To
My Parents, Brothers, Sisters, Brothers-in-Law, and
my wife DIYA who mothered our two sons:
Mowahid who is the love of my life
and
Anas "the angel of paradise" whose departure from my life is a constant source of inspiration for me to do science.

Foreword

Debilitating and fatal, hereditary degenerative diseases deprive their sufferers of a normal quality of life and life span. An effective treatment must not only repair degenerating cells but replenish degenerated cells with live ones. From the first success of mesenchyme transplantation in dystrophic mice reported in *Muscle & Nerve* 1982; 5: 619–627 unto the current >20 chapters documenting biomedical and clinical advances of mesenchymal stem cell transplantation, it becomes apparent that cell therapy has come of age! Better still, Food and Drug Agency (FDA), European Medicines Agency (EMA), and National Medicine Products Administration (NMPA) have granted several biologic license approvals since July 14, 1990, when the world's first human gene therapy and somatic cell therapy was published in *Lancet* 336:114–115.

Cell therapy is a mainstream regenerative medicine characterized with transplantation of biologics including live cells, genes, factors, and/or a combination of them. It replenishes live cells to degenerative organs, and in allografts, offers the normal genome for genetic complementation treatment. It regenerates tissues and organs. Exosomes secreted from cultured cells are often formulated to become molecular medicine. Since a foreign gene and its derivatives always exert its effect on the cell, cell therapy is the common pathway to good health. Debilitating and fatal diseases with no known cure are often results of polygenic aberration, and only cell therapy rather than individual molecular medicine can be effective.

Cell therapists harvesting the innovations and discoveries of developmental cell biologists since the mid-1950s should not forget their teachings. Somatic cell therapies and stem cell therapies utilize different compositions and methods of treatment. It is through continual research in cell identification, quantity, purity, viability, and potency, especially in cell differentiation and transcription, that stem cell therapies will one day overcome the inadequacy of uncontrolled differentiation and carcinogenicity.

This is the seventh book Professor Haider has edited on key issues of stem cells and stem cell therapies. Professor Haider has devoted more than two decades in these arenas, publishing cutting-edge research with complete dedication and passion. In this book, he has compiled the latest advances of encompassing cell therapies from world experts toward treating cancer, heart failure, Type-II diabetes, aging, muscular dystrophies, wounds, ocular diseases, COVID-19, inflammatory bowel disease, cartilage damage, spinal cord injury, cognitive deficits, and ischemic stroke. This

book is classified as a Major Reference Work consisting of 50 chapters from nearly 45 labs around the globe, from the USA to Canada, Europe, China, Japan, Malaysia, and many other countries. With these elite Editor, Publisher, and Authors working in harmony, the world of science and medicine will look forward to new editions of this landmark undertaking in the years to come.

All these drops into the bucket, some representing the life-long effort of the pioneers, others representing novel discoveries and innovations, will all be collected monumentally; for biologics are evolutionary medicine shared by all animals in the last 500 million years, only to be discovered, isolated, manipulated with human innovation, and formulated as Genetic Cell Therapies to provide mankind with long-term efficacy and lesser side effects than herbs, chemicals, surgery, or radiation.

Peter K. Law, Ph.D., Professor, Founder & Chairman

Contents

Volume 1

Part I Cell-Based Therapy Approach: Mesenchymal Stem Cell-Based Therapy 1

1 **Human Mesenchymal Stem Cells: The Art to Use Them in the Treatment of Previously Untreatable** 3
Jan Lakota, Maria Dubrovcakova, and Khawaja Husnain Haider

2 **Sources and Therapeutic Strategies of Mesenchymal Stem Cells in Regenerative Medicine** 23
Mohamed Kamal, Dina Kassem, and Khawaja Husnain Haider

3 **Considerations for Clinical Use of Mesenchymal Stromal Cells** . . . 51
Abdelkrim Hmadcha, Bernat Soria, Juan R. Tejedo, Francico J. Bedoya, Jose Miguel Sempere-Ortells, and Tarik Smani

4 **Stem Cells in Wound Healing and Scarring** 103
Roohi Vinaik and Marc G. Jeschke

5 **Mesenchymal Stem Cells** 127
Maria Alvarez-Viejo and Khawaja Husnain Haider

6 **Mesenchymal Stromal Cells for COVID-19 Critical Care Patients** 163
Abdelkrim Hmadcha, Tarik Smani, Jose Miguel Sempere-Ortells, Robert Chunhua Zhao, and Bernat Soria

7 **Mesenchymal Stem Cell Therapy for Inflammatory Bowel Disease** 193
Mikhail Konoplyannikov, Oleg Knyazev, Peter Timashev, and Vladimir Baklaushev

8 **Extracellular Vesicles-Based Cell-Free Therapy for Liver Regeneration** 221
Mustapha Najimi and Khawaja Husnain Haider

9 Current State of Stem Cell Therapy for Heart Diseases 239
Yong Sheng Tan, Qi Hao Looi, Nadiah Sulaiman, Min Hwei Ng, and Daniel Law Jia Xian

10 Mesenchymal Stem Cells for Cardiac Repair 269
Abdullah Murhaf Al-Khani, Mohamed Abdelghafour Khalifa, and Khawaja Husnain Haider

11 Preclinical Research of Mesenchymal Stem Cell-Based Therapy for Ocular Diseases 323
E. Zakirova, A. M. Aimaletdinov, A. G. Malanyeva, C. S. Rutland, and A. A. Rizvanov

12 Stem Cell for Cartilage Repair 349
Anneh Mohammad Gharravi, Mohammad Reza Gholami, Saeed Azandeh, and Khawaja Husnain Haider

13 Direct Reprogramming Strategies for the Treatment of Nervous System Injuries and Neurodegenerative Disorders 383
Katarzyna Pieczonka, William Brett McIntyre, Mohamad Khazaei, and Michael G. Fehlings

14 Therapeutic Effects of Mesenchymal Stem Cells on Cognitive Deficits 413
Carl Randall Harrell, Ana Volarevic, and Vladislav Volarevic

15 Augmenting Mesenchymal Stem Cell-Based Therapy of the Infarcted Myocardium with Statins 437
Sulaiman Alnasser, Mabrouk AL-Rasheedi, Mateq A. Alreshidi, Saleh F. Alqifari, and Khawaja Husnain Haider

16 Unraveling the Mystery of Regenerative Medicine in the Treatment of Heart Failure 471
Mathieu Rheault-Henry, Ian White, and Rony Atoui

17 Therapeutic Uses of Stem Cells for Heart Failure: Hype or Hope 511
Mathieu Rheault-Henry, Ian White, and Rony Atoui

18 Mesenchymal Stem Cell-Probiotic Communication: Beneficial Bacteria in Preconditioning 545
Ayşegül Mendi, Büşra Aktaş, and Belma Aslım

19 Effects of 3D Cell Culture on the Cell Fate Decisions of Mesenchymal Stromal/Stem Cells 565
Darius Widera

Part II Cell-Based Therapy Approach: Non-Mesenchymal Stem Cell-Based Therapy **585**

20 The Function of Stem Cells in Ocular Homeostasis 587
S. Amer Riazuddin, Shahid Y. Khan, and Muhammad Ali

21 The Potential of Stem Cells in Ocular Treatments 607
S. Amer Riazuddin, Shahid Y. Khan, and Muhammad Ali

22 Myoblast Therapies Constitute a Safe and Efficacious Platform Technology of Regenerative Medicine for the Human Health Industry 625
Peter K. Law, Wenbin Li, Qibin Song, Shi Jun Song, Jun Ren, Manye Yao, Qiaoyun Li, Qizhong Shi, Keqiang Wang, Jing Wang, Lei Ye, Jian-Hua Ma, Khawaja Husnain Haider, Li-ping Su, Ping Lu, Weyland Cheng, Ming Zhang Ao, and Danlin M. Law

23 Adipose Tissue-Derived Regenerative Cell-Based Therapies: Current Optimization Strategies for Effective Treatment in Aesthetic Surgery 691
Yusuke Shimizu, Edward Hosea Ntege, and Hiroshi Sunami

24 Molecular Signature of Stem Cells Undergoing Cardiomyogenic Differentiation 725
Kavitha Govarthanan, Piyush Kumar Gupta, Binita E. Zipporah, Vineeta Sharma, M. Rajasundari, and Khawaja Husnain Haider

Volume 2

25 Stem Cell Applications in Cardiac Tissue Regeneration 769
Vineeta Sharma, Sanat Kumar Dash, Piyush Kumar Gupta, Binita E. Zipporah, Khawaja Husnain Haider, and Kavitha Govarthanan

26 Vascular Functional Recovery and Reparation by Human Endothelial Progenitor Cells 799
Alexander E. Berezin and Alexander A. Berezin

27 Neural Stem Cells 821
Yash Parekh, Ekta Dagar, Khawaja Husnain Haider, and Kiran Kumar Bokara

28 Glial Cells in Neuroinflammation in Various Disease States 849
Derek Barthels and Hiranmoy Das

29 Human-Induced Pluripotent Stem Cell-Derived Cardiomyocytes (hiPSC-CMs) as a Platform for Modeling Arrhythmias 875
Lisa Lin, Tiffany Barszczewski, Patrick G. Burgon, and Glen F. Tibbits

30 Induced Pluripotent Stem Cells 895
Adegbenro Omotuyi John Fakoya, Adekunle Ebenezer Omole, Nihal Satyadev, and Khawaja Husnain Haider

31 Human Stem Cell Differentiation In Vivo in Large Animals 921
John S. Pixley

Part III Cell-Free Therapy Approach **945**

32 Mesenchymal Stem Cell-Extracellular Vesicle Therapy in Patients with Stroke 947
Oh Young Bang, Eun Hee Kim, Gyeong Joon Moon, and Jae Min Cha

33 Mesenchymal Stem Cell Secretome: A Potential Biopharmaceutical Component to Regenerative Medicine 973
Bruna Araújo, Rita Caridade Silva, Sofia Domingues, António J. Salgado, and Fábio G. Teixeira

34 Exosome-Based Cell-Free Therapy in Regenerative Medicine for Myocardial Repair 1007
Khawaja Husnain Haider and Mustapha Najimi

35 Current Trends and Future Outlooks of Dental Stem-Cell-Derived Secretome/Conditioned Medium in Regenerative Medicine 1035
Israa Ahmed Radwan, Dina Rady, Sara El Moshy, Marwa M. S. Abbass, Khadiga Mostafa Sadek, Aiah A. El-Rashidy, Azza Ezz El-Arab, and Karim M. Fawzy El-Sayed

36 Extracellular Vesicles Derived from Mesenchymal Stem Cells . . . 1071
M. O. Gomzikova, V. James, and A. A. Rizvanov

37 Skeletal Muscle–Extricated Extracellular Vesicles: Facilitators of Repair and Regeneration 1097
Laura Yedigaryan and Maurilio Sampaolesi

38 Regenerative Medicine Applied to the Treatment of Musculoskeletal Pathologies 1123
Alberto González-González, Daniel García-Sánchez, Ana Alfonso-Fernández, Khawaja Husnain Haider, José C. Rodríguez-Rey, and Flor M. Pérez-Campo

Part IV Miscellaneous Aspects of Stem Cell Applications **1159**

39 Common Ethical Considerations of Human-Induced Pluripotent Stem Cell Research 1161
Adekunle Ebenezer Omole, Adegbenro Omotuyi John Fakoya, Kinglsey Chinonyerem Nnawuba, and Khawaja Husnain Haider

40 Response of the Bone Marrow Stem Cells and the Microenvironment to Stress 1179
Duygu Uçkan-Çetinkaya and Bihter Muratoğlu

41 Advances, Opportunities, and Challenges in Stem Cell-Based Therapy 1229
Renata Szydlak

42 The Stem Cell Continuum Model and Implications in Cancer . . . 1255
Theo Borgovan, Ari Pelcovitz, Rani Chudasama, Tom Ollila, and Peter Queseneberry

43 Toll-Like Receptor 3 1279
Mohamed Mekhemar, Johannes Tölle, Christof Dörfer, and Karim M. Fawzy El-Sayed

44 Targeting Cancer Stem Cells: New Perspectives for a Cure to Cancer 1303
Beatrice Aramini, Valentina Masciale, Giulia Grisendi, Federico Banchelli, Roberto D'Amico, Massimo Dominici, and Khawaja Husnain Haider

45 Bioengineering Technique Progress of Direct Cardiac Reprogramming 1333
Dingqian Liu, Khawaja Husnain Haider, and Changfa Guo

46 Future Perspectives of Exosomal Payload of miRNAs in Lung Cancer 1367
Beatrice Aramini, Valentina Masciale, Giulia Grisendi, Federico Banchelli, Roberto D'Amico, Massimo Dominici, and Khawaja Husnain Haider

47 Endothelial Progenitor Cells from Bench to Antitumor Therapy and Diagnostic Imaging 1389
Tiziana Annese, Roberto Tamma, and Domenico Ribatti

48 Non-cryopreserved Peripheral Stem Cell Autograft for Multiple Myeloma and Lymphoma in Countries with Low Resources 1421
Mohamed Amine Bekadja

49 A Multilevel Approach to the Causes of Genetic Instability in Stem Cells 1445
Elio A. Prieto Gonzalez

Index 1499

About the Editor

Dr. Khawaja Husnain Haider is currently a Professor of Cellular and Molecular Pharmacology (Stem cells and Gene Therapy) and Chairman of the Basic Sciences Department (Medical Program) at Sulaiman AlRajhi University. He has also served as Principal Investigator (PI) and Co-PI on various NIH-funded stem cells research projects. He has been on the editorial boards of various research journals and has served as an invited reviewer for several respected international journals. His research focuses on the use of DNA, miRNAs, and stem cells as "drugs," a topic that has gained popularity in regenerative medicine. He has published more than 300 book chapters, abstracts, and research papers published in various books and leading research journals, including *Circulation*, *Circulation Research*, *Cardiovascular Research*, *Journal Cellular and Molecular Medicine (JCMM)*, the *Journal of Biological Chemistry*, *Cell Cycle*, *Basic Research in Cardiology*, and *Antioxidant Redox Signaling*. He has also given numerous presentations and edited seven books covering various facets of stem cells and their applications from drug to drug development.

MSCs is a rather simple process. Nevertheless, the biological features (gained from decades of tissue culture experience) are contrary to bureaucratic rules, which govern the good laboratory practice. MSCs cannot be successfully used in the treatment of human diseases if they are not handled optimally akin to the conditions in their natural habitat. Moreover, extrapolation of the data obtained from animal studies (mainly rodents) to humans is unfounded and with little relevance. The therapeutic use of genetically manipulated MSCs in human can be even harmful to patients. The current research paradigm, i.e., the use of MSCs in advanced phases of clinical trials although understandable, is far from personalized medical approach. The use of allogeneic versus autologous MSC in the clinical perspective is still debatable. There is growing evidence that the autologous MSCs derived from sick patients are "ill" in contrast to MSCs derived from healthy allogeneic donors. One can observe various changes at the DNA, RNA, and protein level in these "ill" cells. However, the huge number of cells from ex vivo expanded autologous MSCs can, possibly, overcome these aberrations. The off-the-shelf availability of allogenic MSCs also contributes to their logistic superiority over autologous cells. Moreover, due to almost non-existing immunological barriers, allogenic MSCs are emerging as gold standard and near-optimal cell types for the treatment of various diseases in humans. This chapter reviews the authors experience(s) in the treatment of various diseases with autologous/allogenic MSCs handled optimally ex vivo.

Keywords

Adipose tissue · Allogeneic · Autologous · Bone marrow · Ex vivo · Good biological praxis (GBP) · Human disease · MSCs · Treatment

List of Abbreviations

DMEM-LG	Dulbecco's modified Eagle medium, low glucose
GMP	Good Manufacturing Practices
GVDH	Graft-versus-host disease
LG	Low glucose
LVAD	Left ventricular assist device
MSCs	Mesenchymal stem cells
NYHA	New York Heart Association

Introduction

The paper of Koç (Koç et al. 2000) symbolically "opened the door" for the mesenchymal stem cells (MSCs) in the third millennium. Here, the authors reported about the autologous blood stem cells and in tissue culture (in vitro or ex vivo) expanded bone marrow-derived MSCs in advanced breast cancer patients receiving high-dose chemotherapy. Since then, an enormous amount of material has been published (Musiał-Wysocka et al. 2019). Coming down to the molecular level, our

knowledge each day is growing exponentially. Nevertheless, the primary question remains: What is the "therapeutic mechanism" of the applied MSCs? We call this effect as "posthypnagogic command." After the treatment with MSCs, the effect of healing is present for months, without the proven presence of MSCs. We are not coming in detail here; the reader could educate himself in the enormous amount of literature.

Mesenchymal Stem Cells Current Status: The "Problems" That in Reality Do Not Exist

Practical Approaches: The Golden Standards, i.e., "Good Biological Praxis" (GBP) Using the Historical Laboratory Experience

In our opinion, it is useful to repeat the whole procedure of ex vivo expansion in detail as it has been described in part "*Ex Vivo* MSCs Culture" (Koç et al. 2000): "Mononuclear cells (from bone marrow) were re-suspended at 10^6 cells/mL in Dulbecco's modified Eagle medium, low glucose (DMEM-LG) with 10% fetal bovine serum and 30 mL of cell suspension was plated in a 175 cm^2 flask. MSCs were cultured in humidified incubators with 5% CO_2 and initially allowed to adhere for 72 h, followed by media change every 3–4 days. When cultures reached more than 90% confluence, adherent cells were detached with 0.05% trypsin-EDTA." Later, additional characterizations and refinement added some regulatory rules. These ex vivo expanded MSCs fulfilled the criteria provided (later) by the International Society for Cellular Therapy (Horwitz et al. 2005). Briefly, MSCs are defined by their plastic-adherent properties under standard culture conditions, by their ability to differentiate into osteocytes, adipocytes, and chondrocytes in vitro under a specific stimulus and by positive (CD105, CD73, and CD90) or negative (CD45, CD34, CD14, and HLA-DR) expression of specific surface markers. There are two main sources for their isolation and ex vivo expansion for practical purposes – the bone marrow and the fat tissue. This ex vivo expansion of MSCs is a rather simple process based on their inherent plastic adherence properties. The pilot paper by Le Blanc et al. (2004) described the use of "third party" (here – haploidentical) MSCs for transplantation in a patient with severe treatment-resistant grade IV acute graft versus host disease (GVHD) of the gut and liver after allogeneic stem cell transplantation. For decades, two organs (or tissues), i.e., bone marrow and fatty tissue, were the primary sources for the isolation and ex vivo expansion of MSCs. The task of using allogeneic MSCs (obtained from healthy donors) or autologous MSCs in clinical settings will be discussed later.

MSCs cannot be successfully used to treat human diseases if they are not handled optimally akin to the conditions in their natural habitat. Let us discuss this in depth. As an example, we will consider the research paper published by Yau and colleagues (Yau et al. 2019). The authors claimed that "among patients with advanced heart failure, intramyocardial injection of mesenchymal precursor cells, as compared with the injections of a cryoprotective medium as sham treatment, did not improve successful temporary weaning from left ventricular assist device (LVAD) support

at 6 months. These findings do not support the use of intramyocardial MSCs to promote cardiac recovery as measured by temporary weaning from device support." According to the authors, the patients were randomly assigned to cell therapy group who received intramyocardial injection of 150 million MSCs and a cryoprotective medium treatment group without cells for comparison. The allogeneic MSCs were obtained from healthy donors and expanded in a Good Manufacturing Practices (GMP) certified laboratory. It is evident that the cells were thawed directly before use ("injections of mesenchymal precursor cells, compared to injections of a cryoprotective medium as sham treatment"). The cells were neither washed nor cultivated further for expansion before use. In the opinion of the authors that it is mandatory to use the MSCs that have been freshly prepared and not frozen or thawed immediately before use.

After decades of expanding the MSCs (and other cells) ex vivo (in vitro), we firmly stand behind this point of view. After thawing, the cells need to be cultured at least for 48 h in humidified incubators supplemented with 5% CO_2. Only after this wait period, one should start to consider further experimental (or therapeutic) work using these cells. On the other hand, one can consider growing the cells ex vivo, detaching them when 80% confluent and applying them to the patient in a short time (up to 3 h at room temperature). The practice to use freshly thawed cells (MSCs) makes the abovementioned study (and others in this fashion designed trials) from the biological point of view rather dubious and medically useless.

It should be noted that the number of skeptical articles and comments about the relevance of the MSCs for cell-based therapy is growing (Gomez-Salazar et al. 2020; Curfman 2019). We strongly disagree with the emerging notion. In our opinion, it is necessary to return to the laboratory and to give the MSCs a "second chance" by consequently following the GBP developed during the decades of cell tissue culturing in vitro. We recommend returning to the praxis of small tissue culture centers associated with (or localized within) the hospitals. In coordination with the hospital departments, they could prepare fresh MSCs, which would be "on demand" prepared for use and treat the patients. Logistically, to prepare a total of 20–50 $\times$ 10^6 cells is not a difficult task. One skilled technician could obtain this amount under sterile conditions in 1–2 h. What about the tests for the differentiation and of sterility? Well, yes, one can ask a heretical, unorthodox question: Did anybody ever observe that the MSCs in vitro did not differentiate to osteoclasts, adipocytes, and chondrocytes during appropriate treatment? This has been further discussed elsewhere in the chapter.

Data Extrapolation from Small Animal Studies to Humans Is Unfounded and Without Relevance

The therapeutic use of genetically manipulated MSCs in humans is even harmful to patients. The engineered ("therapeutic") MSCs are genetically modified MSCs that contain a stable gene encoding for protein or enzyme product/s able to kill the tumor cells. A typical example of such a construct is the yeast enzyme cytosine deaminase,

which converts the rather nontoxic 5-fluorocytosine to the cytostatic agent 5-fluorouracil (Kucerova et al. 2007). The results obtained from rodents, i.e., preclinical experimental models, are promising. In a recently published review article, Pawitan and colleagues have stated: "So far, most studies using pre-clinical cancer models have shown consistent results, i.e., the engineered MSCs could inhibit tumor growth and enhance the survival rate of the tumor-bearing animals" (Pawitan et al. 2020). And only one published clinical paper by Lakota et al. (2015) claims the opposite: "Treatment with therapeutic MSCs (i.e., genetically engineered MSCs) of this patient highlighted the following points" (Table 1):

1. There was no evidence of any therapeutic benefit after intravenous administration (not local, i.e., intra-tumoral injection) of the therapeutic MSCs. Six days after the cell administration, the metastatic process did not show any signs of regression. Moreover, 40 days after the treatment, there was a progression of the metastases.
2. After the intravenous administration, the therapeutic MSCs were probably "homing" into the bone marrow despite their adipose tissue of origin. Even a relatively low cell count ($60x10^6$) was able to cause grade 2 (resp. grade 3) thromobocytopenia (resp. neutropenia)

It should be noted that this patient did not receive any systemic chemotherapy in the past. The observed bicytopenia with a nadir neutropenia occurred 48 h after administering therapeutic MSCs (with concomitant prodrug administration). Moreover, in a more recently published paper by Lakota (2018), the author claims that:

(i) There was no sign of any therapeutic effect after intravenous administration (not local, i.e., intra-tumoral) of the "therapeutic" MSCs.
(ii) After the intravenous administration, the "therapeutic" MSCs were "homing" into the bone marrow.
(iii) There has not been any entrapment of the "therapeutic" MSCs in the lungs (after the intravenous administration).

