

Non-Conservative Management of Chylothorax

18

Hyo Yeong Ahn and Hoseok I

Abstract

Chylothorax is caused by lymphatic leakage, which can develop after thoracic surgery and is associated with cancer. Although prospective randomized trials have not been performed, radiological interventions have been performed in several cases with persistent chylothorax, adjunct to 2 weeks of conservative management. The success rate of such interventions is diverse due to anatomical variations, although the results are promising. However, in cases of treatment failure after cycles of interventions, a team approach may be necessary to determine whether surgical management is warranted.

Keywords

Chylothorax · Management · Intervention Surgery

18.1 Introduction

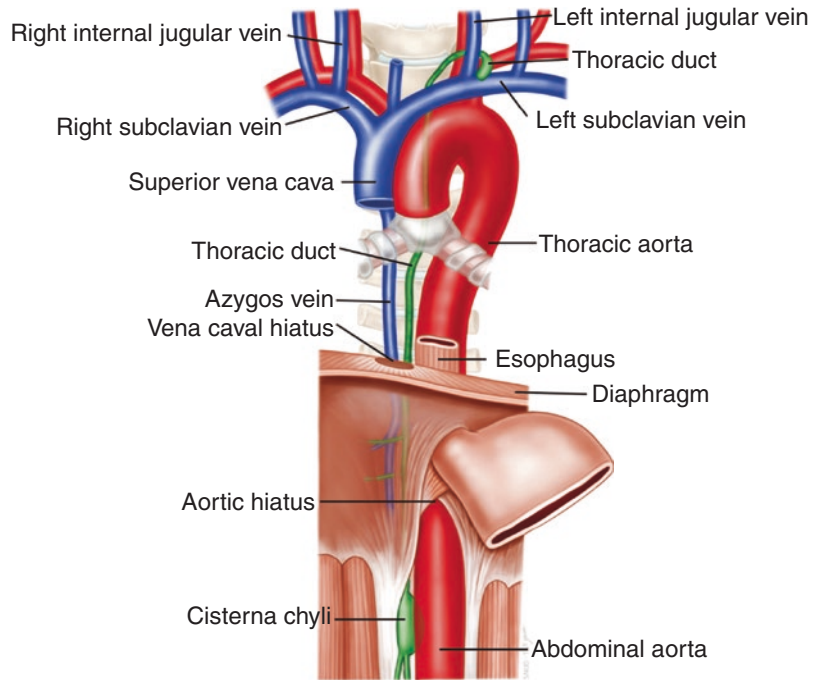

Chylothorax refers to a collection of chyle in the pleural cavity due to leakage from the lymphatic vessels, especially from the thoracic duct. The classification of chylothorax depends on its etiology (traumatic, non-traumatic, or idiopathic). Regardless of the cause, the medical and surgical options to reduce lymph leakage for patients with chylothorax are similar to those for patients with high-flow chylothorax (>25 mL/kg/day) [1–8]. If even repeated interventions are not effective, surgical treatment might be the last option [7, 9, 10]. In the event that surgical management fails, conservative management may be continued until leakage ceases. Unfortunately, the comparison of outcomes between conservative and surgical treatment is limited by the insufficient number of patients with chylothorax for prospective studies to be conducted [7, 8]. In this article, the anatomy of the thoracic duct and the etiology, diagnosis, and treatment of chylothorax are discussed.

18.2 Anatomy

The thoracic duct drains the cisterna chyli, located on the right side of the thoracic vertebrae, which continues on the left from the level of T4 and drains into the left innominate vein (Fig. 18.1). Variations have been observed in more than one-third of the population [2, 9, 11].

Fig. 18.1 Anatomy of the thoracic duct. From the cisterna chyli, the thoracic duct crosses the diaphragm at the aortic hiatus at the level of the 12th thoracic vertebra, and continues to ascend between the thoracic aorta on the left and the azygos vein on the right. It crosses over to the left side between the fourth and sixth thoracic vertebrae. Finally, it ascends behind the aortic arch and the left subclavian artery

These anatomic variations are the underlying cause of the diversity of intervention success rates [2, 9, 11]. Moreover, there is a high risk of tearing along the course of the lymphatic pathway during esophagectomy and lymph node dissection due to the proximity of the course of the thoracic duct to other structures [1, 12, 13]. Any tear in the thoracic duct can quickly lead to the accumulation of large volumes of lymphatic fluid, since it usually transports around 2–4 L of chyle per day [11].

