication as well as other related chronic diseases, including ischemic heart disease, stroke, hypertension, as well as renal impairment.

### 1.5.4 Cost-Effectiveness of Prevention

The preventive measures central at reducing the complication are not only integral for improved foot health but also for reducing the economic burden. It has been emphasized by the Markov model that the cost-utility analysis is critical [14]. It emphasizes that the instigation of the intensive preventions could assist in reducing the occurrence probability for the amputations and foot ulcers by 25%. This strategy would be effective in terms of cost-effectiveness for all the diabetic patients unless they comprise of specific risk factors. It is because these prevention measures would

then be focused on those specific risk factors. Various other researches also confirm these findings. For instance, diabetes foot ulcer's treatment along with its related infections, the amputations below the knee, and the surgeries need the lower limbs revascularize, which account for a substantial diabetic treatment cost [14]. Although, these complications are found to frequently occur, vary few researchers have provided the division of the care in the primary prevention or the secondary preventive measures, which are generally infused together in a single term called secondary preventive measures. This is done for ensuring adequate health and lower incidence of ulceration [75]. However, the use of the primary prevention measures is integral for ensuring adequate health of the patients.

The use of the Markov model for predicting the transition of the patient from one condition to another is observed, with an understanding that this transition is based on the present condition and not the past, where these exist for a continuum. The transition example includes the change in the state of the patient from that of an untreated patient, to treated and then the final outcomes (such as cure, amputation, or death, where the last is an unescapable outcome). There is a need to apply both secondary as well as primary preventive measures at all levels which help reduce the risk among the patients (ranging from low to high), which helps reduce the overall cost. Such as the diabetic foot ulceration is decreased with the 10% (0.90 RR), which cost an individual about $50 per person and would require a greater than 90% probability for amputation reduction (i.e., about $39K) for the diabetic patients. This cost is either equal or lower than that of the standard care, in comparison to the provision of no preventive care. This also provides a reduction of patient's risk from the previous care costs which cost a patient about $125.

The small number of projects are formulated to eradicate or decrease the troubles of DFUs. This is rather due to the acknowledged effects of DFUs on the needs of disconnections, enhancing the expenses of healthcare, and the total lifestyle quality. The scarcity of these projects, even in huge centers of academic healthcare, can be associated with the idea of an exact shortcoming of advantages in the economic aspects. The researchers are in between the far and few, and former models of Markov have not elaborated on the chances for the total savings, where the cost efficiencies are not been represented. The variance in the research from the prior offerings is that one observed the varying levels of success (risk elimination which ranges from 5% to 25%) and allocating the expenses to all and determine a potential threshold of rates to determine the requirement for the measures of prevention. One significant restriction defined by the writers was splitting the patients of low risk from the patients of moderate-to high-risk that can be the reason behind the population having a higher risk to overlook the favor because of the enhanced preventing expense. A complete assessment of the total population will have been warranted to facilitate and support the best usage to prevent diabetic foot ulcers and the following complexities. There is a definite requirement to motivate preventive projects as a way to decline the higher expenses of care.

Several serious and expensive complexities influence the patients of diabetes. It includes the diseases of heart, failure of kidney, blindness, and complexities of the foot. The issues of the foot are usual, threats the life of an individual, and place a

higher burden in the financial aspects on the industry of healthcare, individuals with diabetes along with the families, and the community as well. Each year, greater than one million individuals suffer from lower limb amputation as a result of diabetes. This shows a remarkable issue from the aspect of the economy, specifically if the outcomes of amputation in the extended hospitalization, healing, and an enhanced requirement for the social facilities and home care. In developed states, the long-term (3 years) expenses linked with the starting amputations are anticipated to be as greater as almost approximately US$64,000. This anticipation does not include the indirect expenses as a result of the loss of efficiency, any incurred expenses by an individual affected with diabetes and the person in their family providing the care, and involves no computation to overlook the quality of life. The decline of these expenses, as well as the improved quality of life of individuals affected with diabetes, will need intense care and knowledge to make the results for the health. To invest in the foot care of diabetes and the prevention projects might be one of the most cost-efficient types of the expense of healthcare, offering the project which is target-oriented and applied appropriately. There are a number of reasons for the issues of diabetic foot problems.

## 1.6 Geographic Differences in Clinical Outcome

A substantial difference exists concerning the clinical outcome of the patients across similar countries [76–78]. Several studies have suggested that few patients are being managed considerably well as compared to the others in different countries. This might be because of the lack of emphasis on the clinical space in a certain region as compared to the others [76, 79]. This lack of emphasis might be in the form of training and education intervention introduced for adequate health care and management for the patients as well as a medical staff [76]. This necessitates the need to employ the internationally recognized care components, as well as standard pathways for the referral in general care practices as well as specialized. These principles are generally published by institutes such as National Institute for Health and Care Excellence [80], and International Working Group on the Diabetic Foot [81], though the monitoring of the professional adherence to these practices is not ensured.

## 1.7 Conclusion

The prevalence of diabetic foot ulcers is found across the world, with substantial economic consequences on a small scale (patients and family) as well as on the large scale (society). When the use of the resource is assessed, the broader use of the resource includes estimating the quality of life along with the final outcome. The primary preventive measure concerning the reduction in the foot complication for diabetic patients across Asia as well as Europe includes the use of aggressive glycemic control for the peripheral neuropathy concerning ulceration in the lower limb or infection. Although at the time, the foot ulceration prevention might not be possible,

the prevention of the small ulcer prevention is likely to be feasible, along with sepsis, gangrene, or osteomyelitis.

The chapter also provides insights that education serves as the primary tool for ensuring prevention of the foot ulcer among the patients and is an integral component for the preventive programs. Another potential benefit for using education is it is simple, repetitive as well as dual targeted, for instance, to the patients as well as healthcare workers. Accordingly, the screening of the foot also substantially contributes to the prevention of diabetic foot ulcers. Though, for the prevention to be effective, the government needs to introduce different, effective, prolonged as well as sustainable practices. Similarly, when an education program for the prevention purpose is being formulated, the associated personnel or the healthcare must be considerate toward the fact that individuals are not able to understand the terms such as neuropathy or the foot ulcer.

For instance, the provided education should be tailored as per the understanding of the patient and the social background. Similarly, the focus and the proliferation of the foot care service is required for employing an integrated approach to improve the patient's care outcomes, including disability, mobility, disability as well as mortality. This is necessary for each and every kind of community, such as India and China, where the prevalence of diabetes is found, where the majority of the people reside in rural areas. For this, foot screening practices can be devised, which are not only effective but are also cost-effective for the current healthcare system. Similarly, the chapter provides insights on the issue's guidelines which can help motivate the patients for adequate health of the foot, along with a different educational recommendation.

# Diabetic-Foot Complications in African and Antarctica Continents

2

Zulfiqarali G. Abbas

## 2.1 Introduction

Continent of Africa is the second biggest on the earth, it is almost three times the size of Europe, 1000 ethnic groups live in 54 countries and speak more than 1000 dialects. As of now with 1.1 billion population, Africa is anticipated to increment and reach 2.4 billion in 2050. A great part of the expansion will occur in Sub-Saharan Africa (SSA), which incorporates 46 of African's 54 nations huge numbers of the world's least fortunate nations [1, 2]. Antarctica is the fifth-biggest mainland as far as absolute territory (it is bigger than both Oceania and Europe). Antarctica is an extraordinary mainland in that it does not have a local populace. There are no nations in Antarctica, albeit seven countries guarantee various pieces of it. Antarctica is the main landmass with no perpetual human home. There are, however, human settlements, where researchers and supporting staffs live piece of the year on turning premise [3]. The rate of diabetes mellitus is expanding in the populace over the world. Africa is encountering a quick increment in the commonness of diabetes. In December 2019, it was reported that people with diabetes in Africa are 19 million and if present patterns proceed with the general commonness is anticipated to be 29 million by 2030 and 47 million by 2045, which is increment of 143% [4]. There is currently considerable proof affirming that diabetes has arrived at pestilence extents in many creating or recently industrialised countries, and is relied upon to turn into the dominating medical issue in new developing countries [1]. Diabetes stays a main source of dismalness and mortality in both developed and developing world and force an overwhelming weight on their health services [5–21].

As the prevalence of diabetes is increasing along with it in parallel complications of diabetes will also increase. Among all the complications caused by diabetes, the

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_2

most serious and dreadful complication will be diabetic foot, which will be associated with the highest morbidity and mortality [5–21]. Data across the world are reporting that 40–60% of all lower limb non-traumatic amputation are directly related to diabetes [21–25]. Up to 85% of amputation done in the people with diabetes are due to foot ulcer. There is a 50% risk of developing a serious lesion in the second limb in those people with diabetes who had a previous lower limb amputation within 2 years [21–25]. It has been shown in the literatures from Africa that patients with diabetic foot are associated with peripheral neuropathy compared to peripheral arterial disease (PAD) [5–20].

African continent is developing very fast and becoming more affluent due to urbanisation. At the same time, we report in the literatures increase rates of peripheral arterial diseases in people with diabetes in past two decades, which can be critical and costly [26]. Amputations are expensive, devastating on the people with diabetes and their families, leading to loss of independency and livelihood [26]. Complications of lower limb are associated with high rates of morbidity and mortality [5–21].

Time is tissue, which implies that therapeutic help for diabetic foot ulcers ought to be looked for as fast as could be allowed and intervention should be taken as a medical emergency [21–25]. Time is not tissue, which implies that a patient presenting with a diabetic foot ulcer, with a history of days, weeks or months, means it becomes difficult to save a toe, or a foot or a leg or even prevent death due to delay presentation [21–25]. Ideally these patients with diabetic foot ulcers should not delay to report at health centre.

In African setup reasons for late presentations have been reported by Abbas et al. and are mostly associated with cultural, traditional and customary behaviours [5–9, 13, 14, 19–21]. In the African continent, it is very common to go through many stages before patients actually lands in the health centre. First of all, patient will try to treat a foot lesion at home using a razor blade called bathroom surgery or herbal solution [5–8, 21]. Procedures are performed by relatives or patients themselves. If treatment at home fails then patients would be advised by relatives to see herbalist, faith healer or traditional healer. After going through herbalist, traditional or faith healer and if it fails then patients and relatives will decide to go to nearest primary health care centre or district or regional hospitals where unfortunately we cannot find a health care worker dealing with diabetic foot problems. All these journey delays treatment of diabetic foot ulcer and foot deteriorates. By the time patient is referred to a specialised centre or referred hospital it could be too late to salvage a foot and sometimes even to prevent death of the patient [6–9, 13, 14, 21]. In some community's delay in getting an expert opinion in the hospital is because of fear losing a limb, as according to culture losing a limb in African patients is considered a worse outcome than having a disease. Among health care workers at grass root level can lead to worse outcomes due to lack of knowledge. Awareness and education among health care workers are extremely important specially at the grass root level who are the first to see these patients [6–9, 13, 14, 21].

## 2.2 Pathophysiology of Foot Ulcers

The pathophysiology of diabetic foot lesions is complex and multifactorial. Contributory factors include peripheral neuropathy (sensory, motor, autonomic) peripheral arterial disease, neuro-ischemia, infection, biomechanics, social-economic factors, non-ulcerative lesions of ulcers and local trauma. The pattern of foot ulcer occurrence depends on the varying degree of contribution of each of these factors. For example, an ulcer may be secondary to both ischemia and neuropathy so-called neuro-ischaemic ulcer.

## 2.3 Diabetic Foot Complications

Diabetic foot ulcer is a major public health problem in many African countries [1, 2, 5–22]. It is the main cause of prolonged hospital admission due to late presentation and can lead to high morbidity and mortality [1, 2, 5–22].

### 2.3.1 Peripheral Neuropathy (PN)

Published literature from the Western world reports that PN is the foremost common complication of diabetes, happening in 5–80% of patients with diabetes [27, 28]. Peripheral neuropathy is one of the most common diabetic foot complications affecting patients with diabetes in both developed and less developed world [8, 9, 16–21, 29–48] (Table 2.1).

Diabetic peripheral neuropathy commonly presents as bilateral symmetrical glove and stocking distribution predominately sensory neuropathy. Foot with peripheral neuropathy is classical numb, warm, dry and painless, but pulses are palpable. Typical patient will present with numbness of feet, pins and needles sensation, burning feet, feeling like walking in the sand, stabbing pain, fatigue or weakness of feet. Due to the loss of protective sensation in the feet patient can easily sustain injury.

The resulting loss of sensation in the feet invariably leads to sequelae that include callosities, cracked soles, breakdown of skin or non-discernible injuries, such as burn or rat bite. These complications can result in foot ulcers, which in our set leads to infection, gangrene, amputation or even death [8, 9, 16–21, 29–48]. This is the main reason that peripheral neuropathy with foot ulcers are admitted in the hospital, leads to prolonging stay in and are associated with amputation [8, 9, 16–21, 29–48]. Peripheral neuropathy also remains the most common initiating factor for diabetic foot ulcer (DFU). The prevalence of PN rates across Africa in last two decades has been documented [8, 9, 16–21, 29–48] (Table 2.1).

In a major study performed in Tanzania, Abbas et al. found no differences in the rates of PN among African and Asians diabetic patients with ulcers [17, 18]. In another comparative study, Abbas and colleagues found no significant differences in

the prevalence of neuropathy in patients with foot ulcers from Tanzania, Germany and India [18]. There is no difference across the world in the rates of PN [18]. Published data from the last two decades across Africa have shown wide difference in the occurrence of PN [8, 9, 16–21, 29–48] (Table 2.1).

### 2.3.2 Peripheral Arterial Diseases (PAD)

Peripheral arterial disease is defined clinically in patients with a history of intermittent claudication, rest pain, absence of pedal pulses abnormalities on non-invasive arterial assessment indicates disturb or impaired lower limb circulation [21, 22]. There are no specific diabetes-related peripheral arterial lesions, but the distribution of arteriosclerosis in patients with diabetes is different compare to what is seen in non-diabetes patients. In patients with diabetes, it is more frequently, younger age groups are affected more, no differences in gender, progression rate is faster, it is

multisegmented and more distally [21–22]. It is general to see that ischemic foot is associated with pain at rest, increase risk of foot ulcers, digital necrosis or gangrene and absent pulses. This in turn increases the risk of localised or widespread infection of the lower limbs.

PAD is very common in the industrialised world, but was not that common in Africa and Asia [8, 10, 14, 16–19, 30, 32, 35, 37, 44, 46, 49–56]. Now across Africa and Asia rates of PAD are increasing [8, 10, 14, 16–19, 30, 32, 35, 37, 44, 46, 49–56] (Table 2.2). More people in Africa are adopting the Western style of life as are becoming more urbanised, sedentary lifestyle, lack of exercise, changing diet, etc. Abbas et al. established that rates of PAD in Tanzania are not different by ethnicity as it was in the past [18]. PAD is now playing a more substantial role in the causation of foot ulcer in Africa than was previously thought. Likely, reasons for this include increased urbanisation and adoption of behaviours and diet from the west. Prevalence rates of PAD are increasing across Africa seen in last two decades [8, 10, 14, 16–19, 30, 32, 35, 37, 44, 46, 49–56] (Table 2.2).

Peripheral arterial diseases are underdiagnosed and treated in Africa and we need to conduct more measurements of Ankle Brachial Index [17, 21, 22]. Computer tomography scan angiography of lower limbs are quite comparable in visualising vessels. It is done to evaluate the extent of arterial block and help in the feasibility of revascularization [22].

**Table 2.2** Prevalence of peripheral arterial disease (PAD) across the African continent in last two decades

| Publication year | Author | Ref. No. | Country | Prevalence of PAD (%) |

### 2.3.3 Diabetic Foot Ulceration (DFU)

Diabetic peripheral neuropathy in Africa is still the main underlying risk factor in the causation of diabetic foot ulcers [8, 10, 12, 13]. In one of the studies conducted in Tanzania it showed that 15% of admitted cases were of diabetic foot ulcer and out of this 80% were first-time ulcer [14]. Across African continent prevalence of DFU ranges from 12% to 24% [34, 44, 57–61]. It further showed in the study that the amputation rate was found 33% as a frequent outcome in people with DFU and associated with neuro-ischemic lesions and/or progressive infection [14]. Mortality rate was as high as 54% who presented late with severe foot ulcers Wagner score ≥4 [14]. It has been reported the same with high rates of morbidity and mortality from other parts of Africa [10, 14, 62–67]. It is difficult to obtain consent from patients for surgery due to severe DFU, which can reflect low amputation rates than what is actually expected [14]. Some patients discharge themselves against medical advice with severe DFU and thus risk severe sepsis and may be death [14].

Major factors contributing to development of the DFU in rural Africa are walking bare foot. In particular, farmers walking barefoot, or due to religious obligations people have to walk barefoot and, in some cultures, entering the house we need to take out of footwear. This could be due to culture or may be low income [8, 10, 11, 21]. People with diabetes living below poverty line could be difficult for them to buy appropriate footwear. Flip flop slippers are very cheap and rubber made commonly used in the developing world and rural Africa it is common to produce footwear from worn out motor car tyres [8, 10, 21]. Poverty can lead to unhygienic condition, which is in turn prone to DFU [11–15, 21]. Patients with peripheral neuropathy sustain injuries but presents with DFU when they become symptomatic and by that time foot ulcer has already progressed to fulminating foot sepsis. Most of the time it has been noticed and reported that these patients do not have access to basic education on foot care at primary, district or regional health centre are most at risk developing infected ulcers [12, 13].

### 2.3.4 Diabetic Foot Infection

In Africa first presentation to health centre is usually too late when patient has already developed localised gangrene or full foot gangrenous with severe sepsis. This may not respond to supportive treatment with intravenous antibiotics, intravenous fluids and insulin, this progress to serious systemic infection and high risk of mortality [1, 5–21]. First presentation at health centre is late with severe infected DFU and already has acute limb-threatening conditions leading to foot or leg amputation in 25–50% for patients with diabetes [22–25]. Fungal infection in between the toes is also common and dryness of the feet seen in patients with diabetes develops cracks and fissures on the sole of the feet [16–21]. All these open lesions in the skin lead to secondary bacterial infection [16–21]. We can start with antibiotics initial empirically and then can be changed after the results of culture and sensitivity [68]. According to the International Working Group of Diabetic Foot superficial

swabs are not recommended for culture [22–25]. Obtain specimens of superficial swabs are not useful due to give polymicrobial growth. Deep tissue biopsy is recommended by IWGDF to give proper and useful data [22–25]. Unfortunately, in Africa majority of laboratory services do not have resources to provide or maintain microbiology routine services. Microbiology services are only available in the university tertiary level of the hospitals [68]. Reports of the utility of Gram staining has been published is equally sensitive compare to cultures in the management of diabetic foot ulcer [68].

Infection is the immediate cause of amputation and this varies widely by geographic regions. True rates of amputation following foot infection in Africa remain underestimated [1, 6–21]. There are many cited reasons for amputation in patients with diabetes, but gangrene and infection are common and occur simultaneously [16–21]. Medical health care workers always think (Incorrectly) that a degree of self-neglected among the patients with DFU. This happens because foot with infected ulcers frequently feel no pain due to peripheral neuropath. Developing countries need treatment planning for the prevention and management of diabetic foot infections.

Diabetic foot ulceration, infection and amputation are preventable through organised foot care programmes. Education is the only tool in the developing world that can prevent diabetic foot complications. Education should be targeted to health care workers, patients and relatives and it has shown to reduce complications by 85%.

DFU and infections are very common where services are scarce especially as in Africa, for example, Chiropody services are almost non-existing in Africa. Foot lesions once sustained by the patient are either ignored or detected relatively late. During this process, the patient starts treatment himself at home by home therapy such as socking in herbal medications, applying the herbal medication, etc. This leads to further deterioration of the foot with high risk of morbidity and even mortality due to sepsis [9–16, 21].

### 2.3.5 Amputation

Gangrene and infection appear to be most common cited indications for foot amputation in patients with diabetes [8, 10]. High rates of amputation are seen across Africa from 16% to 55% [8, 10, 61–63, 65–67]. However the true lower limb amputation rate resulting from foot infections in Africa remains underestimated. About 10% of patients who needed and agreed to undergo surgery died due to severe sepsis in Africa before the surgical procedure [8].

### 2.3.6 Mortality

Mortality rates are high in African patients with diabetic foot ulcers [8, 10, 61–63, 65–67]. Abbas and colleagues ascertained clinical correlates for mortality of patients with diabetic foot ulcers in Tanzania. They found that the overall mortality rate was

high in the patients with foot ulcer was 29% and was significantly higher among patients with PAD, neuro-ischaemic, late presentation, or non-healing ulcers [8, 10, 14]. The mortality rate was 54% who presented when gangrene has set [8, 10, 14]. The highest mortality rate has been documented in those patients who did not undergo amputation of the affected limb [8, 10, 14].

## 2.4 Prevention

It is important that it should be directed to people with diabetes and health care workers.

Education is the only tool we have in Africa, which is free of charge for the patients and effective if implemented. Several educations have been conducted and were successful in both the developing and developed world [5, 6, 69–74].

### 2.4.1 Step by Step (*SbS*) Foot Project

Step by step foot project was first and the unique project started from the developing world. It was piloted and conducted in Tanzania and India. This project was launched in 2003 and the curriculum was developed initially focusing developing world. The main aim of this project was to create awareness on diabetic foot, to provide sustainable training on diabetic foot, to transfer knowledge to other colleagues and export ideas to other developing countries, to reduce the risk of lower limb complications and to empower people with diabetes regarding diabetic foot. Several successful projects were done in Tanzania targeting physicians and nurses [69–74]. It was always aimed to train a team from each centre. It all started in Tanzania, developing world exported to other developing countries, later to the second world and finally the first world in Europe [69–74]. Step by step has already touched about 110 countries in the world. In 2009 it was decided to bring surgeons on board. It felt that surgeons should be trained for salvaging diabetic foot. So those centres where physician and nurses were already trained surgeon were asked to join to complete the team. First course of its kind for surgeons was held in Tanzania [69–74]. Several other groups of surgeons were later formed in Europe and Asia. Step by step foot project showed us that ulceration, infection and amputation all are prevented through organised diabetic foot care programmes. Regular education of the staffs and patients, regular follow of the patients and multidiscipline approach to manage diabetic foot ulcers. Step by step reported that above strategic plan there was greater than 50% reduction rates in amputation rate [5, 6, 69–74].

### 2.4.2 Train the Foot Trainer (*TtFT*) Project

In December 2012, a decision was made to introduce Train the foot Trainer project (*TtFT)*. It is almost similar to the original step by step foot project, but here health care workers from different countries in that region are asked to come under one

roof. Once health care workers go back to their own countries, they need to disseminate the knowledges by conducting step by step foot projects. The first successful *TtFT* course was conducted in Brazil in 2012 [75].

## 2.5 Conclusion

Africa is in epidemiological transition with a massive projected increase in diabetes and diabetes-related lower limb complications including peripheral neuropathy, peripheral arterial disease, DFUs and amputations. Unless urgent action is taken to tackle these by developing cost-effective and evidence-based strategies, a situation that is already challenging will become substantially worse. DFUs and amputations rates in patients with diabetes can be reduced by >50% by better education of patients. Education on diabetic foot is the only tool we have in Africa that should be part of the curriculum. It should be targeted at both health care workers and patients.

**Acknowledgments** I would like to acknowledge all our colleagues for their constructive discussion during the genesis of this manuscript. We usually highly appreciate Shabneez Gangji and other staff in diabetes centre's in Dar es Salaam for their assistance.

# Diabetic-Foot Complications in American and Australian Continents

3

Kanakamani Jeyaraman

## 3.1 Introduction

Diabetic foot problems are a challenging health issue with clinical, social, and economic implications and are set to increase in the future, with the world facing the epidemic of type 2 DM. Though developing countries in Africa, Asia, and South America are likely to see the greatest rise, developed countries also are facing similar uptrends. Foot problems consume about 10–12% of the health-care resources available for diabetes and potentially up to 40% in developing countries [1]. It is estimated that every 30 seconds in some parts of the world, a limb is lost due to diabetes and the average annual cost is $8659 per patient. The cost of treating a diabetic patient with foot problems is 5.4 times higher than treating a patient without foot problems in the year of the first episode and eight times higher for higher grade ulcers than lower grade ulcers [2].

Worldwide, about 9.1–26.1 million people with diabetes develop foot ulcers every year [3]. Understanding the epidemiology of the diabetic foot problems is important for the appropriate allocation of health-care resources and budget planning. Knowing the region-specific risk factors can help to develop prevention and treatment strategies relevant to that region. More information is available on the epidemiology of diabetes-related lower extremity amputations (LEA) than the epidemiology of the diabetic foot problem, itself. The incidence and prevalence of diabetic foot problems and diabetes-related LEA vary significantly between different countries and between different regions within countries. The point prevalence of diabetic foot ulcer (DFU) in developed countries range from 1.5–10%. The incidence of DFU in community-based studies in Europe is between 0.5–2.2% and is high at 3–6% in clinic-based studies from developing countries. The incidence rate

could be even higher in high-risk select population, e.g., 30–50% in a diabetic population with previously healed ulcer [1]. Therefore, it is difficult to compare the incidence and prevalence rates from different studies. Factors like the methodology, the study setting, population studied, the definition of the DFU, and the denominator used to calculate the incidence/prevalence rates should be carefully considered for proper interpretation of the data.

## 3.2 Epidemiology of Diabetic Foot Complications

The International Diabetes Federation (IDF) has organized the countries in American continent into two regions—North America and Caribbean (NAC) and South and Central America (SACA). The NAC region consists of the USA, Mexico, Canada, and 21 Caribbean countries and territories. An estimated 357.1 million adults aged 20–79 years have diabetes in this region, with a regional prevalence of 13.3%, the highest of all IDF regions. The SACA region with 20 countries and territories has a regional prevalence of 9.4% with 335.1 million diabetic population living in this region. The Australian continent with three countries Australia, New Zealand, and Papua New Guinea comes under the Western Pacific IDF region. The 2019 IDF data shows that the annual incidence of foot ulceration is 2% and of amputation is 1% in patients with diabetes in high-income countries [4]. This is expected to be even higher in low- and middle-income countries.

Globally, North America has the highest prevalence of diabetic foot problems, about 13.0% (10–15.9%) and Oceania has the least, about 3.0% (0.9–5.0%). Within North America, Canada had a higher prevalence of 14.8% compared to the USA prevalence of 13.0% [5]. Differences in age, duration of diabetes, BMI, presence of hypertension, smoking, and diabetic retinopathy might explain the high prevalence in American countries. There are very few studies from South America regarding the epidemiology of diabetic foot problems.

### 3.2.1 North America and Caribbean

Globally, North America has the highest health-care and economic burden due to diabetic foot problems. Every 30 seconds, about, one million dollars is spent on the inpatient and outpatient care of the diabetic foot, in the USA alone. The estimate of the annual US burden of DFUs is at least $15 billion. The 1999–2000 NHANES data showed a prevalence of 7.7% foot ulcers in patients with diabetes [6]. Data analysis of a subpopulation of Medicare beneficiaries with diabetes in the USA in 2008 showed a point prevalence of 8.0% for white, 8.7% for African-Americans, 4.2% for Asian, 8.6% for Hispanic, 9.6% for American Indian/Alaska Natives, and 5.5% for others [7]. Another analysis of a 5% random sample of Medicare and Private insurance beneficiaries for the period between 2007 and 2011 showed an incidence of 12.8% in Medicare and 4.8% in privately insured patients with diabetes [8].

The Center for Disease Control and Prevention reported that the age-adjusted prevalence of a history of DFU in adults with diabetes in the USA in 2000–2002 was 12.7%. The highest prevalence was in the states of California, Indiana, and Nevada with a prevalence of about 16%. DFU prevalence was lowest in the states of Colorado, North Carolina, North Dakota, Ohio, West Virginia, and Wisconsin at about 10%. In a multivariate analysis, the significant risk factors identified were younger age, longer duration of diabetes, white race, Hispanic ethnicity, obesity, insulin use, and smoking [9].

The Seattle diabetic foot study is one of the few longest and largest prospective studies on the epidemiology of DFU. The study reported an incidence of 5.0 per 100 person-years [10]. Another prospective observational study, the TRIAD study in Michigan conducted between 1999 and 2003 showed that 3% of diabetic patients in managed care had DFU and 2% had amputations [11]. A study from Texas in 2003, reported an incidence of ulceration, infection, and amputation in patients with diabetes was 68.4, 36.5, and 5.9 per 1000 patients with diabetes per year, respectively [12]. Veterans Health administration and Medicare claims data for a cohort of 255,234 patients with diabetes was analyzed for the period from 2000–2004. This data showed that 54.8% had a documented foot condition in 1999 and 26.9 per 1000 had an LEA over the period of 2000–2004 [13].

The prevalence of DFU in Canada is estimated to be around 14.8% (9.4–20.1%) [5]. A nation-wide study in Canada using four linked databases showed a prevalence of 75 per 100,000 and an incidence rate of 42.4 per 100,000 of the general population. The highest prevalence was in Manitoba at 106.2 per 100,000 and the lowest was in Ontario 64.7 per 100,000 population. The average cost per prevalent case was $21,371 [14]. In the ABCD study conducted in the Alberta province of Canada where 2040 diabetic patients self-reported, 18% of the respondents reported peripheral neuropathy, 28% had peripheral vasculopathy, 6% had foot ulcer or infection and 1.4% has had gangrene or amputation [15]. In a recent report, 27.4% of the ABCD cohort in Alberta, reported having diabetic foot problems [16]. Another prevalence study in a remote Northern Canadian Aboriginal community in Manitoba showed that amongst 169 diabetic patients 82% were at high risk of developing ulcers in the future [17].

There is no nation-wide prevalence or incidence data available on diabetic foot problems from Mexico. A small clinic-based study from Tijuana, Mexico showed that 44% of the 205 patients studied were at high risk of developing diabetic foot problems [18]. Diabetic foot problems are very common in the Caribbean region. Foot infections are the leading cause of hospital admissions to the surgical floors in Caribbean public hospitals. In 2001, Walrond reported that on average, 75% of the beds in the surgical wards of a public hospital in Barbados were occupied by patients with diabetic foot problems [19]. A 1-year prospective study in an Eastern Caribbean population showed 13.7% of hospitalized patients had major and 30.0% had minor amputations [20]. A study from a specialist diabetes clinic in Jamaica showed that amongst 188 diabetic patients, the prevalence of amputations was 8.5%, current ulcers were 4.3%, and current foot infections were 3.7% [21]. Amongst 2106

patients with diabetes attending primary care in Trinidad, the prevalence of neuropathy was 49%, previous foot ulceration was 12% and amputation was 4% [22]. Annually, the government of Trinidad and Tobago spends about US $85 million, solely for the inpatient care of patients with diabetic foot infections [23].

### 3.2.2 South and Central America

A cross-sectional study of 11,357 inpatients across 135 health centres in 9 Latin American countries showed a diabetic foot prevalence of 14.8% in hospitalized patients. The prevalence was highest in Chile at 13% and lowest in Bolivia at 3.8% [24]. An epidemiological survey conducted in six health districts in Brazil showed that among 1374 diabetic patients, the diabetic foot was observed in 9%. The prevalence of lower limb amputations was 2.3% of the total sample and 25.6% among individuals with foot complications [25]. A large multicentre cross-sectional study BRAZUPA conducted across 19 centres in Brazil showed a prevalence of active ulcer in 18.6% and amputation in 13.7% of the 1455 patients with high-risk feet [26]. The BRAZUPA study found that younger age at presentation and neuropathy as a significant risk factor for DFU than ischaemic foot, whereas ischemia was more associated with poor outcomes and amputation. In 2014, Brazil spent about Int$ 361 million for the treatment of patients with diabetic foot complications, which is about 0.31% of public health expenses for this period [27]. In a rural community in Ecuador, the prevalence of active diabetic foot disease was 7% in patients with diabetes [28]. A cross-sectional study on 307 diabetic patients from Colombia showed that 13.0% had a history of previous ulcers and 1.6% had amputations [29]. In 2015, a study from Peru reported that US$ 74.5million was attributable to the prevention and management of high-risk diabetic foot [30].

### 3.2.3 Oceania

The Diabetic Foot Australia (DFA) is a national body established in 2005 with the primary goal to end avoidable amputations within a generation, i.e., by 2040. The DFA has recently established a national diabetes-related foot disease strategy for 2018–2022 [31]. The DFA has estimated that in any given day in Australia:

- Thousand people will be hospitalized with diabetic foot problem
- Twelve will undergo diabetes-related amputation
- Four will die due to diabetic foot disease
- Four million dollars will be spent treating diabetic foot disease

The Australian Diabetes Obesity and lifestyle study (AusDiab) is a population-based study in Australia which included 11,247 people aged ≥25 years from 42 randomly selected areas of Australia. This study showed that 19.6% were at risk for

foot ulceration [32]. The Fremantle Diabetes study showed a DFU prevalence of 1.2% in patients with diabetes in Phase I (1993–1996) and 1.5% in Phase II (2008–2011) [33].

There are no population-based studies from New Zealand on the epidemiology of diabetic foot problems. In a study from the Waikato region of New Zealand, out of the 2192 diabetic patients who attended for retinopathy screening, 13% were at high risk of developing diabetic foot disease [34]. Two Maori primary health organizations in Northcote in 2012 reported that 8% of diabetic patients had active foot ulcer [35]. The prevalence of abnormal foot sensations in 459 diabetic patients was 30% in Nauru, 23% in Solomon Islands, and 19% in Vanuatu [36].

## 3.3 Geographic Variations in the Characteristics, Risk Factors, and Outcomes of DFU

The type, site, and etiology of ulcer can vary from country to country depending on the climate, use of footwear, access to health care, physical activity, and culture. In general, diabetic foot problems are predominantly ischemic in developed countries and neuropathic/neuro-ischemic in developing countries [3]. It is believed that due to resource-poor settings, diabetic patients in developing countries have long-term suboptimal glycemic control and are more prone to develop neuropathy. However, the scenario is now changing, and the occurrence of peripheral vascular disease is increasing in developing nations [37]. Similarly, the outcome of the DFU is dependant not only on the biological factors of the individual but also on the management decisions of the health-care professional and the availability of health-care resources.

### 3.3.1 Characteristics of DFU

In the Seattle diabetic foot study, out of 1483 limbs prospectively followed up, 162 ulcers developed over a mean follow-up period of 3.7 years. About half of the limbs with ulcers (49.1%) had clinicians diagnosed with peripheral vascular disease (PVD) and 67.9% had absent monofilament sensations [38]. A study from Ontario on 87 patients showed that 54.4% of DFUs were non-planar, 60.8% were small <1 $cm^2$, 14.4% had gangrene, and 2.4% had osteomyelitis. Preexisting DFUs, multiple DFUs at first presentation, ulcer size >3 $cm^2$ and PVD were associated with delayed healing [39]. In another single center hospital-based study in Ontario, 279 DFU patients were studied over 5 years. Majority of the ulcers (82.5%) were in the forefoot. Palpable pedal pulse and use of total contact cast were associated with better wound healing [40].

A longitudinal study in a tertiary care hospital in Mexico from 2012–2015 on 100 patients with DFU showed that inappropriate shoes and formation of blisters were the two main causes for foot lesions. The size of ulcer ranged from 1.5–8 $cm^2$.

Majority (75%) were plantar; 48% were forefoot ulcers; and 29% were in hindfoot. During the study period, 15% had major and 30% had minor amputations. Wagner Grade 3 and 4 accounted for 73% of the ulcers [41]. In the BRAZUPA study, 14.2% were ischemic, 39.3% were neuro-ischemic, and 45.1% were neuropathic ulcers. Male gender, ischemic foot, hypertension, South/Southeast region of origin, previous history of ulcer, and altered vibration sensations were associated with amputation [26].

A study from a tertiary care hospital at the Northern Territory of Australia reported ulcers in the plantar surface of forefoot (74.9%) were common. More than half (54.8%) had Wagner grade 2 and above [42]. A clinic-based study at the Foot wound clinic in Western Sydney described a median ulcer area of 1.5 $cm^2$ and 45.1% on the plantar aspect of the foot, 16.6% had ischaemic ulcers, and 25.6% had osteomyelitis [43].

Cultural barriers and access to health care also affect the clinical presentation and outcomes of DFU. In Trinidad and Tribago, out of the 446 patients admitted with DFU, about 36.6% were walking barefoot, 42.4% had footwear-related injuries, and 1.6% were due to burns. More than half of them identified the foot injury early but there was a median delay of about 6 days before presentation to the medical practitioner. About one third had tried some home remedies before presenting to the health-care providers [44]. Of note, most of the Caribbean patients with diabetes routinely wear "flip-flops" and the Caribbean health care has successfully used the "slipping slipper" sign in public education campaigns to identify patients with high-risk feet [20]. In Colombia, 76.2% of diabetic patients did not have foot examination over a period of 1 year and many were not asked about dysesthesia and claudication, despite >85% having such symptoms [29].

### 3.3.2 Risk Factors for DFU

Various studies from many different parts of the world have reported the risk factors associated with DFU. Many of these studies analyzed retrospective data. Various demographic and clinical risk factors have been studied and shown to be associated with increased risk of DFU. Age, male gender, height, weight, BMI, ethnicity, poor socioeconomic status, smoking, and alcohol use are the demographic factors that have demonstrated a relationship with DFU. Indigenous populations have long been known to have poor health outcomes and are expected to be at higher risk of diabetes-related foot disease and amputations. The data on the association of ethnicity and the occurrence of DFU is scarce. A study done in 200 patients in Mexico showed that there was no relationship between sociodemographic variables and risk of DFU. Rather, poor knowledge and poor foot care practices have a significant correlation with the development of DFU [45].

A systematic review of 67 studies from 33 countries showed that the patients with diabetic foot were older, had a lower body mass index, longer diabetic duration, and had more hypertension, diabetic retinopathy, and smoking history than patients without diabetic foot [5]. A systematic review and meta-analysis done by

Crawford et al. collated 16,385 individual patient data from ten cohort studies conducted worldwide. Age, sex, height, BMI, smoking, alcohol use, duration of diabetes, HbA1c, Insulin treatment, vision problems, retinopathy, kidney problems, inability to feel 10 g monofilament, absent pedal pulses, absent ankle reflex, reduced vibration perception threshold (VPT), abnormal ankle-brachial index (ABI), foot deformities, history of ulcer, and history of amputation have all been reported to be associated with DFU. However, the meta-analysis found that three factors—history of foot ulceration, inability to feel 10 g monofilament, and absence of any pedal pulse—were consistently and independently predictive of DFU. A combination of these three factors is comparable to other complex approaches to predict the occurrence of DFU and is very simple for clinical use [46].

The Seattle diabetic foot study prospectively looked at the independent effects of multiple potential risk factors. Participants were recruited in 1990 at a single Veteran Affairs Medical clinic in Seattle and followed up until 2012. Significant predictors of foot ulcer were glycosylated hemoglobin (HbA1c), impaired vision, prior foot ulcer, monofilament insensitivity, tinea pedis, and onychomycosis. They concluded that this readily available clinical information can predict the development of DFU and hence help to target the patients who are at high risk of DFU [10]. Another multicenter prospective follow-up study from Massachusetts showed that clinical examination and monofilament tests are the most sensitive to identify feet at risk, whereas foot pressures are very specific and can be used for providing advice on footwear [47]. A cross-sectional study of 117 patients in the Federal district of Brazil identified similar risk factors for DFU—peripheral arterial disease, painful peripheral polyneuropathy, foot deformities, loss of protective sensations, and dry skin [48]. Risk factors identified for DFU in an Australian study were diabetes duration, height, age, and uric acid levels [32].

### 3.3.3 Outcomes of DFU

The natural history of DFU is sobering. About 50–60% die within 5 years. About 50% of DFUs get infected and about 20% end up in amputation. The outcome of the DFU varies widely between and within countries [1]. A pooled analysis of 5 randomized controlled trials (RCTs) in the USA showed that 23.9% ulcers healed within 12 weeks and another 32.8% healed within 20 weeks of receiving good standard care [49]. In Canada, after a 52 weeks follow-up, 86.6% ulcers healed and the mean time to healing was 10.2 ± 10.2 weeks. At 52 weeks, 7.1% have had amputation and 8.9% had died [15]. A prospective cohort study in Brazil showed that 61.8% healed after 1 year [48].

The story does not end with healing and the DFUs that have healed have a high chance to recur. The recurrence rate is 17% per person-year in North America and was not significant in Canada and Cuba [50]. A prospective study from Maryland, the USA between 2012 and 2016 showed a recurrence rate of 30.6% at 1 year and 64.4% at 3 years, in a multidisciplinary setting [51]. Another study from multiple centers including one from Australia showed a similar recurrence rate of 31% at

1 year. The median ulcer-free survival in the healed group was 233 days [52]. A meta-analysis of risk factors for recurrence reported that male gender, smoking, duration of DM, duration of past DFUs, plantar ulcers, PAD, and peripheral neuropathy are associated with recurrence [53].

## 3.4 Epidemiology of Lower Limb Amputation

Lower extremity amputation (LEA) remains the major and most serious outcome of DFU. Globally, 50–70% of all nontraumatic amputations are due to diabetes. Persons with diabetes are 15–40 times more likely to lose a limb than someone without diabetes. About 1.3–7% of the world population has already undergone diabetes-related amputation and, in a year, about 0.9–2.4% will lose their limbs to diabetes [1]. Data on diabetes-related LEAs are abundant. However, comparing the results from the epidemiological studies on LEA is beset by major differences in the study population (general vs. at risk), setting (community vs hospital-based), and the definition of major and minor amputations, to mention a few. Some studies report the rates in the general population and others to report the rates in population at risk, e.g., in patients with DM.

### 3.4.1 Incidence and Prevalence of Diabetes-Related LEA

Great geographic variations exist in the rates of diabetes-related LEA and regional variations within a country are also common. In some countries, amputation rates have declined as a result of foot care initiative programs and projects. In others, either no reduction or an increase in LEA rate has been reported. A nation-wide cross-sectional data from the USA, between 2000 and 2015, has shown a resurgence of LEA after a two-decade long decline. This increase in LEA was more pronounced in men and in the younger age group [54]. Another interesting observation from the US data is the wide variation in the LEA rates between different states. It has been shown using Medicare beneficiaries data that in contiguous portions of southeast Texas, southern Oklahoma, Louisiana, Arkansas, and Mississippi have disproportionately high LEA rates. Low rates of LEA were found through contiguous portions of southern Florida, New Mexico, Arizona, and eastern Michigan [55]. This geographical clustering remained after adjusting for known confounders like age, race, socioeconomic status, access to health care, and frequency of microvascular and macrovascular complications. It is unclear as to the cause of such high variation. It is plausible that this could be due to the biological differences in the disease process itself or due to variations in the implementation of guidelines, availability of health-care resources, health-care provider training, and/or therapeutic preference or patient preference.

Data from the Canadian Institute for health information's discharge abstract database for the period between 2006–2011 shows that the average age-adjusted incidence rate of LEA among people with diabetes was 280.5 per 100,000, whereas

for people without diabetes it was 9.7 per 100,000. Quebec and British Columbia had the lowest and New Foundland and Labrador had the highest incidence rates [56]. A cross-sectional study from the Mexican social security Institute compared the diabetes-related LEA incidence between 2004 and 2013. Sadly, the amputation rates in Mexico increased from 2004 to 2013 [57]. Diabetes-related LEA rates are among the world's highest in Barbados. A prospective study conducted in 1999 for 1 year showed an incidence rate of 936 per $10^5$ patients with DM [58].

There is not much-published data from South America on the epidemiology of lower limb amputations. From 2011 to 2016, 102,056 amputation surgeries were performed in the Brazilian Unified National Health System (SUS), of which 70% occurred in individuals with diabetes mellitus [59]. Another study using the discharge data from 32 hospitals in Brazil for the period between 1985 and 2008 showed an average annual incidence rate of 30 per 100,000 inhabitants of nontraumatic amputations out of which 95% were due to DM [60]. A narrative review by Seguel, from the University of Chile, has reported that the diabetes-related LEA rates have increased by 28% from 2002 to 2006 [61]. A study from Costa Rica between 2001–2007 showed a diabetes-related incidence of amputation was 6.02 per 1000 person-years (8.65 in men and 4.50 in women) (Table 3.1) [62].

The Diabetic foot Australia reports that 12 in 100,000 general population will have diabetes-related LEA every 20 days. Regional variations do exist within Australia. Northern Territory has the highest rates of lower limb amputations, both traumatic and nontraumatic [31]. This disparity in the incidence is thought to be due to the high proportion of Indigenous population in this part of Australia, a population well known to have high incidence of type 2 DM. A clinic-based study in a tertiary care hospital in the Northern Territory showed a high amputation rate of 51.3% after a median follow-up of 5.8 years [63]. A nation-wide study in New Zealand using the Virtual Diabetes Register and the hospitalization data for the period between 2011–2014, showed an annual incidence rate of 98 per $10^5$ diabetic population of major and 152 per $10^5$ of minor. The amputation rates varied fourfold across New

**Table 3.1** Summary of the incidence data from various countries in the NAC, SACA, and Oceania regions

| Country | Year | Incidence (per $10^5$) | Population |
|---|---|---|---|
| USA [54] | 2000, 2009, 2015 | 538, 307, 462 | People with DM |
| Canada [56] | 2006–2011 | 280.5 | People with DM |
| Mexico [57] | 2004, 2013 | Major—100.9, 111.1<br>Minor—168.8, 162.5 | People with DM |
| Barbados [58] | 2000 | 936 (557 minor and 379 major) | People with DM |
| Brazil [60] | 1985–2008 | 30 | General population |
| Costa Rica [62] | 2001–2007 | 920 (360 major and 560 minor) | People with DM |
| Chile [61] | 2002, 2006 | 602 | People with DM |
| Australia [31] | 2012–2013 | 219 | General population |
| New Zealand [63] | 2010–2013 | 250 (98 major and 152 minor) | People with DM |

Some of the incidence rates shown in this table are derived from the original study to get a number equivalent to per $10^5$ population per year

Zealand the lowest observed in Waitemata (53.3 per $10^5$ major amputations) and the highest rate of 190 per $10^5$ in the Tairawhiti district health board. Ethnicity could explain a part of the variation with Tairawhiti having a higher proportion of Maoris than the national average. However, this variation is only marginally affected by other known comorbidities, which indicates that more work is needed to find out the causes of this variation, and more efforts are needed to close this gap [64].

### 3.4.2 Risk Factors for Diabetes-Related LEA

The demographic factors well known to be associated with diabetes-related LEA are age, gender, ethnicity, and socioeconomic status. Marked ethnic differences exist in the incidence of amputation. American studies suggest that LEAs are more likely to occur in African-Americans than in Caucasians. This difference cannot just be explained by differences in access to health care. Studies in Veterans with equal access to health care confirms than Native and African-Americans are at higher risk for diabetes-related LEA when compared to Caucasians, whereas Asian-Americans are at lower risk than Caucasians [65]. Similarly, in Australia Indigenous ethnicity is shown to be a risk factor for amputation [63]. Other person-specific risk factors described in literature are smoking, alcohol use, poor glycemic control, longer duration of DM, presence of other diabetes-related micro and macrovascular complications, insulin treatment, previous DFU, previous amputation, and foot deformities. The Seattle prospective diabetic foot study showed arterial disease and sensory neuropathy are the only limb specific risk factors associated with amputation [66].

## 3.5 Diabetic Foot Infections

Infections of the feet in diabetic patients can develop through DFUs, trauma, skin cracks, fissures, or other defects in the nail bed such as paronychia. The infection can either be a localized superficial skin involvement or can involve deeper skin structures beyond the site of local trauma. The different types of diabetic foot infections (DFI) include cellulitis, abscess, tendinitis, necrotizing fasciitis, septic arthritis, and osteomyelitis. The most common predisposing factor for DFI in a diabetic foot with loss of sensations is DFU. It is estimated that about 59% of DFUs are infected at presentation and infections result in multiple hospitalizations and multiple antibiotic courses, poor wound healing and increased risk of amputations, frequently systemic compromise, and increase in mortality. DFI in combination with PAD significantly increases the risk of amputations [67].

### 3.5.1 Microbial Epidemiology of Infection in Diabetic Foot Patients

The microbiology of the DFI is well studied. With various bacterial culture and molecular approaches, diverse microbiota have been reported in the DFUs/DFIs. Geographic features, patient metadata (e.g., Smoking), duration and location of

infection, and previous antibiotic use will influence the bacterial distribution in an individual patient. For example, in Western countries Gram-positive aerobic bacteria are commonly reported. In warmer climates particularly in Asia and Africa, Gram-negative bacteria are more prevalent. DFUs of shorter duration tend to have simpler microbiota mainly Gram-positive cocci (GPC) and chronic DFUs are usually polymicrobial. Aerobic bacteria are localized in the upper surfaces where the oxygen content is high and anaerobic bacteria are found in deeper infections. Globally, the most common GPC isolated form DFU is Staphylococcus and the most frequent Gram-negative rods (GNB) are from the Enterobacteriaceae family (*E. coli*, Klebsiella, Proteus, etc.). The anerobic bacteria isolated from up to 95% of deep diabetic infections are *Peptostreptococcus* spp., *Bacteroides* spp., and *Prevotella* spp. [68]. Some of the studies from the American and Australian continents are summarized in Table 3.2.

**Table 3.2** Summary of a few studies on the microbial pattern of diabetic foot infections in the American and Australian continents

| Author, year | Country, period of study | Specimen | Bacteria | Most efficient antibiotic | Antibiotic resistance |
|---|---|---|---|---|---|
| Henig et al. [69] | USA, 2018 | 77% tissue and 22% swab | 72% Polymicrobial; 57% of monomicrobial was SA | Not reported | MRSA 31.4%; 56.2% had at least 1 MDRO |
| Citron et al. [70] | USA, 2001–2004 | Tissue culture | 83% polymicrobial; SA in 76.6% and GNB in 19.7% in all cultures | Ertapenem, piperacillin-tazobactam | MRSA 11.8% |
| Sánchez-Sánchez et al. [71] | Mexico, 2011–2016 | Tissue sample | 87.3% SA in all cultures | Levofloxacin, cefalotin, and amikacin | MRSA 42% |
| Víquez-Molina et al. [72] | Costa Rica, 2014–2016 | Tissue sample | 26.6% Staphylococcus in monomicrobial cultures | Not reported | MRSA 9.2% |
| Islam et al. [73] | Trinidad and Tribago, 2011–2012 | Not available | 56.8% polymicrobial; 64.7% GNB | Ciprofloxacin and ceftazidime | MDRO 25.9%; ESBL producing 11.3% MRSA 4.5% |
| Perim et al. [74] | Brazil, 2013 | Tissue sample | 70% polymicrobial 40% GPC in all cultures | Imipenem and gentamicin for GNB | 59% MRSA, 26% of SA were vancomycin resistant |

| Author, year | Country, period of study | Specimen | Bacteria | Most efficient antibiotic | Antibiotic resistance |
|---|---|---|---|---|---|
| Kurup et al. [76] | Guyana, 2019 | Not available | 42.1% polymicrobial; 63% of all cultureswereGNB-Pseudomonas was common among GNB; SA 20% of all GPC | Not reported | MRSA 12.1% of all GPC cultures |
| Valenzuela et al. [77] | Chile, 2013–2018 | Bone culture | 26% polymicrobial; GP 68.4% of all Entercoccus faecalis is the most common GPC | Carbapenems | 44.5% of SA resistant to cefoxitin and 59% of COL SA oxacillin resistant. No vancomycin resistance. 87% of Klebsieallaand 63% of *E. coli* were ESBL producing |
| Commons et al. [78] | Australia, 2012–2013 | 67.3% were non-sterile superficial and deep swabs | 30.5% of all were SA and 20.9% were Pseudomonas | NR | MRSA 11.9% of sterile specimens |

Few studies report the proportion in all positive cultures and others report the proportion only in monomicrobial cultures. *GPC* Gram-positive cocci, *GNB* Gram-negative bacteria, *MDRO* multi-drug resistant organism, *SA Staphylococcus aureus*, *MRSA* methicillin resistant *Staphylococcus aureus*, *ESBL* extended spectrum beta-lactamase, *COL SA* coagulase negative *Staphylococcus aureus*

### 3.5.2 Diagnosis and Assessing Severity of DFI

According to existing literature, many of the noninfected DFUs receive antibiotics leading to antibiotic resistance. It is critical to diagnose an infected diabetic foot for the appropriate use of antibiotics. The diagnosis of infection should be based on the presence of at least two of the following signs: induration, perilesional erythema, hyperesthesia, tenderness, warmth, and purulent exudate. These local signs especially warmth and erythema may not manifest in severe ischemia. Other nonspecific signs are non-purulent discharge, undermining of edges, and friable discolored granulation tissue [79]. Cutaneous bulla, discolored skin, soft tissue crepitus, and fetid odor indicate necrotizing infections. The following findings support the presence of osteomyelitis which can further be confirmed by imaging [80]

- Grossly visible bone or positive probe test
- Larger Ulcers >2 $cm^2$

- Ulcers present for >1–2 weeks
- ESR >70 mm per hour

Several wound classification systems exist to assess the severity of DFI, but none are universally accepted. Meggit-Wagner, ANM-SEGAL, University of Texas, SAD, SSS, GIBBONS, PEDIS, SEWSS, WIFI classification systems combine scores for various elements of diabetic foot characteristics, such as infection, neuropathy, location, ischemia, edema, and the degree of tissue involvement. The International Working Group on the Diabetic Foot (IWGDF) recommends not to use these classification systems to decide management or to assess prognosis in an individual patient with DFU. The only classification systems which would guide to decide treatment in an individual patient are IWGDF/IDSA (Infectious Diseases Society of America) and the WIfI (Wound/Infection/Ischemia) classification in patients with PAD. The IWGDF/ISDA has four grades of severity and will assist with decisions on hospitalization for parenteral antibiotics. Where the appropriate setting is available, WiFi should be used to assess the perfusion and the likelihood of benefit from revascularisation [81]. The SINBAD system is recommended for communications between health-care professionals and for conducting regional/national/international audits to allow comparisons on the outcomes of DFU.

### 3.5.3 Antibiotic Treatment of DFI

The microbiology of DFI is diverse and multidrug-resistant organisms (MDRO) are rapidly emerging all around the world, mostly due to the inappropriate use of antibiotics. The selection of empirical antibiotic therapy is a clinical challenge and should consider MRSA, Pseudomonas, and anaerobes. A metanalysis of 16 RCTs (8 from the USA and 1 multinational study involving the USA, Canada, Latin America, and Australia) including 4158 patients concluded that (a) Piperacillin/Tazobactam was superior to Ertapenem in severe infections but similar for moderate infections; (b) Ertapenem was more effective than tigecycline for moderate to severe infections; (c) the adjuvant use of topical agents such as topical pexiganan and topical gentamycin collagen sponge with systemic antibiotics improved the outcomes, compared with systemic antibiotics alone; (d) the rate of recurrence was significantly lower with the amino-penicillin regimen, compared with those using oral/intravenous ofloxacin, and (5) lower rates of complications with the imipenem/cilastatin regimen, compared with the piperacillin/tazobactam regimen [82]. A Cochrane review in 2015 had some key results on the adverse events and could not conclude the most efficient antibiotics—(a) carbapenems combined with anti-pseudomonal agents had fewer side effects than anti-pseudomonal penicillins, (b) Tigecycline produced more adverse effects than Ertapenem ± Vancomycin, (c) Linezolid caused more harm than ampicillin-sulbactam, and (d) Daptomycin had less adverse effects than vancomycin and other semisynthetic penicillins [83].

## 3.6 Conclusion

Given the devastating effects of the diabetic foot disease on the individual and the nation, many countries have established foot care programs nationally and/or in collaboration with other countries. The EVA project involving five Andean countries—Bolivia, Ecuador, Peru, Columbia, and Venezuela, focuses on education, treatment, and care of diabetes with the primary goal to reduce and prevent diabetes-related amputations. The action plan was to educate both patients with diabetes and healthcare professionals. The Brazilian "Save the diabetic foot Project" was started in 1992 and in the first decade of its activities was successful increasing the awareness on diabetic foot screening and improving management, by setting up foot care teams throughout the country. There are unresolved problems that the project is now confronting, particularly financial barriers. The Guyana Diabetes and Foot Care Project (GDFP) was created in 2008–2013. In phase 1 Interprofessional Diabetes foot center was established at the national referral hospital, and in Phase 2 this expanded to 6 administrative regions covering 90% of the population. This intervention resulted in a 68% reduction in the rate of major amputations and this reduction sustained over 5 years. The Diabetic Foot Canada and Diabetic foot Australia are similar initiatives aiming to reduce the burden of diabetic foot complications. Even with all these initiatives and efforts, diabetic foot problems will continue to rise in pandemic proportions and we should all be well prepared to face this significant public health issue.

# Part II

# Complications and Treatments Updates

# Acute and Chronic Wound Healing Physiology

4

Ayman Fisal Ahmed Foad

## 4.1 Introduction

Diabetic patients are prone to develop wounds in the lower limbs. The predisposing factors include neuropathy, which is a common chronic complication of persistent hyperglycemia, affecting the autonomic nervous system render their skin dry, with a loss of the accommodating sweating reflex, furthermore, the sensory loss for touch and minor injuries let them a prey for repetitive injuries without adopting protective measures. The microvascular and macrovascular complications ultimately result in hemodynamics disturbances and peripheral ischemia. Immunological responses are dampened by diabetes, further enhancing the chance for deteriorating and delaying the healing of the wounds.

Wounds are defined as injury in the skin, mucus membranes, or connective tissues resulting in defects in the structure and/or the function of the organs. Skin ulcers are commonly encountered in diabetics, and they are defined as loss of the continuity of the lining epithelium, which is a stratified squamous epithelium of the dry variety, which reveals the raw surface of the underlying tissue. Ulcers cause a breach in the skin by the loss of the protective keratin, keratinocytes, and a defect in the anchoring basement membrane.

The body response and attempt to repair is dictated by the type of tissue inflicted and by local and systemic factors. The capacity of the cell in the different tissue holds different aptitudes to replicate, divide, and differentiate. The cleanest of the wounds, without foreign bodies contamination facilitating the production of biofilms of potential pathogens has the potential to heal utmost compared to dirty and contaminated wound sites. The cultivation of pathogens at the site of the wound in diabetics is augmented and fostered by hyperglycemia, and low immunity. Wound

healing is notably slower in the lower limbs compared to the scalp or upper limbs. And the closure of the wound or advised timing of removal of the surgical suture is often delayed in the lower limb wounds, this mostly attributed to density of blood supply per surface area. Personal factors have a profound impact on healing. As healing a pone fide anabolic process, the availability of nutritional components essential for building and restoration influences the tempo and the structure of the healing process. Proteins are the building blocks for repairing the damaged structure of tissue and acts as chemical messengers among other substances, governing and orchestrating the healing process, the influx of inflammatory cells, and the differentiation of stromal, endothelial, and epithelial cells. Vitamin C has a pivotal role in cross-linking of collagen fibers and fostering their tensile strength.

## 4.2 Tissue Repair

In the attempt of repair, tissue may undertake tow routes, either healing by regeneration or healing by connective tissue and scar formation. The former route constitutes the complete restitution of the morphology and the function of the injured tissue, and this encompasses a myriad of barrier and secretary functions of the skin. In healing by connective tissue, the gap is filled by the lay down of collagen by fibroblasts and a nonspecialized cell, sealing the gap and resulting in a deranged morphology and function of the skin.

The main factors dictating which repair route execution prevail are:

1. *The Capacity of the Indigenous Cells to Divide*: Epithelial tissues constituting cells are considered as labile cell, and they are constantly dividing and replicating because they are shed on the surfaces, they are in a constant state of renewal, and stem cells often found in a specific niche are capable of divergent asymmetrical replications yielding two daughter cells, one aimed for further division, replication, and differentiation and the other to preserve the stem cell line. The stem cell reserve loses its merit of replication with the advancing age of the subject due to cumulative oxidative cell membrane, organelles, and DNA damage and telomere shortening. Visceral epithelial cells (Liver) assume a dormant behavior notwithstanding they have the capacity to replicate vividly if they summoned. They stay on the side track of the cell cycle and after stimulation enter the cycle and adopt a rapid dividing profile to renovate missing cells or part of organs in a brief time has been noticed after hepatic live donor lobe donation. On the other hand, permanent cells, are terminally differentiating cells incapable of replication, once lost by the injury they are replaced by scar formation. Injury endured on labile cells in case all the other confounding factors are optimized results in a rapid and cosmetically appealing scar.
2. *The Maintenance of the Scaffolding Connective Tissue Frame***:** This constitutes the blueprint of the tissue and forms the track through which the new cells can pave and arrange to replace missing or injured cells. Without these blueprints,

there is no trace of the repair system to follow, and this results in haphazard attempts, culminating in healing by collagen deposition and scar formation.

3. *The Resolution of Inflammation at the Site of Injury*: *Mikhail Bakunin* once said "The urge to destroy is also a creative urge." Repetitive injuries create a milieu of chronic inflammation. By definition chronic inflammation constitutes three processes going simultaneously hand-by-hand; inflammation, tissue injury and loss, and a unremitting attempts of repair. The halt of this vicious cycle compels cessation of the injurious process and its resultant inflammatory process.

## 4.3 Extracellular Matrix

These are structural proteins or proteins complexed with carbohydrates.

They maintain the tensile strength of the tissues, which is mainly attained by collagen, which is imposed by cross-linking of collagen fibers resulting in bundles arranged and aligned toward lines of stress. They give the elasticity of the tissues, which is mainly mediated by elastin. Glycoproteins and mucopolysaccharides can hold water in their cervices and provide the turgor of our organs and tissues. Many growth factors are quenched within their matrices and released after tissue injury to exert their actions. Basement membrane is composed of organized fibrillar collagen anchoring the surface epithelium on one side and attached to subepithelial connective tissue framework on the other side, it provides the sense of polarity to the surface epithelium cells and prevents *anoikis*, a type of programmed cell death occurring upon detachment of the epithelial cell from its basement membrane. Fibronectin, which acts as an adhesive protein anchoring other structural proteins and quenching growth factors.

## 4.4 Cytokines [1]

The cross-talk between the cells in our body is mediated by chemical compounds. These substances mediate and orchestrate highly complexed and tightly controlled processes including housekeeping, tissue maintenance, and repair. Cytokines, growth factors, and mediators ordinarily have *hierarchical* properties; in which one factor can activate many downstream factors. They are also promiscuous in a sense that many factors can activate or culminate in activating a singular downstream effectors or pathways. Many cytokines are promiscuous, in regard they can stimulate many effectors, and they are not faithful for one downstream effector. The cytokines are either secreted in a steady level and their actions determined by tipping of the scale between pro and anti-mediators, or they been secreted only on demand and disappear after achieving their purpose. Cytokines are labile chemical compounds with a finite lifespan, and their secretion start by their release from ready-made stored vesicles with a brief and limited storage, and a subsequent induced prompt synthesis and secretion with a potentially prolonged action.

*The action of cytokines can be exerted by four means*:

(a) *A paracrine* mode of action when the cell secretes the chemical mediator, which exert its function in neighboring cells in its vicinity.
(b) *Autocrine* stimulation when cell secretes the chemical substance that is released one it is surface to bound to a surface receptor, culminating in a self-stimulation loop.
(c) *An endocrine* method in which an endocrine gland or cell secretes a chemical mediator to the bloodstream to circulate and activate distant cells, tissues, or organs.
(d) Lastly, some neurotransmitters are secreted through *synapses* to activate post-synaptic cell.

The first three aforementioned modes of stimulation act in a cascade fashion with downstream amplification and feedback mechanism, the latter, synaptic stimulation often fades and weakens with increased distance.

Cytokines and chemical mediators are classified as cell derived or plasma (liver) derived.

Plasma-derived mediators are synthesized mainly in the liver and secreted and circulate in the plasma as inactive precursors forms, which upon activation enter a cascade loop of activation and amplification. Complement component system and Hageman factor system are examples of liver-derived mediators having intricate relations with the coagulation system and with other loops of amplifications and control proteins. Cell-derived mediators are secreted from inflammatory cells in areas of injury and from quenched reserve within the connective tissue matrix. The ultimate goal of these factors is the fine-tuning of the healing process, otherwise unchecked trophic stimuli might get strayed and result in suboptimal healing or emergence of neoplastic growth.

## 4.5 Healing by Regeneration [2]

It signifies the complete restitution of the original structure and function of the injured tissue with minimum or no scarring. The healing process must endure optimal conditions to secure this option; local factors must be permissible including small wound with approximated clean edges, noninfected wound, and the absence of detritus tissue or foreign bodies. The scaffolding connective tissue framework must be maintained, as the loss of the blueprint yield chaotic infidel restoration. Cell or tissue factors also can influence this option by the regenerative capacity of the injured cells; as labile tissues fare better than stable and permanent cells. Systemic factors also influence this option, including the well-being of the patient, the control of his diabetes, and nutritional status. The healing attempt under these conditions referred by clinicians as the first intension. Optimal conditions may present de novo in the wound or optimized after medical intervention.

## 4.6 Repair with Scar Formation

This type of healing often referred to as second intention healing, and it results in a prolonged healing process, weak scar, and ugly scar (Fig. 4.1). All the aforementioned optimal conditions are not met in this case, or further appropriate interventions were not applied. Local factors controlling wound healing are many, one of the most important factors is the extend of the injury or tissue loss, considering the remaining of scaffolding structure of the tissue made by the basement membrane and tissue framework.

## 4.7 Predisposing Factors for Injuries in Diabetics (Fig. 4.2)

Glucose as a fuel providing molecules is often abundant, due to the relative insulin lacking or resistance, its surplus becomes a bacterial growth-enhancing factor rather than a tissue source of energy. The evidence supporting this notion is not conclusive yet and further researches in this matter are warranted, but some researchers found an increased incidence of surgical wound infection related to hyperglycemia [3, 4]. As the majority of diabetics presenting with DSF complications are elderly, and often share a myriad of diabetic associated macrovascular and microvascular

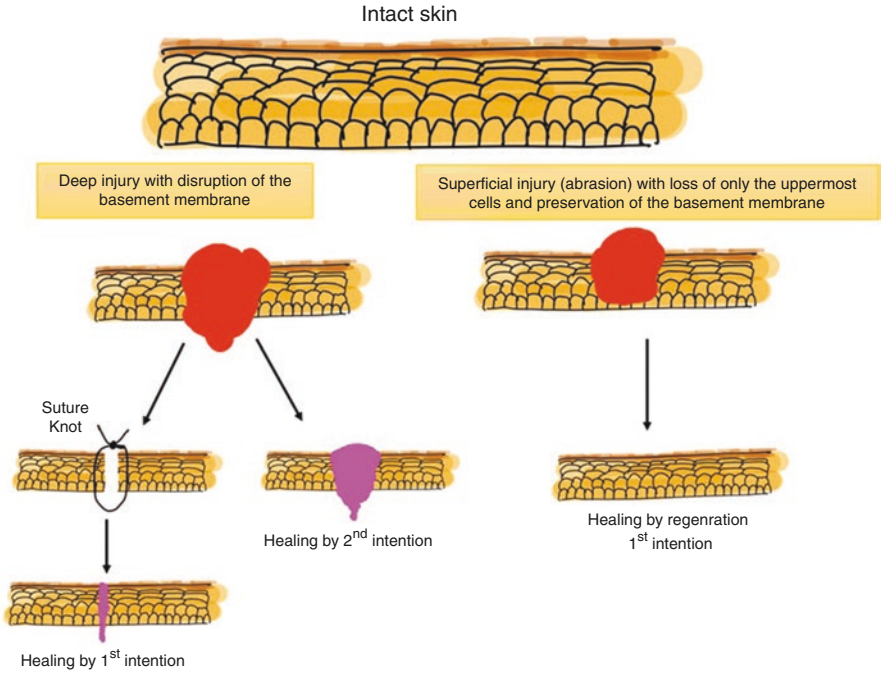

**Fig. 4.1** Healing by regeneration, the first and the second intention

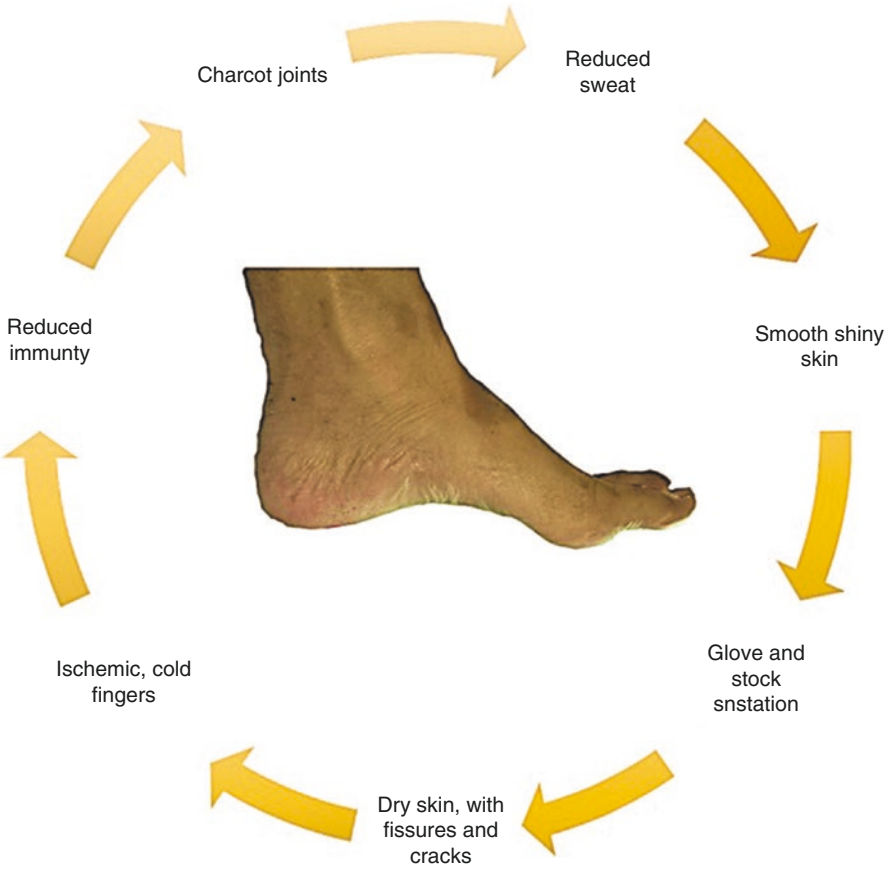

**Fig. 4.2** Factors predisposing to foot injury in diabetics

complications, many confounding factors attribute to the slackening of the healing including cell senescence of fibroblasts and the limited capacity of epithelial cells to cover tissue defects. Diabetic patients often have reduced immunity toward infections. Such infections may cause death in about 5% of diabetics. The pathogenesis beyond this is attributed to the reduced chemotactic, phagocytic, and secretory function of inflammatory cells. Macrovascular and microvascular complications also adversely affect small blood vessels, and capillary culminating in less optimal inflammatory vascular events, vasodilatation, and enhanced permeability. Diabetic retinopathy and cataract affect visual fields and acuity. This may result in repeated and inadvertent traumatic pumping of the lower limbs in furniture within the household. Diabetic patients with DSF may show comorbidities of the cardiovascular and renal system resulting in reflective hemodynamic changes in the systemic and local circulation, and a buildup of toxic levels of metabolites adversely affecting hematopoiesis and the immune system. The loss of sensory feedback imposes the lower limb to repeated trauma, and subsequent gradual injuries and tear of ligaments culminating in subluxation of small joints, malposition of bones, and loss of the normal

arches of the feet. This might result in repeated frictions and pressure ischemia of soft tissue due to unfitting shoes. These deformities lead to a condition known as Charcot joint and compel a special attention by chiropodist or at least a caring household personnel. Diabetic autonomic nervous system dysfunction may cause loss of the skin turgor, with shiny brittle dermis, loss of skin adnexa, and dryness due to lack of sweating.