Table 1 Blood counts of the patient with head and neck tumor during and after the therapy with therapeutic MSCs. (The table is taken from Lakota et al. 2015)

Day	Leukocytes ($\times10^{-12}$/l)	Neutrophils ($\times10^{-12}$/l)	Erythrocytes ($\times10^{-15}$/l)	Hb (g/l)	Plt ($\times10^{-14}$/l)
−2	6.88	4.86	4.41	134	179
0	5.82	3.98	3.71	119	150
+1	4.06	3.41	3.80	119	119
+2	1.99	1.00	3.41	112	100
+3	2.89	1.58	3.72	117	115
+4	3.50	2.16	3.72	115	122
+5	4.50	2.98	3.79	118	129
+6	4.29	2.63	3.89	121	132
+18	6.57	4.66	4.06	125	191

(iv) After local (i.e., in situ) administration, the "therapeutic" MSCs did not migrate to any "neighboring" tissue/organ (the liver, retroperitoneum, abdominal wall) or other distant organs, including the bone marrow.

Thus, the data obtained from small experimental animal models (mice and rats) must not be extrapolated to the humans. Moreover, the unrestrained transfer (although understandable) of the requisitioned data obtained with the MSCs from rodents may negatively influence the research trends in the novel treatment(s) of human diseases. This kind of treatment of human patients is ineffective and can be harmful and dangerous. The systemically administered therapeutic MSCs are rather homing into the patients' bone marrow and not into the tumor tissues. After local application (in the tumor area), their ability to destroy the whole tumor or its metastasis is limited. Nor they are moving to other metastatic tumor localizations.

Current Research Paradigm: MSCs in Advanced Phases of Clinical Trials Although Understandable Is Far from Personalized Medicine

Current praxis is treating human diseases based on evidence-based medicine (Masic et al. 2008, and the Internet). Clinical trials are the cornerstone to assess novel disease treatment(s), and among the clinical trials, randomized clinical trials are considered as the most preferred design as it provides a causal relationship between the medical intervention and the desired effects (Sawchik et al. 2018). A pertinent question here is: Is the same approach valid for MSCs which is fast emerging as a biopharmaceutical? Here we present some of our (published and unpublished) data none of which has been acquired in any registered trial. All of these data were obtained according to the rules of personalized medicine.

(i) Autologous bone marrow-derived MSCs were used for transplantation in ten patients with ischemic cardiomyopathy (Lakota 2014a). All patients had a well-documented history of anterior wall acute myocardial infarction. They were in NYHA stage III or IV. The freshly prepared MSCs were injected into the left anterior descending coronary artery. All of the patients tolerated the MSCs injection well and were discharged from the hospital 3–4 days after the procedure. Six patients died 7, 9, 37, 71, 101, and 119 months after the procedure. Four patients were alive 112, 113, 120, and 121 months after the MSCs-based treatment.

(ii) The allogeneic adipose tissue-derived MSCs were used for the treatment of the patient with 11 years history of ulcus cruris on his left leg, which remained stationary despite trials of conservative treatment (Lakota 2014b). The adipose tissue-derived MSCs (30×10^6) were applied locally (circumferentially). After a single round of MSCs treatment, the ulcus healing progressed "normally" despite repeated courses of standard and high-dose chemotherapy for patient's oncological diagnosis (high-grade non-Hodgkin's lymphoma). The final effect, i.e., restitutio ad integrum, has been observed during 6 months after

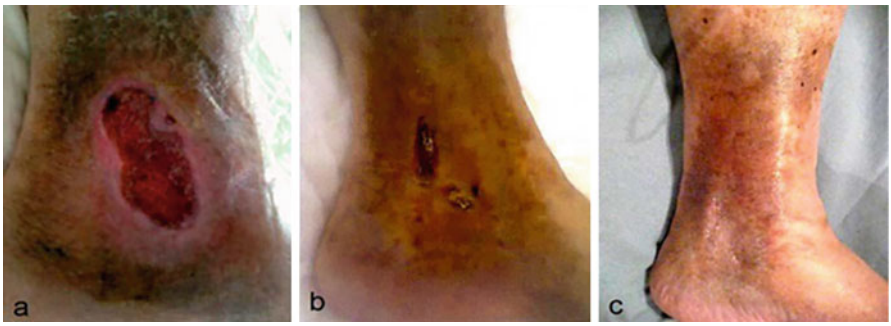

Fig. 1 Healing of the ulcus cruris after local application of MSCs. (**a**) 11/2012, day after application; (**b**) 02/2013, d + 25 after autologous stem cell transplantation; and (**c**) 05/2013. (The figure is taken from Lakota (2014b))

the MSCs-based treatment (Fig. 1). This course of healing did not differ from the patients with ulcus cruris who received allogeneic or autologous MSCs and who did not receive any chemotherapy (Lakota, unpublished).

(iii) Ten patients after allogeneic stem cell transplantation (high-dose therapy for hematological malignant disease) and with severe steroid-resistant grade IV acute GvHD were treated with allogeneic bone marrow-derived MSCs (range 0.3–0.5 $\times$ 10^6 MSCs/kg body weight) (Lakota 2017a). GvHD was successfully resolved in four patients who received MSCs-based therapy (Table 2). In the end, the author claimed: "Moreover, it seems plausible to have the MSCs 'in stock' for fast *ex vivo* expansion to use the freshly prepared cells (rather than frozen, thawed, and immediately used)."

(iv) The autologous bone marrow-derived MSCs and allogeneic adipose tissue-derived MSCs were used to treat aseptic necrosis of the jaw. The treatment was performed in 30 patients over a period of 15 years. Freshly prepared MSCs (20×10^6) from the respective tissues were applied locally. In five patients, MSCs were used twice. The result was a restitutio ad integrum (Fig. 2) (Lakota, unpublished data and Lakota 2017b, in Slovak).

(v) The allogeneic adipose tissue-derived MSCs were used for the treatment of ten patients with sclerosis multiplex. The target dose has been 0.5 $\times$ 10^6 cells/kg bodyweight. The patients were advised not to stop current "official" treatment. Freshly prepared MSCs were delivered intravenously. No adverse effects were observed. The CNS lesions in all patients but one did not progress during 15 years of follow-up after MSCs-based cell therapy (Lakota, unpublished data).

We did not mention all the data obtained by the authors during the last two decades involving MSCs-based cell therapy. The authors never performed any double-blind randomized clinical trials due to logistic and economic reasons. In our hands, personalized medicine and the medical treatment followed the golden rule: "primum non nocere." We followed the aim and principle of helping the sick

Table 2 Patients' characteristics, date of transplantation, date of MSCs infusion, date of the patients' death, and the reason of death. (Haplo Tx: HLA haploidentical transplantation; RI Tx: reduced intensity conditioning transplantation). (The table is taken from Lakota 2017a)

Patient No	Gender	Born	Diagnosis	Transplantation	MSC infusion	Death	Reason of death	Comment
1	M	1971	AML	16.03.04	d + 206	09.11.04	cGvHD	
2	M	1976	HD	30.01.05	d + 1	14.02.05	aGvHD	Haplo Tx
3	M	1971	ALL	13.12.05	d + 9	05.04.06	Disease progression	
4	F	1970	Ph-CML	26.04.07	d + 33	–	Alive (31.12.16)

6	M	1969	ALL	23.02.10	d + 168	16.08.10	cGvHD	
7	F	1973	HD	21.10.10	d + 92, d + 178	22.09.11	Infection	HaploTx
8	M	1987	HD	18.10.11	d + 43	09.04.13	Disease progression	RI Tx

Fig. 2 Healing of the osteonecrosis of the jaw after local application of MSCs. Left: during the surgery; right: 12 weeks after the surgery. (The figure is taken from Lakota 2017b)

and suffering patients in concert to see how serpentine can be the road to establish a new treatment in medicine. It is worth mentioning the following observation. In 2004, Vulliet and colleagues published an interesting research paper of using MSCs in a healthy dog (Vulliet et al. 2004). The authors delivered 0.5 million MSCs/kg bodyweight into the canine left circumference coronary artery. The authors observed ECG changes (ST-segment elevation) in all dogs receiving cell administration which was a characteristic of acute myocardial ischemia. Besides microscopic and macroscopic evidence of myocardial ischemia, the authors also observed increased troponin I in two dogs in which measurements were made. These data suggested that myocardial ischemia occurred after the injection of MSCs at the dose used in this study. Microinfarction was also confirmed with histological and immunocytochemical data.

These results showed a potential complication of injecting MSCs, or probably any similarly sized cell, into the coronary circulation. Although differences between canine and human coronary circulation exist, and different cell types and sizes have been used for selected cytotherapeutic applications, this potential complication should be thoroughly investigated before MSCs are routinely injected into the arterial circulation of the patients. Luckily for us (Lakota 2014a) and for the patients at the time of publishing this paper (Vulliet et al. 2004) as we became aware of that we performed three intracoronary MSCs transplants and three other patients were "on the horizon." Thus, this is another confirmation of how dubious the translation of "(pseudo)clinical" data obtained on animals to human clinics is. Two recently published reviews in this regard have elegantly discussed the donor-related factors and quality of the cell preparation as the possible determinants of the outcome of cell-based therapy in the clinics (Haider 2018; Rady et al. 2020).

A Case of Autologous Versus Allogeneic MSCs, an Unanswered Question

One of the ongoing and inconclusive debates in cell-based therapy is the preference for autologous over allogeneic MSCs. However, the use of allogeneic MSCs for

cell-based therapy is fast emerging as a new paradigm in therapeutics (Karantalis et al. 2016). Starting with the pioneering work of Orlic et al. (2001), preclinical studies have characterized syngeneic, xenogenic, allogeneic, and autologous MSCs; however, most of these studies, especially in the small animals, i.e., mice, rats, etc., have focused on the use of allogenic MSCs due to ease of availability (Orlic et al. 2001, Fukuda and Fujita 2005; Jiang et al. 2006; Haider et al. 2008; Beitnes et al. 2012). Similarly, in large animal translational studies, autologous and allogeneic MSCs have been used without any safety issues with either cell type (Poh et al. 2007; Quevedoa et al. 2009; Chen et al. 2014). But then the question remains why these data have been ignored while designing the clinical trials wherein mostly autologous MSCs have been focused on cell-based studies.

As evidenced by a systematic review and meta-analysis of 82 animal studies involving 1482 animals that both autologous and allogeneic cells are equally effective (Jansen of Lorkeers et al. 2015), but they have their respective advantages and limitations in the clinical perspective. Hence, the clinical researchers should give these parameters due consideration during clinical study design for optimal therapeutic outcomes. The following section discusses in depth the pros and cons of each cell source in the light of the published data and implores that the relevant information should be given due consideration, especially during the design of clinical studies.

A Case for Autologous Cells

On its face, the fear of incompatibility is alleviated with the use of autologous cells. Hence, autologous cells' usage is advantageous as it does not require immunosuppression to support the acceptance of the transplanted cells and their derivative tissue after differentiation posttransplantation. Moreover, treatment with autologous cells is considered a step closer to the fast-emerging personalized medicine. However, on the downside of autologous cell-based therapy, the use of autologous cells is time-consuming and labor-intensive exercise, and clinically less viable option, as it may necessitate biobanking of autologous cells for future use of the cells for every individual. On the same note, it is also not sustainable for diseases where the patient may require early intervention, i.e., myocardial infarction, stroke, etc., and the patient does not have the choice of long waiting time until the harvested cells can be purified and expanded to achieve the required cell number for transplantation. Some essential considerations in case autologous cells are as follows:

Autologous Cells from Patients Are Also "sick"

There is growing evidence that the autologous cells derived from the patients eligible for the cell-based treatment are "sick" compared to the ones derived from healthy allogeneic donors due to their exposure to different risk factors and comorbidities in the "sick" donors (Dimmeler and Leri 2008; Cesselli et al. 2011). Moreover, it is now well-documented that many diseases compromise the stem cell niche homeostasis and seriously affect stem cell properties such that they are rendered unsuitable for cell-based therapy (Perez et al. 2018). For example, Liu et al. have shown that MSCs from diabetic patients have impaired cardioprotective function as compared to the

ones derived from the healthy donors, which was ascribed to the long-term exposure to hyperglycemia (Liu et al. 2013).

We have performed RNA microarray analysis comparing MSCs from two patients with ischemic cardiomyopathy and two healthy donors (Lakota 2014a). Data analyses showed a significantly enhanced gene expression ratio for STAT1α/β (signal transducer and activator of transcription 1-alpha/beta) and ISG15 (ISG15 or g1p2 or ucrp; ubiquitin cross-reactive protein). The decreased ratio of gene expression has been shown for GTP-binding protein RAD. The first analyzed patient died 101 months after the procedure. The second one was alive 120+ months after the procedure.

It should be noted that the MSCs in all patients treated were isolated from their bone marrow. This data clearly shows that ischemic cardiomyopathy is a "systemic" disease. One can speculate about the following fact: How is it possible that the patients with this "damaged" RNA profile in MSCs survived such a long time after the procedure, i.e., such "sick" MSCs were able to repair the damaged myocardium?

Autologous Cells in Elderly Patients Are Also Aged

Another critical aspect generally overlooked during the use of autologous cells is the donor age besides the age of the recipient. A considerable majority of the patient population who are candidates for cell-based therapy are elderly. Using their own (autologous) cells for cell-based therapy and transplanting them back into an aging tissue environment (which has lost the vigor of reparability due to chronological aging) accounts to double negative that significantly hampers the therapeutic outcome (Zhuo et al. 2010).

It is pertinent to mention that similar to any other body cell, stem cells also undergo chronological aging, which is multifactorial, i.e., metabolic alteration, accumulation of reactive oxygen species, accumulation of DNA damage and mutations, telomere shortening, etc. (Oh et al. 2014; Schultz and Sinclair 2016). These metabolic and molecular-level changes lead to loss of their stemness characteristics with age, which is reflected in the impairment of their functionality (Kissel et al. 2007; Bustos et al. 2014). Moreover, chronological aging also leads to a significant reduction in stem cells (Maijenburg et al. 2012). Stenderup et al. carried out a direct in vitro comparison of bone marrow-derived MSCs from young donors (18–29-year-old, $n = 6$) versus elderly donors (68–81-year-old, $n = 5$) (Stenderup et al. 2003). The authors compared the cells for the expression of senescence markers, cell growth, and differentiation potential. It was observed that the cells from elderly donors showed significantly reduced maximal life span in terms of population doublings (PD) and PD rate, and accelerated senescence as evidenced by beta-galactosidase expression as a marker. Similarly, a comparison of bone marrow-derived MSCs from human donors (17–90 years age) showed a significant increase in doubling time beside increased expression of senescence markers with the advancing age of the donor (Zhou et al. 2008).

Chronological aging and obesity also cause a decline in stem cell yield and their ability to hematopoiesis and bone regeneration (Pachon-Pena et al. 2016, Ambrosi et al. 2017). Therefore, it is essential that clinical researchers consider the

consequence of donor age while opting for autologous cell sources (Stolzinga et al. 2008). A direct comparison of the reparability of bone marrow-derived MSCs showed that the rate of old donor bone marrow-derived MSCs had poor cardiomyogenic differentiation potential as compared to the MSCs derived from young donor bone marrow (Jiang et al. 2008). For comparison, the cells were transplanted in the same heart in an experimental animal model of acute myocardial infarction. Khan et al. showed that the reparability of the senescent myocardium is determined by the age of the donor (Khan et al. 2011). All these data signify that MSCs from aging patients show a drastic loss of their biological activity and bring us to an important question if the use of autologous is the real culprit for the modest outcome of the clinical trials reported to date (Shahid et al. 2016).

A Case for Allogeneic Cells

Data emanating from the clinical studies have shown the safety and efficacy of allogeneic MSCs in adult and pediatric patients (Koc et al. 2002; Horwitz et al. 2002). Recent clinical application of allogeneic MSCs in ischemic cardiomyopathy patients vindicated these data and reported that allogeneic MSCs were as good as autologous MSCs in their functionality and efficacy, favorably affecting LV end-diastolic volumes, LVEF, and ventricular remodeling leading to improved quality of life (Hare et al. 2012, 2017). More importantly, these studies did not report any severe adverse reactions associated with the cell-based therapy with allogeneic cells, including immunologic responses. The safety profile of allogenic MSCs has also been substantiated during a systematic review and meta-analysis of 36 clinical studies, including 1012 participants (Lalu et al. 2012). Experimental studies assessing immunological profiling of MSCs have shown that although they are not immunopriviledged, allogeneic MSCs are weakly immunogenic, because they lack MHC class II and co-stimulatory molecules, i.e., CD40, CD80, and CD86, while they have weak MHC class I expression (Machado et al. 2013; Lohan et al. 2014). Moreover, they do show immunomodulation by suppressing the activation and proliferation of immune cells (Asari et al. 2009; Corcione et al. 2006). Their interesting immune profile tips them as a good candidate for cell-based therapy without the need for immunosuppression therapy and takes care of them not being "self" for the recipient (Kariminekoo et al. 2016). These data about the allogeneic MSCs are a step forward towards the ongoing quest for "Universal donor cells," which should be available off-the-shelf as a ready-to-use cell preparation (Kinkaid et al. 2010).

Logistic Advantage of Allogenic MSCs

One of the primary advantages of allogenic MSCs is their logistic superiority over autologous cells (Zhang et al. 2015). Unlike autologous MSCs, which need to be isolated, purified, and expanded in culture before use for each patient, allogenic cells are logistically feasible as they may be readily available off-the-shelf. This ready availability makes possible their use in urgent clinical situations, which is not possible with the autologous cells as it may take 3–4 weeks of isolation, purification,

and expansion before they could be used for delivery. For any cell-based therapy to be of routine clinical significance as a therapeutic modality, it is imperative that the cells must be available off-the-shelf akin to any other conventional pharmacological agent. Despite the fast-emerging innovative field of personalized medicine, drugs are not to be synthesized for each patient; instead, their use is tailored according to the need of the patients who are stratified to enhance therapeutic efficacy (Marshall et al. 2016).

Similarly, in cell-based therapy, which is one form of personalized medicine, cells cannot be prepared for each patient before use; there have to be readily available cell preparations, which can be tailored to the need of the patient. Manufacturing large clinical grade batches of allogenic cell products using GMP, quality controlled for viability, self-renewal, and stemness characteristics will be cost-effective, time-saving, less labor-intensive, commercially favorable, and clinically more relevant for reproducible outcome. Moreover, this off-the-shelf approach fits well with the current pharmaceutical practices, scale-up manufacturing, and may involve automation to make it efficient in manufacturing, thus having a better commercial potential than autologous cells (Malik and Durdy 2015). Additionally, allogeneic MSCs may allow repeated doses of the cells which may be more beneficial than one-time treatment (Poh et al. 2007).

Allogenic MSCs Overcome the Limitations of Aging and Sickness of Autologous Cells

As discussed earlier, autologous cells derived from elderly patients, especially those with multiple comorbidities, may not fetch the desired results. Availability of allogeneic cells from a young healthy may be a better option for cell-based therapy. In a recently published study, which was aimed to identify a set of donors and their donated cells' characteristics with predictive value for optimal osteoblastic differentiation, bone marrow-derived MSCs from 58 patients undergoing surgery for bone fracture were characterized for high osteogenic potential and low adipogenic potential (Kowal et al. 2021). The authors have reported a well-defined criterion that donor cells obtained from male donors, without a diagnosis of osteoporosis and containing a higher fraction of $CD146^{+}$ fraction of cells, together were predictors of high osteogenic potential. Such predefined criterion is also warranted for selecting MSCs for use in the patients who are candidates for cell-based therapy for other diseases.

We will not go into detail here (Lakota 2016); nevertheless, one possible explanation could be that the myocardial repair occurred because of the presence of a considerable amount of ex vivo expanded MSCs. The RNA microarray analysis reflects only the statistically up- or downregulation of specific genes. In another study, Koh and coworkers suggested that pluripotency and the secretion of trophic factors of the bone marrow-derived MSCs in amyotrophic lateral sclerosis patients were reduced in proportion to a poorer prognosis. This may suggest that allogeneic (bone marrow- or adipose tissue-derived) MSCs from healthy donors may be a better option for MSCs therapy in amyotrophic lateral sclerosis patients (Koh et al. 2012).

Quality Control of MSCs Preparation: A Prerequisite for Optimal Prognosis

Autologous or allogeneic MSCs are part of the primary prerequisite of quality of the MSCs preparation for use in the patients (Haider 2018) and remain a fundamental determinant of the outcome of any cell-based therapy procedure and its success (Haider 2017). It encompasses everything from percentage cell count and cell viability, their identification to proliferation and differentiation potential to paracrine action of the cells in the MSCs preparation to ensure that the cell preparation is the best compromise of all these properties. For example, the cells should have the proliferation capacity, but at the same time, unlimited proliferation will add the risk of tumorigenicity. Hence, validating MSCs preparation, both biologically and functionally, will ensure that the cells will do the needful, which is meant for post-engraftment in the clinical settings. Unfortunately, these critical aspects of quality control of the cell preparation in general, and functional assessment in particular, have been generally overlooked during the design of the clinical studies. This has seriously impacted the efficacy of the cells, thus significantly contributing to the modest outcome of the clinical trials in most cases.

For example, bone marrow-derived MSCs, both autologous and allogenic, require in vitro culturing for at least 3–4 weeks. Out from their natural habitat, they are exposed for so long to the unnatural biological environment, which is only partially emulating their natural habitat at best, is expected to alter their biological as well as functional characteristics significantly. All this leads to their senescence or aging in culture due to less than optimal culture conditions (Bonab et al. 2006; Jiang et al. 2017; Shen et al. 2018). Moreover, the long-term culture may render the cells devoid of their specific surface marker expression, i.e., CD29, CD44, CD90, and induce chromosomal instability (Furlani et al. 2009). Transplantation of these in vitro expansion showed no functional effect post-engraftment in experimentally infarcted myocardium. Although various strategies have been developed to recover the culture-induced senescence of cells in terms of their proliferation capacity (Koichi et al. 2011; Tan et al. 2021), the cells may become transformed to be tumorigenic depending upon the culture condition, thus becoming unsafe for cell-based therapy (Rosland et al. 2009; Wolf et al. 2009).

Similarly, the long-term culture of the cells becomes immunogenic due to the settlement of extraneous proteins from the culture medium. These ill effects of prolonged in vitro culture are most pronounced in 2D culture conditions. It is anticipated that the advanced 3D culture conditions in vitro will go a long way in alleviating the effects of cell culture-induced cell senescence due to its biomimetic properties (Hoch and Leach 2014; Jeger-Madiot et al. 2021).

Another typical example is the effect of cryopreservation of the cells in clinical settings. Although the current cryopreservation protocols are well-optimized and successfully preserve the biological and functional characteristics of the cryopreserved cells, some aspects of the technique require further refinement (Mamidi et al. 2012). Cryopreserved MSCs show altered immunomodulatory and therapeutic efficacy with a significant reduction in the number of viable cells. The rate of cell viability, as well as cell clumping, is also an important complication of

cryopreservation that may contribute to micro-occlusions after intra-arterial delivery of the cells as compared to the freshly isolated cells with cryopreservation (Cui et al. 2016). A recent study has reported that the cryopreserved successfully maintained their multi-lineage differentiation, immunomodulatory and anti-inflammatory properties, but they lose some of their stemness characteristics in a reversible fashion, which the cells could recover within 24 h in the culture after thawing (Antebi et al. 2019). Kaplan et al. have elegantly reviewed the effect of cryopreservation of the MSCs biological and functional characteristics (Kaplan et al. 2017).