18.3 Etiology

The etiology of chylothorax can be classified as involving traumatic or non-traumatic injuries to the thoracic duct, although idiopathic chylothorax can also occur [4, 6, 14].

Traumatic Causes (50%)

Direct injury to the thoracic duct, particularly during thoracic surgery (e.g., esophagectomy and lymph node dissection), is the most common

cause of traumatic chylothorax. Other traumatic causes include blunt trauma or penetrating injuries [4, 6, 14].

Non-Traumatic Causes (45%)

In cases of non-traumatic chylothorax, direct infiltration or impeded flow caused by compression and accumulation leads to filtration of the lymphatic vessels. Relatively impeded flow can occur if there is increased lymph production, such as in patients with increased central venous pressure or those with liver cirrhosis and portal hypertension. Chylothorax can develop idiopathically in up to 6% of cases [4, 6, 14].

18.4 Diagnosis

The presence of chylomicrons, measuring approximately 0.5–1.0 μm in size, needs to be confirmed in the pleural fluid. Alternatively, chylothorax can be established by triglyceride content >110 mg/dL and a cholesterol concentration <200 mg/dL. A triglyceride concentration of

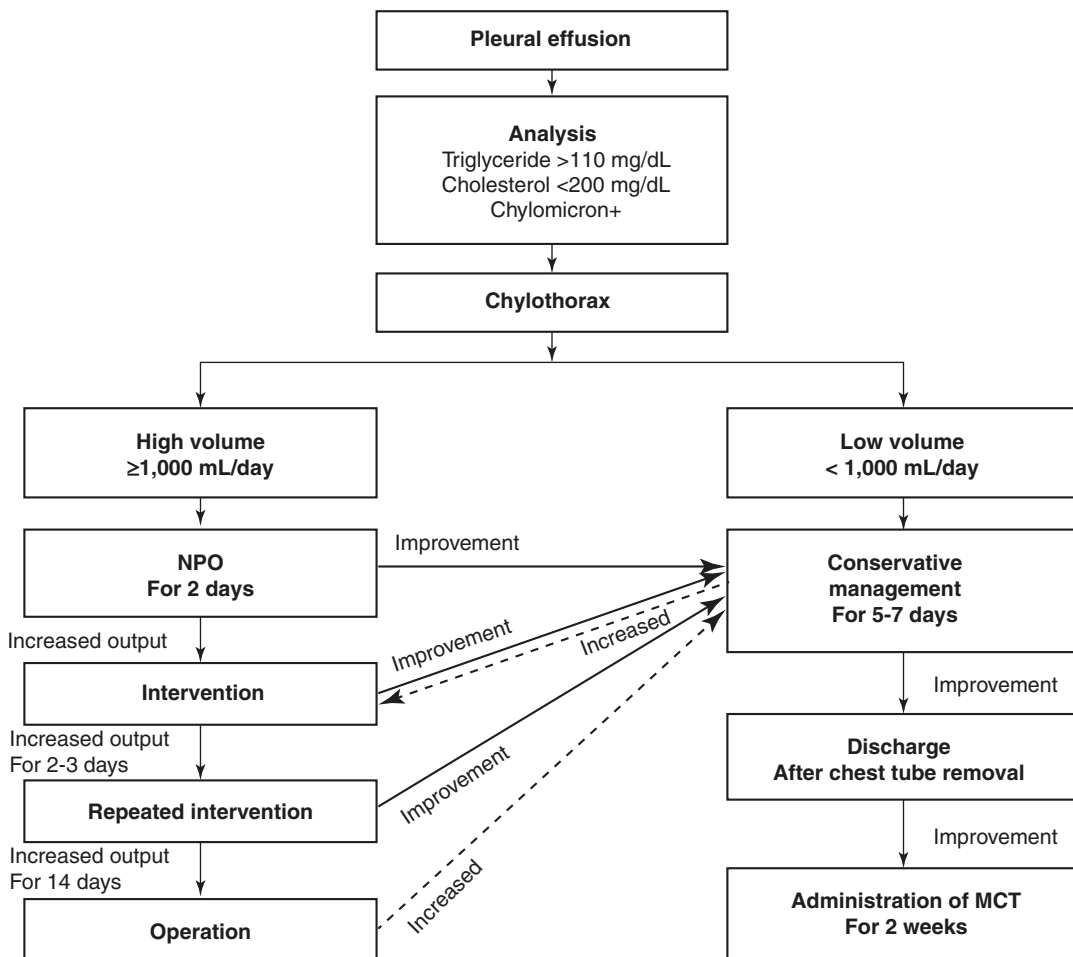

Fig. 18.2 Algorithm of chylothorax management. *MCT* medium-chain triglyceride

<50 mg/dL rules out chylothorax. The differential diagnosis includes pseudochylothorax, which is characterized by low triglyceride content, a cholesterol concentration of >200 mg/dL, and the absence of chylomicrons (Fig. 18.2).

has ensured a systematic and timely process to deliver treatment (Fig. 18.2). Further randomized trials need to be conducted to establish a consensus on chylothorax management.

18.5 Treatment

The appropriate treatment method depends on the etiology and amount of chylothorax. Traditionally, conservative treatment is first administered [7, 9, 13–15]. However, in patients with high-volume chylothorax, the timing of appropriate interventions is important. The development of therapeutic methods and an algorithm

Conservative Treatment

Indications