## 4.8 Phases of Wound Healing [5]

1. *Inflammation Phase*: This is the response of vascularized living tissue to injury and trauma. Ischemic limb may show minimal inflammatory response and necrotic gangrenous tissue only show inflammation at the interface with viable tissue margins. The attempt of the inflammation is to remove and debride the injured areas form offending agents and to scavenge dead cells. The main effectors of inflammation are to display a cellular response with an influx of a myriad of inflammatory cells through the blood vessel portal, which also facilitates edema formation.
2. *Proliferative Phase: and This Is Comprised*:
   (a) *Angiogenesis*: In acute inflammation, the vascular response comprises dilatation and hyperemia at the arterial end and increased permeability at the venular end of the vascular bed. In persistent and chronic inflammation, the continuous injury, inflammation, and attempt to repair go hand-by-hand simultaneously. This necessitates the formation and sprouting of new blood vessels to provide fuel and nutrients and building blocks for the repair process (Fig. 4.3).

   The process of angiogenesis in diabetics is dampened and not optimal, due to microvascular and microvacuolar complications usually encountered in long-standing diabetes and metabolic syndrome. After the injury, the defect of lost or crushed tissue will be filled by inflammatory cells and protein-rich exudation. Proteins dry on the surface and form a scab, which is a coagulated serum on the surface of the wound, and usually overlies a raw granular oozy surface. If the injured epidermis is overlined by a necrotic layer of tissue, an eschar is formed, which can be pearly white and pale in case of ischemia necrosis, or black/black brown in case of vascularized tissue. Circumferential eschar can some time act as napkin-ring or as a plaster which can induce compartment syndrome and impede blood flow to the distal part of the limb, causing Volkmann contracture or necrosis; escharotomy may resolve this issue [6].
   (b) *Collagen Formation*: As the wound mature granulation tissue is formed, which is composed of immature leaky blood vessels within edematous stroma rich in proteins and newly formed extracellular matrix with a plethora of inflammatory cells.
   (c) *Epithelization*: Epithelial cells from the base of the epidermis of flanking skin edges start to form a monolayer from the edges to cover the gap, and as they reach the mid-line and seal the gap they activate a contact inhibition

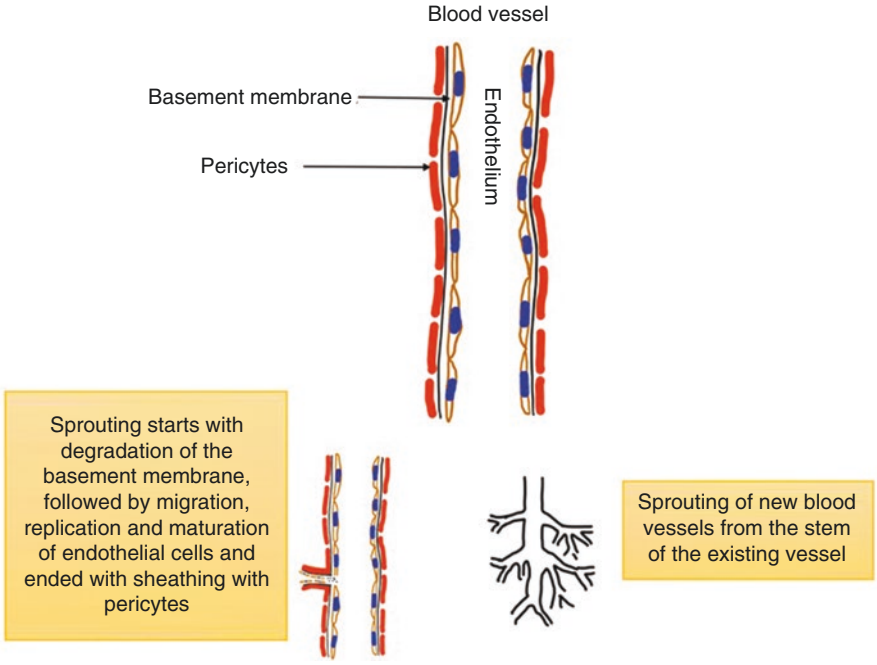

**Fig. 4.3** Angiogenesis is a step of paramount importance in healing

program, a merit of normal non-neoplastic cells, they stop dividing and start a vertical maturation step. This is mediated by the APC β-catenin pathway, in which β-catenin is located in sub-membranous location associated with E-cadherin, a transmembrane protein which functions as an adhesive structure linked in homodimer fashion with adjacent cell proteins. Some times in case of repetitive trauma an exuberant granulation tissue is formed protruding as a hill above the horizontal level of the wound plane, which impedes the union of the epithelial cells coming from the edges of the wound, the term proud flesh is applied to this condition, mimicking the lordotic posture of a proud person. In this case, the epithelial cell should climb up the protuberance of the granulation tissue to meat at the summit.

3. *Maturation Phase*: This is a continuous process. The color of the scar fades from cherry red to pale pink to white as it matures and ages with a more organized matrix and more mature blood vessel surrounded by a dual layer of endothelial and pericyte.

## 4.9 Timing Sequences of Skin Wound Healing

1. *Blood clot (scab)*: its purpose is to stanch the bleeding and provides a matrix rich in growth factors and chemokines. It is formed within 24 h, and neutrophils are noticed crouching from the margins.
2. *Granulation tissue*: starts to develop 1–2 days (peaking at 5–7 days), and is composed of proliferating fibroblasts and endothelium (vascularized loose CT). The

vessels are leaky leading to extravasation of proteins and fluids and creating edema. It provides a framework for subsequent scar formation and continues remodeling.
3. *Cell proliferation and collagen deposition*: primes within 2–4 days after wounding, and neutrophils are largely replaced by macrophages. The granulation tissue scaffolding is converted into a scar (fibroblasts and collagen).
4. *Scar formation*: *starts* 2 weeks with sequential collagen deposition and gradual fading of the vasculature. The red granulation tissue is converted into a relatively avascular scar with a reduction of the inflammatory cells and marching of the epithelial cells to seal the gap.
5. *Wound contraction***:** of larger wounds, proceed with the dominance of myofibroblasts having combined features of fibroblasts with laying downing of collagen, and smooth muscle contractile features causing wound contracture culminating in reduction the surface of the wound.
6. *Tensile strength***:** within 1 week is 10% of the initial strength of the healthy tissue, and increases gradually with advanced bundling and alignment of the collagen fibers towards the line of stress reaching about 70–80% of the initial strength within 3–4 months.

## 4.10 Complications of Wounds in Diabetics

1. *Venous leg ulcers (congested)*: occur in elderly people with chronic venous hypertension (severe varicose veins or congestive heart failure). It fails to heal because of the poor delivery of oxygen to the site of the ulcer.
2. *Arterial ulcers (pale)*: atherosclerosis, Ischemia → atrophy, and necrosis of the skin and underlying tissues (painful).
3. *Neurotrophic ulcers*: found at sites under mechanical pressure, and characteristically appear as friable punched out ulcers surrounded with dry scaly skin [7].
4. *Pressure sores (Decubitus ulcer)*: mechanical pressure and local ischemia pose a dramatic impact in wound healing; this leads to a vicious circle of partial healing and repeated injuries. Protection and guarding against it is more attenable than healing.
5. *Atrophic scar* this leads to a very scant and weak connective tissue lay down, rendering the injured tissue a prey for repeated trauma and dehiscence, which can be brought upon by trivial trauma.
6. *Hypertrophic scar*: this results from excessive scar tissue confined to the edges of the wound. Adversely this may cause ugly big protruding scar and contracture of the skin.
7. *Keloid formation*: this occurs with racial predisposition noticed in black ethnicity. The healing is characterized by exuberant scar formation which is not confined to the edges of the wound.
8. *Wound contracture* occurs if a large area of fibrotic tissue is crossing a joint, this might restrict the full range of joint movement. This is usually anticipated if the wound left to heal under low tension on the relaxed flexed position of the joint.

## 4.11 Factors Influencing Wound Healing [8]

1. *Site of the wound*, it is noticeable that skin injuries in head and neck heals faster than torso, abdomen, and lower limb injury in a descendant order. This is credited to the density of blood supply per surface area in the corresponding tissues.
2. *Type of the tissue*: determine the outcome of the healing process. Labile continuously dividing cells are capable of continuous division and can replace the lost and injured tissues as long as other confounding factors are controlled. Stable tissues have a lesser potential for division. On the other hand, permanent cells or tissue are incapable of division, and cell death is only replaced by fibrosis.
3. *Amount of lost tissue*: small superficial tissue with minimal loss of cells has the potential to heal optimally compared to big wounds with large gaps. With a proper surgical intervention, healing can be augmented.
4. *General condition of the patient*: the presence comorbidities, such as critical atherosclerosis, ischemic heart disease, and heart failure among others, which are frequently encountered in long-lasting and poorly controlled diabetes may adversely interfere or delay healing.
5. *Nutritional status*: well-fed subjects replenished with nutrients, essential minerals and vitamin fare better than starved or deficient subjects. Vitamin D is required for the optimization of almost all steps of cutaneous wound healing [9], nonetheless, vitamin C is also required for the cross-linking of collagen bundles the building blocks of scar tissue. Diabetic patients often are deficient in micronutrient and this may interfere with proper wound healing process [10].
6. *Steroid use* retards the process of wound healing, the administration of dexamethasone in postoperatively increase morbidity and delay wound healing [11]. Glucocorticoids slow the healing and dampen the strength and the abundance of collagen fibers. Researchers found the excess glucocorticoids in patients with *Cushing* syndrome reduces the level of heat shock proteins in wounds, this results in a consequent reduction in angiogenesis and resultant delayed healing [12].
7. *Direction of the wound*: if injuries run parallel to the *Langer* lines, they heal with an esthetically minimal scar compared with injuries running perpendicular to these lines.
8. *Age*: wounds in young individuals or patients with short-lasting diabetes, characteristically have a good and prompt wound healing compared with elderly, long-lasting diabetes, and poorly controlled diabetes [13]. Some researchers argue that the healing in elderlies is merely delayed but the end results are almost the same [14]. There are both undisputable evidence supporting that skin of the geriatric population has both morphological features of skin atrophy and reduction of physiological qualities with advanced aging [15].
9. *Racial factor* also may influence the healing of wounds, as an example, patients with the black ethnic background may have a higher tendency to develop keloids, exuberant scar tissue often exceeds the limit of the wound lead to disfiguring ugly scars [16].

10. *Infection*: can adversely sluggish wound healing as clean wound fares better than, contaminated, dirty, and infected wounds.
11. *Foreign body*: debridement of wounds and removal of contaminants and foreign bodies foster the speed of wound healing.
12. *Genetics*: polymorphism in genes controlling inflammatory response have a slightly deranged healing process. Mutations of structural proteins present with the noticeably delayed healing process.

## 4.12 Muscle, Tendon and Bone Healing

1. *Skeletal muscular tissues* are incapable of dividing and is usually replaced by connective tissues. If severe infection spread and induce a systemic inflammatory response syndrome, skeletal muscles (not necessary at the site of injury) may undergo a waxy coagulative necrosis pattern known as *Zenker's* degeneration.
2. *Tendons* have a capacity of healing and should be optimally kept under tension to reduce contracture and restriction of joint movement.
3. *Bone* has a virtuous capacity to heal, and if infected this capacity is noticeably hindered. Treatment of infection and removal of dead sequestrum hasten healing, on the other hand, the persistence of infection with resurging draining sinuses may be almost sturdy to healing. Diabetic patients may suffer from stubborn bone injuries and delayed union of bone fragments, there are noticeable reduced osteoblastic activity and increased apoptosis especially with accompanied infections. The growth factors controlling the healing process are scarce in the milieu of diabetic ulcers including bone morphogenetic protein and tumor necrosis factor (BMP, TNF) [17, 18].

## 4.13 Gangrene

Diabetic patient develops as a consequence of progressive macroangiopathy and microangiopathy a broad spectrum of potential complications. Gangrene is an atrocious known concern of poorly controlled diabetics. It is a consequence of vascular, neural, and immunological dysfunctions often encountered in diabetic patients. The term originates from the Latin root *gangraena*, which literally means "an eating or gnawing sore." This a special type of cell death is due to peripheral ischemia owed to vascular comprise [7].

1. *Dry gangrene* is a type of gangrene characterized by changes in skin color from shades of redness and blackness with a subsequent tissue breakdown and putrefaction of protein contents resulting in a foul odor [19]. Inflammation only occurs at the margin of the living tissue, manifesting the cardinal signs of inflammation; redness, swelling, hotness, pain (which may be dampened as a result of peripheral neuropathy), and loss of function. Systemic manifestations develop as a response of the body to injury manifesting as fever, anorexia, nau-

sea, and fatigue. Dead tissue falls off spontaneously, with unnoticeable minor trauma, or by surgical debridement [20]. There are no signs of infections at the site of the injury.
2. *Wet gangrene* ensues with secondary bacterial infections, noticeable with pockets of pus and weeping wounds. This poses a more serious impact on the health of the subject and warrants an urgent surgical and medical intervention. Septicemia and septic shock are a frightful complication.
3. *Gas gangrene* on the other hand results from infection with *Clostridium perfringens*, a gram-positive spore-forming bacilli, with a resultant myonecrosis, the spread of infection through tissue plains and liberation of toxins into the bloodstream. Grossly the wound is crepitus upon palpation and shows bubbles and air-filled bullae.

## 4.14 Classification of Diabetic Wounds [21]

Classification systems help to triage patients for suitable clinical care and follow-up. A score also services as a fast-universal way to describe the wound, and alarms for deterioration or assures in case of improvement.

There are multiple widely used classification systems for diabetic wounds, nevertheless, the widely used systems in clinical practice are *Wagner* (Fig. 4.4) and of the *University of Texas* systems.

1. *Wagner system*: in this system, there are 5 grades, grade-0 indicates an intact skin in a diabetic patient, grade-1 signifies the presence of a superficial wound involving the epidermis, dermis, or down to the subcutaneous tissues, grade-2 designates deep extension of the wound to the tendons, underlying bone or a joint

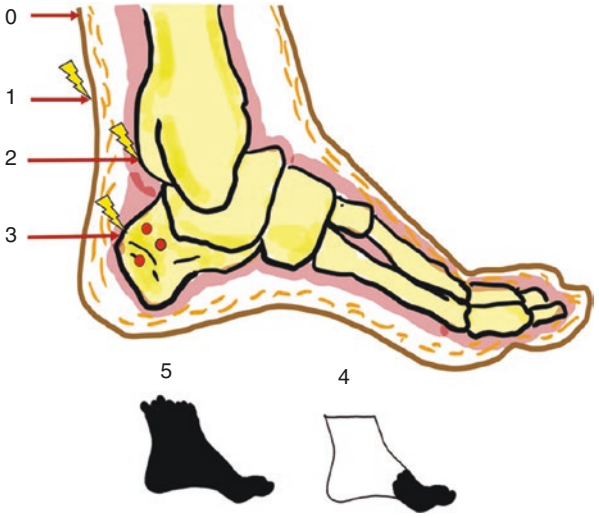

**Fig. 4.4** Wagner classification of diabetic wounds, 0 = intact skin, 1 = epidermal, dermal and subcutaneous tissues, 2 = extension to tendons, muscle, capsule, and bone, 3 = 2+ infection (abscess or osteomyelitis), 4 = partial gangrene, 5 = extensive gangrene

capsule, grade-3 indicates grade-2 lesions with a superimposed infection of the bone or a localized suppurative inflammation, while grade-4 and 5 reserved for partial or extensive gangrene of the foot [22].

2. *University of Texas system*: is a combined system in which stages and grades the wound. Grading of the wound starts with grad-0 for intact skin or a healed remote wound in diabetic patients, grade-1 indicates a superficial cutaneous wound, grade-2 describes a deep wound affecting muscle, tendons, or a joint capsule, grade-3 denotes an extensive wound penetrating the underlying bone or reaching a joint cavity. The staging system of wounds classifies them according to ischemia and infection as follows; stage-A for clean wounds, stage-B for infected wound without peripheral ischemia, stage-C for ischemic clean noninfected wound, and stage-D for infected wounds with ischemia [22].

# 5 Screening of Foot Inflammation in Diabetic Patients by Noninvasive Imaging Modalities

Hyder O. Mirghani

## 5.1 Introduction

Diabetic foot problems (DFP) are common disabling syndromes. DFP is on the rise due to increasing age and high body mass index. DFP is costly, and with a tendency for recurrence. Diabetic foot syndrome which is characterized by high morbidity and mortality is defined as an ulcer of the foot of diabetic patients distal to the malleoli associated with diabetes-related complications. There are several classifications of DFS with some integrating infections [1, 2]. The diabetic septic foot is a component of DFP where infections are categorized as mild, moderate, and severe [3]. Foot inflammation includes osteomyelitis, joint infections, rheumatological diseases, and tenosynovitis. The diagnosis of foot inflammation remains a great challenge particularly in diabetic septic foot and when degenerative diseases are present, mainly due to the overlap between different components (neuropathy, and neuropathic arthropathy). The role of clinical and conventional imaging in the diagnosis of the diabetic septic foot may be limited due to accuracy. The musculoskeletal manifestation of diabetes mellitus including diabetic septic foot become an important focus of diagnostic and therapeutic procedures. Many imaging modalities are in use including plain radiography and to some extent ultrasonography (U/S), computed tomography (CT), and magnetic resonance imaging (MRI). Being a large issue in radiologic units serving other medical departments, musculoskeletal imaging influences further management of patients with diabetes in many aspects. However, it is not always possible to draw a fully reliable unequivocal interpretation in particular for diabetic septic foot [4, 5]. Differentiating soft tissue infections from osseous infection is vital to determine the appropriate therapeutic course. Radiographs are the initially recommended methods of evaluation that can provide

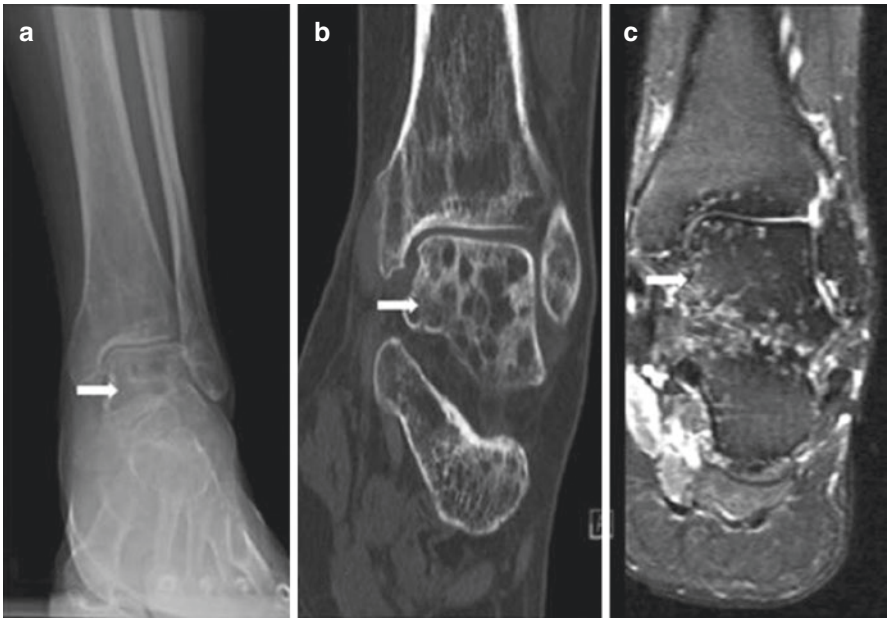

**Fig. 5.1** Plain radiograph, CT, and MRI: A 53-year-old diabetic presenting with pain in the left ankle: AP radiograph (**a**) and the corresponding coronal reformatted CT image (**b**) showing patchy lucencies predominantly in the talus (arrow), also in the distal tibia and fibula. MR image (STIR coronal) (**c**) also demonstrates patchy juxta articular heterogenous signal intensities (arrow) in the talus. This was diagnosed as reflex sympathetic dystrophy. *AP* anteroposterior, *STIR* short tau inversion-recovery [26]

anatomic features and guiding the subsequent mode of imaging, however, they are not often diagnostic of osteomyelitis [6]. A great qualitative leap had been achieved since the introduction of morphologic magnetic resonance (MRI) imaging**.** MRI can differentiate between soft tissue and bone marrow edema. However, the application may be difficult due to the co-existence of infection and neuropathy [7]. A very interesting and promising is the introduction of electromagnetic simulation (EMS) as a noninvasive diagnostic approach. EMS can predict and diagnose peripheral vascular disease with great accuracy than Doppler studies and ankle-brachial index in terms of the extent and site of vessel involvement [8]. In the current chapter, non-invasive imaging of inflammation (mainly thermography, radiography, U/S, CT, MRI, and nuclear studies) regarding diabetic septic foot was discussed (Fig. 5.1).

## 5.2 Skin Temperature and Thermography

### 5.2.1 Skin Temperature Recording

Temperature monitoring of the foot has been used in the prevention of diabetic foot ulcers because abnormal skin temperature distribution can indicate ulcer risk. Skin temperature had been shown to correlate with peripheral neuropathy.

Randomized controlled trials with low risk of bias concluded the effectiveness of daily measurement of feet skin temperature in the prevention of foot ulcers [9]. Many devices are used to measure skin temperature including wearable temperature sensors at certain areas of the sole with alarm signals provided to the user. The temperature data collected can be displayed to the user, sent to other devices, or stored for future use [10]. It is interesting to note that wireless socks are found to be effective, reliable, and accurate in the contiguous measurement of foot skin temperature, the patients found them not different from standard socks [11]. Infrared cameras are a quick, fast, inexpensive, and noncontact tool for assessing skin temperature [12]. A cohort study conducted among patients with diabetic neuropathy and followed for foot ulcers after assessing the difference in temperature between the feet. The temperature was measured by an infrared thermometer, the authors found >2·2 °C difference in feet temperature for impending ulceration is not valid as single measurement, however, validity improves when confirmed the following day and further improves with individual correction [13]. Skin temperature measurement was found to be feasible when combined with the educational component and counseling of patients with foot ulcers [14].

### 5.2.2 Thermography (Thermal Imaging)

Thermographic (thermal imaging) patterns showed various variations between patients with diabetes mellitus and their counterparts without the diseases and can be used for assessing the circulatory status [15]. Furthermore, thermography could be useful for screening of foot ulcers with osteomyelitis [16], A relatively recent cohort with three arms (neuroischemic foot with ulcer, neuroischemic without ulcer, and controls without neuroischemia or ulcers) found that skin temperature was higher among patients with neuroischemia with or without ulceration, no statistically significant difference was observed between neuroischemic feet indicating that the ono-ulcerated feet are of risk of ulcers that can be predicted by thermography [17].

### 5.2.3 Plain Radiographs of the Feet

Due to the presence of deep fascia in the feet, the absence of pain due to neuropathy, and minimal inflammation rubor, it is not easy to assess diabetic septic on the clinical ground especially puncture wounds. Plain X-rays could be of great help. A radiograph is usually ordered first, an excellent overview of structural damage, previous surgery, and neuropathic arthropathy [18, 19]. However, the role of X-ray may be limited due to inaccuracy [5]. Imaging that answered specific questions including ultrasonography and computed tomography will be discussed in the following section (Fig. 5.2).

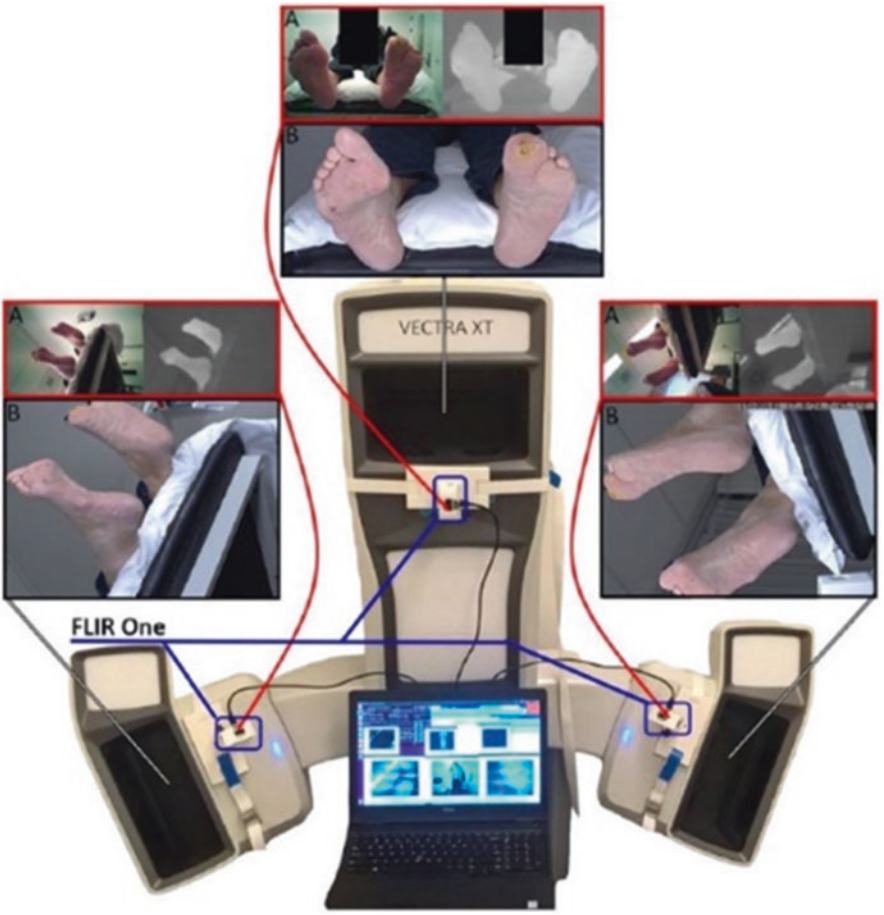

**Fig. 5.2** Imaging setup. In the middle the Vectra XT, 3D imaging system can be seen (white). On the inner side of every viewpoint of the 3D imaging system, a FLIR One IR camera was attached (blue indicator), and connected to the laptop in front of the 3D imaging system. (A) Above each viewpoint the resulting 2D images are provided. On top, framed in red, the two images from the IR camera are shown (left: color image; right: thermal IR image in grayscale). (B) Bottom image, framed in black, is the texture map from the 3D image system [33]

### 5.2.4 Ultrasonography of the Feet

Ultrasonography is easily accessible and helpful for an accurate diagnosis. U/S is helpful in infectious diseases including cellulitis, pyomyositis, tenosynovitis, septic arthritis, and necrotizing fasciitis. The sonographic features include cobblestoning, air collection, abscesses, hyper, or hypoechoic changes. Color Doppler scans help to differentiate infectious from noninfectious causes. U/S is not good in osteomyelitis discrimination and neuropathic osteodystrophy, however, it can guide fluid aspiration for further evaluation. Imaging findings that showed ulcers, sinuses, abscesses,

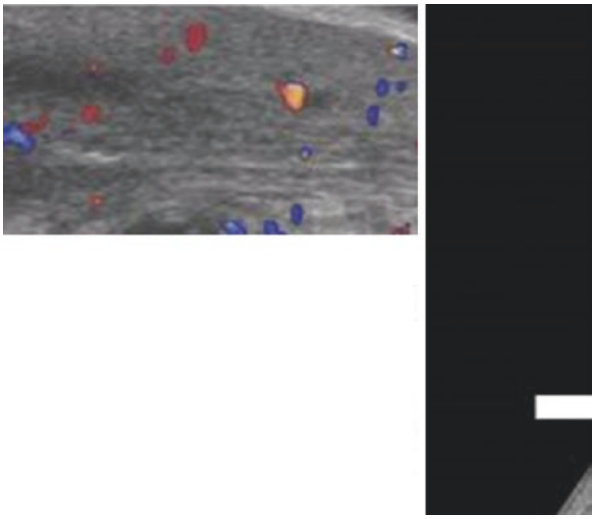

**Fig. 5.3** Transverse color Doppler sonography. *MRI*: The imaging of choice (90% and 83% sensitivity and specificity, respectively) for diabetic septic foot including osteomyelitis and soft tissue infections

or cellulitis favor septic foot rather than osteodystrophy. X-Ray and MRI are other complementary tools [20] (Fig. 5.3).

*The sensitivity and specificity are shown as follows* [21]:

- Bone marrow edema (100% sensitivity and 90% specificity when occurred with tenosynovitis)
- Soft tissue swelling (85.7% sensitivity), soft tissue destruction sensitivity, and specificity (57.1% and 42.9%, respectively)
- Bone destruction (sensitivity of 14.3% and a specificity of 10%)
- Tenosynovitis (55% sensitivity and 50%specificity)

Short tau inversion-recovery (STIR) T2 weighted is the most sensitive modality, MRI can differentiate between osteomyelitis and neuropathic joints. Diabetic Charcot neuroarthropathy (DCN) is a great challenge to both radiologists and the treating physicians, especially in its early stages. In early DCN, the plaint radiographs may not detect osseous fragmentation or dislocation [21, 22], diffusion-weighted MR imaging (with short imaging time and not requiring contrast) are also helpful in differentiation of diabetic osteoarthropathy from osteomyelitis. Recent advances in MR imaging can provide functional quantitative information in addition to structural information, dynamic contrast imaging may detect differences in between the vascularization patterns of neuropathic arthropathy and osteomyelitis. MR angiography and MR neuropathy are discussed elsewhere in this book [23–25]. Also, periarticular and subchondral predilection, multiple bone and joint involvement, the absence of ulcers and sinus tracts, and intact overlying skin, favor the diagnosis of Charcot's neuropathic joint rather than osteomyelitis. Intraarticular loose bodies are also less in neuropathic joints. MR studies help differentiate viable

**Fig. 5.4** Sagittal enhanced T1-weighted fat-suppressed image shows subcutaneous fluid collection with rim-like enhancement

from non-viable tissue directing surgery. Furthermore, it helps detect loculated infections after the failure of joint aspiration and for post-surgery follow-up. Pitfalls of MRI include noninfectious inflammatory conditions including gout, fracture, and neoplasm [19]. Radiographs are insensitive and take 7–15 days to show periostitis and cortical destruction [26].

*NB*: Sixty-one percent of patients with diabetic foot who initially showed T2 marrow signal abnormality (osteitis) are eventually diagnosed as osteomyelitis and deserve aggressive therapy [27] (Fig. 5.4).

### 5.2.5 Computed Tomography (CT)

CT scan is helpful in the diagnosis of soft tissue infections and osteomyelitis (together with sulfur colloid and leucocyte scan) in particular if an MRI scan is contraindicated or extensive artifact from metal is present [6]. Newer hybrid imaging techniques (SPECT/CT, PET/CT, and positron emission tomography/magnetic resonance imaging) are useful techniques [28]. PET/CT with fluorine-18-fluorodeoxyglucose-labeled autologous leukocytes was shown to sensitive (83.3%)

and specific (100%) for the diagnosis of diabetic foot infection complicated by Charcot's neuroarthropathy compared to CEMRI (83.3% and 63.6% respectively) [29].

## 5.3 Radionuclide Procedures

The radiolabeled leukocytes with either $^{99m}$Tc-HMPAO or $^{111}$In-oxine are the standard when osteomyelitis is suspected, it gives 95% accuracy and allowed the differentiation of soft infection. SPECT/CT is mandatory in addition to plantar images to determine the exact location and extent of infection. Radiolabeled non-colloid and white blood cells of bone marrow may differentiate osteomyelitis from Charcot neuroarthropathy and osteomyelitis [30].

## 5.4 Infections of the Feet

Foot infection among patients with diabetes is even more challenging, a reliable and unequivocal answer is not always possible [3]. A multidisciplinary approach is the art of the task to diagnose and follow infection. Infection is defined as the presence of two signs of inflammation or purulence as is classified as follows [31]:

- Superficial: limited in size and depth
- Moderate: deeper or more extensive
- Severe: accompanied by systemic signs or metabolic perturbations

Imaging plays a major role, plain radiographs are the usual initial approach. MRI is the imaging of choice, computed tomography, positron emission tomography, and single-photon emission (SPECT)/CT are increasingly used with different radiotracers [32].

## 5.5 Conclusion

Diabetic foot inflammation can be challenging in terms of diagnosis and thus management, in particular when Charcot osteoarthropathy, infections, fracture, other noninfectious inflammatory disorders including gouty arthritis, and neoplasm. Early diagnosis is vital for the early introduction of a specific therapy. MRI, especially STIR, diffusion-weighted, and dynamic contrast imaging are the modalities of choice for both inflammation and infections. Plain radiographs are the initial investigation providing anatomic and structural features. Computed tomography and ultrasonography are used for special purposes and when magnetic resonance imaging is contraindicated or not sensitive and specific (bone marrow or soft tissue destruction). Radionuclide scans are not in common use due to cost and they are not readily available. Thermography is quick, cheap, and sensitive when available.

# Molecular Mechanism and Biomechanics of the Diabetic Foot: The Road to Foot Ulceration and Healing

6

Mohammad Zubair and Farha Fatima

## 6.1 Introduction

Diabetes Mellitus (DM) is often the most complex disease that is almost vulnerable to all the body organs. Around 415 million individuals are usually affected through diabetes mellitus and most of them are due to the adverse effect of type 2 DM. it is further predicted that by the year 2040, a significant growth is about to take place, as almost 642 million people are detected at the high risks of the given disease is the near future [1]. Since the problem majorly affect the overall human body, there are greater chances among patients for increased impact in the form of diabetic foot ulcer (DFU). It was further regarded that among the overall patients suffering through DM, almost 15% of them are at high risks of DFU. Chronic diseases, recurrence, or the formation of various highly effective diseases are the most popular problems of DFU and are powerful enough to affect the patient's mind. The prevalence of the disease is often found among diabetic patients with ulcers. Researchers suggested that the majority of the amputations are often connected to diabetes mellitus (DM), since the disease weakens the overall body functions of the affected patient. However, the prevalence of the disease in its increased forms often results in morbidity and mortality of the human body.

Diabetic Foot Ulcer (DFC) is defined as the foot affected through the ulceration and is related to the diseases belonging to the neuropathy and peripheral arterial diseases commonly located in the lower limbs of the diabetic patients [2]. The problem is directly associated with neuropathy, infection, and ischemia. Patients who have poor control over diabetes mellitus are usually at the risk of foot ulceration leading toward unfavorable consequences including the poor metabolism of wound

healing along with the increasing risk of infection. The competitive metabolism of the associated patients is often integrated through the decreasing growth of body cells and angiogenesis. It is further associated with the low levels of peripheral blood flow leading toward the damage of the peripheral nerves followed by ulcerations, deformation, vascular diseases, and gangrene. DFU is often regarded as the disease that is connected to the increased financial load over patients who are willing to undergo quality treatment. Clinical experts suggested that the prevention of the disease is possible and is often manageable through early diagnosis, followed by preventive measures and quality treatment through a multidisciplinary professionals and clinical experts associated with the given disease [3]. Since diabetes is detected as one of the growing diseases, it is potentially able to affect other important organs of the human body. The growth of the disease often leads to the disruption and damage of important body parts leading toward severe results. In many cases, the foot is the major affected part of the human body that is specifically found among patients with uncontrolled diabetes.

Significant growth has been observed in the prevalence of disease under certain individuals. It was further regarded that the prevalence of foot ulcers is expected to occur among 9.1–26.1 million individuals suffering from diabetes. The approximation regarding the given disease is provided on an annual basis. Studies further suggested that the proportion of the diseases, i.e., diabetes and foot ulcerations have been high in the past, however, similar consistency has been observed regarding the development of the disease in present. The proportion of the individuals suffering from foot ulcerations due to diabetes has been high than those suffering from active ulcers. The development of this lifetime disease among diabetic individuals has been observed among 15–25% patients [4]. In Indonesia, the given problem has been documented among patients between 17–32%, along with the overall proportion of amputation which is up to 30%. The survival rate of such patients has been observed with an increased limit, i.e., up to 37% in the following years [5].

Another huge concern is often regarded as different complications associated with the problem, which serves as the greatest cause of posing different threats to the economy and public health. The development of diabetes is associated to obesity which in most severe conditions leads toward the formation of chronic DFU and impaired healing of foot wounds. Researchers suggested that the number of diabetic patients is likely to increase up to 366 million till 2030, followed by the diabetic epidemic diseases. Diabetic patients are often exposed to different diseases including the bony wound infections, loss of soft tissues, increased cardiovascular diseases, low levels of extreme amputations, and in most complex and severe cases it leads toward patient's death. The most common problem associated with the disease includes the lifetime probabilities of ulcerations, where almost 25% of diabetic individuals are likely to have neuropathic foot ulcerations leading toward amputations [6].

One of the famous physicians of diabetes suggested that diabetic foot ulcer is not a natural disease, rather it is formed due to external and internal body conditions. This suggests that foot ulceration is not the entire consequence of diabetes rather it

serves as the consequence to the unfavorable contact of environmental risks and pathological developments of the lower limb [7].

## 6.2 Probability of Infections in Nonphysiological Inflammatory Responses

Most of the chronic foot ulcers are usually found in the inflammatory cycle that is often integrated through the development of the granulation tissues. However, the long-term inflammation in the inflammatory phase contributes to the increased defects found in the microcellular defects that ultimately reduce the probabilities of wound recovery [8]. Hyperglycemia usually contributes to decreasing the efficiency of the inflammatory responses, this is due to the altered functions in lymphocytes, neutrophils, and macrophages with reduced phagocytic and cytotoxic abilities [9, 10]. Majorly, the alterations in the cell activities are due to the reduced pressure of the local oxygen, as the impaired processes often contributes to the maximum consumption of oxygen. When considering the wound infections in foot, it has been developed that such incidence is most common and evident among patients with diabetic ulcers rather than those in chronic wounds. This imitates the reduced function of leukocytes. Also, the compression and physical stress leads toward the increase in the loading of local bacteria [11]. In cases where lies a narcotic tissue, there is a greater probability of the rapid increase in the formation of a wide number of microorganisms. It was further indicated that there lies a smooth relationship between the number of local bacteria found in the wounded part and the speed of wound healing. For instance, a single gram of tissue consists of the 105 bacteria then there is an increased probability of the minimum levels of tissue repairs. However, the decreased number of bacteria, i.e., up to 103, usually results in the development of β streptococci in hemolytic. Therefore, in order to cater the increased load of bacteria, it is expected to have an increase in the overall proportion of the lymphocytes mainly belonging to CD4-CD8 ratios. In specific cases, a significant decrease has been detected in this type of relationship, which is followed by the increased number of CD8 cells and a reduction in the total number of CD4 cells. This further suggests that CD8 plays an active role in reducing the healing process of wounds among diabetic individuals. Evidences found through various studies further indicated that the following cells are responsible for the changes in tissue repairs.

Another form of inflammatory response is usually integrated through the increased levels of the oxidative stress that shares a causal linkage between oxidative stress and hyperglycemia, leading toward the major health-related complications and cell damages among diabetic patients. This oxidative stress is generated through several mechanisms such as, Vitamin C, oxygen-free radicals, protein kinase C, and hexosamine pathways [8]. The transfer of the most powerful antioxidant or ascorbic acid is mostly held through the intervention of hyperglycemia. The overall process takes place in fibroblasts and the emplastic. The reachability of the hyperglycemia is often restricted through glycose, due to the similarity found in

both the structures. The activation of nicotinamide adenine dinucleotide phosphate (NADPH), which is a type of enzyme that helps in increasing the activities in the oxidative stress followed by the increase in PKC, and the depletion of NADPH. The effects are significant in increasing the development of the radicals free from oxidation, with reduced synthesis of the glutathione and nitric acid. Moreover, the increased glucose concentrations result in the saturation of the hexokinase enzymes in the glycolytic routes. This results in ceasing the activity of utilizing the altered route of degradation. Finally, the formation of hyperglycemia is undertaken through the intervention of sorbitol and the use of NADPH, which apparently decreases the concentration of the last substance [12].

Diabetes is further characterized through the increased activity of the hexosamine biosynthetic routes, which refers to a qualitative alteration of NADH into NADPH, which is possible due to the obstruction of the glyceraldehyde 6 phosphate dehydrogenase. Concerning the cases where the identification of disease is still not understood, a significant increase is observed in different activities of xanthine oxidase, NADPH oxidase, and arachidonic acid cascade. Among the given elements, superoxide is the only element that is potentially strong in reacting with nitric oxide to form peroxynitrite, which may convert in nitrogen peroxide through the intervention of superoxide dismutase. In the given process, nitrogen peroxide is often used in the formation of the hydroxyl radicals that are integrated through the ferrous and cuprous ions. The biodiversity of vasodilators is often reduced or limited by the superoxide anion through its reaction of nitric oxide. Titanium peroxide then helps in the perpetuation of the premature apoptosis and inflammation of cells that produce matrix. In the final phase, the interaction of the hydroxyl radicals and lipids, proteins, and DNA help in promoting conditions that include, dementia, atherosclerosis, and the reperfusion of injury [13].

## 6.3 Amputation Impaired Response to Infection Diabetic Foot Ulceration

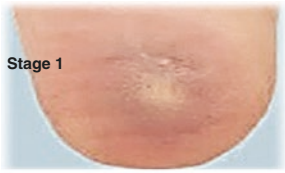
The impact of the growing diabetes problem is however evident through the development and growth in different problems including renal failure (final stage), blindness, minimum extremity amputations, and other permanent disabilities leading toward death. The problem has caused a significant increase in mortality and morbidity of diabetic patients. The most highlighted and outlined effect of the disease is in the form of diabetic foot ulcer, where every 10–25% of patients suffer through the given problem [14]. Foot ulcers are also characterized as the major cause of patient's hospitalization leading toward several financial, social, and health-related consequences [15, 16]. The uncontrolled glycemic control along with foot ulcers also serves as the fundamental factor for limb amputations and further serves as the major consequence of the patient's death [17] (Fig. 6.1).

A significant association has been found between rate of mortality and the amputation among patients with the hemoglobin level of <0.0001 [18]. Infections taking place among diabetic patients such as, peripheral arterial disease is one of the major causes of amputation that usually take place among the old age diabetic population.

**Fig. 6.1** Foot Amputation: Nonfunctional foot with underlying osteomyelitis successfully treated with transmetatarsal amputation and percutaneous tendon Achilles lengthening with 6-month follow-up (note lack of callus or recurrent ulceration). (Adapted from Ref. [86])

The problem has been studied by various scholars, as for instance; in Argentina. Sereday et al. [19] conducted a study by collecting data from 11 different hospitals. Findings of this study indicated that the amputation rate was common among diabetic patients. Besides, the infection was also identified as the fundamental cause of amputation along with the risks of peripheral arterial disease. The rate of amputation varies from country to country. As in Brazil only, Rezende et al. [20] found high rate of amputation, i.e., up to 47.7%. Similar, ratio was identified in Guiana, where before the development of structured national program for diabetes, the rate of amputation was approximately 42% which then decreased due to the increased awareness programs in the given region [18]. The amputation rate in Portugal was up to 5.8%. This was mostly found in the outpatient.

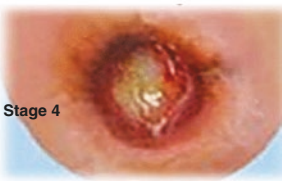
Since infections serve as the most common complication among diabetic patients and are highly associated with diseases such as; peripheral arterial disease and neuropathy, it is important for clinicians to have necessary knowledge regarding the severity of the infection. The idea is crucial as it may assist medical experts in providing the correct treatment to the affected patient. Figure 6.2 below provides important knowledge regarding the identification of infection in patients with diabetic foot ulcers at different stages.



**Stage 1 Non-infected:** no sign of inflammation

**Stage 2 Lenient infection:**
a) Feel pain, cellulitis and hardening of soft tissue.
b) Infection not reached to bones

**Stage 3 Moderate infection:**
a) Cellulitis is near to ulcer with ≥2cm.
b) Infection spread under sheet of connective tissue
c) Reaches to deep muscles, tendon and bones



**Stage 4 Grave infection:**
a) Local toxicity and systemic is prominent like hypotension, azotaemia, abnormal blood count and fever

**Fig. 6.2** Identification of different stages of infection. (Adapted and modified with license no. 4813661460709 from [88])

Most of the diabetic patients experience severe ulceration along with an active infection. The extent of the area that is being affected as a result of infection determines the type of disease management required by the patient. A necrotic lesion found in diabetic foot ulcers when acted by an infection lead toward the formation of wet gangrene. However, in most of cases where infections reach the final stages, the only option left for the treatment is amputation, which is also referred to as unsalvageable foot. Amputations occurring at any part of the foot increase the probability of infection and amputation in the remaining part of foot and thus require more critical care. Desormais et al. [21] in their study found that anemia is also highly associated to amputation resulting in patient's death. This usually happens due to the insufficient delivery of oxygen to the affected area, leading toward poor control of growing infection in diabetic patients [22].

## 6.4 Diabetic Foot Ulcerations and Risk Factors

Several risk factors have been associated with the prevalence of foot ulcers among diabetic patients leading toward the development and exposition of disease toward major threats.

### 6.4.1 Smoking

One of the most common risk factors associated with the given disease is smoking. According to the study conducted by Obaid and Eljedi [23], smoking is majorly associated with the diabetic foot ulcers. This is due to the toxic smoke that is inhaled

during the process resulting in the hypoxia of body tissues that may cause several neuropathic and vascular disorders among patients with lower extremity of diabetes. Researchers suggested that cigarette smoking serves as one of the greatest causes that contributes to the worsening of diabetic neuropathy, which is a type of diabetic foot ulcerations. Oxidative stress produced by smoking creates adverse effects on diabetic individuals. It is further identified as an independent factor that is critical to the development of diabetic neuropathy [24]. The stimulation of the oxidative stress in various organs, including; the blood vessels and the nervous system results in severe damages in the cellular area. One important reason is the supplement of free radicals of oxygen in the human body, which is due to the presence of cigarette smoke [25].

The evidences gathered through in vivo and in vitro indicate the availability of the glycotoxins in the smoke released by the cigarette. These glycotoxins are considerably reactive in the formation of the advanced end products of the glycation (AGE). These end products are located outside the cell [26, 27]. In various smokers, the modification of lipids and proteins leads toward the incorporation of various receptors in order to develop the advanced end products glycation which ultimately results in the activation of the nicotinamide adenine dinucleotide phosphate oxidase (NADPO). The process further includes the induction of oxidative stress through the manifestation of the inflammatory chemokines and cytokines. The excessive development of the reactive oxygen species by the infusion of cigarette smoke leads toward the development of the nitric oxide synthase that increases the stress over glutamate leading toward the influx of $Ca^{2+}$. It further results in the dysfunction of mitochondria, inflammation, and the damage of the deoxyribonucleic acid [28, 29].

In addition, smoke caused by the cigarette develops a sense of resistance to insulin which apparently worsens neuropathy. Studies suggested that secretion of the insulin is at greater risks among smokers. The following conditions can only be catered through the development of maximum resistance to cigarette smoke resulting in the development of high insulin receptors such as the substrate-1ser$^{636}$ phosphorylation.

The effects of cigarette smoking are not only limited to the formation of foot ulcerations among patients, rather it acts as one of the most prominent causes of delayed wound healing. The developments in the given area of knowledge suggested that smoking is mainly associated in producing the higher incidence of the postsurgical complexities. Whereas, ceasing smoking before 3 weeks of surgery reduces the probabilities of impaired wound healing and the rate of postsurgical morbidity is further decreased with a significance fall from 52% to 18%. This suggests that the cessation of smoking is effective in healing severe foot wounds among diabetics. Studies resulted in providing low-level evidences regarding the impact of smoking cessation in minimizing the risks of leg amputations and lesions among those with poor glycemic controls. However, studies suggested that quitting smoking before a certain duration of surgery helps in decreasing the chances of postoperative morbidity [30], which signifies the value of smoke cessation in increasing the chances of improvement in wound healing during the postoperative conditions.

Patients with controlled smoking contributes to reversing the consequences of the lack of oxygen and oxidative stress within human body.

Several clinical developments have been undertaken to develop smoke cessation with maximum probabilities of success among diabetic individuals. These therapies are in the form of bupropion, behavioral interventions, varenicline, and nicotine replacement therapy along with the induction of electronic cigarettes [31].

### 6.4.2 Obesity

Another common risk factor associated with the disease is obesity. Pham et al. [32] through detailed research suggested that diabetic foot ulcers are often related to obesity. While other researchers suggested that BMI ratios have no significant relationship with the prevalence of diabetic foot ulcer. Patients with diabetic foot ulcerations usually have low levels of BMI ranging from 25 kg to 30 kg/m$^2$. Since only few data is available regarding the significance of obesity in causing foot ulceration, therefore it may consider as one of the risks associated with the given problem. Another crucial information in similar cases indicated that the prevalence of the problem is more common among males in comparison to females. The reason includes the increased involvement of males toward the physical activities [33]. Obesity is further characterized as the cause of increasing the risks regarding the development of the peripheral neuropathy that does not depend on the level of glucose control. It also serves as an important source of affecting the small and large fibers in the human body, where large fibers are known to be highly impacted through hyperglycemia [34]. People suffering from both diabetes and obesity are more prone toward the risks of the peripheral developments of neuropathy. This indirectly exerts a greater significance over the idea of controlling both body weight and type 2 diabetes.

Individuals that lack the ability of undergoing through physical activities are more toward the development of obesity, leading toward other hazardous health risks. Contemporary developments in knowledge suggested that people that are least habitual of walking are at the minimal risks of undergoing through foot ulceration, in contrast to those who are more active and practice walking exercises. However, modern studies indicated that people that are not habitual of daily walking are at higher risks of foot ulceration [35]. The most amazing development in this regard initiated that people that undergo a variety of daily activities are at high risks regarding the development of foot ulceration. The idea is crucial here, as people that are not much habitual of undergoing through any such activity must be warned regarding the instant functionality of body in the form of increased variability in everyday activities. Since obesity is responsible for exerting the additional stress over the affected foot, controlled body weight may help in balancing the body forces that are exerted both at the ankle and foot of the affected individuals. The detailed analysis of the idea was developed through case-controlled study that was conducted. Ross et al. [36], according to which no significant association was detected between the increased BMI and the development of critical Charcot neuropathy among the diabetic patients.

### 6.4.3 Immunopathy

According to researchers, the immune system of diabetic patients is much weaker in comparison to those of healthy patients. Foot infection among diabetic patients contributes in weakening body functions that pose various threats on the appropriate functioning of limbs. Patients with uncontrolled diabetes generally cause the increased production of the pro-inflammatory cytokines leading toward inappropriate cell functions including phagocytosis, chemotaxis, intracellular, and phagocytosis killing. The immune system is further affected through the decreased functions of leukocytes, along with the destruction of cellular immunity [1]. Patients with poor glycemic controls usually have significantly low levels of leukocyte phagocytosis, while the development and increase in microbiocidal functions are directly related to the controlled hyperglycemia. Wound healing among individuals with normal glycemic controls is usually held through the low levels of chemotaxis and their impact on cytokines and growth factors followed by the expansion in metalloproteinases. In conditions where diabetic patients are affected through an open wound, a catabolic state is formed in the body of the affected person. The ineffective balance of nitrogen leads toward the lack of insulin. This is due to the breakdown of proteins also known as gluconeogenesis.

The dysfunctions in metabolisms are often followed by the impairment of different fibroblasts, collagens, and proteins that results in the lack of nutrition. Researches however suggested that the impairment of the diseases is mainly held in cases where the serum level of the glucose in the human body is usually decreased or is equal to the 150 ml/dl. High blood glucose serves as an immunity for the growth of bacteria including β-hemolytic streptococci, positive gram aerobic bacteria, etc. in human body. Other common organisms that are identified by the researchers include negative gram aerobes that are commonly found in the foot of the affected patients. Furthermore, it was developed that the soft tissues of foot, muscle sheaths, tendons, etc. are ineffective in resisting the development of the infection within foot. Since certain parts of foot are interconnected therefore the transfer of infection from one place to another is often impossible in most of the cases, leading toward the development of the osteitis. In most of the cases where necessary care is not provided toward the foot ulcers, the results are in the form of development of various complications including the gangrene.

### 6.4.4 Unbalance Between Metabolism and Nutrient Delivery

In most of the diabetic patients, the abnormal diabetic is mostly due to the low concentration levels of ATP (adenosine triphosphate) along with high concentration of lactate and glucose. Among diabetic, the low levels of wound healing are also due to the increased concentration of cellular metabolism, macrophages, fibroblasts along with other leukocytes. In other conditions, the insufficient concentration of the growth factors found in the diabetic ulcers promotes a significant decrease in growth factors including; PDGF, insulin-1 (IGF-), fibroblast growth factor (FGF),

Osteopontine, transforming factor-β1 in growth, TGF-β1, interleukin-8, and -10. It further contributes in the supra regulation of TNF-α, Il-1 and angiopoietin-21 [37]. The delay of angiogenesis is regulated with the low level of osteopontine along with the increased concentration of the angiopoietin-2, where the first contributes to the continuation of the process and latter restricts it.

A recent development suggested that micro RNA serves as an important contributor in the identification of the pathological developments of foot wounds among diabetic patients. In a physiological perspective, the precursor of the micro RNA, when evolved through the enzyme dicer is converted to the micro RNA, that functions in providing the translations of the RNA messengers [37]. A considerable change in the cellular gene expression has been observed with a significant decrease in the dicer enzymes among the diabetic group of rants. It was further observed that the biological mechanisms are highly impactful in decreasing the concentration of the keratinocyte proliferations among diabetic users. The expression of the micro RNA is integrated through the hypoxia-1α inducing factor, i.e., HIF-1 α, which serves as an important factor in promoting diabetes. This in turn provides the encoding of gene E2F3 transcription which helps in the provision of the keratinocytes. Finally, the increase in HIF-1α helps in the concentration of the proliferation of keratinocyte.

## 6.5 Altered Biomechanics in Diabetic Foot

Biomechanics serves as the basic art of implementing the rules and scientific laws that are associated with different fields of learning such as the architecture, engineering, physics, and mechanics that are usually applied to the living subjects. The committed practitioners of the present day, including those belonging to the Functional Lower Extremity Biomechanics (FLEB) have managed to conduct such interpersonal practices by implementing their abundant knowledge, professional experience followed by the use of technological devices that may contribute in providing the Evidence-based practice of Biomechanics [37, 38].

When discussing the biomechanics of the foot, it can be characterized into the functional segments following two fundamental ways. Following the first part, i.e., the Midtarsal joint it is divided into the forefoot and the rearfoot. While, latter divides the foot into second and the third rays reaching toward the medial and the lateral arch segments (as indicated in Fig. 6.3). The medial arch comprised talus, calcaneus, navicular, and talus along with the three cuneiforms and with three different metatarsals. Calcaneus, cuboids along with fourth and fifth metatarsals contributes to the development of the lateral arch. Both arches are further connected through transverse roof surface of the bone which is also known as the vault of the foot. The efficiency of vault in bearing heavyweights and related functioning is due to the support of healthy soft tissues that makes it compatible with the lifetime functioning [39]. Whereas, in cases where vault works in an off-centered position, it poses different challenges such as the excess in flexibility, arch, stiffness, or collapsing leading toward the excessive burden over postural

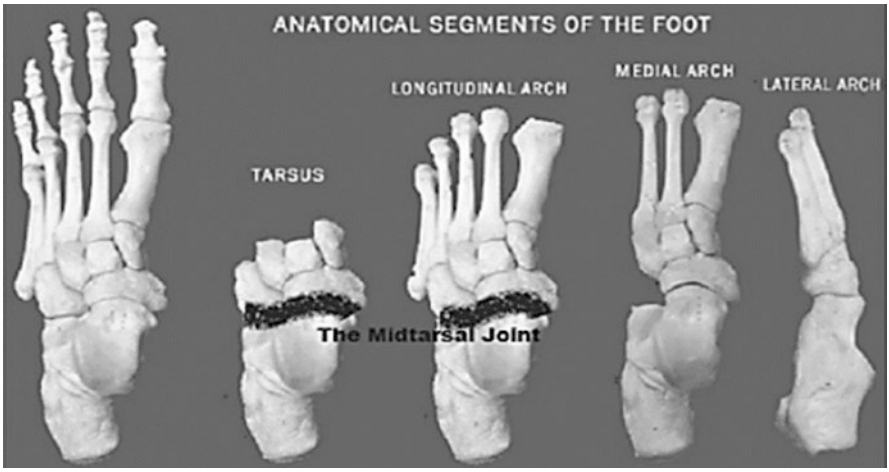


**Fig. 6.3** Anatomical structure of the foot. (Adapted from Ref. [39])

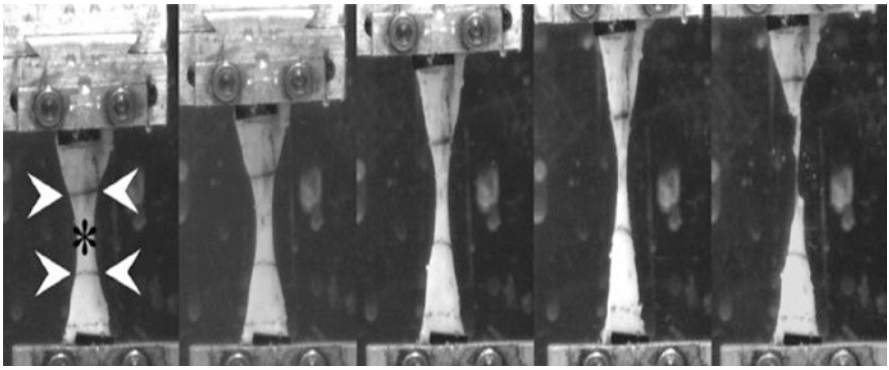

**Fig. 6.4** Biomechanical testing of skin in Diabetic foot. (Adapted from Ref. [89])

and pedal bones, muscles, joints, tendons, integumentary organs, and ligaments. Among patients with diabetic foot ulcerations, several risks have been highlighted that are responsible toward altered biomechanics of the foot (Fig. 6.4). The overall situation is intervened through the loss of protective sensation (LOPS), peripheral arterial disease, and the loss of proprioception. The risk factors are however significant in maximizing the chances of the altered foot biomechanism and are highly connected in the form of the chained process leading toward the uncertain foot conditions. Certain important biomechanical risks have been outlined that are commonly found among diabetic patients. The factors include, ground reactive conditions and forces, stiff or hard shoes, the central elements of the biomechanical pathology, weight and mass of the diabetic individual, activity and the fitness level along with the state of health.

### 6.5.1 Contributing Factors to Altered Biomechanics in Diabetic Foot

Most of the deformities found in diabetic patients are held due to the altered foot biomechanics. Hyperglycemia causes the glycosylation of the connective tissues aggravates the hyper pronation of the foot, which ultimately increases the forefoot pressure over gait and stance [40]. Several causes have been identified that contributes to the development of the diabetic foot mechanism.

#### 6.5.1.1 Diabetic Neuropathy

Neuropathy is often related to the loss of sensation that is majorly found among 20% of diabetic individuals. The problem is often encountered among patients suffering from type 2 diabetes and serve as the accommodating factor in developing a foot ulcer. Neuropathy or peripheral neuropathy serves as the loss of impairment of normal body functions related to the nervous system and is often related to the weakening of sensory, motor, and autonomic functions in diabetic patients. The prevalence of neuropathy among diabetic patients is comparatively high ranging from 16% to 66% [1].

The problem is mostly caused among diabetic patients resulting in the damage of various nerves found in the human body. However, in most of the patients, the problem is not visible through symptoms. While in others, signs such as chronic pain, numbness, tingling, loss of feeling at multiple body parts including, hands, legs, and feet are commonly associated with the presence of diabetic neuropathy. It has been estimated that approximately 60–70% of diabetic patients form neuropathy to a certain extent, where risks increase by the time with the gradual increase in the age of the affected patient. The most common signs of diabetic neuropathy are visible among those who had been suffering from diabetes for more than 25 years. Besides, it is also found among patients who have uncontrolled sugar and glucose level, and are overweighed [41].

#### 6.5.1.2 Peripheral Neuropathy

Peripheral neuropathy acts as the fundamental causative factor for the altered biomechanics of the diabetic foot ulcer [32]. There lies a significant gap in the presence of normal protective and the proprioceptive abilities among patients with diabetic foot, and the given functions are almost absent by the time disease develops visible progress. Following this, peripheral neuropathy serves as the direct contributor for the inability of individuals in managing accommodation to the ground reactive forces and also acts as the fundamental source of joint subluxation. Since the diabetic foot works to make useful adjustments in the sensory feedback caused by gait. This feedback however is interrupted as a result of the development of peripheral neuropathy. For instance; in a standing position, the person managed to make minor adjustments by creating a balance through the body and the foot [42]. This helps in minimizing the prolonged pressure in any particular part of the body. Therefore, it can be inferred that peripheral neuropathy significantly contributes to increases the

chances of problems during ambulation. Several causes have been identified that participate in the development of peripheral neuropathy. Some of them include, toxic exposures, excessive use of medicines, systemic disease, hereditary disorders, and other body infections. However, the most common causes that are easily controlled include; hypothyroidism, diabetes, and nutritional deficiency.

Peripheral neuropathy is also identified as one of the most common factors that contributes to the development of long-term complications specifically for diabetic neuropathy. It was further analyzed that almost 40% of patients suffering from type 2 diabetes show significant signs of neuropathy.

#### 6.5.1.3 Peripheral Motor Neuropathy

Peripheral motor neuropathy is similar to that of the abnormality in the gait functions which will be discussed in the proceeding sections. Motor neuropathy is associated with developing the alterations in the anatomical structures of the foot and joint, which ultimately causes weakness and damage in the small intrinsic muscles. This leads toward the imbalance in movement causing muscle damage, followed by other significant characteristics including; plantar flexion taking place at the metatarsal head and clawing of toes.

#### 6.5.1.4 Autonomic Neuropathy

Autonomic Neuropathy (AN) is commonly associated with the long-term occurrence of the diabetic mellitus. In most of the cases that are associated with lower probabilities of DM, AN result in the arteriovenous shunting leading toward the development of distension in the foot veins along with the dilation of the small arteries. Neuropathic edema is potentially strong enough to create different obstacles, hindering the treatment process of the diuretic therapy. Patients suffering through neuropathic experience swelling in feet, along with a sudden change in the body temperature.

Autonomic neuropathy further contributes to decreasing the autonomic nerve roots that are responsible for innervating the skin glands specifically responsible for sweating while involving the appendage tissue that ultimately causes dryness in the skin and low elasticity levels. This specifically takes place in the middle third region of the leg, where discoloration of the region takes place. The following conditions contributes to the formation of deep cracks on the downward region of the feet, resulting in the development of frequent injuries specifically among diabetic patients. The dryness occurring in the skin when forms a serious condition, develops the skin fissures that may ultimately cause infection proceeding toward the development of mild ulceration in diabetic feet.

### 6.5.2 Structural Foot Deformity

Restricted joint mobility, foot amputation, along with other structural foot deformities creates a significant impact on the diabetic patients who have problems associated with peripheral neuropathy, ranging from areas with increased pressure,

ineffective weight bearing, along with abnormal obstruction of forces contributes in posing the maximum risks of ulcerations. Among diabetic patients, the structural deformity of the foot is highly associated with the decreased joint mobility. Nonenzymatic glycosylation that is found in the periarticular soft tissues exposes significant risk in the form of limited or reduced joint motion. The conditions are mainly common among diabetic patients with significant signs of neuropathy, resulting in the intrinsic musculature through atrophy that may cause hammering of different digits [43].

The reduction in motion then limits the ability of the foot in providing support to the ambulatory ground reactive forces which ultimately increases the plantar pressures. However, limited or reduced joint mobility is referred to as the hallux ability to bear the 50° of non-weight passive dorsiflexion [44]. In addition, glycosylation is potentially strong in affecting the resiliency factor in the Achilles tendon that pulls the foot toward the equinus, while potentially increasing the risk probabilities for foot ulcerations among diabetic patients. Therefore, to provide effective treatment, clinicians need to undertake the structural abnormalities among different patients. These structural abnormalities however include reduced joint mobility, claw toes, calluses, and bunions, along with flat feet that are significant in the identification of different pressure points on the foot that is susceptible to the future developments of the ulceration [45].

### 6.5.3 Gait Dysfunction

Gait refers to the way a person walks (Fig. 6.5). Whereas, abnormal gait or gait dysfunction refers to the type of abnormality that is specifically associated with the abnormality in walking and thus takes place when the human body is unable to

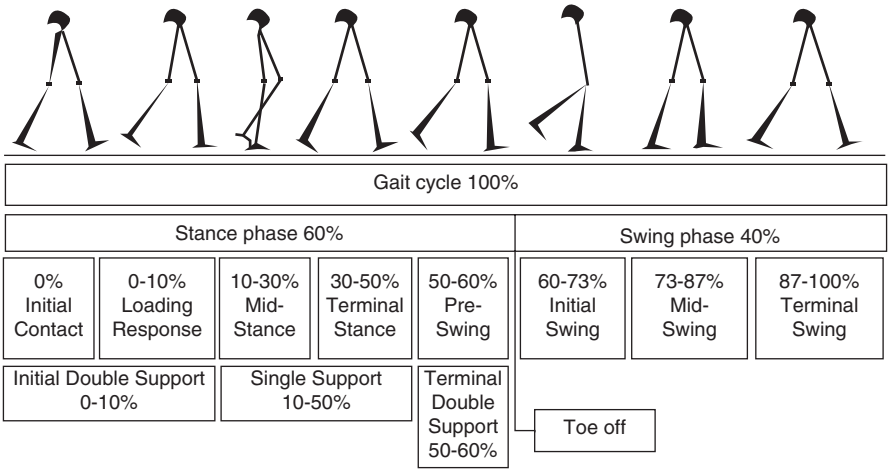

**Fig. 6.5** Normal gait cycle source. (Adapted under license no. 4810900954855 from Ref. [90])

function in the usual manner. Factors such as; genetic characteristics, illness, injury, or any sort of abnormality associated with human leg or feet serve as the fundamental cause of gait abnormality. In certain cases, gait abnormalities are controlled by the time, while in other cases this acts as a permanent lifestyle.