Conclusion

In our opinion, the question of the use of autologous versus allogeneic MSCs remains unresolved. Autologous MSCs, although sick, are returning home after ex vivo expansion when they are used for cell-based therapy. Allogeneic healthy cells are here on demand. The immunological barriers do not (in practice) exist. According to the authors' experience, one should not be afraid to use them in all cases when there are doubts about the current availability of autologous MSCs. No single negative effect has been ever observed. Therefore, the summary of theoretical pros and cons cannot solve up to date this problem.

In conclusion, we would like to remind the reader of the old rule which governs the laboratory praxis. This is what we call "good biological praxis" (GBP). One should not create problems where they do not exist. Or, better, with humbleness, we should approach the divine principles in nature which we receive as gifts. With these gifts earlier hidden, we will be able to treat previously untreatable. MSCs are the current example. Human medicine is hotly waiting.

Abstract

During the past decade, mesenchymal stem cells (MSCs) have made their mark as a potential weapon in regenerative medicine. Since their first isolation by Friedenstein in the late 1970s of the last century, MSCs have opened new avenues

in the field of regenerative medicine. The main fascination about MSCs lies in their ease of isolation and large ex vivo expansion capacity, as well as demonstrated multipotency and immunomodulatory activities. Basically, several reports have proved that MSCs isolated from different sources possess different characteristics and potentials. In addition, the mechanisms by which these cells can help regenerate tissues and treat several diseases have been proved to be far more complicated than ever thought of. Moreover, a growing body of research has revealed that the therapeutic effects of MSCs occur largely via paracrine signaling and secreted extracellular vesicles, which act as "signalosomes" controlling fundamental cellular functions in recipient cells. In this chapter, we will discuss how MSCs isolated from different sources such as bone marrow; the prototype MSCs, adipose tissue, and umbilical cord differ in their characteristics as potential sources of allogenic versus autologous cell therapy options. Besides, we will clarify the main documented mechanisms of action which MSCs play in regenerative medicine including their differentiation to tissues of mesenchymal versus non-mesenchymal lineages. Additionally, the immune-modulatory effects of MSCs will be discussed as an important arm in their therapeutic potential. Finally, we will discuss the potential of extracellular vesicles produced by MSCs as an emerging cell-free alternative to stem cells therapy.

Introduction

Mesenchymal Stem Cells

During the past decade, the field of mesenchymal stem cells (MSCs)-based research has witnessed huge progress due to unraveling many of their exceptional biological features and stemness characteristics, as well as the encouraging results of several preclinical and clinical studies. Thus, it is now widely accepted that MSCs could provide a revolutionary therapeutic intervention for various diseases (Batsali et al. 2013; Wang et al. 2012). MSCs were first reported in the early 1970s when a population of plastic-adherent, fibroblast-like, non-hematopoietic cells were isolated from bone marrow (BM) (Friedenstein et al. 1974). Later, in the early 1990s, based on their properties, the term "mesenchymal stem cell" was proposed (Caplan 1991). The term "mesenchymal" is derived from the word mesenchyme, which refers to loosely organized tissue during embryonic development broadly associated with connective tissues (Viswanathan et al. 2019). Its noteworthy here that the acronym "MSCs" has also been designated for "*multipotent mesenchymal stromal cells*" (Horwitz et al. 2005).

Nevertheless, although both terms have been commonly used interchangeably in the literature, it is pertinent to mention that the International Society for Cellular Therapy (ISCT), now called the International Society of Cell and Gene Therapy, has clarified through a couple of position statements that the term "mesenchymal stem cell" is not equivalent to "mesenchymal stromal cells." Moreover, the latter refers to a bulk population with notable immunomodulatory as well as secretory and homing properties (Horwitz et al. 2005; Viswanathan et al. 2019). They have suggested that the term "mesenchymal stromal cells" can be used to describe the heterogeneous bulk population of cells, which includes fibroblasts, myofibroblasts, and even a relatively small proportion of stem/progenitor cells, but excludes endothelial and hematopoietic cells (Viswanathan et al. 2019).

Notably, the ISCT has defined specific minimal criteria for the proper characterization of MSCs so that the research data from various research groups may be compared (Dominici et al. 2006). This criterion includes:

1. MSCs are plastic-adherent when maintained in well-defined and standardized culture conditions.
2. MSCs must express some mesenchymal cluster of differentiation (CD) surface markers like CD105, CD73, and CD90 and lack the expression of hematopoietic stem cell-specific markers like CD45, CD34, and CD14.

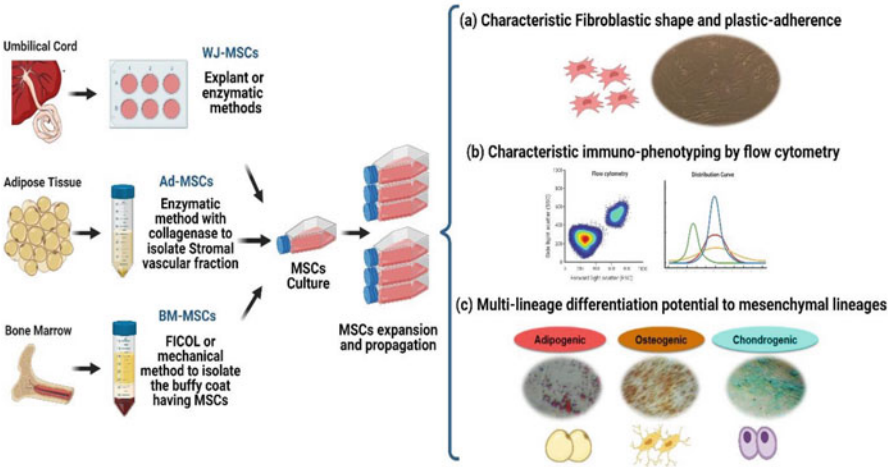

Fig. 1 Isolation and characterization of MSCs from different tissue sources, including umbilical cord, adipose tissue, and bone marrow. After isolation, MSCs from different tissue sources exhibit ISCT criteria based on plastic adherence, immunophenotyping, and trilineage differentiation potential of osteogenic, adipogenic, and chondrogenic phenotype. (Created with Biorender.com)

3. MSCs should exhibit multilineage differentiation potential to adopt adipogenic, osteogenic, and chondrogenic phenotypes in vitro in the presence of specific chemical cues.

These essential characterization criteria are summarized in Fig. 1.

Sources of Mesenchymal Stem Cells

So far, MSCs have been successfully isolated from various tissues, including adult tissues such as adipose tissue, BM, peripheral blood, dental pulp, skin, muscle, endometrium, ovary, as well as perinatal/fetal sources, like the placenta, umbilical cord blood (UCB), and umbilical cord (UC) matrix/tissue (Da Silva Meirelles et al. 2006; Jackson et al. 2010; Ma et al. 2014; Vasandan et al. 2014; Niezgoda et al. 2017; Berebichez-Fridman and Montero-Olvera 2018; Ghamari et al. 2021; Zolbin et al. 2021). Despite all of these being MSCs from different tissue sources, they significantly differ from each other in terms of their proliferation, self-renewal, paracrine action, and even differentiation potential. For example, MSCs obtained from UCB are rich in a more primitive cell population than those obtained from the BM (Hass et al. 2011; Wang et al. 2016b). Similarly, adipose tissue-derived MSCs (Ad-MSCs) have specific features, such as their transcriptome, proteome, and immunoregulatory properties as compared to the BM-derived counterparts (Strioga et al. 2012; Li et al. 2015a). Similarly, the contributing factors causing divergence in MSCs' characteristics include age, sex, the health status of the donor, etc.

For example, MSCs derived from a young donor (8–12 weeks) and elderly donor rats (24–26 months) was assessed for their responsiveness to anoxia and assessment reparability of infarcted myocardium post engraftment in an experimental animal model of acute myocardial infarction (Jiang et al. 2008). The young donor-derived cells were more resistant to apoptotic signals upon anoxic exposure than their counterparts. Similarly, the young donor-derived MSCs showed more cardiomyogenic differentiation after transplantation and better preserved the global cardiac function of the infarcted myocardium. Similar results have also been reported by Wang et al. while comparing young and old BM-derived MSCs in an experimental animal model for cardiac repair (Wang et al. 2008).

BM-derived MSCs have been the most extensively studied and denoted as the "gold standard" of MSCs among MSCs derived from different tissue sources (Arutyunyan et al. 2016). From among the most important tissues sources of MSCs, we will discuss in this chapter BM-derived MSCs, Ad-derived MSCs, and Wharton's jelly-derived MSCs (WJ-derived MSCs) with particular emphasis on the latter two as the most well-studied types of MSCs in regenerative medicine.

Bone Marrow-Derived MSCs

BM-derived MSCs constitute a heterogeneous group of cells. They were the first MSCs to be isolated and reported in 1966 by Friedenstein and colleagues. They isolated a population of cells from guinea-pig BM with fibroblast-like plastic adherent phenotype in vitro with colony-forming abilities. These cells could self-renew, express mesenchymal markers, such as CD29, CD44, CD73, CD90, and CD105, CD106, and CD166, and lacking in the expression of hematopoietic markers, such as CD14, CD34, and CD45, and capable of spontaneous bone formation in the diffusion chambers (in vitro), besides inducible osteogenesis in the presence of transitional epithelium (Friedenstein et al. 1970). Later on, in 1991, Caplan suggested changing the name to "mesenchymal stem cells" and ascribed these cells as responsible for bone and cartilage formation in the embryo and responsible for their repair and turnover in adult life (Caplan 1991). Caplan also described the role of some extrinsic factors and the inherent genomic potential to control the rate and phenotype of the cells in the emerging tissue from these cells and predicted their emergence as a novel therapeutic modality for the repair of skeletal tissues. While describing the mesengenic process, Caplan described a pivotal role of MSCs in terms of undergoing proliferation, lineage commitment, and terminal differentiation to adopt the desired phenotype, that is, osteogenic, chondrogenic, and adipogenic (Caplan 1994). Going further, in 2017, Caplan has now suggested to rename MSCs as "medicinal signaling cells" to reflect on the ability of MSCs to migrate to the site of injury and participate in the repair process (Caplan 2017).

Although BM-derived MSCs are the most extensively studied, well-characterized, and widely used cells in clinical settings, MSCs represent only 0.001–0.01% of mononuclear cells in the BM. Due to this small fraction, BM-derived MSCs necessitate in vitro expansion to acquire sufficient numbers for

in vivo use (Pittenger et al. 1999). In this regard, various in vitro strategies have been adopted that include culturing of cells under serum-free conditions to 3D-culturing that simulate the natural habitat of the cells (Bhat et al. 2021).

Advantages of BM-Derived MSCs

BM-derived MSCs show multipotent differentiation potential toward different embryonic lineages. These lineages include the mesodermal lineage, that is, adipocytes, chondrocytes, osteocytes, endothelial cells, and skeletal muscles, ectodermal lineage, that is, neurons, retinal cells, and endodermal lineage, that is, hepatocytes and insulin-producing cells (Friedenstein et al. 1970; Polisetti et al. 2010). However, the ability of MSCs to adopt different lineage phenotypes is considered tissue source of MSCs-dependent. For example, BM-derived MSCs show stronger osteogenic but lower adipogenic potential than Ad-MSCs, but they both offer similar chondrogenic potential (Xu et al. 2017). Similarly, a comparison of synovial membrane-derived MSCs and BM-derived MSCs showed that the latter have enhanced osteogenic differentiation potential, although their chondrogenic potential was similar (Gale et al. 2019). This multilineage differentiation enables BM-derived MSCs to provide vast therapeutic applications for different diseases in regenerative medicine (Haider and Ashraf 2005).

BM-derived MSCs are still the most used MSCs in clinical settings (Wang et al. 2016a). Interestingly, BM-derived MSCs were the first "stem cell drug" to be registered by the Food and Drug Administration (FDA) as a drug (Prochymal™) against graft vs. host rejection disease (GvHD) (Prasad et al. 2011). Presently, BM-derived MSCs have more than 400 registered clinical trials with almost 160 completed trials involving a broad scope of immune, chronic, cardiovascular, and degenerative diseases, for instance, diabetes mellitus, neurodegenerative diseases, and heart diseases (ClinicalTrials.gov 2019).

Limitations of BM-Derived MSCs

Despite the advantages mentioned earlier, a few limitations have led to cautious advancement of BM-derived MSCs to the clinic in regenerative medicine. For example, the isolation of BM-derived MSCs is very complicated and more invasive than UCB, adipose tissue, and WJ. Harvesting of BM-derived MSCs can cause possible discomfort and morbidity due to the invasive BM aspiration process (Mazini et al. 2019). In addition, BM-derived MSCs isolation may require centrifugation to separate mononuclear cells from RBCs, platelets, and granulocytes (Naji et al. 2019). Moreover, the limited yield of cells necessitates in vitro expansion, which may result in altering the immunogenic status and differentiation potential of cells. However, several reports have reported that BM-derived MSCs exhibit signs of early senescence during in vitro culture expansion. All these problems directed researchers to search for alternative sources of MSCs.

Adipose Tissue-Derived MSCs

Ad-MSCs constitute a heterogeneous population of cells isolated from adipose tissue of different body parts. They exhibit all the essential characteristics of the MSCs

proposed by the ISCT, namely plastic adherence, expression of mesenchymal cell-specific surface membrane markers and lacking in hematopoietic stem cell-specific surface membrane markers, and the ability to undergo trilineage differentiation, that is, adipocytes, chondrocytes, and osteocytes. Like the other tissues-derived MSCs, Ad-MSCs also offer several unique advantages over other sources of MSCs (Bourin et al. 2013; Fathi and Farahzadi 2009). Besides the typical mesenchymal surface markers, Ad-MSCs also express primitive cell surface markers of core circuity of self-renewal, that is, OCT4, NANOG, SOX2, and the neurogenic lineage-specific genes, that is, NEUROD1, PAX6, and SOX3 (Gentile et al. 2019). Although similar in surface marker expression to BM-derived MSCs, the yield of Ad-MSCs is approximately 500 times more than the BM per gram of the respective tissue (Hall et al. 2010). They show higher proliferative potential without losing much of their stemness properties (Zhu et al. 2008). Another study comparing BM-derived MSCs and Ad-MSCs derived from patients with coronary artery disease has shown the superiority of Ad-MSCs in their response to low oxygen culturing that renders them more suitable for transplantation for cardiovascular therapy (Adolfsson et al. 2020).

Advantages of Adipose Tissue-Derived MSCs

Ad-MSCs propose several advantages over BM-derived MSCs that make them of special interest in the clinical perspective. Firstly, the ease of availability in tissue harvesting and isolation of the Ad-MSCs from the harvested tissue constitutes a significant advantage of these cells. Similarly, Ad-MSCs can be isolated from subcutaneous fats of different parts of the body, including the abdomen, thighs, and buttocks, with far less invasive procedure than the BM-derived MSCs. This less invasive procedure is associated with lesser donor morbidity, pain, or complications than the BM-MSCs (De Ugarte et al. 2003). Second, the lipoaspirate showed a higher population of MSCs, reaching 10% compared to the scarce population of 0.01–0.001% of the mononuclear cells of BM-derived MSCs (Kern et al. 2006; Zhu et al. 2008). Ad-MSCs from lipoaspirate might reach 500 times that obtained from BM (Marigo and Dazzi 2011). Thirdly, and most importantly, Ad-MSCs showed better-culturing abilities, greater proliferation capacity, and they can maintain their phenotype longer in culture (Kunze et al. 2020). These properties are very significant in producing many "clinical grade" MSCs for clinical applications. Besides, several reports have shown that Ad-MSCs could differentiate into different cell types of the three developmental germ layers (endoderm, mesoderm, and ectoderm), including adipocytes, osteoblasts, chondrocytes, neurocytes, and hepatocyte (Chen et al. 2016; Dai et al. 2016). These properties render Ad-MSCs as a front-runner for clinical applications.

Limitations of Adipose Tissue-Derived MSCs

Although Ad-MSCs clinical applications have increased lately, several limitations must be overcome (Mazini et al. 2020). Ad-MSCs yield, culture properties, and differentiation capacities are dependent on several factors, including the harvesting/isolation methods and the donor health conditions (Zhang et al. 2020a). Harvesting cells by excision has a better yield than lipoaspiration and directs the cells toward mesoderm and ectoderm differentiation rather than the endoderm associated with the

lipoaspirate (Bian et al. 2016; Gnanasegaran et al. 2014). Besides, no single controlled procedure exists to isolate reproducible Ad-MSCs following Good Manufacturing Practice (GMP) (Kassem and Kamal 2020c; Kim et al. 2015; Koh et al. 2016).

Moreover, Ad-MSCs properties are highly affected by the medical comorbidity of the patients. For example, obesity of the donor induces early senescence in the Ad-MSCs. The cells obtained from obese patients showed inadequate proliferative capacity due to upregulation of p16, p53, IL-6, and MCP1, but their emigrational capability was sustained (Conley et al. 2020). Similarly, results about the declining function of adipose tissue-derived stem cells have also been reported with extensive passaging (Zhu et al. 2008). It has also been reported that the differentiation capacity and the proliferative potential of Ad-MSCs are highly influenced by the donors' conditions such as age, BMI, suffering from diabetes mellitus, exposure to radiotherapy, or endocrine therapy (Varghese et al. 2017). For example, the differentiation potential of Ad-MSCs from diabetic patients is significantly lost due to generalized inflammatory response in the patients (Barbagallo et al. 2017). However, further investigations are required to confirm the clinical significance of such differences (Zhang et al. 2020a).

Isolation of Adipose Tissue-Derived MSCs

Generally, adipose tissue is harvested using different methods, that is, liposuction, resection, micro-fat harvesting, etc., and each one of the methods has advantages and limitations and significantly affect the yield and characteristics of the Ad-MSCs thus derived therefrom, as discussed elsewhere (Prantl et al. 2021). The tissue harvesting step is followed by subsequent washing of the harvested adipose tissue to remove the contaminating erythrocytes. The tissue-digestion step is next followed in a typical protocol that may be achieved either mechanically or enzymatically and centrifuged to separate the stromal vascular fraction (SVF). The cells of SVF are then suspended in serum-containing media for culture and expansion of Ad-MSCs.

Coleman's method is most commonly used to harvest adipose tissue from among the many methods reported in the literature to date for harvesting adipose tissue (Alstrup et al. 2020). The method of harvesting can influence the number of Ad-MSCs obtained, the stemness, the proliferative capacity, the multilineage potency, and the aging rate of the isolated cells (Bajek et al. 2017). For example, it was reported that surgical resection is associated with a large number of Ad-MSCs showing a higher rate of clonogenicity. On the other hand, cells isolated by lipoaspiration showed increased proliferation and the least aging rate. Some other methods for the isolation of Ad-MSCs, the process of adipose tissue harvesting may involve surgical resection, power-assisted lipoaspiration, laser-assisted lipoaspiration, etc. (Khazaei et al. 2021; Fontes et al. 2018).

As for the digestion of the adipose tissue, mechanical digestion methods, such as shaking, centrifugation, or filtration, are cost-effective but these are time-intensive and harsh on the cells to inflict mechanical damage on the cells. This may also lead to a poor yield of the viable cells (Khazaei et al. 2021). Several enzymes were used for digestion of the adipose tissue, such as collagenase, trypsin, and dispase (Bourin et al.

2013; Yang et al. 2011; Zhu et al. 2013), However, adipose tissue digestion with collagenase is the gold standard among the currently used methods (Banyard et al. 2015). However, as collagenase is of bacterial origin, using high-grade enzyme preparation and removing excess enzyme by centrifugation is essential to ensure safety and decrease toxic effects on the cells for subsequent clinical applications (Aguena et al. 2012). Still, the methods for adipose tissue harvesting and isolation of Ad-MSCs from the harvested tissue require more efforts to standardize and apply GMP to ensure the production of "clinical grade" cells for patient applications.

Clinical Applications of Adipose Tissue-Derived MSCs

Several excellent reviews have been published discussing the clinical applications of Ad-MSCs for different diseases (Shukla et al. 2020; Zhang et al. 2020a). Zhang and colleagues have presented an excellent review of various applications of Ad-MSCs for wound healing and the treatment of bone, cartilage, nervous system, liver, heart, skin, and even trachea and gall bladder. These studies are either preclinical or clinical studies. Shukla and co-workers (2020) published a review to discuss extracellular vesicles with a focus on exosomes derived from Ad-MSCs for clinical applications. These reviews reflect an increasing interest of the researchers and the ever-growing applications of Ad-MSCs in regenerative medicine to treat various diseases.

Umbilical Cord-Derived MSCs

Human Umbilical Cord Structure and Function

During pregnancy, the placenta and growing fetus are connected by the UC, also called "the naval string" (Spurway et al. 2012) that prevents umbilical vessels from kinking, compression, or torsion during movement of the fetus, thus ensuring proper blood supply to the fetus (Kim et al. 2013). Anatomically, the human UC comprises an outer layer of amniotic epithelium enclosing a vein and two arteries embedded within a mucoid connective tissue. The mucoid connective tissue enclosing the three umbilical vessels or the UC matrix is known as "Wharton's jelly." Thomas Wharton first described WJ in 1656 (Wharton 1656). In the early 1970s, UCB was reported as a natural reservoir and a rich source of hematopoietic stem cells (Knudtzon 1974). Nowadays, UCB has many therapeutic applications for various hematopoietic and non-hematopoietic disorders in the clinics (Munoz et al. 2014; Roura et al. 2015). Given their extensive regenerative potential, the collection, and banking of UCB and its derivative stem cells as part of personalized medicine (Harris 2014), including very small embryonic-like stem cells (Bhartiya et al. 2012), is gaining popularity for use as an autologous source of cells for cell-based therapy (Badowski and Harris 2012; Um et al. 2020).

The first report providing robust evidence that WJ-derived stromal cells can be classified as MSCs was published by Wang et al. (2004), which showed that the cells derived from WJ displayed a fibroblast-like phenotype when expanded in vitro (Wang et al. 2004). Also, these cells expressed high levels of MSCs markers

CD29, CD44, CD73, and CD105 but lacked the expression of the hematopoietic-specific markers, that is, CD31, CD34, and CD45. Moreover, those cells could differentiate into osteogenic and adipogenic lineages under favorable culture conditions (Wang et al. 2004). More interestingly, treatment with 5-azacytidine or cardiomyocyte-conditioned medium, the cells expressed cardiomyocyte-specific markers, that is, N-cadherin, cardiac troponin-I. UCB is also a source of MSCs, but to a much lesser extent than WJ (Arutyunyan et al. 2016; Sibov et al. 2012). Compared with the success rate of harvesting MSCs, it has to be almost 100% from WJ compared to a meager 6% from UCB (Shetty et al. 2010). A direct comparison of various protocols of MSCs isolation from UCB and WJ tissue has been provided by Salehinejad et al. (2012). These protocols are developed to optimize the methodological aspects of the procedure. The latest advancement in this regard is the proteolytic enzyme-free method for the isolation of MSCs (Singh et al. 2019). It is noteworthy that the therapeutic potential of MSCs derived from these two UC compartments could differ significantly in preclinical and clinical settings (El-Demerdash et al. 2015; Kassem and Kamal 2020b).