Conservative management is considered the first-line modality for all patients with chylothorax [7, 9, 13–15].

Methods

Nothing by mouth or a diet containing medium-chain triglycerides (MCT) reduces the flow of

lymph and may allow spontaneous closure of the leak in the thoracic duct [7, 9]. Adequate fluid and electrolyte replacement with proper nutrition should follow. Additionally, pleural drainage may be done for lung re-expansion and pulmonary function optimization. The administration of octreotide may be considered if drain output persists [16].

Prognosis

The resolution rate after conservative treatment ranges from 16% to more than 75% [7, 9]; however, this figure is lower in patients with high-volume chylothorax (>1000 mL/day). In the event of marked drain output reduction under conservative treatment, a good therapeutic outcome can be achieved after a few weeks of a strict MCT diet.

Interventional Treatment

Indications

Lymphangiography is advisable for almost all patients with persistent chylothorax for the identification of the level of the tear. This applies for both traumatic and non-traumatic chylothorax [4, 6, 11, 16–18].

Methods

Resolution of the thoracic duct leak spontaneously occurs in up to 50% of cases [4, 6, 11]. However, lymphangiography is advisable for the occlusion of chyle fistulas, as has been reported in some cases.

Thoracic Duct Lymphangiography

Thoracic duct lymphangiography, which is performed intranodally via the bilateral inguinal or femoral lymph nodes (Fig. 18.3a–d) [4, 16, 18], requires a 26G needle and a short catheter (Cook, Bloomington, IN, USA) fitted to a luer-lock syringe containing 3–5 mL of lipiodol. Ultrasonography and intermittent fluoroscopy are used to confirm intranodal lymphatic vessel puncture and to guide the subsequent injection of lipiodol at 3 mL/min, respectively. If nodal rupture occurs

during the injection, the upper lymph nodes may be directly punctured under fluoroscopic guidance to continue lipiodol administration, which is ceased after the opacification of the lumbar duct or cisterna chyli. The total amount of lipiodol is limited to 20 mL to minimize the risk of pulmonary fat embolism.