The identification of the neurological disorders that are highly associated with developing changes in the human balance, posture, and gait functioning has been an important part of the clinical practice. The most foremost type of gait disability is significant in posing a substantial disability in completing the overall movement or the gait cycles. One of the most significant symptoms includes the occurrence of frequent falls creating prominent obstructions in walking smoothly. This is apparently connected to the development of injury, as a consequence where an individual fails to manage the recurrent falls. Another common issue associated with the gait includes the freeing of gait that acts as the fundamental cause of patient's fall that specifically takes place among those suffering from Parkinson disease (PD). In the given case, patient feels a sudden freeze of the leg while attempting to move forward [46, 47]. However, in most of the cases associated with gait disorders, the signs of the posture and balance are highly visible leading toward the early diagnosis of the disease.

Gait abnormality such as the asymmetrical reduced arm swing is the earliest symptom found among patients with PD [48, 49]. Foot injuries that commonly takes place among patients while walking are the consequences of gait occurrence during the normal walk. Diabetic patients tend to fall due to high risks of impaired vision, hypoglycemia along with the increased occurrence of the abnormal gait.

Normal gait functioning is interlinked to the individual ability of maintaining the safe gait, while acting effectively in the changing environments and in conditions that demand different gait functioning. The quality of an individual in maintaining the gait functioning is significantly associated with the person's ability of performing the everyday tasks in an independent manner while minimizing the risks of falling [50]. Diabetic patients due to internal weakness tend to take smaller steps while walking which actually demands an additional support [51]. Among various factors such as aging, psychological factors are also of fundamental importance in managing and influencing one's gait pattern. Patients suffering through peripheral neuropathy and diabetes mellitus are more toward gait instability [52].

Two common phases of gait, i.e., swing and stance serve as the essential components of ambulation. The swing phase is associated with the non-weight-bearing location where the foot is set free to move forward. Whereas, the stance phase takes place when the heel is in contact with the floor and ends with by lifting off the toes. Considering this, the stance phase takes place when limb bears the entire weight of the body. The foot is found to be more flexible during the stance phase of the gait, which allows it to absorb and bear the overall shock.

The extrinsic and intrinsic mobility plays an important role in managing the foot biomechanics among diabetic patients. Structural changes are further important that eventually takes place among diabetic patients. This is followed by the structural changes that take place within the capsule, ligament, and tendon of the diabetic patients followed by the disorganized patterns at the following places [53]. The changes are

important as they lead toward reduced tensile strength and elasticity which ultimately result in the development of stiffness and subluxations in the foot. The overall changes occurring in the foot leads toward the altered biomechanics of foot [54].

In normal conditions, abnormal gait is characterized into different types depending upon the appearance and symptoms proposed by the individual walk. The first includes the spastic gait, which is in the form of dragging one's feet. This usually occurs when one is really stiff in managing the normal walk resulting in feet dragging.

Another type includes scissors gait, where the person tends to hit his/her legs during normal walking. This is due to the inward bending of one's leg which makes him/her unable to enjoy the normal work. Third type includes the steppage gait, this occurs in cases where an individual's toes are pointed toward the surface of the grounds. This type of movement usually takes while walking.

Waddling gait is another type of gait abnormality. A person suffering through this type of walking abnormality usually take each step from side to side. It is further held by undertaking short steps and involuntary body movement, i.e., body swinging. This type of problem is usually diagnosed through different imaging techniques to identify the type or the location of the injury, damages in body tissues, or broken or weaken bones of the affected person. Despite the treatment, the problem cannot be cured to the fullest.

### 6.5.4 Limited Joint Mobility

Limited Joint Mobility (also referred to as cheiroarthropathy) is a frequently inserted disease among ten diabetic patients. The disease is characterized based on its tendency to limit the mobility of the patients, particularly the joints. Other common characteristics associated with it include thickening of the skin as well as waxiness mostly for the fingers dorsal surface; however, the changes in the skin may also appear when the mobility is not restricted [55]. A proper definition of the limited joint mobility is difficult to gain consensus upon; however, the general idea is it causing finger joints nonpainful contracture. The most common and significant complication resulting from it is diabetic foot ulcer which is considered to be a major economic, social as well as medical burden globally. The occurrence of foot ulcers among diabetic patients accounts for almost 25% and is generally associated with limb amputation. Limited joint mobility is categorized as one of the major risk factors leading to the development of diabetic foot ulceration. Fernando et al. [56] showed that limited joint mobility leads to foot ulcers as it substantially damages tissue at the subtalar joint by exerting abnormal pressures at the susceptible sites.

The prevalence of limited joint mobility for diabetic patients is found to account for 8–58% [55]. The variation in this percentage is based on the population, and the way the mobility among the patients is measured. Studies have emphasized that substantial care must be practiced when the mobility of different parts is being examined to avoid any confusion resulting from other diabetic problems. The incidence of limited joint mobility is found for both type 1 diabetic patients as well as

type 2 diabetic patients [55]. The risk of developing limited joint mobility is linked to the increase in the value of glycated hemoglobin (A1C) as well as the length of the prevalence of diabetics, though, it may emerge at the early stage. Smoking and age are categorized as other risk factors for the emergence of limited joint mobility among diabetic patients.

#### 6.5.4.1 Classification

Over the years, the classification of the foot ulcer has emerged, though, none has been accepted at a universal level [57]. The classification of the foot ulcer as per Wagner-Meggitt is mainly based on the depth of the wound, which comprises of six grades of the wound [58]. These grades are intact skin, superficial ulcer, deep ulcer to the tendon, joint or bone, deep ulcer with osteomyelitis or abscess, forefoot gangrene, and last whole foot gangrene, ranging from 1 to 6, respectively. Similarly, the treatment method of limited joint mobility differs from the intensity of the disease. However, generally, strict diabetes control is recommended to any such patient.

## 6.6 Causal Pathways to Foot Ulcerations

Different causes have been identified that serve as the fundamental pathways of foot ulcers. The first and the most significant cause include Diabetic Peripheral Neuropathy (DPN), which refers to different symptoms associated with the problems of the nervous system and diabetes mellitus. Boulton et al. [59] in their study provided the most common definition of diabetes mellitus, which states that "DPN refers to different symptoms that are caused due to the dysfunction of the peripheral nervous system among patients suffering from diabetes mellitus. These symptoms are studied by excluding other causes. In Western regions, peripheral neuropathy is further identified as the most commonly growing complication that are found among 50% patients with diabetic mellitus. The problem however is considered the most common type of peripheral neuropathy found in the given region. The most significant and commonly found diabetic neuropathies include symmetrical, distal, and sensorimotor neuropathy.

Diabetic neuropathy is further associated with the autonomic nervous system, while during the development of foot ulcers among diabetic patients' sympathetic peripheral autonomic neuropathy of lower limb is implied. DPN can be characterized through several symptoms depending upon the severity of the disease. The most extreme form of the disease involves symptoms where a high level of pain penetrates through the disease following various other problematic symptoms. These symptoms are in the form of different nociceptive that is usually in the form of pain held as a result of severe burning or fall from the height. The following symptoms have been presented by various diabetic patients who were attending clinical assistance as a result of severe inflammation, shooting pain, or even stabbing, freezing sensations along with minor but constant ache. Most of such patients experienced severe pain at night [60]. The symptoms however may vary from time to time and gradually take place. Shakiness or instability while standing is another

important sign of DPN among patients with diabetes mellitus leading toward sensory dysfunction and subsequent variations taking place in motor response. Patient's unsteadiness in most of the severe cases leads toward trips and sudden falls, developing its association with severe depression [61].

Another cause of foot ulcer is the occurrence of several microvascular complications that are associated with patients' poor vision. The following symptoms take place as a consequence of diabetic retinopathy that is the most common predictor of developing foot ulcers among diabetic patient. In addition, patients who have undergone through dialysis treatment are more toward the development of foot ulcerations [62]. Furthermore, a direct association between dialysis and foot ulceration has been identified. The factor is crucial and serves as an independent risk factor for developing pathways for diabetic foot ulcerations [63].

Trauma serves as another major cause of developing foot ulcerations among patients. In various patients' trauma may occur as a consequence of the high pressure exerted on the affected foot, the presence of any foreign body inside the shoe, or due to an ill-fitting shoe. In most of the western regions, unfitting footwears serve as the most common cause of trauma leading toward the development of foot ulcers. A detailed analysis of pathways for foot ulceration is provided in Fig. 6.6.

## 6.7 Diagnosis of Foot Ulcerations

The detailed examination of the feet may help in the identification of the disease. Risks of foot ulcers are generally detected through the screening of the peripheral and neuropathy arterial diseases. Patients undergoing through the given disease are

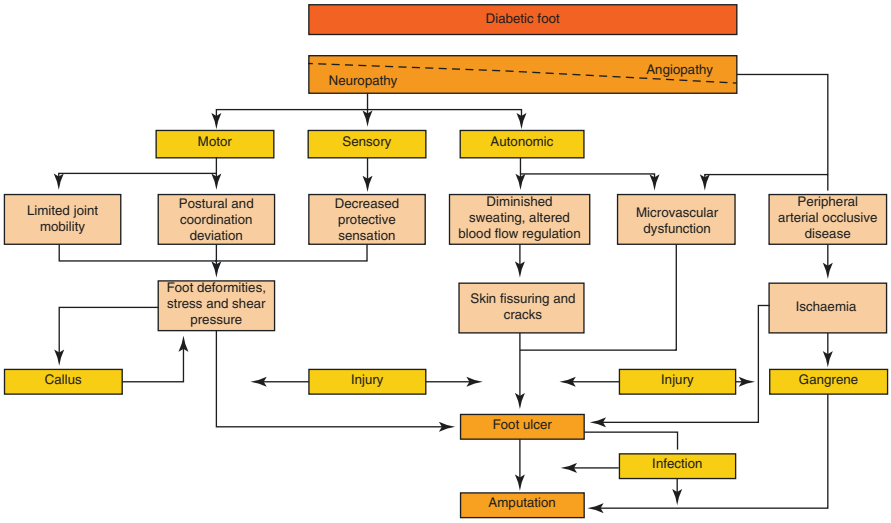

**Fig. 6.6** Pathways for foot ulceration. (Adapted with license no. 4810921023311 from Ref. [91])

**Fig. 6.7** Diabetic foot gangrene

initially assessed through the general symptoms of sepsis or toxicity of the disease, the conditions however include low responsiveness of patients, abnormal behavior of the body, patient looking severely sick, and reflecting abnormal behavior. Patients undergoing through foot ulcers tend to undergo through a strict examination of the disease along with the regular follow-ups for the diagnosis and the prevention of the disease including the gangrene and ulceration of foot (Fig. 6.7). Examination of the disease includes the detection of lesions including the fungal infections, deformation of nails, skin, and cracks fissures, calluses, macerated web spaces, and other types of deformities including the pes cavus, hammer, and claw toes that ultimately increase the possibilities of ulceration among diabetic patients. The temperature of the foot can be felt through the dorsum of the individual hand, where an extremely cold foot suggests the presence of ischemia while a warm foot followed by the increased redness and swelling might contribute to inflammation including the cellulitis and the acute Charcot foot [64].

In most of the middle and low incoming countries, almost 75% of patients are exposed to diabetes. As for instance; in India the ration of the diabetic patients increased up to 70 million individuals, the ration is further expected to rise up to 125 million in the proceeding years of 2040 [65]. According to the guideline provided by the National Institute for Foot Health and Care, the diabetic patients follow a system based on three different rankings, the first includes the preventive measures related to the diabetic foot, the next include the protection of foot from any such disease ranging from the community level for management and care of the simple foot-related problems followed by the tertiary care provided by the multidisciplinary health care providers that can appropriately handle the growing problems of the foot [64]. The cases are however different in most of the low and middle incoming countries, where primary care is often provided through the untrained doctors. In such areas, treatment measures are not undertaken by the multidisciplinary doctors and are available at minimal ratio in such tertiary care centers.

Therefore, in areas with a low level of preventive measures, it is highly recommended to have quality doctors that may provide quality care services related to the foot ulcerations. The following measures are particularly essential for countries

with a high level of diabetic patients who are usually the victims of the growing problem. Other than this, such countries must have certain referral hospitals that are specifically designed to provide treatments for such injurious problems. These health care centers are responsible for providing the services including nail care, callus debridement along nail surgeries including wound debridement and major and minor amputations. The examination and the prevention of the disease are possible through the definite care provided by the multidisciplinary health care providers that are provided through various facilities including the orthoses and vascular intervention.

### 6.7.1 Common Diagnostic Techniques of Foot Ulcerations

#### 6.7.1.1 Diagnosis Through Tests

Often, a common method that helps in the diagnosis of foot ulcerations includes the bedside tests that is the measurement of the pressure exerted on the ankle. The method is useful in estimating the ratio of the required pressure to obstruct the blood flow in the ankle in comparison to the brachial artery. These measurements are regarded as the ankle-brachial pressure index (ABPI) ratios. Clinical experts however suggested that the accuracy regarded the exerted pressure is found by the measurement of the toe pressure along with the toe brachial pressure index (TBPI). The following method is mainly used in cases with calcified crural vessels, which are mainly found among diabetic patients. The method is performed by the use of cuff that is tied around the toe to restrict the flow of blood in the given area. TBPI measurements that are attained <0.7 represents the normal conditions of the body. In addition, the degree of ischemia is measured through the microvascular transcutaneous oxygen pressure ($tcPO^2$) that provides major information regarding the microcirculation of blood in the affected area [66].

### 6.7.2 Radiological Tests

Another common source of collecting information about the given problem is the use of radiological tests. The use of radiological methods such as duplex ultrasonography is important in the identification of arterial lesions. The following examination is provided based on the hemodynamic values and anatomical evaluation to determine the level of stenosis. Collins et al. [67] provided important information in their study, according to which duplex ultrasonography occupies 88% sensitivity and 94% specificity levels. The levels increase when measuring lesions that are located above the knee. Similarly, CT angiography is another important method that is used for the imaging of the arterial tree measuring from heart to toe. Studies suggested the high accuracy levels of the given technique with sensitivity and specificity levels of 95% and 96% respectively. The specificity levels are expected to drop up to 91% when examining the imaging of tibial vessels [65, 68]. Certain adverse effects of the given techniques have been detected, including the impact of radiation

and nephrotoxicity levels in the contrast dye. High levels of creatinine serum such as 44.20 μmol/l are commonly associated with the risk factors of nephropathy. However, in some rare cases, patients require the examination through renal replacement therapy during CT angiographies.

Another common radiological method includes the examination through magnetic resonance angiography (MRA) that provides imaging of the arterial system with a sensitivity and specificity ratio of 95% and 97% respectively [66]. Magnetic resonance angiography (MRA) in this regard is characterized in providing than worse imaging of tibial vessels in contrast to CT angiography. However, for certain researchers, MRA technique is still much better in the identification of the pedal vessels. This type of examination is mainly held among patients with diabetes mellitus who are undergoing through the critical limb ischemia. It was further suggested that the technique is safe, since it avoids the use of radiation. Another important method used in the identification of arterial lesion includes digital subtraction angiography (DSA), which is recognized as the top most preferred method for examination. The technique is comparatively much better than all other methods, due to its efficiency in providing the overall mapping of the arterial tree which can be easily analyzed by clinical experts. Since DSA serves as a 2D technique, therefore it lacks the ability to provide 3D imaging. Other drawbacks of DSA include the low accuracy levels in determining the eccentric lesions, pedal vessels, and patent distal crural.

Other complexities are in the form of inducing the ionizing radiations that result in renal failure and further require the use of costly tools that can be operated through highly experienced and skilled medical professionals. Norgren et al. [69] mentioned that DSA techniques involves minor probabilities of severe risks in the form of adverse reactions, and includes minimal chances of mortality. Treatment guidelines provided by the UK National Institute for Health and Care Excellence preferred the use of duplex ultrasonography in imaging the arterial tree among patients with diabetes mellitus. Similarly, MRI technique must be preferred when additional imaging is required for the examination. The process however must be integrated before revascularization. Lastly, CT angiography must be provided to individuals with weak metabolism and are unable to bear MRI.

### 6.7.3 Revascularization

Revascularization refers to the treatment that includes the preservation of cell tissues during severe ischemia conditions, since the excessive loss of tissue results in the form of amputation or even death. The important goal of the given treatment is to restore skin perfusion [69, 70]. The process is integrated through endovascular sources that include the stenting and balloon angioplasty through surgical measures. In most cases, bypass techniques are involved to create a segment around the disease. Studies suggested that most patients are not treated through revascularization treatments due to the presence of ischemic limb ulcers among diabetic patients. Such patients possess 53% chances of survival, i.e., wound healing. Others

suggested that patients with diabetic mellitus and CLI are refrained from any such treatment, since the rate of amputation among such patients is 46% [71].

In contrast to this, patients suffering from the ischemic legs with normal glycemic levels when examined through revascularization resulted in reduced amputation rates [72]. The failure of bypass technique is associated with the excessive loss of tissue and high amputation rates. Another risk factor connected to the issue is the time duration involved between bypass and blood occlusions. The rate of amputation is said to be low among patients who have maximum time involved in the functionality of bypass. The most probable explanation, in this case, includes the loss of tissue, and the recovery of ulcer which contributes in posing minimum risks toward the consequences of bypass failure. In contrast to this, patients undergone through a first-line surgery supported by drug therapy usually results in providing improvised clinical outcomes by the involvement of revisualization. It is of greater significance that patients with diabetes mellitus need more critical care than those with normal glycemia levels.

### 6.7.4 Surgery

In most adverse conditions of foot ulcerations, surgical techniques are involved to cater to the disease. The first technique includes endarterectomy that is provided to patients undergoing through CLI. Another important technique includes the bypass surgery that is based on the use of prosthetic material or veins to recover from lesions. The techniques are of greater significance when performed under the controlled examination of anesthetics, since the disease takes a longer duration for recovery. Similarly, distal anastomosis that is usually much longer requires long duration in attaining the prevention from any further infections. Surgeries involving the prosthetic bypass below the knee involves greater patency levels than that provided in vein bypass. Patients suffering from diabetes usually involve distal bypasses covering the popliteal arteries that are reachable to the ankle.

## 6.8 Wound Healing Process

In most of the normal conditions, the wound healing process is mainly associated with the interplay among several types of cells that are often contacted through different hormonal and soluble chemical activities in the human body. In most of the infected areas, platelets are often gathered and combined leading toward different factors that are often responsible for the formation of clot and matrix within the human body. The fibrinogen found in the human body are often transformed into fibrins, this is due to the development of the thrombin that results in the formation of a network of various platelets that are often developed at the site of the injury.

Moreover, the growth factors and the cytokines make the blood vessels as permeable that in results allow that transfer or the movement of leukocytes that are attracted to the affected area in the human body. Furthermore, the formation of various products takes place here that are formed due to the decomposition of the elastin and collagens such as; cytokines interleukin-1 (IL-1), TGF-β, platelet factor IV along with TNF- α. Therefore, the accumulation of the macrophages and the neutrophils helps in the removal of contaminating bacteria along with other factors that are generally found at the affected part of the body. A significant role is played by the given factors that are responsible for the emancipation of several growth factors that are highly useful in the formation of tissue structures. The factors are often regarded as VEGF (vascular endothelial growth factors) and PDGF platelet-derived growth factors.

In addition, several factors are responsible for the proliferation and the migration of cells. These factors include keratinocytes and the epidermal growth factors. Cell migration is further developed through the secretion of the matrix metalloproteinases (MMP) that is essential for the degeneration of clot and extracellular matrix (ECM) that are generally found at the wound site. The incomplete digestion of the extracellular matrix generates long spaces in the migrating cells. The process is mainly regulated through the creation of a uniform balance between the development and the degradation of new tissues. Similarly, collagen synthesis is helpful in the formation of the tissue for the second time and is majorly stimulated through different growth factors including; platelet-derived growth factor (PGF), Transformation growth factor (TGF), and epidermal growth factor (EGF). The final stage of the wound healing process includes the contraction of wounds, that takes place through the activity of mesenchymal cells.

### 6.8.1 Process of Wound Healing Among Diabetic Patients

In diabetes, it has been noticed that all the stages of wound healing are often affected by the adverse effects of the diabetic foot syndrome. This leads toward the development of the final picture including the formation of a diabetic wound that serves as the fundamental mark of diabetic foot syndrome. Among diabetic patients, several growth factors including the chemokines and cytokines have different serum levels of macrophages, fibroblasts, keratinocytes, platelets, and endothelial cells. The following factors are mainly responsible for initiating the wound repair process along with its preservation leading toward the significant decrease in the inflammatory responses. In various diabetic patients most of the wounds are characterized through the decreased level of various growth and receptors including; nerve growth factors (NGF), transformation growth factor β (TGF- β1), keratinocyte growth factor (KGF), substance P, along with CGRP. Therefore, the minimal levels in the following growth factors contributes to the poor regeneration of tissue followed by the impaired recovery of wound (Fig. 6.8).

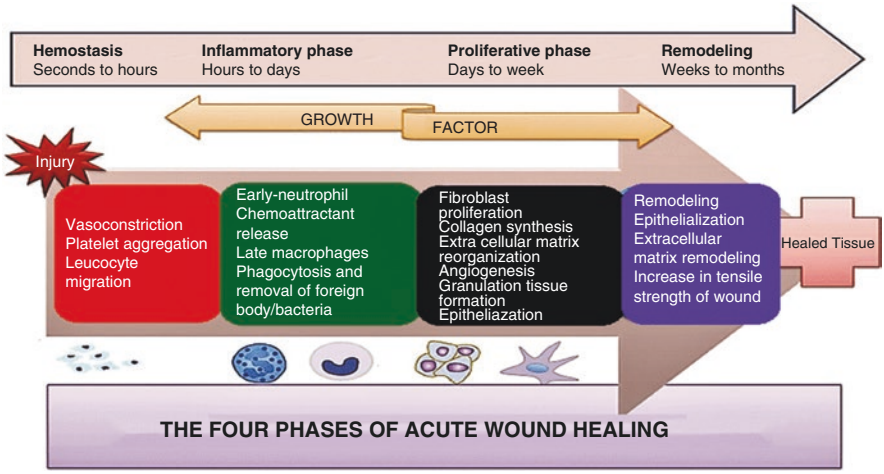

**Fig. 6.8** Distinct and overlapping phases of wound healing (Adapted from Ref. [87])

### 6.8.2 Phases of Wound Healing

One of the most common reasons found among the diabetic patients is sepsis, leading toward the development of various infections including ulcers, chronic nonhealing wounds [73]. The general development in treatment measures is often associated with controlling diabetes, whereas among patients with foot ulcerations these treatments are associated with the general foot or wound care to refrain it from the development of any further disease in the human body. A significant focus is provided to the regeneration of different infections along with providing immunity in minimizing the growth of these infections [74]. In the treatment care of the diabetic foot, the wound healing processes are often followed by the impairment resulting in the development of different diseases including the anatomical changes. Whereas, in severe foot ulcerations among diabetic patients, most of the nonhealing wounds results in death. The wound healing processes are often dependent upon patient's health, the position or the location of wound, age, and other factors that are considerable in providing health-related treatments. For treating a wound, several processes are being presented to evolve the repair of wound in the human body. The healing process is initiated through various events; the first includes the hemostasis restorations, leading toward the formation of different clots in the affected area. It further includes the inflammation and proliferation of wounds, formation of tissues, epithelization, and the contraction of wounds. The final phase of the recovery includes the remodeling of the cutaneous tissues [75] (Fig. 6.8).

## 6.9 Management of Diabetic Foot Ulcers

### 6.9.1 Debridement

Management of the diabetic foot ulcerations requires maximum efforts. Debridement is one of such techniques that is used in conditions that involve the formation of the hyperkeratotic tissues over the plantar region of the foot. The problem is mainly caused due to the exertion of severe pressure. Regular debridement helps in reducing the exerted pressure which is due to the formation of excessive hyperkeratotic tissue, which creates a direct impact in the form of increased stress. The treatment methods are initial measures that are effectively reducing the probabilities of ulceration among diabetic patients. The process includes the removal of the layer that releases the gathered fluid in the affected area, while opening the ways for foot recovery. Wounds that are deep and are connected to both bones and the tissues require in depth debridement to remove the overall probabilities of the occurrence of non-viable tissue and toxic fluid. The effective and careful debridement is useful in decreasing the time duration required from the recovery.

### 6.9.2 Offloading

This is the most recommended method and often serve as the first choice of providing treatment for patients with foot ulcerations. The main goal of the method is to reduce the over loading of weight found in the affected area. The method is essential in redistribution of the weight in the overall affected area. Removable and unremovable casts are used to promote offloading through different orthotic devices including custom footwear and other fabricated shoes. The total contact cast is categorized as the most effective type of offloading and is determined as the gold standards in the clinical treatments. The main advantage of the process includes the short-term healing time of the given disease. Since the contact cast is non-removable, therefore patients might undergo through a rapid recovery due to continuous treatment.

### 6.9.3 Wound Dressings

The extremity of the disease is controlled through the regular wound dressing that helps in protecting the wounds from the external environment that carries poisonous or even the most harmful substances. The development of contact between such environmental elements with the wounded area promotes the extension of the problem resulting in the increased deformity of foot. Moist dressings are provided to such areas through the continuous maintenance of wound healing that promotes the

migration of cells. Clinical experts regarded this method as one of the basic actions conducted at the time of identification of any such disease, which is not possible in dry dressings. Wound dressings that are provided by the incorporation of silver resulted in ineffective efforts in treating diabetic foot ulcers.

### 6.9.4 Negative Pressure Wound Therapy

In most of the clinical settings, negative wound therapy is the mostly used and recognized treatment method, that helps in the exemption of the wound fluid present in the sealed wound. The therapy is widely associated with the conditions that involve increased wound healing and have closure contact of wound. Besides, improvised perfusion and the development of new granulated tissues are the major benefits associated with the application of negative pressure at the central location of the disease [76].

## 6.10 Clinical Guidelines to Treatment

The current approaches to the treatment of the foot ulcerations among diabetic patients generally involve the combined efforts of physician, nurses, physio therapists, orthotist along with other care givers. The present practices in the treatment measures suggest that patients' education regarding the given problem is significant in this regard. Other important measures include patient's diet monitorization, foot inspection, maintenance of glucose levels up to normal, foot screening along with the modification of footwear is of greater significance [77]. Various researchers suggested that the interprofessional approach helps in the provision of significant improvements in the rate of amputation and foot ulcerations among diabetic patients [78]. The prevention of ulcer is still majorly dependent upon the interventions of footwear. Most of the care providers still follow the contemporary theory of ulcerations and is regarded as an important aspect of ulcer prevention. Furthermore, the intervention of footwear is commonly concerned with minimizing the exertion of increased weight over the affected area. It also contributes to minimizing the repetition of loadings.

Most of the researchers provided valuable suggestions in this regard. According to which, the goal of the footwear intervention must be to minimize the exerted pressure up to 30%. This is due to the fact that redistribution of the plantar pressure helps in breaking tissue [77]. Areas that are at greater risks of deformity and callusing foot can be easily addressed and recovered through the intervention of footwear People undergoing through diabetes mellitus and peripheral neuropathy (DMPN) accounts for majorly 53% variance in the plantar pressure of fore foot [79]. Other best practices include the provision of the improvised practices including the structural changes and centers of the elevated pressure that are specific to patients, followed by the examining of the impact created through the footwear. Researchers

suggested that the intervention of footwear among diabetic patients is mainly dependent upon patient's adherence to the given treatment, as patients with the adherence level of below 80% usually create a negative impact over the efficacy of footwear among the target individuals [78, 80]. Moreover, the intervention of the footwear technique helps in providing a visible improvement in the rates of re-ulcerations. Therefore, the intervention of footwear must be in accordance with patients' physiological needs to observe definite results. Studies conducted through the randomized controlled trials suggested that in major cases people with DMPN provided minimal cases of foot re-ulcerations [77]. The results were common among patients who were suggested to wear the custom footwear with careful monitorization of the pressure relief. Findings indicated that the majority of the re-ulcerations were detected among patients who were recorded with a maximum adherence level. The idea is crucial as it demonstrates the value of both patient's adherence level and relief evaluation.

Recommendations regarding the prevention of ulceration majorly rely upon overloading factors. The development in the scientific interventions further suggested that diabetic patients must be liable to wear custom footwear to prevent the future developments of the disease. An RCT investigation conducted by Rizzo et al. [81] suggested that the ulceration incidence was least common among individuals that have undergone through the primary care in the form of custom footwear for 5 years. Therefore, it is considered that custom footwear serves as one of the most common treatment measures among patients either with or without history of ulcerations and diabetes. Despite the development of the risk factors, the need regarding the development of useful biomarkers is found to predict the future tissue damage. In addition, the development of more explicit screening practices is of greater need, as it may assist physicians and health care experts in the identification of the crucial time point for offloading the footwear interventions. Other important considerations include the interventions of footwear and screening processes that help in the prevention of deformity of tissues are important. The factors include the rate of foot bearing activity and the extent to which the affected foot efficiently functions.

A significant consideration is provided to the weight-bearing activities, since they are responsible for increasing the stress tolerance level of plantar tissues. Therefore, clinicians must incorporate such activities among the affected patients to refrain from various long-term damage in the tissues of the affected area. This helps in the prevention of the greater risks associated with different activities that are progressed through weight-bearing activities. Walking programs or weight controlling exercises are of critical value here as they might contribute to increasing the life expectancy of the affected area of diabetic patients [82]. Other important measures of the basic treatment include patient's knowledge regarding the stressed posed on the affected foot during everyday activities of patients. However, the abnormal stress that is provided to another foot may result in damaging the soft tissues. The basic guidelines are important and serve as an essential part of human knowledge, specifically for those suffering from major foot ulcerations. Patients following the given guidelines may prevent further damage to the affected foot area.

### 6.10.1 Advancing Clinical Methods

#### 6.10.1.1 Weight-Bearing Activity

The primary focus in improving glycemic controls is significantly provided to glycemic control. For advanced clinical measures, the following guidelines seemed to be vague in the clinician's perspective of promoting the exercise among diabetic patients who are at greater risks of foot ulcerations. The functionality of the above-related activities includes maximum complications when applied to practical measures, due to the differences in the physical conditions of comorbidity among diabetic patients. This might be due to the fact that in most cases the plantar tissues lose the level of required fitness even before the occurrence of foot ulceration. In such cases, it has been suggested that extensive offloading in the prevention phase may result in the occurrence of foot ulcerations in the future. Individual and clinical efforts regarding the high weight-bearing activities and glycemic controls are effective techniques to develop resilience for the breakdown of soft tissues. The idea regarding the increased probability of ulcerations because of the increase in weight-bearing activities is still not clear and varies from cases to cases. Studies conducted in the given framework indicated that weight-bearing activities serve as a useful tool in developing maximum prevention against the occurrence of ulcerations [83]. It was further developed that DMPN patients provided positive results regarding the weight-bearing activities and thus indicated that the method is sufficiently effective in reducing the level of ulceration among such patients.

Researchers further examined the effect of weight-bearing and non-weight-bearing exercises and their effects on everyday activities along with the levels of HbA1C among people with DMPN. Visible improvements were detected in the weight-bearing individuals, which were related to the performance of everyday activities. However, no visible difference was observed in the rate of ulceration among both the groups. The results are specific to the type of activities performed including the walking, balancing, and length strengthening exercises. Therefore, it is suggested that weight-bearing activities may be considered as the mediating source of involving greater changes in the form of prevention of foot ulceration and thus can be viewed as an important guideline for patients with DMPN.

Clinical studies conducted in the given idea suggested the need for providing regular instructions to patients regarding the value of weight-bearing activities in controlling the glycemic levels and managing the integrity of plantar tissue. Notably, for some researchers, the development of the protocols related to the weight-bearing activity along with the practical implication of the exercises that help in promoting the management of patal tissues and ulceration are still questionable. This is due to the lack of effective biomarkers that help in providing extended knowledge in managing the integrity of plant tissue. Current treatment guidelines further include the adjustment of the treatment dosage that is provided with respect to patient's need. The inclusion of the weight-bearing activity serves as an additional factor here, that is related to the extent of providing stress over the affected area during the weight-bearing activities. Considering this, it is important to understand how often weight is being provided along with the way of creating stress among the given individuals.

Another important consideration includes the dynamic foot functions that specifically focus on the behavior of foot during a crucial period of foot ulceration. Dynamic foot functions are further assessed through different approaches. The first includes the single segment approach that focuses on modeling the complete foot while considering it a rigid body that moves with the ankle joint on the tibia. Though the approach is useful, it may cover the regional pathological characteristics of foot functions. Single segment modeling of foot among people with DMPN resulted in the development of mixed findings related to different factors that are potentially responsible for tissue breakdown. Different findings have been developed regarding the forefoot plantar pressure, joint mobility, and the motion of ankle during physical activity such as; walking. Researchers suggested no definite linkage between both dynamic and passive ankle motion. Similarly, no significant distinction was observed among individuals with or without DMPN [84]. Another study conducted by Sacco et al. [85] detected a significant decrease in the pressures exerted on the plantar tissue. The results were common among DMPN patients than in healthy patients. One probability for such types of different results may be due to the embedded motion of the mid foot and forefoot presented through the single segment model.

Another common approach is termed as the multi-segment approach that typically allows the evaluation of foot functions providing the explicit reality of the anatomical foot functions. The technique is useful in providing increased knowledge about the pathological and normal foot functions. Researchers identified significant alterations in the kinematics of people with the history of DM and ulcerations, by employing the multi-segment foot modeling approach. Comparative analysis of the given results concludes that the level of motion, when studied through multiple foot segments, is comparatively different among patients with DMPN than those with healthy foot. Other than this, the unlikeliness found in the metatarsal motion of individuals specifically in forefoot regions, provide greater contributions in increasing the pressure on plantar tissues toward certain locations.

## 6.11 Conclusion

Foot complications among diabetic individuals are developed through the complex interactions between macrovascular and microvascular irregularities. The development of diabetic foot ulcerations serves as the major contributor in promoting diseases including; peripheral neuropathy, ischemia, and foot lesions. The disease is highly risky as it reduces the individual ability to feel or respond to hurt or pain in the affected foot. External factors such as the inappropriate footwear, thermal injury along with the development of environmental contact with the disease lead toward the formation of complex conditions in diabetic foot ulcerations.

The preservation of the planter tissues among patients with diabetic foot ulcerations is indeed a challenging process for people that are exposed to high levels of diabetes. Similarly, the prevention of the neuropathic foot ulcerations serves as a greater challenge for care providers. The effectiveness of the preventive measures regarding the increase in foot ulcerations mostly depends on the glycemic controls,

the management of the integrity of plantar tissues, as well as the intervention of the advance neuropathic process. It is highly critical for clinicians to provide developmental information regarding the interplay between different factors including the frequency of weight-bearing activity, the pressure exerted on the plantar tissues, and the quality of foot functions during the imposition of stress. Another important task includes the regulation of the effective balance between the required stress to overcome the consequences of ulcerations. Similarly, the effectiveness in loading parameters must be integrated through the evolved damage in the contingent tissues during and after the process of stressing.

Knowledge and the level of education of patients are equally important in controlling and preventing the foot from severe damages. Also, weight-bearing activities such as; balancing, walking, exercises related to the leg straightening are of greater importance in creating an influence over the health and functions of the affected person. A proper scheduling of such activities is important to minimize the effects of neuropathy along with the management of stress over the plantar tissue uploading. The dynamic foot function when integrated through the multi-segment modeling is important for the prevention of first-time ulcerations. Treatment-related to the foot ulceration requires regular screening to examine the strength of foot muscles. The overall information suggests that preventive measures can only be implemented by the development of the exercise programs that are functionally effective in improving the overall ulceration conditions of foot among diabetic patients.

# 7 Foot Pressure Abnormalities, Radiographic, and Charcot Changes in the Diabetic Foot

Ahmad Faraz, Hamid Ashraf, Saifullah Khalid, and Razeen Fatima

## 7.1 Introduction

Diabetes Mellitus (DM) has become one of the biggest healthcare challenges of the twenty-first century and it has become one of the major causes of morbidity and mortality across the world. According to the International Diabetic Federation, 425 million had diabetes in the year 2016 and by the year 2045, the number will escalate to 629 million [1]. One of the most common complications of diabetes is Diabetic Neuropathy. According to the American Diabetic Association diabetic neuropathy is "the presence of symptoms and/or signs of peripheral nerve dysfunctions in people with diabetes after exclusion of other causes" '[2]. The prevalence of diabetic peripheral neuropathy can be as low as 16% to as high as 66% [3, 4]. While the incidence of amputation in diabetic patients is 10–20 times greater than in non-diabetic patients [5].

## 7.2 Forces on Foot During Weight-Bearing

During weight-bearing, foot is exposed to ground reaction forces (GRF), so while standing a person exerts a force equivalent to weight and an equal amount of force (GRF) is exerted by ground in opposite direction. GRF has a parallel component when a person is moving where a deformable force is present. Deformation forces can be categorized as Stress and Strain, stress is the force exerted on the body per unit area, and it is a measure of internal forces on surrounding particle. Stress perpendicular to the body is a compressive force, while stress parallel to the body is shear stress. A strain is the deformation of any material due to stress [6]. During standing stress is perpendicular to the body, so the pressure is greater at the heel than at the forefoot [7].

Weight is mainly distributed on three prominent points of the foot: 1. center of the heel, 2. the first and the 3. fourth–fifth metatarsal heads. Weight-bearing on foot while standing is evenly distributed on these three prominent points, thereby providing optimal stabilization. Distribution of pressure on the plantar surface depends mainly on body weight [8], age [9], and abnormalities of the foot secondary to any disease [10].

When a person is standing, weight is evenly distributed on both the feet but when a person is walking stress is much higher because of multiple reasons as follows: (1) During the gait cycle both the feet come in contact with the ground for only 22% of the cycle, hence one foot is exposed to force of weight for a longer period. (2) During walking GRF moves anteriorly from heel to forefoot and portions of the foot makes contact with the ground during different stages of gait cycle. The heel comes in contact with the ground during ~64% of the stance phase while the forefoot is in contact during the last 59% of the stance phase [11]. (3) GRF vary with the phases of gait, the peak pressure is exerted during the initial contact and loading and the push off phase of the terminal stance, so the heel and forefoot experience higher pressure [6].

## 7.3 Forces on Diabetic Foot

### 7.3.1 Disorder of Mobility

Decreased movement of ankle joint impedes the normal rollover of the sole throughout the stance phase of the gait cycle, it may be a result of early heel rise and early loading of the forefoot. During the push off phase, the altered mobility of the great toe can cause early landing of the great toe [12]. Altered movement of these joints can lead to increased plantar pressures and it further increases the risk of ulceration.

### 7.3.2 Structural Foot Changes

Neuropathy secondary to prolonged hyperglycemia leads to several structural changes in the foot of these patients. These include intrinsic muscle wasting, hammertoes, claw toes, hallux valgus, dislocation of a smaller toe, and changes in

height of arches. The structural deformity may lead to increased plantar pressure by diminishing the support surface or by raising the prominence of bony points (metatarsal heads and bunions). Amputations of partial foot and Charcot fractures also decrease the support surface and may cause high plantar pressure [13]. Diabetic foot ulcer occurs most commonly on the site of maximal load, there was a lateral shift of pressure on the forefoot [14]. DPN patients often present with hammertoe deformity which may lead to increased plantar pressure at the lesser toe [15, 16]. In patients of diabetes with neuropathy, there is a regional difference in plantar shear values, therefore shear-forces can help in predicting the site of ulcer formation and in designing footwear [17]. Patients with multiple deformities are more prone to higher plantar pressure and ulceration. However, the repetition of stress on a particular site is a more important factor, than the magnitude of pressure or shear stress [18].

The lifetime risk of foot ulcer in patients with diabetes is 10–15% Barrett et al. [19] and Stokes et al. [14] found out that foot ulceration is common in areas of high foot pressure in patients of peripheral neuropathy. Due to peripheral motor neuropathy in diabetes, muscles of the foot like long and short flexors and intrinsic muscles become weak, which then causes decreased loading of toes. This leads to increased pressure on metatarsal heads. Seventy percent of normal toe loading is transmitted through the hallux, so when toe loading is decreased all the pressure is then transmitted by metatarsal instead of the hallux. This is why the first metatarsal is the most common site of neuropathic ulcers [20]. The mobility of subtalar joints is significantly reduced in patients of diabetic neuropathy with ulceration. The axis of the subtalar joint is oblique to all three body planes [21, 22]. When the heel strikes the ground, there is loading of the forefoot, with pronation of subtalar joint which allows molding of soft tissue to surface and absorption of shock. It is then followed by the supination of a subtalar joint which makes the foot rigid to enable leverage for stride. The reduced subtalar joint movement in the foot with ulceration will probably lead to uneven distribution of forces [23]. The presence of abnormal forces (both vertical weight-bearing and horizontal shearing) at the ulceration site is the key factor in the development of ulceration in the insensitive neuropathic foot [24]. Decreased joint mobility in association with neuropathy is the main etiological factor for high foot pressure that is often found in diabetes patients and is associated with foot ulceration.

### 7.3.3 Soft Tissue Abnormality

The diabetic patient often has stiffer and thinner plantar soft tissue especially in an elderly subject [25]. The soft tissue under the first metatarsal head most commonly has increased stiffness, which may lead to decreased shock absorption and increased peak pressures under dynamic conditions. Reduced thickness of plantar tissue is associated with an increase in peak plantar pressure [26]. The formation of calluses under the forefoot was also associated with an increase in plantar pressure and also increases the risk of ulceration [27].

## 7.4 Association of Neuropathy with Ulceration

Sensory neuropathy in diabetes lead to decreased sensation and loss of protective sensation, a patient may not be able to localize pain or discomfort due to overloading of plantar surface [28]. Ulcers and lesions remain undetected and may cause deterioration of trivial injury.

### 7.4.1 Altered Gait Pattern

There is a decrease in plantar pressure due to short steps with a shuffling gait, it would increase the duration of the foot flat and the area of weight-bearing [29]. Shuffling gait results in an increase in the foot to floor contact area and time. However, shuffling gait is an inefficient gait since patients get fatigued easily [30].

### 7.4.2 Pressure Changes with Ulceration

High plantar pressure in patients of diabetic peripheral neuropathy (DPN) cause diabetic foot ulcer (DFU). But plantar pressure during ulceration is not raised [31]. Forefoot plantar pressure is raised in patients of active ulceration despite the increased stance phase owing to slow walking speed. However, faster speed lead to increased pressure at the heel, medial, and forefoot while decreased pressure in the midfoot and lateral forefoot [32]. The extended stance phase is insufficient to decrease plantar pressure in an ulcerated foot [33]. In patients of diabetes with neuropathy previous history of ulceration demonstrates increased plantar pressure, but patients with active ulceration do not show higher plantar pressure which may be because these patients protect the part with ulceration [34]. Also, poor glycemic control in patients of diabetes may lead to abnormal plantar pressure [35]. Other factors like excess weight gain also play an important role in elevated plantar pressure [36].

## 7.5 Clinical Findings Predicting High Plantar Pressure [37]

- *History*
  - Prior ulceration
  - Prior surgery involving the metatarsal bones
- *Physical finding*
  - Callus*
  - Hemorrhagic callus*
  - Blister or macerated skin*
  - Limited hallux dorsiflexion (less than 30°)
  - Prominent metatarsal heads inadequately covered with soft tissue**
  - Other plantar bony prominences

- *Radiograph finding*: Charcot fracture
  - *High pressure or shear capable of injuring soft tissue is being generated.
  - **Detected by gently stroking a finger across the plantar surface of the forefoot.

## 7.6 Charcot Foot

One of the overwhelming complications of DPN is the development of Charcot foot (CF) or Charcot neuropathic osteoarthropathy (CN). CF is named after the famous French neurologist Jean-Martin Charcot, who first identified the neuroarthropathic changes in patients of tertiary syphilis [38]. William Riley Jordan in 1936, first depicted the connection between Diabetes Mellitus and painless neuropathic arthropathy of the ankle [39]. It is an uncommon issue that is characterized by the destruction of bones and joints prompting fractures, dislocation, deformity, and amputation. CF is frequently associated with DM, alcoholic peripheral neuropathy, tertiary syphilis, leprosy, spinal cord injury, Charcot-Marie-Tooth disease, and idiopathic neuropathy. Currently, the number of patients of diabetes is increasing worldwide, and these patients are living longer because of better diabetes care. This has prompted a circumstance where DM is the most common reason for CN and the number of patients with CN is expected to rise. The reported incidence of CF varies widely in the literature from 0.1–7.5%, because of different diagnostic criteria used, different inclusion criteria, and different duration of diabetes [40]. Recently, a study from India revealed a high prevalence of CN (9.8%) in patients of type 2 DM with DPN [41].

## 7.7 Pathogenesis of Charcot Foot

The exact pathogenesis of CF is not yet clear, and there is no single factor for CF development, some neuropathic DM patients develop CF while others do not. Several factors predispose an individual to the development of Charcot Foot. The popular explanations for the production of CF include the "neurovascular" hypothesis suggested by Charcot himself, which indicates that there is a lack of vasoregulation resulting in high flow state and opening of arteriovenous shunting due to underlying autonomic neuropathy [38]. Such increased blood flow contributes to increased flux of monocytes and osteoclast, resulting in the bone washout of structural calcium. The net result is localized osteopenia and continuous weight-bearing resulting in deformation. The hypothesis of "neurotraumatic" proposed by Volkmann and Virchow indicated that repetitive microtrauma to the foot induces an uncontrolled inflammatory cascade in the absence of protective sensation, resulting in collapse and joint destruction in CN [42]. Most likely CF occurs because of combination of these factors. The discomfort is not experienced by patients in the presence of sensory neuropathy and chronic microtrauma continues unabated. Motor neuropathy affects the foot stress mechanisms resulting in irregular plantar tension and deformation. Autonomic neuropathy contributes to local osteopenia by

increasing the local blood flow. If fracturing occurs in healthy people, it results in the release of pro-inflammatory cytokines like tumor necrosis factor α (TNF α) Interleukin 1β (IL-1β) and Interleukin 6 (IL-6). This, in turn, leads to enhanced expression of receptor activator the nuclear factor kβ ligand (RANKL) [43]. This pro-inflammatory cytokine state promotes osteoclast formation from the precursor cells to mature and activate. NF kB also stimulates osteoprotegerin synthesis from osteoblast that antagonizes RANKL [44]. In normal individual fracturing is compounded with pain, it contributes to bone splinting, and with time the pro-inflammatory condition may relieve. Unlike a normal person, when an individual with severe DPN experiences an acute Charcot foot impairment of pain sensation allows for sustained ambulation with repeated injury, resulting in persistent pro-inflammatory condition, contributing to chronic local osteolysis [45]. All these factors lead to bone destruction, fracture, dislocation at the foot, and ankle joint.

Hyperglycemia results in excessive nonenzymatic collagen glycation and binds to other protein molecules with the amino groups, contributing to the development of advanced glycation end products (AGEs). Binding of AGEs to their receptor (RAGE) prevents the differentiation of human mesenchymal stem cells [46]. They induce apoptosis of osteoblast and results in increased osteoclastogenesis through the RANKL/NF-kβ pathway. All these factors together with neuropathy lead to the continuance of inflammation and death. Calcitonin gene-related peptide (CGRP) normally secreted from the nerve terminals, has been documented to be critical in maintaining the integrity of joint capsules, as well as inhibiting RANKL synthesis. Any reduction of CGRP from the nerve terminals would affect the health of the bone and the strength of the joint. Both peripheral and autonomic neuropathy was shown to be linked with decreased release of CGRP, resulting in persistent RANKL action [47].

## 7.8 Clinical Presentation

The diagnosis of CF in acute stages requires a high index of suspicion. Patients are ordinarily present in the sixth or seventh decade. CF can have both acute and chronic presentations. The early symptoms of acute CF include mild to moderate discomfort, swelling of the affected limb, increased local temperature, and erythema [48]. The difference in temperature between the two limbs is ≥2 °C, which can be determined by an infrared thermometer. Pain is less when compared to cellulitis. At this stage, it can mimic cellulitis, deep vein thrombosis, or acute gout (Table 7.1). Clinical features such as raised temperature and increased heart rate are absent, peripheral pulses are well maintained in the diseased limb or it can be bounding also [49]. Elevation of the affected leg leads to a substantial reduction in the edema and erythema. Imaging studies like X-ray is not useful at this juncture as they may not reveal any changes (Fig. 7.1). Nevertheless, magnetic resonance imaging can provide some evidence for early diagnosis [50]. If proper diagnosis and treatment are not made at this stage, it may lead to additional destruction of bone and subsequent permanent damage.

**Table 7.1** Difference between cellulitis and acute stage of Charcot foot

| Features | Cellulitis | Acute Charcot foot |
|---|---|---|
| Age | Any | 5–7 decade |
| History of diabetes | +/– | + |
| Neuropathy | +/– | + |
| Deformity | – | +/– |
| Pedal pulses | Normal/reduced | Bounding |
| Pain | +++ | +/– |
| Fever/tachycardia | + | – |
| Pus discharge | +/– | – |
| WBC count | ↑ | Normal |
| MRI (low intensity on T1 and T2 hyperintensity) | Absent | Present |
| Calcaneal BMD | Normal | Reduced |

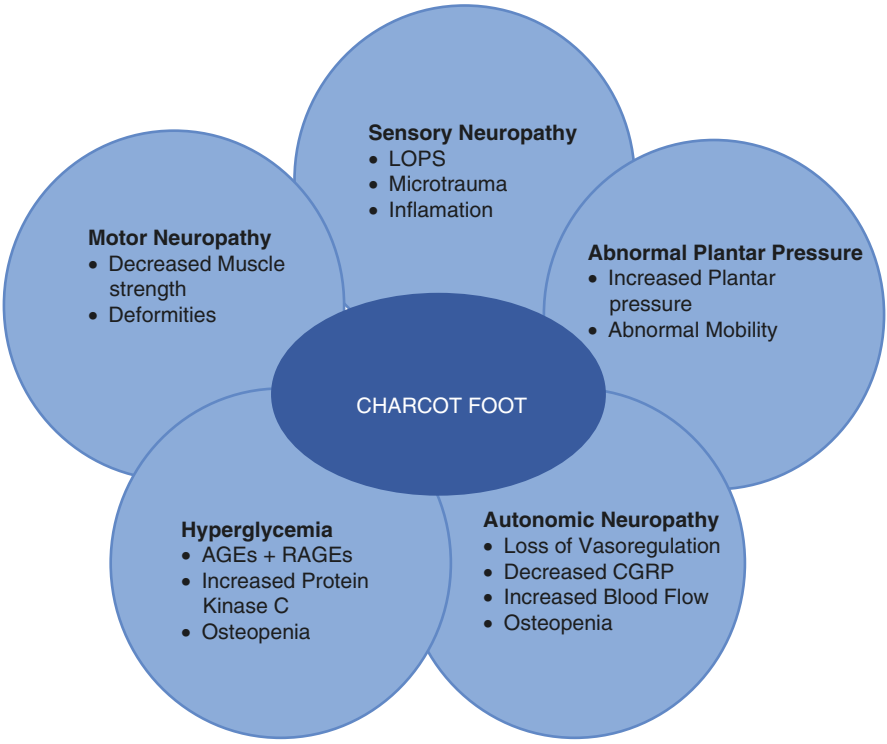

**Fig. 7.1** Pathogenesis of Charcot foot. (*AGEs* advanced glycation end products, *CGRP* calcitonin gene-related peptide, *LOPS* loss of protective sensation, *RAGEs* receptor of advanced glycation end products)

Following the resolution of acute stage patients often land in chronic CF in which residual deformity has developed. Breakdown of the midfoot arch leads to the development of Rocker bottom foot which is the characteristic of chronic CF. Patients present clinically with features suggestive of neurological, vascular, musculoskeletal, and radiographic abnormalities [51].

Neuropathy is present in all patients with CF, and this can be detected by five simple clinical tests. During the screening exam, two of these should be used regularly, typically the 10 g monofilament and one other test. Four remaining tests comprise, vibration test using 128 Hz tuning fork, ankle reflex, pinprick sensation, and biothesiometry. Though patients have insensate foot, up to 50% of them give a history of preceding trauma, which is often trivial [50]. Deformities in CF can be varying from trivial to grossly evident deformity (Fig. 7.1). Feet deformities result in irregular high-pressure on the plantar surface weight-bearing area, rendering it vulnerable to ulceration.

Involvement in CF is unilateral in most of the cases, but the bilateral presentation has also been reported in 9–75% of cases. An Indian study revealed bilateral presentation in 16% of cases. The most commonly affected site is midfoot in the literature, while an Indian study revealed midfoot involvement in 43% of patients. If the sinus tract is present or probe test is positive than osteomyelitis should be strongly suspected [49]. The differences between chronic Charcot foot and osteomyelitis have been enumerated in Table 7.2.

## 7.9 Radiological Features of Charcot Foot

Plain X-ray is the main imaging tool for the initial assessment of CF as it is readily accessible, inexpensive, and provides information on bone mineral density, joint orientation, and stability. While taking a radiograph, emphasis should be on non-weight-bearing A-P, lateral and oblique X-rays of the foot and ankle. The earliest sign of CF on a plain radiograph is Localized demineralization, while the first sign of diabetic neuroarthropathy on X-ray is metatarsal head flattening. CF is characterized by Subchondral or periarticular changes in the midfoot and multiple joints were involved without soft tissue changes. X-Ray of CF in later stages shows marked periarticular osteopenia in the bones of the foot and periosteal reaction. It is difficult to visualize trivial changes of CF like minor fractures and edema of marrow on Plain Radiograph. The sensitivity and specificity of X-rays are around 50% in the acute phase of CF

**Table 7.2** Difference between osteomyelitis and chronic Charcot foot

| Features | Osteomyelitis | Chronic Charcot foot |
|---|---|---|
| Location | Toes and metatarsal heads | Commonly midfoot |
| Distribution | Multiple bones/joints | Focal |
| Deformity | Absent | Present |
| Soft tissue changes | Inflamed, sinus tracts, abscess formation | Subcutaneous tissue edema |
| Bone marrow edema | Periarticular | Around ulcers, fistula tracts |

**Table 7.3** Classification of Charcot foot

| Eichenholtz classification | Sanders and Frykberg |
|---|---|
| Natural history and radiological | Anatomical |
| Stage I: Developmental; redness, swelling, and raised temperature | Pattern 1: Forefoot involvement; phalanges, interphalangeal, and the metatarsophalangeal joints |
| Stage II: Coalescence; active period of the disease process when bony destruction and deformity occur | Pattern 2: Tarsometatarsal |
| Stage III: Stage of reconstruction; commencing when the destructive process "burns out" and the bone consolidates with the resulting deformity | Pattern 3: Cuneonavicular, talonavicular, and calcaneocuboid articulations |
| | Pattern 4: Talocrural joint |
| | Pattern 5: Involves the posterior calcaneus |

**Fig. 7.2** X-ray foot lateral view: shows diffuse osteopenia and marked periarticular osteopenia in the bones of the foot, and subtle periosteal reaction with cortical irregularity in the lateral aspect of first metatarsal with extension to all metatarsophalangeal joints. Deformed contours at the distal end of the proximal phalanx with medial flexion deformity at the interphalangeal joint. Skin and subcutaneous tissue edema are also present

[50]. Eichenholtz classifies CF based on X-Ray. He divides CF into three stages: bone dissolution (stage I), bone coalescence (stage II), and bone remodeling (stage III) (Table 7.3). X-Ray in chronic stages of CF, shows decreased inclination angle of calcaneum, obliteration of the first talo-metatarsal angle (Fig. 7.2) [48]. Since the sensitivity and specificity of X-Ray are low in acute CF, magnetic resonance imaging (MRI) is an investigation of choice in the initial stage of CF. MRI offers exceptional details about the anatomy and pathological changes in both soft tissue and bone. MRI has high sensitivity and specificity for diagnosing osteomyelitis, it can also help in distinguishing between osteomyelitis and diabetic foot. Further, it is the first-line investigation for the assessment of diabetic patients with a complicated foot [52]. MRI shows soft tissue edema, joint effusion, interruption of Lisfranc ligament, and subchondral bone marrow edema in the acute phase of CF. MRI shows low signal intensity on T1W and high signal intensity on T2W images of bone marrow edema. The subchondral region shows characteristic differential signal enhancement of bone

marrow [52]. Radionuclide study can be used in CF. The sensitivity of Triple phase technetium-99m methylene diphosphonate (Tc-99m MDP) is high but specificity is low for the diagnosis of osteomyelitis (95–100% and 25–38%, respectively). Since the site of infection involves the recruitment of white blood cells (WBC), labeled white cell scans (In-WBC) provide a very precise diagnosis of osteomyelitis with an accuracy level of 80–90%. Both In-WBC scans and three phases of Tc-99m MDP can be used to diagnose patients with high suspicion of osteomyelitis. Nowadays positron emission tomography (PET) scanning has been used to differentiate between osteomyelitis and Charcot foot. According to a few studies PET scan has better sensitivity and specificity than MRI [53].

## 7.10 Management of Charcot Foot

CF care aims to provide a healthy, plantigrade foot that works in a shoe and also to avoid persistent ulceration. Factors affecting CF treatment include the disease phase, the presence or absence of deformity, infection, and comorbidity. Depending on the severity of the disease, the goals of the treatment should be personalized and realistic. CF treatment may vary from modified footwear to limb amputation [52].

### 7.10.1 Medical Management

Medical management of CF comprises, offloading the affected foot, correction of bony abnormalities, and reducing additional foot fractures. Acute phases of CF typically need medical management. Such management protocols are generally based on expert opinions since the evidence from randomized control trials are lacking.

### 7.10.2 Offloading

Offloading is the most important component of management in acute CF. Offloading could slow the progression to deformity. The gold standard for offloading of affected foot is the total contact cast (TCC). Application of TCC decrease the physical stress, it further reduces the inflammation and edema, thereby decreasing the bone and joint destruction. TCC providing cover to the entire foot, including the ankle joint, also providing an adequate cushion with cotton-based bandages over a bony prominence to avoid ulceration, should be used. The patients should be kept under close monitoring, and a new cast should be applied, at a regular interval of 3–7 days [54]. The application of TCC leads to perseveration of the plantigrade foot, which enables it for weight-bearing in a shoe or brace. Usually, in the first few weeks, there is a significant decline in the edema. Repeated cast change is necessary, to avoid “pistoning” with declining edema. The use of

crutches or wheelchair should be encouraged, thereby preventing weight-bearing on the affected limb. The cast needs to apply until the edema has subsided and the temperature variance among the two limbs is less than 2 °C. The average time of cast application in chronic CF with ulceration is 5 weeks, with progression to therapeutic footwear at 3 months. An alternative device for offloading the active stage of CF is a prefabricated removable walker brace. The advantage is the low cost in comparison to TCC, but it has a problem of inability to fit severe deformities and possibly incomplete compliance [52].

### 7.10.3 Antiresorptive Therapy

Bisphosphonate, due to its anticlastic activity is an appealing treatment method for acute CF. Among the bisphosphonate, Pamidronate has been the most commonly used agent. Bisphosphonate decreases the Charcot foot activity, which is evident by a decrease in skin temperature, pain, and edema. They can be used besides immobilization and offloading. The adverse effects of bisphosphonates and their contraindications for use should be kept in mind before prescribing them [55].

### 7.10.4 Bone Growth Stimulation

Ultrasonic bone stimulation is a newer technique, which has been used for the healing of new fractures in acute CF. In patients of CF with arthrodesis, direct current electrical bone growth stimulators were used. Findings were encouraging, but more evidence is required before its routine use. At this point, it is at best an adjuvant to the established treatment [52].

## 7.11 Surgical Treatment

Surgical treatment of CF is primarily dependent on the expert opinion of treating surgeons. Surgery has been utilized for removal of infected bone in osteomyelitis, correction of prominent bony points to accommodate the foot in the therapeutic footwear. This decision is primarily based on expert opinion and small, uncontrolled retrospective case series. Before surgical treatment patient's other comorbidities, compliance, site, and severity of deformity, infection, or joint instability should be considered. The surgical procedure includes release and augmentation of Achilles tendon, plantar osteotomy, debridement of the osseous points, arthrodesis, and open reduction with several methods of internal fixation with or without external fixation. Currently, we do not have enough evidence for the superiority of any procedure. Now there is a group that has suggested earlier surgical repair of deformity and arthrodesis, based on the idea that it will contribute to an improved patient-perceived quality of life [56].

# Aerobic and Anaerobic Bacterial Infections and Treatment Strategies

8

Tarek Hassan M. Kabil

## 8.1 Introduction

The wound infections are defined by the classical findings of inflammation or the presence of purulence. The wounds Infections are classified into mild (superficial and limited in size and depth), moderate (deeper or more extensive), or severe (accompanied by systemic signs or metabolic disturbances) [1].

Diabetic foot ulcers (DFU) and its infections are usually inadequately managed due to poor knowledge of the microbial agents associated with the ulcers [2]. Therefore, diabetic foot ulcers should be evaluated for microbial agents before treatment is instituted. The study of microbial infection and investigating the pathogens infecting diabetic foot ulcers and their susceptibility pattern in uncontrolled diabetes mellitus can help in the improvement of the patient's management and reduce the frequency of amputation [3].

## 8.2 The Microbiology and Rate of Infection in DFU

Wounds and other soft tissues can be infected by a variety of aerobic and anaerobic species of bacteria, either singly or in combination. The diabetic foot infection is mostly mixed infection, and polymicrobial involving both aerobic and anaerobic bacteria but mono-microbial infection can occur. A study recorded 100% infection rate with mono-microbial infection occurred among 28.0% of the subjects while polymicrobial infection affected 72.0% of the subjects [3–7]. On the other hand, Pal and Gupta reported that patients with very long hospital stay had negative culture reports [8]. The knowledge of the contribution of the entire microbiome to clinical outcomes is limited. However, the development of complex microbial communities,

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_8

that involve strict anaerobes and Enterobacteriaceae, may contribute to poor clinical outcomes in DFUs. DFUs which fail to heal are likely to be persistently colonized with heterogeneous microorganisms including anaerobes and Enterobacteriaceae [9]. The aerobic bacteria associated with diabetic foot infection include Gram-positive cocci such as *Staphylococcus aureus*, *Staphylococcus saprophyticus*, *Staphylococcus epidermidis*, *Streptococcus pyogenes*, pneumococci, *Streptococcus mutans*, Gram-positive rods as *Bacillus subtilis*, and Gram-negative rods as *Pseudomonas aeruginosa*, Proteus *species*, *Escherichia coli* and *Klebsiella pneumoniae* [10]. Ramakant et al., reported *P. aeruginosa* as the most common gram-negative isolate in diabetic foot ulcer patients in their study [11].

Anaerobic organisms, such as *Clostridium* species, *Bacteroides* species as *Bacteroides fragilis*, and anaerobic *Streptococci* such as *Peptostreptococcus*, may be present in infections of wounds, such as lacerated wounds and soiled deep wounds [1, 10, 12]. Mixed infections, in DFU, with Gram-positive cocci and coliform bacilli, are frequent. Polymicrobial infections with anaerobes include fusiforms or fusospirochete associations [5]. This was confirmed by other studies that showed that the diabetic foot ulcer severity of grade 4 is commonly infected with mixed bacteria including Methicillin-resistant *Staphylococcus aureus* (MRSA), and ESBL *Klebsiella* species [8, 13]. The polymicrobial nature of the infection was demonstrated, in a study, with 84% aerobic and 16% anaerobic species of bacteria were isolated. *Pseudomonas aeruginosa* (26.98%) followed by *Staphylococcus aureus* and *Klebsiella* sp. (16.66%) were the more frequently isolated aerobic bacteria. The anaerobic isolates were *Bacteroides* species (62.5%). *Peptostreptococcus* sp. (29.16%) and *Clostridium* sp. (8.3%) [6]. Another study was carried out to isolate and identify the microorganisms infecting DFUs. Seventy percent of these infections were polymicrobial. *Staphylococcus aureus* was the only Gram-positive bacterial isolate, 31.9%, and the most prevalent isolate. Regarding Gram-negative isolates, the study showed a dominance of Gram-negative bacteria among the isolates with *Pseudomonas aeruginosa,* 24.7%, the most common Gram-negative isolate, and *Klebsiella pneumoniae* the least isolated pathogen [3].

The patients who have chronic diabetic foot wounds or who have recently received antibiotic therapy may be infected with Gram-negative rods. Patients with diabetic foot accompanied by foot ischemia or gangrene may be colonized with obligate anaerobic pathogens [14]. There is no significant relationship between the duration of diabetic foot ulcers and infection rates. Also, infection rates are not significantly associated with gender [3, 14].

## 8.3 Pathogenesis of Infection

Peripheral vascular disease in the form of macro and microangiopathy of DM will lead to the decreased blood supply of foot tissues and when a wound occurs, it will become more susceptible to infection than nondiabetic wound where the infection rate coincides with blood sugar levels. Also, various immunological disturbances play a secondary role in DM foot infections [6, 14–16]. Foot infections in diabetic

persons are common and form a serious problem. Typically, diabetic foot infections begin in a neuropathic ulceration wound [1]. The major predisposing factor to mixed infections of diabetic foot with more than one bacterial species is foot ulceration, which is usually related to peripheral neuropathy. In some of these mixed infections, a pathogenic synergy may be evident with two or more species acting in concert to cause more damage to the tissues than would be caused by either alone. The presence of devitalized tissues provides suitable conditions for the growth of anaerobic organisms. In addition, the preliminary infection with aerobic bacteria leads to the consumption of the available oxygen, which may encourage the growth of clostridia and other anaerobic bacteria [6]. Cellulitis, necrotizing cellulitis, and wet gangrene are deep diabetic foot infections that drag the patient to the option of amputation [3]. Besides, osteomyelitis can occur in many diabetic foot wound patients [1].

## 8.4 Laboratory Examination

The sending of specimens for culture may not be required in patients with mild or previously untreated DFUs. Generally, for the examination of wound swabs, specimens of pus, exudate, or tissue for detection of the common pathogens, a panel of basic procedures are to be applied. The obtained specimens are to be sent for culture before starting empirical antibiotic therapy in all cases of infection [14]. The basic procedures include a naked-eye examination of the specimen, the microscopical examination of a Gram-stained film, and culture on aerobic and anaerobic blood agar plates, on MacConkey agar and in Robertson cooked-meat broth. The growth seen on the plates is to be identified and, if significant, it should be tested for antibiotic susceptibility.

### 8.4.1 Sample Collection and Processing of the Sample

The debrided tissue sample from deep sites of DFU is used for smear preparation. The tissue samples, whatever obtained by biopsy or ulcer curettage identify pathogens more frequently, and non-pathogens less frequently when compared with wound swab samples [14, 17, 18]. A sterile container without fixative reagent is to be used for the sample curetted from infected tissue and for fragments of an excised tissue. Pus or exudate should be submitted in a small screw-capped bottle, a firmly stoppered tube or syringe, or a sealed capillary tube [19]. If there is a suspected delay in the transit of specimens to the laboratory, the samples should be placed in the appropriate transport media. Brain heart infusion broth is used as transport media for aerobic culture to be incubated overnight at 37 °C. For anaerobic culture, the sending of pus in oxygen-free gassed-out vials or special transport media as Robertson cooked-meat media is recommended. In the case of sample by swabbing, the swab is to be dropped into a cooked-meat broth. The pathogens may grow in the directly seeded broth and in its subcultures when they cannot be recovered in culture from the conventional swabs. Therefore, the arrangement of an immediate extra

swab taken from the lesion in the clinical setting dropped into a cooked-meat broth, and send to the laboratory with the collected packaged swabs is recommended [6, 19, 20].

Gram-stained film of the sample is to be examined for the presence of pus cells, bacteria, and morphology, arrangement, and spore formation [6]. The samples should be homogenized in a tissue grinder with a little sterile broth, then cultured [19]. The culture plates have to be overnight incubated at 37 °C for 18—24 h, then examined for the relative numbers and types of the colonies. In addition, the performance of the tests for the identification and the determination of the antibiotic sensitivities is required. In case of absence of growth on the plates, or no growth of an organism seen in the Gram-stained film, the blood agars should be reincubated both aerobically and anaerobically for another 24 h. If the plates still showed no growth, they can be discarded. However, if there is a suspicion of the presence of a slow-growing pathogen such as some species of Bacteroides, a longer incubation up to 7 days is recommended. The growth in the cooked-meat broth after 24–48 h is indicated by turbidity in its appearance [21].