Advantages of WJ-Derived MSCs

WJ-derived MSCs possess exceptional stemness properties due to the presence of a primitive cell population (Troyer and Weiss 2008; Fong et al. 2011). WJ-derived MSCs have several advantages over other types of stem cells. First of all, they can be easily isolated from the readily available UC tissue discarded at labor as medical waste. Thus, unlike BM-derived MSCs, the isolation of WJ-derived MSCs is non-invasive, and unlike ESCs, the availability and use of WJ-derived MSCs are without any moral and ethical concerns (Hass et al. 2011). Second, WJ-derived MSCs isolated from neonatal tissue have more primitive characteristics than adult tissue-derived MSCs (Frausin et al. 2015). They are believed to represent an intermediate state between ESCs and adult stem cells (Marino et al. 2019). Interestingly, WJ-derived MSCs exhibit a mix of human ESCs and MSCs-specific markers and maintain stemness for several serial passages (Nekanti et al. 2009). Interestingly, while they possess several characteristics of ESCs, they do not form teratomas upon transplantation (Troyer and Weiss 2008). Third, WJ-derived MSCs are immune-privileged due to human leukocyte antigen-G (HLA-G) expression, besides lacking in the expression of human leukocyte antigen- antigen D-related (HLA-DR) like other MSCs types (La Rocca et al. 2009). These immunomodulatory properties were reported to prevent rejections even after xeno-transplantation of post-differentiated MSCs without immunosuppression (Moffett and Loke 2003). A direct comparison of MSCs derived from four different tissues, adipose tissue, BM, WJ, and UCB, have shown that WJ-derived MSCs possess the highest immunomodulatory effects (Li et al. 2014). Given their excellent immunomodulatory properties, WJ-derived MSCs are an attractive choice when immune cellular therapy is required (Najar et al. 2012). Finally, WJ-derived MSCs, and their counterparts isolated from UCB, both have an excellent potential for biobanking (Chatzistamatiou et al. 2014).

Limitations of WJ-Derived MSCs

Despite many advantages of WJ-derived MSCs over other stem cell types, several limitations have hampered their successful translation from the bench-to-bedside. For example, among these limitations is the requirement of in vitro expansion, which is significantly affected by culture conditions. For WJ-derived MSCs, the serum is an essential component of the culture as well as cryopreservation media; however, the use of culture-expanded cells causes serious immunological reactions due to the residual animal serum proteins from animal serum slowly settled on the cells' surface during long-term culture. This adversely alters the immunological characteristics of the cells besides reducing their therapeutic benefits post engraftment (Li et al. 2015b).

It is noteworthy that several alternatives of xenogeneic serum have been suggested to achieve humanized stem cell culture using human alternatives for the xenogenic protein (Bieback et al. 2009; Tekkatte et al. 2011). Given its unique growth factor and cytokine-rich composition, one proposed alternative is platelet-rich plasma (PRP) (Kandoi et al. 2018; Haider 2017). The authors observed at least a twofold increase in the yield from the explant culture with significantly preserved immunomodulatory properties of the cells. Besides enhancing the safety aspects of the in vitro cultured cells, xeno-free culture expansion also improves their therapeutic functionality (Kang et al. 2020). Besides the xenoprotein-free culture system, Obradovic et al. have reported in vitro expansion protocol that closely mimics the natural habitat of the cells in terms of low oxygen presence (Obradovic et al. 2019). The authors reported that the cells cultured under 3% oxygen conditions retained their expression of OCT4A, OCT4B, NANOG, and SOX2 expression and showed excellent migratory capacity. Another limitation of WJ-derived MSCs is the lack of standardized protocols for their processing, cryopreservation, or banking. These include the isolation of WJ-derived MSCs from fresh tissue versus frozen ones (Fong et al. 2016).

Additionally, during prolonged in vitro culture, WJ-derived MSCs have been reported to show changes in their transcriptome profile, compared to the early passage cells, where these cells might exhibit a progressive decline in their physiological properties; a phenomenon known as "Cellular aging" (Gatta et al. 2013). Regarding the clinical application of WJ-MSCs, similar to stem cells from other tissue sources, various parameters, such as the best route of administration, time of injection, dose of the cells, frequency of doses, as well as the time intervals between multiple injections, remain controversial issues (Kamal and Kassem 2020).

Isolation Methods of WJ-Derived MSCs

Various isolation protocols have been optimized and reported to generate WJ-derived MSCs from the UC tissue. Primarily, these protocols are based on tissue explant and chemical enzymatic digestion approaches, which are incidentally the two methods for WJ-derived MSCs isolation (Han et al. 2013; Xu et al. 2010). Sometimes a mix between enzymatic and mechanical digestion approach, using enzymes like collagenase with/without hyaluronidase or trypsin, followed

by passing the treated WJ through an 18-G needle syringe (Azandeh et al. 2012). The explant method is based on the ability of the MSCs to move and migrate from the tissue and adhere to the plastic surface (Goyal et al. 2018). It is generally described as cutting the UC into shorter pieces, excision of the blood vessels, and fine chopping of the WJ sections of the cord tissue, followed by plating those fine fragments with complete media. Besides being cost-effective and reproducible, the primary advantage of the tissue explant method is that it does not affect the vitality of cells. It is noteworthy that enzymes may degrade the cell membrane during enzymatic digestion, resulting in further damage to the cells (La Rocca et al. 2009). Hua and co-workers concluded that the 10 mm size tissue explant method is the optimal protocol for isolating MSCs from UC (Hua et al. 2013).

Clinical Applications of WJ-Derived MSCs

Over the last many years, the published data from the preclinical experimental studies have demonstrated the safety and highly promising therapeutic potential of WJ-derived MSCs. In vitro characterization reveals a primitive cell population positive for OCT4 and NANOG expressing cells (Pirjali et al. 2013; Shaer et al. 2014). Based on the hypothesis that tissue source may determine the biological characteristics and functionality of the derivation MSCs, a recent study by Laroye and colleagues have shown a better profile of WJ-derived MSCs as compared to the BM-derived MSCs in mice model of sepsis by caecal ligation and puncture (Laroye et al. 2019). Various clinical trials have been conducted to test the safety, feasibility, and efficacy of WJ-derived MSCs-based cell therapy for many diseases, including graft versus host disease (GvHD), bone/cartilage disease, immunological diseases, diabetes mellitus and its complications, cardiac disease, liver disease, neurological disorders, as well as cancer (Abbaszadeh et al. 2020). Many of these clinical trials have been completed and demonstrated the safety and efficacy of WJ-MSCs (Can et al. 2017). The latest application is the effective use of WJ-derived MSCs in patients suffering from COVID-19 pneumonia (Zhang et al. 2020b). Intravenous infusion of WJ-derived MSCs has shown promising results due to their strong immunomodulatory actions (Shi et al. 2021).

Therapeutic Strategies of Using MSCs

MSCs have made their mark as a promising therapeutic option for many regenerative medicine applications. Originally, MSCs were thought to mediate their reparative potential by virtue of a multilineage differentiation capability that enabled them to replace damaged cells (Mahmood et al. 2003; Murphy et al. 2003). However, later on, a growing body of evidence has revealed that in response to tissue injury, MSCs home into the site of tissue damage and can mediate tissue repair via paracrine action through the release of soluble and insoluble secretome and immunomodulatory activities (Chen et al. 2008; Karp and Teo 2009). The various therapeutic strategies of MSCs have been summarized in Fig. 2.

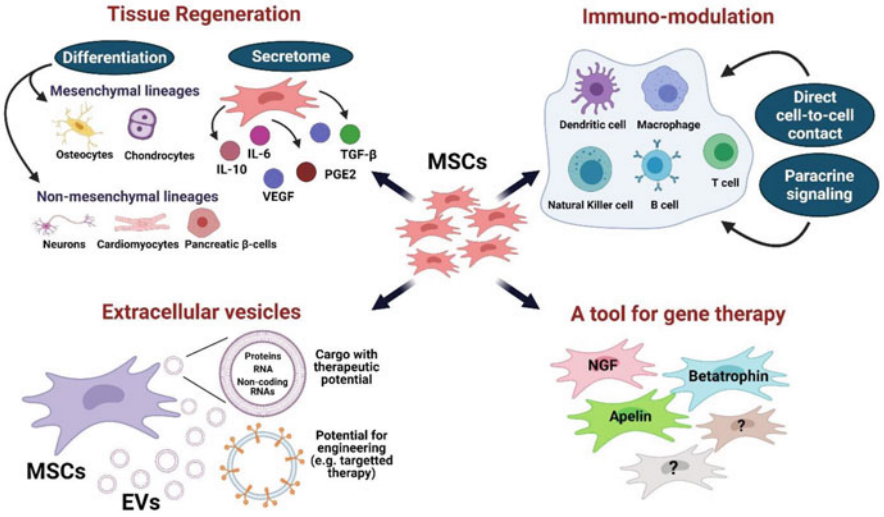

Fig. 2 Therapeutic strategies of MSCs including their ability to regenerate damaged tissue, either by direct mechanisms or indirectly via secretion of cytokines, growth factors, exosomes, and immune system modulating agents. (Created with Biorender.com)

Tissue Regeneration

Irrespective of their source, MSCs have demonstrated remarkable capability to regenerate various tissue types, especially those of mesodermal origin, such as muscle, bones, and cartilage (Pittenger et al. 2019; Le et al. 2020), as well as cardiomyocytes, neurons, and pancreatic β-cells (Farini et al. 2014).

For instance, MSCs have exhibited an excellent regenerative capacity for bones and cartilage repair, both in experimental as well as clinical settings (Kangari et al. 2020). Elucidating the cascade of events involved in the bone repair process, the transplanted cells caused the mobilization of macrophages, induced functional switch from pro-inflammatory to pro-resolving phenotype, and recruitment of endothelial progenitor cells and cells with osteogenic potential intrinsically from the BM (Tasso et al. 2013). Tadoeschi et al. proposed that transplanted MSCs modified the in vivo environment conducive to angiogenesis and bone regeneration (Todeschi et al. 2015). Additionally, the transplanted cells also undergo endothelial differentiation to participate in the formation of the new capillary network (Chen et al. 2009). Various strategies have been adopted to enhance the efficiency of bone repair. For example, Zhou et al. used in vitro osteogenically induced human MSCs for bone tissue engineering in mice to repair skull defects (Zhou et al. 2015). The latest advancement in this regard is the use of scaffold-based delivery of MSCs to enhance their efficacy. Li et al. used a composite scaffold of WJ and chondroitin sulfate loaded with human UC-derived MSCs knee repair in a rodent model (Li et al. 2021). At a molecular level, a variety of mediators with regenerative effects include,

transforming growth factor-beta (TGF-β), vascular endothelial growth factor (VEGF), indoleamine 2,3-dioxygenase (IDO), bone morphogenic proteins (BMPs), and others (Granero-Moltó et al. 2009; Qin et al. 2014) have a significant role therein.

Interestingly, MSCs-based therapy also represents a novel efficient therapeutic strategy for cartilage repair owing to its outstanding chondrogenic differentiation potential (Le et al. 2020). MSCs secrete several bioactive factors, which help to restore the extracellular matrices (ECMs) that are essential for the recovery of cartilage functions (Lories and Luyten 2011). Finally, engineered scaffolds have also been used in combination with MSCs and exogenous biochemical stimuli, and demonstrated profound progress in cartilage regeneration (Smith and Grande 2015).

Immunomodulation of MSCs

Although MSCs were initially used to exploit their regenerative capacity and reparability, however, the therapeutic potentials of MSCs have been attributed more to paracrine action and immunomodulation with partial contribution from multilineage differentiation (Ceccarelli et al. 2020). It is now well-established that MSCs exhibit a hypoimmunogenic phenotype as they lack the major histocompatibility class II (MHC-II) and release of immunomodulatory cytokines (Lacy et al. 2021). Thus, these characteristics enable them to evade recognition by the recipient immune system (McIntosh et al. 2006; Puissant et al. 2005). These immunemodulatory effects of MSCs collectively involve cell-to-cell contact-dependent mechanisms and paracrine effects by releasing a plethora of cytokines and growth factors that regulate the immune functions besides decreasing the secretion of pro-inflammatory cytokines (Sotiropoulou et al. 2006; Zhou et al. 2018).

Interestingly, Ad-MSCs are superior in immune-modulatory effects than BM-derived MSCs in a matched donor (Melief et al. 2013). This superiority can be attributed to Ad-MSCs' ability to suppress lymphocyte proliferation, inhibit monocytes-derived dendritic cells, natural killer (NK) cytotoxic activities, and the secretion of higher levels of cytokines (Melief et al. 2013; Russell et al. 2016; Valencia et al. 2016).

MSCs influence innate immunity and adaptive immunity through the two axes mentioned earlier, the cell-to-cell contact and the paracrine action. MSCs affect almost all the immune cells through cell-to-cell contact, including T-cells, B-cells, NK cells, macrophages, and DC (Zhou et al. 2019). It has been documented that MSCs inhibit naïve T-cells and memory T-cell responses to communicate with the antigen-presenting cells (Krampera et al. 2003) and inhibit the proliferation of CD4+ and CD8+ T-cells through galectin-1 (Gieseke et al. 2010). Besides their effects on T-cells, MSCs also increase the survival of quiescent B-cells through cell-to-cell contact (Franquesa et al. 2015).

It is important to mention that infused MSCs, such as UC-MSCs, reside in the lungs, are phagocytosed by the monocytes causing changes in the monocyte's phenotype and function and modulate the adaptive immune system responses

(de Witte et al. 2018). Moreover, MSCs suppress the cytotoxic NK cells' granular polarization (Hu et al. 2019). In this regard, Ad-MSCs are known to switch activated inflammatory M1 macrophages to an M2 macrophage-like phenotype via prostaglandin E2 (PGE2) release (Manferdini et al. 2017).

Regarding the second axis of cytokine secretion via paracrine mechanisms, the MSCs secretome consists of many cytokines, chemokines, and growth factors, such as transforming growth factor-β1 (TGF-β1), PGE2, IFN-γ, hepatocyte growth factor (HGF), indoleamine-pyrrole 2,3-dioxygenase (IDO), tumor necrosis factor-α (TNF-α), fibroblast growth factor (FGF), and nitric oxide, besides many others (Salgado et al. 2010; Li and Hua 2017; Zhou et al. 2019). Interestingly, these bioactive molecules are encapsulated in extracellular vesicles, such as exosomes, micro-vesicles (MVs), or apoptotic bodies, depending on the type of cells of their origin (Ferreira et al. 2018).

MSCs inhibit T-helper 17 (Th17) differentiation by IL-10, PGE2 induction, and IL-17, IL-22, and IFN-γ inhibition (Ghannam et al. 2010). Moreover, MSCs can also inhibit CD4+ T-cells activation via the secretion of programmed death ligand-1 (PD-L1) and PD-L-2 (Davies et al. 2017). MSCs can also inhibit IL-2 induced NK cells activation by the secretion of IDO and PGE2 (Spaggiari et al. 2008). Additionally, MSCs-derived IL-6 protects neutrophils from apoptosis and preserves them in the BM niche (Raffaghello et al. 2008). IL-6 can also prevent the differentiation of monocytes toward an anti-inflammatory IL-10-producing phenotype (Melief et al. 2013). Also, MSCs-derived PGE2 empower MSCs to suppress the differentiation of monocytes to mature DCs (Spaggiari et al. 2009).

Even the conditioned media (CM) of MSCs containing both soluble and insoluble factors (MSCs-derived exosomes) shows immune-modulatory effects emphasizing the involvement of paracrine actions of the cells. MSC-derived exosomes have been shown to augment neutrophil viability. In contrast, MSCs-derived CM increases neutrophil function, demonstrating that both MSCs-derived exosomes and CM are helpful for improving immunity by modulating neutrophils (Mahmoudi et al. 2019). Additionally, MSCs-derived EVs can attenuate DC maturation, as well as pro-inflammatory cytokines (IL-6 and IL-12p70) and upregulation of the anti-inflammatory cytokine TGF-β (Reis et al. 2018). Besides, MSCs-derived exosomes trigger macrophage polarization (Lo Sicco et al. 2017) by enhancing the formation of anti-inflammatory M2 macrophages over M1-like inflammatory macrophages via downregulation of IL-23 and IL-22 (Hyvarinen et al. 2018).

Extracellular Vesicles/Exosomes Derived from MSCs

Interestingly, a growing body of research has revealed that MSCs mediate several therapeutic/beneficial effects via secreting extracellular-vesicles (EVs) (Newton et al. 2017). Generally, the secreted membrane-enclosed vesicles, collectively called EVs, include exosomes, ectosomes, microvesicles, apoptotic bodies, and other EV subsets (Lötvall et al. 2014).

Initially considered the "garbage bags for the disposal of cellular waste," MSCs-derived exosomes are now emerging as important mediators of intercellular communication. They have a specific cargo of DNA, mRNA, miRNA, proteins, growth factors, etc. (Haider and Aramini 2020). The content profile of exosomes is cell-type dependent and constantly fluctuates with many determinant factors, including the microenvironmental factors in which the cells are present at a particular time point. They have notably exhibited therapeutic potential for various diseases and are fast emerging as innovative tools in nanomedicine (Kassem and Kamal 2020a; Norouzi-Barough et al. 2021; Wei et al. 2021). Based on these characteristics, exosomes are defined as nano-sized bioactive vesicles derived from the cell's endosomal membrane system and secreted into surrounding body fluids (Théry et al. 2018).

Exosomes can reprogram the recipient cells acting as "signalosomes" for controlling fundamental cellular functions by transferring their cargo to the recipient cells (Gangoda et al. 2015; Bjorge et al. 2018). Recently, exosomes have sparked great interest as a potential cell-free therapy alternative to the current cellular therapies (Haider and Aslam 2018). MSCs-derived exosomes are gaining special attention among the different cell types due to their unique cargo and ease of manipulation (Janockova et al. 2021). Like their parent cells, exosomes stimulate functional recovery and cellular regeneration in various disease conditions (Derkus et al. 2017). However, unlike their parent cells, they have no critical safety concerns; they pose no risk of tumor formation or any concern regarding the immune rejection by the recipient, and they can pass through biological barriers, that is, the blood-brain barrier, more efficiently. Moreover, since exosomes are naturally equipped to mediate intercellular communication via the transfer of genetic information to recipient cells, they can be utilized as drug delivery systems for gene therapy applications (Colao et al. 2018). MSCs from various tissue sources, Ad-MSCs, BM-derived MSCs, and UCB-derived MSCs, are efficient and established mass producers of exosomes (Yeo et al. 2013; Janockova et al. 2021). Furthermore, MSCs-derived exosomes have been suggested to act through the protein-based mechanism of action as well as micro-RNAs and/or packaged metabolites (Luther et al. 2018; Showalter et al. 2019; Toh et al. 2018).

Conclusively, exosomes derived from MSCs provide a novel platform for a wide array of therapeutic strategies for various disease conditions and eventually may develop into a standardized allogeneic off-the-shelf immunomodulatory and regenerative therapeutics. After extensive evaluation for safety and efficacy studies in the preclinical experimental animal models, they have moved to clinical assessment and www.clinicaltrials.gov shows 226 registered clinical studies involving evaluation of exosome delivery for various diseases, including cardiovascular diseases, stroke, cancer, and COVID-19 pneumonia.

MSCs Act as an Efficient Tool for Gene Therapy

Over the past few years, due to their homing capacity (Karp and Teo 2009) and immunomodulatory activities (Song et al. 2020), MSCs have been nominated as an

efficient tool for gene therapy to treat several pathological conditions, lying at the intersection of cell and gene therapy. Several techniques have been used to generate genetically modified MSCs leading to the up-regulation or down-regulation of native genes related to their regenerative potential or immunomodulatory functions. Alternatively, genetic engineering has been used to modulate them to serve as carriers of transgenes by introducing foreign genes of interest. The genetically modulated cells serve as tiny little factories that continue to secrete the product of the overexpressing genes that significantly contribute to the therapeutic effects of the genetically modulated MSCs (Varkouhi et al. 2020). Such a novel approach using genetically-modified MSCs as gene delivery vehicles widely expand the spectrum of the possible applications of MSCs in various diseases (Oggu et al. 2017).

Interestingly, several cell-therapy pre-clinical studies employing genetically modified MSCs in various critical illness conditions such as acute myocardial infarction, acute liver failure, or even acute lung injury revealed promising results (Varkouhi et al. 2020). Furthermore, genetically engineered MSCs have been used as a vehicle to deliver biological agents to various tumors in preclinical cancer models. In these studies, MSCs have been engineered to express prodrug-converting enzymes, cytokines, pro-apoptotic factors, or antiangiogenic agents either single or multiple transgene overexpression to promote their therapeutic benefits after transplantation (Jiang et al. 2006; Mohr and Zwacka 2018; Mosallaei et al. 2020). Simultaneous overexpression of Akt and angiopoietin-1 has been shown to enhance their endothelial commitment (Lai et al. 2012). MSCs have also been used as carriers of microRNAs, either by genetic modulation to improve their survival and reparability post engraftment (Kim et al. 2012). Transgene overexpression in MSCs has also been used for their reprogramming to pluripotency (Buccini et al. 2012). Conclusively, MSCs indeed represent an efficient tool for gene-therapy applications in regenerative medicine.

Abstract

The clinical application of stem cells continues to fascinate the scientific and clinical communities. Despite the controversies surrounding this field, it is clear that stem cells have revolutionized regenerative medicine. Cell therapy is a progressively growing field that is moving fast from preclinical model development to clinical application. In this regard, outcomes obtained from clinical trials reveal the therapeutic potential of stem cell-based therapy that deals with unmet medical treatment for several disorders with no therapeutic alternatives. The application of stem cells in regenerative medicine is addressing a wide range of clinical conditions using various types of stem cells. Mesenchymal stromal cells (MSCs) have been established as promising candidate sources of universal donor cells for cell therapy due to their contributions to tissue and organ homeostasis, repair, and support by self-renewal and multi-differentiation, as well as by their anti-inflammatory, anti-proliferative, immunomodulatory, trophic, and pro-angiogenic properties. Various diseases have been successfully treated by MSCs in animal models. Additionally, hundreds of clinical trials related to the potential benefits of MSCs are in progress or have concluded satisfactorily. However, although all MSCs are considered suitable to exert these functions, dissimilarities have been found among MSCs derived from different tissues. The same levels of efficacy and desired outcomes have not always been achieved in the diverse studies that have been performed thus far. Therefore, collecting information regarding the characteristics of MSCs obtained from different sources and the influence of other medical and physiological conditions on MSCs is important for

assuring the feasibility, safety, and efficacy of cell-based therapies. This chapter will update and discuss the state of the art in MSCs' cell-based therapies and provide relevant information regarding factors to consider for the clinical application of MSCs.