Thoracic Duct Embolization

Prior to the procedure, the duct and its adjacent structures (e.g., the aorta) are visualized with cone-beam computed tomography. Thoracic duct embolization is performed by gaining access to the thoracic duct via direct puncture of the lumbar duct or cisterna chyli with a 21G Chiba needle through the transabdominal route [2, 14, 19]. After transabdominal puncture of the cisterna chyli, a 0.018-in. (0.46 mm) Transend guidewire (Boston Scientific Corp., Natick, MA, USA) is used to enter the thoracic duct and is advanced further before the introduction of a 2.0 F or 2.2 F microcatheter (Terumo, Tokyo, Japan), employing an over-the-wire technique (Fig. 18.3e, f). Digital subtraction angiography, aided with a microcatheter, is used to establish the chyle leakage sites, which are then subjected to Concerto microcoil embolization (Medtronic, Jacksonville, FL, USA) proximal to the leakage sites and embolized using a mixture of *N*-butyl cyanoacrylate (NBCA, Histoacryl; B Brown, Melsungen, Germany) and lipiodol (weight ratio 1:1). Coil embolization is done to prevent NBCA migration to the left subclavian vein due to the longer NBCA polymerization time in the lymphatic vessels than in the blood vessels. Lipiodol is injected after establishing needle access to the lymph node. Fluoroscopic images of the cisterna chyli are obtained, and under fluoroscopic guidance, the cisterna chyli is directly punctured using a 21G Chiba needle. A 0.018-in. (0.46 mm) guidewire and microcatheter are used to cannulate the thoracic duct, which is then embolized using Concerto 3EA microcoils and an NBCA/lipiodol mixture (weight ratio 1:1). This procedure has a success rate of over 90% in chylothorax cases [1, 2, 4, 14, 19, 20].

a guidewire, (d) digital subtraction angiography to define the chyle leakage site, (e) microcoil embolization above the leakage site, and (f) embolization using an *N*-butyl cyanoacrylate and lipidol mixture

Needle Disruption

Needle disruption to reduce lymphatic flow may be performed in cases of small prevertebral lymph vessels, which are anatomic variants in 30% of patients [2].

Transjugular Intrahepatic Portosystemic Stent Shunt

In hepatic chylothorax, transjugular intrahepatic portosystemic shunts may be considered to reduce lymphatic flow [21].

Prognosis

Due to occurrences of non-traumatic chylothorax in patients with underlying diseases, the success rate of interventions is lower than that of traumatic chylothorax [4]. The reported overall success rate in non-traumatic chylothorax management ranges from 27 to 68% [6, 8, 11]. Radiologic intervention might still be considered relatively safe and effective as some studies have reported complication rates of 3% and no critical complications [6, 8, 11].

Surgical Treatment

Indications

Surgery might be the last option if the leak persists for more than 2 weeks, even with conservative treatment or a radiological intervention, or if there is a high-volume chyle leak of more than 1000–1500 mL/day [10, 21–25].

Surgical Methods

Surgical techniques include thoracic duct ligation, mass ligation of the tissue, pleurodesis, and pleuroperitoneal shunting [10, 21–25]. Thoracic

duct ligation is performed by ligating or clipping above the right diaphragm, between T8 and T12, regardless of the surgical site (Fig. 18.4). Preoperative administration of olive oil, ice cream, or heavy cream may be done for better identification of the tear site. Alternatively, mass ligation of tissue around the presumed course of the thoracic duct may be considered. As a way to approach the thoracic duct, direct vision might be generally considered; however, in selected cases, video-assisted thoracic surgery could be another option [21, 24, 25]. If the aforementioned operations are not practically feasible, pleurodesis may be performed to induce inflammation and subsequent adhesion between the visceral and parietal pleura. If leakage persists after performing the above-mentioned procedures, insertion of a pleuroperitoneal shunt or external permanent drainage should be considered [10, 21–25].

Prognosis

Generally, surgical interventions have a success rate of approximately 90%, with complications occurring in up to 38.3% of cases [10]. Considerable mortality rates of up to 25% have been reported [10, 25].

18.6 Conclusion

The development of other interventional methods for chylothorax management is limited by individual competency levels. According to the authors' personal observations in the past 4 years, there is a learning curve for the performance of these procedures at our center. Additionally, anatomic variants of the cisterna chyli or lymphatic vessels have fewer puncture sites to access the thoracic duct for intubation. Nevertheless, lymphangiography remains a promising option for leak resolution [11, 18, 26]. This radiological intervention is considered relatively safe and effective, as shown by its success rate of 52% and complication rate of 3%, without fatal complications [6, 8, 11].

Although radiological interventions have been performed in several cases of persistent chylothorax, whether the outcomes are successful might be affected by the individual radiologist. Therefore, surgeons should be well informed of the anatomy of the thoracic duct, and a team approach may be necessary to determine whether surgical management is warranted in cases of treatment failure after cycles of intervention.