The preliminary performance of antibiotic sensitivity tests to give an early indication of an aspect of antibiotic sensitivity will assist in the identification of colonies of species with constant sensitivities. Also, it can help in the isolation of resistant strains from mixed cultures by selecting the colonies from the inhibition zones. Therefore, it is a good practice to apply one or two antibiotic discs on the inoculum areas of the aerobic blood agar plates before incubation as 1-unit benzylpenicillin disc and a 10 mg gentamicin disc. Also, it is wise to place a 5-pg. metronidazole disc and a 50-pg. neomycin disc on the anaerobic blood agar plates. The use of the metronidazole discs, differentiate strict anaerobes to be inhibited rather than aerobes or facultative bacteria. In addition, the inhibition of most aerobes caused by neomycin discs can help the identification of many anaerobes that are resistant to it [19].

### 8.4.2 For Aerobic Culture

For aerobic culture, the broth showing growth has to be subcultured on Blood agar, Chocolate agar (both incubated in presence of 5–10% $CO_2$), and MacConkey agar. The identification of the growth of organisms is to be made by Gram staining, colonial morphology, and biochemical tests [19, 22].

#### 8.4.2.1 For Cultivation of Anaerobic Bacteria

The specimens for culture of anaerobes require complete absence of oxygen from the atmosphere and using media that allow the growth of anaerobes in these strict anaerobic conditions.

#### 8.4.2.2 Anaerobic Incubation

For cultures of anaerobes, oxygen must be removed from the atmosphere, either by using it for combustion or by replacing it with an inert gas. It is recommended that all media for the growth of anaerobes should be incubated under strictly anaerobic

conditions. The technique of repeated evacuation of jars and filling with nitrogen tends to dehydrate cultures and unsuitable for very strict anaerobes. The hydrogen and carbon dioxide, single or a mixture is commercially available, where, cylinders of the compressed gases are fitted with valves to deliver the gases at low pressure. Commercially available Hydrogen generators are a safer technique than holding hydrogen-containing gas cylinders in the laboratory. After putting the plates into the jar, the lid is clamped on. Approximately 6/7 of the air is evacuated (pressure is monitored on a vacuum gage). The pump is disconnected and the pressure is increased to 160 mmHg with $C0_2$ and then to 760 mmHg with hydrogen. The oxygen-adsorbing envelope (AnaeroGen) removes oxygen from the atmosphere in anaerobic jars. The process does not produce hydrogen and does not require catalysts. It produces 10% $CO_2$ in the anaerobic atmosphere [19]. Petri dishes with the medium uppermost and lid downwards has to be placed inside the jar. Vented Petri dishes should be used, like sealing of the lid to the bottom of the unvented Petri dish interferes with the removal of oxygen inside the Petri dish.

A smear from the inoculated Robertson cooked-meat broth showing turbidity, is to be subcultured on Neomycin Blood agar plate with the addition of metronidazole disc to identify anaerobic bacteria. Neomycin Blood agar plate is incubated for 2–3 days at 37 °C in an anaerobic jar with Gaspaks. The organisms are to be identified using Gram staining and colony morphology [6].

## 8.5 Antibiotic Sensitivity Testing and the Susceptibility Pattern of the Bacterial Isolates in DFU

Applying Clinical Laboratory Standards Institute (CLSI) guidelines is recommended during performing the antibiotic susceptibility testing by Kirby Bauer method of disk diffusion, following the culture of a smear prepared from 24 h cultured broth [23]. Many studies reported that *Staphylococcus aureus* and *Pseudomonas aeruginosa* exhibit a low susceptibility and a high resistance to ampicillin, cotrimoxazole, and gentamycin [24, 25]. The antibiotic susceptibility profile of the Gram-positive and Gram-negative bacteria isolated from D.M. patients with foot ulcers was investigated. Gram-positive bacteria were sensitive to Vancomycin (100%) and Gram-negative bacteria were sensitive to Imipenem, Meropenem, and Levofloxacin. Aerobic bacteria showed resistance to the cephalosporin group of antibiotics. *Pseudomonas* aeruginosa was found sensitive to Levofloxacin, less sensitive to Meropenem and Imipenem, but displayed resistance to cephalosporins [6]. A study showed that the susceptibility of the isolates to the used antibiotics in DFU, was low and none of the isolates showed 100% susceptibility to any of the tested antibiotics. A low level of antibiotic susceptibility of the isolates tested was observed with ampicillin and cotrimoxazole. The Gram-positive isolate, *Staphylococcus aureus*, was more susceptible to erythromycin (67.7%), followed by amoxicillin (61.2%). The Gram-negative isolate, *Pseudomonas aeruginosa*, was more susceptible to ciprofloxacin (80.4–100%), followed by zinacef (25.0–66.7%), and amoxicillin (50.0–64.7%). Erythromycin was the most effective antibiotic against *Staphylococcus aureus*. Augmentin and ciprofloxacin were effective against Gram-negative rods [3].

## 8.6 The Treatment Strategies of Diabetic Foot Ulcer

The infection of diabetic foot ulcers can be prevented by practicing good hygiene measures in and around the foot ulcer [2]. The early observation and careful follow-up of diabetic patients with infected wounds are required to ensure the appropriateness and effectiveness of the applied medical and surgical treatment regimens [14]. In addition, the clinicians and healthcare organizations are required to monitor the outcomes of management to improve the processes carried out during care for diabetic foot infections [1]. Diabetic foot infections require coordinated management with a multidisciplinary foot-care team that should include a medical microbiologist or an infectious disease specialist. The foot-care team should, also, recruit surgeons with experience and interest. This team takes attention of both local (foot) and systemic (metabolic) issues of the DFU [26–31]. The improvement of the patient's management and reduction of the frequency of amputation can be achieved through the clear knowledge of the microbial agents associated with the diabetic foot ulcers. This can be done by investigating the pathogens infecting the ulcers and testing their antimicrobial susceptibility pattern [32–34].

Chronic wounds in D.M. patients are associated with high morbidity and healthcare expenditures. A study of neuropathic diabetic foot ulcer (DFU) patients explored the role of colonizing microbiota in wound healing, clinical outcomes, and response to interventions. The strain-level variation of *Staphylococcus aureus* and genetic signatures of biofilm formation was found to be associated with poor clinical outcomes. Therefore, the DFU microbiota may be used as a marker for clinical outcomes and response to therapeutic interventions. *Corynebacterium striatum* and *Alcaligenes faecalis* isolated from the chronic wounds in D.M. patients were previously considered commensals or contaminants, but surprisingly they are found to significantly impact wound severity and healing [35].

Regarding treatment, no available evidence to support antibiotic use in treating clinically uninfected ulcers. It is not known whether systemic or local antibiotic treatment can lead to better outcomes or if a particular agent can be more effective in this regard. Also, there is no particular antimicrobial agent to be recommended for resolution of diabetic foot infection, ulcer healing, or the prevention of amputation [36–39]. However, antibiotic therapy is necessary for all infected wounds, not alone, but in combination with appropriate wound care. The strategy is to select an empirical antibiotic based on the suspected microorganisms and the grade of severity of the infection. The definitive use of chemotherapy should be based on the clinical response to the empirical antibiotic used and on both the culture results and susceptibility testing profile. The local antibiotic susceptibility testing data, as the occurrence of prevalent methicillin-resistant *S. aureus* (MRSA) or any other resistant bacteria and the recent use of antibiotics, must be considered [40–42]. Regarding to the treatment of most of the mild diabetic foot infections, oral antibiotics of appropriate bioavailability can be used, usually, for a period of 12 weeks but some may require treatment extension to another 12 weeks. On the other hand, the treatment of some of the mild superficial infections is just, topical chemotherapy [43, 44].

In DFU patients who have mild-to-moderate infections and do not receive antibiotic therapy, chemotherapy can be sufficient for aerobic Gram-positive cocci [36].

In many of the moderate infections, and some cases of osteomyelitis, appropriate oral antibiotics with adequate bioavailability can be used. A period of 24 weeks is usually enough for treating moderate and severe infections. This period depends on the structures involved in DFU infection, wound vascularity, the adequacy of debridement, and the type of soft-tissue wound cover [45]. Usually, broad-spectrum antibiotic regimens are required for diabetic patients at risk for infection with antibiotic-resistant organisms or with chronic infections, previously treated, or severe infections. In case of severe infections with pending culture results and antibiotic susceptibility, the empirical treatment with broad-spectrum antibiotic is indicated [1]. The failure of response of DFU infection to the prescribed antibiotic courses in a clinically stable patient drags the attention to the need of discontinuing all antimicrobials and after a few days, new specimens are to be collected for another optimal culture [14].

Treatment of diabetic patients with osteomyelitis requires a duration of treatment for at least 46 weeks that probably becomes longer with the presence of the infected bone, but shorter on entire infected bone removal. The antibiotic therapy should be continued until there is an evidence of resolution of the infection but not until a wound healing occur [43, 44, 46, 47].

Surgical consultation and intervention ranging from debridement to resection or amputation may be needed in diabetic foot infections [45, 48–52]. These diabetic foot infections are specially accompanied by a deep abscess, extensive bone, joint involvement, crepitus, substantial necrosis, gangrene, or necrotizing fasciitis. Evaluation of the limb's arterial supply and revascularizing is indicated in cases with ischemic foot in these infections [15, 16]. The debridement, rather than antibiotic treatment, significantly shifts the microbiota in DFU patients to favorable outcomes [35, 53–57]. The healing of DFU infection requires the provision of optimal wound care in the form of proper wound cleansing, debridement of any callus and necrotic tissue, and off-loading of pressure, together with the appropriate antibiotic treatment [45, 48, 50–52]. The regular follow-up of the patients is needed with proper dressing of the wounds and off-loaded of pressure. There is no evidence for recommending the use of wound healing agents or products for infected foot wounds or a specific wound dressing [58–60].

## 8.7 The Role of Adjunctive Therapies for Diabetic Foot Infections

Selected adjunctive measures may be useful for some nonresponding DFU patients [1]. Trials were carried out by systematic reviews to define the role of adjunctive therapies for diabetic foot infections. They suggested that applying systemic hyperbaric oxygen therapy and granulocyte colony-stimulating factors may help in preventing amputations in patients with severe infections or in patients with inadequate response to chemotherapy, despite the correction of their local and systemic adverse factors [61–64].

Interestingly, the development of diabetic foot ulceration can result from the increased magnitude of the local mechanical repetitive stresses on the foot by the use

of inappropriate footwear or walking barefoot [65–68]. DFUs are one of the leading causes of lower extremity amputations, therefore, it is of paramount importance to prevent DFUs [69–73]. To help prevent diabetic foot ulceration, it is recommended that diabetic patients wear appropriate footwear designed to reduce repetitive stresses at all times. The adherence and prescription of wearing footwear has been studied, and evidenced effective and important maneuvers for ulcer prevention in diabetic people [67, 68, 74–83]. In this regard, ten key recommendations were published in Australia guidelines to guide the health professionals to select the most appropriate footwear for an individual with D.M. to meet the specific foot risk needs.

Updated Australia recommendations for selection of the footwear for diabetic patients are:

1. Wearing footwears that fit, protect, and accommodate the feet shape.
2. Always wear socks within footwear to reduce friction and shear.
3. Education to diabetics, their relatives, and caregivers about the importance of foot ulcer prevention by wearing the appropriate footwear.
4. In intermediate- or high-risk diabetic foot ulceration, the diabetic is instructed to obtain the footwear that fits, protects, and accommodates the shape of feet from a trained professional.
5. Diabetics with intermediate- or high-risk of foot ulceration are motivated to wear their footwear both indoors and outdoors.
6. In intermediate- or high-risk of foot ulceration, diabetic patients, or their relatives and caregivers are motivated to check the feet after footwear removal to ensure there are no trauma, ulceration or signs of abnormal pressure, and check their footwear before wearing, to ensure that there are no foreign objects in, or penetrating the footwear.
7. Prescription of medical grade footwear with custom-made in-shoe orthoses or insoles should be considered for people with a pre-ulcerative lesion or a foot deformity.
8. Prescription of medical grade footwear with custom-made in-shoe orthoses or insoles with a demonstrated plantar pressure-relieving effect at high-risk areas for healed plantar diabetic foot ulcer patients.
9. The prescribed footwear should be reviewed every 3 months to guarantee it still fits adequately, protects, and supports the foot.
10. Prescription of appropriate off-loading devices to heal plantar diabetic foot ulcers [84].

## 8.8 Summary

This chapter:

- Emphasizes the importance of the knowledge of microorganisms associated with diabetic foot ulcer (DFU) infections in the management of these infections and the prevention of their suspected complications.

- Discuss the microbiology and rate of infection in DFU, the various pathogens and colonizers associated with DFU infection.
- Outlines the pathogenesis process in infections of DFU.
- Demonstrates the laboratory examination procedures, starting from sample collection and processing, passing through the methods of cultivation aerobically and anaerobically, and finally testing the susceptibility pattern of significant isolates from DFU.
- Maps the treatment strategies of DFU, and drawing the attention to the coordinated management of DFU with a foot-care team.

## 9.1 Introduction

Diabetes and its related complications are considered as one of the major causes of morbidity and mortality round the globe [1]. Diabetes is a noncommunicable metabolic syndrome may either characterized by defective or decreased level of insulin secretion [2]. The current estimate on global diabetes epidemiology reveals that

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_9

roughly under half of billion population is affected by diabetes and associated pathologies and is projected to increase by around 50% by 2045 [3].

One of the most severe and dreadful complications of diabetes mellitus is diabetic foot infections (DFIs). These infections are consequent to skin ulceration characterizes with loss of peripheral neuropathy (protective sensation) and also with some forms of trauma. The developed wounds serve as ideal spot for the colonization and multiplication of a wide range of pathogenic microorganisms and facilitate their entry into tissues leading to the inflammatory response [4]. Infectious disease society of America classified diabetic foot infections as mild, moderate, and severe subject to extent of damage been done to infected foot [5]. However, the majority of infections are superficial while about quarter of total infection is deep enough which spread from epidermal layer to inner regions including subcutaneous tissues and bones leading to necrotic fasciitis, osteomyelitis, and septic arthritis [6]. Patients with DFIs are also shown to develop some level of peripheral arterial disease as describe with restriction in blood supply to tissues and causing oxygen deficit needed for cellular metabolism (Ischemia) which results into peripheral tissue dysfunction [7]. These types of invasive infections are the most frequent and severe in patients with diabetes mellitus [8]. It has been estimated that nearly one-third of patients with diabetes develop a diabetic foot ulcer at one or other stage of disease progression [9]. Furthermore, diabetic foot infection/diabetic foot ulceration exponentially increases the probability of amputations, with a factor of 155 times higher than those patients having no diabetes [10]. Recent study also has shown that patient anxiety related to amputation is extremely high, a person with diabetes and associated foot infection feared amputation more than death, as compared to diabetic patients without foot infection/foot ulceration pathologies [11]. Death risk associated with diabetic foot infection is also significant when infection runs deep into the internal tissues [12]. It has been estimated that 5 year mortality rate of patients with diabetic foot infection/ulceration is about 50% that is higher than those of different types of cancer including prostate cancer, breast cancer, and Hodgkin lymphoma [13, 14].

Since DFI/DFU are colonized with numerous pathogenic microorganism, the problem is further compounded with increasing incidence of antimicrobial resistance among them [10]. Progression in colonization of these microorganism leads to the development of biofilm, a self-embedded bacterial community with altered metabolic and physical parameters [15]. These microbial biofilms when formed and specially reached to internal tissues possess great difficulty in the removal and subsequent getting rid of infections [16]. Antimicrobial therapy constitute a major component of DFIs management practices, however injudicious and inappropriate use of antibiotics make it difficult to eliminate multidrug-resistance bacteria. Thus it is indispensable to have a broader and subjective understanding of drug resistance among the microbial community with special focus drug resistant biofilm formation in infected feet for successful treatment regimen. In this chapter, an attempt has been made to present a brief review of different type multidrug-resistance bacteria (MRSA and ESβL) associated with diabetic foot infections with special focus on biofilms formation.

## 9.2 Microbiology of DFIs/DFUs

The microbiological profile of DFIs/DFUs is varied and depend upon specific geographical/environmental setting, duration, and stage of progression of the disease, antibiotic use history, and significance of infections [17]. Further, the development of infection varied with aspects such as microbial load at specific time, diversity among the colonized microbial population, presence of pathogenic/invasive microorganism, and synergistic association between the populations [18]. Once the microbial load reaches greater value than 105 organisms per gram of tissue, the infection is considered to be initiated [2]. As evident from a different culture and non-culture based techniques, different aerobic and non-aerobic bacterial communities have been identified. At initial stage of simple epidermal infection, Gram-positive cocci (*Staphylococcus* and *Streptococcus* spp.) were mainly found to colonize. While, in case of chronic infections/ulcerations may be characterized with predominantly polymicrobial communities of different type of aerobic pathogens such as *Staphylococcus*, *Streptococcus*, *Enterococcus*, *Pseudomonas* spp. along with pathogenic anaerobes [19, 20]. *Pseudomonas aeruginosa* and *S. aureus* are predominant Gram-negative and Gram-positive bacterial species present in feet infections/ulcers [21, 22]. Studies carried out at tertiary care center in developing countries revealed that infections caused multidrug-resistant aerobic microbes, as mention above, are predominant [23, 24]. Moreover, in these geographical regions with warm climates, *P. aeruginosa* is more prevalent while *S. aureus* is less prevalent [25, 26], which may be attributed to environmental factors, footwear, personal hygiene, antibiotic treatment history, etc. [19]. Whereas, in colder regions, Gram-positive aerobes predominantly *S. aureus* is more common than members of Enterobacteriaceae and *Pseudomonas* [4]. Deeper chronic DFIs associated with ischemia, necrosis, foul odor, or gangrene are predominantly occupied with anaerobes [27]. The most abundant anaerobic bacterial pathogens found in infected feet is *Bacteroides fragilis,* which has been reported in various studies [28, 29]. Although it was also evident from these studies that the abundance of anaerobic microflora is low and also have a lesser impact on the progression of infection or their significance in the infection is not clearly understood [29].

Recent studies highlighted the increasing incidence of multidrug-resistance pathogens in DFIs and resultant grave outcomes [30]. *Staphylococcus aureus* is one of the major causative organisms in the majority of all clinical DFIs associated with clinical phenotypes ranging from acute paronychia to deeper chronic osteomyelitis and severe soft tissue necrosis [30, 31]. Methicillin-resistant *Staphylococcus aureus* (MRSA) is now considered as a chief infectious agent in the feet infections of diabetic persons specifically for skin and soft tissues. These MRSA associated skin and soft tissue infections are more difficult to eradicate in diabetic patients when compare to those having no diabetes at all [32]. However, there is still a need for objective research to attribute the consequences that MRSA has on other clinical outcomes in patients with diabetes-associated foot infection [33]. Continues progression of antimicrobial resistance (AMR) in Gram-negative bacteria have now encompassed nearly all the available representative of present antibiotic arsenal. Resistants have

been emerged against advanced generation cephalosporins which are attributed to the emergence of extended-spectrum beta-lactamases (ESβL) and AmpC-β-lactamases [34]. "Pan resistant" isolates of Gram-negative bacterial species of Pseudomonas and Acinetobacter are of severe life-threatening nature which is being reported in DFIs [35]. Among other factors responsible for the development of AMR in microbial communities residing in diabetic foot settings, biofilm formation is considered as a major driving force. Biofilms provide protective barriers against antibiotics treatment, moreover, the altered metabolic rate of bacteria enclosed in bacteria also supplement their resistance potential [10, 15, 36]. Biofilms formation is multistage process and well-known virulence factors enabling the bacterial community to cope with challenging environmental stresses such as the presence of antimicrobial in the settings. As mention above, it is well known that microbial cells in surface-attached biofilms are physiologically distinct from their planktonic counterparts residing in the liquid medium [37]. The overall resistance observed in biofilms is different from than those of planktonic cells, sometimes 1000 times higher [38]. Since DFIs are associated with polymicrobial drug resistance microbial communities, polymicrobial biofilms further complicate the problem of drug resistance and possess an even greater challenge for effective antibiotic therapy [15, 36].

## 9.3 Methicillin-Resistant *Staphylococcus aureus* (MRSA) and Diabetic Foot Ulcers

Methicillin was the first synthetic penicillin introduced in 1960 to treat the infection caused by *S. aureus*. However, the joy was short-lived as methicillin-resistant strains of *S. aureus* (MRSA) surfaced in hospitals [39]. This was followed by several outbreaks of MRSA leading to severe morbidity as well as high mortality [40].

There are kinds of MRSA, one is hospital-acquired (HA-MRSA) and the second one is community-acquired (CA-MRSA). HA-MRSA is also known as nosocomial infection as it acquired from hospital and other medical settings while CA-MRSA as the name suggests is acquired from the community. Diabetic people are prone to both HA and CA-MRSA due to the presence of pores and ulcerations [41].

MRSA produces a penicillin-binding protein PBP2a having low binding affinities for most of the penicillin as well as cephalosporins/cephamycins. Methicillin resistance in *S. aureus* is attributed to the presence of Staphylococcal cassette chromosome mec (SCCmec) element, that carries methicillin-resistance determinant mecA. CA-MRSA carries *SCCmecA type IV* or *V* elements while HA-MRSA carries larger *SCCmecA type I*, *II*, *III* elements along with multidrug resistance (MDR) genes [41].

In the current review, we discuss the reports on MRSA infection in diabetic foot infection published in the last 10 years. Centre for Disease Control (CDC) recognizes MRSA as microorganisms having a serious threat level. Incidence and prevalence of MRSA differ in different geographical zones. According to a report published by US military Health system for a period of 5 years (2005–2010), HA-MRSA bacteremia decreased from 0.7 to 0.4 cases per 100,000 patients per

year while CA-MRSA bacteremia came down from 1.7 cases per 100,000 patients per year to 1.4 cases per year [42]. In a retrospective case-control study conducted in China on 118 type 2 diabetes patients with DFI, *S. aureus* was found to be the most common pathogen (25.6%). High percentage of *S. aureus* was found to be MRSA (63.4%) and a high proportion of these MRSA satisfied the criteria for hospital-acquired MRSA (HA-MRSA) infection [43]. Lavery et al. [44] did a cohort study to evaluate the risk factors for MRSA in patients admitted with DFIs. They reported the presence of MRSA in 29.8% infections and risk factors for MRSA diabetic foot infections were history of MRSA foot infection, MRSA nasal colonization, and multidrug-resistant organisms ($p < 0.05$). Positive predictive value (PPV) and negative predictive value (NPV) of nasal colonization with MRSA to identify MRSA diabetic foot infections were 66.7% and 80.0% (sensitivity 41%, specificity 90%). In another study conducted on 318 patients in a USA hospital, around 46% patients with diabetic foot infection (DFI) had *S. aureus* infection of which 15% had MRSA infection [45]. In a similar investigation, 80 DFI specimen were collected in a hospital in Iran over a period of 1 year. Phenotypic identification resulted in 35% MRSA and 32% *S. aureus* were found to be resistant to methicillin carrying *mecA* gene by PCR [46]. In Korea, a pilot study on 737 patients with DFUs admitted between January 2012–December 2016 was conducted. Among 832 microbial isolates, 13.7% (114) were identified as MRSA [47].

In a study in Southwest China, 428 patients were enrolled and 555 strains were cultivated. Among isolated bacteria, 85 were *S. aureus,* of which 17 were MRSA [48]. A prospective investigation of 261 with DFIs in intensive care unit of a tertiary care hospital was performed over a 2-year period. A total of 289 isolates were cultivated and the most abundant bacteria were found to be *S. aureus* (26.9%). Among *S. aureus*, 23.7% were resistant to methicillin [24]. Recently, in Kenya, a cross-sectional study was conducted to identify bacteria in DFUs and to compare conventional microbiological methods with RT-PCR for the detection of MRSA. RT-PCR based identification of MRSA was accomplished in isolated bacteria whereas, culture methods could not identify MRSA among isolated bacteria [49].

## 9.4 Extended Spectrum Beta-Lactamases and Diabetic Foot Infection

Extended-spectrum beta-lactamases (ESβL) are enzymes produce by certain bacteria that can hydrolyze cephalosporins like ceftazidime, ceftriaxone, cefotaxime, and oxyiminomonobactum [50]. Gram-negative bacteria, especially Enterobacteriaceae and *Pseudomonas aeruginosa* are known to produce ESβLs [50]. Most ESβLs are derivatives of TEM or SHV enzymes. There are now >90 TEM-type β-lactamases and >25 SHV-type enzymes. With both of these groups of enzymes, a few point mutations at selected loci within the gene give rise to the extended-spectrum phenotype. TEM- and SHV-type ESβLs are most often found in *E. coli* and *K. pneumoniae*; however, they have also been found in *Proteus* spp., *Providencia* spp., and other genera of Enterobacteriaceae. In recent years a new family of

plasmid-mediated ESBLs, called CTX-M, that preferentially hydrolyze cefotaxime has arisen. They have mainly been found in strains of *Salmonella* enterica serovar Typhimurium and *E. coli*, but have also been described in other species of Enterobacteriaceae [51].

The emergence of ESβLs has rendered the current antimicrobial therapy ineffective as they make infection-causing bacteria resistant to cephalosporins, the "workhorse" antibiotics. ESβL producers often are associated with multidrug resistance, so any delay in the identification and failure to treat infections caused by ESβL producing pathogen can lead to severe morbidity as well as mortality [52]. It is therefore imperative to review the prevalence of ESβL producers in patients with DFUs in order to control the spread of infection. In India, over a period of 1 year 191 samples were collected from indoor patients with DFIs in a tertiary care hospital. ESβL production was observed in 46.51% of the 43 isolated *E. coli* strains and 44.44% of the 27 *K. pneumoniae* isolated [53]. Zubair et al. [54] studied 60 patients with DFI. They found that 23.3% patients were infected by multidrug-resistant (MDR) strains and 45% of the isolated Gram-negative bacteria were ESβL producers. The prevalence of $bla_{CTX\text{-}M}$ (33%) gene was highest followed by $bla_{SHV}$ and least was $bla_{TEM}$ gene. In another study conducted by the same group in a tertiary care hospital of North India over a period of 3 years, it was found that out of 127 isolates belonging to Enterobacteriaceae, 81.9% were found to be positive for the bla gene, of which $bla_{CTX\text{-}M}$ showed 81.8% positivity, followed by $bla_{TEM}$ (50%) and $bla_{SHV}$ (46.9%) [55]. Similarly, a retrospective study was carried out between June 2007 to July 2008 in Kuwait on the microbiological profile of DFIs and their drug susceptibility. ESβL producers were identified from the 777 pathogens isolated. Double disk synergy and ESβL test revealed 11% and 14% of the *E. coli* and *K. pneumoniae* were producing extended-spectrum beta-lactamases, respectively [56].

In Egypt, 91 patients with DFUs were examined and a total of 135 Gram-negative bacteria was recovered from ulcer specimens. Initial screening results demonstrated 114 bacteria as ESβL producers but confirmatory test revealed that 58 of these 114 bacteria produced ESβL and 8 of these were plasmid mediated. Majority of these 8 strains carried 2 or more ESβL genes on the same plasmid. The most common combination was $bla_{CTX\text{-}M}$ and $bla_{TEM}$ ($n$ = 3/8; 37.5%), followed by $bla_{SHV}$ and $bla_{CTX\text{-}M}$ ($n$ = 2/8; 25%) and $bla_{CTX\text{-}M}$ + $bla_{TEM}$ + $bla_{SHV}$ ($n$ = 1/8;12.5%). One strain of harbored a plasmid (pECDF16) coding for the three ESβL genes [57].

Clinical samples from 150 patients were collected over a period of 1 year and examined for the incidence of ESβL, AmpC, and MBL producing *Pseudomonas* spp. Majority (80%) of the isolated *Pseudomonas* spp. were multidrug resistant and 22.9%, 42.8% and 14.4% of the Pseudomonads produced ESβL, AmpC, and MBL, respectively. Mortality was found to be 20% in these patients [58]. In a study conducted in Pakistan, among the isolated bacteria 66% of the *K. pneumoniae* were found to produce ESβL. Overall prevalence of β-lactamase (bla)-CTX-M, bla-CTX-M-15, bla-TEM, bla-OXA, and bla-SHV genes was found to be 76.9%, 76.9%, 75.0%, 57.7% and 84.6%, respectively, in Gram-negative DFI isolates. The prevalence of antibiotic resistance genes was considered alarmingly high in the studied DFIs [59]. In a recent report, a pilot study was conducted across 19 centers in

Turkey, between May 2011 and December 2015. In total, 791 patients with DFIs were included in the investigation and 536 microorganisms were isolated. Antibiotic resistance profiling revealed that 21% *Pseudomonas aeruginosa* were multidrug resistant and 38% *E. coli* and *K. pneumoniae* were found to be ESβL positive. Further, 3% [24] mortality was also reported [30].

## 9.5 Biofilm and Diabetic Foot Infections

Biofilms are a complex structure of microorganisms encapsulated in a matrix of exo-polysaccharides or exo-polymeric substances that attach to living or inert surface [60]. Most biofilms are polymicrobial and consist of bacteria, fungi, viruses, protein, extracellular DNA, and several biological factors. Biofilms not only confers resistance to the microbes residing in biofilm mode but protects the microbes and helps survive in hostile environmental conditions [61]. Several reports have emerged that studied the formation of biofilm and the presence of multidrug-resistant microorganisms in DFIs [62, 63].

### 9.5.1 Biofilm Formation

Biofilm formation takes place by the reversible attachment of the microbe as the first step. This attachment is facilitated by pili, flagella, surface appendages, or specific receptors. This is followed by EPS mediated irreversible attachment to the substratum. In the third stage, cells multiply and microcolony formation takes place. In the fourth step, biofilm matures by the growth and differentiation of the cells, and finally in the fifth stage biofilm cells disperse actively or by passive detachment [64]. EPS plays a key role in the formation and maintenance of biofilm. EPS protects the cells from the harsh environment, prevents the entry of antimicrobials, and protects from the action of the immune system. EPS also protects the biofilm cells from dessication, facilitates ion exchange, houses, and maintains degradation enzymes and carries nutrients [65].

### 9.5.2 Biofilm Virulence and Wound Care

Diabetic foot ulcers/infections are included in the class of chronic wounds. The annual incidence of foot ulcers in diabetic patients is 1–4% in the USA, with a lifetime risk of occurrence of between 15% and 25%. In 2006, the total cost of treatment, amputation, rehabilitation, and long-term care of diabetic foot ulcers in the USA totaled $10.9 billion [66]. Therefore, it is very important to study how biofilms are the cause of persistent infections and hamper effective wound care. Cells residing in the biofilm mode are sessile and in comparison to their free-living planktonic counterparts are metabolically less active. Reduced metabolic activity increases resistance to antimicrobials as most antibiotics are effective against actively

dividing cells as, for example, beta-lactams target peptidoglycan, aminoglycosides disrupt the protein synthesis and quinolones interfere with DNA replication [67]. Further, EPS prevents the entry of antimicrobials and protects from the action of the immune system [65]. Stimulation of the immune system without effectively curing the infection causes collateral damage to the surrounding tissues and inflammation becomes chronic. This not only aggravates the wounds but impedes the healing action considerably [61].

Biofilm increases the probability for the transfer of drug resistance genes carried on mobile genetic elements like plasmids. This transfer of resistance genes can be intraspecies as well as interspecies, thus making the infections more virulent and persistent [68].

In addition to the drug resistance, tolerance to antibiotics is another property of the biofilm cells. Tolerance is not plasmid mediated but is believed to be a result of metabolically inactive biofilm cells [69]. Tolerance to drugs is a transient phenotype that allows the maintenance of a subpopulation of cells in the wounds, called *persister* cells. Upon suspension of the drug therapy, the persister cells regenerate to give rise to biofilm cells that retain the similar susceptibility profile of the original biofilm, so the persister cells are maintained. Drug therapy is rendered ineffective, treatment failure of the wound occurs and infections become persistent [70].

Removal of necrotic tissues and microbial load through debridement is an essential and important part of the wound care [71]. Since EPS facilitates irreversible attachment of the biofilm cells to the wound bed, it makes debridement rather difficult and incomplete as some cells remain attached to the wound bed and are not removed. These leftover cells regenerate and form biofilms again leading to recurrent infections [72].

Biofilm formation is a dangerous property of the microbiome that colonizes diabetic foot wounds. Consequently, the last few decades have seen a major problem in treating DFU infections due to the ever-increasing rate of colonization by drug-resistant pathogens. The presence of MRSA, ESβL, and MβL producing bacteria along with the formation of polymicrobial biofilms are some of the major causes of the DFI/Us healing impediment [15].

## 9.6 Conclusion

The severity of the diabetic foot infections and the huge amount of money that is involved in the prevention, treatment, and control have made researchers as well as medical practitioners to understand the mechanisms involved and device strategies to interfere with them. Diabetic foot infections caused by biofilm-forming bacteria that produce mecA and ESβL enzymes are on the upsurge and are very much responsible for the increasing amputations. The resistance of DFIs to antimicrobials has made treatment very challenging. Further, dissemination of the resistant strains coupled with the slow development of new antibiotics has made the task of treating DFIs herculean. Therefore, new alternative approaches are required to combat the problem of drug resistance.

# Fungal Infection: The Hidden Enemy?

10

Mohammad Oves, Mohd Ahmar Rauf, Fohad Mabood Husain, Mohammad Zubair, Iqbal M. I. Ismail, and Arun Iyer

## 10.1 Introduction

In the current years, reports on the fungal infections are increasing in the human population. The eradication of disease provides a challenging task to health care researches and doctors [1]. Fungal infection is occurring in humans and animals when and invasive fungal sp. attached to the body parts and controlled enough immune systems for its growth. The reports on fungal Infection is increasing due to the increasing the human population and lifestyle become modernize resulting in changing medical practice and require intensive care of emerging disease which mostly leads to the immunocompromised in the patient [2].

Fungi can make alive in the air, soil, water, plants, and animals and live naturally in the human body, and it exists in two forms fungi molds [3–5]. Mold colonies

consist of filamentous strands called hyphae, whereas yeasts are typically single, small, oval cells. Some fungi are dimorphic, existing as either yeasts or molds depending on the external environment. Like other microbes, some fungi are helpful and some harmful. Whenever harmful fungi invade the body, they can be challenging to kill, as they can survive in the environment and reinfect the person trying to get better. Superficial and subcutaneous fungal infections can affect the surface skin, keratinous tissues, and mucous membranes and cause irritation and abruptness [6]. Worldwide, millions of people suffering from skin diseases caused by the fungal infection. However, superficial fungal infection is rarely life-threatening while debilitating effects on a person's quality of life. But sometimes it becomes highly contagious and spread to other individuals or become an invasive and systemic infection. Systemic fungal infections can be life-threatening and are associated with high morbidity and mortality [6, 7]. In a specific geographical location, some fungal infections may cause by either an opportunistic microorganism that infects an at-risk host or may be associated with a more invasive organism. The diagnosis of systemic Infection is difficult, and the exact incidence determination is difficult and the causative agent could be confirmed by autopsy. The count of fungal species in millions, but only a few of them can make people sick. Fungi can cause the number of different types of infection and disorders such as allergies or asthma, skin rushes, nails and lungs infection, meningitis sometimes bloodstream infections [8]. The most fungal infection recurrently comes across result from the inhalation of conidia, which can intensify allergic response atopic and nonatopic animals and humans [9, 10]. Sometimes the primary source of infection is inhalation by immunocompromised patients, which cause invasive pulmonary disease. Another primary source of infection is gastrointestinal routes due to eating of contamination foods [11, 12]. *Aspergillus fumigatus* and *Aspergillus flavus* cause the most significant fungal infection which leads to invasive aspergillosis [13, 14]. *A. niger*, *A. terreus*, and *A. nidulans* species of fungi also cause severe infection and lead to the mortality of immunocompromised patients [14–17]. The high number of fungal infections are not reportable and unrecorded due to lack of knowledge of fungal taxonomy. However, the researcher estimated appoximetly1.5 million species exist globally while only ~70,000 have described formally by the features [18]. Near about 300 fungal species have virulence factor may because disease and harmful to humans, only a few of them able to influence the central nervous system of human [19, 20].

In general, the filamentous fungi are characterized by branching hyphae, with septate hyphae containing species *Aspergillus* spp., *Fusarium* spp. and Mucoromycetes with non-septate hyphae containing species are *Rhizopus*, *Rhizomucor*, and *Mucor*, and additionally moniliaceous species with light-colored as molds. Dark pigmented molds are seen less common and include species which are considered as true neurotropic fungi [20, 21]. Dark pigmented fungi *Cladophialophora bantiana* are most commonly find in India, *Verruconis gallopava* was recovered worldwide while, *Exophiala dermatitidis* was also encountered worldwide but most common in East Asia, *Rhinocladiella mackenziei* is mainly recovered from the Middle East [21, 22]. The dimorphic fungi grow well in two morphological stages at lower temperature below 25 °C as a molds in environment

and higher temperature up to 37 °C as a yeast-like *Blastomyces*, *Histoplasma*, *Coccidioides*, and *Paracoccidioides* are restricted to specific endemic areas [23–25]. This book chapter focuses on the unique hidden infections caused by fungus in humans. Number of localized opportunistic fungal infections that affect any human not only in older adults but in older people age-related physiological changes and some fungal infection becomes more serious. Here we discussed only hidden infection caused by fungus in neonatal to old age humans and required protection and treatment.

## 10.2 Mycobiont Reservoir in the Human Body

### 10.2.1 Fungal Infection in the Oral Cavity and Treatment

Fungal infection in the mouth to gastrointestinal (GI) tract may occur due to overgrowth of invasive mycobiota, sometimes high exposure to the contaminated consumable items and water [26, 27]. The degree of the disease be contingent on the primary risk factors of an individual body, such as immunosuppression by the different diseases like diabetes, and ranges from colonization, localized Infection, or fungemia, to aggressive life-threatening. The oral cavity is one of the primary mucosal locales where asymptomatic carriage of fungi was exposed [28]. The diversity in the oral mycobiota is low and controlled by the *Ascomycota phylum* species, such as *Candida* spp. [29]. While in culture-independent strategies have uncovered the nearness of a few individuals from the Saccharomycetaceae family (*Candida albicans*, *Candida dubliniensis*, *Candida rugosa Candida pararugosa*, *Saccharomyces cerevisiae*, *Hanseniaspora uvarum*, and *Pichia* spp.), and *Fusarium* species, that speaks to most of the parasitic species found in the oral cavity [29]. During the dysbiosis, the oral mucosa is less identified, and most of the studies focused on the overgrowth of *Candida albicans* upon immunosuppression and diabetes [30]. During the culture-independent investigation of the oral cavity sample of HIV-infected patients, mycobiota revealed the overgrowth of *C. albicans* while other species *Dothideomycetes* spp. and *Leotiomycetes* spp., related to the phylum Ascomycota, was also increased [29–32]. Although, oral mucosa is easily infected by the *Candida albicans* because of its adherence properties and high level of adherence properties and found 40–65% of healthy adult mouths as oral commensalism. In the mouth, papillated dorsal surface of the tongue and beneath a maxillary denture and palatal mucosa are preferred reservoir sites for Candida [33]. Such type of infection become pathogenic and increased due to compromised host interaction. These interactions between host and organism may be local or systemic. The salivation decreasing and weaning of dentures are considered local factors, while Infection during diabetes mellitus, pernicious anemia, and AIDS is known as systemic infection [34]. *C. albicans* infection can cause the weak immune system of its host and cause oral candidiasis, and it occurs in different form denture erythematous, pseudomembranous, erythematous, hyperplastic [35, 36]. Median rhomboid glossitis is a form of oral candidiasis was investigated by researchers. The number of drugs is

available in the market for the treatment of oral candidiasis, such as nystatin, clotrimazole, ketoconazole, and fluconazole. Three times oral rinse with the Chlorhexidine as a disinfectant for dentures [37].

### 10.2.2 Gastrointestinal Tract Fungal Infection and Treatment

The lower gastrointestinal tract is containing more diverse fungal communities than the mouth or upper gastrointestinal tract. Here most of the species are belongs to the genera of *Candida*, *Saccharomyces*, *Aspergillus*, *Cryptococcus*, *Malassezia*, *Cladosporium*, *Galactomyces*, and *Trichosporon* [38]. However, some commensalism fungi able to influence host immunity, but it is not the only way of fungi infection. Some commensal fungi species are present in the food items, and air and the environmental source might activate the immune response in the gut—for example, *Histoplasma* spp., *Blastomyces* spp. and *Coccidioides* species cannot colonize the mucosal surfaces, but they can cause severe infections in the lung [39, 40]. In some studies observed temporal instability in fungal variability of the intestinal mycobiota, due to most of the infection based studies rely on the sampling of fecal and other materials. While in recent studies, from the mucosa-associated fungi suggest that a more stable community, the intestinal mycobiota [41, 42]. Sometimes this mycobiota perturbed by the intestinal disease [43]. These intestinal fungi are reservoirs in the proximity of the intestinal mucosa, and it might be interacting with the epithelium and the mucosal immune system. During bacterial dysbiosis, target lower gastrointestinal tract, and an inflammatory condition is known as inflammatory bowel disease (IBD) [44]. Recently, observed the fungal burden in the colonic mucosa become increased during the IBD, such as Crohn's disease and ulcerative colitis [45, 46] During the chronic intestinal inflammation, exits, the number of fungal species has reported in several studies [45–47]. It is confirmed and recovered a high number of cultivable *C. albicans* from the feces of IBD patients [48]. In Crohn's disease, the patient observed the inflamed mucosa of the intestine due to the high growth of *Candida albicans* and *Candida parapsilosis* [49]. The continuous increasing inflammation in the gut mucosa of mice due to the high rate of colonization of *Candida* sp. [50]. In a few investigations, find the Ascomycota phylum decrease and expansion of *Basidiomycota* spp. [51], while in another study, contradictory results observed in IBD patients. The development of clone libraries based on the 18S rDNA denaturing gradient gel electrophoresis (DGGE) from patients with Crohn's disease [52]. They have to find a high number of fungal diversity and richness in the feces and the mucosa when compared to the healthy individuals or colitis induced intestinal inflammation of individuals [53, 54]. In a study, immunocompromised patients have found 41% of individuals gastrointestinal infected while 22% affecting the lower part of the track and mostly infection caused by the *Aspergillus* or *Candida* sp. [55]. Candida infections in the mucosa/submucosa of the intestine where the organisms preferentially colonize the previously infarcted bowel [56]. In several studies, pathologists considered the sepsis caused a major role in

mortality; sometimes, fungemia was paying a contributory role in many cases, and combined infection of Candida and Aspergillus in jejunal caused fatal gastrointestinal hemorrhage [57–59].

German Society for Hygiene and Microbiology (DGHM) has defined the intestinal fungal Infection based on symptoms and enumeration of yeast up to, or $>1 \times 10^5$ cells/g of stool consider pathogenic colonization and causing diarrhea and require specific medical treatment [60].

Antifungal agents such as amphotericin B, ketoconazole, fluconazole, and the various formulations of itraconazole are effective in most cases [61]. During intestinal infection, dietary supplements and measures are essential to control the colonization of fungal pathogens. To control the intestinal yeast infection, the patient should avoid the consumption of refining sugar and carbohydrates because Yeast cells metabolize a high rate in the presence of low molecular weight carbohydrates. Recommended foods are fiber-containing vegetables and roughage, which provide little nutrients for yeasts cell development and promote gut motility and support the natural flora of the intestine, which have natural antagonistic activity toward yeasts [62]. As such, food rich in roughage contributes to fortifying the body's defense system and to healing mycoses of the gastrointestinal tract [60].

### 10.2.3 Lung Infection Caused by the Fungal Pathogen

Lung infection caused by fungal pathogen mainly by Aspergillus and Cryptococcus, both are widespread mold species which can appropriately sporulate and released conidia [9, 63]. These conidia are air born and dispersed in the air and arrive in the human airways and enter into the pulmonary alveoli [64]. In a healthy human, inhaled conidia are engulfed by alveolar macrophages and destroyed in the phagocyte oxidase-dependent pathways [14]. While in immunocompromised individuals, these conidia not able to destroy by phagocytosis, and here the attached to the mucous and spreading and tissue invasion by fungal hype, they caused several human diseases like asthma allergies and lethal infections [65, 66]. Sometimes, the fungal infection site makes granulomas that occur due to the integration of different immune cells later it degenerate to scars and calcified; it can be detected by the X-ray imaging analysis. Whenever the cellular immunity becomes impaired due to some immunosuppressive disease, then fungal infection control is too difficult. Airborne fungus and its spore are inhibiting in dust and avian, it inhalation causes *Cryptococcosis*. It mainly caused by *Cryptococcus neoformans* and *Cryptococcus gattii* [67]. Cryptococcal meningitis is the most severe outcome of the Cryptococcus infection because it invades the blood-brain barrier, and fungal cells directly penetrate the endothelial cells on the blood vessels of the brain [68]. In some reports, *C. neoformans* find in the brain cells and sometimes caused severe colonization [68]. *Pneumocystis jirovecii* causes lung infection and induced Pneumocystis pneumonia and Endemic mycosis, it is also found in non-HIV immunocompromised patients with a deficiency in adaptive immunity, or individuals taking prolonged

high-dose systemic glucocorticoids [69, 70]. Worldwide most of the region's incidents of endemic mycoses are increasing due to rapidly growing the immunocompromised population. Exposure to the soil containing bat or bird droppings causes *Histoplasma capsulatum* infection with patients also present pneumonia symptoms described as acute/chronic pulmonary histoplasmosis, and severe cases may culminate in respiratory failure and death [9, 71].

### 10.2.4 Fungal Infection Stimulus of Age, Sex, Diet, and Environment

The number of studies reveals the high variability in the mycobiota between different individuals, and this distinction leads to the dysbiosis between healthy and infected ones [43]. In general, the mycobiota in a human body or animal significantly influenced by the environment, gender, age, diet, and geographical location [72, 73]. According to gender-wise male individual mycobiota contain a high number of *Aspergillus* spp. and *Tremellomycetes* spp. while a female has *Candida* spp. [74, 75]. In most cases, some mycobiota decease age-wise, and some increase, for example, during the infant stage, the genera such as *Aspergillus*, *Tremellomycetes*, and *Penicillium* are abundant and fungal diversity overall decreases with age [73–76]. Likewise, the mycobiota of the skin decreases with age, and it may happen due to the high rate of sebaceous gland secretion in the skin that favors the colonization by lipophilic fungi species *Malassezia* [75]. The fungal diversity exists among different ethnicities due to variables in consumer behavior and lifestyle. Diet also significantly influences the fungal and bacterial diversity in humans; it depends on specific vegetables, cereals, fruits, and dairy products consumption [77–79]. If any individual feed on the animal-derived diet or cheese, then fugal load increase in human faces [38]. The based on DNA sequencing human gut microbiome study reveals each person has a unique microbial gut profile that influenced by lifestyle and diet [80, 81]. If avoid a vegetarian diet and high consumption of sugar contains food, which leads to an increase in *Candida* sp. in the gut [80–82]. Based on the commensal relationship, individual human fungal diagnosis is too tricky and isolation of fungi from different body parts does not indicate pathogenicity [76].

### 10.2.5 Auditory Infections

In the mid ear, fungal infection occurrence is sporadic, but sometimes otitis media case serious problems [83]. In the immunocompetent children are facing ear problems by Infection of *Candida albicans* [83]. In the warm, humid climates, *Aspergillus* sp. is the most common pathogen and case otomycosis or external otitis sometimes [84, 85]. These symptoms resemble bacterial otitis and pruritis pain more prominent than pain.

### 10.2.6 Neuroinfections Caused by Fungi

The rate of fungal infections is expanding each year, with more noteworthy quantities of infections noted among patients having a place with high-chance gatherings, for example, HIV-infected people and AIDS patients, transplant beneficiaries, and immunosuppressed patients treated with chemotherapeutics or corticosteroids, just as those experiencing hematological sicknesses and incessantly sick patients [86] Certain conditions may incline the patient to the improvement of a particular etiological specialist: ailment/treatment-related and hereditary elements (delayed anti-infection treatment, neutropenia, steroid treatment, transplantation, ceaseless granulomatous sickness, CARD9 lack, neurosurgery, and rashness in babies—Candida; diabetic ketoacidosis, necrotic consumes, renal disappointment, and intravenous medication use—Mucoromycetes; birds contact—Cryptococcus and Histoplasma; deferoxamine treatment and iron over-burden—Mucoromycetes [87–90]. Some fungi's like Cryptococcus, Coccidioides, and Histoplasma, can likewise cause disease in immunocompetent patients. In USA, it was evaluated that intrusive mycoses brought about by *Candida* spp. are accountable for about 2–228 infections for each million populace every year, while *Cryptococcus neoformans* is liable for 30–66 infections and *Aspergillus* spp., 12–34 infections [91, 92]. The most well-known CNS fungal contamination overall is cryptococcal meningoencephalitis. Dispersed mycosis is frequently connected with CNS inclusion. It is evaluated that somewhere in the range of 67% and 84% of patients with intrusive cryptococcosis create CNS mycosis, 3–64% create obtrusive candidiasis, 40% blastomycosis, 25% dispersed coccidioidomycosis, and 5–20% scattered histoplasmosis, while 12% produce mucormycosis and 4–6% obtrusive aspergillosis [93–95]. Remember that in clinical presentation, cases of FIsCNS differ depending on the form of etiological factors. Diverse methods of CNS sore that occur, depending on the size of the fungal structures that build in the human body, for example, blastospores or hyphae. Blastomyces, Histoplasma, Coccidioides, Paracoccidioides, Cryptococcus, and Candida enters the blood vessels and causes local necrotic lesions, with meningitis and subpial ischemic lesions, while Aspergillus, Cladosporium, and Mucoromycetes infiltrate large blood vessels and can cause strokes [96–98].

### 10.2.7 Fungal Cooperation with the BBB and CNS Attack

The pathogenesis of FIs-CNS is not yet completely comprehended. Infiltration of the pathogen over the blood-brain barrier (BBB) is a fundamental advance for CNS attack. The coursing pathogens in the blood should initially be captured in the brain microvasculature and afterward transmigrate into the brain parenchyma over the blood-brain barrier BBB. Three components have been depicted for pathogens to cross the BBB. transcellular movement, paracellular relocation, and the Trojan Horse Mechanism [99–101]. Those instruments are best comprehended for Cryptococcus and Candida. *C. neoformans* precisely captured in the brain

vasculature can cross the BBB by both immediate and circuitous components. Direct mode of incorporating BBB section through transcytosis of endothelial cells, while indirect mode incorporates movement within phagocytes as Trojan Horse Mechanism. Likewise, the paracellular section of the *C. neoformans* between endothelial cells has been additionally recommended. To trigger the translocation forms, chiefly through paracellular and transcellular systems, connections between pathogen protein atoms and BBB are essential. Ongoing examinations show that utilizing the transcellular component by *C. neoformans* in brain microvascular endothelial cells (BMECs) requires protein kinase C-alpha actuation. The CPS1 quality is required for *C. neoformans* adherence to the surface protein CD44 of human BMECs. The dispersal of the pathogen into the brain is constrained by Isc1 quality encoding a chemical that hydrolyzes inositol [102, 103].

As of late, Huang et al. demonstrated that the attack of *Cryptococcus neoformans* into human BMECs is interceded through the lipid raft endocytic pathway by means of the intracellular kinase-DYRK3 [104, 105]. Adherence of *C. albicans* to the extracellular lattice is encouraged by fibronectin, laminin, and vitronectin. It was shown that *C. albicans* intrusion of brain endothelial cells is intervened by the fungal attacks Als3 and Ssa1 [106, 107]. Als3 ties to the gp96 heat shock protein that is communicated explicitly on brain endothelium, advancing endothelial transcytosis by the growth [108–110].

Trojan horse pathway begins with contamination of a phagocyte in the peripheral region. Once disguised, the pathogen may effectively control the phagocyte to advance relocation toward the brain. The contaminated phagocyte arrives at the brain and clings to the luminal side of brain vessels and crosses the BBB, either paracellularly or transcellular. In conditions of decreased invulnerability, the BBB porousness builds, which encourages the entrance of growths into the brain. The pathogens get to the brain parenchyma and multiply causing brain irritation. As the pathogenic variables need to beat the successful barriers encompassing the brain, intrusions are generally connected with immunocompromised states. Consequently, the actuation of nerve cells by fungal cells and the declaration of resistant improving and immunosuppressing cytokines and chemokines assume a deciding job in pathogenesis of FIs-CNS. CNS association happens as the blood-brain barrier, and cerebral and subarachnoid spaces are crossed by the attacking organisms. This procedure is supported by different blood-brain barrier disturbances, for example, injury, medical procedure, or actuation of microglia and cytokines: TNF-α upsets the tight intersections of the barrier. The rate and degree of contamination are affected by the harmfulness of the growth and the movement of the host insusceptible framework. White blood cells, microglia, astrocytes, and endothelial cells assume significant jobs in forestalling disease by repressing fungal development through the creation of cytokines (INFγ, TNF-α, IL-1β, IL-6, and IL-12), chemokines, nitric oxide, and superoxide anion, and by the declaration of MHC I and II particles [111]. TLR-2, 4, and 9 are answerable for the acknowledgment of fungal antigens: polysaccharide case (*C. neoformans*), pseudohyphae (*C. albicans*), or conidia (*Aspergillus* spp.); anyway TLR-2, Dectin-1, and CR-3 are answerable for the acknowledgment of sugars, for example, mannose and β-glucans, present on the

outside of *A. fumigatus* and *C. albicans*. Fungal pathogen-related subatomic examples are associated with starches (chitin, mannoproteins, phospholipomannan, and β-glucans) in the cell wall which may permit fungal infections to be constrained by empowering the actuation of microglia yielding master lymphatic and humoral reactions. The enactment of microglia cells relies upon the proximity of opsonins and T cells.

## 10.3 Treatment of FIs-CNS

Treatment of FIs-CNS Fungal neuroinfections is portrayed by higher death rates and more unfortunate visualization than viral and bacterial infections, and parasitic intrusions. Quick analysis and the utilization of suitable treatment are urgent in forestalling a frequently lethal result. The decision of antifungal treatment relies upon the fungistatic and fungicidal activity of the medication. The fungal cell film or divider segments (ergosterol, chitin, and β-glucans) are significant focuses of the primary gatherings of antifungal specialists in current use, except for flucytosine (antimetabolic impacts). Amphotericin B deoxycholate (AmBd) is profoundly harmful and has poor CNS infiltration, however, it is considered as a potential agent against cryptococcal meningoencephalitis, in combination with flucytosine, and neuroinfections caused by the other fungal agents and possess high BBB penetration (e.g., voriconazole); in these cases, lipid formulations of amphotericin B (L-AmB) ought to be favored [112–114]. Among antifungal medications, voriconazole, fluconazole, and flucytosine promptly enter into the CNS, yet itraconazole and posaconazole just infiltrate to a minor degree [115–117]. Voriconazole is suggested as an essential treatment for CNS aspergillosis, while liposomal amphotericin B (L-AmB) is saved for intolerant patients [118, 119]. Clinical information demonstrates that isavuconazole shows palatable action in obtrusive aspergillosis and scattered mucormycosis in CNS [120]. Notwithstanding pharmacological treatment, careful expulsion of injuries is likewise conceivable. By and large, a blend of careful mediation and antifungal treatment builds the endurance pace of patients with FIs-CNS. It has been demonstrated that neurosurgery is related to an improved result in patients treated with voriconazole for CNS fungal infections [121].

## 10.4 Conclusion

Every individual on the planet is sustaining commensalism with numerous microorganisms. These microorganisms are varying in diversity including fungi also variable in each individual and depends on the early life, age, dietary and cultural habits and geographical location. These fungal diversity composition sometime imbalance and disrupts the immune system and cause a hidden infection in the body and which leads to fungal diseases. Fungal infection in the mouth to gastrointestinal (GI) tract may occur due to the high load of contaminated consumable. The degree of the disease of an individual body depends on immune power. If individual sufferings

from the immunosuppression by the different diseases like diabetes and HIV and wide ranges of diseases affected from colonization of the number of fungi and leads to the fungemia and life threatening.

# Diabetic Foot Syndrome: Risk Factors, Clinical Assessment, and Advances in Diagnosis

11

Thomas Antony Thaniyath

## 11.1 Introduction

Diabetic foot disease (DFD) or syndrome (DFS) is factors' complex array in the macro-vascular (e.g., peripheral arterial disease) and microvascular (e.g., damage in the peripheral nerve) problems which affect diabetic patients and it is estimated one in three of diabetic patients will have the risk of DFD development as well as 10% of them will be developing DFU (Diabetic Foot Ulcer) in their lifetime [1, 2]. WHO defined DFS as "ulceration of the foot (distally from the ankle and including the ankle) associated with neuropathy and different grades of ischemia and infection" [3]. DFU is considered diabetes' serious complication, which may lead to lower extremity amputation, which amounts amid 0.03–1.5% of patients with DFD [4, 5]. Compared to nondiabetic individuals, higher risk for major amputations that is nearly 30–40% has been found in type 2 diabetic patients [6]. Sensation loss due to diabetic peripheral neuropathy, ischemia caused by peripheral arterial diseases or their mixture may contribute to the development of foot ulcers in diabetic patients [7]. In another review, based on epidemiological data, it is estimated that 15% of the cases resulted in peripheral arterial occlusive disease (PAOD), only neuropathy is responsible for diabetic foot syndrome's 50% cases approximately, whereas angiopathy and neuropathy combination results in the development of foot ulcerations which is nearly 35%. The diabetic foot is a distinctive example of diabetic neuropathy's painless complication. The process of nociception-the pain perception developing from encoding's neural processes as well as the noxious stimuli processing is worsening in the diabetic foot. Painless diabetic neuropathy is the underlying main cause for diabetic foot ulcers' development, as it results in painless injuries and inflammation [8]. In addition to the above mentioned etiological factor for the diabetic foot ulcers development, the studies show a clear correlation among incorrectly fitted shoes and foot ulceration in older people with diabetes

T. A. Thaniyath (✉)

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_11

mellitus. In these studies, the patient with present ulceration, up to five times are likely not to wear correctly fitted shoes in comparison to patients that do not have any foot ulceration [9, 10]. The above evidence is cemented in a review by Andrew and Hylton, stating that the potential for the diabetic foot ulceration occurrence is greater in diabetic patients, who wear incorrectly fitting shoes than those without diabetes [11]. The objective of this chapter is to highlight the diabetic foot syndrome development risk factors, clinical features as well as recent progress in disease's early detection.

## 11.2 Risk Factors

In a clinical scenario, when diabetic patients are being dealt with them it is of utmost importance that causal pathway must be considered to the foot ulceration as the best method to prevent DFU formation is the risk factors reduction. The four primary components that must be considered are foot deformities, minor trauma, peripheral arterial disease (PAD), and peripheral neuropathy [12].

### 11.2.1 Diabetes: Duration and Glycemic Control

Long-standing and uncontrolled glycemic profile of the patient influences the peripheral arterial and neuropathy disease complications' development by complicated metabolic pathways. The consequences of these complications lead to loss of sensation and ischemia, which alone or in combination may result in foot ulcers [1, 13]. In a study by Vibha et al. [13] including 620 participants with type 2 diabetes mellitus, 70.5% of 321 patients ($p < 0.001$) with DFS had a history of diagnosed DM for more than 6 years. The duration, as well as high level of glycated hemoglobin, has a strong link with the neuropathy progression and development [1, 14, 15]. It is observed in Diabetes Control and Complications Trials (DCCT) that the HbA1c level's intensive control effectively reduced the neuropathy incidence in 1441 type 1 diabetes mellitus patients by 60% [16]. In another study on type 2 diabetes mellitus, intensive insulin treatment enhanced vibration perception threshold and nerve conduction velocity than those who were under conventional treatment [17]. However, the UK prospective diabetes study (UKPDS) with 3867 type 2 diabetes patients did not show any glycemic control effect on the neuropathy prevalence [18].

#### 11.2.1.1 Peripheral Neuropathy

It is diabetes' common and intractable complication, which causes feeling lost in the lower limb and increases the amputation risk, with the prevalence of 1–2% of diabetic patients [19]. Peripheral sensory neuropathy disrupts the normal protective reflex mechanisms, resulting in a severe trauma or repeated unnoticed mild ones causing wounds. Abnormalities in proprioception cause defective weight support while walking, which also promotes callus or ulcer formation. Sensory and motor neuropathy result in irregular foot mechanism as well as structural alterations and

autonomic neuropathy alter sweating and superficial perfusion, which promotes the skin drying and fissure formation [20]. In 2004, van Schie and associates concluded in a case-controlled trial that the neuropathic patients without an ulceration history are at high risk for future ulceration [21].

#### 11.2.1.2 Peripheral Arterial Disease

The risk for PAD (peripheral arterial disease) development is more in diabetic patients as well as it is an estimated two- to fourfold enhancement in risk in comparison to the non-diabetic population. The epidemiological studies observed that the 9.5%PAD prevalence in adult diabetic patients versus 4.5% in the nondiabetic population [22–28]. It is described as a clinical disorder with peripheral arteries' occlusion or stenosis, in which the primary cause is atherosclerosis. Epidemiological studies confirmed the association of diabetes with atherosclerosis. PAD is an important analyst for diabetic foot ulceration development as physicians must evaluate the lower limb vascular status as well as particularly for the ischemia signs, during the patients' examination with diabetes and diabetic foot syndrome [20]. In their cross-sectional study conducted in 2017, Tresierra-Ayala and García Rojas concluded that PAD is among those factors that are associated with type 2 diabetes patients to diabetic foot ulceration and highlights the significance of early assessment as well as peripheral arterial disease treatment.

#### 11.2.1.3 Other Pathological Factors

The other factors, which influence the healing of ulceration in diabetic foot syndrome patients, are the infection and other comorbidities presence [29–31].

### 11.2.2 Sociodemographic Factors

Several pieces of research suggest the role of sociodemographic factors in diabetes patients with foot ulceration development [32–35]. These studies notify in older patients the high prevalence of DFU, those with low socioeconomic factors, and lower education. Vibha et al. [13], in another community based cross-sectional study observed the high prevalence of DFU among patients with advancing diabetes long duration, sedentary lifestyle, low socioeconomic status, and age.

### 11.2.3 Foot Deformities

The risk of amputation in patients with DFU rises from 1.7-fold in those with peripheral neuropathy to 12-fold in patients with both foot deformity and sensory loss [36, 37]. Several studies identified that foot deformities as the main contributing element and foot ulceration prediction, possible by skin predisposing to high pressure at foot deformity site [38–40]. Van Schie and associates highlighted the clear relationship between the foot deformities, muscle weakness, and motor nerve conduction deficit in accordance with muscle and individual nerves they

innervate [21]. However, they relating conduction deficit of motor nerve with foot deformities, there is no suitable conclusion on the role of abnormal nerve function in the causation of foot deformities.

### 11.2.4 Incorrectly Fitted Footwear

The modern footwear fulfills three purposes: form, function, and fit [41]. Of these, function intends to protect the feet of the individuals from the risk of injuries and the term fit pertains to how the footwear will maintain the foot's morphology [42]. These statements represent the significant role of footwear in the protection of feet from the risk of injury and to keep the morphology of the foot. The incorrectly fit footwear contributes to pathological alteration in foot morphology, such as hallux valgus and toe deformity [43, 44]. In addition to the above changes, it causes skin lesions like corns and calluses [45], which predispose the foot to ulceration especially in diabetes patients [10].

## 11.3 Clinical Assessment Guidelines and Advances in the Diagnosis of Diabetic Foot Syndrome

For diabetes as well as diabetic foot syndrome management the significance of foot and footwear evaluation for the deformities existence, gait's abnormalities, and patient's ability to perform physical activities and to determine the risk for the development of ulceration is signified by the clinical practice guidelines [46]. Diabetes patients' screening comprises the individuals' identification who are at high risk of complications development through appropriate screening tests based on appropriate clinical practice guidelines (CPG), which defines standards for health care according to evidence-based interventions [47]. It is proved by several studies, that the patient outcomes are improved when evidence-dependent clinical practice guideline suggestions are used in health care [48]. With appropriate use of reliable clinical practice guidelines, it can be delayed the serious complications of diabetes and diabetic foot syndrome to a certain extend. The international health community and organizations such as WHO and IDF made recommendations with the objective of decreasing the amputations rate by 50% in diabetic foot disease and it suggested that protection program and foot screening implementation for patients at ulceration risk can decrease both health care cost and morbidity [49]. Several internationally accepted CPGs are available for the screening and assessment of diabetes patients and DFS. However, in a systematic review article, Formosa et al., pointed out the inadequacy of these guidelines and recommends the inclusion of current development in science and information technology in accordance with political and ethical issues, competing priorities, assessment tests' specificity, and sensitivity, economic considerations, health system capacity issues, and epidemiological considerations, on revision of guidelines [47].

### 11.3.1 Highlights of Major Guidelines in Diabetic Foot Disease Prevention and Management

#### 11.3.1.1 National Health and Medical Research Council (NHMRC) Australia; 2011 ("https://www.baker.edu.au/Assets/Files/Foot_FullGuideline_23062011.pdf")

NHMRC clinical guidelines constructed according to evidence-dependent recommendations from literature's systematic review. It recommends temperature perception, vibration, and pinprick's sensory modalities and Achilles reflexes that are dependent on neuropathy disability score [47] to demonstrate the degree of peripheral nerve involvement. Visual inspection of feet and structural deformities and ulceration is an important recommendation of this guideline. For the foot's arterial perfusion the most useful indicators are toe pressure or toe-brachial pressure index, ankle-brachial pressure index, along with peripheral foot pulses' palpation [47]. NHMRC recommends the appropriate footwear and hosiery and the use of therapeutic footwear if indicated. It also considers the use of "Foot Deformity Score" for marking deformation in foot and consists of the following deformities: Charcot's neuro-arthropathy, abnormally wide feet, high-arched, or excessively flat feet, previous amputations, callus, hammer/claw toe, and hallux deformity. The score helps to measure the joint mobility limitation. Foot care education and training provision to all diabetes patients, help to prevent foot complications related to diabetes.

Based on the NHMRC guidelines, it is categorized diabetes patients on the possibility of developing foot complications:

1. Low-risk group: those without risk factors as well as without foot ulcer/amputation history. Yearly evaluation is recommended.
2. Intermediate risk group: those with one risk factor such as foot deformity, PAD, or neuropathy and without foot ulcer/amputation history. Advised to seek expert evaluation every 3–6 months period.
3. High-risk group: those with two or more risk factors as well as/or foot ulceration/amputation history. Recommend for specialized assessment for foot protection programs, including suitable footwear, podiatry review, and foot care education.

In short, NHMRC, 2011 guidelines, provide evidence-based criteria on diabetic foot ulcer management and prevention. It suggests yearly screening of all diabetic patients for prevention and patients with high risk should receive expert and integrated multidisciplinary foot care, comprises wound dressings and debridement, off-loading, and standardized ulcer assessment [50].

#### 11.3.1.2 Canadian Diabetes Association (CDA), Canada; 2013 ("http://guidelines.diabetes.ca/app_themes/cdacpg/resources/cpg_2013_full_en.pdf")

CDA guidelines recommend annual screening (more frequently in patients with higher risk) of diabetic patients for peripheral neuropathy presence with 10 g monofilament over the feet's distal plantar surface. The PAD screening/detection is done

with ABPI (ankle-brachial pressure index) with adjunct influence and palpation of foot pulses and systolic toe pressure determination by spectral Doppler waveform analysis, transcutaneous oxygen pressure, and photoplethysmography. Patients' assessment includes determination of bony foot deformities, movement limitation(s) of ankles, and toe joints for the detection of risk for diabetic foot syndrome. It advises the use of expert-designed therapeutic footwear and the foot care education provision for patients with a high risk of foot ulceration. It also recommends the provision of education on foot care for caregivers as well as healthcare professionals for the early detection of signs of DFS, including feet's visual inspection for infection evidence, skin temperature, callus pattern, and skin changes. For the patients who develop foot ulcers, CDA highly recommends the expertise of multidisciplinary healthcare management intending in preventing recurrent foot ulceration as well as amputation.