Keywords

Advanced therapy · Cell therapy · Clinical trial · Good manufacturing practice · Immunomodulation · Inflammation · Medicinal products · Mesenchymal stromal cells · Trophic factors

Abbreviations

Ad-MSCs	Adipose tissue-derived MSCs
AGEs	Advanced glycation end products
ATMPs	Advanced therapy medicinal products
bFGF	Basic fibroblast growth factor
BM-MSCs	Bone marrow-derived MSCs
CAFs	Cancer-associated fibroblasts
Cas9	CRISPR-associated protein 9
CCL	Chemokine (C-C motif) ligand
CFU-F	Colony-forming unit fibroblast
CRISPR	Clustered regularly interspaced short palindromic repeats
CXCL12	C-X-C motif chemokine 12 (or SDF1)
Dkk-1	Dickkopf-1
ECs	Endothelial cells
EMA	European Medicines Agency
ESCs	Embryonic stem cells
EVs	Extracellular vesicles
FBS	Fetal bovine serum
FDA	Food and Drug Administration
GM-CSF	Granulocyte-macrophage colony-stimulating factor
GMP	Good manufacturing practice
GPS	Glycotransferase-programmed stereo substitution
GVHD	Graft-versus-host diseases
GVL	Graft-versus-leukemia
HCELL	Hematopoietic cell E-selectin/L-selectin ligand
HGF	Hepatocyte growth factor
HLA-DR	Human leukocyte antigen-DR isotype
HLA-G5	Human leukocyte antigen-G5
HSCT	Hematopoietic stem cell transplantation
IBMIR	Instant blood-mediated inflammatory reaction
ICAM-2	Intercellular adhesion molecule 2
IDO	Indoleamine-2,3-dioxygenase
IFN-γ	Interferon-gamma
IGF-1	Insulin-like growth factor 1

IL	Interleukin
IL-1α	Interleukin-1 alpha
IL-1β	Interleukin-1 beta
iPSCs	Induced pluripotent stem cells
ISCT	International Society for Cellular Therapy
ITP	Immune thrombocytopenic purpura
LFA-3	Lymphocyte function-associated antigen 3 (or CD58)
MCP-1	Monocyte chemoattractant protein 1
MHC-HLA	Major histocompatibility complex-human leukocyte antigen
MMP-2	Matrix metalloproteinase 2
MSCs	Mesenchymal stromal cells
PAI-1	Plasminogen activator inhibitor-1
PDGF	Platelet-derived growth factor
PD-MSCs	Placenta-derived MSCs
PGE-2	Prostaglandin-E2
RA	Rheumatoid arthritis
SDF-1	Stromal cell-derived factor 1
SLE	Systemic lupus erythematosus
SSc	Systemic sclerosis
STC1	Stanniocalcin-1
TALENs	Transcription activator nucleases
TbRIII	Type III TGF-β receptor
TGF-β	Transforming growth factor beta
TNF-α	Tumor necrosis factor alpha
tPA	Tissue plasminogen activator
TRAIL	TNF-related apoptosis-inducing ligand
Trx1	Thioredoxin-1
TSG-6	Tumor necrosis factor-stimulated gene-6
UCB-MSCs	Umbilical cord-derived MSCs
VCAM-1	Vascular cell adhesion protein 1
VEGF	Vascular endothelial growth factor
ZFNs	Zinc finger nucleases

Introduction

Regenerative medicine is a novel emerging medical approach that drives the current understanding of biological and medical processes and suggests new treatments. As defined by the European Medicines Agency (EMA) and the US Food and Drug Administration (FDA), advanced therapies include cell and gene therapy and tissue engineering (Iglesias-López et al. 2019). Advanced therapies open up a broad set of translational fields and targets in areas of unmet medical need. In this regard, cell-based therapy through the application of cells, either alone or engineered, as a pharmacologically active substance seeks to restore the functioning of damaged

tissues or organs through the protection of cellular integrity, the replacement of damaged cells, and the promotion of trophic, anti-inflammatory, and immunomodulatory effects among others. However, while the progression of cell-based therapy in early-phase clinical trials with patients has progressed promisingly, the translation from laboratory to bedside to late-phase clinical trials has not been as rapid as expected. It is necessary to consider that these new therapeutic alternatives also involve unknown side effects that must be detected and characterized in-depth to improve and ensure safety, feasibility, and efficacy of cell application (García-Bernal et al. 2021; Hmadcha et al. 2020; Soria-Juan et al. 2019; Escacena et al. 2015; Gálvez et al. 2013).

In this regard, mesenchymal stromal cells (MSCs) are the most common cell type used in cell-based therapy due to their unique biological properties, including easy expansion and culture. The MSC-Committee of the International Society for Cellular Therapy (ISCT-MSC) first proposed that plastic-adherent cells of the bone marrow (BM) generally described as "mesenchymal stem cells" should be defined as "multipotent mesenchymal stromal cells." In contrast, the term "mesenchymal stem cells" should be reticent for a subset of these cells that show stem cell activity by clearly stated criteria. As the acronym MSCs may be used to define both cell populations, the combined definition "mesenchymal stem/stromal cells" is probably more appropriate, especially when the "stemness" of the whole MSC population is not demonstrated (Horwitz et al. 2005). Recently, this committee offers a position statement to clarify the nomenclature of "mesenchymal stem/stromal cells." The ISCT-MSC committee continues to support the use of the acronym "mesenchymal stromal cells" but recommends that this should be complemented by the tissue origin from which the cells were derived, which would highlight tissue-specific properties: that they be referred to as "stromal" unless there are rigorous in vitro and in vivo evidence of their stemness supplemented by a robust matrix of functional assays to demonstrate the "mesenchymal stromal cells" properties. Thus, they should not be defined generically, but based on the intended therapeutic mode of action (Viswanathan et al. 2019).

The MSCs are now considered as "cellular medicament" but are widely accepted to represent a heterogeneous population of multipotent non-hematopoietic progenitor cells with varying degrees of stemness, which mean that they have self-renewal and multi-differentiation abilities, the capability to differentiate into multiple cell types, including adipocytes, chondrocytes, and osteoblasts, depending on in vitro culture conditions (Soria-Juan et al. 2019).

The MSCs reside in almost all tissues, are found in virtually all post-natal organs and tissues, and are derived from the mesodermal germ layer. Furthermore, MSCs can be obtained from easily accessible sources by minimally invasive methods (e.g., peripheral blood, adipose tissue) and can be rapidly expanded in large scale for clinical use (Escacena et al. 2015). This allows producing a patient-specific cellular medicament (e.g., autologous medicinal product) within a therapeutic time window. In addition, the possibility of obtaining MSCs from adult tissue circumvents the ethical issues associated with the use of embryonic source (Lo and Parham 2009;

Ramos-Zúñiga et al. 2012). MSCs are inexpensively isolated and are easily expanded in vitro due to their fibroblastic characteristic and high adherence to plastic. MSCs are characterized by a specific pattern of membrane markers, consisting of the expression of CD73, D90, and CD105 and the absence of expression of CD14, CD34, CD45, and human leukocyte antigen-DR (HLA-DR), making them promising candidate sources of donor cells for use in cell-based therapy and transplantation (Horwitz et al. 2005).

MSCs function in tissue repair and support, contributing to tissue homeostasis. Even though the exact origin of MSCs remains elusive, there is strong evidence that MSC progenitors are found in the perivascular zone (Escacena et al. 2015) in an environment that promotes a quiescent state, ensuring the maintenance of homeostasis. Upon tissue damage, MSCs enter the bloodstream and are attracted to pro-inflammatory cytokines in the areas of injury. Therefore, MSCs have been termed "guardians of inflammation" (Prockop and Oh 2012). The cytoskeleton, extracellular matrix molecules, cell-cell contacts, adhesion ligands, and receptors are involved in the repair process. While the exact mechanisms related to MSCs' migration to specific sites and through the endothelial cell layer are still unknown, chemokines and their receptors may play a role in this process (Hmadcha et al. 2020; Petrie et al. 2009).

Furthermore, MSCs' survival, permanent engraftment, and differentiation into resident cells were thought, initially, to be necessary to obtain the beneficial effects of these cells, and clinical experience and several experiments have shown that one of the primary functions of MSCs, most likely their critical function, is to secrete several bioactive molecules related to the microenvironment "niche" in which these cells are located. Consequently, the secretome reproduces most of the effects of MSCs transiently; in this sense, MSCs secrete a wide variety of pro-inflammatory and anti-inflammatory cytokines, chemokines, growth factors, and prostaglandins under resting and inflammatory conditions (Hmadcha et al. 2009).

These molecules are associated with immunomodulation (indoleamine-2,3-dioxygenase (IDO), prostaglandin-E2 (PGE-2), transforming growth factor beta (TGF-β), human leukocyte antigen-G5 (HLA-G5), and hepatocyte growth factor (HGF)), anti-apoptosis (vascular endothelial growth factor (VEGF), granulocyte-macrophage colony-stimulating factor (GM-CSF), TGF-β, stanniocalcin-1 (STC1), and insulin-like growth factor 1 (IGF-1)), angiogenesis (VEGF, monocyte chemoattractant protein 1 (MCP-1), and IGF-1), local stem and progenitor cell growth and differentiation support (CSF complex, angiopoietin-1, and stromal cell-derived factor 1 (SDF-1)), anti-fibrosis (HGF and basic fibroblast growth factor (bFGF)), and chemoattraction (chemokine (C-C motif) ligands 2 and 4 (CCL2, CCL4) and C-X-C motif chemokine 12 (CXCL12 also called SDF1)) (Meirelles Lda et al. 2009).

MSCs display a low expression of major histocompatibility complex class I human leukocyte antigen (MHC-HLA class I), while they are constitutively negative for HLA-class II; likewise, they do not express costimulatory molecules such as CD80, CD86, CD40, and CD40L. However, MSCs share the expression of surface markers, such as vascular cell adhesion protein 1 (VCAM-1), intercellular adhesion molecule 2 (ICAM-2), and lymphocyte function-associated antigen 3 (LFA-3 or CD58) with the thymic epithelium, which is crucial for the interaction with T cells

(Hmadcha et al. 2009; Le Blanc 2003). Whereas MSCs remain in a quiescent state showing anti-apoptotic properties and contributing to homeostasis, in an inflammatory environment (presence of IFN-γ, TNF-α, IL-1α, and IL-1β), they begin to exercise their immunomodulation abilities, inhibiting the proliferation of effector cells and their cytokine production. In the same way, MSCs can block various immune cell functions (Hmadcha et al. 2009; Cagliani et al. 2017).

There is a complex "cross-talk" interaction between MSCs and endothelial cells (ECs). MSCs increase the proliferation and migration of the ECs, promoting early events of angiogenesis and decreasing the permeability of the monolayer of the ECs. In direct co-cultures of MSCs and ECs, MSCs increased the persistence of pre-existing blood vessels in a dose-dependent manner (Duffy et al. 2009). Moreover, beneficial therapeutic effects of the use of conditioned media of MSCs have been reported; even it is therapeutically better than the cells themselves (Burlacu et al. 2013; Shrestha et al. 2013) and to stimulate the proliferation of local ECs (Potapova et al. 2007). Likewise, in addition to direct "cell-cell" contact, speculation has been made with a possible transfer of mitochondria or vesicular components (secretome) that contain mRNA, microRNA, and proteins (Tan et al. 2021). Not only have this, the exosomes, secretory extracellular vesicles (EVs) from MSCs, also been identified to produce the same immunomodulatory activity as MSCs (Haider and Aramini 2020). Targeting the MSCs' secretome as an acellular therapeutic agent could provide several advantages over the use of cell-based therapies for various diseases paving the way for cell-free therapy (Haider and Aslam 2018; Bari et al. 2019).

Altogether, these features constitute an area of research in expansion in the last decade and make MSCs an eligible therapeutic candidate to be evaluated within clinical trials for a plethora of diseases such as diabetes and diabetes complication and cardiovascular and neurological diseases; in immune-mediated disorders, such as graft-versus-host diseases (GVHD), multiple sclerosis (MS), Crohn's disease (CD), and osteoarthritis (OA); and even in immune-dysregulating infectious diseases such as the novel coronavirus disease 2019 (COVID-19) (see ▶ Chap. 6, "Mesenchymal Stromal Cells for COVID-19 Critical Care Patients," of this book for review on COVID-19).

When writing this chapter (May 2021), 1.276×10^3 publicly and privately funded clinical studies worldwide in which MSCs have been used have been reported and registered in the US National Library of Medicine database (NIH-ClinicalTrials.gov). Although the therapeutic efficacy of MSCs has been demonstrated in different disease animal models and numerous human phase 1/2 clinical trials and generally communicated, only very few (84 studies) phase 3/4 clinical trials using MSCs are registered (Table 1) and have demonstrated the expected potential therapeutic benefit. Almost all registered clinical trials are early phase 1/2 with safety as the primary objective. For efficacy and effectiveness issues, other advanced phases are mandatory. In all cases, one cannot consider these issues (efficacy nor effectiveness) unless phase 3 clinical trials are developed (García-Bernal et al. 2021) (Fig. 1).

Even though MSCs and their EVs have been shown to have high potential benefits in regenerative medicine and cell-free-based therapy, their clinical application remains controversial; thus, considerations and determination of possible side

effects need to be addressed to optimize the clinical application of this double-edged sword cellular medicament. This chapter updates and discusses the state of the art in MSCs' cell-based therapies and provides relevant information regarding factors to consider for the clinical application of MSCs.

Biological Characteristics

Phenotypic Profile

Since Friedenstein and colleagues first isolated a colony-forming unit fibroblast (CFU-F) from BM, BM has been widely used as a source of MSCs for many investigations and clinical trials. In addition to BM (BM-derived MSCs), MSCs have been isolated from different tissues, such as adipose tissue (Ad-MSCs), umbilical cord (UCB-MSCs), dental pulp, synovial liquid, and amniotic fluid. All these tissues vary in their cellular components, signals, and factors secreted, resulting in different immediate microenvironment conditions, thus developing

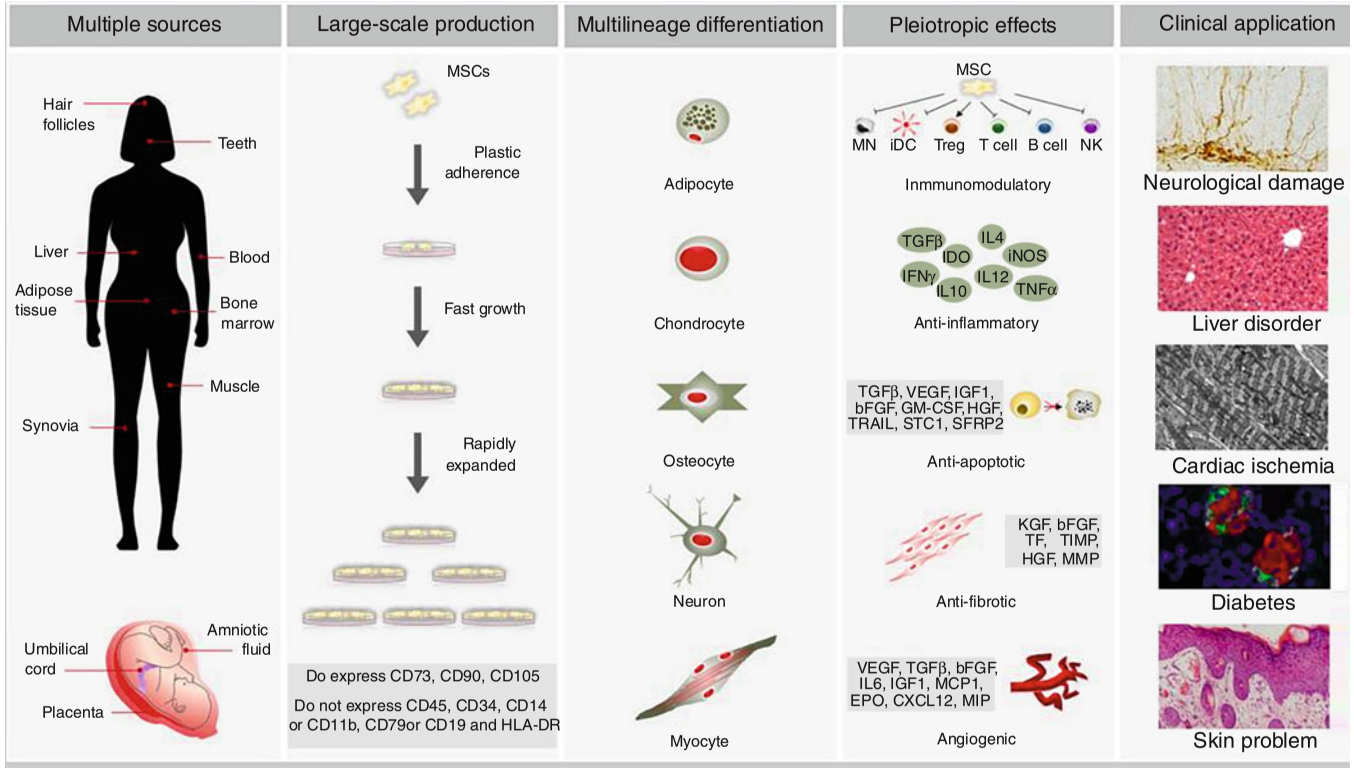

Fig. 1 The MSCs have multiple potential advantages for their clinical application. Among other advantages, MSCs can be isolated from various sources, are produced on a large scale, differentiate into various cell types, and have pleiotropic effects. Such advantages make MSCs suitable for clinical application in different disease conditions, such as neurological damage, liver disorders, cardiac ischemia, diabetes, or skin problems. (Re-published from Hmadcha 2020,

several physiological niches (Hmadcha et al. 2009; Escacena et al. 2015). Although isolated and long-term cultured MSCs of most tissues show similar immunophenotypic characteristics, some differences have been found among MSCs of different tissue origins according to data obtained by in vitro experiments. In 2006, the International Society for Cellular Therapy (ISCT) published the minimal criteria to define MSCs by nomenclature and by biological characteristics to allow studies from different groups to be compared and contrasted. These criteria include the co-expression of markers such as CD73, CD90, and CD105, a lack of expression of hematopoietic markers (CD45, CD34, and CD14) and HLA-DR, multipotent differentiation potential, and adherence to plastic (Horwitz et al. 2005). However, several researchers have noted that Ad-MSCs express CD34 and CD54 in early passages and have lower expression of CD106 and that umbilical cord blood-derived MSCs (UCB-MSCs) express CD90 and CD105. Other markers have been used in different studies, and other differences have emerged, such as VEGFR-2 (Flk-1) expression, which was significantly higher in periosteum-derived cells than in adipose tissue- and muscle-derived cells, or the rate of NGFR positivity, which was much higher in muscle-derived cells than in other mesenchymal tissue-derived cells (Escacena et al. 2015).

Although some immunophenotypic differences have been documented, many researchers consider that these differences could be due to distinct extraction methods and different culture methodologies, resulting in variations of MSC surface markers. Therefore, this chapter aimed to investigate markers and characteristics that are more specific to select better sources of MSCs for clinical applications. Likewise, expanding the cells in vitro is necessary to obtain the desired numbers for therapeutic approaches. Changes in the proteomic phenotype of MSCs have been observed during high passages, although no proper approaches to examine the state of cells continuously during long-term in vitro culture have been established (Capra et al. 2012). Some researchers ascribe these variations to the adaptation of cells to the environment; thus, determining the biomolecular markers that are involved in these variations is essential for obtaining a better phenotypic characterization of these cells and thus for achieving more effective cell therapy in the future (Escacena et al. 2015).

Fig. 1 (continued) article published under CC-BY terms). Abbreviations: bFGF basic fibroblast growth factor, CXCL12 C-X-C motif chemokine 12, EPO erythropoietin, GM-CSF granulocyte-macrophage colony-stimulating factor, HGF hepatocyte growth factor, HLA-DR major histocompatibility complex class II DR, iDC immature dendritic cell, IDO indoleamine-2,3-dioxygenase, IGF1 insulin-like growth factor 1, IL-10 interleukin-10, IL-12 interleukin-12, IL-4 interleukin-4, IL-6 interleukin-6, INF-γ interferon-γ, iNOS inducible nitric oxide synthase, KGF keratinocyte growth factor, MCP1 monocyte chemoattractant protein 1, MIP macrophage inflammatory protein, MMP matrix metalloproteinases, MN monocyte, NK natural killer cell, SFRP2 secreted frizzled-related protein 2, STC1 stanniocalcin 1, TF tissue factor, TGF-β transforming growth factor beta, TIMP tissue inhibitor of metalloproteinases, TNF-α tumor necrosis factor α, TRAIL TNF-related apoptosis-inducing ligand, Treg regulatory T cell, VEGF vascular endothelial growth factor

MSCs' Proliferation

The proliferative activity of MSCs is another feature that may be affected by the different origins of MSCs. The rate and persistence of MSC proliferation appear to vary between source tissues. MSCs are considered adult stem cells, and unlike embryonic stem cells (ESCs), these cells have a limited proliferative capacity. Physiological niches maintain adult stem cells in an undifferentiated state; however, when MSCs are cultured in vitro, they age, which affects their therapeutic properties, such as alterations in phenotype, differentiation potential, global gene expression patterns, miRNA profiles, and even chromosomal abnormalities, particularly after long-term culture or when cells of multiple doublings are used (Escacena et al. 2015). Large numbers of MSCs are needed for therapeutic applications, and in vitro expansion is required to produce the desired MSC numbers. In vivo, MSCs represent 0.0001% of nucleated BM cells, and their number decreases with the donor's age. The quantity of MSCs (CFU-Fs) among nucleated BM cells decreases with age from one MSC in 10^4 BM cells in newborn to one MSC in 10^5 cells in teenagers and one MSC in 10^6 cells in older individuals (Caplan 2009).

Furthermore, MSCs from older human donors differ significantly from younger donors in morphology, replicative lifespan, doubling time, healing capacity, and differentiation potential. Sufficient evidence has indicated that MSCs from older donors have limited therapeutic efficacy. Some studies have suggested that the difference between preclinical and clinical findings is due to the donor age (Stenderup et al. 2003; Escacena et al. 2015). Therefore, considering that several age-related diseases exist and that elderly patients are potential users of cell therapy, understanding the molecular and biological effects of aging on MSCs is essential for developing safe and effective MSC-based autologous cell therapy. Meanwhile, the use of allogeneic MSCs may be a treatment option for these specific patients. As commented below, MSCs elude allogeneic rejection, and their infusion is feasible and well-tolerated, with no adverse effects (McAuley et al. 2014; Liang et al. 2010).

Differentiation Capacity

MSCs can differentiate in vitro into several mesenchymal lineages, including adipose tissue, bone, cartilage, and muscle (Pittenger et al. 1999; Prockop 1997; Bruder et al. 1997). Furthermore, MSCs can differentiate into ECs, neurons, and glial cells because MSCs express genes related to specific lineages rather than those of the mesenchymal lineage (Woodbury et al. 2002). Although multilineage differentiation is another minimal criterion advised by the ISCT and undoubtedly represents a fundamental property of MSCs, this ability depends primarily on the source tissue from which these cells are derived. As such, Sakaguchi and colleagues (Sakaguchi et al. 2005) compared human MSCs isolated from BM, synovium, periosteum, skeletal muscle, and adipose tissue. The cells were expanded by similar processes; synovium-derived cells had the most remarkable ability for chondrogenesis; adipose- and synovium-derived cells, for adipogenesis; and BM-, synovium-, and

periosteum-derived cells, for osteogenesis. In another comparative analysis, UCB-MSCs showed no adipogenic differentiation capacity compared to BM- and Ad-MSCs (Kern et al. 2006).

As discussed by Horwitz (Horwitz et al. 2002), who used differentiated MSCs in a study to test the regeneration of damaged tissues, BM-derived MSCs can engraft after transplantation, differentiate to functional osteoblasts, and contribute to the formation of new dense bone in children with osteogenesis imperfecta. Most likely, the microenvironment in which MSCs are transplanted directly influences in their distinct differentiation pathways. New insights into the biological characteristics of MSCs are needed to achieve future therapies.

Cellular Transformation

In general, successive passages or long-term cultures induce genetic instability and cell transformation. Several authors have described that MSCs cultivated in vitro can be expanded multiple times without an apparent loss of differentiation potential or chromosomal alterations and even that long-term MSC cultures can develop chromosomal abnormalities but without an obvious potential for transformation (Koç et al. 2000; Le Blanc et al. 2004; Ringdén et al. 2006; Fang et al. 2006; Ning et al. 2008). Although no tumor formation in humans has been reported after the administration of MSCs, several factors must be considered that can contribute significantly to the induction of cytogenetic abnormalities, such as aspects related to the manufacturing process of the cellular medicine (e.g., culture conditions and duration of cell expansion) and heterogeneity of the MSC population (e.g., cells in different stages of duplication). The tumorigenic potential of a cell therapy medicament may depend on intrinsic and extrinsic factors, such as the administration site in the patient (due to the receptor's microenvironment) and/or the manipulation of the culture ex vivo.

Mechanism of Action

Cell Migration Toward Damaged Tissues

The success of an advanced therapy medicinal product initially depends on its ability to reach target tissues. MSCs possess inherent tropism toward damaged sites controlled by many factors and mechanisms, including chemoattractant signals. For instance, the C-X-C motif chemokine ligand 12 (CXCL12) is a frequent triggering factor at the injury site. It has been demonstrated that a subpopulation of MSCs expresses the C-X-C chemokine receptor type 4 (CXCR4) that binds to its ligand, the CXCL12, to mediate cell migration (Wynn et al. 2004; Ma et al. 2015). Aside from CXCR4, MSCs express other chemokine receptors, such as CCR1, CCR2, CCR4, CCR7, CCR8, CCR9, CCR10, CXCR1, CXCR2, CXCR3, CXCR4, CXCR5, CXCR6, and CX3CR1 (Sordi et al. 2005; Von Lüttichau et al. 2005; Honczarenko

et al. 2006; Ringe et al. 2007). These receptors are essential to respond to triggering factors at the site of injury. In addition, MSCs also express cell adhesion molecules, including CD49d, CD44, CD54, CD102, and CD106 (De Ugarte et al. 2003). These chemokines and cell adhesion molecules orchestrate the mobilization of MSCs' injury sites in a similar manner to white blood cells (Kolaczkowska and Kubes 2013). MSC mobilization is a multistep process that encompasses the attachment of free circulating MSCs in the bloodstream to transmigrate between ECs with the ultimate goal of migrating and engrafting to the target tissue.

Tissue Repair

Once recruited in the injured site, MSCs contribute to tissue repair and regeneration by activating several mechanisms. A growing body of research has demonstrated that MSCs display pleiotropic effects, which give them enormous therapeutic potential. MSCs secrete various mediators of tissue repair in response to injury signals, including anti-apoptotic, anti-inflammatory, immunomodulatory, anti-fibrotic, and angiogenic agents (Caplan and Dennis 2006; Meirelles Lda et al. 2009; Maltman et al. 2011; Escacena et al. 2015). Among pleiotropic effects, anti-inflammatory and immunomodulatory properties are mainly responsible for the therapeutic benefits of MSCs. As sensors of inflammation, MSCs release soluble factors, such as TGF-β, IDO, TNF-α, IL-10, and INF-γ, which interfere with the immune system and modify the inflammatory landscape (Prockop and Oh 2012). Pivotal studies showed that MSCs inhibit the proliferation of T and B cells (Di Nicola et al. 2002; Corcione et al. 2006; Song et al. 2019), suppress the activation of natural killer cells (Sotiropoulou et al. 2006), and prevent the generation and maturation of monocyte-derived dendritic cells (English et al. 2008; Spaggiari et al. 2009). Furthermore, MSCs can promote the generation of regulatory T cells (Maccario et al. 2005), which exert immunosuppressive effects. Although soluble factors play a key role in the immunosuppressive activity of MSCs, cell-to-cell contact also influences immune responses (Ren et al. 2010; Li et al. 2019). For instance, direct contact between MSCs and pro-inflammatory macrophages has been shown to induce immune tolerance by inducing tumor necrosis factor-stimulated gene-6 (TSG-6) production (Li et al. 2019). MSC mediated modulations of the immune response set in motion essential inflammatory processes that significantly promote tissue repair and regeneration by driving healing, scarring, and fibrosis (Julier et al. 2017).

Immunomodulatory Potential

The immunomodulatory properties of MSCs and their immune-privileged condition make these cells good candidates for use in several clinical trials related to chronic, inflammatory, and autoimmune diseases. MSCs interact with cells of the innate or

adaptive immune system (T cells, B cells, NK cells, monocyte-derived dendritic cells, and neutrophils) (Di Nicola et al. 2002; Raffaghello et al. 2008). For a cell to be recognized by the immune system, the expression of major histocompatibility complex (MHC) and co-stimulatory molecules is necessary. MHC class I and class II human leukocyte antigens (HLAs) are master triggers of robust immunological rejection of grafts because they present antigens to cytolytic T lymphocytes (CTL). Human mesenchymal stem cells (hMSCs) are characterized by low expression of MHC class I HLAs but are constitutively negative for class II HLCs; these cells do not express co-stimulatory molecules such as B7-1, B7-2, CD80, CD86, CD40, and CD40L (Hmadcha et al. 2009; Le Blanc 2003). However, similar to the thymic epithelium, MSCs express the surface markers VCAM-1, ICAM-2, and LFA-3 (Le Blanc 2003; Conget and Minguell 1999), which are crucial for T-cell interactions.

Although a T-cell response should be expected, hMSCs can modulate the activation and proliferation of both $CD4^+$ and $CD8^+$ cells in vitro by arresting T cells in G0/G1 phase (Glennie et al. 2005; Benvenuto et al. 2007). Different studies have suggested that cell-cell interactions and certain soluble factors are the mechanisms used by MSCs to mediate the immune response. Factors, such as IDO, TGF-β1, IFN-γ, IL-1β, TNF-α, IL-6, IL-10, PGE-2, HGF, HLA-G5, and others, are secreted by MSCs or released after interactions with target cells. As mentioned above, MSCs remain in a resting state, display anti-apoptotic properties, and maintain different cells such as hematopoietic stem cells (HSCs), thus contributing to tissue homeostasis. However, in an inflammatory environment such as that created by cytokines such as IFN-γ, TNF-α, IL-1α, and IL-1β, MSCs begin to exert their immunosuppressive effects and polarize, inhibiting the proliferation of effector cells and their production of cytokines. In this regard, IFN-γ is postulated as a "licensing" agent for MSC anti-proliferative action. MSCs may also acquire behavior as antigen-presenting cells (APCs) under specific concentrations of IFN-γ (Stagg et al. 2006; Uccelli et al. 2008). However, no consensus regarding what concentration of IFN-γ is more necessary for MSCs to show inhibitory or APC functions exists.

Likewise, TNF-α is another pro-inflammatory cytokine involved in the MSC immune response, and TNF-α enhances the effect of IFN-γ. IFN-γ, with or without the help of TNF-α, stimulates the production of IDO by MSCs, inhibiting the proliferation of activated T or NK cells and thus enhancing the homing potential and reparative properties of these cells; however, some potential risks are associated with the role of IFN-γ (Krampera et al. 2006; Sivanathan et al. 2014). Some authors have maintained that the immunomodulatory properties of MSCs are comparable, while others have argued that MSCs of different tissue origins or species cannot have equivalent and comparable immunomodulatory properties (Najar et al. 2010; Yoo et al. 2009; Ricciardi et al. 2012; Krampera 2011). For example, MSCs from perinatal sources (umbilical cord and amniotic membrane) show a higher immunomodulatory capacity, differential gene expression profiles, and paracrine factor secretion compared to BM-MSCs (Wegmeyer et al. 2013). Lee and colleagues found that HLA-G, a specific MHC-I antigen that is critical for maintaining the

immune-tolerant state of pregnancy and that is a contributing factor to the induction of more substantial immunosuppression, is strongly positive only in placenta-derived MSCs (PD-MSCs) (Lee et al. 2012a). This is in contrast to BM-derived MSCs and Ad-MSCs and suggests that the immunophenotype of PD-MSCs may be superior to other MSCs in terms of their immunosuppressive function (Hunt et al. 2005). Nonetheless, some authors claimed that BM-derived MSCs were more immunomodulatory than PD-MSCs (Fazekasova et al. 2011). And others concluded that the immunomodulatory capacities of BM-derived MSCs and Ad-MSCs are similar but that differences in cytokine secretion cause Ad-MSCs to have more potent immunomodulatory effects than BM-derived MSCs (Melief et al. 2013).

Bartholomew and colleagues (Bartholomew et al. 2002) showed that allogeneic MSCs prolonged skin graft survival in baboons. Mouse MSCs have been used in related experiments; these cells use inducible nitric oxide synthase (iNOS) for immunosuppression instead of IDO. These findings indicate that MSCs differ between species (Ren et al. 2009). Since then, several preclinical models have been used to analyze the biological effects of MSCs and their ability to modulate immune responses, considering that not all animal models mimic human diseases. Once more, these differences could be due to isolation procedures, to culture methodology, or, more likely, to differences in the microenvironments where cells reside. These and other findings lead us to conclude that determining whether these differences may be relevant for clinical applications and whether MSCs of a particular tissue type are more appropriate for specific therapies or diseases.

Preclinical Applications

Preclinical models are essential for clinicians, researchers, and both national and international regulatory agencies to demonstrate the safety and efficacy of MSC-based therapies (Krampera et al. 2013). Because MSCs can exert immunomodulatory properties and act on different immune cells in vitro and in vivo, these cells have begun to be used against autoimmune diseases based on multiple autoimmune experimental models. Pioneer studies in experimental autoimmune encephalomyelitis (EAE), a model for multiple sclerosis, reported that MSCs derived from numerous tissue origins show efficacy against neurodegenerative disorders (Zappia et al. 2005; Rafei et al. 2009; Constantin et al. 2009; Bai et al. 2009; Zhang et al. 2005). BM-MSC and UCB-MSC treatments have improved clinical and laboratory parameters in systemic lupus erythematosus (SLE) (Sun et al. 2010). Furthermore, ameliorating effects have been observed in experimental mouse models of rheumatoid arthritis (RA) (González et al. 2009). Diabetes is another autoimmune disorder in which MSCs have been employed (Jurewicz et al. 2010; Lee et al. 2006). Although promising results and progress have been observed in this field, the interspecies differences, and contradictory experimental outcomes, and the inability to recreate the complete pathophysiology of some diseases make it necessary to search for new animal models for comparable results.

MSC-Based Therapy for Autoimmune Diseases

The MSCs are being used to facilitate the engraftment of transplanted HSCs and treat graft-versus-host disease (GvHD) after allogeneic hematopoietic stem cell transplantation (HSCT) based on their immunomodulatory properties and provide appropriate conditions. However, preclinical and clinical experiments with MSCs do not always show similar results for the prevention and treatment of GvHD. In a study using a mouse model of GvHD (Sudres et al. 2006), MSCs suppressed alloantigen-induced T-cell proliferation in vitro in a dose-dependent manner but yielded no clinical benefit regarding the incidence or severity of GvHD. Instead, when UCB-MSCs were administered in weekly doses in a xenogenic model of GvHD, a marked decrease in human T-cell proliferation was observed, and none of the mice developed GvHD. No therapeutic effect was obtained when UCB-MSCs were administered at the onset of GvHD (Tisato et al. 2007). In the same line of research, serial infusions of mouse AD-MSCs could efficiently control the lethal GvHD that occurred in recipients transplanted with haploidentical hematopoietic grafts (Yañez et al. 2006). Mixed results have also been achieved in human patients. One study found that the co-transplantation of culture-expanded MSCs and HSCs from HLA-identical sibling donors after myeloablative therapy accelerated hematopoietic engraftment (Lazarus et al. 2005); however, a significant reduction of GvHD symptoms was not shown, although the incidence or severity of GvHD did not increase. Koç and colleagues (Koç et al. 2000) reported a positive impact of MSCs on hematopoiesis; rapid hematopoietic recovery was observed in a clinical study with breast cancer patients who received autologous HSCT together with autologous MSCs.

Therapeutic effects have also been reported at the onset of GvHD, such as the case of a 9-year-old boy with severe treatment-resistant GvHD after allogeneic HSCT for acute lymphocytic leukemia who received haploidentical MSCs derived from his mother. He showed improvement after two administrations of MSCs (Le Blanc et al. 2004). Similar results have been obtained in steroid-refractory GvHD pilot studies with BM-MSCs and AD-MSCs (Ringdén et al. 2006; Fang et al. 2006). Several infusions appear to be required to maintain the level of active immunomodulation by MSCs. Similarly, the expression of pro-inflammatory cytokines such as IFN-γ in the environment at the time of MSC administration is required by these cells to exert their immunosuppressive effect. A lack of MSC "licensing" can result in the absence of the desired therapeutic effect.

While evidence that MSCs are effective in combination or after HSCT in specific hematological and non-hematological diseases has been shown, adverse reactions and risk factors intrinsic to this practice have been reported. In a pilot study, HLA-identical sibling-matched HSCs were transplanted with or without MSCs in hematological malignancy patients. Although MSCs were well-tolerated and this treatment effectively prevented GVHD, six patients (60%) in the MSC group and three (20%) in the non-MSC group had 3-year disease-free survival rates of 30 and 66.7%, respectively. The relapse rate in the experimental group was higher than that

in the control group, suggesting that MSCs may impair the therapeutic graft-versus-leukemia (GVL) effect (Ning et al. 2008). In vitro and in vivo studies regarding the relationship between the immunosuppressive properties of MSCs and the stimulation of cancer growth have been performed. Mouse MSCs from the BM, spleen, and thymus injected together with a genetically modified tumor cell vaccine could equally prevent the onset of an anti-tumor memory immune response, thus leading to tumor growth in normally resistant mice (Krampera et al. 2007). In another in vivo experiment with a murine melanoma tumor model, the authors observed that the subcutaneous injection of B16 melanoma cells led to tumor growth in allogeneic recipients only when MSCs were co-injected (Djouad et al. 2003). The functions of MSCs can be influenced by the existing microenvironment, making them acquire supportive properties toward cancer cells and decrease immune reactions (Galiè et al. 2008). Therefore, potential risks related to the growth support and enhancement of undetected or "resident" cancer exist, and the administration of MSCs in these patients must be thoroughly evaluated.

MSCs for Cancer Treatment

The therapeutic benefits of MSCs have prompt their use in cell-based strategies to treat different diseases, including cancer (Hmadcha et al. 2020). Similar to damaged tissues, tumors exert chemoattractant effects on MSCs that influence their recruitment to tumor sites. The CXCL12/CXCR4 axis is one of the most frequently studied signaling pathways in mobilizing MSCs to the tumor microenvironment (Gao et al. 2009; Xu et al. 2009; Lourenco et al. 2015; Wobus et al. 2015; Kalimuthu et al. 2017). However, the ability of MSCs to migrate toward cancerous tissue is also controlled by other agents, including diffusible cytokines, such as IL-8, growth factors such as TGF-β1 or platelet-derived growth factor (PDGF), and extracellular matrix molecules, such as matrix metalloproteinase 2 (MMP-2) (Nakamizo et al. 2005; Birnbaum et al. 2007; Bhoopathi et al. 2011). Once the tumor niche is reached, MSCs interact with cancer cells via direct and indirect mechanisms that affect tumor development. The paracrine action of MSCs is one of the main mechanisms involved in cancer regulation and is mediated by multiple factors, including growth factors and cytokines. These paracrine factors affect cellular processes involving the tumor cell cycle (e.g., cell proliferation), cell survival, angiogenesis, and immunosuppression/immunomodulation, allowing MSCs to regulate cancer.

The paracrine agents can be directly secreted into the extracellular space or packaged into EVs for spreading in the tumor milieus (Rani et al. 2015). The interaction of MSCs with the tumor cell cycle is the most commonly accepted process by which MSCs exert their therapeutic effects (Fathi et al. 2019). By inhibiting proliferation-related signaling pathways, such as the phosphatidylinositol 3-kinase/protein kinase B (PI3K/AKT), MSCs can induce cell cycle arrest and reduce cancer growth (Lu et al. 2019). In addition, MSCs can undergo differentiation into other cell types, such as cancer-associated fibroblasts (CAFs), to directly

contribute to cancer progression (Jotzu et al. 2011; Barcellos-de-Souza et al. 2016; Aoto et al. 2018).

Accumulating evidence indicates that the cross-talk between MSCs and tumor cells results in both pro-tumor and anti-tumor effects, raising safety concerns for clinical application in oncology (Barkholt et al. 2013). The discrepancies in the ability of MSCs to promote or suppress tumor development may be attributable to differences in experimental tumor models, MSC tissue source, dose or timing of the MSC treatment, cell delivery method, control group chosen, and other experimental conditions (Bortolotti et al. 2015; Bajetto et al. 2017). In this regard, a study demonstrated that direct (cell-to-cell contact) or indirect (released soluble factors) interaction between umbilical cord MSCs and glioblastoma stem cells produces divergent effects on cell growth, invasion, and migration (Bajetto et al. 2017). Moreover, the application of MSCs for cancer patients is a more complex situation in which other factors have to be taken into consideration. For instance, the pathological conditions of each patient may induce cellular and molecular changes in MSCs that interfere with their therapeutic effects (Capilla-González et al. 2018; Pérez et al. 2018; Rivera et al. 2019). Therefore, it is important to be cautious while drawing conclusions from a single study regarding the therapeutic effects of MSCs in cancer.

The Anti-tumor Activity of MSCs

Although compelling evidence shows a pro-tumorigenic role of MSCs, these cells also have potent tumor-suppressive effects that have been exploited as cancer therapeutics. Previous studies have demonstrated that MSCs release cytotoxic agents, such as TNF-related apoptosis-inducing ligand (TRAIL) that selectively induces apoptosis in different types of cancer (Wiley et al. 1995; Hao et al. 2001; Takeda et al. 2001; Akimoto et al. 2013). Recently, a report indicated that BM-derived MSCs promote apoptosis and suppress the growth of glioma U251 cells through downregulation of the PI3K/AKT signaling pathway (Lu et al. 2019). Likewise, intravenously transplanted MSCs were found to suppress tumor growth by blocking AKT activation in a Kaposi sarcoma mouse model (Khakoo et al. 2006). In mammary carcinomas, umbilical cord MSCs attenuated cell growth and triggered apoptosis through inhibiting ERK1/2 and AKT activation (Ganta et al. 2009). The Wnt signaling pathway has also been involved in the ability of MSCs to inhibit tumor cell proliferation (Qiao et al. 2008a, b). A mechanistic study of the inhibitory effect of MSCs on breast cancer cells demonstrated that the protein dickkopf-1 (Dkk-1) released from MSCs blocks tumor growth via depression of Wnt signaling (Qiao et al. 2008a). In contrast to investigations describing the pro-angiogenic effect of MSCs (Zhang et al. 2013; Li et al. 2016), the anti-tumor activity of MSCs via the inhibition of tumor angiogenesis has also been documented. A study reported that BM-derived MSCs restrict vascular growth in 1Gli36 glioma xenograft through the downregulation of the PDGF/PDGFR axis (Ho et al. 2013). In particular, the expression of PDGF-BB protein was significantly reduced in tumor lysates when

treated with MSCs, which correlated with reduced levels of activated PDGFR-b and the active isoform of its downstream target AKT (Ho et al. 2013).

In a melanoma mouse model, transplanted MSCs inhibited angiogenesis in a concentration-dependent manner, leading to reduced tumor growth (Otsu et al. 2009). Confirmatory in vitro studies suggested that the anti-angiogenic effect was due to MSC-induced capillary degeneration (Otsu et al. 2009). Furthermore, MSCs have elicited anti-tumor immune responses through released inflammatory mediators, such as the multifunctional cytokine TGF-β. Like several signaling molecules, TGF-β plays a dual role in cancer development (Bierie and Moses 2006). Besides the aforementioned pro-tumor functions, TGF-β signaling exhibits suppressive effects in cancer (Dong et al. 2007; Guasch et al. 2007). While the expression of type III TGF-β receptor (TbRIII) decreases during breast cancer progression, restoring TbRIII expression suppresses tumorigenicity (Dong et al. 2007).

The Pro-tumor Activity of MSCs

The pleiotropic effects of MSCs that promote tissue repair and regeneration may also confer pro-tumor functions to these cells. For instance, metastatic human breast carcinoma cells were found to induce the secretion of the chemokine (C-C motif) ligand 5 (CCL5) from MSCs, which enhanced tumor invasion (Karnoub et al. 2007). Seminal reports demonstrated that MSCs could also inhibit apoptosis in tumor cells by secreting pro-survival factors such as VEGF and bFGF (König et al. 1997; Dias et al. 2002). Numerous studies converged on the finding that MSCs contribute to cancer pathogenesis by releasing inflammatory factors that promote immunosuppressive effects. For example, an in vitro study showed that MSCs isolated from gastric tumors mediate cancer progression through the secretion of IL-8 (Li et al. 2015). This pro-inflammatory chemokine favors the recruitment of leukocytes. It is known that recruited leukocytes, such as macrophages and neutrophils, facilitate cancer initiation and progression (Guo et al. 2017; Powell et al. 2018). Similarly, MSCs are able to secrete TGF-β that promotes macrophage infiltration at the tumor site and facilitates tumor escape from immune surveillance (Kim et al. 2006; Byrne et al. 2008). Compelling evidence indicates that MSCs can also support tumor angiogenesis, an essential process in cancer progression that supplies tumors with oxygen and nutrients. For instance, MSCs recruited in breast and prostate tumors were found to increase the expression of angiogenic factors, including TGF-β, VEGF, and IL-6, which contribute to tumor growth and vascularization (Zhang et al. 2013).

Similarly, a correlation between increased expression of TGF-β and higher microvessel density was observed in hepatocellular carcinomas of mice receiving intravenous injections of human MSCs (Li et al. 2016), which further supports that MSCs may enhance tumor angiogenesis via TGF-β. Furthermore, MSCs can also respond to soluble factors secreted from cancer cells and differentiate into CAFs, a cell type within the tumor microenvironment capable of promoting tumorigenesis (Mishra et al. 2008). In particular, TGF-β secreted from cancer cells plays a critical

role in the differentiation of MSCs into CAFs (Jotzu et al. 2011; Barcellos-de-Souza et al. 2016; Aoto et al. 2018).

It is known that the transition of MSCs into CAFs contributes to tumor progression in part by their active secretome. Profiling of the secretome shows that it is rich in many bioactive molecules, including immune-modulating agents (CXCL12, granulocyte-macrophage colony-stimulating factor), pro-angiogenic factors (VEGF, TGF-β, PDGF), pro-survival factors (hepatocyte growth factor, insulin-like growth factor 1, interleukin 6), and extracellular matrix modulators (MMP, tissue inhibitor of metalloproteinases) among others (Kalluri 2016). Cell engulfment has also been identified as an interacting process between MSCs and cancer cells that enhances tumor aggressiveness. A recent report demonstrated that breast cancer cell engulfment of MSCs leads to changes in the transcriptome profile of tumor cells. These changes are mainly associated with oncogenic pathways. This MSC engulfment enhances epithelial-to-mesenchymal transition, stemness, invasion, and metastasis of breast cancer (Chen et al. 2019).