#### 11.3.1.3 Scottish Intercollegiate Guidelines Network (SIGN), Scotland; 2013 ("https://www.nabcop.org.uk/resources/scottish-intercollegiate-guidelines-network-2013-sign-134/")

SIGN guidelines advise the screening of all diabetic patients by trained health professionals for developing diabetic foot disease's risk. Early assessment for the presence of neuropathy with 10 g monofilament and a neurothesiometer and PAD using Doppler ultrasound detecting ABPI. It recommends arterial reconstruction for all patients with limb ischemia. Simple tests should be used to detect structural abnormalities in these patients and advises preventive footwear and orthoses. Foot care education by a multidisciplinary team is advised for all diabetic patients. SIGN guidelines categorize diabetic patients into:

(a) Low-risk patients with absence of risk factors for diabetic foot: recommends yearly screening by qualified health care expert and provide with verbal and written education, self-management plan, with emergency contact details and suitable access to a podiatrist if needed.
(b) Moderate risk patients with single risk factors: Annual evaluation by a podiatrist, Patient-oriented treatment plan, and provision of written as well as verbal education with emergency contact details.
(c) High-risk patients, having more than one risk factor or amputation/ulceration history: yearly evaluation by a podiatrist with a well-tailored patient-oriented management program with written as well as verbal education with emergency contact details and transfer for expert involvement is needed.
(d) Active diabetic foot disease: a multidisciplinary foot care team's member manages it with a well-tailored patient-oriented management program with written as well as verbal education with emergency contact details and transfer for expert involvement is needed.

#### 11.3.1.4 National Institute for Health and Care Excellence (NICE), England and Wales; 2015 ("https://www.nice.org.uk/guidance/ng19")

NICE guidelines encourage foot's visual inspection and self-monitoring by diabetes patients themselves. It recommends the screening of all diabetic patients for neuropathy and PAD presence by monofilament test or vibration utilizing calibrated tuning fork/bio-thesiometer and palpation respectively. It recommends the provision of adequate training to healthcare professionals as well as those concerned in the diabetic foot assessment. Patient education must be an ongoing basis with different methods until optimal for patients. Specialist footwear and insole should be provided in patients with diabetes and previous ulceration. It also recommends annual review and management plans including diabetic patients' education regarding foot care with low current risk. Patients with elevated neuropathy risk or no pulses or another risk factors should be followed up every 3–6 months for evaluation of foot for enhanced foot care education, footwear, and vascular assessment. High-risk groups with previous ulcers, skin changes, deformity, absent pulse, and neuropathy should be followed up every 1–3 months. The examination includes for nail protection, specialist footwear and skin and insoles, specialized foot care education, vascular assessment, and feet inspection. In case of ulcerated foot and foot care emergency such as new ulceration, swelling, and discoloration, refer the patient with 24 h to a multidisciplinary foot care team. The team must be comprised a diabetologist with expertise in lower limb complications, nurse expert in diabetic wound dressing, and a highly qualified specialist podiatrist as well as orthotist. Revascularization should be considered for the patients of possible benefit. Patients with nonhealing ulcer are suggested with intensive systemic antibiotic therapy.

#### 11.3.1.5 Deutsche Diabetes Gesellschaft (DDG), Germany; 2014 ("https://www.diabetesde.org/system/files/documents/fileadmin/users/Patientenseite/PDFs_und_TEXTE/Infomaterial/Gesundheitsbericht_2014_kl.pdf")

DDG guideline recommends the provision of continuing education programs for diabetic patients and caregivers on foot care intending in preventing diabetic ulcers as well as periodical evaluation of both feet for deformities and limited mobility. It suggests the screening for neuropathy with 10 g monofilament test and/or Rydell-Seiffer tuning fork vibration. The peripheral arterial sufficiency assessment is done with ABPI determination, arterial occlusion pressure over posterior tibial artery, and dorsalis pedis artery measurements, and foot pulses palpation. It advises periodical evaluation of footwear in all diabetics and the provision of footwear as per the diabetic foot risk. Categorizes the diabetic patients in to:

- Risk category 0: no PAD, no sensory neuropathy and recommends annually evaluation.
- Risk category 1: sensory neuropathy with or without deformation: evaluation in each 3–6 months.

- Risk category 2: PAD with or without sensory neuropathy: a specialist examination in each 2–3 months.
- Risk category 3: amputation or ulcer history: specialist evaluation in each 1–2 months.

#### 11.3.1.6 Institute of Clinical Systems Improvement (ICSI), USA; 2014 ("https://www.icsi.org/guideline/diabetes/")

ICSI guideline for diabetic foot prevention as well as management suggests diabetic patients' annual/biannual screening for foot risk assessment as well as foot care counseling to prevent microvascular complications of diabetes. It suggests consideration of foot care specialist if the followings are present: the patient is not able to care their own feet properly, requires suitable footwear, or has conditions like foot deformation(s), the infected lesion(s), or ulcers, thick calluses or deformed nails. Consider vascular surgeon if the patient develops peripheral vascular disease signs and symptoms like claudication and/or peripheral pulses lack. In all patients diagnosed with diabetes, it advises the provision of education/self-management through a healthcare team and feet's daily self-observation for nail problems, redness, and lesions in addition to dermatological changes of color, sweating, infection, ulceration, callus, bleeding, and blistering. The examination of the foot must include the observation for the limitation of joint mobility. It recommends a patient-tailored foot care education based on their individual needs, knowledge as well as the presence of risk factors. It also highlights the importance of physical activities of moderate-intensity exercise at the rate of 150 min per week as well as resistance training three times per week till contraindicated.

#### 11.3.1.7 NZSSD (New Zealand Society for the Study of Diabetes)—Podiatry Special Interest Group; 2014 (www.nzssd.org.nz/healthprofs/pdf)

NZSSD guidelines recommend screening of all diabetic patients by health professionals from the diagnosis time yearly, in case there exists no risk for diabetic foot disease and provision foot care education to each people diagnosed with diabetes as part of multidisciplinary care. In the presence of risk, it advises more frequent assessments every 3–6 months. People with a high diabetic feet risk must consult a multidisciplinary foot care team or a specialist diabetic foot clinic. The screening for neuropathy is done with perception threshold using bio-thesiometer, vibration test using 128 Hz tuning fork, 10 g monofilament. The screening of peripheral arterial disease is done through the rest pain/or symptomatic claudication evaluation and dorsalis pedis artery palpation. The identification of foot deformations and its management is an essential step according to this guideline.

The diabetic foot disease patients are suggested to use cushioned, high-quality sports, or running shoes. It is advised to wear custom made footwear or orthotic insoles in patients who have high-risk feet, deformation, or have previous amputation history with the aim to prevent callus formation or to reduce its severity and to avoid recurrence of ulceration.

#### 11.3.1.8 International Diabetes Federation (IDF); 2015 ("https://www.idf.org/about-diabetes/54-our-activities/222-idf-clinical-practice-recommendations-on-the-diabetic-foot.html")

IDF recommends the provision of a self-management education program which is patient-centered as the main part of therapy for all type 2 diabetes patients from the diagnosis time and ongoing process depending on requirements' regular assessment. An appropriate multidisciplinary team should be assigned to educate the people individually or group-wise considering the suitability of the program and individual and encourages the use of modern technologies as a communication method. Screening of the patients for neuropathy is done with 10 g monofilament or 128 Hz tuning fork. Quantitative measurement is done with bio-thesiometer. It also recommends the use of a non-traumatic pinprick test. The posterior tibial arteries and dorsalis pedis palpation are done for the screening of PAD and quantitative assessment with Doppler measurement of brachial/ankle pressure ratio. Less than 0.9 is considered as the cutoff point for the presence of vascular occlusive disease. The patients are categorized into three groups as per the foot assessment findings;

(a) No added risk: There exist no risk factors such as the previous foot ulceration or amputation history, symptoms of peripheral neuropathy and PAD. Advises the foot care education provision.
(b) At risk: Presence of one risk factor. Review the patient consistently after 6 months by the foot care team. The evaluation processes include the inspection of both feet and ensures the local management provision. Footwear evaluation and suitable advice and enhancement of foot care education.
(c) High risk: There exist two or more risk factors. The foot care team reviews the patient in a more frequent way of 3–6 months gap. The process comprises the inspection of both feet and the local management provision as described. Footwear evaluation and providing specialist insoles as well as shoes if described as well as ensure the suitable intensified foot care education provision.

The patient must be sent to a multidisciplinary foot care team immediately in 24 h after there is of occurrence/presentation of foot ulceration/infection. They should be provided with appropriate wound management. The IDF guidelines classify the infection as;

1. Severe: Accompanied by systemic features of sepsis
2. Moderate: Deeper than skin and more extensive cellulitis
3. Mild: Superficial with minimal cellulitis

Long-term antibiotic therapy should be considered if indicated. In suspected cases of osteomyelitis, appropriate investigations should be considered. Reduction of weight and methods for optimum distribution of pressure should be done such as the use of crutches. The management of vascular insufficiency is the next consideration if needed. The patient should be provided with specialist footwear and orthotic

care along with individualized foot care education to prevent recurrence after recovery along with optimal blood glucose regulation.

#### 11.3.1.9 International Working Group on Diabetic Foot (IWGDF); 2015 ("https://iwgdfguidelines.org/")

IWGDF guidelines emphasize the patient education necessity and patient ability assessment to understand the messages, sufficient self-care skills, and motivation to act accordingly. It points to the essentiality of assessment of joint mobility limitation and foot deformation(s). The guideline advises the annual screening of all diabetic patients for peripheral arterial and neuropathy disease presence as well as recommends the suitable footwear to accommodate the modified deformities and biomechanics. IWGDF guidelines raise five key elements for the assessment, screening for the diabetic foot risk: foot at risk's consistent examination and inspection, a foot at risk's identification, education, and family of foot care for prevention and treatment, suitable footwear provision and non-ulcerative pathology treatment such as callus, nail, and skin pathology by specialized podiatrist [49]. This IWGDF 2015 guideline upholds the necessity of three tier foot care management [49]: the different level team includes:

- Level 1—diabetic nurse, podiatrist, and general practitioner
- Level 2—specialized diabetic nurse, podiatrist, surgeon, diabetologist
- Level 3—specialized foot center with multiple disciplines specialized in diabetic foot care

#### 11.3.1.10 American Diabetes Association (ADA), USA; 2019 ("Diabetes Care 2019;42(Suppl 1):S124–S138. https://doi.org/10.2337/dc19-S011")

ADA 2019 guidelines provide a comprehensive criterion for diabetic foot evaluation as well as treatment:

1. ADA recommends for the foot's annual assessment in every diabetic patient for early identification of risk factors for amputation and ulceration and those with signs of prior ulceration/amputation or sensory loss must evaluate their foot on each visit.
2. Check for the nephropathy, retinopathy, cigarette smoking, vascular surgery/angioplasty, Charcot joint, amputation, and ulceration history.
3. Neuropathy's current symptoms were assessed such as vascular occlusions like claudication, and fatigue, numbness, and burning, and pain.
4. The foot examination must consist of skin inspection, foot deformities assessment, and neurological involvement, and peripheral arterial disease assessment.
5. The neurological assessment should be done with 10 g monofilament with a minimum of one other test such as vibration, temperature, or pinprick.
6. The vascular assessment includes pulses palpation in feet and legs. The patients with claudication signs or absent or reduced pedal pulses must be evaluated with ankle-brachial index as well as for other appropriate assessment methods.

7. To all diabetic patients provision of general preventive foot care education.
8. ADA recommends referring the patients with high risks such as smoking habit, history of prior lower extremity amputation, those with peripheral arterial disease, or protective sensation loss, to a foot specialist for ongoing prevention and life-long surveillance.
9. The specialized therapeutic footwear use is suggested for the patients with greater risk for diabetic foot such as severe peripheral neuropathy, amputation history, or foot deformities.
10. Multidisciplinary management is suggested for foot ulceration and high-risk foot patients.

### 11.3.2 Methods for Peripheral Neuropathy Screening as Well as the Assessment in Diabetic Patients

Painless ulceration of foot as well as/or arthropathy are the cardinal features of diabetic foot. The underlying painless neuropathy is the reason for the masking of the inflammation and the painless repeated foot injuries in diabetic patients. The skin ulcers are completely insensitive to pain and Charcot's joint may reflect with faint dull aching upon load bearing [8]. It is determined that peripheral neuropathy is greatly related to the lower limbs and feet and the most common component for the causation of foot ulceration in diabetic patient [51–53]. The diabetic neuropathy, in most of the patients, affects both the large-fiber nerves of the limbs and in turn, alters the sensations of muscle control, position perception, vibration, and touch, as well as small-fiber nerves for autonomic function, pain, and thermal perception [54]. The diabetic peripheral neuropathy incidence enhances with diabetes duration and age as well as it is common in patients with uncontrolled glycemic profile and obesity [53, 55]. These facts indicate the management and early detection significance of such a condition. Table 11.1 lists important screening tools for peripheral neuropathy's detection. Apart from the abovementioned questionnaire, almost all clinical tools use other confirmatory tests for the confirmation of neuropathy.

#### 11.3.2.1 Touch Sensation Tests

##### 11.3.2.1.1 Semmes-Weinstein Monofilament Test (SWMT)

In every diabetic patient, the test must be done at least once in a year as a part of foot evaluation or the occurrence of a new foot ulcer. During the test, the examiner uses 10 g monofilament, which is calibrated as it requires 10 g of force for bending on touching the foot skin, to know the feel of filament on touch by the patient on closing his/her eyes. The examiner uses the filament on ten different sites randomly on each foot. The maximum score is 10 as the client feels the monofilament at all sites (Fig. 11.1) of touch. Holding the monofilament perpendicular to the skin of the foot and along with a steady, smooth motion, the skin is touched until there is nearly 1 cm bending of filament and after that, for nearly 2 s it is held. On an area, the test is repeated three times, if a patient failed to respond on touch. Mark the positive

**Table 11.1** The initial neuropathic pain screening tests

| No | Name of instrument | Major components measures | Grading |
|---|---|---|---|
| 1 | Douleur Neuropathique en 4 (DN4) | Questionnaire for various neuropathic pain, and tactile dynamic allodynia, pin hypothesis and touch's physical examination | Score ≥4/10 specifies the peripheral neuropathy's presence |
| 2 | LANSS (Leeds Assessment of Neuropathic Symptoms and Signs) scale | Elicits five symptoms and two clinical signs of diabetic peripheral neuropathy | Maximum score is 24. Patient's score ≥12 indicates diabetic peripheral neuropathy |
| 3 | MNSI (Michigan Neuropathy Screening Instrument) | It consists of 15 self-answerable questions and 5 physical assessment criteria, which include monofilament test, great toe's vibration perception, ankle reflexes, ulceration, and feet's appearance | Maximum score is 10. For peripheral neuropathy, a score ≥7 believed to be positive |
| 4 | TCNS (Toronto Clinical Neuropathy Score) | Includes assessment of symptoms, sensory loss, and ankle reflexes [56] | Based on the score it classifies into severe neuropathy (≥12), moderate neuropathy (9–11) and mild neuropathy (6–8) |
| 5 | NDS (Neuropathy Disability Score) | Assessed by measuring vibration perception, thermal and Achilles tendon reflexes and pinprick sensation | Severity grading: severe (9–10), moderate (6–8), mild (3–5) and none (0–2) |
| 6 | UENS (Utah Early Neuropathy Scale) | Measures the pin sensation, allodynia/hyperesthesia, deep tendon reflexes, and motor deficits | Maximum score is 42. 24/42 are devoted to sensory loss's anatomical mapping to pin in lower leg and foot [57] |
| 7 | NPQ (Neuropathic Pain Questionnaire) | The questionnaire consists of 32 items: Selected 12 for NPO-SF(short form) 10 related to quality of pain and 2 related to changes in sensitivity [58, 59] | Such tool demonstrated 64.5% sensitivity and 78.6% of specificity with 73% of total forecast accuracy [59] |
| 8 | NPSI (Neuropathic Pain Symptoms Inventory) | This neuropathic tool contains 12 questions on the severity of spontaneous pain, severity of painful attacks, the severity of provoked pains, and the severity of abnormal sensations | The grade reaches from 0–10, where 10 represents the worst pain and 0 for no pain |
| 9 | NSS (Neurological Symptom Score) | 17 item questionnaire, which addresses motor, sensory, and autonomic functions | Specificity as well as sensitivity of 67% and 82% respectively [60] |
| 10 | DNE (Diabetic Neuropathy Examination) score | Examine four questions on muscle strength, reflexes, and sensation on index finger and big toe | Maximum score is 16 points. Fast and reliable clinical scoring system for the evaluation of peripheral neuropathy [61] |

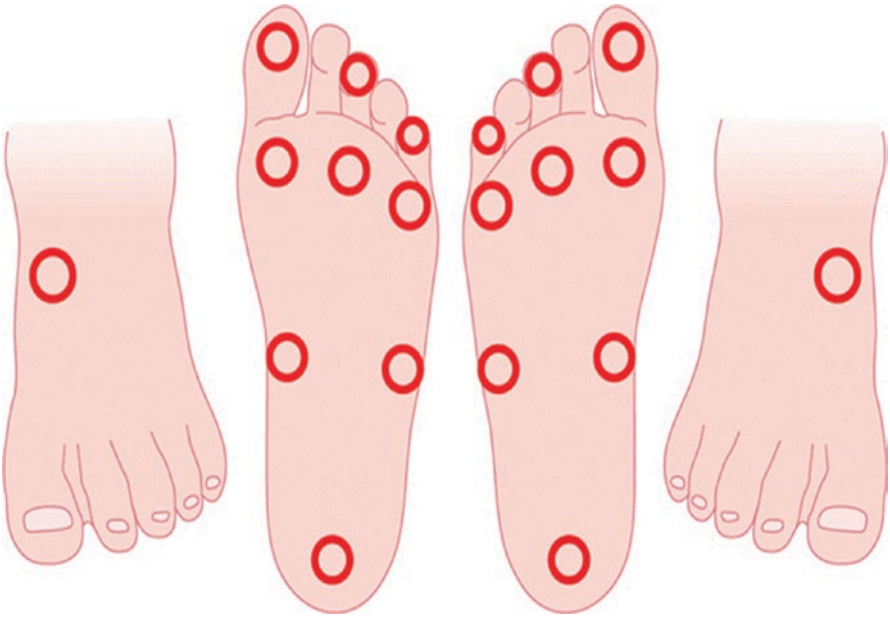

**Fig. 11.1** Sites for the monofilament test

result numbers among the total tested sites number. For example, the score 7/9 indicates the seven sites of positive responses, and only nine sites were tested as there is amputation in the patient's right great toe [62].

#### 11.3.2.1.2 Neuropen

This is sensitive as well as an inexpensive alternative approach for evaluating nerve function for identifying moderate to severe neuropathy patients. The sites for tests are restricted to high-pressure areas on the each hallux's plantar surface, and first, second, third, and fifth metatarsal head. The neuropen sensitivity for detecting neuropathy in comparison with the NDS (score $\geq$ 6/10) is higher specificity of the test improves, in a mixture of abnormal Neurotip and abnormal monofilament responses were utilized (68%), instead of the tests of individual (57% and 41%, respectively) [63].

#### 11.3.2.1.3 von Frey Hair Test

The assessment is done with von Frey hair (Fig. 11.2) in five repeated tests at four sites such as leg's lateral part on the dominant lower limb, lateral malleolus, first metatarsal, and interphalangeal joints of the great toe. A positive test is recorded when at least three times out of five hair is felt by the patients. The score of "0" and "1" indicates normal and abnormal, respectively [64].

**Fig. 11.2** von Frey hair

#### 11.3.2.1.4 Ipswich Touch Test (IpTT)

Using the index finger's tip, the examiner touches gently on first, third, and fifth toes' tips and hallux's dorsum in both feet, for 1 or 2 s without a push, prod, tap, or poke, with patient's eyes closed. Peripheral neuropathy is defined with a score ≥2 insensate sites out of eight. The IpTT is a reliable, simple without the expense, and always at hand, a tool for the screening and detection of high-risk patients of foot ulcers [65].

### 11.3.2.2 Tests for Vibratory Sensation

#### 11.3.2.2.1 Tuning Fork Test

Vibration sensation is determined by the on–off method placing a vibrating 128-Hz tuning fork at first toe' dorsum to nail bed's proximity on the bony prominence. Patients are requested for reporting the vibration perception's start as well as the cessation. After that, the examiner's thumb distal phalanx dorsal aspect is applied with the tuning fork. Furthermore, a standardized form is used to record the time (in seconds) when according to the perception of the examiner the vibration sensations were faded. On each toe, the test should be repeated twice, and the results should be marked on a standardized form. Also, vibration testing threshold can be described as the total number of times there was no vibrating tuning fork's application as well as vibration's dampening, and the score varies among 0–8. Furthermore, as per the difference in time among perception period signified by the examiner as well as the patient defines the peripheral neuropathy [66].

VibraTip

One of the novel tools is VibraTip used to replace the tuning fork as a source of vibratory stimulus. A vibratory stimulus is produced by it which is the same as 128 Hz tuning fork as well as it is utilized at times of foot examination for DPN detection. Following assessment through the MTEP (Medical technologies Evaluation Program) process, it has been described by the NICE Medical Technology Guidance 22 that VibraTip has a great potential in improving the DPN detection as well as for the NHS cost savings is provided. Although, it cannot be

proved against these reasonable doubts due to the available clinical evidence's lack [67].

Bio-Thesiometer

Essentially, the Bio-thesiometer is an "electrical tuning fork" in which a predetermined level of amplitude can be set as well as there will be a gradual increase in amplitude till vibratory sensation's threshold is acquired. On the contrary, the lowering of amplitude is done until there does not exist any vibration. For each case, at a specific level, the determination of amplitudes is done with the greatest accuracy. Being a simple, sensitive, and comfortable method, it is suitable for screening for detection and evaluation of peripheral neuropathy [68].

#### 11.3.2.3 Tactile Circumferential Discriminator

The TCD is a sensory testing device that is portable, which is meant for testing the function of large nerve fibers. TCD is highly sensitive and cost-effective for the community screening for foot ulceration's risk patients identification [69]. The TCD comprises of a handheld disc along with increasing circumferences eight protruding rods, which are meant for assessing the tactile function. In a controlled study by Vileikyte et al. [69], TCD is found a reliable and effective technique for population screening to identify neuronal dysfunction and risk for diabetic foot ulceration.

#### 11.3.2.4 Ball-Bearing Test

A steel ball-bearing with various diameters is used to examine each foot's plantar area over the second metatarsal head. Patients are requested for barefoot walking on flat ground along with the attached plaster of ball-bearing. The contralateral foot is applied with an empty control plaster. The ball-bearing score is defined by the least diameter that can be felt by the patient (range 1–6). The steel ball-bearing test with its high sensitivity and specificity is to be considered for both the evaluation of protective sensory reflexes and screening of patients for risk to neuropathic ulceration [70].

### 11.3.3 Methods for Peripheral Arterial Disease Screening and Assessment in Diabetic Patients

In diabetic patients, peripheral arterial disease's assessment, as well as early detection, have a significant part in diabetic foot ulcers' prevention as well as management. Even with PAD's high prevalence in diabetic patients, many of them do not report the symptoms of PAD and the symptoms like pain may be blunted by the neuropathic pathology in peripheral nerves [71–74]. The abovementioned facts explain the need for proper screening methods disease in diabetic patients for detecting peripheral arterial.

#### 11.3.3.1 Physical Exam

During the activity, the leg pain (intermittent claudication) and clinical signs like an absent or weak pulse around distal arteries evidence for the peripheral vascular disease's presence and indicates the ulceration risk [75].

#### 11.3.3.2 ABPI Measurement

It is the ratio between the SBP measured on ankles and arms and an effective validated and reproducible screening test for lower limb vascular insufficiency's severity as well as presence's objective assessment. It consists of quantitative methods that are noninvasive to determine the lower limb arteries' patency. It can be easily carried out by any healthcare professional clinic with a Doppler ultrasonic sensor and a BP cuff [76, 77]. The ABPI value of >0.9 is indicative of peripheral arterial disease in both diabetic as well as nondiabetic patients [78].

MESI ABPI MD®, a new device that in clinical settings for PAD screening gives an easy solution along with the ABI's precise, accurate, and fast measurements and depends on an improved oscillometric technology [75].

#### 11.3.3.3 Ultrasound

Doppler ultrasound is useful for identifying narrowed or blocked arteries as well as evaluating the flow of blood in the blood vessels. Arterial duplex ultrasonography demonstrated a 99% specificity and 95% sensitivity for occlusive disease detection, with 92% sensitivity and 97% specificity for hemodynamically significant disease [79].

#### 11.3.3.4 Angiography

Different methodologies for angiography such as DSA (digital subtraction angiography), contrast material-enhanced magnetic resonance (MR) angiography, and CT (computed tomographic) angiography for peripheral arterial disease detection [80].

## 11.4 Summary

This disease's most usual complication is Diabetic foot disease which causes high morbidity among diabetic patients and leads to high chances for amputation of the lower limb in these patients. The extensive searches in this field identified a number of risk factors which will provoke this complication in diabetic patients, such as comorbidities, peripheral arterial disease presence, peripheral neuropathy disease presence, and glycemic control extension and disease duration. The diabetic foot syndrome development is also influenced by sociodemographic factors such as the age of the patient, financial background, and lifestyle. In addition, the presence of foot deformities and ill-fitting footwear contribute to the causation of this complication of diabetes. Since the diabetic foot syndrome carries a high negative effect on patients' life quality as well as morbidity along with financial burden to the community, risk's early detection for diabetic foot syndrome development and prompt diagnosis and management of the condition has

a pivotal role. Different screening tests are described in this chapter for the early evaluation of the peripheral arterial and peripheral neuropathy diseases' presence. There are several guidelines, highlighted above, which suggests various methods and diabetic foot disease management, including multidisciplinary methods and podiatric care.

## 12.1 Introduction

Foot-related complications are accountable for up to 50% of all diabetes-related hospital admissions. Lifetime risk of foot ulcer in patients with diabetes is 10–15% and infection complicates over 50% of these ulcerations [1]. Diabetic foot infections (DFIs) are associated with significant morbidity, mortality, reduced quality of life, economic burden, discomfort, need for hospital visits, wound care, antibiotic therapy, and often surgical measures like debridement [1, 2]. More than one-fifth of moderate or severe diabetic foot infections are associated with some level of amputation [3].

Diabetic patients are more prone to infection, secondary to altered immune response, altered circulatory status, and the presence of neuropathy [3]. Sixty percent of lower limb amputation occurs secondary to infections [4–6], making infections the immediate preceding event of this dreaded outcome. Loss of protective sensation predisposes recurrent breach in the skin of diabetic foot, and different kinds of microorganisms colonize and multiply on these ulcers, and this leads to tissue destruction and causes an inflammatory reaction that is regarded as clinical infection [7]. These infections can involve the deeper tissues like bone and leads to osteomyelitis [8]. The presence of ischemia secondary to peripheral arterial disease

https://doi.org/10.1007/978-981-15-7639-3_12

(PAD), leads to necrosis and delayed or nonhealing of the ulcer [9]. Infection together with ischemia significantly increases the risk of limb amputation [8].

Management of DFI needs identification and accurate classification of the foot lesion, careful collection of the specimen for culture, timely initiation and careful selection of empirical and definitive antimicrobial therapies, providing timely surgical debridement are needed [9].

Chronic diabetic foot ulcer (DFU) is frequently contaminated with more than one pathogens.

*Staphylococcus aureus* and *Pseudomonas aeruginosa* are frequently encountered causative pathogens in DFIs. But the distributions of these pathogens vary geographically and they also depend on the duration of the wound, previous use of antimicrobials, and the importance of nosocomial infections [9]. The use of unsuitable antibiotics can lead to drug-resistant bacteria, thereby making the choice of antibiotics difficult [10].

## 12.2 Etiopathogenesis of Diabetic Foot Infection

Multiple pathological process which gets activated in patients of diabetes mellitus ultimately affects foot. Any structure from the skin, subcutaneous tissue, muscles, nerve fibers, vasculature to bones can be involved. The reasons for the increased incidence of these disorders in patients with diabetes mellitus (DM) involve the interaction of several pathogenic factors: neuropathy, abnormal foot biomechanics, PAD, and poor wound healing. Development of ulceration in diabetics precedes the development of infection [11]. The presence of peripheral sensory neuropathy hinders with normal protective sensations, this leads to sustain major or recurrent minor trauma to the foot, frequently without knowledge of the injury to the patients. After breech in skin continuity because of repeated trauma, microorganism may colonize the site and proliferate. This leads to destruction of the local tissue and initiates the cascade of inflammation, which can have systemic manifestation [12].

### 12.2.1 Peripheral Neuropathy

Some form of involvement of peripheral nervous system is present in 60% of diabetic patients [10–12]. Loss of protective sensation is an early phenomenon in the development of diabetic neuropathy [13]. All three kinds of nerves (sensory, motor, or autonomic) are usually affected. The involvement of motor nerves leads to imbalances between the flexor and extensor musculatures of foot, leading to deformities in the form of clawing, prominent metatarsals heads, foot drop and equinus deformity. These deformities lead to abnormal distribution of plantar pressure, increasing the risk for ulceration [14].

The involvement of sensory nerves manifests as either positive symptoms such as tingling, burning and pain, or negative symptoms such as numbness. Sensory loss in the form of loss of pain, temperature, touch, and vibration sensation in the feet lead to

ill-fitting shoes or early signs of foot abnormality that may go unobserved by the patient and remains uncorrected. The presence of callus is common in neuropathic ulcers and interferes with the healing potential of an ulcer, predisposing to infection [15].

Involvement of the autonomic nervous system manifests as loss of sweat gland function, leading to dry skin, vulnerable to cracking, and infection. Loss of autoregulation leads to increased blood flow. This manifests as edema and osteopenia [16, 17].

### 12.2.2 Peripheral Arterial Disease

Appearance of atherosclerosis is accelerated in diabetes. Risk of atherosclerosis is two to three times higher in patients with diabetes when compared with nondiabetic population [18]. Risk factors for the development of atherosclerosis are the degree and duration of hyperglycemia, dyslipidemia, obesity, smoking, and a family history of atherosclerosis. Both micro- and macrovessels are involved in diabetic patients. The arteriopathy is also associated with endothelial dysfunction, enhanced arteriovenous shunting, abnormal hyperaemic response to inflammation, enhanced capillary permeability leading to swelling over the lower limb. These changes are associated with delayed and abnormal healing processes in a diabetic foot ulcer [19]. Reduction in the blood supply to the affected limb exacerbates the problems due to neuropathy. Initial features of vascular involvement in the limbs includes atrophic foot, absence of hair on the dorsum, cool temperature of the limb, and thin shiny and atrophic skin [20].

### 12.2.3 Immune Dysregulation

Patients with diabetes are more susceptible to infections, as hyperglycemia is associated with impaired leukocyte function (chemotaxis, phagocytosis, and killing), structural changes in macrophages, raised inflammatory cytokines, and impairment of polymorphonuclear cell functions [21]. In addition, elevated glucose is a nice medium for the growth of microorganism [18, 19]. Hyperglycemia is also associated with impaired granuloma formation, the protracted occurrence of abscess, compromised production of proteins, fibroblasts, and collagen because of insulin deficiency besides the presence of nutritional inadequacy leading to poor wound healing [22].

### 12.2.4 Foot Deformity

The involvement of motor nerves leads to imbalances between the flexor and extensor musculatures of foot leading to deformities. These deformities lead to abnormal distribution of plantar pressure, increasing the risk for ulceration. Recurrent trauma from walking and weight bearing or unfitting footwear, leads to augmented plantar

pressures, causing the development of callus and break in skin continuity. This causes the formation of blister, tearing of skin and fissuring [23]. Ligament and tendons become inflexible secondary to reduced elasticity and lead to contractures. The presence of these deformities increases the risk of foot ulceration in diabetes.

## 12.3 Prevention of Diabetic Foot Infection

Awareness of the conjecturers of foot ulcer occurrence, which may be modified by evidence-based interventions, is essential for making a strategy to prevent DFU. Such strategy requires a cohesive approach, education, and awareness of both the patient and treating physicians [24]. Meaningful achievement in the management of diabetic foot-related complications can only be accomplished with a motivated multidisciplinary team approach, with the help of good communication and concerted efforts between the various players. The aim is to provide proper care to the right patient at an appropriate time and in the required amount. Preventive measures are required for both better patient outcomes and cost-effectiveness [25]. A multidisciplinary attitude is suggested for persons with high-risk feet and foot ulcers, particularly those with a previous history of ulcer or amputations [17].

Annual comprehensive examination of foot should be performed, to detect the risk factors for DFU. Foot examination is required at every visit in patients with established loss of protective sensation (LOPS) or previous history of foot ulceration [26]. A careful history regarding foot ulceration, amputation, Charcot foot, any vascular procedure, smoking, retinopathy, nephropathy and intermittent claudication should be obtained. A careful examination of skin integrity and foot deformities should be done. Examination of pedal arteries by palpating the pedal pulses should be done. Neurological examination should focus on detecting LOPS. Use of 10-g monofilament is recommended for detecting LOPS. 10-g monofilament along with any one additional test (pinprick sensation, temperature, or vibration sensation by a 128-Hz tuning fork, or ankle reflexes) should be performed [27].

The negative monofilament test is indicative of LOPS, whereas two normal tests (and no abnormal test) rules out LOPS [27].

Patients with low risk should be examined annually; those with high risk should be examined at each visit. Prevention of foot ulcer occurrence and recurrence entails good glycaemic control, ongoing specialized foot care, and appropriately fitting shoes which has an established effect on the release of plantar pressure [28]. Good education of patient by a dedicated and focussed team may enhance the patients' observance of management recommendations [29]. Management of foot ulcer requires standard protocols for wound care, including off-loading with bed rest, total contact cast, custom-made cast walkers and healing sandals, radical wound debridement. Steps helpful in reducing the foot ulceration and infections are given in Table 12.1.

**Table 12.1** Steps helpful in reducing the foot ulceration and infections

| | |
|---|---|
| • Self-care of foot<br>• Daily examination of feet daily for blisters, scratches, cuts, and inflamed areas<br>• Examination of toe webs<br>• One should always check between the toes<br>• Daily cleaning of feet with mild soap<br>• Dry carefully, especially between the toes<br>• Avoid extreme temperatures<br>• Check the water temperature with hand or elbow prior to bathing. Electric blanket, hot water bottles should be avoided<br>• Avoid barefoot walk<br>• Self-removal of corns should be avoided | • Footwear care<br>• Use properly fitting shoes<br>• Always wear shoes with socks or stockings<br>• Sandals with thongs between the toes should be avoided<br>• Remove shoes during the day to release pressure<br>• People with neuropathy or increased plantar pressure need well-fitted walking shoes or athletic shoes that cushion the feet and redistribute pressure<br>• People with deformities need extra wide or deep shoes<br>• **When to report to doctor**<br>• Cuts, fissures, callus, or breaks in the stem<br>• Alterations in color or discoloration of the foot<br>• Ingrowth of nails<br>• Numbness or loss of sensation<br>• Any apparent deformity |

**Table 12.2** Summary of IDSA guidelines for obtaining culture form diabetic foot ulcer

| |
|---|
| Clinically uninfected wounds: Specimen for culture is not recommended |
| Infected wounds: Properly obtained samples for culture before initial empiric antibiotic therapy |
| Mild infection in with no history of antibiotic use: Cultures may be unnecessary |
| Samples should be obtained from deep tissue by biopsy or curettage after cleaning and debridement |
| Avoid samples collection via swab, especially from inefficiently debrided wounds |

## 12.4 Empirical Management of Diabetic Foot Infection

Empirical antibiotic therapy is needed in the initial management of diabetic foot infections. Many factors may guide to avoid choosing either an unnecessarily broad or inappropriately narrow regimen antibiotic. Before choosing the empirical therapy it is important to document the presence of infection, and if it is present than grade its severity [30, 31]. Since DFU is often chronic, and infected with a number of microorganisms, so proper collection of the microbiological specimen is very important in order to isolate the actual pathogens and their antimicrobial sensitivity. Collection of culture specimen with a swab is not recommended, since they do not provide precise results. Specimen obtained from deep infected tissue or bone should be cultured [32–34]. The culture from superficial swab and deep tissue samples provides discordant results [32, 35]. Culture and sensitivity should be repeated when patients are not responding to the treatment [36]. The Infectious Disease Society of America provided guidelines for the collection of specimen from DFU in 2012 (Table 12.2) [37].

Several basic points need to be considered prior to antibiotic prescription. Initially, the foot infection should be classified clinically. The criteria established by the Infectious Diseases Society of America [37] or the International Working Group on the Diabetic Foot [36] can be used for the same. Those with severe infection, require broad-spectrum parenteral antibiotic therapy, till the culture reports are available. Patients with mild to moderate infection can be often managed with a narrower spectrum antimicrobial agent. Many patients with mild to moderate infections will improve, with the help of proper supportive care, debridement, pressure off-loading, and wound dressing [38]. Antibiotic therapy should always cover aerobic Gram-positive cocci, especially *Staphylococcus aureus*, which is both the most common and virulent pathogen in DFU. Decision to provide coverage for methicillin-resistant *S. aureus* (MRSA), will depend upon the presence or absence of risk factors for MRSA [39]. Risk factors for MRSA include history of recent hospitalization, prior antibiotic intake and renal replacement therapy. Enterococci are often grown on culture, but they rarely cause the infection and are simple colonizer [40]. They require treatment only when patients fail to respond to standard therapy. Up to two-third patients with chronic DFU have infection with aerobic Gram-negative bacilli. Enterobacteriaceae are the commonest Gram-negative isolates from chronic DFU, and these are covered by newer broad-spectrum antibiotics. Once therapy for Gram-negative organism has been decided then the next question is to whether target *Pseudomonas aeruginosa* or not. Findings from a recent study from Korea has identified smoking and previous antibiotic use as a risk factor for *Pseudomonas aeruginosa* [35]. Pseudomonas species is generally found as part of a polymicrobial infection [41]. Another factor that needs especial consideration is the presence of obligate anaerobic microorganism, as they have been found to be present in a significant number of patients [42, 43]. They are commonly found as a part of mixed infection with aerobes, rather than as an only pathogen [44]. Risk factor for anaerobes includes peripheral arterial disease, limb ischaemia and resultant necrosis or gangrene. The presence of foul-smelling discharge from the wound gives clinical clue to the presence of anaerobes. Good debridement leads to removal of necrotic material, and thus eradicating many of the anaerobes and uncovering those remaining to air, could be all that is needed to manage these potential pathogens. Anaerobic coverage is needed only when there is a robust clinical feature of anaerobic infection, i.e., the classical “fetid foot” [45].

Lastly, the route of administration needs some discussion. With the advent of an oral agent with very high bioavailability, results with oral therapy are comparable with parenteral therapy [46]. The result of antibiotic therapy is dependent upon the concentration of antibiotic at local site, rather than on the route of administration. So even though started on parenteral therapy, once they improve, they can be switched to oral therapy [47]. Patients with mild infection can be treated with topical therapy. Table 12.3 summarizes the guidelines for antibiotic treatment for the empirical management of diabetic foot infections.

**Table 12.3** Guidelines for antibiotic treatment for the empirical management of diabetic foot infections

| Type of infection | Additional characteristic | Likely pathogen | Suggested antibiotic |
|---|---|---|---|
| Acute | No systemic features, no previous antibiotic use, low risk for MRSA | Methicillin sensitive Gram-positive cocci | 1st generation cephalosporins, clindamycin |
| | Penicillin allergy or intolerance | Methicillin sensitive Gram-positive cocci | Clindamycin, fluoroquinolones (FQ) |
| | High local prevalence of MRSA, previous antibiotic use | Methicillin-resistant *Staphylococcus aureus* | Clindamycin, doxycycline, trimethoprim/sulfamethoxazole, linezolid, daptomycin |
| Chronic | No systemic feature | Methicillin sensitive Gram-positive cocci Gram-negative bacilli | Second or third generation cephalosporin, aminoglycoside |
| | Previous antibiotic treatment | Methicillin-resistant staph aureus Gram-negative bacilli ± Anaerobes | b-Lactam, b-lactamase inhibitor; second- or third-generation cephalosporin; group 1 carbapenem; FQ ± aminoglycoside |
| | Necrotic, gangrenous ischaemic limb; foul odor | Methicillin-resistant *staphylococcus aureus* Gram-negative bacilli | Clindamycin (±FQ); metronidazole (+FQ); b-lactam, b-lactamase inhibitor; carbapenem, cefepime |
| | Greenish discharge, smoking, macerated ulcer | *Pseudomonas aeruginosa* | Piperacillin/tazobactam, cefepime, imipenem, meropenem, Fluroquinolones |
| | Risk factors for resistant Gram-negative bacilli | ESBL, MDR Gram-negatives | Piperacillin/ tazobactam + aminoglycoside, imipenem, meropenem |

## 12.5 Recent Advances in Prevention and Empirical Treatment of Diabetic Foot Infection Prevention of Diabetic Foot Infection

Various associations have provided guidelines for the management and prevention of DFU. The International Working Group on the Diabetic Foot has given many evidence-based recommendations to doctors for the prevention of DFU, which can have a substantial influence in decreasing the risk of ulcer recurrence and decreasing the load of this ailment on patients and society [48]. Recent work of the cost-effectiveness of existing integrated and novel methods and of the effectiveness of scientific support and patient response for improving self-management and treatment adherence may foster the development of further effective approaches for averting ulcer recurrence. Adherence to the preventive measures are an important part of management, particular emphasis on behavior and its role in observance to and results of therapy will also be significant [49].

### 12.5.1 Achieving Optimal Off-Loading

Off-loading is the cornerstone in the management of DFU. The instruments for off-loading in DFU are total contact casts and removable cast walkers, and they are capable to reduce forefoot peak pressure by 90%, compared to barefoot walking [50]. Off-loading devices for the primary or secondary prevention of DFU have a larger margin for improvement in terms of off-loading capacity. Recently, the art of making customized preventative off-loading footwear has benefitted from the availability of advance plantar pressure calculation devices. Two types of modalities have been successfully used. One technique is to incorporate plantar pressure measurement devices into the manufacture of insoles by an electronic milling machine [51]. The second technique is to measure the plantar pressure on users' feet, at the time of wearing conventional footwear, and then the footwear is modified according to the observed pressure values. Many cycles of plantar pressure measurement followed by the footwear adjustment can be done. Both the approaches have been found to be effective in reducing the recurrence of DFU [52, 53]. But to achieve optimal benefit adherence to off-loading is essential.

### 12.5.2 Thermal Monitoring for DFU Prevention

Another emphasis of current technological developments has been the early identification at risk foot in the pre-ulcerative phase. As the temperature is raised in any inflammation, assessment of temperature multiple times daily over feet, has been found to be effective in the prediction of diabetic foot ulcer [50]. The presence of elevated temperature can be used to counsel persons to reduce their physical activity to reduce their risk of developing a DFU [16]. These suggestions are based on the premise, that an inflammatory response starts in the foot regions, which are exposed

to disproportionate physical strain. If two similar sites on two different feet have temperature difference than the warmer site is likely reflective of pre-ulcerative inflammation [50]. In order to reduce the progression to ulcer formation, patients are directed to decrease their physical movement if they notice a "hot spot." Patients can restart their normal physical activities, when temperatures difference normalizes among the 2 feet. Handheld thermometers have been most commonly utilized to assess foot temperatures [50, 52]. Newer version, using a telemedicine system along with a floor mat with embedded temperature sensors has been assessed [49]. This system is easy to use, with individuals need to step on it for 20 seconds. The automated system then analyses the temperature profile of the 2 feet. Using a cut-off of ≥2.22 °C difference between matching sites on opposite feet, the mat identified 97% of DFU with an average time duration of 37 days. Compliance with the mat use was high with 86% of individuals using the mat at least 3 times per week, and average use was 5 times per week. The cut-off of 2.22 °C yielded 97% sensitivity but the specificity was only 43% specificity [50]. The smart socks with the capability of measuring the foot temperature, over one or several times a day, are under development [49]. Because of its ease of use, the temperature-monitoring socks provide the opportunity for continuous temperature assessment. A probable upcoming alternate to instrumented socks is the footwear capable of monitoring the temperature on the plantar surface of the feet. Along with identifying injury to the feet, plantar thermal sensors could deliver the added advantage of monitoring footwear adherence [51].

### 12.5.3 Molecular Methods for Detection of Pathogens

The diabetic foot infections are variable in character and poses challenge during management. Detecting the variety of microbes colonizing the diabetic ulcer is of paramount importance, and this involves the proper specimens obtained from the wound after debridement [53]. Traditional culture and sensitivity was the only way to detect the causal organism in a DFI for many decades. Frequently fastidious growing microbes are not detected, leading to biased and late results by using traditional bacteriology procedures. Lately, molecular microbiology techniques (direct PCR, 16 ribosomal DNA sequencing, denaturing gradient gel electrophoresis, pyrosequencing, etc.) have confirmed the occurrence of larger numbers and varied varieties of species in various types of wounds than had previously been documented [54]. Techniques of molecular genetics are evolving, and microbial multiplicity of the infected ulcers can be more conveniently and sensitively detected by utilizing the advanced molecular techniques than traditional bacteriological methods [55]. One of the advanced techniques for the detection of microbes depends on PCR amplification method with specifically designed nucleotide primers. PCR has been proposed to be safer, precise, and speedy technique than traditional bacteriological methods for detecting viruses and bacteria [56]. Almost all the studies with molecular microbiological techniques have shown that most DFU has many more bacterial species, than were previously identified based on the results of traditional bacteriological methods [56]. PCR has been found to be sensitive, selective, and specific

assay that can detect a smaller number of cultivable as well as non-cultivable organisms. One of the study from our center revealed, that the use of the PCR technique improved the rate of identifying pathogens in pus samples than traditional bacteriological methods. Also, PCR is rapid (4 h) when compared to that of the culture-based methods (48–72 h). The PCR-based technique leads to improvement in the speedy diagnosis of most commonly found bacteria, also yielding greater detection rates of pathogens. PCR has been found to be exceptionally sensitive and dependable being able to detect 100% of culture-confirmed bacterial samples. It also identified few culture-negative, but clinically significant diabetic foot infections, suggesting high level of efficiency [57].

## 12.6 Summary

There are many difficulties and unmet needs in the management of DFI, comprising a lack of knowledge and awareness of diabetes and its complications, lack of appropriate podiatry services. Management of DFI needs a concerted effort involving a team of health care professionals devoted to the care of diabetes, particularly associated with foot complications. A suitable awareness of the diabetic foot in terms of its biomechanical etiology and the causative risk factors for DFI, availability of newer techniques, involving both clinical and surgical interventions and crucial offloading strategies to reduce wound pressure is required, among the managing team is needed to efficiently managing DFI in India.

# Prevention of Diabetic Foot: Indian Experience

13

Vijay Viswanathan and A. Sai Prathiba

## 13.1 Introduction

Diabetes mellitus, a chronic metabolic disease, is a major risk factor leading to mortality and morbidity due to its potential microvascular and macrovascular complications. The most common cause of hospitalization among diabetics is the diabetic foot infection, apparently, it is the most severe complication and at the same time, the therapy is expensive too. Amputation is 10–20 times more common among diabetic people than non-diabetics, in particular, it is estimated that every 30 s a lower limb or a part of the lower limb is lost somewhere in the world as a consequence of diabetes [1].

## 13.2 Epidemiology and Problem of Diabetic Foot in India

The global prevalence of the disease is going to be tripled in the next 30 years. The International Diabetic Federation (IDF) states that in 2017, there were 451 million people with diabetes worldwide which is further expected to increase to 693 million in 2045 [2]. The prevalence of this disorder is increasing rapidly among native and migrant Asian populations [3]. ICMR has conducted INDIAB (INDian DIABetes) study in 2011 which has revealed that among all the states in India, Tamil Nadu stands third with 4.8 million patients with diabetes and 3.9 million in prediabetic stage [4]. A study conducted by Murray et al. to identify the Global Burden of the Disease in 2010 had published startling results. He classified diabetes as one of the leading specific causes of Years lived with Disability (YLD) which underscores the burden imposed by diabetes on the individuals. When we refer to the fatal

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_13

outcomes, it was estimated that five million deaths all over the world were attributable to people with diabetes in the age group 20–99 years [5]. Systematic and prospective study comparing risk factors for diabetic ulceration and treatment outcomes between centers in industrialized nations and developing countries was carried out in three centers [6] [Southeast Germany (GER), Dar-slaam, Tanzania (TAN) & Chennai, India (IND)] contained 613 consecutive patients with diabetic foot lesions and found that the most important underlying factor of foot ulceration in patients from all three centers was diabetic neuropathy. 368 (60%) of the 613 patients sampled were treated for new diabetic foot lesion. Patients were predominantly male in all three centers and had type 2 diabetes. The average duration of diabetes until the initial foot lesion started was in GER for 14 years and in IND for 12 years, but in TAN for only 5 years. The patient's age was 71, 56, and 51 years. The most common cause of foot lesions in GER was insufficient footwear (19%), although lack of shoes, improper foot care, and burns were the primary precipitating factors among TAN and IND patients. Indicates that there are considerable differences between Western and developing-country diabetic foot patients which should be taken care of while conducting prevention program.

In a developing country like India, the economic boom, the lifestyle changes, migration from rural to urban areas seem to affect diabetes. Contrastingly, this increase in diabetes should have accelerated a large number of studies given the diversity and ethnicity, yet there remains a serious lacuna that needs to be addressed. This can seriously attenuate the proportions of people affected by diabetes in the upcoming years [7]. A multicentric study to estimate the pattern and causes of amputations among diabetics has revealed that infection was the major cause of amputations in India. Among these, a majority (70%) of amputations were minor (involving tarsometatarsal joints, metatarsal bones, toes, or rays). Below-knee amputation was found to be very common among major amputations. Over half of the amputations involved were only toes and rays. Neuropathy was highly prevalent (82%) among the diabetic study population. This study can be generalized to some extent to a national level [8].

## 13.3 How to Diagnose High-Risk Feet in a Primary Care Center

MNSI: This is Michigan Neuropathy screening instrument which includes 15 item self-answered questionnaires and to assess neuropathy in lower extremity based on vibration sensation and ankle reflex [9]. Diabetic peripheral neuropathy needs to be identified using a simple, inexpensive tool that can screen sensation loss. A graduated tuning fork was used to test vibration perception scores in subjects with sensory neuropathy detected by abnormal biothesiometry. The graduated tuning fork was suitable to detect sensation loss in the feet with high specificity (100%) and fair sensitivity (52%). Furthermore, it was simpler and cheaper to use in outpatient department [10].

**Table 13.1** Neuropathy Disability Score (NDS) scoring [12]

| Neuropathy Disability Score (NDS) | | | |
|---|---|---|---|
| | | Right | Left |
| *Vibration perception threshold*<br>128-Hz tuning fork; apex of big toe: normal = can distinguish vibrating/not vibrating | Normal = 0<br>Abnormal = 1 | | |
| *Temperature perception on dorsum of the foot*<br>Use tuning fork with beaker of ice/warm water | | | |
| *Pin-prick*<br>Apply pin proximal to big toe nail just enough to deform the skin;<br>trial pair = sharp, blunt;<br>normal = can distinguish sharp/not sharp | | | |
| *Achilles reflex* | Present = 0<br>Present with reinforcement = 1<br>Absent = 2 | | |
| | NDS Total out of 10 | | |

People unable to perceive variations in temperature might have distal symmetric neuropathy. So the need of the hour was to use an instrument that can detect temperature sensitivity. Though the above test was simple and specific, it was not sensitive-enough. Thus, Tip-therm, a pen-like instrument was tested to find if it can be used as an ideal instrument to measure temperature perception in type 2 diabetics. The results were astounding. Tip-therm when compared with monofilament and biothesiometry (established methods of diagnosing diabetic neuropathy) had high specificity (100%) and sensitivity (97.3%) in diagnosing diabetic neuropathy [11]. The NDS score below is used to assess the signs of neuropathy (Table 13.1).

## 13.4 Development of Footwear in Chennai

Many studies have emphasized the use of specially designed shoes to prevent relapses in diabetics with previous ulceration. Prescription footwear has demonstrated to be a significant factor in preventing ulcer recurrence and amputation [13]. It is for this reason that uniquely designed footwear, in collaboration with the Central Leather Research Institute (CLRI) and Central Footwear Training Institute (CFTI) is available in Chennai. The use of this therapeutic footwear is important especially for Indians as they walk barefoot or wearing improper footwear in extreme heat conditions which can worsen neuropathy.

## 13.5 Effect of Foot Care Education to Prevent Amputation

The beneficial effects of foot care education cannot be underestimated since there are numerous studies to prove this worthwhile. A study by Vijay et al. has revealed that foot care education and intensive management have proven effective in

preventing newer problems and surgeries. There was less frequent recurrence of ulcers and faster healing process in subjects who adhered to foot care advice. Simple advices like examination of feet, how to perform a pedicure, and using proper footwear has reduced foot complications to a larger extent [14]. Another study has proven that foot infections have occurred in 65% of the subjects who did not follow foot care procedures [15]. Amputations rate came down to a considerable extent after the formation of national foot care and health education and prevention in some island populations, such as Fiji and Nauru [16]. In order to reduce the burden of diabetic foot complications, effective foot care advice must be emphasized. The importance of wearing an appropriate footwear and foot care education for all high-risk patients cannot be underscored.

## 13.6 Use of Modern Technology in India for Wound Care

### 13.6.1 Hyperbaric Oxygen Therapy (HBOT)

This treatment involves breathing 100% oxygen in a special room under normal atmospheric pressure, thereby making more oxygen available into the bloodstream to promote healing. A systematic review conducted on HBOT in healing foot ulcers was proven to be effective in subjects with concomitant ischemia [17]. The importance of HBOT as adjunctive therapy was proven in a study by Ezhilarasi et al. where it was seen that HBOT has a positive effect in initiating the healing process of ulcer than the standard treatment involving offloading, wound debridement and glucose control [18].

### 13.6.2 Vacuum-Assisted Closure (VAC) Therapy

This involves using an electronic vacuum pump to apply negative pressure across the wound surface. This is particularly useful in large diabetic wounds where bone, tendon, joint capsule, and fascia are exposed after wound debridement. A clinical trial done among 60 cases with foot ulcers from 3 centers in India for the evaluation of recombinant human epidermal growth factor (REGEN-D™ 150) after administering for a period of 10 weeks found that the trial subjects had reduced wound healing time for the period of 9 weeks compared to the placebo. This trail demonstrated the efficacy of this gel in accelerating the wound healing process [19].

## 13.7 Conclusion

Diabetic neuropathy which affects the nerves of the feet causes severe damage thereby leading to amputation. With India becoming the diabetic capital of the world, there is a need for more and more people to be aware of the treatment, prevention, and cure of foot ulcers. Educating the patient about maintaining optimum

glycemic control, using appropriate footwear at all times, avoiding foot trauma, performing daily examinations of feet, and reporting changes to health care professionals should be insisted.

# Low-Cost Management of Diabetic Foot

# 14

Zulfiqarali G. Abbas

## 14.1 Introduction and Epidemiology

Diabetes mellitus is a condition with serious outcomes for people with diabetes across the world [1–3]. Diabetes affects all people in the world, has no limitation for age, sex, or status of the person. In 2019 prevalence of diabetes in the world was 463 million [3]. People are living longer, dietary pattern is changing, lifestyle is more of sedentary it is expected that diabetes prevalence rates to increase to 578 million by 2030 and 700 million by 2045 [3].

The continent of Africa is going to suffer and will be hit hard by diabetes and its complications than the rest of the globe. In Africa, people with diabetes are going to increase and will be double every decade we move forward [3]. In 2017 patients with diabetes were 14.2 million, within 2 years in 2019 it increased to 19 million and it is now predicted the way it is increasing to reach 29 million by 2030, and by 2045 to reach 47 million, which is the highest increase in diabetes in Africa than any region of the world of about 143% [3].

Much of the increase in population will happen in Sub-Saharan Africa, which includes many of the poor of the poorest countries. Similar to other parts of the globe as the population will grow, more people in Sub-Saharan Africa will live in cities, consume more processed food, and develop obesity, heart disease, cancer, and type 2 diabetes [4]. People would live longer as life expectancy in undeveloped parts of the region will increase [4]. Diabetes in the world remains one of the leading causes of morbidity and death [5–18]. Complications caused by diabetes, for example, related to eye, kidneys, cardiovascular system, but the most dreadful complications are of diabetic foot ulcers, which are related to highest rates of morbidity and mortality [5–18]. Septic diabetic foot can be extremely serious costly [5–23].

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_14

Approximately, 40–60% of all lower limb amputations across the world are performed in patients with diabetes [18, 19]. One million amputations are performed in the world on people with diabetes [18, 19]. The year 2005 was designated to world diabetic foot. It was estimated by the International Working Group of Diabetic Foot (IWGDF) that every 30 s a lower limb is lost due to diabetes somewhere in the world [18, 19]. Today after 15 years in 2020 it was estimated that now every 20 s a lower limb is amputated due to diabetes somewhere in the world [18, 19]. The situation is getting worse rather than improving after all the preventive programmes going on all over the world. With the increase in diabetes-related conferences, diabetic foot conferences, etc., but still instead of improving things are getting worse.

## 14.2 Diabetic Foot Ulcer Financial Burden

Literature most of them published regarding the cost of treating a diabetic foot ulcer comes from western developed world like USA, Sweden, Holland, and the UK. We are lacking literature on the cost of treating diabetic foot from developing countries. It was important to set up a study to estimate the cost of treating diabetic foot ulcers in the developing world. A study was set up to conduct the cost of treating diabetic foot ulcers in five different countries in the world from three continents [20]. All the countries that participated in this study were given a similar case to estimate the cost in their own country. The cost was estimated to the patient and to the society of treating foot ulcers in five different countries from three continents with completely different health care practices, reimbursement policies, and gross domestic products [20]. It was noted that treating the cost of the same ulcer to the same endpoints in all five countries was estimated at $3060 in Tanzania, which is only 1.6% of the US cost of $188,645 [20].

Medical insurance or reimbursement of medical expenses is not available in the continent of Africa. Management of complicated diabetic foot ulcer can cost more than 2 years of average income for the patient [20]. During the foot ulcer management, the loss of productivity caused by unemployment or sick leave is an added cost to the family, relatives, and community [20–23]. For example, in Senegal the cost of amputation has been estimated to be about 3200 USD not including the orthopaedic equipment [23]. It is devastating and catastrophic if a patient is the only bread earner in an extended family and is very common in Africa [20–23].

## 14.3 What Is the Reality on the Ground?

### 14.3.1 Peripheral Neuropathy (PN)

Where ever you are in the world peripheral neuropathy one of the complications of diabetes is the most common. Peripheral neuropathy in the literature ranges from 5–80% of patients with diabetes in the western world [24, 25]. Across Africa, the prevalence rate of peripheral neuropathy is shown the same as seen in the developed

world [1, 2, 5–11, 13–16, 26–30]. In the literatures, it has shown that there is no difference in ethnicity or race where ever you are in the world, from Africa being an African, Asia being an Asian or European being Caucasian [14, 15].

### 14.3.2 Peripheral Arterial Disease (PAD)

Peripheral arterial diseases are one of the important complications of the diabetic foot, which causes high rates of morbidity and mortality. Commonly seen in the western world and used to be not seen in the developing world that is Africa, Asia, and South America. Time is changing and situation across the African continent the rates of PAD are increasing [1–5, 14, 18, 31–34]. As the continent of Africa develop the same time communities in Africa becoming more urbanized, sedentary lifestyle, lack of exercise, change of diet, adopting lifestyle of western people, etc. PAD is increasing in African at the cost of Africa is developing.

### 14.3.3 Diabetic Foot Ulcers and Amputation

In Africa rates of diabetic foot ulcers are more leading to high morbidity and mortality all over the continent. A study done in Tanzania in 2002 showed 15% of diabetes patients admitted are of foot ulcers, 33% of patients ended up with amputation and 54% of the patients died because of late presentation to the referral hospital are already with extreme pathology (Wagner score $\geq 4$) [11]. This is true and seen in most of the parts of the African continent that are with high rates of amputation and death [1, 2, 4, 5, 7, 9, 12, 35–38].

## 14.4 What Are the Strategies and Challenges?

Developed world has increased research in the past over 20 years on molecular, epidemiology, and genetics. An increase in research of genetics has actually not benefited in patients care and outcome in many countries where basic routine diabetes and diabetic foot care are needed. Increased diabetes burden and limb complications funds allocated in the developed world are most of the time offset for high-tech, medication and antimicrobial are always available. Adequate diabetic foot care delivery in North America is due to the high cost of healthcare insurance rates. The only work that has had any significant impact on patient outcomes in the field of epidemiology carried out in developing nations, including from the African continent, especially for the complication of diabetes is in the diabetic foot, which has been implemented the findings in evidence-based practice. The health systems in the African continent become overwhelmed when there is an increased incidence of PAD [1–5, 14, 18, 31–34].

The major challenges remain that how do we actually achieve successful solutions of the diabetic foot in a poor resource's country, without the high technology

and resources available in developed nations? With the existing epidemiological realities and plan in relatively small amounts that could really boost the better outcomes of diabetic foot complications.

## 14.5 Managing the Diabetic Foot in Low-Cost Setting

In African diabetes patients, almost all foot ulcers are infected on the first presentation as can be seen in the published literature [1, 2, 5–11, 14–16, 18, 35–39]. Patients most of the time present to health centres are already too late with gangrene and infection (Wagner score $\geq 4$) or infection has gone to stage of septicaemia and no response to regular antibiotics [11].

Diabetic foot infection is very common in most low resource countries, where no podiatrist facilities, could be several other causes like lesions initially are ignored or noticed relatively late or after unsuccessful home treatment like use of herbal medication, bathroom surgery, soaking in herbal water, application of home remedies, going to faith healer, etc. It is due to these reasons most of the patients with diabetic foot get medical help when serious infection has set in or gangrene of limb has started. It becomes difficult to save foot if presented late to the centre. This can be prevented and can be reduced through proper foot care [18].

Least foot infection is cellulitis, the involvement of deep soft tissue infection is involvement of fascia, muscles, and deep tissue and osteomyelitis when bone is involved [11, 18, 19]. Chronic foot ulcers progress to spread to underlying bone from soft tissue inflammation in an ulcer. Osteomyelitis can be diagnosed by a simple bedside test by probing to the bone beneath an ulcer with a sterile blunt instrument, bone radiography, isotope bone scans, or histology. In Africa, the fact is that most of the centres do not have nuclear medicine services and histology tests routinely available. Abbas and colleagues usually use simple bedside test of probing the bone beneath an ulcer to diagnose the presence or absence of osteomyelitis. When osteomyelitis is detected, the necrotic tissue will be removed until the viable tissue is evident, followed by antibiotic treatment. If the prognosis of foot ulcer looks poor then it is referred for surgical assessment with a view to remove necrotic bone or undergo an amputation if necessary and followed by medical treatment.

The role of microbiology sampling is restricted to the identification of probably pathogens and the sensitivity to antibiotics. Superficial swab specimens for culture and sensitivity are not very useful due to polymicrobial growth, which are largely uninterpretable, but the infection is diagnosed purely on clinical grounds [18, 19, 39].

Deep tissue biopsy gives more useful information. In resources poor countries, microbiology services do not have routine facilities for analysing biopsy specimens [39]. For this reasons, Abbas and colleague had to look for the solution for less developed countries by conducted epidemiologic and microbiology studies and the use of antibiotics.

The use of Gram staining is forgotten as a bedside test and can be done at any place in the world with poor resources. Abbas and colleagues looked at the utility of Gram stains in comparison with culture and sensitivity in the management of limb ulcers in persons with diabetes. We found a sensitivity of more than 90%. In this study, it was concluded that there is no difference in Gram staining and culture for microbiology [39]. Patients with infected foot ulcers empirical broad-spectrum antimicrobials (without microbiology cultures), can be used in conjunction with surgical debridement yielded similar or better outcomes than antimicrobials chosen by antimicrobial susceptibility testing of pathogens isolated from deep tissue cultures [18, 19, 39]. Patients with infected foot ulcers, surgical debridement in conjunction with empirical broad-spectrum antimicrobials (without microbiology cultures), can be used yielded similar or better outcomes than antimicrobials chosen by antimicrobial susceptibility testing of pathogens isolated from deep tissue cultures [18, 19, 39].

Different preparations of antibiotics have limited availability, as well as the cost of some of them, is a major problem in less developed countries, and hence contributes to the relatively poor outcome of infected ulcers and further emphasis the need for early expert assessment. The use of cheap broad-spectrum antibiotics comes from India, as suggested by Abbas and Archibald [6], as there are similar or better than the more expensive western antimicrobials.

## 14.6 The Surveillance System's Problems and Solutions

Any surveillance system demands first and foremost huge amounts of funding followed by human resources for data collection, statistics analysis of data, etc. Abbas and colleagues had to face challenges in the management of the diabetic foot is to implement and maintenance of this surveillance system. It is important to establish a surveillance system for diabetic limb complications in low and middle-income countries for a number of reasons as follow: (1). To screen high-risk foot (PN and PAD) through this surveillance data; (2) To take proper preventive measures for the selected high-risk diabetes populations and (3) To intervene effectively as needed.

The largest surveillance systems for limb complications in Africa have been instituted by Abbas and colleagues in Tanzania [1–3, 5–11, 13–16]. Due to various reasons surveillance system has been sustained like strict case definition of limb complications, quality questionnaire, the commitment of the staff who are also trained in the collection of data and utilization of these data for evidence-based practice. It has been shown by Abbas and colleagues in Tanzania by maintaining this system it has been seen a good and positive approach on patients, relatives, and friends to know about patient medical condition and how to deal with diabetic foot complications. Patients are more knowledgeable in handling diabetes and its complications. Appointments are maintained and are also reminded by the administrator to attend clinics. In turn involvement of patient's active gives the opportunity to validate further treatment and preventive interventional diabetic foot projects.

## 14.7 The Importance of Regional/District Hospitals

In developing countries regional or district hospitals are considered large centres with limited resources, but can provide medical, surgical, and basic laboratory services for every region is a way of optimizing resources. This set up is seen mostly in the developing world like in Africa, Southeast Asia, Latin America, and the Caribbean. Regional hospitals are big centres in the region of the country that are the teaching centres for all the disciplines in the medicine. It commonly house medical, surgical, and laboratory facilities including microbiology specialized units. Regional and district are government hospitals and are under the control of the ministry of health. Government agencies from developed countries like World Health Organization, United States Agency for International Development, etc. would generally prefer to maintain collaborative efforts with sentinel centres for reasons such as adequate infrastructure, trained staffs, and access to the ministry of health. The same applies to diabetic foot complications surveillance system and activities in Tanzania.

## 14.8 Time Is Tissue—The Decision to Seek Medical Help

Time is tissue means the decision to seek medical help in regard to diabetic foot. It is a medical emergency in the field of diabetic foot. As we are all aware that myocardial infarction and cerebral vascular accidents are medical emergencies, in the same way, septic diabetic foot is a medical emergency. What is not known is patients with a diabetic foot ulcer delaying for days, weeks, or a month means a difference in saving a toe, foot, leg, or even saving a life. These patients need to attend the health centre as soon as possible. Abbas and colleagues found in Africa delay presentation was mostly due to cultural traditional and customary behaviour. People with diabetic foot ulcers initially with small lesions on foot, patient, or a relative will try to teat at home by using a razor blade or herbal solution and we call it as bathroom surgery. Next move of the patient will be if this home treatment fails to go to see faith healer or herbal doctor. People in the village and towns usually have very high respect and faith in faith healer. Herbalists are existing in Africa at almost every corner of the cities advertising and claim that cure to all diabetic complications. Patient will decide to move to primary health centre when herbal medications given by herbalist fails. Primary health centres are not trained or equipped to treat diabetic foot ulcers so patient will now go to district or regional hospitals, where we also have no diabetic foot specialist. All these leads to delay in presentation to main specialized referral hospital. By the time patient report at referral hospital it is too late to save foot even prevent death from severe sepsis [11, 18, 35–39]. People with diabetic foot ulcers who strongly beliefs in cultural traditions will prevent getting proper and accurate treatment of diabetic foot and this in turn leads to amputation or death as an outcome [18]. Unfortunately, some patients delay in getting expert opinion because of fear losing a limb as in Africa loss of limb is considered worse thing. At grass root level due to lack of knowledge among healthcare personnel can

lead to poor outcomes. It is common practice in the Africa continent soaking diabetic foot, which is a good medium for *pseudomonas* infection and can worsen the condition of the foot. In some centres due to lack of trained personal dealing diabetic foot ulcers management and therefore patients suffer if treated inadequately for a long time [1–3, 5–11, 13–16].