The Imprint of Disease on MSCs

One of the strategies to obtain MSCs for therapeutic purposes is an autologous approach. These cells are collected from patients by more or less invasive methods, isolated, seeded in culture under good manufacturing practice (GMP) quality standards, and re-injected into the patient. Nevertheless, when body's repair mechanisms are insufficient or ineffective, this treatment results in a homeostatic imbalance in the organism, producing degradation and disease and compromising the pool of endogenous cells, thus resulting in low efficacy. Some conditions/diseases provoke changes in the BM microenvironment, which is one of the primary sources of MSCs, thus producing changes in the endogenous pool of MSCs and altering their biological features (Mazzanti et al. 2008). MSCs from patients with acute myeloid leukemia showed abnormal biological properties, including morphological heterogeneity, limited proliferation capacity, and impaired differentiation and hematopoiesis supportability (Zhao et al. 2007).

MSCs derived from patients with multiple myeloma showed impaired immune-inhibitory effects on T cells, decreasing their osteogenic potential (Li et al. 2010). Poor proliferation, differentiation potential, and cytokine release defect were found in BM-derived MSCs derived from patients with aplastic anemia, another hematopoietic disorder (Chao et al. 2010; Bacigalupo et al. 2005). Although the mechanisms remain unknown, MSCs appear to be involved in autoimmune pathologies. For instance, MSCs derived from patients with autoimmune diseases display the following altered functions; MSCs from rheumatoid arthritis (RA) patients have an impaired ability to support hematopoiesis and lower proliferative and clonogenic potentials (Papadaki et al. 2002; Kastrinaki et al. 2008). MSCs from immune thrombocytopenic purpura (ITP) patients have a reduced proliferative capacity and a lower inhibitory effect on T-cell proliferation than MSCs from healthy donors (Pérez-Simón et al. 2009). MSCs from systemic lupus erythematous (SLE) patients

display deficient growth, abnormal morphology, and upregulated telomerase activity (Nie et al. 2010; Sun et al. 2007). MSCs from systemic sclerosis (SSc) patients display early senescence (Cipriani et al. 2007). In metabolic diseases such as diabetes, alterations in autologous MSCs have also been documented.

A study using MSCs from type 2 diabetic mice showed that the number of these cells was diminished and their proliferation and survival abilities were impaired in vitro. Moreover, diabetic MSC engraftment produced only limited improvement in the diabetic subjects and could not produce the same therapeutic outcomes as in their nondiabetic counterparts in vivo (Shin and Peterson 2012). Advanced glycation end products (AGEs) accumulate in the tissues of aged people, and these products are involved in diabetes and musculoskeletal diseases. In 2005, Kume and colleagues (Kume et al. 2005) investigated the effect of AGEs on MSCs. They showed that AGEs inhibited MSC proliferation, induced MSC apoptosis, and interfered with MSCs' differentiation into adipose tissue, cartilage, and bone. Type 2 diabetes-derived Ad-MSCs have been found to have functional impairments in their multilineage potential and proliferative capacity because of prolonged exposure to high glucose concentrations (Cramer et al. 2010).

Diabetic-derived Ad-MSCs have an altered phenotype related to plasminogen activator inhibitor-1 (PAI-1) expression levels and display reduced fibrinolytic activity (Acosta et al. 2013), which suggests that the immunogenicity of MSCs could have associated effects on the coagulation system (Wang et al. 2012; Moll et al. 2012). Thus, MSC-based therapy could lead to thrombotic events in particular recipients. Although the possibility of healing with autologous cells is desirable, little is known regarding the influence of different disease states and concomitant medications on MSCs (Benvenuti et al. 2007; Lee et al. 2009). Thus, although the use of autologous MSCs for cell therapy is widespread, their use in humans must be handled with extreme caution. Researching and analyzing both the risks and benefits of this therapy in individual patients and for each disease are necessary.

Considerations for Clinical Applications

Several clinical trials are in progress to ensure the safety and efficacy of MSCs used as medicaments. For cell-based products, it must be considered that cells are living products and that their interactions with body fluids remain unclear (Acosta et al. 2013; Moll et al. 2014). Phase 1 clinical trials are the first step in investigating a new drug. They include pharmacokinetic and pharmacodynamic studies in which the patient's safety plays an essential role in the development of medicaments. The primary goal of phase 2 clinical trials is to provide preliminary information regarding the drug efficacy and safety supplement data obtained in phase 1 trials. For efficacy and effectiveness issues, other advanced phases are mandatory. In all cases, one cannot consider these issues (efficacy nor effectiveness) unless phase 3 clinical trials are developed (García-Bernal et al. 2021; Hmadcha et al. 2020; Escacena et al. 2015). Usually, safety evaluations are based on possible complications derived from the procedure in a time-dependent manner after administering the cells. Efficacy

parameters focus on the improvement of clinical effects at a given time. MSC-based cell therapy is a relatively new therapeutic option for certain diseases, and data regarding the long-term monitoring of patients remain lacking.

Nevertheless, the administration of MSCs is considered a feasible and safe procedure with no adverse events reported. However, the risks associated with stem cell therapy (Herberts et al. 2011) must be considered because these risks increase the probability of an adverse event. The cell source, donor origin, product manufacturing, and recipient disease status are important factors related to the safety and efficacy of MSCs. In this regard, the use of bovine proteins in the medium used to culture these cells (Horwitz et al. 2002) and the observed formation of ectopic tissue in animal models (Breitbach et al. 2007; Kunter et al. 2007), as well as malignant transformation (Wang et al. 2005; Røsland et al. 2009) and immune responses, must be evaluated before wider clinical applications and registration are accepted.

Safety Concerns

Cell therapy is incredibly complex due to the nature of the product. The mode of action is not always clear, and the potency tests are imprecise, by which it might not be possible to predict the risks thoroughly. When considering the use of expanded MSCs ex vivo for clinical applications, it is necessary to consider a series of potential risks that could affect the cellular product.

The administration of stem cells could affect the host's immune system. These cells could directly influence the immune system (e.g., pro-inflammatory environment) or have an immunomodulatory effect. Although MSCs have been considered immune-privileged in this regard, long-term exposure to the culture medium can make them more immunogenic by positively regulating the normal set of histocompatibility molecules (Moll et al. 2011, 2014). On the one hand, the allogeneic use of the cells entails a greater risk of rejection by the immune system. This rejection could lead to a loss of the function of the administered cells, and consequently, their therapeutic activity could be compromised. The use of immunosuppressants could limit these risks, but, in turn, could cause adverse reactions due to immunosuppressive medication.

On the other hand, MSCs isolated from healthy donors have shown uniform and consistent properties, while patients with some degenerative and inflammatory disease differ in their biological and functional characteristics (Capilla-González et al. 2018; Rennert et al. 2014). In this regard, studies with MSCs from diabetic patients suggest that the hyperglycemic environment and other metabolic disorders associated with diabetes affect the endogenous cellular reserve and their proliferation, differentiation, and angiogenic capacity, among other cellular characteristics (Minteer et al. 2015; Rennert et al. 2014; George et al. 2018; Moll et al. 2019). Once infused in the recipient, the cells come into direct contact with the tissues, bloodstream, and other host cells; the cell-recipient interaction process still needs a thorough investigation and characterization.

Physiologically, MSCs reside in the perivascular compartment of almost every tissue (Bianco et al. 2008; Crisan et al. 2008); however, one of the hurdles to the sustained success of their therapeutic effect is early cell loss. This is primarily due to the incompatibility responses after systemic infusion of cells, a reaction termed as instant blood-mediated inflammatory reaction (IBMIR) suggesting that the immune and inflammatory system reacts to cells that generally are not in contact with the blood circulation (Gupta et al. 2014; Moll et al. 2011, 2014, 2019, 2020; Bianco et al. 2008; Crisan et al. 2008; Nilsson et al. 2014). Even more, it has been further shown that different MSC products display varying levels of highly pro-coagulant tissue factor, a decrease in tissue plasminogen activator (tPA), or an increase in PAI-1 and may adversely trigger the IBMIR or microthrombosis in the target tissue (Acosta et al. 2013; Moll et al. 2019). Although MSCs are considered to be safe, they can promote fibrinolysis (Hashi et al. 2007; Neuss et al. 2010; Moll et al. 2020).

Safety and efficacy are the basic pillars that support the viability of clinical application to treat any disease. Except for hematopoietic stem cell transplants, stem cell therapies used to treat any disease are considered medicinal products; therefore, their development, approval, and use must be per the specific standards established nationally and internationally for such medicines. Thus, regulatory authorities guarantee the safety of the studies (Fig. 2).

Cell Manufacturing for Clinical Use

Except for hematopoietic stem cell transplants, stem cell therapies used to treat any disease are considered drugs; therefore, their development, approval, and use must be per the specific standards established for such medicines nationally and internationally. In this context, MSCs are now considered as "cellular medicament" and are called advanced therapy medicinal products (ATMPs) and are under regulation No. 1394/2007 (Escacena et al. 2015; Gálvez et al. 2013). Relating production processes and development staff, clinicians and researchers must achieve GMP procedures under European regulations (Sensebé et al. 2013; Gálvez et al. 2014). Currently, no standardized manufacturing platform exists, although most facilities employ standard release criteria to measure sterility, viability, and chromosomal stability to meet European or FDA regulations (Phinney 2012; Iglesias-López et al. 2019).

Although regulation establishes common parameters to follow, different protocols are used to isolate these cells, and the processes, plating densities, and reagents used cause the results to differ from each other. Donor selection in terms of age and disease status is another variable to consider due to known MSC donor-to-donor heterogeneity (Phinney et al. 1999). The cell source is another important factor related to the efficacy of the product. As reported previously, MSCs derived from different tissues do not consistently achieve the same level of efficacy. Additionally, culture media used for the production of MSCs could affect the basic characteristics of cells; thus, designing a fully defined medium free of animal and human origins is crucial.

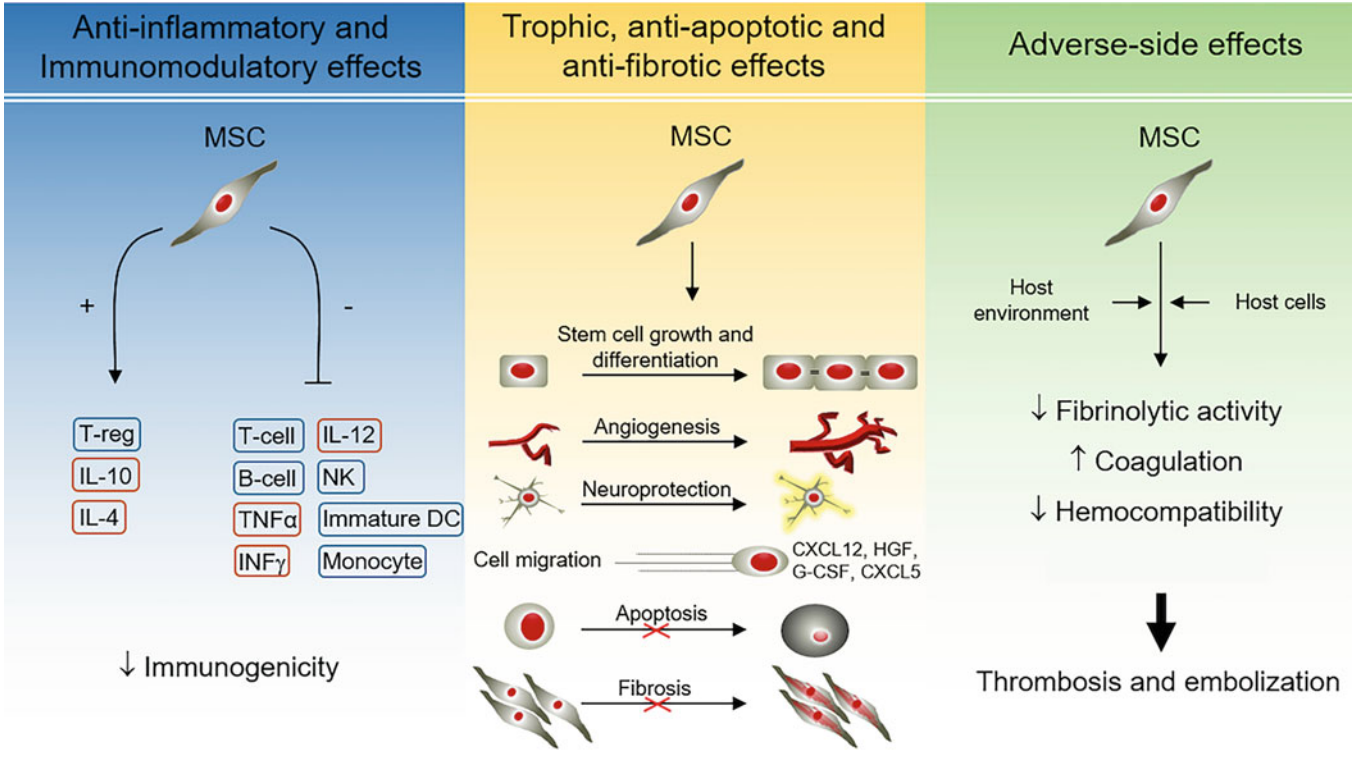

Fig. 2 The MSCs possess a wide range of paracrine effects, including anti-inflammatory, immunomodulatory, trophic, anti-apoptotic, and anti-fibrotic properties. These are mostly mediated by molecules released by MSCs, but also by direct cell-cell contacts. For cell-based therapy, the paracrine properties of MSCs have beneficial effects for the patient. However, the interaction between MSCs and the host can lead to adverse side effects. (Re-published from

Thus far, no MSC-based medicine product has marketing authorization in the European Union, although four gene and cell-based products have a valid marketing authorization awarded by the EMA. However, since 2011, three MSC products have received marketing approval in other regions (Ancans 2012). The MSCs' field continues its upward progression, with a growing number of established companies established and ongoing clinical trials, but remaining challenges must be overcome. Bottlenecks exist regarding donor selection, cell sources, isolation protocols, culture media used, open-culture systems, bioreactors, and recipient disease status. Establishing a standardized and comparable process is also crucial to ensure biological and functional equivalence between product lots.

Considerations for Cellular Medicament

General Considerations

The cell expansion and culture protocol are not standardized, although the regulatory agencies (e.g., EMA, FDA) recommend a set of standards to be followed to produce cellular drugs. Currently, there is no protocol or universal definition for stem cell culture and expansion. The different sources of origin, and the different methodologies for obtaining tissue cells, make it very difficult to compare research groups in search of the fastest, most effective, economical, high-yielding, efficient, and clinical-grade quality method. Cell viability after the infusion is poor; in this regard, it is known that very few cells survive after infusion. Although the in vivo follow-up is ethically and technically complicated, it is necessary to continue investigating this line to understand the intrinsic mechanisms of integrating the infused cells in the concrete microenvironment.

The cellular dose to obtain the desired effects is also unknown. Investigations with HSCs have revealed that the administration of sufficient cells promotes faster cell recovery and reduces hospitalizations (Mohty et al. 2011). Preclinical studies using murine animal models have established a minimum dose of 1×10^6 cells/kg of weight, a quantity necessary to obtain quantifiable but weak benefits (Shabbir et al. 2009; Mastri et al. 2012). The dose for cellular treatment is probably influenced by the patient's body weight and the biodistribution of paracrine factors secreted by MSCs in the human body; however, most clinical trials use a similar cell dose (Tan et al. 2012; Jiang et al. 2011). The doses used have been insufficient in most cases to show clear therapeutic benefits. This fact leads us to design future trials to test different cell doses. Likewise, the frequency of administration is currently unknown.

Fig. 2 (continued) Soria-Juan 2019, article published under CC-BY terms). Abbreviations: B-cell B lymphocyte, CXCL C-X-C motif chemokine ligand, DC dendritic cell, G-CSF granulocyte colony-stimulating factor, HGF hepatocyte growth factor, IL interleukin, INF-γ interferon-γ, MSC mesenchymal stem cells, NK natural killer cells, T-cell T lymphocyte, TGF-α transforming growth factor α, Treg regulatory T cell

The effectiveness of cell therapy is probably related to the number of others applications (Cobellis et al. 2008; Teraa et al. 2015; Molavi et al. 2016), similar to that established with conventionally used medications. The timing and the ideal number of cellular applications are still unknown. Since conventional medicines are depending on the dose, cellular therapy may need to be adjusted accordingly. The most suitable cell type remains a challenge for regenerative medicine. Knowing which cell type is most appropriate for each particular pathology or if a combination of these would be more recommended is another big issue in cell therapy.

The method for the cellular administration continues without giving conclusive results because cell viability must be preserved as much as possible, and compromised tissue is often associated with ischemia, fibrosis and inflammation, which could impair cell survival, therapeutic delivery of stem cells in the distal areas to the damaged tissue appear to offer some advantage. There are no conclusive findings of a more significant benefit within the existing modes of administration, so this is another variable to have into account for future clinical trials. The desired therapeutic effect depends on many factors since mechanism of action of stem cells in tissue regeneration is likely to be multifaceted. Cellular competition can be dictated by the ability of injected cells to migrate, survive, integrate, differentiate, and produce functional paracrine mediators ("cell-cell interactions"). It is known that many diseases (e.g., diabetes, cancer, etc.) affect the phenotypic and therapeutic properties of stem cells. Finally, for the therapy to be effective, the recipient tissue must respond favorably to the injected cells, which would result in the activation of endogenous regeneration mechanisms (Lee 2010). Understanding integration of the exogenous mechanisms (injected cells) with the endogenous (host) will play a decisive role in the future clinical use of adult stem cells (Acosta et al. 2013; Moll et al. 2019).

Attempts to Improve the Therapeutic Outcomes of Cellular Medicament

Advances in the production compliance under good manufacturing practices (GMP) standards of more sophisticated cellular products are now opening up the way for the second generation of cell therapy clinical trials. One of the reasons why unmodified MSCs have not shown the therapeutic efficacy expected in human clinical trials is that, after their systemic infusion (intravenous), these cells become trapped in the vascular filters (fundamentally the liver and lung) and only a small percentage reach the target tissues. Therefore, strategies must be designed that favor migration, nesting, and localization in the inflammatory and/or infectious focus to increase their effectiveness. Biodistribution and long-term follow-up of these cells in animal models show that only a few cells remain after long periods. This will support the idea that most of the effects of MSCs are based on a "hit and run effect."

To increase the concentration of ATMPs in the injured tissue, the CD44 antigen on MSCs' cell membrane by enzymatic fucosylation has been converted into hematopoietic cell E-selectin/L-selectin ligand (HCELL) glycoform (Dimitroff et al. 2001;

Pachón-Peña et al. 2017). This molecular change favored the migration of the MSCs to the inflamed tissues (Sackstein et al. 2008; García-Bernal et al. 2020). This method, called glycosyltransferase-programmed stereo substitution (GPS) of cell surface glycans, has been optimized for its clinical application so that the reagents used (glycosyltransferases and buffers) have been specifically formulated to preserve cell viability and phenotype (García-Bernal et al. 2021). Moreover, this modification not only increases the adhesion of the MSCs to the endothelium, but it also enhances their transmigration through it by activating the alfa4/beta1 integrin in the absence of chemokine stimulation (López-Lucas et al. 2018). Therefore, this modification by fucosylation could improve the efficacy of the treatment with MSCs by increasing the migratory capacity of the cells to the inflamed tissues after being administered systemically (García-Bernal et al. 2020). Other strategies may include expressing CXCR4. These strategies will help to engineer new generation of MSCs for use when both increased migration and targeting and an increased power are required. Expression of the CXCR4 receptor will increase the migration of the MSCs toward the inflammatory focus (Zhu et al. 2021). On the other hand, the co-expression of the anti-inflammatory cytokine IL-10 and/or the anti-infectious cytokine IL-7 will increase the anti-inflammatory effect (IL-10) and even the anti-infective effect (IL-7) (Mao et al. 2017).

Furthermore, the extensive use of fetal bovine serum (FBS) in the MSC-expansion media represents an explicit limitation for the introduction of ATMP at the clinical level. Currently, cell expansion is carried out in culture media supplemented with FBS (Gottipamula et al. 2013). The SFB used must be a clinical-grade (free of animal pathogens). Associated with the growing demand for MSCs, this has led to a series of technical and ethical conditions of production (using a high number of bovine fetuses) and geographic (zones free of prion diseases), which have had an impact on their price (Kinzebach and Bieback 2013; Wessman and Levings 1999). The substitution of FBS by human serum and platelet lysate also represents technical limitations mainly related to the supply of human material and the absence of uniformity of the lots. All these considerations force the development of robust processes of production of MSC in chemically defined culture media free of animal and human components. These media are supplemented with recombinant proteins (albumin, insulin, TGF-β, and bFGF), iron, selenium, and an antioxidant system (2-mercaptoethanol) (Badenes et al. 2016; Jayme and Smith 2000). Although several serum-free media are found in the literature and market (Chase et al. 2010; Ishikawa et al. 2009), there is still no effective means of functioning.

The therapeutic efficacy of MSCs has been further optimized by genetically modifying MSCs to produce trophic cytokines or other beneficial gene products in numerous preclinical models by transfecting MSCs with viral or non-viral vectors (Jiang et al. 2006; Haider et al. 2008; Kim et al. 2012a, b). These MSCs have been successfully modified to express therapeutic peptides and proteins to express therapeutic peptides and proteins in animal models (Zhou et al. 2021). For example, MSCs expressing thioredoxin-1 (Trx1, a potent antioxidant, transcription factor, and growth factor regulator) improved cardiac function in post-myocardial infarction rat models (Suresh et al. 2015). Simultaneous overexpression of Akt and Ang-1 in

BM-derived MSC not only enhanced their reparability of the infarcted myocardium with sustained beneficial effect (Jiang et al. 2006, 2008), but it also led to non-hypoxic stabilization of HIF-1 to enhance their endothelial commitment (Lai et al. 2012a) and increased their proliferation potential via the involvement of miR-143 (Lai et al. 2012b). The MSCs expressing IL-12 showed potent anticancer activity against melanoma, breast cancer, and hepatoma (Gao et al. 2010; Han et al. 2014). In addition, interferon-γ-expressing MSCs inhibited tumor growth in mouse models of neuroblastoma and lung carcinoma (Relation et al. 2018; Seo et al. 2011). Similar to these advances achieved in animal models, several MSC-based therapies are under clinical development.

Both viral and non-viral vectors, however, have some limitations (Kim and Haider 2001). Non-viral vectors exhibit transient gene expression and low transfection efficiency. In contrast, viral transduction is associated with an increased risk of chromosomal instability, insertional mutagenesis, and proto-oncogene activation, despite the inherent high transfection efficiency (Cheng et al. 2019). It has been reported that adverse immune reactions induced by viral transduction impair transgene stability (Mingozzi and High 2013; Wang et al. 2018). Thus, limitations and adverse responses must be assessed when modifying MSCs by transfection. Several studies have sought to use MSCs derived from induced pluripotent stem cells (iPSCs) to obtain better expansion capacity. In fact, therapeutic transgenes could be inserted into iPSC-derived MSCs before MSC derivation. Such a strategy could eliminate insertional mutations and ensure stable expression of transgenes during a prolonged expansion (Zhao et al. 2015). Therefore, MSCs derived from iPSCs may be a renewable source of MSCs for theranostic applications. It is pertinent to mention that BM-derived MSCs have also been successfully reprogrammed to pluripotent status and used for the efficient repair of infarcted myocardium in an experimental animal model (Buccini et al. 2012).