Most of the patients with diabetes are not aware of the need for early reporting to the health centre due to lack of knowledge in the peripheral of the countries in Africa. Lack of knowledge makes things worse by peripheral neuropathy and reduce pain sensations. Patients with loss of protective sensation can sustain unnoticed injuries like rat bite at night [16]. Checking of the feet daily at night to detect injuries or crack due to dry skin is not done due to lack of knowledge on preventive measures of foot care [16]. In contrast, to those with symptomatic (painful) peripheral neuropathy, which is a common complication in both among highly literate and very low literate people with diabetes, but it does not prevent complication even due to education status and not associated with better outcomes [1–3, 5–11, 13–16].

## 14.9 Sustainable Infrastructure Solution

In Africa education is the most powerful tool for avoiding diabetic foot ulcers. Foot care education is lacking for people with diabetes at the grass root level or district and in some regional health centres [9, 10]. Unfortunately, an ulcer leads to an infected diabetic foot ulcer due to lack of very basic education and hence patient presents severe limb-threatening condition, which leads to amputation in people from 25–50% [19]. The most important thing is the education programme at the primary level to prevent complications of foot ulcer in the developing world [40–47]. In the developing world, the only tool, we have is education, which is free to the patient and can be effective if implemented effectively.

A preventive programme should be targeted health care workers and it should include five main pillars of the preventive diabetic foot as follow: (1). Regular inspection and examination of the feet and footwear, (2). Identification of high-risk patients, (3). Educational of the high-risk patients, relatives, friends, and health care workers, (4). Appropriate footwear for diabetic patients, (5). Treatment of non-ulcerative pathology. By implementing these five pillars limb amputation can be reduced by or more than 50%. Several successful preventive educational programmes have been carried out in developed and developing countries [41–46]. It has been noted, organized, implemented, and published the outcome of the educational programme showed foot complications reduced by more than 50% [41–46].

## 14.10 *'Step by Step'* Foot Project

It is, for this reason, we had started '*Step by Step*' (*SbS*) *f*oot project to improve educational skills and the management of diabetic foot problems [41, 44–46]. The main goals of the *SbS* foot projects were as follows: (1) Raising awareness among

health care workers and patients about diabetic foot problems, (2) Providing effective education in diabetic foot management and to sustain it for health care workers, (3) Cascading the knowledge and skills among health care workers and export ideas to other developing countries, (4) To reduce the risk of complications of the lower limb in people with diabetes, (5) Encourage people with diabetes to take better care of their feet, report earlier, and seek help when problems arise [41, 44–46].

Step by Step foot project showed greater than 50% reduction of amputation rates [41]. Ulceration, infection, and amputation all were prevented through this step by step foot project. It was recorded through this programme which included a preventive and therapeutic approach to save diabetic foot limb [41, 44–46]. It is mandatory that health care workers involved in taking care of patients with diabetes should be able to conduct simple screening of peripheral neuropathy, peripheral arterial, and muscular skeletal system to identify patients with high-risk feet.

It is important that an educational programme should be planned in such a way that people with diabetes should receive maximum information from health care workers. Abbas and colleagues targeted centres at primary health centres who were dealing with the people with diabetes in Tanzania—the first people to see diabetic foot complications. Before we had *SbS* many developing countries, we had a lack of proper management of diabetic foot, lack of trained health care workers, no podiatry services, no specific curriculum of diabetic foot management for the training of health care workers in the country. There is still no concept of a super specialist of diabetic foot. This was the reason *SbS* foot project was designed aimed to educate these health care workers at the primary level and was instituted in several regions across Tanzania [41]. The *SbS* was started in these centres and health workers were largely untrained professionals [41, 44–46].

Step by Step foot project is an educational programme focussing on all the aspects of diabetic foot. It consists of two parts basic and advanced course given a year apart and each course lasts for 3 days. It is very important that eligible centre selected for this course participants should come in pair (doctor and nurse) dealing people with diabetes. All attending health care workers on registration of the first basic course were given educational material and screening, diagnostic and therapeutic basic kit on diabetic foot [41, 44–46].

Educational material directed to diabetic foot ulcers information was given to all the participants, which were in the form of written, posters for the clinics and audio–visual. All these materials either written in the form of booklet or audio–visual were targeted both health care workers (doctors and nurses) and patients [41, 44–46]. Curriculum for step by step foot project was prepared by diabetic foot experts from the developing world on all the aspects of diabetic foot for the health care worker. Step by Step focussed on all aspects of diabetic foot, which includes formal lecture, live workshop with patients, live demonstration on patients and live patients and hands-on experience [41, 44–46]. Once basic and advanced courses are done all the participants are expected to cascade the information knowledge to fellow colleagues and have course at the centre. Basic and advanced foot care educations are given to all health care providers [41, 44–46].

Normal patient with diabetes has no risk can receive normal general education once a year and is enough. Whereas patients with mild to moderate risk foot it means peripheral neuropathy can received education every 6 months. On the other hand, patients with peripheral neuropathy, peripheral arterial diseases and or deformity should receive education every 3 months. Patients with high risk mean all above with a past history an ulcer or previous history of an amputation should receive aggressive foot education every 1–3 months. Patients with a disability who cannot look after themselves special education is given to their assistances and care provider [41, 44–46]. Basic course was conducted in 2004 and advanced course was in 2005 and since the introduction of the *SbS* diabetic foot training programme has improved outcomes of diabetic foot ulcers, as we can see more ulcers are reported at the peripheral health centre at the early stage and more awareness has been created among the patients with diabetes. It has been noticed that a smaller number of patients are referred to tertiary hospital of the country and hence less amputations are registered [41]. Health care workers are now aware of diabetic foot and training is conducted among other health care workers [41, 44–46].

Step by Step foot piolet course conducted in Tanzania was shown to be successful during the period of 2004 and 2005. This leads to recruited further training of 30 private centres which includes 30 teams of medical officers and nurses in total of 60 participants. The same pattern was followed as follow initial with government centres [41, 44–46]. This time cobblers were invited from respected centres in 2010 to extend the approach along with medical workers to make a good training team [41, 44–46].

Centres where physicians and nurses were already trained in government and private health facilities in total of 45 centres, surgeons were invited from the same centres and facility have surgical facilities. In 2009, the first of its kind in the world *SbS* diabetic foot surgical training project specifically aiming surgeons from selected centres in 20 regions was conducted in Tanzania. The main aim was to prevent amputation by salvaging diabetic feet and hence reduce rates of amputation [41].

One of the aims was to export an idea of *SbS* to other developing countries. To date, this original *SbS* diabetic foot project has been conducted in Africa (Democratic Republic of Cong, Guinea, Botswana, Malawi, Kenya, Ethiopia, Egypt and Zimbabwe, Nigeria), and beyond Africa (Pakistan, Saudi Arabia, and Caribbean Barbados, St Lucia, St Maarten, St Kitts and the British Virgin Islands) [41, 44–46].

## 14.11 'Train the Foot Trainer'

In December 2012, a *SbS* foot care project was transfer to Train the Foot Trainer (*TtFT*) course. Step by Step foot care project could not reach to all the countries in the world. It was decided to conduct *TtFT* course target health workers from different countries in that particular region to come under one roof and then disseminate the knowledge once they go back to their own countries [44–47]. The First *TtFT* course was conducted in Brazil with participants from 14 countries in the continental of South America. In July 2013 course was conducted in Tobago from 22

countries [44–47]. In November 2014 it was exported to Dubai and in February 2015 *TtFT* course was conducted in Slovenia where 17 Eastern European countries participated. In November 2016 it went to the Western Pacific region and trained health care workers from 13 countries. In 2020 it was conducted in the Mena region and trained health care workers from 14 countries.

This is the only unique project which actually started in the developing world (Dar es Salaam, Tanzania) and exported to developing and now developed world and it has touched 110 countries in total [44–47].

In my opinion, to achieve a goal of reducing amputation rates is by focussing only on education. Education is the only powerful tool that can work all over the world. Once we educate the health care worker who would in turn educate other of his colleague in the centre and around his region will have a cascading effect. These healthcare workers in the primary health centre of each country being in the front line of diabetic foot to see would, in turn, educate patients, families of the patients, relatives, and friends.

## 14.12 Conclusion

In summary, in this manuscript, several reasons of poor diabetic foot care have been discussed in length. While we are waiting for the better technology to improve the situation, the priority at this point and time should be basic principles of training and management in this neglected specialist filed of diabetes. This task can be achieved at a minimal cost. Over the last 20 years, it has shown in developing countries a considerable reduction in the number of major amputations being undertaken for diabetes. The key to improvement is education and to empower health care workers to educate patients with diabetes.

**Acknowledgments** We would like to acknowledge for the helpful discussion with all our colleagues during the genesis of this manuscript is appreciated. We are grateful to Shabneez Gangji and other staff in Dar es Salaam for their assistance.

## Abbreviation

| | |
|---|---|
| ECM | Extracellular matrix |
| rhEGF | Recombinant human epidermal growth factor |
| rhPDGF | Recombinant human platelet-derived growth factor |
| S4PL | Syndecan-4 proteo liposomes |

## 15.1 Introduction

Growth factors are the naturally occurring polypeptides promoting growth and differentiation of cells in the body and also the repair of tissue [1, 2]. Growth factors such as Platelet-Derived Growth Factor (PDGF), Vascular Endothelial Growth Factor (VEGF), Fibroblast Growth Factor (FGF), Insulin-like Growth Factor (IGF), Hypoxia-inducible factor (HIFs), Transforming Growth Factor beta-1 (TGF-β-1) have also been implicated in playing role in the process of diabetic foot ulceration (DFU) [3]. Growth factors have been implicated to play a role in both normal and impaired wound healing. The growth factors are responsible for the rapid increase in the cell number and therefore can be used in enhancing the process of wound healing in the case of DFU. Recently, various clinical interventions have been reported emphasizing the role of growth factors for the healing of the wound [4].

Diabetes mellitus is one of the common metabolic diseases, which is due to the failure of the machinery to maintain the normal blood glucose level and includes defects such as failure of insulin secretion, insulin action, or both. There are three

main types of diabetes viz. Type-1 diabetes resulting from the loss of the insulin-secreting β cells of the pancreas; Type-2 diabetes resulting from the peripheral resistance of insulin and the third one, gestational diabetes mellitus resulting from deterioration of glucose tolerance occurring particularly in third trimester [5–7]. Diabetes mellitus has been reported to have a high incidence rate in the adult population [8]. The various symptoms that are associated with diabetes mellitus include polyuria, polyphagia, polydipsia, hyperglycemia, retinopathy, nephropathy, risk of foot ulceration, etc. Further, patients are at a very high risk of lower extremity amputation and the main reason leading to amputation includes peripheral neuropathy, infection, peripheral vascular disease, and foot ulceration.

Diabetic ulcers are mainly lesions in which a loss of the epithelium is involved. These abrasions may also expand to the deeper layers, dermis, and sometimes to the muscles and bone. DFU is one of the most common predisposing factors which leads to lower extremity amputation. About 4–10% of the population suffering from diabetes is estimated to have foot ulceration [9–11]. The various risk factors which are responsible for the increased incidence of ulceration in the foot include gender (male has more risk), having diabetes for more than 10 years, high body mass index (BMI), diabetic neuropathy, peripheral arterial disease, poor glycemic control, and the structural abnormalities and deformities in the foot such as claw toes, flat foot, hallux valgus, etc. [12–15]. The diabetic foot has been classified into two categories viz. (1) the neuropathic foot in which the factor responsible for the disease is the neuropathies and (2) neuroischemic foot in which apart from neuropathy, occlusive vascular disease is the primary risk factor [16].

Wound healing is a process that involves the activation of cellular machinery such as fibroblasts, platelets, endothelial cells, macrophages, and keratinocytes. Wound healing involves four phases, i.e., hemostasis, inflammation, fibroplasia, and maturation. The phases of wound healing are summarized in Fig. 15.1.

Induction of hypoxia is a necessary requisite for wound healing, which is followed by the release of Vascular Endothelial Growth Factor (VEGF) by the fibroblast, macrophages, and epithelial cells of the body leading to the phosphorylation

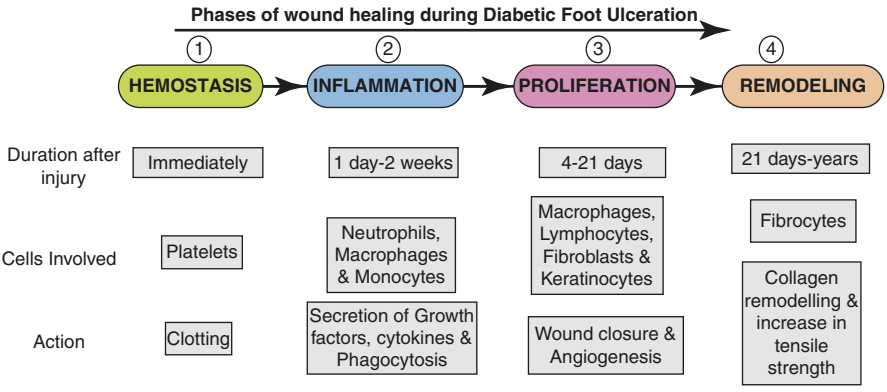

**Fig. 15.1** Phases of wound healing during diabetic foot ulceration

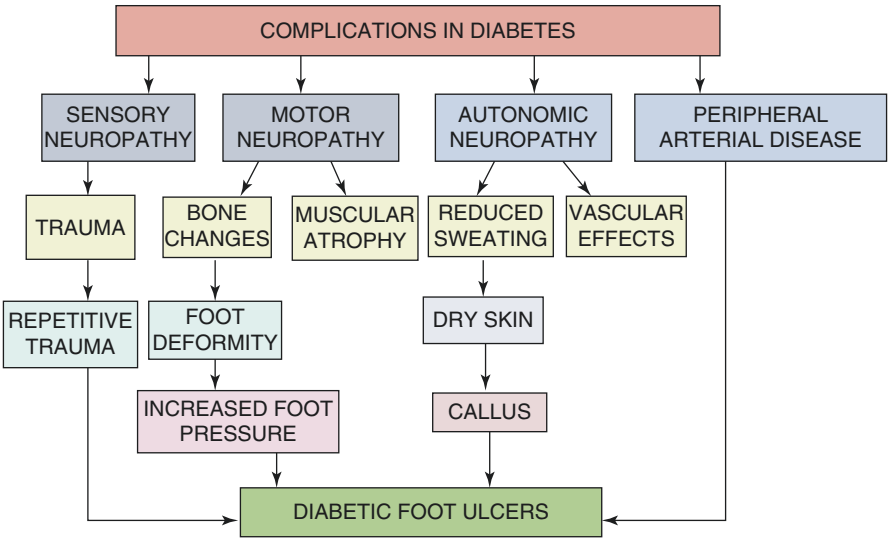

**Fig. 15.2** Risk factors associated with diabetic foot ulceration

and ultimate activation of nitric oxide synthase. These series of events are decelerated in the patients of diabetes due to the blood glucose level [17]. In this chapter, we will be focusing on the various growth factors that play a major role in the treatment of DFU.

## 15.2 Factors Responsible for Diabetic Foot Ulceration

DFU is a common complication related to diabetes. Many risk factors (Fig. 15.2) are responsible for the pathogenesis of diabetic foot ulcers. In most of the cases, it results from the synchronous action of these multiple causes. However, the factors that have been implicated to be the major cause of DFU are ischemia resulting from peripheral vascular diseases and peripheral neuropathy. In approximately 90% of the cases of DFU, damage to the nerve affecting the motor, sensory, and autonomic fibers has been observed. This condition is referred to as diabetic neuropathy [18, 19]. Damage to the nerves innervating intrinsic foot muscles results in an imbalance in the flexion and extension of the affected foot. This results in anatomical foot deformations thereby leading to the breakdown of skin and ulceration.

Peripheral diabetic neuropathy is a condition in which sensation is lost in the feet as a result of repetitive injuries. Due to the loss of sensation, wounds go unnoticed and undetected and keep on worsening leading to foot ulceration. The condition is further worsened by an infection in the ulcer leading to foot amputation particularly in patients with peripheral arterial disease. Peripheral arterial disease is another cause of foot ulceration. It is a dysfunction of the circulatory system in which the supply of blood to the limbs is reduced by narrowed arteries. This increases the risk

of cardiovascular diseases as well as foot ulceration [20]. An injured limb requires an increased rate of blood flow, and any decrease in the blood supply results in foot ulceration, which further progresses to limb amputation [21, 22]. DFU also results due to the uncommon foot plantar pressure, which is mainly due to deformities in foot structure such as hallux valgus, claw toes, flatfoot, and Charcot neuropathy, which is a condition causing bone and joint architecture destruction and loss of function. In addition to the above risk factors, gender, cigarette smoking, impairment of vision, impaired levels of blood glucose are also the causative factors of ulceration [22, 23]. Studies have shown the prevalence of foot ulceration more common in males rather than females [23]. Certain socioeconomic factors, such as lack of access to health care facilities and poor education, are also found to be correlated to frequent foot ulceration [22, 23].

## 15.3 Development of Ulcer in Diabetes

Ulcers in diabetic patients are a result of synchronous effects of motor, sensory, and autonomic neuropathy. Motor neuropathies result in foot deformities and biochemical abnormalities in the foot. Sensory neuropathy is a loss of protective sensation in the foot. Furthermore, autonomic neuropathy leads to decreased sweating in the foot thereby resulting in dry skin [24]. The combined effect of these neuropathies is the formation of callus which is the initial stage of diabetic ulcer formation. After callus formation, continuous trauma, stress, and repetitive injuries lead to skin breakdown thereby resulting in the formation of foot ulcers [24].

## 15.4 Therapeutic Role of Various Growth Factors in the Lesioning of Ulcers

Growth factors are the molecules that regulate the growth of cells and repair of tissues by modulating various cell signaling pathways. They are involved not only in case of healthy wound healing but also in the impaired wound healing process. Growth factors play a role in wound healing by inducing cellular proliferation, migration, chemotaxis, the formation of the extracellular matrix, establishment of cell integrity, and angiogenesis. The effect of growth factors in strengthening the process of wound healing has been demonstrated by various *in vitro* and *in vivo* studies. Among the growth factors playing role in the process of healing of diabetic foot ulcers, the most frequently studied are PDGF, FGF, EGF, VEGF, and TGF-β1 [25–27]. The sequential process of wound healing requires several growth factors and cells resulting in the appropriate closure of the wound. A decrease in the level of growth factor secretion, as well as an increase in the destruction of growth factors, may lead to a delay in the process of wound healing. Therefore, growth factors may serve as an effective therapeutic agent in the treatment of DFU. Various growth factors along with their source of origin and mechanism of action have been summarized in Table 15.1.

**Table 15.1** Summary of the various growth factors with their source of origin and mechanism

| Growth factor | Description | Source | Mechanism |
|---|---|---|---|
| PDGF | Represent a family of four closely related peptides encoded by four genes (A, B, C, and D). These four peptides get activated by the formation of homo- or heterodimer (AA, AB, BB, CC, and DD) | Platelets, fibroblasts, macrophages, and vascular endothelial cells | Chemoattractant for fibroblast, neutrophils, monocytes<br>Promotes the proliferation of fibroblasts and the production of ECM |
| FGF | Binds to heparin and heparin sulfate. FGF family includes 22 members and 5 distinct receptors | Fibroblasts, macrophages, and endothelial cells | Increased cellular proliferation, migration, epithelialization, restoring, and remodeling of ECM |
| EGF | Founding member of the EGF family proteins | Platelets, fibroblasts, and macrophages | Reduction in the healing duration |
| VEGF | A subfamily of PDGF family of growth factors. Five isoforms include VEGF-A, placental growth factor, VEGF-B, VEGF-C, and VEGF-D | Platelets, fibroblasts, macrophages, and keratinocytes | Increased proliferation and migration of keratinocytes and upregulation in the VEGFR2 mRNA expression level |
| KGF | A signaling molecule which is also known as FGF-7 | Fibroblasts | Enhanced healing by re-epithelialization and formation of granular tissue, mitogen for epithelial cells |
| TGF-α | Encoded by the TGFA gene. Binds to EGFR | Platelets, macrophages, and keratinocytes | Stimulates angiogenesis |
| TGF-β1–3 | Member of the EGF family of proteins. Functions by interacting with EGFR | Platelets, fibroblasts, macrophages, and keratinocytes | Chemoattractant for macrophages, mitogen for fibroblasts, stimulates granulation tissue formation |
| IGF | Related to proinsulin | Fibroblasts, macrophages, neutrophils, and hepatocytes | Enhances the re-epithelialization and fibroblast proliferation |

### 15.4.1 Platelet-Derived Growth Factor (PDGF)

PDGF is released and delivered to the wound by the platelets and the local fibroblasts of the injured capillary vessels [28]. It is a 30 kDa dimer formed of two chains A and B. Two additional chains C and D were later identified. Each chain is encoded by the gene present on chromosomes 7, 22, 4, and 11, respectively [29–31]. PDGF exists as a family of homo-heterodimeric growth factors, including PDGF-AA, PDGF-AB, PDGF-BB, PDGF-CC, and PDGF-DD [32]. The four isoforms of PDGF (A, B, C, and D) form dimers and activate the downstream tyrosine kinase receptors resulting in the reorganization of actin filament and proliferation of the fibroblast cells inducing the formation of myofibroblasts [33]. PDGF plays a role in various

phases of diabetic wound healing. PDGF based topical interventions are used for the treatment and induction of healing in case of neuropathic diabetic foot ulcers. Administration of PDGF to wounds has been found to significantly increase the influx of fibroblasts and the cells involved in inflammation.

PDGF is also known to enhance the deposition of extracellular matrix protein and the formation of collagen [34]. Further, PDGF acts as a cellular chemoattractant and promotes the migration of various cells such as fibroblasts, neutrophils, and monocytes to the site of injuries. Besides, PDGF is also responsible for the differentiation of fibroblast cells into myofibroblast thereby supporting the contraction of collagen fibers and the wound [35]. The effectiveness of the topical application of recombinant human PDGF (rhPDGF) in the healing of chronic lower extremity neurotropic ulcers has been reported by Steed [36]. Another study by Bennett et al. [37] reported the benefit of topical application of PDGF in the treatment of non-healing, well-perfused ulcers [37]. According to a report by Mandial et al. [38], exogenous daily application of PDGF is effective and safe in the healing of lower extremity non-healing diabetic ulcers. Further, the topical application of PDGF increases the rate of ulcer closure and also enhances the formation of granulation tissue at the site of the ulcer. The approach of co-delivering PDGF-BB with an enhancer such as Syndecan-4 Proteoliposomes (S4PLs) has been found to significantly increase the wound healing activity of PDGF-BB. This shows that the delivery of syndecan-4 is an effective and beneficial method to enhance the wound healing activity of PDGF-BB [39]. A similar study by Rangaswamy et al. [40] showed that the wounds of the patients treated with rhPDGF contracted more than the non-treated control cohort. The above studies indicate that the PDGF dressings are more effective and can be used for the healing of diabetic wounds and ulcers. PDGF is sold as Regranex/Becaplermin and has also been approved for clinical use by the US Food and Drug Administration (FDA) [41–44]. The treatment of DFU with Becaplermin along with good care of the wound has been found to be more effective in treating the foot ulcer [45, 46].

### 15.4.2 Epidermal Growth Factor (EGF)

EGF family includes members such as EGF, TGF-α, and Heparin-binding EGF. EGF acts by binding to its receptor EGFR and stimulating cell growth, proliferation, and differentiation. EGF is produced by platelets, macrophages, monocytes and stimulates the growth of epithelial cells around the wound. It also acts on smooth muscle cells and fibroblasts [47–49]. The role of EGF in the treatment of DFU has been determined by various clinical studies. In case of early human wound repair, EGF stimulates epithelialization and has also been reported to stimulate the healing process in chronic wounds such as the DFU [48, 50, 51]. The role of rhEGF in diabetic foot ulcers on Wagner's Grade 1 and 2 (the most commonly used classification system for diabetic foot ulcers) ulcers has been reported by Singla et al. [52]. This study involved 50 patients and concluded that the administration of rhEGF could reduce the length of healing time of the ulcer. Another

study involved a double-blinded controlled trial with 50 patients in which rhEGF was applied intra-lesionally. The study demonstrated that rhEGF increases the rate of healing of ulcers and also improves the epithelialization of the wound [53]. In the case of chronic diabetic foot ulcers, the effectiveness of rhEGF has also been reported [54]. A recent study involving 294 patients and four randomized controlled trials have shown the potential of rhEGF in increasing the rate of diabetic ulcer healing and found a fourfold increase in the healing process [55]. According to another study, the treatment of diabetic patients with EGF resulted in complete healing of 76% of patients [56]. As compared to the conventional povidone-iodine dressing group, the group that has been treated with EGF topically has a 100% probability of wound healing in 7 weeks. The result of this study also suggests that EGF, when applied topically, causes a reduction in the number of non-healing ulcers [57]. A genetically engineered form of EGF is Regen-D™ which has been expressed in *E. coli* before being purified. Regen-D™ is a topical gel used at a dose of 150 μg/g and is applied two times a day until the wound is completely healed. The clinical trial carried out with Regen-D™ showed a healing rate of about 9 weeks and a success rate of about 86% [58]. Another form of EGF is Easyef, which is a dermal spray solution (50 mg/mL). It is a recombinant human EGF which comes with a generic name of Nepidermin and recommended to apply two times a day until the wound is fully closed. The clinical trial of Easyef in South Korea and Vietnam has shown more than 50% complete healing [54, 59]. The results of the above studies suggest the potential role of EGF in the treatment of diabetic foot ulcers.

### 15.4.3 Transforming Growth Factor (TGF-β)

TGF-β is a member of a group of cytokines collectively referred to as TGF-β superfamily. TGF-β regulates the growth, differentiation, organization, apoptosis of epithelial cells. TGF-β1, TGF-β2, and TGF-β3 are the forms found in mammals. Out of them, the predominating form is TGF-β1. The cells producing TGF-β include macrophages, fibroblasts, keratinocytes, lymphocytes, and platelets [49, 60, 61]. In the process of wound healing, TGF-β1 is produced early, and an increase in the concentration of TGF-β1 is observed after 5–7 days [62, 63]. TGF-β1 stimulates the chemotaxis of inflammatory cells and the synthesis of extracellular matrix [60]. TGF-β also enhances the production and incorporation of fibronectin and collagen into the extracellular matrix [49]. Another study by Crowe et al. [64] observed that, the absence of TGF-β1 delays the process of wound healing [64]. Topical application of TGF-β1 has been found to stimulate the process of wound repair in young ischemic rabbit skin by increasing the rate of granulation tissue formation [65]. In the healing of partial-thickness and full-thickness wounds like wounds on a distal limb and perforated tympanic membrane in rat, the benefits of local application of TGF-β has been reported [66–68]. Further, TGF-β has also been reported in the healing of hypertrophic scars and chronic ulcers in humans [69, 70].

### 15.4.4 Fibroblast Growth Factor (FGF)

FGF is a family of closely related polypeptides, including acidic FGF (aFGF/FGF-1), basic FGF (bFGF/FGF-2), few oncogenic proteins (int-2, hst/K-FGF) and KGF. Among them, aFGF, bFGF, and KGF are the most important regulators of wound healing [71–74]. Both aFGF and bFGF have a strong affinity for heparin sulfate making them insoluble molecules that are always associated with the extracellular matrix. Basic FGF has a lot of cells as its target including most of the cells involved in the process of wound healing [75]. FGF is produced by endothelial cells, neural cells, keratinocytes, and smooth muscle cells [61]. FGF stimulates the proliferation and migration of a number of cells (endothelial cells, chondrocytes, myoblasts, and epithelial cells) involved in wound healing both *in vitro* and *in vivo* [60, 73, 76, 77]. Acidic and basic FGF are also angiogenic factors and play a role in the process of angiogenesis. Since angiogenesis mainly occurs during the healing of wounds and fractures, FGF is evaluated mostly in the healing tissues [76, 78]. An upregulation of bFGF is observed which is followed by an increase in the phosphorylation of ERK 1/2 proteins [79] thereby suggesting that FGF regulates wound healing by ERK 1/2 signaling cascade. Despite being accepted as an important factor in the healing of the diabetic wound, the use of FGF in the treatment of diabetic foot ulcers is not much reported. A recent study on the use of recombinant human bFGF in the treatment of periodontal intra-bony defects has shown that recombinant bFGF can promote wound regeneration but its efficacy is not satisfactory on clinical level [80]. Some clinical studies have reported the use of bFGF in wound healing [81], but later it was shown that the exogenous application of bFGF failed to support wound closure and bFGF gets washed away by other molecules in the areas of wound thus failing to stay in the areas of the wound [82]. The use of a form of recombinant human bFGF namely Fiblast® spray has been reported by Uchi et al. [83]. It is a lyophilized powdered form and has a generic name Trafermin and is supplied in a spray like formulation. The formulation is applied 5 cm away from the site of ulcer with an approximate dose of 30 μg per day. It binds to the ECM of several tissues and has been shown to improve the process of healing [83]. Further, if bFGF is combined with other drugs, its efficacy could be improved for treating diabetic ulcers.

### 15.4.5 Vascular Endothelial Growth Factor (VEGF)

VEGF is similar in structure to PDGF and placental growth factor [84] and was discovered mainly as playing a role in increasing the permeability of blood vessels to the circulating molecules in tumor cells. VEGF is produced mainly by tumor cells, endothelial cells, macrophages, pericytes, smooth muscle cells, lymphocytes, monocytes, granulocytes, and megakaryocytes [85, 86]. VEGF is a cell-specific mitogen with potential angiogenic activity. Angiogenesis mainly occurs during the healing of wounds and fractures. During the repair of the wound, angiogenesis provides the essential nutrients required for wound healing and helps in the formation

of granulation tissue [87]. An increase in the expression of VEGF mRNA/protein within a day of wounding has been reported [88–91]. In case of rabbit tracheal reconstruction [92] and dermal ulcer of the ear [93], an increase in the healing process has been reported through the application of VEGF. Further, gene therapy with VEGF has also increased the deposition of granular tissue in case of rabbit ear wounds [94] and increased the healing of the wound in the skin of rat [95]. The above studies suggest the great potential of VEGF in the treatment of wounds by the delivery of VEGF via the gene transfection method. Further, a decrease in the level of VEGF-A has been observed in patients with DFU as compared to the patients without DFU. This further leads to a decrease in the level of VEGF receptor-2 [96] which was supposed to be the cause of poor healing of wound [97]. A study by Amoli et al. [98] further confirmed the role of VEGF in DFU. The study reported that a low frequency of AA genotypes and A alleles of the VEGF gene is associated with the incidence of ulcers in the foot of diabetic patients [98]. Recombinant human VEGF (Telbermin) has undergone a phase I trial in 2008 [99] on chronic neuropathic DFU. The trial was done on 55 patients with type 1 and 2 diabetes. They were divided into two groups of 29 and 26 patients. The first group received Telbermin whereas the second group received a placebo. It was reported that Telbermin has a tendency of increasing the rate of healing of ulcer and also reduces the duration of ulcer healing [99]. Lois et al. [100] reported that the use of FGF-2 loaded nanoparticles and fibrin-based scaffold with VEGF could promote the healing of the wound in diabetic mouse models [100]. The above studies suggest the role of VEGF in the treatment of diabetic ulcers and further suggests that rhVEGF combined with other components might be used as an innovative therapeutic approach to the treatment of DFU.

### 15.4.6 Keratinocyte Growth Factor (KGF)

KGF is a heparin-binding growth factor promoting the growth, proliferation, migration, and morphogenesis of epithelial cells thus encouraging the repair of injured tissue and skin. Keratinocytes form epithelium over the wound in the epithelialization phase of wound healing and also induces the deposition of collagen in the wound [101]. A truncated form of rhKGF-2 is Repifermin. It has been reported to be used in the healing of chronic venous stasis ulcers [102, 103]. The study reported that Repifermin accelerated the process of wound healing significantly and 75% of patients treated with Repifermin achieved wound closure as compared with placebo.

### 15.4.7 Insulin-Like Growth Factor (IGF)

IGF, previously known as somatomedin is produced in the liver and exists in two forms IGF-1 and IGF-2 which produce glycogen and glycosaminoglycans, respectively. It is present in high concentrations in the platelets and is released by platelets during the clotting of the wound. It has been reported that in the case of diabetic

mice and humans, the level of IGF-1 is reduced and IGF-2 is increased in the epidermal basal layer. Also, after wounding, the expression of both IGF-1 and IGF-2 is delayed. All these results in a delay in the healing of wounds [104, 105]. During the healing of the wound, IGF participates in cellular granulation in patients of DFU. IGF-1 expression is lowered in patients with diabetes which leads to a failure in cell granulation. IGF is a potent mitogen for fibroblasts and keratinocytes and enhances the production of ECM [106].

## 15.5 Molecular Targets in DFU and Their Delivery Systems

The management of DFU is based on the molecular targets which are directly or indirectly involved in the modulation of DFU. The molecular targets of DFU as discussed in the previous sections of this chapter include growth factors such as PDGF, EGF, VEGF, FGF, IGF, KGF, and TGF. Several agents can directly or indirectly influence these molecular targets by suppressing or enhancing the expression of growth factors and factors stimulating angiogenesis. Several approaches such as the use of growth factors, dual growth factors, cytokines modulators, anti-inflammatory drugs, MMP inhibitors, ECM stimulators have been evaluated in the treatment of DFU but have shown little achievement.

For the use of growth factors in the treatment of DFU, two points need to be considered. First, the use of growth factors effectively for therapeutic purposes depends on the delivery system. This area has been covered by the use of specialized delivery platforms like the use of polymer gels, coated dressings, chamber devices, and nanoparticles [107–110]. Micro and nanospheres are synthesized using natural and synthetic materials such as Poly Lactic-Co-Glycolic Acid (PLGA), Gelatin, and Chitosan [111–113]. For entrapping growth factors, PLGA is the most commonly used polymer due to its biocompatibility and biodegradability. It is also less hydrophilic, absorbs less water, and degrades slowly allowing the sustainable release of the drug [114, 115]. Also, the degradation of PLGA produces lactate which stimulates angiogenesis, activates the pro-collagen factors, and also recruits endothelial cells at the site of the wound. Human recombinant EGF-loaded PLGA microspheres have been developed by Dong et al. [114], which demonstrated an 85.6% encapsulation efficiency. Preclinical and clinical studies have reported that EGF-PLGA-MS when applied topically to wounds resulted in an increased fibroblast proliferation rate and also improved wound healing as compared to using human recombinant EGF alone. Another study reported that the use of bioinspired hydrogels, which are based on the nanomorphology of algal adhesive along with gum Arabic, calcium, pectin when combined with bFGF serves as a promising treatment for wound healing and enhance the cell proliferation, wound epithelialization and deposition of collagen [116].

The second key point that needs to be considered in growth factor therapy is that complex microenvironments are generated at the sites of chronic inflammation, making them difficult to be treated by a single growth factor [117]. The strategy for this is the sustained delivery of growth factors such that they can resist the

proteases in the wound microenvironment. Further, the secretion of growth factor at the appropriate time and in appropriate concentration is necessary to achieve positive outcomes. Appropriate wound care is done with the combined action of several cell types such as fibroblasts, platelets, etc. [118]. Recently, one exciting study related to surgical sutures reported that standard surgical threads can be bio-activated with a genetically modified form of microalgae to release both oxygen and recombinant growth factor at the site of the wound [119]. Gene therapy is another new option for wound treatment. Shi et al. [120] reported the transfer of genes of VEGF-A and PDGF-B for DFU in rats for the treatment of wounds [120] and observed positive results. However, this field further requires thorough investigation. Therefore, Research is still going to assess more beneficial treatment options for DFU.

## 15.6 Conclusions

Impaired wound healing is a common diabetes-related complication in diabetic patients. Several studies have reported the importance of growth factors in the treatment of DFU. The molecular steps involved in the healing of ulcers in diabetic patients have also been critically studied to contribute to DFU management. Significant improvements have been made to develop newer approaches such as the use of dual growth factors, cytokine modulators, anti-inflammatory drugs, MMP inhibitors, and angiogenesis stimulators. Although several compounds for the treatment of DFU have been reported, the concern remains in their efficiency, side effects, and cost-effectiveness. Further, the integrity, stability, and the release efficiency of these compounds is a major concern and needs thorough preclinical and clinical studies. Several recent studies generate hope for the researchers in designing novel delivery systems for the growth factors (single or in combination). Drug delivery systems based on the use of combination pharmaceutical products appear as one of the future innovative approaches for treating DFU. A combination of materials such as a combination of growth factors, dressings, and scaffolds can be used to improve the efficiency of the treatment. The release efficiency of each of the biomaterials used in the treatment needs to be regularly checked to attain desirable results, and the degradation of the growth factors in the area of the wound should be minimized. The efficacy of these approaches needs further studies and exploration in the future.

# Stem Cells in the Treatment of Diabetic Foot Ulcers

16

Rashid Mir, Imadeldin Elfaki, Ajaz Ahmad Waza, and Faisel M. AbuDuhier

## 16.1 Introduction

*Diabetic foot ulcer* is a major clinical complication of type 2 diabetes mellitus and remained an important clinical challenge to global health. The prevalence of Diabetic foot ulcers is 16–25% among type 2 diabetes mellitus patients in the Americans. Diabetic foot ulcers (DFU) are an economic burden on our health care system and society. Diabetic (DFUs) are the leading cause of lower limb amputation and is the most common chronic complication from T2D (Type 2 diabetes) and affecting 4–10% of patients. More than 85% of amputations are preceded by an active foot ulcer. Clinical complications of Diabetic foot ulcers are a major cause of hospitalization and amputation in the T2D (Type 2 diabetes) patients. Effective treatment options for curing Diabetic foot ulcers are very far from optimal. Diabetic foot ulcers are a type of wound and its healing is a physiologic response involving the disruption of normal skin architecture therefore requires temporal and spatial coordination of many cell types as well as cytokines.

*Diabetic foot ulcer* wound healing is the most complex process susceptible to dysregulation secondary to systemic and local factors such as T2D or diabetes and

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_16

ischemia which lead to chronic wounds. Diabetic foot ulcer wounds are epidemic as they heal poorly and recur frequently and create a profound impact on the health care system therefore creating an urgent for developing new and advanced therapies. Most of the amputations occurring in the populations with T2D (Type 2 diabetes) reported being due to Diabetic foot ulcer. Several symptoms have been reported of a localized wound infection that indicates Diabetic foot ulcers few of them are as—edema, heat erythema, bad odor from one or both feet and purulent exudate, pain are classic signs of infection linked with wound infection. The various signs specific to secondary symptoms are serous exudate, friable granulation tissue, discolored granulation tissue, pocketing of the wound base, delayed healing, wound breakdown, and foul odor.

*Diabetic foot ulcers* are vascular disease. It is reported that blood does not flow normally to the tissues and the ulcers do not heal because of poor blood supply. In several cases of Diabetic foot ulcers several foot nerves are damaged that lead to long-term loss of feeling in the foot. In the wounded feet, there is a tingling and painful feeling. The sensitivity to foot pain is reduced because of the nerve damage. Due to nerve damage, poor hygiene painless wounds are formed leading to ulcers besides the use of tobacco which inhibits blood circulation. Diabetic foot ulcers physiology has shown autonomic dysfunction that leads to the drying of the skin. This induces the increased axial and mechanical stress on the patient skin. The drying makes Diabetic foot ulcers more prone to injury.

*The gold standard for Diabetic foot ulcer* wound management is composed of diagnostic etiology, vascular inflow to reduce ischemia, controlling of infection, off-loading of pressure, and debridement of nonviable tissue. It has been reported that only despite advanced and optimal treatment options still only 51% of Diabetic foot ulcers heal within 15–20 weeks however more than 50% under *recurrence* within 19 months. Therefore improved, novel, and modern methods of Diabetic foot ulcer wound healing are required.

Current treatment options are reported to recover about 31% of Diabetic foot ulcers and even the most modern and advanced therapies like cell-based therapies composed of skin-derived fibroblasts and keratinocytes however only 50% cure rate has been reported, therefore leaving a void and a tremendous scope for developing new effective therapeutic options for Diabetic foot ulcers. It has been established that mesenchymal stem cell therapy (Stem cell) holding a great promise as an advanced therapy for Diabetic foot ulcers. Stem cell therapy has been reported to have a great potential in accelerating the healing of Diabetic foot ulcer wounds.

Mesenchymal stem cells proved to high curative potential as they secrete stimulatory molecules and provide base for collagen scaffolding that can generate a template on which new tissue can be rebuilt and regenerate. Several studies established that mesenchymal stem cell—scaffold device is a pre-conditioned and its regenerative and reparative properties can be maximized. Mesenchymal stem cell therapy (Stem cell) therapy has limited scope because of the requirement for invasive harvesting techniques, having short cell survival in vivo and immunogenicity.

Several studies established that embryonic stem cell-derived mesenchymal stem cells are more advantageous and superior to adult-derived mesenchymal stem cell

because they have high potency, display a consistent phenotype and have the proliferative ability. Because of the ethical issues, the utilization of Adult-derived mesenchymal stem cell has become limited by the ethical issues. The limited use of embryonic stem cells is due to invasive harvesting techniques, limited cell survival in vivo, and high immunogenicity with the use of embryonic stem cells. Similarly, the Induced pluripotent stem cells (iPSC) have a high potential for self-renewal, are pluripotent, and can differentiate into any adult cell type. They can be used in wound healing as well as regenerative medicine. Induced pluripotent stem cells (iPSC) have translational potential and enhanced therapeutics. Induced pluripotent stem cells (iPSC) can be harvested non-invasively and can be transplanted autonomously and reducing immune rejection. Induced pluripotent stem cells (iPSC) iPSC are capable of differentiation into all cell types in the human skin.

### 16.1.1 Role of Induced Pluripotent Stem Cells (iPSC) in Diabetic Foot Wound Healing

#### 16.1.1.1 Pluripotent Stem Cells

Pluripotent stem cells are commonly called as master cells, which are able to produce any type of cell and are able to self-renew, i.e., can produce more copies of them. iPSCs are pluripotent stem cells derived from adult somatic cells through reprogramming strategy. Such cells have the capability to differentiate into any type of adult cell and therefore have emerged as a novel strategy for wound healing therapy [1]. IPSC have the capability to augment diabetic wound healing via direct and paracrine signaling [2]. They are a source of autologous and allogeneic cell types and therefore can improve the outcome in DFU wound healing. Although iPSCs can differentiate into various cell types essential for DFU healing, but have not been exploited yet for the repair of chronic wounds [3, 4]. Till date, iPSC have not yet been used to treat recalcitrant DFUs.

#### 16.1.1.2 Current Methods for Generating Induced Pluripotent Stem Cells

Induced pluripotent stem cells (iPSCs) are produced by artificial reprogramming/manipulation of adult cell. Currently, different strategies are followed to achieve reprogramming and are discussed in Table 16.1.

Although different strategies like nuclear transfer, cell extracts, forced expression of defined factors, synthetic molecules, and miRNA are adapted to produce iPSCs, but the optimal method is yet to be explored. Out of all these, the forced expression technique is well defined and the most studied one.

### 16.1.2 Dysregulation of Wound Healing in Diabetic Wounds

Long-standing diabetes is associated with numerous complications like cardiovascular diseases, cerebrovascular diseases, neuropathy, retinopathy, nephropathy, and

**Table 16.1** Techniques adopted for iPSC production

| Method | Technique | Refernces |
|---|---|---|
| Nuclear transfer | In this technique, the nucleus of a somatic cell is allowed to fuse with a mature enucleated oocyte. | [5, 6] |
| Cell extracts | This technique involves incubation of differentiated cells with ES cells extracts, so to induce them to express profiles of ES cells. | [7, 8] |
| Forced expression of defined factors | This technique involves the transfection of embryonic cells with a known combination of different genes like Oct4, Sox2, c-Myc, Klf4, Lin28, Stat3, Nanog, UTF-1, Esrrb SV40LT, Wnt3a, hTERT, Nr5a2, and p53 siRNA. | [9, 10] |
| Synthetic molecules | This technique involves the use of low molecular weight compounds for reprogramming purposes. For example, Reversina is used to produce cells with adipogenic and osteogenic differentiation potential from myoblasts. Other compounds used for this purpose include valproic acid (VPA), Suberoylanilide hydroxamic acid (SAHA), valproic acid (VPA), trichostatin A (TSA), BIX-01294, 5′ azaC, dexamethasone, and BayK8644. | [11, 12] |
| miRNA | This technique involves the use of microRNAs to alter the protein profile of the target cell. | [13, 14] |

poor wound healing. Out of these complications, poor wound healing also called DFU is devastating and can even lead to amputation. A normal healing process is not followed during diabetic wound healing but a dysregulation in proliferation, deposition of extracellular matrix, and cell migration has been observed [15, 16]. Role of hypoxia and hypoxia inducible factor-1 (HIF-1) in wound healing and extracellular matrix deposition is well established in fibroblasts essential for wound healing [17]. HIF-1 activates wound repair associated genes like GLUT-1 (transporter -1) and VEGF (vascular endothelial growth factor) [17]. Duscher and his colleagues found that the deletion of HIF-1 in fibroblasts resulted in delaying wound healing with poor vascularization [18]. Similarly, insulin is considered to be a key factor in the wound healing process and selective insulin resistance (insulin unresponsiveness) has been found in fibroblasts and endothelial cells. As a result, insulin-associated endogenous signaling mediated through the IRS/PI3K/AKT pathway is not activated in these wound healing essential cells [19, 20].

### 16.1.3 Human-Induced Pluripotent Stem Cells in Ischemic Wounds

Ischemia is a condition resulted from a decreased blood flow to some tissue/organs and occurs due to obstruction of the arteries. Insufficient blood flow to brain and heart can lead to heart attack and stroke respectively, while decreased blood flow to skin can lead to wound formation. Currently, iPSC are being studied in various ischemia disease models, which includes myocardial infarction, retinopathy,

osteonecrosis, and peripheral arterial disease. As evident from skin-related wound healing studies, it has been observed that iPSC healing potential is mainly attributed to their pro-angiogenic property [21]. Till date, iPSCs have been investigated with respect to peripheral arterial disease models but research has not been carried out yet regarding wound healing in severe ischemic limbs. In peripheral arterial disease models, iPSC has been found to ameliorate ischemia by decreasing inflammation, enhancing angiogenesis and by reconstitution of viable cells. Use of human-induced pluripotent stem cell-derived endothelial cell (hiPSC-EC) in combination with VEGF in a hind limb ischemia mice model promotes regeneration of muscles and decreases inflammation [22]. Furthermore, hiPSC-EC has been found to increase angiogenesis (increased number of angiogenic related cytokines and growth factors) and therefore resulted in increased blood flow to ischemic limbs [23]. It has been observed that injecting hiPSC-derived pericytes into murine limbs challenges with ischemia is associated with increased limb reperfusion by fourfold [24].

### 16.1.4 Limitations of Induced Pluripotent Stem Cells to Achieve Wound Healing

Although the use of iPSC has emerged as an exciting and innovative strategy in the field of regenerative medicine and holds the potentials to enhance wound healing. Before using in clinical settings, their role must be fully understood with respect to their tumorigenic potential [1]. HiPSC derived from chronic disease patients can be reprogrammed into the cells identical to those derived from a healthy individual. But iPSC-EC obtained from mice with induced diabetes are linked with poor healing and therefore, demands further studies to fully understood the nature of hiPSC derived from healthy and diseased donor.

Before using Induced pluripotent stem cells (iPSC) for human use, major hurdles associated with them must be overcome first. Non-integrative methods like the use of small particle and protein transfer for the generation of hiPSC should become speedier and more efficient [25]. Standardized procedures should be developed for teratoma formation assays to confirm pluripotency, so as to derive meaningful conclusions about cell lines. A proper platform for transferring hiPSC into a wound area should be determined. Furthermore, it is important to determine an ideal niche for hiPSC, so as to achieve enhanced intracellular signaling and cell survival.

New strategies/protocols are need of the hour to eliminate undifferentiated hiPSC cells before transplant, as they have tumorigenic tendency. A good number of studies have investigated the tumorigenic tendency of iPSC transferred directly to the murine tissues, but till date no such event has been examined after injection of hiPSC into the cutaneous tissue [26]. Thus it is important to further investigate iPSC in model animals that mimic human skin for their safety and efficacy before their human use.

### 16.1.5 Induced Pluripotent Stem Cells Reveal Distinct Cellular and Tissue Phenotypes

Diabetic foot ulcers (DFU), have emerged as a major complication associated with diabetes, and to treat these wounds, the use of iPSCs has gained much attention. Recently, it has been reported that iPSC-derived fibroblasts showed enhanced migratory potential in two-dimensional (2D) culture conditions [2]. Interestingly, iPSC-derived fibroblasts (obtained from DFUs) has been found to possess distinct morphology and biochemical composition than parental DFU fibroblasts, when cultured in three-dimensional (3D) conditions [2]. Furthermore, enhanced diabetic wound closure has been reported by using 3D tissues (obtained from iPSC-derived fibroblasts) as compared to primary DFU fibroblasts [2].

## 16.2 Mesenchymal Stem Cells (MSCS) for Diabetic Foot Wound Healing

Mesenchymal stem cells (MSCs) also called multipotent mesenchymal stromal cells are able to self-renew and have the ability to differentiate into various tissue-forming cell lineages like myocytes, chondrocytes, osteoblasts, tenocytes, and adipocytes [27]. These stem cells can be obtained from different tissues like adipose tissue, bone marrow, and umbilical cord.

### 16.2.1 Role of Mesenchymal Stem Cells (MSCs)

Various studies have reported that MSCs are able to accelerate wound closure by increasing wound healing [28, 29]. It has been reported that human MSCs (derived from bone marrow) are able to cause wound closure via enhanced migration of keratinocytes and fibroblasts in in vitro conditions [30]. Smith and his colleagues reported an increased wound closure by murine MSCs (derived from bone marrow) via enhanced migration of dermal fibroblasts [31]. Similarly, Jeon and his colleagues reported an increased migratory potential of skin fibroblasts during culturing in umbilical cord blood MSC-conditioned media [32]. The beneficial role of MSCs on skin regeneration and cutaneous wound healing has been well defined and the process is complex. MSCs enhance different processes like wound closure, angiogenesis, re-epithelialization, and formation of tissue granulation, as well as modulate inflammation and regulate extracellular matrix (ECM) remodeling, as shown in Table 16.2. Furthermore, MSCs associated with beneficial effects are mainly attributed to paracrine signaling [33, 34].

### 16.2.2 Mesenchymal Stem Cells (MSCs): Mechanisms of Action

An intense research had been carried out during the past decade to better understand the molecular mechanism associated with MSCs during regeneration and wound healing. Administrated MSCs promote tissue regeneration and wound healing

**Table 16.2** MSCs associated increased cutaneous wound healing

| | | | |
|---|---|---|---|
| Mesenchymal stem cells | Increased migration of keratinocytes and fibroblasts | Wound closure | Wound healing |
| | Increased expression of HGF and VEGF | Angiogenesis | |
| | Increased density of microvessels | | |
| | Decreased inflammatory cells | Inflammation | |
| | Decreased expression of TNFα and IL-1 | | |
| | Decreased expression of ICAM1 | | |
| | Increased expression of SOD and GPx | | |
| | Decreased expression of MMP-1 | ECM remodeling | |
| | Increased expression of collagen and elastin | | |
| | Increased proliferation of fibroblasts and HaCaT cells | | |
| | Increased thickness of the regenerated epidermis | Skin regeneration | |
| | Increased skin appendages | | |

*SOD* superoxide dismutase, *GPx* glutathione peroxidase, *TNF-α* tumor necrosis factor-alpha, *HG* hepatocyte growth factor, *HaCaT* immortalized human keratinocyte, *ICAM1* intercellular adhesion molecule 1, *MMP-1* matrix metalloproteinase-1, *IL-1* interleukin-1, *VEGF* vascular endothelial growth factor

through different mechanisms, which include differentiation, migration/homing, paracrine effects, and immunomodulation. Understating the molecular mechanism of each step would be quiet helpful to enhance treatment efficacy, safety, and patient's outcome after administration of MSC.

### 16.2.3 Differentiation of Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) have the ability to differentiate into different cell types like epithelial cells, osteocytes, adipocytes, chondrocytes, cardiomyocytes, hepatocytes, vascular endothelial cells, and neurons, and therefore have emerged as a potential cell-based therapy to treat different human diseases [35]. Injection of MSCs (derived from bone marrow) around a cutaneous wound has been found to increase closure of wounds with enhanced angiogenesis, re-epithelialization, and cellularity. Apart from this, MSCs were found to synthesize a keratinocyte-specific protein namely keratin, suggesting differentiation of MSCs into keratinocytes [36]. Furthermore, MSCs have been found to differentiate into epidermal keratinocytes and skin appendages [37].

### 16.2.4 Migration/Homing of Mesenchymal Stem Cells (MSCs)

The process of delivering MCSs to the site of wound/injury is known as *homing*, and the process is complex. Therapeutic potential of MSCs mainly dependents on paracrine and juxtacrine signaling factors, which are essential for increasing regeneration from endogenous (stem) cells.

In response to injury, certain specific ligands or receptors are upregulated, which not only help in adhesion, infiltration, and trafficking of MSCs, but also provide a feasible niche for marinating pluripotency and self-renewal [38]. Furthermore, MSCs trapped in blood vessels of wound/injured site secretes various cytokines and growth factors that promote wound healing [39].

### 16.2.5 Paracrine Effects of Mesenchymal Stem Cells (MSCs)

Paracrine signaling associated with MSCs are important for exerting their therapeutic effects [40]. MSCs associated with paracrine signaling promote various beneficial effects on different cell types, which include modulation of proliferation, gene expression, cell survival, and migration [41]. The presence of cytokines and growth factors in MSC-conditioned media promotes wound repair and increases epithelialization, due to the presence of growth factors and cytokines [36]. Conditioned medium obtained from bone marrow-derived MSC has been reported to attract endothelial progenitor cells and macrophages to the wound area [42].

### 16.2.6 Immunomodulation of Mesenchymal Stem Cells (MSCs)

Suppression of inflammation is considered to be an important event for healing to occur successfully and MSCs possess anti-inflammatory effects. Surface of MSCs possesses low levels of MHC-I (histocompatibility complex-I) and lacks molecules like MHC-II, CD 40, CD 86, and CD 80, thus allowing their successful allogeneic transplantation [43]. Liu et al. observed very low quantity of pro-inflammatory cytokines (like TNF-α and IL-1) and inflammatory cells, when cutaneous rat wounds were transplanted with MSCs (derived from human umbilical cord) [44]. It has been observed that co-culture between human dermal fibroblasts and MSCs (derived from murine bone) resulted in decreased expression of ICAM1 (intercellular adhesion molecule 1) mRNA [45]. Decreased expression of ICAM1 is considered to be essential for suppressing inflammation during wound repair [46].

### 16.2.7 Optimizing of Mesenchymal Stem Cells (MSCs) Therapeutic Effect

A potential disadvantage associated with the use of MSCs for the treatment of chronic wounds is a variation in cell survival proportion after implantation. On the other hand, MSCs have potential to proliferate fast and therefore does not pose dose-limiting hindrance during MSC therapy. MSCs can be applied in high doses to the wound area or close to the wound, through biomaterials [47]. It has been reported that the use of biomaterials ensures longer MSCs viability, furthermore the use of cell encapsulation technology effectively protects MSCs from mechanical stress, which is a common event during DFU [48]. It is important to better understand the

MSCs niche in diabetic cutaneous wounds, as microenvironment in the niche is essential in controlling MSCs cell fate.

### 16.2.8 Preclinical Studies on the Stem Cell Usage for Diabetic Foot Ulcers

T2D is resulted from by the genetic and environmental risk factors interaction [49–52]. There are long-term and short-term complications of DM. The long-term complications include the macro vascular complications such as coronary artery disease, peripheral vascular disease, and stroke. Whereas microvascular diabetes complications include neuropathy, nephropathy, and retinopathy [53]. Diabetic foot ulcers (DFU) is a public health concern all over the world. Diabetic foot ulceration and amputation are caused by diabetic cardiovascular and diabetic neuropathy complications. It is considered as a very important cause of illness and deaths among diabetic patients [54]. Every year there are more than one million lower limb amputations because of DFU, and that about 60% of all nontraumatic lower limb amputations are caused by the of diabetes ulcerations [55]. Moreover, DFU costs about 9 billion USD for treatment and care [56]. DFU results from infections, low blood supply, hypoglycemia, and diabetic neuropathy [56].

Stem cells are multipotent cells with the potential of self-renewing and differentiation into multiple tissue-specific daughter cell types with specialized functions [57]. The stem cells are found in all human tissues and play critical roles in growth and homeostasis [58]. The major classes of stem cells include the embryonic (obtained from embryos of human in preimplantation stage), Adult stem cells (derived from tissues of adults), and the induced pluripotent stem cells (iPSCs) which resemble the ESCs and obtained from genetic reprogramming of various somatic cells from many animal species [58]. Due to the ability of the stem cells in self-renewing and differentiation into diverse cell types, they were studied in regenerative medicine for treatment of diabetes mellitus, tumors, and the immunodeficiency virus [49]. The multipotent mesenchymal stem cells (MSCs) represent a good origin for regenerative therapy of inflammation, tissue injuries, tumors, and Diabetic foot wounds [49, 57, 59]. The sources of the MSCs include bone marrows, brain, gingiva, peripheral blood, lungs, heart, and adipose tissues [57, 59].

### 16.2.9 Source of Mesenchymal Stem Cells

Stem cells can be obtained from the bone marrow. The stem cells obtained from the bone marrow are called the mesenchymal stem cells (BM-MSCs). The BM-MSCs represent an efficient and safe option for DFU therapy [57]. Intramuscular transplantation has been shown to be the most effective way. However, differentiation and numbers of BM-MSCs are reduced with increasing age [60, 61]. The BM-MSCs do not stimulate immune reactions, and they are able to resist the cellular immune response (cytotoxic T and NK lymphocytes) [9] and inhibits the effects of the

interferon-gamma (IFN-γ) derived from the T-cells [57, 62]. The BM-MSCs migrate and form the blood vessels in the DFU which would accelerate the wound healing through the protein C-C chemokine receptor type 7, intercellular adhesion molecule 1 (ICAM-1) and the Akt-dependent mechanism cells [49, 63]. The Mesenchymal Stem cells obtained from Umbilical Cord Blood (UCB-MSCs) are able to move like BM-MSCs and have similar multilineage differentiation capacity surface antigen on the cells [49, 61]. The UCB-MSCs have some biological advantages such as increased proliferation capacity, a shorter doubling time, a longer culture time, and a higher anti-inflammation effect [57, 64]. These advantages make the UCB-MSCs more convenient than the BM-MSCs for the application of stem cells in regenerative therapy. Animal and in vitro studies have shown that the UCB-MSCs reduces the neurodegeneration in DFU via the secretion of the neurotrophic factor, the nerve growth factor (NGF) in the femoral nerve that supplies the gastrocnemius muscle of rat diabetic foot. In addition, UCB-MSCs secrete the vascular endothelial (VEGF) and the basic fibroblast (bFGF) growth factors that improve the blood supply for the foot and accelerate diabetic wound healing [57, 64, 65].

### 16.2.10 The Usage of the BM-MSCs for Diabetic Foot Ulcers in Clinical Studies

The autologous transplantation of BM-MSCs in clinical trials demonstrated decreased pain and size of the wound, in addition to normal liver and kidney functions [66]. The leg perfusion has also improved which decreased the amputation size in critical limb ischemia [57]. The autologous biograft in mixture with BM-MSCs accelerate the ulcer healing and improve the skin angiogenesis and thickness in cases with DFU [57]. The intramuscular injection of BM-MSCs in the quadriceps thigh muscles in patients with DFU resulted in the maintenance of blood sugar and decreased levels of C-reactive protein and tumor necrosis factor alpha levels, in addition to increased vascular endothelial growth factor level [62]. In another study, the intramuscular injection of UCB-MSCs in patients with critical limb ischemia resulted in mild adverse side effects such as diarrhea; mouth wound, and elevated levels of serum creatinine [67, 68]. The body urticaria was treated with antihistamine and the other adverse effects improved without interference [67, 68].

### 16.2.11 Limitations of the Use of the UCB-MSCs

Limitations of the use of the UCB-MSCs include privacy and ethical issues in addition, to the high costs of the umbilical cord blood preservation. The Mesenchymal stem cells derived from the peripheral blood have been reported to be used frequently in clinical studies. The injection of PB-MSC and angioplasty improved the healing of DFU [49, 56]. In a case-control study, 30 patients with DFU have been treated with stem cells derived adipose tissues (ASCs), and the control group ($n$ = 29) have been treated with polyurethane film for 12 weeks [49]. After the

treatment period complete wound healing was achieved in 80% of the group treated with ASCs, and 50% in the control group with no observed side effects [69].

## 16.3 Administration Route Stem Cell Therapies

One of the most important aspects of the stem cell therapy to improve patient's *treatment* and the outcome is the route of administration of the *stem cells*. Mesenchymal stem cell therapy has been established as a potential, advanced, and effective treatment for Diabetic foot ulcers and can be an alternative treatment to amputation for T2D patients without other treatment options for revascularization. It has been reported that preclinical and clinical studies can be utilized for designing future randomized clinical trials. There are different *routes* of *administration* of *stem cells* used in Diabetic foot ulcers including

1. Nonvascular administration of stem cell therapy
2. Topical administration of stem cell therapy
   (a) Intramuscular
   (b) Subcutaneous
   (c) Intradermal
   (d) Hydrogel and Scaffold
   (e) Spray and Drops
3. Systemic endovascular administration of stem cell therapy
   (a) Endovascular Intraarterial
   (b) Endovascular Intravenous

### 16.3.1 Nonvascular Injections

Nonvascular injections into tissue have been established as the most utilized route of administration to directly treat Diabetic foot ulcers DFU. More than 28 preclinical studies (52%) have been reported to utilize direct nonvascular injections to directly treat Diabetic foot ulcers [56]. Recently 31 clinical studies (86%) have been conducted with excellent results utilizing direct nonvascular injections to treat Diabetic foot ulcers as depicted in Table 16.3 [56].

**Table 16.3** Intramuscular (Nonvascular injections) as administration routes for stem cells its advantages, disadvantages and use in clinical and preclinical studies

| Administration route | Injection |
|---|---|
| Clinical studies | 31 (86%) |
| Preclinical studies | 28 (52%) |
| Administration route subtype | Intramuscular |
| Disadvantages | Poor engraftment, high cell death, low addressing |
| Advantages | Low risk, simple and inexpensive |
| Preclinical studies | 2 (3.7%) |
| Clinical studies | 24 (66.7%) |

**Table 16.4** Topical (Subcutaneous and Intradermal) as administration routes for stem cells its advantages, disadvantages and use in clinical and preclinical studies

| Administration route | Topical |
|---|---|
| Preclinical studies | 23 (43%) |
| Clinical studies | 31 (86%) |
| Administration route subtype | Subcutaneous and intradermal |
| Advantages | Inexpensive, simple, painless, and low risk |
| Disadvantages | Low addressing, high cell death, and poor engraftment |
| Clinical studies | 3 (8.3%) |
| Preclinical studies | 6 (11.1%) |

### 16.3.2 Topical Administration of Stem Cell Therapy

Topical administration is also called direct administration stem cells that require a high concentration of stem cells adjacent to the wound as well as at the surface of the wound. It should be kept in mind that the stem cell administration timing is potentially important so that the mesenchymal stem cells undergo functional interaction with the wound cells at critical stages of the healing process. The frequency of direct administration has been performed frequently in 23 (43%) preclinical studies and five clinical studies (14%) [56] as depicted in Table 16.4.

### 16.3.3 Collagen Hydrogels and Scaffolds Administration of Stem Cell Therapy

Collagen hydrogels are composed of cross-linked hydrophilic polymer networks called extracellular matrix (ECM). The extracellular matrix (ECM) has a property of swelling when coming in contact with water and the extracellular matrix (ECM) is a natural occurring hydrogel which can provide the best microenvironment which provides support to stem cells found resident in tissues, making this polymer desirable for tissue engineering applications using stem cells. It has been established that Collagen hydrogels and scaffolds can be utilized for culturing stem cells in several different tissue engineering applications, including blood, neural tissues [69]. It has been reported that the use of collagen hydrogels or hydrogel scaffolds have attractive characteristics like shape adaptability, ability to access parts of the body that are difficult to reach, and improve the engraftment capacity as well as the survival of the injected Mesenchymal stem cells. These collagen hydrogels or hydrogel scaffolds have the potential to be combined with materials yielding some new or novel hybrid materials that increase cell survival, making it more desirable for drug delivery [69, 70]. Several research studies have reported that collagen hydrogels and scaffolds can be utilized as vehicles to deliver to tissues and cells [71]. It has been reported that hydrogel and scaffold delivery were used in 9 (16.7%) preclinical studies and 0 (0%) clinical studies [56] as depicted in Table 16.5. Similarly, spray and drops administration routes delivery were used in three (8.3%) preclinical studies and clinical studies six (11%) [56] as depicted in Table 16.5.

**Table 16.5** Topical (spray and drops and hydrogel and scaffold) as administration routes for stem cells its advantages, disadvantages, and use in clinical and preclinical studies

| Administrative route | Topical | |
|---|---|---|
| Preclinical research studies | 23 (43%) | |
| Clinical research studies | 5 (14%) | |
| Route subtype | Spray and drops | Hydrogel and scaffold |
| Advantages | Painless, simple, low risk, and inexpensive | Better retention and engraftment, low risk, high cell density, good spacing control |
| Disadvantages | Poor engraftment, high cell death, low cell density, and good spacing control | High protocol complexity, expensive and may need debridement |
| Clinical studies | 3 (8.3%) | 0 (0.0%) |
| Preclinical studies | 6 (11.1%) | 9 (16.7%) |

**Table 16.6** Systemic Endovascular (Intraarterial and Intravenous) as administration routes for stem cells its advantages, disadvantages, and use in clinical and preclinical studies

| Administration route | Systemic endovascular | |
|---|---|---|
| Preclinical research studies | 5 (9%) | |
| Clinical research studies | 6 (17%) | |
| Administration route subtype | Intraarterial | Intravenous |
| Advantages | Can be done during angioplasty, possible | Glucose homeostasis optimizing effect immunomodulation |
| Disadvantages | Poor engraftment<br>Low addressing<br>High surgical risk | Complex<br>Expensive |
| Clinical studies | 6 (16.7%) | 0 (0.0%) |
| Preclinical studies | 1 (1.9%) | 4 (7.4%) |

### 16.3.4 Systemic Endovascular Administration of Stem Cell Therapy

Endovascular stem cell administration has been reported in more than five (9%) preclinical and six (17%) clinical studies [56] as depicted in Table 16.6. Intraarterial stem cell delivery has been conducted in one preclinical study (1.9%) and six (16.7%) clinical studies [56] as depicted in Table 16.6. Intravenous stem cell delivery has been conducted four (7.4%) preclinical studies [56] and no clinical studies were conducted till date as depicted in Table 16.6.

Kwon et al. [72] performed a single local injection of allogeneic BM-mesenchymal stem cells that potentially increased the wound healing strength in a rat Diabetic foot ulcers (DFU) model however no significant increase in wound strength was reported by multiple intravenous injections ($P = 0.06$). O'Loughlin et al., [70] in his preclinical studies topically administered stem cells with collagen scaffolds and fibrin spray in a rat Diabetic foot ulcers model, a significant correlation in wound healing was documented similarly Falanga et al., [73] performing preclinical studies delivered stem cells with collagen scaffolds and fibrin spray and reported improved wound healing. In all these three studies, there was a significant correlation in wound healing when at least $1 \times 10^6$ stem cells were delivered respectively. Intraarterial stem cell administration proved to be the effective route for immunomodulatory applications in rat kidney transplantation when compared to intravenous administration therefore the reducing the incidence of arteritis, glomerulitis, and tubulitis ($P < 0.01$) [74].

In case of murine diabetic model, multiple intravenous mesenchymal stem cell doses induced high impact on glucose homeostasis, thereby decreasing blood sugar levels after two doses and total remission of T2D within seven doses [75]. It has been reported that the bench-to-bedside approach is the aim of government policies in the globe with collaborations developing between Stem cell Research laboratories, biotechnology industries, pharmaceutical, academia, and clinicians. This bench-to-bedside approach is the focus of government policies throughout the globe with collaborations developing between Stem cell Research laboratories, pharmaceutical, and biotechnology industries, academia, and clinicians. Several research studies have established that mesenchymal Stem Cell therapy that can be utilized to translate technology to a variety of dermatological disorders. Mesenchymal stem cell therapy has increased the attractiveness for industrial investment for further research and development of these products. The most important characteristic for the successful utilization of mesenchymal stem cell treatments is the conducting of rapid and robust randomized controlled clinical trials. It is concluded that stem cell therapy is a potential, advanced, and effective treatment for Diabetic foot ulcers and is utilized as an alternative to amputation for T2D patients for revascularization. This therapy is utilizing tissue engineering as well as regenerative medicine.

# Alternative Medicine in the Management of Diabetic Foot Ulcers/Infections

17

M. Ahmed Mesaik, Hyder O. Mirghani, and Fakhralddin Elfakki

## 17.1 Introduction

Alternative medicine is nowadays a challenge for healthcare providers and its application remains like to "*separate the pearls from the mud*" [1]. The rising rate of diabetes globally, the search by the patients for better holistic medicine, and the doubt of some patients about the efficacy of current modern medicine made the fitness of the above statement more obvious day by day. We have to admit that segregating efficacious complementary alternative medicine (CAM) treatments from fake treatments will remain a challenging task, and the absence of properly planned and piloted efficacy trials for many treatments further complicates the problem [2]. Nonetheless, to achieve a better collaboration with patients, health care providers must consider the patients' wishes and likeliness in using CAM and provide truthful advice about CAM treatments to those patients. As well both the patient and the health care provider must be well aware of the limitations of the currently available treatments in alternative medicine.

## 17.2 What Is Alternative Medicine?

In the beginning, we need to define alternative medicine. In a broader term the complementary and alternative medicine (CAM), are functionally defined as treatments and healthcare practices that are not taught widely in medical schools and are not generally available in the US hospitals [3]. Whereas the National Center for Complementary and Alternative medicine (NCCAM) defines CAM as those healthcare and medical practices that are not currently an integral part of conventional medicine [4]. When describing these approaches, people often use "alternative" and "complementary" interchangeably whoever there are little bit differences in their mean as it is considered complementary when a nonmainstream practice is used *together with* conventional medicine, while considered as an alternative when a nonmainstream practice is used *replacing or in place of the* conventional medicine [5].

## 17.3 The CAM Included

The different branches of CAM include acupuncture, nutritional advice or lifestyle diets, massage therapy, herbal remedies, biofeedback, meditation, and imagery or relaxation techniques. Other treatments included in this definition of CAM were homeopathic treatment, spiritual healing or prayer, hypnosis, and traditional therapies such as Chinese, Ayurvedic, and Native American medicine. However, not all of them are useful in case of diabetes and the diabetic foot ulcer based on the literature available we are here listing the Alternative and Complementary Practices that are currently in use in case of the diabetic foot ulcer:

### 17.3.1 Massage

A review based on a meta-analysis that included 27 trials on pharmacological, nonpharmacological, and alternative treatments. Cakici and his co-workers reported *reflexology* and Thai *foot* massage to show beneficial results. They reported signs of progress in *diabetic* peripheral neuropathy symptoms linked with *reflexology* and Thai *foot* massage [6]. Another systematic review based on meta-analyses revealed traditional Chinese medicine *foot* bath while combined with Chinese acupoint massage is more effective for the treatment of DPN alone [7]. Other types of massage like the APIYU massage was proven effective for improving *foot* sensitivity and reducing blood glucose *among diabetic patients* [8]. While the addition of compressed air to the message was found to enhance *ulcer* healing which is thought to act by improving the local tissue oxygenation around the *ulcers* [9]. Additionally, the use of Ozone ($O_3$) therapy and quick application of the $O_3$ to an ulcerated foot are rising as new modalities for treating DFUs [10].

### 17.3.2 Ayurveda Medicine

Ayurveda medicine: Ayurveda is a traditional Indian system of medicine that is more than 3000 years old, consisting mostly of a specific diet, oily infusions, medicinal plants, and yoga. It is based on a naturopathic and anthropological belief in association with the Hinduistic religion. This type of medication has been practiced widely in India but so far it has only been insufficiently appreciated by western medicine, especially psychiatry. An exception is Scharfetter from Zürich who wrote a review article on this topic in 1976. Nevertheless, particularly the immunological mechanisms of psychotic and affective disorders can probably be influenced by the application of ayurvedic methods; however, the empirical data source, particularly concerning randomized controlled trials and meta-analyses regarding psychiatric disorder symptoms is limited. Even if Ayurveda is applied in a highly individualized manner, this should be rapidly improved for further evidential assessment. The first positive experiences in the neuropsychiatric field in Germany are already available.

*Use of Ayurveda medicine*: Bhandari et al. reported a case of Diabetic Foot Ulcers (DFU) in a 70 years of age patient with a repeated history of Ray's Amputation who was managed by an integrated approach Ayurveda and Allopathy medications and procedures. Several local plant materials have been used, after proper washing and cleaning of the ulcer. The plant used in their trials including Nyagrodha *Ficus benghalensis*, *Ficus glomerata*, *Ficus religiosa*, *Thespesia populnea*, *Ficus lacor*. Besides the use of special oil where Jasmine is the chief ingredient. This is in addition to maintaining the blood sugar level by the proper food, lifestyle, and medications [11].

The study involved 23 patients of diabetic wounds/ulcers who were treated with a local application of *Securinega leucopyrus* leaf paste with *Sesamum indicum* oil, whereas, in Group B, Betadine ointment was applied on the affected parts, once a day for 30 days. In Group A, diabetic wounds treated with Katupila paste got healed within 28 days with minimal scar formation without any complications, compared to Group B, the wound was healed completely only in two patients within 28 days. In both groups, no patients reported any adverse drug reaction during the entire course of treatment as well as in the follow-up period. The study concluded that the drug Katupila Kalka possesses a wound healing effect with very fine scaring [12]. In another study the local application of *S. leucopyrus* paste once every day resulted in restoration and healing within a month with normal pigmentation and a minimal scar. The case also informed for possible antimicrobial activity of the tested materials [13].

#### 17.3.2.1 *Katupila* Leaves

*Katupila* leaves have has been found to act as an antiseptic and its paste is used in folklore to extract any extraneous materials from body tissues without surgery [14]. The leaves and the bark are rich with a vast number of important phytochemicals

such as alkaloids, terpenoids, steroids, flavonoids, saponins, phenol, and glycosides [15]. The plant was used in the management of wound healing in different forms [16]. Previous clinical studies on this plant in oil form and Kalka (dry powder mixed with sesame oil) also showed encouraging results in the management of nonhealing wounds. The study concluded that *Katupila Kalka* leaves possess cleaning, healing, and depigmentation properties and has a wound healing property.

*Securinega leucopyrus* as a known herb for the treatment of diabetic foot care was formulated in another study in the name of *Thumari gel* for management nonhealing ulcers. In this case, the herb *S. leucopyrus* in the form of a gel applied to the wound and was found very effective in the healing of multiple superficial ulcers [17]. Other cases as well reported its healing potential in a mixer form with *Sesamum indicum* oil where ulcers fully healed within 4 weeks with minor pigmentation [18, 19]. The authors stated that the healing effect could be related to the increase in fibroblast activity, neovascularization, and collagen depositions.

#### 17.3.2.2 Curcumin

Studies evidenced the promotional effect of the natural polyphenol compound curcumin on neovascularization in wound healing of diabetes. Curcumin is known to target multiple signaling molecules. You et al. demonstrated the curative effects of curcumin on ischemic hindlimbs in diabetic mice as it promotes the function of endothelial progenitor cells (EPCs) in the ex-vivo assay. The curcumin application improved the blood reperfusion and increases the capillary density in ischemic hindlimbs. The in vitro studies prove the effect of curcumin on angiogenesis, migration, and proliferation abilities of EPCs. They proposed that curcumin could exert its effect via modulating the functions of EPCs and up-regulation in the VEGF-A and Ang-1 activity [20]. A case report of Brazilian type 2 diabetes mellitus patient, treated for 30 days with photodynamic therapy along with curcumin and blue light-emitting diodes (LEDs), where accelerated wound and complete ulcer healing was noted [21]. Another study conducted to evaluate the efficacy of curcumin nutritional supplements in animal studies. Authors noted the curcumin to exert the most remarkable healing activity beside the L-Arginine, or vitamin E supplements [22].

#### 17.3.2.3 *Commiphora molmol* (Myrrh)

"Jinchuang ointment" is a traditional Chinese herbal medicine complex for the treatment of incised wounds. For more than 10 years, it has been used at China Medical University Hospital (Taichung, Taiwan) for the treatment of diabetic foot Infections and decubitus ulcers. Three different cases are presented in this study. "Jinchuang" ointment is a mixture of natural product complexes from nine different components, the ingredients include myrrh beside dragon's blood, catechu, frankincense, and other different natural components. In vitro cell-based assay was used to test for the biological activities of the ointment the two assays were wound healing and tube formation assay results show that this herbal mixture holds strong activities including stimulation of angiogenesis, cell proliferation, and cell migration, which provides a scientific base for its clinically observed therapeutic effects on nonhealing diabetic wounds [23].

A herbal mixture containing myrrah was reported to modify gene expression markers in the wound in a rat model for type 1 Diabetes. The equal amounts of *Aloe vera*, Henna, *Adiantum capillus-Veneris*, and Myrrha, were mixed with Vaseline and applied as an ointment on wound-induced diabetic and nondiabetic rats. RNA was extracted from the healing region of the wound at different interval days [7, 14, 21] for cDNA extraction. Changes in Tgfb1, Mmp3, Mmp9, Il6, and Tnf α genes expression was monitored by the real-time PCR. The expression of the Mmp3, the Tnf α, and the Tgfb1 genes from wound tissue was significantly different ($p < 0.05$) between the two treated groups [24].

The use of CAM products in the topical treatment of diabetic foot disorders is very common among central Asian Muslim countries patients. Honey is regarded as the most preferable topical preparation alone or in combination with other natural remedies including black seeds and myrrh. The most commonly used CAM product for foot ulcers in Saudi Arabia was Honey (56.6%) followed by *Commiphora molmol* (Myrrh) in (37.4%) [25]. This point will be elaborated later in this chapter.

## 17.4 Acupuncture and Diabetic Foot, Reporting the Benefits

There is growing evidence that acupuncture is an appealing practice to the general practitioners in the clinical field worldwide especially in the last 25 years [26]. This is more clear in the result of a clinical trial evaluating the application of pestle needle on diabetic foot which reports a significant improvement of the sensory nerve function; besides, it reflects an obvious improvement of the patient-quality of life (QOL) especially patients with high-risk of diabetic foot [27].

Further trials using sham procedures confirms the effectiveness of acupuncture on relieving numbness, spontaneous pain, and alteration in temperature perception in the lower extremities, as well as rigidity in the upper extremities [28]. On the other hand, there is remarkable scientific evidence supporting the quality of reports from acupuncture trials that involve patients with diabetic peripheral neuropathy (DPN); factually, most of these clinical trials have shown noticeable recovery of the clinical symptoms of DPN using acupuncture. Similarly, a systematic review of clinical trials on the effect of electropuncture and diabetic painful neuropathy (DPN) has proven a positive effect and improvement of the DPN and Dpn, as well [29–33].

### 17.4.1 Acupoint and Appropriate Site for Needle Insertion

A systematic review about the appropriate selection of acupoint for acupuncture revealed that there is common and frequently used foot sites for conducting acupuncture in the treatment of diabetic gastroparesis (DGP); and hence, the compatibility laws for acupoint selection were mainly located in the upper-lower selection, three selection, three regions selection, local selection, and anterior-posterior selection. Further additional study supporting the effectiveness of using both Governor vessel acupoint and local meridian acupoint simultaneously for the greater effect of acupuncture [34, 35].

### 17.4.2 Herbal Medicine, Placental Extract, and Low Laser Therapy Use on Acupoint

A randomized clinical trial assessing the effect of Chinese Herbal Medicine (CHM) and Tangzhuang Ointment (TYO) for chronic diabetic foot ulcer (DFU) discloses a potential safety and efficacy as well as double healing rate in comparison to the conventional therapy [27, 36, 37]. Unique trials revealed a significant acceleration and regulation of the wound healing process after the application of hominis placenta (HP) and placental extract at the acupuncture points in the middle region of the upper and lower wounds [38–40]. Although it is not yet clinically approved, results from a systematic review revealed that low-level laser therapy has a significant beneficial effect on the treatment of diabetic foot ulcers [41].

### 17.4.3 The Adverse Effect of Using Acupuncture

Despite a considerable number of published reports on the adverse effect related to acupuncturing techniques in the Chinese literature; however, according to a case study report, most of these unsuccessful clinical experiences are related to lack of cleanliness and sterility before the application of acupuncture on diabetic foot [42, 43].

## 17.5 Use of Maggot Debridement Therapy

Maggot debridement therapy (MDT) had a significantly positive effect on wound healing when compared to conventional therapies. It does not only shorten the healing period but also enhanced the healing level of chronic ulcers. Therefore, it could be used as an alternative in the treatment of chronic ulcers. It is assumed that these maggots fighting wound infection as the larvae ingest resident bacteria and kill them [44, 45]. Other proposed mechanisms include moistening of the wound by increased exudate, the production stimulated by the larvae ingesting necrotic tissues, or dilution of the wound discharge by the maggots' secretions [46]. currently, doctors consider the use of MDT to be the last option when orthodox treatments failed [47].

## 17.6 Regenerative Therapy, and the Adipose-Derived Stem Cells (ADSCs)

One therapeutic strategy that rises recently as promising regenerative therapy of chronic diabetic wounds utilizes adipose-derived stem cells (ADSCs). ADSCs can differentiate into multiple cell lineages and are considered an alternative to bone marrow-derived mesenchymal stem cells. They can be easily drawn from the adipose tissue and are expandable in a cell culture system. The studies displayed ADSCs to enhance diabetic wound healing through increasing epithelialization and

granulation tissue formation, anti-inflammatory and anti-apoptotic effects, and release of several cytokines needed for the regeneration. Some clinical trials showed that ADSCs treatment in patients with diabetic ulcers caused enhanced ulcer evolution, lower pain scores, and improved claudication walking distances with no reported complications. ADSCs have a promising potential in the regenerative therapy of chronic diabetic wounds. Further studies are required to confirm their efficacy and they are in vivo long-term safety [48]. Furthermore, Dong et al. examined an injectable poly(ethylene glycol) (PEG)-gelatin-based hydrogel system for creating a functional stem cell niche for the transfer of adipose-derived stem cells (ASCs) into diabetic wounds and for effective delivery and engraftment of the stem cells. Significant in vivo improvement in stem cell retention was reached. The decrease in inflammatory cell infiltration enhances neovascularization and remarkably accelerates wound closure in diabetic mice were observed, suggesting a promising potential for the treatment of chronic diabetic wounds [49].

## 17.7 Honey and Diabetic Septic Foot

Diabetic septic foot remained to be a serious problem despite the advances in the field of antimicrobial therapy. Nearly a quarter of patients with diabetes mellitus had a lifetime risk of developing foot complications. The diabetic septic foot may constitute up to 80% of lower limb amputations. Although the majority of diabetic ulcers involve the toes. However, lower limb amputation is unavoidable if the proper treatment is not provided in due time. Wound healing is complex, so treating wound infections is intensive, and costly. Diabetic foot ulcers precede amputation in 85% limiting physical and social activity and leading to poor quality of life. Due to the emerging of antibiotic-resistant pathogens, attention has been directed to natural products for clinical practice. For these reasons, many forms of therapies have been adopted including topical honey [25, 50].

Honey as a remedy of wound care backdated to ancient times. There are many types of honey [51]. The product may be used alone or in combination with other forms of complementary alternative medicine including herbs and other natural products. It is interesting to note that patients with diabetes may use honey for the treatment of diabetes foot with or without clinical consultation because they thought that it is not important to discuss with the attending physicians [52]. Diabetic foot ulcers are difficult to treat due to poor wound healing of patients with diabetes, chronic inflammation, and colonization of resistant organisms. Honey (ordinary or Manuka) exhibits antibacterial activity mainly due to its osmotic effects leading to bacterial dehydration, also, the acidic nature of honey inhibits bacteria, moreover, methylglyoxal (MGO, one of the phytochemical factors) and other ingredients with antibacterial activity had been identified within honey. The mechanism of the antibacterial of honey is not fully understood, but interruption of cell division, cell lysis, and abnormal protein regulation were observed [50]. The action of Manuka honey on bacteria is high only after 24 h because MGO is low in fresh honey, the concentration of this important ingredient increases when stored

at 37 °C [53]. Antioxidants and other ingredients found in Honey act synergistically to reduce both acute and chronic inflammation, also honey activates proinflammatory cytokines and the anti-inflammatory (TNF-α and IL-1β cytokine IL-6, respectively). Importantly, the heat treatment of honey negatively affects the anti-inflammatory actions of honey. Thus supermarket honey is not as effective as a treatment remedy for ulcers [54–56]. When comparing Manuka honey with silver dressing, there is no strong evidence of the superiority of one over the other compound in dressing [50]. A case report showed that honey was effective for an ulcer with tendon exposure [57]. Mohamed et al. [58] reported the treatment of diabetic foot ulcers with commercial honey, offloading, and debridement. A case series (eight diabetic feet ulcers, followed for 3 months) showed that Royal may be an effective dressing measure [59]. A prospective pilot study [60] examined patients with Wagner grade 1–111, and gangrenous ulcers (96 patents, followed for 6 months). The investigators used an ointment containing Royal jelly and panthenol, surgical treatment and saline dressings were applied, but no other specific treatment was given. The research concludes the safety of their ointment and they recommended double-blind randomized controlled trials. A prospective study from Makkah, Saudi Arabia [61] used local honey as a thick layer for dressing the complicated diabetic ulcers (172 patients, followed for 15 months). The authors stated that honey significantly reduced the rate of amputation and improve wound healing. A randomized controlled trial [62] published in the year 2008 (Newcastle Ottawa quality assessment = 7) showed that honey dressing is as effective as povidone-iodine, the study assessed Wagner grade-II ulcers foot ulcers among patients with type 2 diabetes mellitus and followed till healing.

A double-blind placebo-controlled clinical trial [63] included 25 patients with 64 diabetic foot ulcers and followed for 3 months. Offloading, infection control, debridement, and vascular surgery were applied when indicated. The authors found no superiority of topical Royal Jelly over placebo. A randomized controlled trial with a reasonable number (348) and followed for a maximum of 120 days, assessed Beri-honey-impregnated dressing compared to normal saline dressing. The authors showed that honey is more effective in diabetic ulcer healing [64]. A pilot open-labeled randomized controlled trial (31 patients followed for 12 weeks) observed the superiority of Nanocrystalline silver over Manuka honey in terms of ulcer size reduction rate [65]. Eddy et al. [66] reviewed the literature in the year 2008 and stated that honey as a topical therapy for DFUs is cost-effective. However, risks and benefits need to be weighed. A systematic review of five randomized trials and observational studies [67] conducted in the year 2016 showed that honey is safer, however, efficacy cannot be concluded due to quality issues. Zhang et al. [68] conducted a network analysis including 21 randomized control trial and 2159 patients and compared nine dressing including honey, the authors concluded that amniotic membrane and hydrogel dressings are preferred for healing diabetic foot ulcers with no differences between the others including honey.

Because there are many types of honey (e.g., Manuka, Sidr honey, and *Nigella sativa* honey) with various subtypes [51]. Furthermore, honey activity may be dependent on the weather conditions where the bees were raised, grazing grounds,

and the natural structure of the blossom nectar. Also, the medical and surgical treatment applied together with topical honed may differ. Thus it is difficult to conclude its effect. The reviewed RCTs showed conflicting results (some showed no superiority over placebo, others showed topical honey is superior to saline dressing), similar to povidone-iodine and inferior to Nanocrystalline and amniotic membrane dressing.

# Modern Phytomedicine in Treating Diabetic Foot Ulcer: Progress and Opportunities

18

Mohamed Ali Seyed and Siddiqua Ayesha

## 18.1 Introduction

Diabetes mellitus is a severe chronic metabolic disorder observed with hyperglycemic conditions [1], substantially related to morbidity and mortality worldwide and affects health care spending of various countries [2, 3]. There are two commonly categorized types of DM, which are Type 1 (T1DM) (diminished production of insulin) and Type 2 (T2DM) (impaired response to insulin and β-cell dysfunction). Both lead to conditions like hyperglycemia, excessive urine production, compensatory thirst, increased fluid intake, blurred vision, unexplained weight loss, lethargy, and changes in energy metabolism. T2DM very well characterized by increased blood glucose and impaired insulin secretion and its action [3, 4] and constitutes about 90% of the people with diabetes. Physiologically, a drop in the blood glucose level results in decreases in the release of insulin and an increase in glucagon. Previous studies have identified three significant defects associated with the onset of T2DM like increased hepatic glucose production, diminished insulin secretion, and impaired insulin action [5, 6].

## 18.2 Epidemiology of T2DM

The incidence of diabetes is rapidly increasing worldwide at an alarming rate [7] and its occurrence was increased gradually since the year 1995 from 4% to 5.4% or more by the year 2025 [8] and by 2040 it is predicted to surge over 642 million. The World Health Organization (WHO) continuously cautioned that it would affect

https://doi.org/10.1007/978-981-15-7639-3_18

mostly the developing countries. The organization also estimates that the disorder affects nearly 51–72 million people, which is approximately 42% prevalence increase in the developed nations, however, in the developing countries it goes from 84 to 228 million (170% increase) [8–10]. The International Diabetes Federation (IDF) also estimates the total number of T2DM diabetic subjects to be around 40.9 million in developing countries like China, India, Malaysia, and Saudi Arabia this is further set to rise to 69.9 million by the year 2025 [11, 12]. The vast majority of affected patients in the developing countries are between the age of 45–64 years, while it is >65 years for developed countries [10].

For the past few decades, the diabetes status paradigm from being described as a mild disorder of the aged people to affect now young and middle-aged population of both genders to morbidity and mortality among them. Because of this alarming prevalence of this disorder, it is naturally gaining much in almost all six human-occupied continents of the world [13]. The prevalence of T2DM not only influences the quality of life but also affects vital organs such as the brain, heart, and kidney. Such a problem is seen even more frequently when T2DM is accompanied by hypertension and dyslipidemia and both are known to influence small artery structure and function [14, 15]. In line with this, T2DM patients' small arteries have also shown an enlarged media thickness to lumen diameter ratio compared with normal subjects [16].

## 18.3 Screening and Diagnosis of T2DM

The obese condition and family history are the two most prominent established risk factors for T2DM, in which the family history predisposes individuals to develop T2DM [17]. Besides the above, unhealthy eating habits, sedentary lifestyle and old age are other risk factors involve in the development of T2DM. Besides the above, high blood pressure elevated cholesterol level, and peripheral insulin resistance are also other factors which caused either by receptor defect or by a post-receptor defect with an insulin-secreting defect [18].

### 18.3.1 Endothelial Dysfunction Induced by T2DM

Diabetic patients are prone to impair endothelial function, which is an early sign of pro-atherogenic vascular abnormality [19]. Impaired endothelial function is one of the well characterized by a change in endothelium toward reduced vasodilatation and a pro-inflammatory state, which is very much associated with cardiovascular diseases including hypertension, coronary artery, chronic heart failure, peripheral artery disease, diabetes, and chronic renal failure [20]. Various mechanisms involved in the endothelial dysfunction which include reduced vasodilatation, reduced NO generation, oxidative excess, and reduced production of hyperpolarizing factor [21]. Decreased insulin sensitivity leads to the induction of two major pathways emerging from the insulin receptors. The first pathway is phosphoinositide 3-kinase,

phosphoinositide-dependent kinase-1, and Akt/protein kinase B leading to marked depression of eNOS. The second pathway is nitrogen activated protein kinase leading to mitogenic effects [22, 23].

Besides the above, hyperglycemic conditions lead to the formation of advanced glycation end-products (AGE), as they play a role to quench nitric oxide (NO) and impair endothelial function [24]. To support this fact, the acute hyperglycemic condition diminishes endothelium-dependent vasodilation in humans in vivo [25]. Hyperlipidemia, specifically hypertriglyceridemia conditions along with low serum high-density lipoprotein (HDL) cholesterol concentration is associated with insulin resistance common in patients with T2DM [26].

### 18.3.2 Pathophysiology and Complications

The quality of life and characteristic features of T2DM in adult and elderly patients commonly measured by the appearance of symptoms like tiredness, lethargy, and related decreased work performance and fall [27]. Insulin resistance in insulin target cells mainly the liver, skeletal muscle, and adipocytes are considered as an initial characteristic feature among T2DM patients, whereas the following features like increased stimulation and secretion of insulin followed by a gradually diminished function of islet beta-cell reserve demonstrated in chronic condition. Eventually, a complete insulin deficiency state resulted in clinical diabetes [28–30].

It is well demonstrated that T2DM is also associated with numerous microvascular and macrovascular complications [13], where the progressive pathophysiology of T2DM is characterized by declined insulin sensitivity because of decreasing β cell function [31] and decrease of incretin function [32]. Decreased insulin function leads to chronic hyperglycemia and acute glycemic variations that lead to excessive protein glycation and induce oxidative stress [33]. To compensate for the above, Incretin, a group of gastrointestinal hormones that stimulate β-cells and increases the insulin secretion. The long-term complications are macrovascular complications (hypertension, dyslipidemia, myocardial infarction, stroke, etc.), microvascular complications such as diarrhea, diabetic neuropathy, nephropathy, retinopathy, neurogenic disorder, sexual dysfunction, impaired cardiovascular reflexes, and diabetic foot ulcer [27].

### 18.3.3 Microvascular Complications (MVC)

Diabetic retinopathy (DR) is an MVC, which plays a major in the cause of visual disability and blindness in people with diabetes [34]. Its severity ranges from non-proliferative and pre-proliferative to more severely proliferative DR in which the abnormal growth of new vessels occurs [35]. The prevalence of DR increases with prolonged duration of diabetes [36]. People with DR showed association with younger age onset, tobacco use, insulin treatment, abnormal blood lipid levels, renal disease, elevated homocysteine levels, and a diet high in fat [37–39]. Poor

glycemic control is also responsible for DR [40, 41]. The other microvascular alterations associated with DR such as capillary basement membrane thickening, increased permeability of endothelial cells, and formation of microaneurysms, etc. [42, 43].

### 18.3.4 Diabetic Neuropathy

It is evident that nearly one-half of the diabetic population has a certain form of peripheral neuropathy (PN) [44]. People with diabetes have frequently autonomic neuropathy, including cardiovascular autonomic dysfunction manifested as abnormal heart rate and vascular control [45]. Poor glycemic control, age, duration of diabetes, tobacco use dyslipidemia, and hypertension are responsible for peripheral neuropathy [46]. Hyperglycemia impairs neuronal microvasculature, which is mediated through the abnormal initiation of signaling cascades [47]. However, most of the diagnostic techniques failed to define diabetes-related cardiac autonomic neuropathy. The clinical abnormalities like resting tachycardia, exercise intolerance, resting heart rate variability, slow heart rate, silent myocardial infarction, and increased risk of mortality [48, 49]. Poor maintenance of blood glucose, age, obesity, hypertension, and smoking are the major factors responsible for Cardiac neuropathy among diabetic patients [50].

### 18.3.5 Diabetic Nephropathy (DN)

Diabetic nephropathy is a serious condition frequently manifested in both T1DM and T2DM patients. Microalbuminuria progresses and terminated in renal failure [51] among diabetic patients. It is presumed that nearly one-fourth T2DM patients express microalbuminuria. Other characteristic features of Diabetic nephropathy are a thickening of glomerular hyperfiltration ultimately leading to glomerular and tubular sclerosis and renal failure [52, 53]. Besides the above, the following such as hyperglycemia, dyslipidemia, and hypertension are also other major causes of diabetic nephropathy.

### 18.3.6 Macrovascular Complications of Diabetes

Nearly 80% of T2DM patients will develop or die of macrovascular disease [54]. The importance of preventing the macrovascular complications of T2DM has started to receive greater attention. To support this, previous studies have established the encouraging impact of treatments of hypertension on diabetic individuals [34]. The following conditions such as peripheral vascular disease (PVD), coronary artery disease (CAD), and cerebrovascular events (CVA) are termed as macrovascular complications [55]. Although, DM was considered an independent risk factor for the development of atherosclerosis, which in turn responsible for a record number

of deaths in patients with T2DM, which accounts for more than 50% of macrovascular complications. Besides the above, the growing population is another major coronary risk factor identified for the CAD epidemic in numerous developing Asian countries including China and India.

Many studies have demonstrated that parallel to the increase in coronary heart disease (CHD) in these countries especially urban and semi-urban areas there has been a tremendous incidence of diabetic-related hypertension, high LDL cholesterol, low HDL cholesterol, and the other metabolic syndrome prevalence [54–56]. Death occurrence among diabetic patients with CAD is greater when compared to their nondiabetic counterparts. Studies have further established the correlation that myocardial infarction in diabetics was more common among diabetic patients with CAD than normal controls [57, 58]. It is interesting to note that diabetics have a fivefold more risk for first MI and a twofold more risk for a recurrent MI than people who previously had an MI but no evidence of hyperglycemia. Diabetic explosions witnessing countries like India and China appear to be more prone to both diabetes and CAD compared to other developing countries [59]. PVD normally defined as a syndrome of the blood vessel, which is not part of the heart or brain. The most common type of PVD, normally detected in lower extremity also called the lower extremity arterial disease (LEAD). Recent evidence suggests that elevated serum triglyceride and dyslipidemia, hypertension, etc. are responsible for 80% of diabetic death worldwide [60].

### 18.3.7 Cerebrovascular Disease

DM considered one of the well-established risk factors for stroke. The risk is up to two- to fourfold greater in diabetes cases [61]. Diabetic patients, who experienced stroke have more severe neurological lesions and disability [62–65]. Besides the above, other traditional risk factors such as hypertension, dyslipidemia, heart failure, and atrial fibrillation [66] and their increased incidence also contribute to stroke. Hyperglycemia is a potent predictor of fatal and non-fatal stroke [67]. Diabetic retinopathy, proteinuria, microalbuminuria, increased inflammatory markers, and hyperuricemia are other factors contributing to the risk of stroke [67, 68] in people with diabetes.

### 18.3.8 Peripheral Artery Disease

Peripheral artery disease (PAD), characterized by occlusion of the lower extremity arteries responsible for pain [69] and which result in functional impairments [70] and disability. Diabetics have more chance (15 times) of developing lower extremity amputations when compare to their normal counterparts [71]. In addition, PAD always correlated with the length and severity of the patient's diabetic condition [72, 73]. Hyperglycemia particularly glycation hemoglobin has been shown to be an independent risk factor for PAD [74].

The simplest test available in the clinic to screen PVD is palpitation of peripheral pulses and this is the usual clinical tool to assess the occlusive arteries in peripheries. Although the absence of peripheral, tibial, popliteal, or femoral pulses on peripheral examination are clinically significant [74], one cannot rule out the possibility of using traditional standard techniques such as angiography, color duplex ultrasound, and continuous waveform Doppler [75] for diagnosis of PVD. Hypertension is the primary avertable cause of the two major causes of mortality: coronary artery disease (CAD), and cerebrovascular disease (CVD). Hypertension increases the twofold risk for CAD and sevenfold for CVD and congestive heart attack by fourfold. In addition, studies have also shown that an increase in blood pressure of 5 mmHg is associated with risk for CVD (by 34% increase) and CAD (21%) [76].

## 18.4 Inflammation Is Associated with Insulin Resistance

Compelling evidence linking inflammation to insulin resistance derives from both epidemiological studies and experimental data in humans and animal models [77, 78]. In a cross-sectional study with the inclusion of 70 healthy individuals aged between 21 and 94 years old showed that with advancing age there was a positive correlation of plasma concentrations of tumor necrosis factor-alpha [79] but shown a negative correlation with whole-body glucose disposal. To support this, in 439 nondiabetic women followed in the Women's Health Study, fasting insulin was strongly correlated with plasma acute-phase reactant C-reactive protein (CRP), with a smaller yet again nonsignificant trend for the pro-inflammatory cytokine, interleukin-6 (IL-6) [77]. In addition, in an analysis of 1008 nondiabetic men and women, a strong association was identified between plasma CRP concentration and insulin sensitivity [80]. Furthermore, a linear rise in CRP levels was noted with T2DM is associated with an augmented risk of cognitive impairment among older T2DM patients with rapid age-related cognitive decline, and a higher incidence of dementia. Although the specific causative factors responsible for cognitive impairment in T2DM are yet to be identified, it is most likely multifactorial one. Inflammatory mediators may, therefore, have a role in the accelerated development of cognitive impairment in people with diabetes either by a direct effect on the brain or through an influence on the development of vascular disease [81].

## 18.5 Diabetic Foot Ulcer (DFU)

DFU often called a disease of the lower limb or foot ulceration. It often considered as one of the most severe peripheral arterial diseases (PAD), often resulted in amputation because of the combined complications of neuropathy and infection, normally DFU often ignored by patients. However, risks related to this microvascular condition can be taken care of significantly by optimizing glycemic control by early screening/detection and intervention [82].

Diabetic foot infection (DFI) commonly described as the infection caused by various microbial pathogens associated with a tissue injury [83] due to competitive metabolism, toxins, intracellular replication, or antigen–antibody response [84]. Multiple pathogenic microorganisms cause the DFI in DM patients to become very inflamed followed by soreness with delayed wound healing. The causative microorganisms include aerobic bacteria likes *S. aureus*, *S. pyrogens*, *P. aeruginosa*, *P. mirabilis*, *E. coli*, *K. pneumoniae*. Anaerobic bacteria are *C. perfringens*, *B. fragilis*, and yeast such as *C. Albicans* [85].

DFU is one of the most significant and disturbing problems with substantial socioeconomic impact [86]. The occurrence of foot ulceration witnessed worldwide between 4% and 10% of patients; however, the condition is more prevalent among older patients [87, 88] in the developing countries. Infections in DFU patients are difficult to treat because these infected patients have weakness in microvascular circulation, which limits the access of phagocytic engulfing cells to the infected area and results in a poor concentration of antibiotics in the infected tissues [89].

To support the above fact, nearly 85% of all amputations performed in diabetic elderly patients only [90]. Previous studies have estimated that 5% of all patients with diabetes present with DFU history, however, high risks patients who may develop complications of foot ulceration are still existed about 15% [87, 88]. Although neuropathic origins are the most probable causes for foot ulceration, these causes are greatly preventable among T2DM patients especially in the high incident countries in the next 20 years. Would the healing process takes a short time (about 20 weeks) and curable for the neuropathic origin of diabetic patients, whereas neuro-ischemic ulcers take longer and will more often lead to limb amputation [91].

### 18.5.1 Pathophysiology and Complications of DFU

The important driven factors responsible for the increase in the ailment of DM are vascular problems as well as the delay and failure in the execution of the wound healing phases [92, 93]. Microbial infection often follows diabetic foot ulceration due to vascular complications like insufficiency in oxygen supply, neovascularization, and reduced leukocyte function. It is well characterized that DFU infections are listed as simple cellulitis to more complex chronic osteomyelitis, which is frequently witnessed with hospital admittance and rise in pathogenic microbial infections, which finally lead to the extremity in foot amputation [92–94]. In diabetes patients, mild, moderate, and severe foot infections are all considered serious because of various contributing factors like an open wound, patient's immune deficiency may rapidly extent the infection into the subcutaneous tissue and deeper structures [95]. Impaired microvascular circulation characteristic of diabetes limits transport of phagocytic cells and antibiotics to the infected area, predisposing diabetic patients to more recurrent and potentiate the foot lesions more vulnerable that are more difficult to treat. As a result, it requires careful wound management with surgery [96], topical applications [93] of cream, or suitable medications to correct metabolic defects or intravenous antibiotics [97, 98].

In general, the wound is termed as a disruption in the cellular, anatomical, and functional epithelial continuity of the skin consequent to physical, chemical, thermal microbial, or immunological insult; in other words, it is a disrupted state of the tissue, caused either by physical, chemical, microbial, or immunological insults to normal tissue [99]. According to the current wound forecast, indicate that nearly 6.5 million people suffer from normal chronic wounds worldwide [100, 101].

### 18.5.2 Processes Involved in Wound Healing

Previous studies have demonstrated that aberrations in the connective tissue, which contribute to the delay or improper wound healing process leading to the formation of DFU specifically the chronic ulcer [102]. Briefly, in all types of wounds, the following four well-coordinated but overlapping phases are involved in the wound healing process, which is hemostasis, inflammation, proliferation, and tissue remodeling or resolution [103–105]. The tissue repair requires the coordination of different cells, growth factors, and cytokines [106]. It begins with the first phase of hemostasis immediately after injury, with vascular constriction and fibrin clot formation, this results in the release of various pro-inflammatory cytokines and growth factors like fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), transforming growth factor (TGF)-β and epidermal growth factor (EGF) [107]. Once the first phase control bleeding and clot formation, then various leukocytes and immune cells like neutrophils, macrophages, lymphocytes sequentially infiltrate and migrate to the affected site by chemotaxis mechanism, followed by the establishment of molecular interactions between them and promote the inflammatory phase [108]. Although these leukocytes and immune cells produce proteases and various reactive oxygen species (ROS), which cause some additional bystander damage [109], however, a significant function of neutrophils in the clearance of invading microbes and cellular debris in the wound or affected site [105, 110]. Besides the above, many studies have established that wound healing processes are influenced or affected by various other factors like infections, nutritional status, medications and hormones, type and sites of wound, and chronic diseases like diabetes [105, 110, 111].

With regard to uncontrolled diabetes, improper wound healing in patients may possibly lead to diabetic foot ulcers or into amputation, especially in poor resource settings. Due to limited awareness and the poor aseptic healthcare condition in wound infection is still a paramount challenging problem faced by developing countries [112]. Besides the above, wound infection is very common in most developing countries because of poor hygienic conditions [113, 114].

Although the precise pathogenesis of poor wound healing in diabetic wounds not adequately understood so far. However, the mechanisms responsible for the delay in wound healing in diabetic patients have been well established [115, 116]. To support the above, many in vivo and clinical investigations have supported the delay in the synthesis of collagen, reduced angiogenesis, and impairment epithelial formation during the proliferative phase [117–120]. Besides the above, other factors

implicated in the delayed healing process such as reduced production of necessary growth factors like VEGF, delayed or compromised inflammatory response, reduction in nitric oxide synthase (NOS) activity and excessive protease enzyme activity [121, 122] demonstrated in different phases of the wound healing process [123–127] are yet to be elucidated in detail. Moreover, no approved growth factor and cell therapies are available to treat diabetic foot ulcers or diabetic-related other types of wounds.

## 18.6 The Role of Medicinal Plants for the Treatment of DM and Wound Healing in DFU

It is well-known that the potential attributes of herbal plants as therapeutics for numerous diseases, which are proven by their mechanism of action practically in all major system of medicine [128]. Impairment in diabetic wound healing is seen as a very severe health problem universally by the health experts despite its association with nonspecific etiology in some cases. Hence, it is essential to consider the value of traditional phytomedicine as one of the right approaches for treatment particularly in poor resource settings [124]. The bioactive principles from various herbal plants contribute their vital role in wound management and care as disinfectants, debridement, and the provision of adequate environment for the natural healing process [129]. The World Health Organization (WHO) has encouraged the use of medicinal plants for the treatment of diabetes and has also recommended for the more verifiable scientific evaluation of the hypoglycemic activities of various plant species [130].

Traditionally most of the Asian and African tropical countries are considered as a reservoir of medicinal plants by employing common knowledge and practice to treat various ailments such as ulcers, boils, sores, and wounds including diabetes [110, 131, 132]. Nearly 10–15% of known 300,000 species of higher plant worldwide have a history of their use for various diseases in the traditional medicine practice [131, 133]. In this regard, many studies have established the beneficial attributes of several species of medicinal plants for therapeutic development considering their availability and low risk nature. In recent years, several plants and their bioactive principles have shown their efficacy in the treatment of T2DM and its complications. Although numerous ethnobotanical reports provide lists of medicinal plants like *Syzygium cumini*, *Momordica charantia*, *Gymnema sylvestre*, *Tinospora cordifolia*, *Ocimum tenuiflorum*, *Allium sativum* L. (Rason)/*Allium cepa* (Onion), *Catharanthus roseus* (Madagascar Periwinkle), and *Pterocarpus marsupium* (Indian Kino) [134, 135] exhibited antidiabetic activities. In addition, a growing number of additional plants like *Aegle marmelos*, *Pterocarpus marsupium, Azadirachta indica*, *Asteracantha longifolia*, *Trigonella foenum-graecum* (Fenugreek), *Achyranthes aspera*, *Swertia chirayita* also proven their antidiabetic efficacy. Recently, curcuma longa also gained interest in the metabolic disorder [136], yet the search for additional potential medicinal plants and plant-derived novel drug leads are being explored continuously using advanced techniques for new therapeutic development.

It is evident that applications of herbal derived phytocompounds/bioactive principles have been in use for many decades both by traditional medicine practitioners [137, 138] as well as in the modern system of medicine [137] as therapeutic agents [139]. These compounds have encouraged researchers and pharmaceutical firms to examine the role of medicinal plants to assess their potential wound healing properties and isolate individual chemical entities associated with wound healing. The blood glucose-lowering capacity of some herbal plant extracts has been confirmed in human and animal models of T2DM along with few well-established conventional drugs, which are derivatives of these medicinal plants. An example of that type of therapeutic compound is metformin, a derivative of *Galega officinalis* [140].

Wound healing of DFU is a long awaiting development in health care systems [141]. Even after accomplished wound healing, re-ulcerations occur frequently and commonly lead to minor or major amputation of lower extremities [142]. To treat diabetic foot ulceration, traditional medicine practitioners have employed various practices including medicinal plant applications because of their abilities to promote wound healing and to prevent infection without causing severe side effects [143]. This continued practice and the advent of new efficacious plant-derived traditional medicines have prompted renewed interests in recent years because herbal treatment may be an alternative approach for the treatment of wounds.

The importance of herbal derived bioactive principles and their efficacy against various diseases have drawn global attention as safer alternatives in the management of various infections including diabetic wounds [144]. However, still many anti-diabetic herbal plants not explored in detail, which might provide useful sources for the development of newer drugs or drug leads for T2DM [145]. The available literature on medicinal plants with blood sugar lowering ability is vast with various claims. The purpose of this chapter to highlight and discuss the wound healing efficacy of few prominent medicinal plants and their biologically active substances used to treat diabetes as well as their cellular targets and mechanism of action, this will aid for the better management of diabetic wounds and related microbial infections [144].

Currently, the metformin is the only clinically approved natural antidiabetic drug offered for the treatment of diabetes [140]. This book chapter review aims to outline and discuss the current DM and DFU management approaches with the incorporation of medicinal plants for the prevention as well as for the treatment. Since it is very difficult to comprise all plants and their therapeutic claims with demonstrable evidence in a single book chapter, hence, we have chosen only selected commonly used antidiabetic plants for the benefit of readers.

### 18.6.1 *Gymnema sylvestre* (Gs)

***Gymnema sylvestre* (Gs)** (Fig. 18.1) is a medicinal plant belongs to the family of Asclepiadaceae. Various tropical countries like India, Africa, and Australia uses this herb traditionally for various purposes [146, 147]. Its efficacy indicated that it possesses not only blood sugar-controlling/antidiabetic properties but also shown

**Fig. 18.1** *Gymnema sylvestre* (Gs)

certain benefits like improving urination and stomach ulceration [148–151]. Recent studies have shown that Gymnemic acid molecules, which are a group of triterpenoid saponins [147, 152], alkaloids, acidic glycosides, and anthraquinones [153] responsible for antidiabetic action. Besides the above, the hyperglycemia-induced conditions like rising in urea, uric acid, and creatinine together with decreased glomerular filtration rate were substantially inhibited in the Gs extract treated in diabetic rats [150]. In a clinical study subjected with 22 T2DM patients were given 400 mg Gs extract daily along with their oral hypoglycemic drugs. The study results have shown that almost all patients treated with extract have revealed decreased blood sugar. Nearly 95% of patients (21/22) were able to stop their oral medication and maintain blood sugar control with the Gs extract alone [154]. In addition, another study was postulated that Gs enhance the production of endogenous insulin [155].

### 18.6.2 *Aegle marmelos*

***Aegle marmelos*** (Fig. 18.2), commonly known as Bael, a plant of Indian continental origin belongs to family Rutaceae [156]. The following bioactive principles such as mucilage, pectin, volatile oil isolated from Bael leaves have demonstrated an excellent antidiabetic property and significantly demonstrated antioxidant activity [157]. In addition, both fruit and root extract showed anti-amoebic and hypoglycemic activities [156]. This plant also exhibited various pharmacological activities by bioactive principles extracted from the root and fruits like alkaloids like aegeline and marmelline, steroids, essential oils, and coumarins such as scoparone, scopoletin, umbelliferone, marmesin, and skimming [158]. Besides the above, xanthotoxol, imperatorin, and alloimperatorin also added in the list. It also contains polysaccharides like galactose, arabinose, uronic acid, and L-rhamnose, which may obtain after hydrolysis. Apart from the above chemical constituents, more than 100 new

**Fig. 18.2** *Aegle marmelos*

**Fig. 18.3** *Pterocarpus marsupium*

compounds have been isolated, the following such as psoralen, marmelide, fagarine, cuminaldehyde, eugenol, marmesinin, marmelosine, luvangetin, auraptene, skimminine, aegelin, lupeol, cineole, citral, citronellal, and tennins have exhibited spectrum of actions against many diseases [159–161].

### 18.6.3 *Pterocarpus marsupium*

***Pterocarpus marsupium*** (Fig. 18.3) belongs to the family Leguminosae and predominantly grows in most parts of India and Sri Lanka. Previous studies [162, 163] have established that *P. marsupium* as a promising herbal plant because of its

antidiabetic efficacy. This plant extract contains various potential phytocompounds. In line with this, the antidiabetic activity of various fractions from the bark was evaluated on lipid profile, blood glucose level, etc. [164, 165]. In addition, an aqueous extract of wood exhibited hypoglycemic activity [166]. The other potentially bioactive compounds are diarylpropane derivative, propterol; stilbene, pterostilbene; hydrochalone, pterosupin; benzofuranone, marsupsin, and polyphenolic compounds exhibit various other pharmacological activities.

## 18.7 Antidiabetic/Antihyperglycemic/Hypoglycemic Activity

Previous studies [164, 165] have demonstrated that the alcoholic extract of the bark of *P. marsupium* has shown beneficial effects on blood glucose-lowering ability. To support further, an aqueous extract of *P. marsupium* wood and bark was assessed for the antihyperglycemic and hypoglycemic effect in normal and alloxanized diabetic rats [166, 167]. These studies showed that the aqueous extract exhibited a slight but important hypoglycemic effect in normal rats and a significant and clear dose-dependent antihyperglycemic effect evaluated the antihyperglycemic activity of phenolics from *P. marsupium*. The phytocompounds like marsupsin and pterostilbene, which significantly decrease the blood glucose level of hyperglycemic rats [162, 168].

### 18.7.1 *Momordica charantia* (Karela)

*Momordica charantia* (*M. charantia*) (Fig. 18.4), also known as bitter melon found throughout India belongs to family Cucurbitaceae [169]. The whole plant, especially the seeds and fruit, has significant pharmacological effects namely, abortifacient, anthelmintic, contraceptive, antimalarial, laxative, dysmenorrhea, eczema, gout, jaundice, leprosy, piles, pneumonia, psoriasis, rheumatism, and scabies [170,

**Fig. 18.4** *Momordica charantia*

171]. In many countries and regions, this plant is considered to treat diabetes because it contains many potential phytocompounds with the spectrum of pharmaceutical activities, which include antidiabetic ones [162, 172]. Besides the above, *M. charantia* used broadly as an herbal medication for diabetes [173]. The fresh juice of the unripe fruit of this plant confirmed blood glucose-lowering action in an experimental Streptozotocin (STZ) induced animal models as well as human clinical trials [174]. In this regard, a novel phytochemical inhibits guanylate cyclase enzyme [175]. Other phytochemicals are α- and β-momorcharin, momordin, and cucurbitacin B. Alcohol-derived extract charantin from *M. charantia* consist of mixed steroids, which are more effective than the oral hypoglycemic agents tolbutamide such as tolbutamide, chlorpropamide, and glibenclamide in an animal study [170, 176–179].

Previous studies [180, 181] have confirmed that aqueous extract of *M. charantia* stimulates insulin secretion of cells in pancreatic islets of obese-hyperglycemic mice. Besides the above, it plays a vital role in the regeneration of β-cells in STZ-diabetic rats or recovery of destroyed [182] cells. In addition, polypeptide-P isolated from the bitter gourd in clinical trials showed convincing hypoglycemic activity [172]. The major pure cucurbitane compounds of *M. charantia*, 5,19-epoxy-3,25-dihydroxycucurbita-6,23(E)-diene, and 3,7,25-trihydroxycucurbita-5,23(E)-dien-19-al have been demonstrated to have hypoglycemic effects in the diabetes-induced male ddY mice [183–185] suggested that the antidiabetic mechanism of *M. charantia* extracts may be due to enhancing insulin secretion by the islets of Langerhans, reducing glycogenesis in liver tissue, enhancing peripheral glucose utilization and increasing serum protein levels [181].

### 18.7.2 *Trigonella foenum-graecum* (Methi)

***Trigonella foenum-graecum*** (Fig. 18.5), belongs to the family of Fabaceae, which is found all over India, its bitter taste seeds are frequently used as a constituent of spices [186–188] and leave as green leafy vegetables in a diet [189]. Traditionally both seeds and leaves have proven their medicinal qualities, as they possess

**Fig. 18.5** *Trigonella foenum-graecum*

anti-hyperlipidemic and antioxidant properties [186, 190, 191]. In fact, *Trigonella foenum-graecum* seed powder lowered blood sugar levels among diabetic patients [192]. In addition, *Trigonella foenum-graecum* seed powder solution exhibited its potential in improving dyslipidemia in newly diagnosed type II diabetic patients [192]. To support this, study results showed that the *Trigonella foenum-graecum* seed powder solution showed a substantial decrease in TC, TG, and LDL-C levels and an increase in HDL-C level [186, 189].

The components such as saponins, 4-hydroxyleucine/4-hydroxyisoleucine, trigonelline, alkaloid, high fiber [156, 167] and diosgenin [193] are responsible for its various therapeutic potential [194, 195]. Several animal experimental studies have shown that the following active principles such as alkaloid trigonelline, nicotinic acid, and coumarin extracted from a defatted portion of the seed confirmed their antidiabetic potential of *T. foeneum-graecum* [196–198]. Furthermore, fenugreek seed powder exerts have been reported to have neuroprotective effects that probably mediate through a decrease in hyperglycemia and oxidative stress [195, 199]. However, in order to provide adequate confirmation, more research required including comprehensive chemical and pharmacological studies in order to isolate and characterize specific bioactive compounds from *Trigonella foenum-graecum* seed powder [192] and appropriate elucidation of its mechanism of action needs future study.

### 18.7.3 *Chromolaena odorata*

*C. odorata* (L.) (Fig. 18.6) King and Robinson is a well-known Devil or Siam weed found in many parts of the world [105]. It is widely, recognized for its traditional wound healing value with another spectrum of pharmacological actions. Although this plant initially identified in Vietnam and named *Eupatorium odoratum* and used exclusively for the treatment of burns, wounds, skin infections, and inflammation [200].

**Fig. 18.6** *Chromolaena odorata*

#### 18.7.3.1 Bioactive Principles of *C. odorata*

*C. odorata* extracts from various parts of the herb exhibit spectrum of pharmacological potentials like antioxidant [201], analgesic, and cytoprotective [202], anti-inflammatory [203], and other medicinally significant properties. Most of the extracts, mostly the leaf derived one facilitates fibroblast and keratinocyte proliferation at wound sites that enhance the healing of wounds [139, 203–205].

Many studies convincing evidence have shown that *C. odorata* exhibited antimicrobial activity against a wide array of pathogens [200, 203, 206–209]. Besides the above, other activities have been demonstrated and verified such as antimalarial, phytopathogenic [210], antiprotozoal [211], anti-biofilm [208], antihepatotoxicity [209], anthelmintic, and wound healing [139, 201, 205]. Adverse drug reactions and the huge expenditure on microbial infections including DFU [211, 212] in many developing and poor resource setting counties had made the management and control of infectious diseases ineffective [213, 214].

***Justification: Need for Phytomedicine to Combat Microbial Pathogens*** For decades until the present, herbal resources, mostly medicinal plants and their extracts derived drug leads are in practice for many medicinal purposes. In the era of reduced therapeutic options to treat multidrug-resistant infections, there is an urgent need to discover new antimicrobial compounds with diverse chemical structures and novel mechanisms of action. Antimicrobials of plant origin have the enormous therapeutic potential [215, 216]. Recently, much attention has directed toward plant extracts and biologically active compounds isolated from popular plant species [105, 139, 205]. The use of medicinal plants plays a vital role in covering the basic health needs in developing countries and these plants may offer a new source of antibacterial, antifungal, and antiviral agents with significant activity against infective microorganisms [217–219]. A recent study by [139] has shown that the ethanolic leaf extract of *C. odorata* showed a relatively larger zone of inhibition in diameter than Streptomycin against all tested organisms.

Phytochemicals such as tannins, flavonoids, alkaloids, and several other aromatic compounds or secondary metabolites such as glycosides, phenols, saponins, and steroids [220–222] have potential curative properties. To support the above claim, the antimicrobial compounds of *C. odorata* (flavonoids) are effective at inhibiting the growth of pathogens by binding to the bacterial cell wall, leading to inhibition of cell wall biosynthesis [213, 223]. In addition, tannins inhibit the growth of many fungi, yeasts, bacteria, and viruses. A recent study [139] also revealed the presence of alkaloids and saponins in the leaf extract further confirming their role in the microbial inhibition.

### 18.7.4 *Astragalus membranaceus*

*Astragalus membranaceus* (Fisch.) Bge (Fig. 18.7) belongs to family Leguminosae. Astragali Radix (AR) is a derivative of this plant especially from dried root [224,

**Fig. 18.7** *Astragalus membranaceus*

225] and has been used in Traditional Chinese Medicine (TCM) for hundreds of years to reinforce superficial resistance and promote growth of new tissue [226]. Besides the above, studies have reported its various pharmacological properties such as cardioprotective [227, 228], immunomodulatory [229, 230] as well as insulin-sensitizing [231–233] effects.

With regard to wound healing, a study reported that the aqueous crude extract of AR was demonstrated to promote fibroblast proliferation, both in cell line and in primary culture from diabetic foot ulcer patients, which was considered as the crucial step in wound process [234–237]. The primary constituents of AR include polysaccharides, saponins, flavonoids, amino acids, and trace elements [238, 239]. Saponin and isoflavone-enriched AR extract also promote angiogenesis in human endothelial cells [240] and calycosin was the active angiogenesis-promoting isoflavonoid isolated from AR [241].

### 18.7.5 *Rehmannia glutinosa libosch*

*Rehmannia glutinosa libosch* (Fig. 18.8) belongs to family Scrophulariaceae often viewed as safe and chief grade herb practiced in traditional Chinese medicine (TCM). This plant chemical composition contains more than 70 compounds including iridoids, saccharides, amino acid, inorganic ions, as well as other trace elements [242]. The principal compound Rehmanniae Radix (RR), a derivative of the root [243] of this plant played a role in remove pathogenic heat from the blood, nourish "yin" and promote the production of body fluid [244, 245]. Initially, RR recommended by TCM to relieve symptoms of diabetic patients, febrile diseases, skin eruption, and epistaxis [226]. Various scientific studies proved that RR and its active principals possessed a wide spectrum of pharmacological properties on various structures including the nervous system (reviewed by [242]). To support this, a study by [246] has shown that RR extracts inhibiting the progression of diabetic

**Fig. 18.8** *Rehmannia glutinosa libosch*

nephropathy. More specifically, the aqueous extracts of RR could stimulate fibroblast proliferation [234, 235] and be effective in promoting diabetic foot ulcer healing in rats through the processes of tissue regeneration, angiogenesis, and inflammation control [235, 247, 248]. However, ethanol extract and oligosaccharide fraction demonstrated hypoglycemic activity in streptozotocin (STZ)-induced diabetic rats and glucose-induced hyperglycemic rats, respectively [249, 250]. A study by [118] attempted to evaluate the potencies of individual AR and RR in different mechanistic studies. The study used AR and RR in the ratio of 2:1 and named as NF3. This study carried out to investigate whether herb–herb interaction between AR and RR in NF3 is involved in the diabetic wound healing process or not. In fact, the study results have confirmed that NF3 enhanced diabetic wound healing in rats by various mechanisms such as tissue regeneration, angiogenesis promotion, and inflammation inhibition. To support the above, a report from the clinical study, on the use of two herbal formulae (F1 and F2)/principal component of herbs, RA and RR prevented legs from limb amputation in diabetic patients [251] and were effective in enhancing fibroblast proliferation—the main step in wound healing [234, 252].

## 18.8 Possible Mechanism of Action of Medical Plants on Wound Healing

In recent years, increasing attention with growing demand and obtainability phytocompounds has encouraged the need to understand the principles responsible for their therapeutic activities and effectiveness. Many studies have reported that bioactive principles contained in herbal plants have growth factor-like activity or has the ability to stimulate an early expression of growth factors [105, 139, 205, 253]. For example, stimulation of fibroblasts has been observed in the wound healing process

by plant extracts [254]. In addition, many plant extracts have been known to stop fresh wound bleeding, also inhibit microbial growth, and promote wound healing [247]. Many active compounds enhance the process of wound healing by increasing various activities such as the viability of collagen fibrils, strengthen collagen fibers and increasing the blood circulation, preventing cell damage and/or promoting DNA synthesis [255–257].

To support the above, plant extracts with antioxidant activity play a vital role in promoting the wound healing process as therapeutic agents [139]. The antioxidant activities are mostly associated with the free radical scavenging action of phytocompounds in the extracts acting either singly or synergistically. The following bioactive principles of medicinal plants like alkaloids, flavonoids, triterpenes, tannins, and saponins have exhibited their key roles in wound healing effects [258]. This study report indicates that flavonoids possess both potent antioxidant and free scavenging activities by reducing lipid peroxidation and enhanced vascularity. Tannins plays a vital role in free radical scavenging activity, whereas, triterpenoids and saponins involve in enhancing the wound healing process by wound reduction and enhanced epithelialization [256–258]. Besides the above, trace elements such as zinc and Vitamin C from plant sources contribute to their role in wound healing. For example, zinc acts as a cofactor in many enzymatic reactions including zinc-dependent matrix metalloproteinases, which enhance keratinocyte migration during wound repair, whereas, Vitamin C plays a role in collagen formation [259].

## 18.9 Concluding Remarks and Future Directions

In summary, DM especially DFU is a debilitating status with a significant loss to quality of life among affected patients mostly in developing countries. Additionally, currently available treatments for this complication are usually not as effective as they brought poor clinical outcomes. This is mainly clarified by the insufficient knowledge of its underlying mechanisms and treatment methods. Although the interest in research and management of DFU has increased in recent years, it is still in the infancy state among diabetes complications in terms of research efforts and resource allocation worldwide despite current treatments inadequate outputs. Additionally, the complexity of its management needs to be addressed on a multidisciplinary approach including the adaptation of phytomedicines with rigorous research approach and appropriate trails that should gather all expertise necessary for the optimal management of each aspect of this complication.

Over the years, globally the use of traditionally herbal plants played a vital role in the treatment of DM specifically T2DM. Numerous types of plant-derived bioactive principles representing various types of chemical compounds such as alkaloids, glycosides, galactomannan, gum, peptidoglycan, glycopeptide, amino acids, and inorganic ions have shown potential therapeutics for diabetes. Therefore, there is plenty of possibility of developing potential antidiabetic drugs from medicinal plants for human use. However, it is still not very clear whether we can use phytomedicine alone as an alternate to combinatorial drug of non-natural origins or as

adjuvant drugs along with standard insulin therapy for managing diabetes. In this regard, future investigations are still required to elucidate the comprehensive details of issues such as phytomedicines and properties, an effective dose of each compound, and probable side effects on wound healing processes in diabetic and non-diabetic conditions.

Phytomedicines are important to manage pathological conditions of many diseases including DFU caused by various pathogens and free radicals, as they are nature's gift for not only healing wounds but also contributing to affordable healthcare. Explore the antimicrobial, antioxidant bioactive principles from natural resources; identification and isolation of those natural products are simultaneously presenting enormous scope for their better therapeutic application for treatment of human disease, mainly infection-related complications. Hence, the phytochemical screening and assessment of the antimicrobial, antioxidant activity of medicinal plants play a very important role in identifying new compounds of therapeutic and industrial importance. Therefore it is time for researchers, to identify and explore many currently practicing traditional therapeutic knowledge and medicinal plant sources and interpret them according to the recent advancements to fight against microbial pathogens, reactive oxygen species (ROS), in order to give them a deserving place. This is crucial to its potential future drug design, development, and application for the treatment of wounds in both animal and human medicine and cost-effective health care. In this regard, future studies on the wound healing potential of topical herbal formulations must incorporate careful consideration of the chemical makeup of the final therapeutic product. The future should bring much more high-quality research not only to the area of DFU but also to phytomedicines from basic research to properly conducted clinical trials. Regarding future clinical studies, in addition to the need for thorough consideration of characterization and batch-to-batch reproducibility of topical botanical therapeutics used in the clinic, properly designed randomized controlled trials are suggested.

Besides the above, therapeutic application of cytokines, growth factors and their soluble receptors could be investigated to determine the extent of their involvement and acceptability in wound healing and treatment. Fibrotic processes are continuous and characterized by collagen synthesis, downregulation of degradative enzymes involved in removing scar tissue and fibrosis has been reported to be inhibited by antibodies, peptide receptor antagonists. Research into interactions between fibrotic processes and antibodies could also provide useful information on wound healing. To conclude, a better understanding of the mechanisms of initiation, progression, and resolution of wound healing could lead to the discovery of new therapies that are very much needed. However, despite limitations on the degree and extent of the applications of phytomedicines in the treatment of diabetic wounds, it shows considerable promise and can indeed herald exciting new therapeutic strategies in wound healing. Yet, further research and large clinical trials are recommended to confirm the efficacy and safety of specific medicinal plants and their mechanisms of action, especially on diabetic wound healing.

# Management of Diabetic Foot Ulcer by *Hirudo medicinalis*, the "Healing Leech"

19

Sumbul Rehman

## 19.1 Introduction and Prevalence

Diabetic Foot Ulcer (DFU) is a chronic open wound on the bottom of the foot, a most common lower extremity complication of prolonged and poorly controlled blood sugar level in 15–25% of diabetes patients [1]. It occurs due to two main severe complications viz. Diabetic neuropathy and peripheral vascular disease. Among this, 14–25% of patients got complications to an extent that it needs to be amputated due to complications [2], and thus it has become the leading cause of nontraumatic lower extremity amputations in the USA. And it is observed that at every 30 s, a lower limb amputation is carried out due to diabetes throughout the world. The mortality rate due to diabetic foot gangrene is just next to that of cancer.

Diabetic foot ulcer is more prevalent in men as compared to women with a fasting blood sugar level of 220 mg (%) [2]. Mostly found in Native Americans, African Americans, Hispanics [3], and older men, patients using insulin or with diabetic-related multiple organopathy like kidney, eye, or heart. The use of alcohol or tobacco or being overweight may also play an important role in its progression.

With the continuous uncontrolled rise in blood sugar level, numerous problems arise which lead to vessel diseases that limit or prevent blood from reaching the toes, fingers, hands, and feet. When blood flow becomes severely restricted, the affected tissue can die. This is the leading cause of amputation among people with diabetes. Losing a digit or limb due to complications from diabetes is a major concern for millions of people worldwide. The most effective way to stop this process is to increase circulation to the affected tissues without the risk of blood clots. Various clinical studies have reported that leech therapy can play a vital role in healing the ulcer.

### 19.1.1 DFU in Type 1 and Type 2 Diabetes Mellitus

Diabetic foot ulcer is a chronic ulcer, chronicity in terms of its nonhealing after appropriate treatment for 3 months, and is unable to heal even after continuous treatment for 12 months and its grading varies with complication [4]. It is usually found to be of grade 4 or 5.

For many years diabetic wound ulcer was classified as per Meggitt-Wagner ulcer classification system (Table 19.1) [5].

Wagner's classification was later revised by Brodsky [6], to assess the depth of the lesion and ischemic changes in DFUs, to ease the treatment modalities in diabetic neuropathy (Table 19.2).

- *Depth of lesion*—Graded from 0 (when there is no break in the skin) to 3 (presence of abscess, or exposed bone, osteomyelitis), and 4 (necrotic foot area) to 5 (entire foot get necrotic).
- *Ischemic changes*—Graded from A (No Ischemia) to D (Complete Gangrene).

And recently diabetic foot classification is remodified, as it gets beyond ulceration too and infection may or may not be present in DFU. So, as diabetes has been classified as type 1 and type 2 diabetes mellitus; its complication has been classified into three (Table 19.3) [7].

Among these Type 1 diabetic foot complications accounts for 86.6–91.06% admission to the hospitals that may occur individually or in combination and thus become the major cause of amputation.

**Table 19.1** Meggitt-Wagner classification of foot ulcers

| Grade | Description of the ulcer |
|---|---|
| 0 | Pre- or post-ulcerative lesion completely epithelialized |
| 1 | Superficial, full-thickness ulcer limited to the dermis, not extending to the subcutis |
| 2 | Ulcer of the skin extending through the subcutis with exposed tendon or bone and without osteomyelitis or abscess formation |
| 3 | Deep ulcers with osteomyelitis or abscess formation |
| 4 | Localized gangrene of the toes or the forefoot |
| 5 | Foot with extensive gangrene |

**Table 19.2** Bodsky's modification in Wagner classification of wound ulcers

| | 0 | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|---|
| A | Callus or scar | Superficial wound | Wound penetrating to tendon/capsule | Wound penetrating to bone/joint | Necrotic foot areas | Necrotic foot, entire |
| B | Infection | Infection | Infection | Infection | Infection | Infection |
| C | Ischemia | Ischemia | Ischemia | Ischemia | Ischemia | Ischemia |
| D | Infection + ischemia | Infection + ischemia | Infection + ischemia | Infection + ischemia | Infection + ischemia | Infection + ischemia |

**Table 19.3** Classification of diabetic foot ulcer based on lesions

| S. No. | Type of lesions observed | Type of diabetes | Nature of ulcer |
|---|---|---|---|
| 1. | Cellulitis, wet gangrene, abscess, necrotizing fasciitis, osteomyelitis, etc. | Type 1 diabetes foot complication | Infective DFU |
| 2. | Nonhealing ulcers, peripheral arterial disease, hammer toes, entrapment neuropathies, diabetic neuro-osteoarthropathy, etc. | Type 2 diabetes foot complication | Non-infective DFU |
| 3. | Like-charcot foot with infected ulcer, nonhealing ulcer with osteomyelitis, etc. | Type 2 diabetes foot complication | Mixed DFU |

### 19.1.2 Pathophysiology and Clinical Presentation of DFU

Along with the severity of glucose level in the blood with time, its formation is due to the combinatorial factors such as foot deformity, traumatic conditions, lesser blood flow toward the extremities, neuropathy which lead to reduced or complete lack of sensations. Presence of vascular diseases worsens the condition, as the ability of the body to fight infection already got reduced due to diabetes and it further got complicated by reducing its ability to heal at the site and thus there always remains a chance for an infection.

Prolonged Sugar level with associated complications proceeds to develop cracks in the feet which turn into chronic wound ulcers, as a result of a combination of growth factor fabrication, accumulation of collagen, fibrosis, and abnormal pressure. It is soon encroached by the inflammatory response which lasts longer, inflammatory cells like neutrophils; macrophages, T-lymphocytes, fibroblasts, and prostaglandin E2 (PGE2) secrete enzymes that result in pain, redness, warmth, and swelling indispensable for the healing cascade [8]. And DFU is characterized by a series of exasperated and extended inflammatory response.

It is clinically manifested by loss of sensation in lower extremities; redness and swelling at the bottom of the foot along with some exudate of purulent odor. To confirm, superficial pain perception along with temperature, light, and pressure sensation is examined. Sometime when peripheral neuropathy predominates it is represented as muscle cramps in both the limbs along with burning sensation; pins and needles; shooting, sharp, or stabbing pains; which aggravate at night often worse, which are usually present in peripheral neuropathy [5]. In such cases, Neuropathy Symptom Score (NSS) is adopted which is considered a high predictive value to screen for peripheral neuropathy in diabetes [9].

As tissue death cannot be reversed, surgical removal of the affected tissue (debridement) or amputation of the limb is the only treatment option left when gangrene has advanced. Thus foot ulceration precedes 85% of diabetes-related amputations in the USA [10]. But researches have shown that its development can be prevented and amputation rate can be minimized by some preventions or following some alternate therapies like leech therapy/Hirudinotherapy.

### 19.1.3 Prophylaxis and Treatment of DFU in Molecular Science

DFUs are associated with complexities of vascular disease and ischemia which delays healing. Atherosclerosis along with ischemia contributes to amputation in 90% diabetic patients [8]. Capillary thickening produces inelasticity, vasoconstriction and condition worsened with the over-loaded microbial growth; so, its treatment becomes more perplex as lack of sterility delays healing.

It seems to be a great challenge to manage the wound if some basic principles are not routinely followed. So, paramount care is needed while thoroughly examining the patient's condition. A comprehensive systemic approach to assess and treat by elucidating underlying areas of concern need to be specifically addressed which leads to favorable outcomes. Due to variation in the complexity of the diabetic patient and wound condition, it is mostly represented by variation in clinical condition. In such cases, a multidisciplinary approach, molecular as well as holistic approach is recommended to attain higher success rate in improving patient condition. Medical/holistic management of the patient must commence concurrently with wound management [11].

Diabetic patients recurrently need improved control of their hyperglycemia, renal insufficiency, sustenance, and other associated medical comorbidities that may adversely distress the healing of wound. DFU can be prevented by following regular podiatric care immediately and its treatment always aims to reduce the risk of infection and amputation and thus, improving the quality of life and reduce health care costs. It can be attained if the emphasis is given on healing, faster the healing, lesser will be the chances for an infection.

The key to successful wound healing is regular podiatric medical care to ensure the following "gold standard" of care taken sequentially:

- Off-loading—reducing the pressure from the area.
- Removal of the dead skin debris.
- Proper cleaning and use of medications in dressings or therapies of the ulcer.
- Use of antibiotics, if infected.
- Improving blood circulation.
- Prevention of infection.
- Management of blood glucose level and other health ailments associated.
- Surgery: though a number of noninfected foot ulcer can be treated without any surgeries, but in some cases, certain excision of bone(s) is needed to be done to reduce the pressure on the affected site or to correct the deformity like bony unions, hammertoes.

Earlier it was a practice "to let the wound open." But in the present era with polluted air, this will worsen the condition. It is quite evident that open wounds give a nice diet for microorganism present in the air and give rise to infection. So, they must be kept covered and moist by dressings with proper topical medications. Healing time varies with the available condition of ulcer, but appropriate wound management enhances the speed of the healing process [8, 12].

Although allopathic medicine offers an enormous amount of treatment modalities to heal the ulcer in every respect including lumbar sympathectomy or spinal cord stimulation as a part of neurovascular interventions; negative pressure wound therapy (NPWT), electromagnetic stimulation or enhanced local oxygen therapy for local mechanical therapy; vasoactive growth factors or tissue-engineered skin product for topical therapy; systemic therapy with hyperbaric oxygen or intravenous therapy with agents such as prostaglandins [12–16].

Besides the higher cost and time taken to heal DFU before it reaches the dreadful condition of being amputated, these nonhealing diabetic wounds remain to mystify. And unfortunately, in spite of having all such great scientific technologies, newer strides observed in technological innovations with a wide range of treatment for wounds in the present century, these ulcers remain to perplex and encounter the healers [16, 17].

It demands non-surgical approaches to be introduced to aid the wound management [18]. So, an attempt should be made to combine it with the traditional practices that were followed in ancient times to overcome such dreadful conditions along with the present-day treatment. It is evident that wound healing can be enhanced by improving blood circulation to the ulcerated site which can be attained with non-invasive methods like Medical leech therapy (MLT).

## 19.2 Therapeutic Bleeding by Medicinal Leech Therapy (MLT)/Hirudinotherapy: A Medical Basis

### 19.2.1 Historical Background

Since ancient times, physicians formed the elite, the upper crust of the medical system from where the bloodletting through leech therapy arrived. Being a humankind's belief about "blood" which flows through the veins of history, it was observed that nature expulsion of blood in the form of menstruation lead to an idea of therapeutic bleeding—phlebotomy; and thus bloodletting was performed by venesection, wet cupping or leeching. It sounds to be a traditional practice of Medieval era, but studies of the nineteenth century confirm its scientific use in certain health ailments.

Leech like hematophagous animals have been used since ancient times for a series of biologically active compounds present in their saliva especially the anticoagulant factor, which prevent blood clotting. Historically, their use date backs to ancient Egypt and the beginning of civilization by ancient Egyptians, Indians, Arabs, and Greeks [19]. Promising property of its substantial use in medicine lies in its own meaning, as the word "Leech" is derived from an AngloSaxon word "Laece" which means "to heal" and thus they are used since then as a means of local depletion (bloodletting) [20, 21]. Historically they are first reported by a pupil of Aesculapius, Themison (80–40 BC) in Greece and the oldest therapeutic book about leech is Leech-dom [22]. Avicenna (980–1037 AD)-an eminent Unani Physician also delineated in his famous encyclopedia "Canon of Medicine," that leech can suck blood from deep veins which cannot be reached by the conventional wet

cupping and he acclaimed leeching for skin diseases. Later, it is reported to be found in a painting in an Egyptian Tomb of around 1500 BC, and in twelfth century, Abdul Latif Baghdadi also cites its therapeutic use after surgery. Ibn Maseehi (1233–1286 AD) has also detailed about the two forms of leeches in his treatise "*Umda Fi Jarahat*"—detailed basic treasure of surgery and differentiated the medical leeches from the nonmedical (poisonous) ones according to their shape and color [23]. It was also well mentioned in the literature of Ayurvedic System of Medicine as evident in Sushruta Samhita [19, 51, 52]. Renaissance of its medical journey reached its zenith in seventeenth and eighteenth century AD in Europe, while it was in use by Arabs for bloodletting.

It predates the medieval era by a substantial chunk of time, although their popularity does not remain to be constant, it varied with time. Their revival from the benighted era reached its zenith in early nineteenth century and reached to its peak in Europe between 1825 and 1850 to an extent that supplies become exhausted, 50,000 leeches were used during the course of 1831 by the Manchester Royal Infirmary, in the UK, in France "Leech Farms" were unable to meet the demand and in 1833, over 41,500,000 leeches were imported into France, and only nine or ten million exported. In one of the instances Richard Arnold, a Savannah physician, in 1838 complain regarding the cost of leech to be "only in the reach of the rich," when they were sold at 50 cents each [20, 24]. Later they were used by the physicians of the emperor and influential academic surgeons, but then it saw a downfall toward the end of the century, as it become associated with lay therapist and quackery.

With the advent of "germ theory," the western medicine reached to its peak, and the leech therapy was considered as "the myth of the past" and gradually lost the favor. Bloodletting using leeches and other methods enjoyed resumption in the early nineteenth century, particularly in France, when in 1922 Surgeon Termier recommended direct application of leech, and he described it as "hirudinization of the blood," renowned scientist Bottenberg also established the general indication of leech therapy in 1935 [25]. Later, MLT enjoyed an International come back in 1960 when many scientific researches took interest in their use for microsurgeries because of their promising effect shown in postoperative venous congestion and graft rejections. And, it was on such a big scale that a specific medicinal leech farm first of its kind was established in Swansea in 1981 by Dr. Roy Sawyer which now supplies leeches to the hospitals all over the world [23]. Leech therapy further got the new impulse of treatment modality after initial publications by Upton's group in 1980s [25, 26].

Researches remain to be continued for its beneficial use in many clinical conditions. And, it was found to be effective in sustaining retrieval of compromised microvascular free tissue transfer, and it was observed that the salvage of compromised, venous congested tissues can be improved by early application of leech. They help to improve blood flow to regions where it has slowed or stopped, thus prevent tissue death. This caused a renaissance of leech therapy and now they are used for their therapeutic value globally. Although many complaints were made regarding the continuous oozing of blood from the site of leech bite even after its withdrawal, but later this phenomenon was explained by John Berry Haycroft, a

Birmingham chemist in 1884. He discovered the presence of an anticoagulant "hirudin" which is injected by the leeches in the blood that keeps it flowing through the capillaries [27].

And the twenty-first century has revealed a number of studies, which confirms its efficacy in many health ailments like circulatory disorders, skin diseases, arthritis, etc. Now, leech sale and its use have been permitted, only for its use in microsurgeries and plastic surgeries by the Food and Drug Authority of USA (FDA) [26].

### 19.2.2 Medicinal Leeches

There are more than 600 leech species which belong to the Class Hirudinea which in habitat aquatic (ponds, streams, lake, and the sea) as well as moist terrestrial regions. They are widespread in many parts of the world with great abundance in North America, Europe, and Southeast Asia. Among various species present globally, European medical leech *Hirudo medicinalis*—specifically known as "Healing Leech," is preferred over American species *Hirudo decora*, as it sucks less blood through its superficial incision. There are other species too, which vary in length and their ability to suck the blood used for therapeutic bloodletting such as *Hirudinaria manillensis*, *Hirudo nipponia*, *Hirudo verbena*, and *Hirudo orientalis* [28] (Fig. 19.1).

*Hirudo medicinalis* belong to the Phylum Annelida; a family of "fresh-water parasitic invertebrates." They are hermaphrodite, multi-segmented, carnivorous worms having sucker-blade like three jaws with tiny rows of around 100 teeth in each jaw, which pierce host skin to slit the skin of the host. Contaminants present around cause the stress to the leech, as a result, a slimy mucous secretion lies over their body.

### 19.2.3 Medicinal Leech Storage, Its Application and Removal

Medicinal leech should always be collected from an authentic supplier. Throughout Europe, it is supplied by an International Swansea-based company Biopharm which was established in Hendy, South Wales (U.K) in 1812, from where it is moved in 1984. They are supplied in a specialized container having gel for short transference or distilled, non-chlorinated water for long transport. From Leech farm to be used

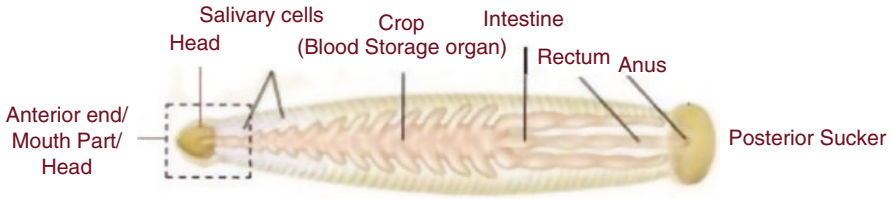

**Fig. 19.1** Anatomical description of *Hirudo medicinalis*

for therapeutic purpose FDA recommends to maintain 10–15 leech per plastic/glass container having fresh distilled water; water volume/leech should not be less than 0.7 L. A very small percentage of salt is added as directed and kept at 4 °C in a cool dark place with a minimal perforation in the jar. The water of the jar should be replaced after alternate days depending upon the turbidity. Before, their therapeutic use they should be taken out at normal RT to regain their active motility [29].

Before application inclusion criterion along with specific bio-markers hematologic evaluation must be checked. Then only, it should be applied in a proper hygienic and sterile condition.

As a part of protocol of wound management skin is washed thoroughly with sterile water. Leech is taken out with a pair of long non-toothed forceps from the container (it is preferred that leech should be docile, which can be attained if it is applied immediately when it is taken out from refrigerator). Sometime, it needs a plastic syringe with plunger removed; in which leech is placed and inverted over the wound site, and sometime it directly attaches itself to the wound site. In some cases, blood droplets from a small prick helps in their attachment over the site. Proper supervision is always needed to restrict it to the site only, unnecessary movement can be avoided by restricting their movement by dampened gauze [30].

On a single application, live leeches attach themselves, by the suckers present at both the ends to the target area on the patient undergoing treatment. The narrow anterior end is the mouth with around 300 teeth in three sets of jaws, which leave a Y-shaped scar later [31]. Instantly it releases hirudin, a potent anticoagulant along with anesthetic and other chemical agent present in its saliva; after which it grow thrice of its size after sucking up to 15–20 mL of blood in rhythmic contractions during 10–30 min in a single feed, after which it usually drop itself [32]. If it fails to do so, a flat slim blunt blade is intervened in between the skin and the anterior sucker; once it is achieved the leech body is slightly holded by the posterior end too, and is put back in the separate container. Sometime 5% topical cocaine can be used to paralyze it and get it to detach from the skin. It should never be forcibly detached to avoid skin excoriation. They are discarded as per the protocol of bio-hazardous waste, immersed in 70% ethanol for 5–10 min.

Hirudin along with other co-factors causes blood thinning and vasodilatation which cause bleeding to be continued for 8–10 h, after its removal. During this time, it should be washed thoroughly and some protocols suggest the use of heparin to prolong bleeding [30] while some suggest hydrogen peroxide to control the effect of anticoagulant [33]. It varies with patient condition, so regular observation of color and appearance of tissue site along with vital signs and blood count should be monitored throughout the process. Prolonged treatment in large area of skin may demand blood transfusion.

### 19.2.4 Natural Conformation in Leech Saliva

Extensive research studies done on leech saliva have confirmed that it is rich in active biomolecules that act in multiple ways. There are more than 20 molecules whose mechanism of action is well defined as anticoagulant, anti-inflammatory,

**Fig. 19.2** Potential bioactive ingredients of leech saliva

analgesic, platelet inhibitory, thrombin regulatory, antimicrobial, etc. but still much is to be explored before making any strong assumption. Just after their attachment to the host skin, they release all these biologically active compounds in balanced set and along with 100 different types of peptides and proteins [34]; it includes the following which gets released into the bloodstream for health benefit (Fig. 19.2):

Hirudin (an antithrombotic factor), Hyaluronidase (a diffusing substance which increases the permeability of connective tissues to absorption by reducing the viscosity), Calin (suppresses the adhesion of platelets to collagen and act as antithrombotic), Destabilase (lysozyme with glycosidase potential, act as antibacterial as well as thrombolytic), Apyrase (Nonspecific Platelet Aggregate Inhibitor), Eglin (Inhibitor of alpha-chymotrypsin, subtilisin, chymosin, granulocyte proteinases, elastase, and cathepsin G), Bdellins (Plasmin Inhibitor), Decorsin (acts as an antagonist of platelet glycoprotein II b-III a and is a potent inhibitor of platelet aggregation), Hirustasin (a specific inhibitor of the blood coagulation Factor Xa), Guamerin (Human leukocyte elastase inhibitor), Piguamerin (inhibits plasma and tissue kallikrein and trypsin), Gallin (thrombin inhibitor), Gamma-Glutamyl Transpeptidase, Platelet Active factor Antagonist (important compound for the treatment of thromboembolic disorders and inflammation), Ornithine rich peptide active. Besides these, it also contains acetylcholine, histamine like vasodilators that prolong bleeding time. Certain enzymes like fibrinase and collagenase that reduce scar tissue and adhesions and help reduce fibroblast formation in hypertrophic scars and keloids [28, 34–36, 38, 39].

They collectively act as

- Local anesthetic
- Local vasodilator
- Anticoagulant agents (hirudin)
- Analgesic and anti-inflammatory
- Platelet aggregation inhibitors (calin, saratin, for instance)
- Collagen inhibitors that prevent its adhesion on surface

They trigger the immune system also to do the work and thus all these collectively prevent clotting and improve circulation, and prevent tissue death. The leeches leave behind small, Y-shaped wounds that usually heal without leaving a scar. Medicinal leeches most often come from Hungary or Sweden (Fig. 19.3).

**Fig. 19.3** Leech attachment to the skin through its anterior sucker leaving Y-shaped scar

### 19.2.5 Therapeutic Property of Medicinal Leech Therapy (MLT)

MLT, which was once considered to be an eternal part of the traditional system of medicine viz. Ayurveda and Unani System of Medicine substantially benefitted many practitioners following allopathic medicine too. And a revival in its use is observed due to its simple and inexpensive means of preventing complications and for the common aim of providing benefit to the mankind to treat nervous system abnormalities, dental problems, skin diseases, plastic or reconstructive surgeries, and infections.

And now, past many years leech therapy preferably referred as hirudino therapy is used to treat a wide range of conditions by medical professionals. Like the post-operative treatment of a scalp avulsion as reported by Henderson et al., in 1983 [37]; Russia in the 1900s found newer uses of leeches for the treatment of hypertension, migraines, phlebitis, varicose veins, arthritis, hemorrhoids, and ovarian cysts and in the USA, plastic surgeons used them to drain blood from wounds after limb amputation. In 1970s their demand revived again to its heights of popularity after the success got in finger reattachment procedures and soft tissue surgeries of the face, and later in various other plastic or reconstructive surgeries, specifically due to their ability of preventing scab formation. It is due to the presence of an anticoagulant that they secrete into wound which allows them to heal from inside outward. Small leeches were preferred to be used after microsurgeries on the face or neck.

Alleged benefits of medicinal leeches have been substantially extended after the exploration of various chemicals present in the leech saliva, that are now been used by the pharmaceutical companies for their use in various medical conditions that can be improved by their proper use like in high-risk cases of limb amputations as a complication of diabetes, circulatory disorders to treat blood clots and varicose

**Fig. 19.4** Leeches applied on diabetic foot ulcer

vein; for preserving soft tissues and promoting healing after facial reconstructive surgeries like forehead, nose, lip, cheeks. Its effect on blood clotting further helps to heal naturally and completely leaving behind minimal or no scar (Fig. 19.4).

### 19.2.6 Therapeutic Uses

MLT has been used efficiently for the treatment of circulatory diseases, as various clinical forms of coronary heart disease, stable angina, and postinfarction cardiosclerosis has also been reported [28, 38–43] which to an extent confirm the inhibition of platelet aggregation by the chemicals present in leech saliva.

Baskova et al. [41] also confirm their on the endothelial vasomotor function of medium and small resistance arteries. Further, he studied that its effect is not just the local, but it is a systemic effect which normalizes stiffness of the arterial wall. This process is supposed to involve the salivary cell secretion of the medicinal leech, which is able to raise the NO level both in cells and in extracellular fluid and to activate *e-NOS* and *n-NOS*, as it has been shown recently in the culture of human vascular endothelial cells (HUVEC).

There is also evidence by Gasic et al. [44] where salivary gland extract showed anti-metastatic effect which can be attributed to the anti-platelet-aggregating, anticoagulant, and anti-proteolytic enzyme activities present in leech saliva. Ammar and his co-workers [45] also proved its efficacy in prostate cancer through in vitro and in vivo antitumor activity with no apparent side effects. It can be attributed to its ability to inhibit cellular proliferation, prevention of cellular adhesion, and anti-inflammatory properties. Although its activity may vary with different types of cancer. Further, due to its proven anti-inflammatory and anesthetic properties, it can be used to reduce tenderness and pain in joint diseases like osteoarthritis [46].

Other claims made for MLT includes its use in the treatment of migraine, infertility, baldness sinusitis, glaucoma, chronic renal failure, hepatitis, cystitis, Alzheimer's disease, and many more [47–50]. Although due to its therapeutic properties specifically due to the bioactive molecules in its saliva, it is mentioned to be used in various health ailments as mentioned by many [47–50], but the story may not be true always, unless and until it is scientifically verified. So, before using it clinically it should be scientifically re-validated for its claim made.

### 19.2.7 Contraindications

Hirudinotherapy is an easy remedy which involves a lower end risk of side effects, compared to other. So, people with anemia, blood clotting conditions, or compromised arteries are not considered as candidates for leech therapy. And so, are the children under the age of 18 years old, pregnant women and immune-compromised people are also usually advised to avoid it. Further, it can be harmful in other conditions too, if used wrongly. So, it is always advised to use a healthy, fresh leech and patient should be told well, before the procedure to be done, to restore the mental condition while the blood oozes out from the wound.

Sometime it is observed that blood continues to ooze out from the leech bite site in spite of leech removal; so it should be treated accordingly. In some cases, leeches move out to other area of the body, which may cause unnecessary blood loss; so a continuous supervision is necessary (Fig. 19.5).

## 19.3 Healing Ulcer in Diabetes

Medicinal Leech therapy can help in the healing of the ulcer by improving blood circulation along with other chemicals present in leech saliva that work as co-factors in diabetic wound ulcer healing. Several case studies have reported its use successfully. MLT has been a traditional practice in various evidence-based medicine; and in Ayurveda also it is followed successfully; like in an observational single case

**Fig. 19.5** Blood oozing out from the attached leech site

done without control at an Ayurvedic Hospital in Mumbai (India) [51]. In the study done by Dwivedi, he discussed the case of a 45-year-old male diabetic patient having inflamed infected DFU on both the foot at Planter surface; with pus, bleeding purulent smell was treated with MLT. Along with the general care for wound with Ayurvedic therapy and control of diabetes with western medicine, leech therapy was employed. It was used weekly in four sittings for 30 days; using three leeches at the wound site. Follow-up was taken regularly and the changes in clinical features were noted, it is well documented photographically weekly and the DFU get completely cured. Rampure [52] have also discussed a case study of 52-year-old male patient, being cured with leech therapy as a part of Ayurvedic Panchkarma. Four leeches were applied once a week on the nonhealing irregular inflamed ulcer with mild pus discharge at the left ankle joint after proper antidiabetic treatment which was properly healed after 30 days.

Similarly as per the Unani system of medicine, Zaidi [53] has also illustrated wound healing by leech therapy in a 60-year-old diabetic lady along with Unani medicine used as blood purifier and deobstruent. Foot ulcer was of fifth grade that was almost turned into gangrene with severe foul smell in the necrosed area and causing much pain in the left foot; thus was in all facing the prospects of amputation. Hirudinotherapy was followed for a period of 20 days that minimize the painful condition and helped in almost complete healing during the course of 3–5 months, with complete removal of necrosed area [53].

Follower of Alternative and Complementary Medicine in Iran, Hajtalebi [54] also details about a case study done on 58-year-old diabetic patient having two chronic wound of Stage II/Grade III on the right foot and was left for amputation. After proper anti-hyperglycemic control over sugar level along with medicinal herbs, he was able to successfully cure the foot ulcer within 60 days. It was done by application of 10–12 leeches being placed inside and around the wound during 16 sessions after every 2–4 day. Another study mentioned by the same author in 2017, also re-confirms the use of leech therapy in DFU [55]. As mentioned by the author a 74-year-old lady with a prolonged history of 20 years with diabetes was treated in such a severe condition when all allopathic medicines were exhausted before uncontrolled blood sugar level and sepsis and as it was not responding to any such treatment, it was left for amputation only. The patient had a severely infected cyanosed sore on the big toe of her right foot, for at least 2 months, and the unadorned inflammation was spread over the other fingers and continued to the ankle. In the meantime, she was provided with the present-day treatment, which did not benefit her and the suffering of the patient was increased along with the wound condition that worsened day after day. Physician started the treatment by giving dietotherapy, along with medicinal herbs, and modern blood sugar control drugs. Leech therapy was used to treat the ulcer using six medium-sized leeches in ten sessions, once after 3 days inside and around the wound and after ten sessions the wound was found to be completely healed and the blood sugar also came to the controlled conditions in 40 days of treatment.

## 19.4 Conclusion

Several successful clinical stories elaborating on the logistic pathway behind the therapeutic efficacy; that leech therapy can be used widely in healing the diabetic wound ulcer and the rate of amputation can be minimized to an extent. Established mechanism of action for its medicinal value lies in the pharmacological synergy which occurs among the chemicals present in leech saliva where hyaluronidase and collagenase got released after leech bite, histamine like molecule further cause vasodilatation, concurrently blood coagulation is inhibited by the combined inhibition of platelet aggregation, coagulation cascade, and kinin activity along with inhibition of inflammatory reactions under analgesia. So, a combination of traditional therapies like Medicinal leech therapy which act in many ways to treat not only the wound, but also reducing the associated complications, along with the synthetic antidiabetic drug can provide with 'patient's healing. Still, Molecule based community at a large is skeptical about most of the claims made by holistic based healers, but scientific researches going on leech therapy are showing a promising role in the treatment. And so, they are relied upon, since centuries as an essential part of medical care. The present-day scientists have limited their role and leeching nowadays is being used only in microsurgeries to relieve the venous congestion. An enormous amount of therapeutic property lies in their saliva, which needs to be explored further. So that they could be relied upon and used for medical care needed.

# Nanotechnology and Diabetic Foot Ulcer: Future Prospects

20

Mohammad Azam Ansari, Khursheed Ali, Zeba Farooqui, Hanan A. Al-Dossary, Mohammad Zubair, and Javed Musarrat

## 20.1 Introduction

Diabetes was discovered independently in several parts of the world prior to the time there were no physicians or chemists. Interestingly, the discovery of diabetes was made by observing that insects tend to attract toward the sweet urine of certain diseased persons [1]. In 2010, the International Diabetes Federation (IDF), claimed four million deaths under the age groups of 20–79 years, globally [2]. In 2013, rapid growth in the prevalence of diabetes was observed affecting 382 million people worldwide [3] with a figure of 30.3 million affected individuals in the USA alone in 2015 [4]. According to the World Health Organization (WHO), diabetes

holds the status of a chronic disease associated with lengthening of hyperglycaemic conditions due to inability or complete irreversible damage of insulin exuding pancreatic cells [5]. During the 1980s, the WHO classified diabetes as insulin-dependent diabetes mellitus (IDDM) or type 1 diabetes, and non-insulin-dependent diabetes mellitus (NIDDM) or type 2 [6]. In 1997, the classification of diabetes was updated as mere type 1 and type 2 diabetes while discarding IDDM and NIDDM by the WHO [7]. According to medical acquaintances, diabetes crops up due to prolonged hyperglycaemic conditions arising due to some abnormalities surfacing in the normal functioning of the pancreatic cells. In fact, pancreatic α- and β-cells are dedicated to sustain blood glucose (BG) levels in the bloodstream of healthy individuals. Strictly, an increased BG concentration signals the β-cells of the pancreas for the secretion of the hormone insulin which in-turn stimulates the processes of hepatic glucose uptake and extra-hepatic glucose uptake from the blood. On the contrary, when BG level falls below a minimum threshold, α-cells of the pancreas are signaled for the secretion of hormone glucagon which stimulates hepatocytes for the breakdown of stored glycogen into glucose and releasing it into the bloodstream, thereby attaining normal glycemic levels [8]. The defects in insulin-secreting pancreatic β-cells are characterized by metabolic disorder, resulting in elevated BG concentrations. One such anomaly is called type 1 diabetes mellitus (T1DM), which arises due to an autoimmune disorder, characterized by complete destruction of the insulin-secreting β-cells and its survivors are completely dependent on exogenous insulin [9]. In general, the documented medico-literature reports normal BG levels to be in a constricted range of 70–110 mg/dL after 2–3 h of a meal or undergoing an overnight fast [10]. Besides, type 2 diabetes mellitus (T2DM) is characterized either by the inability of the pancreas to secrete sufficient insulin or insensitivity of insulin or a combination of both. The prolonged hyperglycaemic (BG > 120 mg/dL) patients are prone to develop multiple health complications such as neuropathy, retinopathy, nephropathy, peripheral vascular disease, and coronary heart disease. Conversely, in case of hypoglycemia (BG < 60 mg/dL), the low BG level reflects anxiety, perspiring, an extreme appetite which may lead to lethargy, coma, and sometimes even death. Strictly speaking, the level of BG within the salutary window of 60–120 mg/dL is the hallmark of sustaining a healthy life.

Besides, DFUs are generally identified as a chronic microbial infection site due to the manifestation of a wide range of pathogens. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are of the frequently identified bacteria which readily form chronic biofilm matrices in order to evade bactericidal effects and accumulate antibiotic resistant against a broad range of conventional antibiotic agents. Thus, the clinical management of multiple drug-resistant (MDR) bacteria-infected DFUs become very challenging. Interestingly, among the modern therapeutics modalities, metal or metal oxide-based nano-formulations and antibiotic-nanoparticles (NPs) assemblies are being debated hotly as an alternative and promising remedy against MDR, globally. Nevertheless, this chapter precisely highlights a landscape of the current trends of NPs based therapies against biofilm-forming MDR bacteria and infected DFUs healing.

## 20.2 Diabetic Foot Ulcer (DFU)

Diabetic foot ulcer (DFU) is a "corollary of snags" of diabetes mellitus (DM) which eventually leads to constrained mobility, amputations, and even death. One of the most vital features of DFS is diminished sensitivity to pain after primary damage. The affected person does not show normal pain-averting manners or respond for "timely urgent help." Besides these, dysregulation in any of the progression's escorts to deferred or non-curable phenotypes as commonly evident in DFUs. Thus, the dysregulated metabolism in diabetics leads the development of adverse secondary pathophysiological outcomes affecting multi-organ system imposing multifaceted complications [11]. DFU is one of the most distressing unremitting complications of diabetes which is developed in 26.1 million people, globally [12]. A DFU is often a low-affair inching, unproblematic surprise that blankets a sudden rising flood of complications in its dark portals. In medical terminology, DFU is defined as a deep tissue inflicted infection, ulceration, and/or destruction allied with neurological aberrations and varying degrees of peripheral vascular disease in the lower limb of the patients with DM. The durational incidence of DFUs arrays from 19% to 34% of total diabetic patients [12]. Estimated 15–25% of the diabetics are at major risk to develop DFUs [13], which may later result in the most dreaded consequence in the 108,000 lower limb amputations performed per year in the USA [4], due to lack effective therapies. The 1-year progression past amputation is poor, resulting in the mortality rate of about 44% [14]. According to Jeffcoate et al. [15], highlighted the practice of effective and advanced wound management therapies can play a crucial role in healing the chronic DFUs up to 59% without amputation.

## 20.3 DFUs Classification

The salient characteristics of ulcers such as location, appearance, size, and depth provide scope to map the progress during healing. Beyond this physical assessment, the chronic wounds, i.e., DFUs are subjected to their etiological verification, for neuropathic, ischemic, or neuro-ischemic symptoms [16], and, hence provide bases to classify the ulcers accordingly [17]. In general, delayed healing effects are assigned to the peripheral vascular complications due to increased wound depth which likely augment infections. Nevertheless, it is a proper classification which addresses the challenges generally faced by clinicians. Albeit, the intriguing field of DFUs prompted the clinicians and scientists to categorized DFUs through proper classification parameters such as (1) location of ulcer, (2) depth of wounds, (3) neuropathy, and (4) ischemia [18] to facilitate interdisciplinary understanding.

Following are the most importantly used classification systems

1. University of Texas classification
2. Wagner-Armstrong grades classification
3. Brodsky depth-ischemic classification
4. International working group classification

### 20.3.1 University of Texas Classification

The classification of the University of Texas (UT) establishes an informative bridge between infection peripheral arterial diseases (PAD) [19, 20]. The UT classification uses numerical 0, 1, 2, and 3 to depict the pre- or post-ulcerative lesions, the involvement of tendon, capsule, and bone, reaching tendon or capsule and reaching bone or joint, respectively. Similarly, alphabets A, B, C, and D are used to indicate the presence or absence of infection and ischemia (A = absence of both, B = infection only, C = ischemia only, D = both).

### 20.3.2 Wagner-Armstrong Grades Classification

Wagner-Armstrong grading classification is an integrated system that explains the deepness of the lesions according to Wagner with precise information on infection and PAD well in accordance with the UT classification. Hence, the collective cataloging is consigned as Wagner-Armstrong classification but readily avoided in case of severe deformities such as ischemia and associated infections [19, 20].

### 20.3.3 Brodsky Depth-Ischemic Classification

Brodsky, a foot and ankle specialist modified Wagner-Armstrong grading classification system highlighting the subtle but accurate differences between the lesions of grade 2 and 3 and the vascularity of foot with respect to the grade of prescribed treatment grade [21].

### 20.3.4 International Working Group Classification

In 2001, the International Working Group (IWG) on diabetic foot devised a risk assessment scheme in order to assure the plausible complications [22]. Later, the IWG devised scheme was widely accepted, predicting, and classifying the diabetics prone to develop foot problems [23].

### 20.3.5 PEDIS Classification System

The PEDIS classification system developed by IWG on Diabetic Foot, to only targets DFUs via three medico-pathological conditions namely wound, infection, and ischemia in well-coordinated evaluation approach [24], however, it lacks a general description of wound, loss of tissue and the limb salvageability. Later, this system was described in reference to specific concerns of infection with an exceptional follow-up scheme in 2012 IDSA (Clinical Practice Guideline for the Diagnosis and Treatment of Diabetic Foot Infections) and 2014 WIfI classification method [25].

### 20.3.6 Kobe Classification

In 2011, the Department of Plastic Surgery, Kobe University, Japan, published a four-level classification system popularly known as Kobe classification. This system is primarily based on the etiology and treatment of [26].

## 20.4 DFU Global Epidemiology

The global prevalence of DM has been estimated around twofold in respect to the threshold line of 2.8% in 2000 to 4.4% by 2030, devastating nearly 350 million individuals [27]. In reference to the diabetes epidemic [28], it can be argued that the increase in DFUs patients is due to the rapid pace growing number of people with DM. Within western countries, approximately 10% of the total population suffers from diabetes [29], at the rate of around 3% and 0.1% per year new episodes of DFUs and active Charcot foot, respectively [30, 31].

Importantly, the prevalence of DFUs is 1.6–6.3% while having lifetime risk about 15–25% [13], indicates that one million of 50 million inhabitants of a country may become DFUs patient lifetime. Surprisingly, alone in USA, the cost of diabetes in 2012 was $245 billion however 43% of total cost spent in the medical care of diabetics. The total medical care expenditures of people living without diabetes are surprisingly 2.3-fold lesser as compared to diabetics [32]. Comparatively, the huge expenditures in diabetes clinical management can be assigned to nearly 6.7 million diabetics who are surviving with DFUs or infections out of 785 million of diabetes-associated outpatient calls between 2007 and 2013 [33].

## 20.5 Etiology and Pathophysiology of DFU

In 1818, Mott provided the first recognizable description of a neuropathic ulcer. According to the description, sole of diabetic's foot experiences (1) hardening of surrounding cuticle, (2) loss of insensitivity to a great level diminishing all modalities of sensation and, (3) palpable ankle pulses with, (4) warm, pink, and the dry foot itself [34]. Due to loss of sensations, a person with diabetes often remains unaware about the formation of lesions until notices the discharge of pus or blood. Nevertheless, the determination of a DFU etiology is carried out by taking primary characteristics of ulcers such as depth, size, appearance, location, etc. Secondly, a lesion is supposed to be categorized neuropathic, ischemic, or neuro-ischemic [35]. The etiology of DFUs is therefore closely integrated with the incidence of peripheral neuropathy and repetitive trauma due to painful walking activities with DFU foot [36], which therefore later leads the structural deformations, compromised joint movements and even partial foot amputations as liabilities of peripheral neuropathy to diabetics. Strictly speaking, in case of the diabetic foot, concentrated pressure area due to abnormal weight-bearing and shear forces enhance the risk of ulcer development [37–39]. In 1983, Brand highlighted that the discrete shear forces

for a long period of time can augment local inflammation, focal tissue ischemia, and destruction, which eventually prompt the ulceration [40].

### 20.5.1 Pathophysiology of DFU

Like multifaceted etiology of DFUs, a normal foot lesion involves simultaneous action of a multicomponent milieu while converting into a chronic DFU [18]. Also, diabetic neuropathy is one of the general complications of diabetes and has emerged as one of the major causes of substantial morbidity and increased mortality [41].

#### 20.5.1.1 Neuropathy

Diabetic peripheral neuropathy (DPN), popularly known as loss of sensation, frequently occurs in diabetics' is one of the most common complications amongst several neuropathic syndromes which is activated as main DFU initiating factor [42]. DPN is a multifaceted entity that encompasses (1) focal and multifocal neuropathies, e.g., mononeuropathy, amyotrophy, radiculopathy, multiple lesions mononeuritis multiplex and entrapment and, (2) symmetrical neuropathies, such as autonomic and acute sensory [43, 44]. According to Tesfaye et al. [45], DPN is a proportional, length-dependent sensorimotor polyneuropathy that induces metabolic and micro-vessel variations in response to exposure chronic hyperglycemia and cardiovascular risk descriptions. Furthermore, the presence of diabetic retinopathy and nephropathy in diabetics suggests that polyneuropathy is an attributable trait for diabetes.

#### 20.5.1.2 Microangiopathy

The functional changes in microvascular function such as endothelial dysfunction and abnormal neurovascular control decrease the blood flow into DFU significantly causing a delay in wound healing [46, 47]. Specifically, the involvement of endothelial proliferation in diabetics can cause arteriolar occlusion [48]. Besides, a wide range of structural and functional abnormalities such as the gaseous and nutrient exchange between blood and tissue cells observed affecting the cutaneous microcirculation across different capillary beds over the disease time [49]. Overall, it can be articulated that the impaired microvascular function affects the direct or indirect healing of DFUs.

#### 20.5.1.3 Delayed Wound Healing

The process of wound healing does meet its end where a wound is closed, but continues till complete healing. In fact, the wound curative mechanism is a highly dynamic process involving the overlapping of hemostasis, proliferation, inflammation, and re-modeling that engrosses multiple cell types (like keratinocytes, endothelial cells, fibroblasts, macrophages, and neutrophils). In DFUs, the deregulation in any of these factors contributes macro- and microvascular, neuropathic, immune functions, and biochemical malfunctions which result significantly in the delay of healing process [41, 50]. Besides these intrinsic factors, the evolution of DFU also

involves some parallel extrinsic aspects such as callous formation, repeated trauma, excessive pressure, and wound infection [51, 52]. Beyond, MicroRNA profiling of epidermis and dermal fibroblasts of diabetic foot skin (DFS) and healthy nondiabetic foot skin (NFS) highlighted the presence of subtle genomic changes such as deregulation of five miRNAs and upregulation of MiR-31-5p and miR-31-3p in DFS [52].

#### 20.5.1.4 Infections

Infection is the most important factor complexing foot ulcer clinical management. However, besides ischemia, many factors such as peripheral neuropathy [53], and vascular insufficiency [54], contribute ulceration in the diabetic foot. For instance, medical occult ulcers form insidiously subterranean to the callus [55, 56]. Besides, an array of soft associated abnormalities including edema, abscess, ulcer, arthritis, and cellulitis were found commonly in the diabetic foot [57, 58]. Furthermore, infected ulcers or soft tissue infections lead to osteomyelitis which extends to the bones [59]. On an average, about 15% of diabetic foots suffer from osteomyelitis [57, 58]. Soft tissue infection is important because >90% osteomyelitis in DFUs results from the spread of soft tissue infection [60]. Besides these, more than 60% of all infections are caused by microbial biofilms [61] as per recent report of the National Institute of Health (NIH). Overall, the severity of infections in DFUs is subjected to their sign and extent of inflammation and depth of infected tissue, as per PEDIS validated classifications of diabetic foot infection and Infectious Diseases Society of America (IDSA). In DFUs, the bacterial infection causes multilayer microbial matrix formation, popularly known as biofilms, provides the resistant to antimicrobials agents and contributes to delaying wound healing [62, 63].

Nevertheless, DFUs generally in diabetics are at greatest risk maintaining microbial infection and hence clinicians evaluate such types of lesions for the possibility of infection [64, 65]. Purulent drainage of pus along with other inflammatory signs including erythema, induration, inflammation, pain, softness is a potential indicator of infection. However clinical signs on juncture contradict the implication and severity of infection. For example, fever at 102 °F indicates the wound is deeper with a serious infection and maintains extensive necrosis, pus, and cellulitis in diabetic foot, whereas, 12–35% patients hospitalized for limb-threatening infection have significant fever [64, 65].

## 20.6 Microbiome and DFU

### 20.6.1 Microbiology of DFU

The DFU microbiome can be defined as the totality of microflora, their genomes, and interactions within multilayered microenvironment commonly known as biofilm. In general, chronic lesions or wounds are prone to develop polymicrobial biofilms which are composed of Corynebacterium, Pseudomonas, and Staphylococcus [66–68]. The DFU microbiome is often regarded as playing pivotal role in delayed

lesion healing [66] by attenuating the antimicrobial effects therapeutic agents potentially by modifying or shielding their respective targets. Recently, Wolcott et al. [69] have studied 2963 microbiomes from chronic wounds including DFUs, and found a large number of anaerobic bacteria while Staphylococcus followed by Pseudomonas as the most prevalent microbes. Besides, Gardner et al. [70] specifically explored the biodiversity and bioburden of the DFU microbiome of 52 patients using 16S rRNA gene PCR method and identified Staphylococcus in about 94% of DFUs and both anaerobes and Proteobacteria to the tune of 100% of these wounds [69]. This study has also highlighted the fact that the diversity DFU microbiome significantly varies as a reduction of anaerobes and Proteobacteria as lesion depth decreases.

Therefore, it would be appropriate to say that the DFU microbiomes possess intrinsic potential to be translated certainly while being influenced by external factors because an open DFU cavity often contains numerous bacteria of either commensal or colonizing nature, some of which holds the capacity of becoming invasive pathogens [71]. Slater et al. [72] have observed that wound depth beyond the bone can yield the recovery of same microorganisms in swab as well as deep tissue samples, whereas, only 65% organisms can be recovered from swab specimens compared to deep tissues cultures with the exemption of Corynebacterium species likely as colonizers or contaminants [73]. Thus, clinicians require standard interpretation criteria for whether a microorganism is potentially invasive or colonizer. At the same time, the limb-threatening infections (LTI) and non-limb-threatening-infections (NLTI) in diabetics also reflected significant microbial diversity. For instance, NLTI with no earlier antimicrobial therapy maintains Staphylococcus aureus and group B streptococci specifically [74–76]. Precisely, S. aureus isolated from NLTI patients also found to accumulate methicillin-resistant (MRSA) in the soft tissue of ulcers as compared to the skin [74]. In 2010, Lipsky et al. [77] have also observed an increase from 11.6% to 21.9% in MRSA prevalence in diabetes patients between 2003 and 2007 [77]. While, LTIs were observed generally polymicrobial in type yielding on an average of 2.3–5.8 bacterial species per deep tissue culture from a single lesion sample including both Gram-positive cocci and Gram-negative rods cells [71, 74, 78–80]. Strictly, MRSA, streptococci, Enterobacter species, Proteus species, Klebsiella species, *Escherichia coli*, and *Pseudomonas aeruginosa* were prominent among these clinical infections. Among the anaerobes, Prevotella species, Pepto streptococcus species and Bacteroides species, including those of the *B. fragilis* group, are more often recovered [81, 82].

### 20.6.2 Biofilm and Antimicrobial Resistance in DFU

The growing concern of antibiotic-resistant strains [83, 84], embedded in highly complex and multicomponent biofilm matrices, has led IDSA (Infectious Diseases Society of America), assigning *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and Enterobacter species as "ESKAPE pathogens" due to ever-changing dynamics of the host and decreasing treatment regimen against them [85]. In general,

*Staphylococcus aureus* (Gram-positive) and *Pseudomonas aeruginosa* (Gram-negative) are assigned as potential biofilm producers in many chronic infections, due to their resistance to antibiotics [86, 87]. Albeit, there is no doubt that the antibiotics can work well provided the bacteria are in their planktonic state. Contrarily, chronic wounds such as DFU often acquire organized aggregates or coexisting clusters of bacteria in biofilm matrices which are comprised of liquid polysaccharides, proteins, and extracellular DNA (eDNA), which constitute the extracellular polymeric substances [88]. Therefore, the formation of biofilms in chronic wounds can be argued as a core reason for the failure of about 65–80% antibiotic treatment modalities and causes delays in wound healing [89–91].

According to Wang et al. [92], despite target specific acceleration of tissue engineering to halt the normal orchestrated and schemed course of wound healing cascades (including hemostasis, inflammation, proliferation, and remodeling), >25% diabetics of survived limb amputation due to chronic DFUs [93, 94]. Recently, Ch'ng et al. have suggested the role of polymicrobial bacterial biofilms as the likeliest reason for delayed healing in prolonged chronic infection [95], by sustaining the influx of pro-inflammatory cells and impede host response parallel [96–98]. The community of bacterial biofilms most commonly composed of *Staphylococcus*, *Pseudomonas*, and *Corynebacterium* [66, 68], and irreversibly adhered to the tissue surface in wounds by getting embedded self-produced extracellular polymeric substances (EPS) matrix [99]. This EPS often shields the bacteria in biofilms to rescue from antibiotics and host innate immune cells in order to create an immediate microenvironment for bacteria to accumulate resistant by either mutation or gene transfer [62]. Precisely, there is >50% higher risk of biofilm formation in chronic wounds in diabetics compared to nondiabetics [89, 100–102], because on an average a >90% of such wounds can provoke excessive inflammation by the activation of immune complexes causing long-standing release of inflammatory cytokines, thus slowing the cutaneous wound healing [103, 104]. Nevertheless, as a usual chronic wound type, DFU does not encompass the normal course of healing cascades due to polymicrobial biofilms infections.

## 20.7 Risk Factor and Prevention of DFUs

### 20.7.1 Risk Factors

Foot ulceration is around 25% high [13] and 40–80% frequent [105] in diabetic patients causing a huge risk of morbidity and mortality. The study of Lavery et al. [106] highlighted the peril of hospitalization with the lower-extremity amputation reported to be approximately 56-fold and 155-fold higher in diabetics with DFUs compared to diabetics without DFU, respectively. Furthermore, according to the Centre for Disease Control and Prevention, alone in the USA, diabetes has become a devastating complication causing blindness in adults at an average rate of 24,000 individuals per year [107], whereas, around 43% diabetics enter for dialysis and transplantation [108]. Besides, twofold to sixfold diabetic population is more likely

to develop risk of heart disease, whereas and twofold to fourfold more likely to have a stroke as compared to nondiabetics. Drastically, diabetes can result in 15-fold to 40-fold greater risk of amputations in diabetics compared to nondiabetics which were estimated the loss of 82,000 limbs per year due to diabetes [109]. Typically, in diabetics, the epidemiology of individual risk factors such as diabetic peripheral neuropathy (DPN) an impairment of nerves that alters autonomic, motor, and sensory functions [42], the compromised vascular system believed to contribute both macro- and microvascular peripheral vascular disease, resulting in ischemic limb because of the abridged healing capacity of wounds itself [110], and musculoskeletal deformities such as a presence or absence of hammertoe or bunion play a major role in ulceration pathway in respect to negative and positive pressure and friction [111].

### 20.7.2 Treatment Modalities

Treatment of DFU infections is a complicated and economically cumbersome job that requires long-term medications and hospitalization. Indeed, treatment of DFU infections is teamwork including experienced physicians, surgeons, podiatrists, and competent and trained dressing nurses. Therefore, an average treatment cost of a DFU with Wagner grade I in five industrialized countries was estimated at $3096 in 2010; however, if complications come to amputation, the cost will rise to almost $107,900 [112]. Beyond, evaluation of DFUs begins with a detailed clinical history and physical examination. The standard wound care however is a multifaceted procedure which includes debridement, unloading of DFU, use of appropriate antibiotics schedules, and advanced dressings, etc. However, the superficial topical dressings, lotions, ointments, and acellular matrices may proffer some advantages depending on the wound environment, but many wounds deserve refined and sophisticated therapies in addition to the standard curative modalities to accomplish complete wound closure [113]. Nevertheless, the latest treatment modalities are based on necrotic debris removal, infection control, and relieve in chronic pressure on DFUs. In addition to antibiotic therapy, the treatment of DFUs has been developed through bioengineered tissue engraftment in order to accelerate the wound healing process by releasing required growth factors, cytokines, and other proteins adequately [114]. Also, the less toxic, hazardous, and expensive biomaterials accelerate wound healing and control infection, which can be envisioned as novel treatment modality [115]. Both synthetic and natural polymers are underlined to investigate their intrinsic therapeutic potential to trigger the regeneration of damaged dermal and epidermal tissues [116].

Besides, in view of antibiotic based treatment modalities, advanced technologies such as DNA microarray and multiplex real-time PCR are in use nowadays to analyze both virulence and resistance of microbial strains [117, 118]. Thus, systemic antibiotic therapy is required to control DFU infection clinically but not appraised as the lone cure [120–122]. To date, different systemically active antibiotic agents such as ertapenem, linezolid, doripenem, dalbavancin, ceftobiprole, tigecycline, or daptomycin [123–126] have shown significant antimicrobial activities against the bacterial isolates of DFU.

### 20.7.3 Preventive Management

Diabetes patients unfortunately develop multiple complications such as peripheral vascular disease, chronic renal disease, ulcerations, gastrointestinal diseases, or cardiac diseases. Therefore, an organized multi-disciplinary DFU care team is needed to manage the prevention and cure of diabetes patients via predictive, preventive, and mechanistic strategies. In view of historical background, Dr. Elliot P. Joslin (Joslin Diabetes Centre, USA established in 1952) reviewed that DFU complications deserve a team of specialists in order to manage DFU infections [127]. This is very obvious since the ultimate target is the complete healing of wound and limb salvage while curing DFUs. However, there are several inexpensive and feasible strategies which can play a crucial part in the clinical management of DFUs such as, (1) assembling of a competent diabetic foot care team, (2) strong commitment to delivering the highest quality health care, (3) psychosocial and educational trainings for to DFUs and, (4) underscoring the role of footwear and the state of the art techniques in the prevention of DFUs.

Generally, the term "quality health care" is the indicator of quality assurance essentials which reflect the commitment of "undertaking the right thing at the right time in the right way for the right person" intending to have the best achievable results [119]. According to this quality paradigm, the quality care of DFU patient, in fact, encompasses via four matrices and the three of them are process-based channels, namely the evaluations which provide adequate facilities at the correct time and the apt accomplishment of the services. The fourth evaluation requires the "best results" outcome assessment [128].

Beyond, individuals with diabetes and DFUs face traumatic events such as elevated levels of mental stress, anxiety, feeling of helplessness, and temporary conditions of cognitive perplexity while going through the course of diabetes [129, 130]. Specially, the four periods merit unique mention like the onset of diabetes, maintenance, and prevention of health, early commencement of complications, and the phase of illness where complications dominate [130, 131]. Therefore, motivation and patients' trainings to create adequate skills to take care of itself play a vital job in the prevention of DFUs. In fact, diabetes patients with DFUs must understand all the instructions of DFUs preventive and caring guidelines.

Furthermore, diabetes and diabetes complications provoke progressive developments in foot structures and their functions. The morphological changes majorly observed in the tissues of foot–ankle complex [132–134]. Precisely, these changes in tissues affect the tendons and ligaments, cartilage, muscles, peripheral sensory system, skin, foot morphology, and patient's weight due to a complex cascade of intrinsic events. Besides these, for instance, if a diabetic is seriously compromised, the most important challenge is the prevention of ulcerative infections. For this, the primary preventive measure to be taken is dialog with the patient for proper, containment, and shielding footwear rather than remedial. According to peripheral neuropathy based investigations, the proper footwear is intended to (1) redistribute the plantar pressure in order to shun highly localized and contained pressure peak, (2) reduce the friction and abrasion, (3) deterrence of mechanical and thermal trauma

and (4) the restoration or maintenance of foot function during walk. Thus, the function of footwear in the avoidance of diabetic foot complications is taken as a serious preventive action.

## 20.8 Nanotechnology as an Innovative Approach for Accelerating Wound Healing in DFU

### 20.8.1 Nanotechnology and DFU

As defined by the World Health Organization (WHO), Diabetic foot is an "ulceration of foot associated with neuropathy and different grades of ischemia and infection" that leads to tissue breakdown. Treatment for diabetic foot ulcer includes dressings, infection management with antibiotics, wound debridement, off-loading, and surgical revascularization [135, 136]. Recently, modern approaches to wound dressing received great attention. These dressing can release peptides, therapeutic agents, growth factors (GFs), stem cells, and other bioactive substances that afford the favorable microenvironment for successful healing and curing by controlling wound humidity and soaking up excess exudates.

Such dressings could reduce inflammatory cytokines and excessive protease levels while amplifying the GFs in the wound biochemical environment, thus, decreasing tissue degradation and enhance tissue formation [137]. However, in developing countries, people still use natural substances (herbs, plant extracts, honey) in the treatment of infections including diabetic wounds. In cases of persistent DFU conditions that do not respond to standard treatment procedures, skin grafting including autograft, allograft, xenograft, and bioengineered skin substitutes (artificial skin), are considered as alternative options [138]. Despite these interventions, approximately 40–70% of chronic ulcer patients remain unhealed. For the patients with impaired or delayed wound healing ability, new strategies/methods need to be developed for the acceleration of wound healing process, decreasing the infection and reduction in the scar formation.

During the past few decades, nanotherapeutics have emerged as one of the promising strategies to overcome the chronic and persistent nature combined with the associated complications of non-repairing wounds. Nanoparticles (NPs) facilitate the targeted delivery of active drugs that are usually not bioavailable in vivo due to short half-life, poor solubility, and/or leakage from the spot of the wound. The major advantage of nanoparticles-based treatment is the high surface area to volume ratio which increases the degrees of probability of interaction with biological target and offers improved penetrating ability to the wounds. Nanoparticle-based drug delivery allows a controlled release of the drug that let the continuous interaction between drug and target. There are two key criteria of nanomaterials employment in wound healing: (1) nanomaterials with inherent therapeutic properties advantageous for wound healing (2) nanomaterials as delivery medium for therapeutics. Silver, gold, copper, zinc oxide, cerium oxide, yttrium oxide, titanium dioxide, carbon-based nanoparticles and nanoparticles bearing nitric oxide are most studied

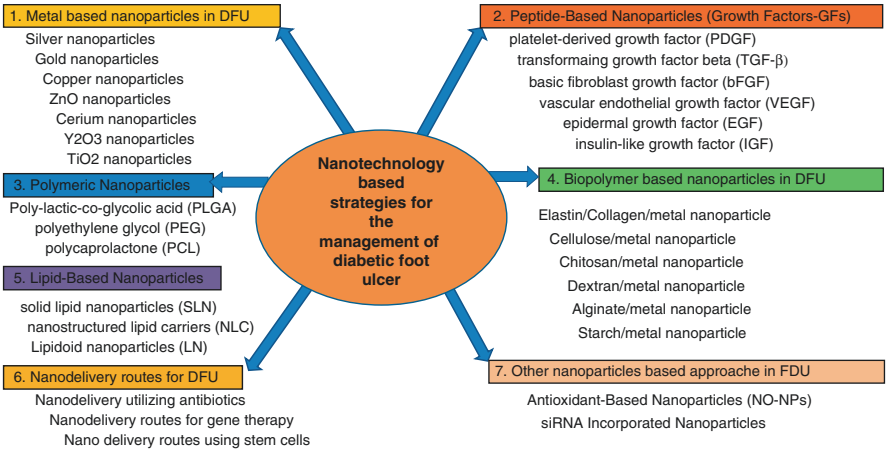

**Fig. 20.1** Various nanotechnology-based strategies and approaches for the treatment and management of diabetic foot ulcer

metallic and non-metallic nanoparticles for wound healing due to their inherent antibacterial properties. Different nanotechnology-based strategies for the treatment, cure, and management of diabetic foot ulcers have been shown in Fig. 20.1.

## 20.8.2 Nanoparticles for Treatment of DFU

### 20.8.2.1 Metal Nanoparticles and DFU

Silver nanoparticles (AgNPs) are the most studied nanoparticles in wound care management because of their known antibacterial effects [139]. The antibacterial effects of Ag are mediated by the interaction of $Ag^+$ with three main constituents of the bacterial cell viz. (1). peptidoglycan composed cell wall, (2) bacterial DNA and, (3) proteins and enzymes involved in essential cellular processes such as electron transport chain (ETC). In addition, AgNPs have shown to be anti-inflammatory in property and promotes wound healing by reducing the release of cytokine, thereby, decreasing the infiltration of lymphocyte and mast cell [140, 141]. Dressing impregnated with AgNPs have shown to be efficient in wound healing in diabetic mice [142]. Likewise, gold nanoparticles (AuNPs) have been widely studied for medical applications. Leu et al. [143] combined AuNPs with the antioxidant epigallocatechin gallate (EGCG) and α-lipoic acid (ALA) hastening the diabetic wound healing by the regulation of inflammation and angiogenesis. In another attempt, researchers synthesized antimicrobial Au nanodots that inhibited the growth of MDR bacteria and promoted healing in the rodent wound model [144]. The antimicrobial peptide surfactin was found to be self-assembled on Au nanodots by hydrophobic interactions with the molecules of 1-dodecanethiol that served as the capping agent on the Au nanodots. The NPs demonstrated much higher antibacterial wound healing effect against MDR bacteria (like methicillin-resistant *S. aureus*) infected wound

than the free surfactin. This enhanced effect is due to the capability of the fabricated NPs to disintegrate the bacterial membrane. Copper NPs (CuNPs) have also gained special attention in managing diabetic foot ulcer infection. Recently, Xiao et al., synthesized copper-based metal-organic framework NPs (Cu-MOFNPs), which are known to degrade rapidly in protein solutions, can be customized for slow release of $Cu^{2+}$, minimizing its toxicity and improving its efficacy of healing DFUs. Incorporation of folic acid with Cu-MOFNPs enabling the controlled release of $Cu^{2+}$ enhanced biocompatibility [94].

#### 20.8.2.2 Metal Oxide Nanoparticles and DFU

Metal oxide NPs (ZnO, $TiO_2$, $CeO_2$, and $Y_2O_3$) are among the most attractive options for DFU as they are comprised of essential mineral elements for the human body. ZnO NPs are effectively used for wound healing as their own strong antibacterial properties and can stay at the wound site for a longer time period, thus, escalating the healing process. In a recent study, Steffy et al. [145] biosynthesized ZnO nanoparticles that displayed strong bactericidal properties against multidrug resistant strains isolated from DFU. $CeO_2$NPs have strong free radical scavenging properties [146]. Further, Ce atom has dual oxidation state +4 and +3, meaning that its reduction from the oxidation state of $Ce^{4+}$ to $Ce^{3+}$ resulting in oxygen vacancy. This improves the potential of the $CeO_2$NPs of healing DFUs followed by free radical scavenging activity. $Y_2O_3$NPs are nontoxic to neutrophils and macrophages. Also, $Y_2O_3$NPs require maximum free energy for the formation of oxide from yttrium than other metal oxides, hence it is considered for the treatment of DFU [147].

#### 20.8.2.3 Biopolymer Based Nanoparticles in DFU

##### 20.8.2.3.1 Cellulose and Its Derivatives/Metal Nanoparticle for DFU

The wound healing ability of cellulose is reported in several studies as it can accelerate the healing process via the release of numerous growth factors (GFs). Cellulose-based materials integrated with antibacterial and antimicrobial agents are designed which can be used for healing diabetic wounds. Cellulose acetate nanofibers embodied with AgNPs were used as wound dressing showed high production of collagen ensuring its use as wound healing material [148]. Bamboo cellulose nanocrystal based nano-bio-composite hydrogels soaked with AgNPs effectively heal diabetic wound in mice by decreasing inflammation with concomitantly generating collagen [149]. A bacterial cellulose incorporated with AuNPs was also studied as a healing material prepared as nanocomposites [150]. These nanocomposites material showed magnificent antibacterial properties with outstanding moisture retention ability.

##### 20.8.2.3.2 Chitosan/Metal Nanoparticle for DFU

Chitosan is a cationic polymer that can interact with anionic components of microbial cell membranes resulting in the disruption of the membrane and other intracellular constituents. A fusion composite of PLGA NPs entrenched in chitosan

nanofibers was studied to deliver dual growth factors (VEGF and PDGF) exhibiting improved wound healing via VEGF mediated angiogenesis and PDGF interceded tissue regeneration [151]. AgNPs collagen/chitosan scaffold [152], scaffold containing colloid Au/chitosan [153], chitosan-based Cu nanocomposite [154] are also studied for their wound healing application.

#### 20.8.2.3.3 Dextran/Metal Nanoparticle for DFU

Dextran based hydrogels are very soft and pliable and were able to encourage complete skin regeneration without any addition of GFs and cytokines [155]. AgNPs incorporated dextran hydrogel was tested against Bacillus cereus for its antibacterial effect and concluded to be an effective antibacterial material with adequate biocompatibility and biodegradability [156]. Păunica-Panea et al. [157] prepared dextran and collaged based composite incorporated with ZnO as antimicrobial agent having potential for skin regeneration and wound healing.

#### 20.8.2.3.4 Alginate/Metal Nanoparticle for DFU

Alginate is a biopolymer that is readily used in the treatment of diabetic wound incorporation of NPs on alginate-based hydrogel that has been reported to improve wound healing process. Mohandas et al. [158] developed alginate hydrogel/ZnO NPs composite bandage. The prepared nanocomposite exhibited improved antibacterial activity and enhanced.

#### 20.8.2.3.5 Elastin/Collagen/Metal Nanoparticle for DFU

Akturk et al. [159] designed composites of collagen/gold nanoparticles for rapid wound healing and in vivo study showing that the gold nanoparticles were biocompatible with the cells of skin tissue. The scaffolds of elastin and silk fibroin have been developed for the treatment of burns and it was found that porous scaffolds were mechanically stable, biocompatible, and most importantly mimicked the properties of extracellular matrix (ECM). Further, it has been tested and found that these porous structures accelerate and improve the healing and finally confirmed that it suits excellent wound healing material [160]. Kawabata et al. [161] developed a novel wound healing material in form of silk elastin sponge. In vivo study shows that silk elastin fastens the healing process and thus it can be applied to various wounds that are difficult to treat with the aqueous solution [161].

#### 20.8.2.3.6 Starch/Metal Nanoparticle for DFU

Starch is a carbohydrate biopolymer macromolecule and found in abundance in potato, rice, wheat, cassava, and maize. Due to its biocompatible nature, easy availability, low cost, renewability, nontoxic and thermoplastic nature, it is used in various biomedical applications such as drug delivery systems, stents, scaffolds of tissue engineering, orthopedic surgery, and bone cement [162–166]. Antimicrobial hydrogel containing starch coated with copper nanoparticles has been developed by Villanueva et al. [167] exhibit a great potential of using it as wound healing material.

### 20.8.3 Lipid Based Nanoparticles

There are various lipids based NPs which show promising effect against chronic wounds. Nanostructured lipid carriers (NLC) and Solid lipid nanoparticles (SLN) are potent drug delivery systems attracting much interest as efficient and nontoxic carriers for various active compounds [168–172]. These nanoparticles have been tested in vivo for topical administration of growth factors by administering recombinant human epidermal growth factor (rhEGF) encapsulated SLN and NLC. These NLC-rhEGF and SLN-rhEGF showed enhanced efficiency of encapsulation and a faster rate of wound closure [173]. Wound dressings embedded with Ag sulfadiazine loaded SLNs were developed in the treatment of skin lesions [174]. Furthermore, SLNs have been tested for delivering other bioactive molecules such as opioids like morphine [175], resveratrol [176] for wound healing [177, 178]. PLGA NPs were used to transport rhEGF for the enhancement of the closure of full-thickness diabetic wounds [179]. Proteoliposome was also tested to deliver growth factor co-receptors along with growth factors that showed increased re-epithelization and angiogenesis [180]. Phenytoin-loaded lipid nanostructured carrier was found to be enhancing the healing of neuropathic DFUs [181].

### 20.8.4 Antioxidant Based Nanoparticles (NO-NPs)

The biomedical application of nitric oxide (NO) in the treatment of chronic ulcers has emerged because of their antibacterial and antibiofilm activity against a number of bacterial sp. It has been reported that NO induces angiogenesis, re-epithelialization, fibroblast, and collagen synthesis and increases the level of growth factors and inflammatory cells [182]. Blecher et al. [183] reported that post-topical application of NO-NPs in diabetic mice, NO-NPs accelerated the closure of the wound with high level of blood vessels, increased content of collagen fibroblasts and reduced inflammatory cells. In a similar in vivo study, it has also been reported that NO-NPs hasten the wound healing, mediate propagation, and resettlement of fibroblasts with increased collagen expression and elevate the level of anti-inflammatory cytokines along with TGF-β (transforming growth factor-beta) in diabetic mice [184].

### 20.8.5 siRNA-Based Nanoparticles

Kasiewicz and Whitehead [185] investigated that the topical application of siTNFα-loaded LNPs compacted the expression of TNFα in nondiabetic wounds by 54% at 500 nM dose, whereas 250 nM affected about 43% gene silencing in diabetic mice and they observed that the siTNFα-loaded LNPs closed the wound in diabetic mice faster than control wounds by reducing the duration and severity of chronic diabetic wounds [185]. In another study, Kasiewicz and Whitehead [186] reported that lipidoid loaded-siTNF-α NPs downregulates the TNF-α and MCP-1 expression and accelerate the closure of DFUs. Kim and Yoo [187] developed MMP-2

siRNA-incorporated linear polyethylenimine (LPEI) complex onto a nano-fibrous mesh which efficiently suppressed the level of MMP-2, promoting and accelerating the wound healing in diabetic murine wounds [187]. Randeria et al. [188] constructed GM3S (ganglioside-monosialic acid 3-synthase) thiolated-siRNA conjugated with AuNPs. The constructed GM3S SNA, efficiently accelerated the relocation and propagation by diminishing the level of ganglioside GM3S and, consequently accelerating the wound healing in type 2 diabetic wound model.

## 20.9 Nanodelivery Routes for DFU

### 20.9.1 Nanodelivery Utilizing Antibiotics for DFU Treatment

Treatment of DFUs through antibiotics faces several challenges due to the increase in antibiotic-resistant strains. Reformulations of antibiotics using nanoparticles provide a promising solution against antibiotic resistance, toxicity stability, and solubility. Chakraborty et al. [189] tested the efficacy of folic acid coupled nano-sized-chitosan vehicle loaded with drug vancomycin against drug-resistant *S. aureus*. As folic acid is a vital nutrient required for nucleotide synthesis by bacteria, it mediates the transport of vancomycin loaded chitosan nanoparticles into the cytoplasm via endocytosis. Chitosan, gelatine, and EGCG NPs have been incorporated in polyglutamic acid and gelatin hydrogels enclosing activated carbon fibers with gentamicin, to create a wound dressing for enhancing rejuvenation and inhibition of microbial growth [190].

### 20.9.2 Nanodelivery Routes for Gene Therapy in DFU

Sustained gene delivery therapy has attracted many researchers as a promising option for the treatment of DFU. The gene therapy can deliver growth modulating genes to the cells at the wound site, thus assist in the improvement of the reparative process. Several nonviral vectors such as PLGA and others have been developed to improve the efficiency of gene therapy [191].

### 20.9.3 Nano Delivery Routes Using Stem Cells in DFU

It has been suggested that the amalgamation of stem cells props up angiogenesis and re-epithelialization in chronic wounds [182]. The nanotechnology-modified stem cells showed enhanced and improved production of hVEGF, cell viability, and engraftment into the target tissues. After implantation of scaffolds seeded with VEGF-expressing stem cells (hMSCs and hESdCs), about twofold to fourfold higher vessel concentration was observed in comparison to the control cells. It has been suggested that direct delivery of MSCs (mesenchymal stem cells)/nano scaffold to the wound can induce the fast death of the cell [192]. Hamdan et al. [193] proposed that

the nano scaffold/BM-MSC (Bone marrow-derived mesenchymal stem cells) nanocomposite exhibits useful novel advance for wound cure and skin generation in acute full-thickness skin wounds [193]. Thus, nanotechnology-based delivery of stem cells may play an imperative role in the therapeutic management of DFU [191].

## 20.10 Conclusion and Future Prospects

In conclusion, it is observed that the microbial infections, accumulation of bacterial biofilm, and development of chronic ulceration in diabetics are coherent events which all together lead complicates the treatment of DFUs. Furthermore, the accumulation of MDR in causative bacterial strains has accentuated the challenges of DFUs treatments. Systematic reviews on DFUs treatment highlights that clinical management is a huge economic burden, globally. Recently, nanotechnological-based nano-formulation and nanodelivery techniques using nanoparticles have revolutionized the medical field for the diagnosis and treatment of various microbial infections and other diseases. The various nanodelivery systems such as nanoparticles drug delivery systems, peptides-based delivery systems, biopolymer-based systems, polymeric gene delivery systems, stem cell delivery systems, and free radical scavenging systems by exploring nanotechnology are found to be very effective and gained worldwide popularity as an alternative for the treatment of bacterial infections and DFUs. Therefore, the summary of nano-formulations development and their remedial impacts against MDR and wound healing presented herein encourages the clinicians and researchers to device novel yet inexpensive, less risky, and more promising antibacterial formulations.

# Correction to: Nanotechnology and Diabetic Foot Ulcer: Future Prospects

Mohammad Azam Ansari, Khursheed Ali, Zeba Farooqui, Hanan A. Al-Dossary, Mohammad Zubair, and Javed Musarrat

**Correction to:**
**Chapter 20 in: Mohammad Zubair et. al.,**
**Diabetic Foot Ulcer: An Update,**
**https://doi.org/10.1007/978-981-15-7639-3_20**

The book was inadvertently published with an incorrect spelling of the author's surname name in Chapter 20 as Mussart whereas it should be Musarrat. This error has now been corrected with this erratum.

The updated online version of this chapter can be found at
https://doi.org/10.1007/978-981-15-7639-3_20

M. Zubair et al. (eds.), *Diabetic Foot Ulcer*,
https://doi.org/10.1007/978-981-15-7639-3_21