Interestedly, CRISPR-Cas9 technology was used to obtain highly homogeneous MSCs. Genetic modifications of MSCs can be performed with greater efficiency and specificity using CRISPR/Cas9 technology (Gerace et al. 2017). This is faster, cost-efficient, and easier to use compared to alternatives such as transcription activator nucleases (TALENs) and zinc finger nucleases (ZFNs) (Faulkner et al. 2020). CRISPR/Cas9 has been widely employed in the stem cell field, particularly in MSC research, including knock-in, knock-out, gene activation, or gene silencing. In this regard, the application of CRISPR/Cas9 in MSCs has demonstrated its efficacy in treating diseases, such as myocardial infarction (Golchin et al. 2020). Targeting gene knock-in further promoted the differentiation capacity of MSCs and, in turn, improved the insufficiency of functional cells at local sites (Miwa and Era 2018). Genetically modified MSCs have been evaluated in clinical trials, such as the "TREAT-ME-1" clinical trial, an open-label, multicenter, first-in-human phase 1/2 trial, which aimed to evaluate the safety, tolerability, and efficacy of the application of genetically modified autologous MSCs-apceth-101 in patients with advanced gastrointestinal adenocarcinoma (von Einem et al. 2019). Despite promising advances in this field, further research is still needed to obtain solid evidence on the differentiation and regenerative potentials of MSCs in vivo. Undoubtedly, the

next-generation sequencing and genotyping techniques could serve as valuable tools to improve the efficacy of targeting specific cell types for personalized medicine.

Besides, priming MSCs with exogenous small molecules has been found to boost their therapeutic function. Since current MSC manufacturing cannot meet the requirements of clinical trials in terms of production scale, the alternative is to enhance the function of limited cells by priming MSCs. Cell priming, or cell preconditioning, is a commonly used concept in the field of immunology and has been adapted to the stem cell arena (Lu et al. 2010; Haider and Ashraf 2012; Carvalho et al. 2013; Noronha et al. 2019) by ex vivo addition to MSCs of pro-inflammatory cytokines, such as IFN-γ, TNF-α, IL-1α, and IL-1β. More priming approaches are currently being proposed and optimized to improve MSC function, proliferation, survival, and therapeutic efficacy (Afzal et al. 2010; Kim et al. 2012a, b; Lu et al. 2012; Kim et al. 2018; Mead et al. 2020). In this regard and as mentioned before, other approaches are focused on enhancing the therapeutic effects of cell therapy products regulating their biological characteristics (Mangi et al. 2003; Mei et al. 2007; Lee et al. 2012b; Liao et al. 2017).

The beneficial effects of PDGF-BB to restore the defective phenotype of therapeutic MSCs derived from type 2 diabetic patients have been demonstrated. The pretreatment with PDGF-BB potentiates proliferation, migration, and homing of defective MSCs and recovers their impaired fibrinolytic ability. Furthermore, PDGF-BB has been found to exert its beneficial effects through the ERK-SMAD pathway. Therefore, the pretreatment with PDGF-BB represents a suitable strategy to produce more effective MSCs for autologous therapies (Capilla-González et al. 2018).

Concluding Remarks and Future Perspective

Treatments based on the use of human stem cells are novel and promising therapeutic alternatives for some diseases. Currently, the use of living cells as a medicinal product is becoming realistic. Cell therapy should be safe, pure, stable, and efficient. Cell-based products are more complex and depend on the physiological and genetic heterogeneity of the patient. Obtaining as much information as possible with the appropriate and available technology at our disposal is essential for ensuring the safety, reliability, quality, and effectiveness of the manufactured product. MSCs are leading the way into a new era of regenerative medicine, and their multifaceted features make them powerful candidates to become tools to treat several diseases. However, their indiscriminate use has resulted in mixed outcomes in preclinical and clinical studies. While MSCs derived from diverse tissues share some common properties, they markedly differ in terms of their differentiation abilities, growth rates, healing capacity, and gene expression profile.

Similarly, the disease status of donors and recipients is a critical factor to consider when using MSCs as therapeutic agents because factors such as the MSC behavior with body fluids and specific disease environments remain unclear. Available data suggest that some tissue-specific MSCs are more appropriate than others according

to particular pathologies. Although no severe adverse effects related to the application and testing of MSCs in humans have been reported to date, some evidence has indicated that specific patient profiles are not suitable to be treated with these therapies. Thus, multiple bottlenecks for the standardization of therapeutic protocols exist. Future well-designed clinical trials, advanced-phase clinical trials (phase 3/4), and long-term monitoring of patients are crucial for obtaining additional information regarding the therapeutic use of MSCs.

Abstract

Stem cells are cells with the ability for self-renewal and differentiation into a myriad of cellular lineages. Here, we discuss their potential in skin regeneration, focusing on traumatic and nontraumatic healing and scarring. We identify and

elaborate on the various types involved, including embryonic stem cells (ESCs) and ESC-like cells, induced pluripotent stem cells (iPSCs), and mesenchymal stem cells (MSCs). We discuss the role of iPSCs and MSCs in attenuating inflammation and fibrosis, thus promoting wound closure in models of defective wound healing and reducing both normal and aberrant scarring (i.e., keloids). In particular, we focus on MSCs and fibrotic changes, detailing their inhibitory function in TGFb/Smad signaling, and thus postinjury scar formation. Furthermore, we elaborate on ESCs and ESCs-like populations, discussing applications in normal skin appendage regeneration and recovery of nonhealing wounds, while ESCs-like cells function as a potential source of profibrotic keloid myofibroblasts. Although ESCs-like populations are implicated in scarring, the discussed studies posit that harnessing certain stem cell subpopulations could be an attractive strategy for rapid, scarless wound healing. This has implications in conditions of chronic inflammation and impaired healing and vascularity (e.g., diabetes) as well as traumatic conditions that necessitate rapid skin regeneration, such as burns.

Keywords

Mesenchymal stem cells · Embryonic stem cells · Stem cells · Therapy · Transplantation · Wound

Abbreviations

ADMSCs	Adipose tissue-derived MSCs
ADSCs	Adipose-derived stem cells
AT	Adipose tissue
BMP-2	Bone-morphogenetic protein-2
CM	Conditioned medium
ECM	Extracellular matrix
EGF	Epidermal growth factor
EMT	Endothelial-to-mesenchymal transition
EPCs	Endothelial progenitor cells
ESCs	Embryonic stem cells
GDF	Growth differentiation factor
HIF-1α	Hypoxia-inducible factor
IFN	Interferon
IL	Interleukins
iPSCs	Human-induced pluripotent stem cells
LIF	Leukemia inhibitor factor
MMP	Matrix metalloproteinase
MSCs	Mesenchymal stem cells
NK	Natural killer
PDGF	Platelet-derived growth factor
PGE2	Prostaglandin E_2
SSEA	Stage-specific embryonic antigen

TGF-b	Transforming growth factor
TNF-a	Tumor necrosis factor-a
VEGF	Vascular endothelial growth factor

Introduction

The integumentary system serves as a protective barrier against pathogens, dehydration, and fluid loss (Lee et al. 2006). Damage to skin integrity can occur due to nontraumatic (e.g., diabetic ulcers) or traumatic (e.g., burns) conditions and results in a carefully coordinated wound healing process comprised of overlapping phases of cellular migration, proliferation, and extracellular matrix deposition (Eming et al. 2007). However, disruptions or alterations in cellular signaling may culminate in a spectrum of poor wound healing, from chronic nonhealing wounds to excessive scarring (Eming et al. 2007). Either of the outcomes necessitates extensive, costly medical interventions, impairs patients' quality of life, increases trauma, and enhances mortality. Therefore, significant efforts have been devoted to the development of rapid, scarless wound healing therapies.

Regenerative medicine has emerged as an alternative to traditional wound care and focuses on stem cell therapy. Stem cells are an endogenous reservoir of cells that can self-renew and differentiate into a myriad of cell types. Poor wound healing and chronic wounds are correlated with either depletion in resident stem cells or an insufficient response in extensive injuries such as full-thickness burns (Nijnik et al. 2007; Zouboulis et al. 2008; Van Zant and Liang 2003). Therefore, exogenous administration is an attractive potential therapeutic strategy. In this chapter, we discuss the role of stem cells during normal, impaired wound healing, and "overhealing" (i.e., hyperproliferative scars such as keloids and hypertrophic scars). We elaborate on the key endogenous stem cell subtypes involved in skin regeneration, including embryonic, mesenchymal, epithelial, and melanocytic stem cells. Furthermore, we discuss the role of harnessing stem cells in therapy for patients with defective healing or excessive scarring, underscoring the broad application of stem cell therapy in wound-healing aberrancies.

Wound-Healing Process

Normal Wound Healing

Physiologic cutaneous healing consists of an inflammatory, proliferative, and remodeling phase (Fig. 1) (Gonzalez et al. 2016). Wound healing begins with hemostasis, or coagulation and fibrin clot formation. The fibrin clot serves as a scaffold to recruit key mediators involved in healing, including fibroblasts, keratinocytes, endothelial cells, and leukocytes (i.e., neutrophils and monocytes) (Broughton et al. 2006; Witte and Barbul 1997). In particular, activation of macrophages plays a significant role in the inflammatory phase, and macrophages regulate

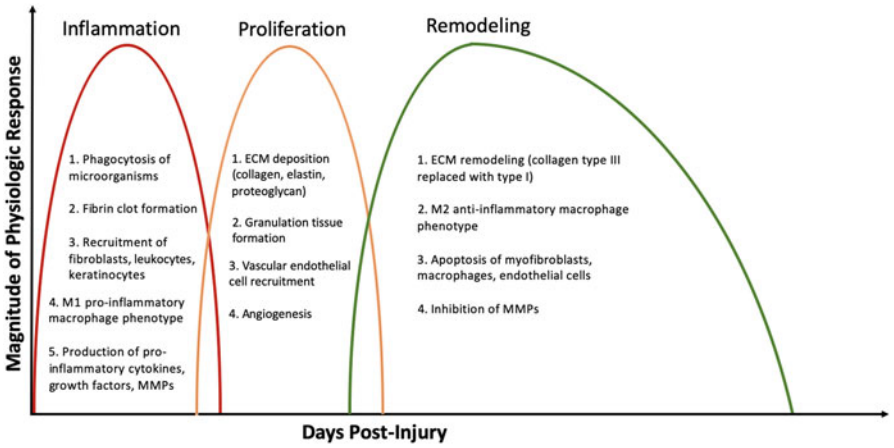

Fig. 1 Stages of post-trauma wound healing

the production of cytokines, angiogenesis, and recruitment of fibroblasts to the wound bed (Rodero and Khosrotehrani 2010). Fibroblast recruitment prompts type III collagen, proteoglycan, and elastin secretion during the proliferative phase, which results in granulation tissue formation (Tracy et al. 2016). This is coupled with the recruitment of vascular endothelial cells by vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor (TGF-b) secretion and angiogenesis (Corliss et al. 2016). This phase is followed by a tissue-remodeling phase after wound closure during which macrophages, fibroblasts, and endothelial cells are removed via apoptosis (Larouche et al. 2018). At this point, the wound site contains a primarily acellular collagenous matrix with predominantly type III collagen, which is replaced with type I collagen over time (Xue and Jackson 2015).

In addition to the cells mentioned above, wound healing is in part mediated by stem cells, which secrete paracrine factors to recruit various cells and are present in all skin layers: epidermis, dermis, and hypodermis (Wong et al. 2012; Ito et al. 2005; Levy et al. 2005). In the epidermis, endogenous stem cells are comprised of three key populations – the basal layer of the inter-follicular epidermis, sebaceous glands, and the hair follicle bulge or lower region of the outer root sheath (Fig. 2) (Fuchs 2008). These stem cells have several key features in common, such as expression of K5, K14, and p63 and association with the basement membrane (Fuchs 2008). Under physiological conditions, differentiation of stem cells consistently replenishes the relevant skin components as mentioned above. Interestingly, cells from these components are capable of replenishing each other during injury. For example, reepithelialization in partial thickness injuries relies on the migration of cells from sebaceous glands and the hair follicle bulge (Rittié 2016). While these cells are not essential for wound closure and are eventually replaced with interfollicular epidermal stem cells during recovery, they significantly expedite wound closure (Ito and Cotsarelis 2008). Delayed healing is a risk factor for increased infection,

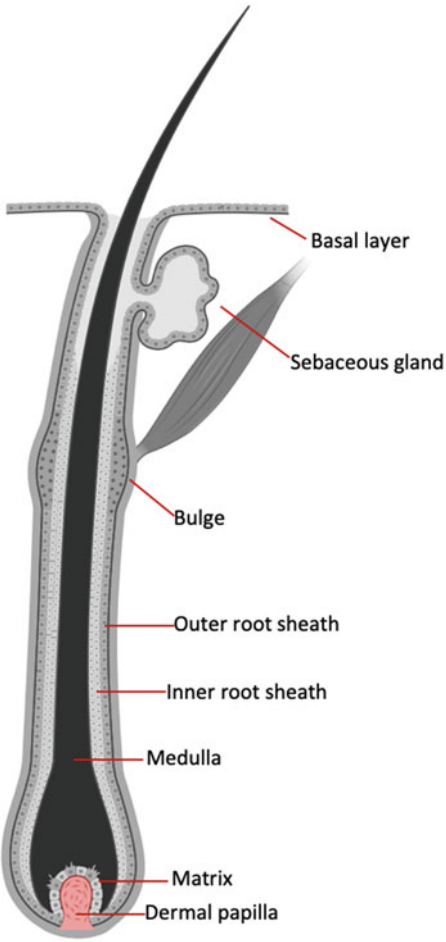

Fig. 2 Anatomy of the hair follicle

hypertrophic scarring, and mortality, rendering these stem cell sources potential targets in regenerative therapy (Finnerty et al. 2016).

Interestingly, dermal signaling (e.g., expression of BMP2 and BMP4) can also contribute to epithelial regeneration (Plikus et al. 2008). An example of this is the contribution of dermal sheath cells to melanocyte maturation. Melanocytic stem cells, which reside in the outer root sheath of the lower permanent portion of hair follicles, are responsible for pigmentation (Lee and Fisher 2014). However, dermal sheath stem cells additionally can differentiate into epidermal melanocytes, likely via mesenchymal-epithelial transition (Li et al. 2011). These cells reside within dermal papillae of hair follicles and are subdivided into three distinct populations based on the transcription factor Sox2. Sox2-expressing cells are involved with Wnt, BMP, and FGF signaling, while Sox2-negative cells exploit Shh, insulin growth factor (IGF), Notch, and integrin signaling (Kellner and Coulombe 2009; Driskell

et al. 2009; Biernaski et al. 2009). Importantly, dermal sheath stem cells can differentiate into a wound-healing fibroblast (myofibroblast) phenotype, which has implications in scarring that will be discussed later (Jahoda and Reynolds 2001). Another dermal stem cells' source is dermal perivascular regions, which function as a niche for mesenchymal stem cells (MSCs) (Jackson et al. 2012). These cells protect the integrity of the local wound-healing matrix via inhibition of matrix metalloproteinase (MMP) pathways and promotion of neovascularization (Jackson et al. 2012). MSCs can also be isolated from various sources, including bone marrow and adipose tissue (AT), and are later recruited to the site of injury in response to factors such as hypoxia-inducible factor (HIF)-1α (Martinez et al. 2017). MSCs, in turn, promote endothelial progenitor cell (EPC) migration, which facilitates angiogenesis and wound closure (Li et al. 2018).

AT is another key source of multipotent skin stem cells (adipose-derived stem cells, ADSCs) that maintain the multilineage differentiation potential (e.g., smooth muscle, endothelium, and bone) (Frese et al. 2016). These ADSCs are associated with perivascular cells and promote vascular stability under normal conditions (Cherubino et al. 2011). Additionally, evidence suggests that ADSCs can enhance macrophage recruitment and anti-inflammatory polarization, fibroblast migration, VEGF-mediated angiogenesis, fibroblast growth factor-2 (FGF2), bone morphogenetic protein-2 (BMP2), and MMPs after injury (Lee et al. 2009). This culminates in neovascularization and deposition, and maintenance of a collagen matrix. While current studies suggest that ADSCs are intimately associated with vascular regeneration, additional research is needed to elucidate their role in the maintenance of skin integrity in normal wound healing (Hutchings et al. 2020; Yu et al. 2018; Lu et al. 2018). Given that AT is enriched in stem cells, ease of isolation, and the plasticity of ADSCs, these cells could potentially be harnessed for wound-healing applications in conditions of impaired healing.

Impaired Wound Healing

Cutaneous wounds are of two subtypes: acute wounds (e.g., lacerations, abrasions, and surgical wounds), which generally heal uneventfully, and persistent, chronic wounds (e.g., diabetic ulcers). The latter occur secondary to interruptions in the healing process as a result of underlying medical conditions, including metabolic diseases (diabetes, obesity) and compromised blood supply (vascular disease, radiation injury) (Ojeh et al. 2015). Impaired circulation and enhanced tissue hypoxemia compromise wound healing by decreasing nutrient and oxygen supply, and hence the metabolic activity of cells involved in the repair, including keratinocytes and fibroblasts (MacKay 2003; Gottrup 2004). Additionally, patients with chronic wounds show an inadequate cellular response to relative hypoxia at the injury site. Under normal wound-healing conditions, hypoxia results in the activation of HIF-1a and recruitment of MSCs to the wound bed (Hong et al. 2014). As indicated earlier, these cells, in turn, promote EPC migration and neovascularization to enhance oxygen delivery to the site of injury (Li et al. 2018). However, EPCs obtained from patients with chronic wounds such as

diabetes show decreased hypoxia-induced adhesion, migration, and proliferation (Vasa et al. 2001; Tepper et al. 2002; Loomans et al. 2004). This culminates in impaired angiogenesis and prolonged ischemia, further compromising wound healing (Capla et al. 2007). As discussed in the context of routine wound healing, ASCs also play a key role in improving vascularization and maintaining the collagen matrix. Complementarily, diabetic wounds exhibit functionally impaired ASCs, which results in diminished growth factor production (Cianfarani et al. 2013).

Combined with abnormal cytokine signaling, decreased growth factor production detrimentally impacts wound-healing outcomes (Galkowska et al. 2006). In addition to promoting revascularization, factors such as FGF also contribute to the recruitment and replication of stem cells (i.e., MSCs), further enhancing growth factor production (Rodrigues et al. 2010). Lack of growth factors is associated with impaired recruitment and function of vascular endothelial cells and multiple stem cell lineages. The source of these factors is macrophages, and the altered macrophage activity (e.g., in diabetic ulcers) is a responsible cause and result of altered signaling pathways (Maruyuma et al. 2007). Macrophages obtained from chronic diabetic wounds release fewer growth factors relative to healthy tissue macrophages, functioning as a significant cause of decreased angiogenesis and impaired healing in these patients (Toma et al. 2005; Yamanishi et al. 2012). Taken together, growth factors and stem cells have a complementary relationship, and aberrancies in either can result in impaired or excessive healing.

Excessive Wound Healing

On the opposite spectrum of healing is overhealing or pathological scarring, which includes hypertrophic scars and keloids. The scarring has significant detrimental physical, social, and psychological consequences, providing an impetus for further research regarding tissue regeneration. Many studies focus on differentiating mechanisms underlying adult versus fetal wound healing, which is scar-free. Interestingly, midgestational fetal wounds heal rapidly and are characterized by regeneration of all skin components (including skin appendages) and maintenance of identical collagen patterns to uninjured tissue (Hu et al. 2014). This contrasts to adult wounds, which lack skin appendages and heal by a fibroproliferative response characterized by a disorganized collagen network, resulting in scar tissue that vastly differs from intact skin (Fig. 3) (Hu et al. 2014).

We compare mechanisms in the fetal healing process to adult skin repair to understand the causative factors underlying pathological scarring. Fetal wounds differ from adult wounds regarding to inflammatory responses, extracellular matrix (ECM) components, and differential growth factor expression (Mast 1992). For example, fetal wounds exhibit a paucity of immune cells, lower levels of the proinflammatory cytokine IL6 and elevated anti-inflammatory IL10, immediate collagen deposition with a higher Type III to Type 1 collagen ratio, higher VEGF and HIF-1a production, and a lack of profibrotic myofibroblasts compared to postnatal wounds to list a few distinctions (Table 1) (Lo et al. 2012). In addition to

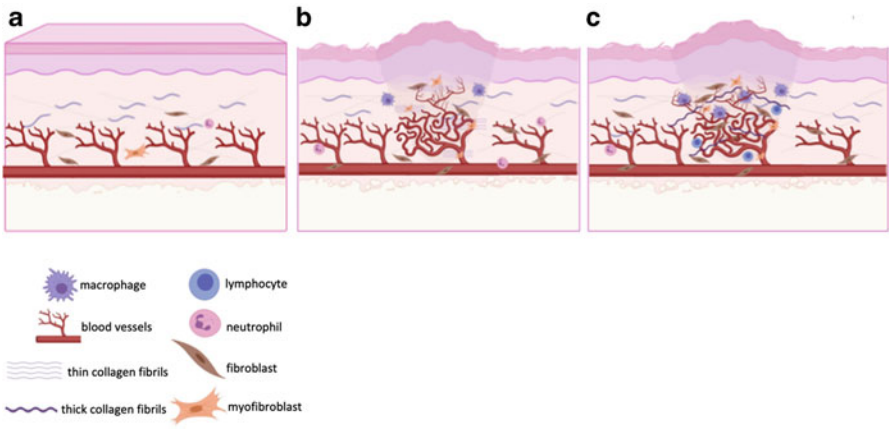

Fig. 3 Anatomy of (**a**) normal skin, (**b**) hypertrophic scar, and (**c**) keloid

Table 1 Comparison between fetal versus adult wound healing. (Modified from Lo et al. (2012))

Characteristics	Fetal	Adult
ECM collagen		
Deposition rate	Immediate	Delayed
Histology	Fine, reticular, and basket-weave	Dense parallel bundles
Type III/type I ratio	Higher	Lower
Cross-linking	Low levels	High levels
Inflammatory response		
Inflammatory cells	Few	Many
IL6 and IL8	Low levels	High levels
IL10	High levels	Low levels
Growth factors		
VEGF	Higher	Lower
TGF-b1 and b2	Low levels	High levels
HIF-1a	Higher	Lower
Fibroblasts and stem cells		
Myofibroblasts (day 14)	Absent	Present
MSCs presence	Higher levels at injury site	Lower levels at injury site

HIF hypoxia-inducible factor-1a, *IL* interleukin, *MSCs* mesenchymal stem cells, *TGF-b* transforming growth factor-b, and *VEGF* vascular endothelial growth factor

the aforementioned factors, fetal wounds also exhibit differences in epidermal and dermal stem cell location and function. For example, postnatal epidermal stem cells reside in the hair follicle bulge, which fetal skin lacks (Nowak et al. 2008). Additionally, as skin development progresses, these epidermal stem cells change in the pattern of cell division. Cell divisions are predominantly symmetric and parallel to the basement membrane initially in embryonic development. In later stages, stem cells begin to undergo asymmetric cell division, which correlates with

a transition from a scar-free to scarring healing phase (Hu et al. 2014). While a significant amount of research is focused on epidermal stem cells, differential responses in dermal stem cells likely contribute to aberrant scarring (Hu et al. 2014). Hereto, we identified stem cells as contributors to skin regeneration and a promising therapeutic option in impaired healing.

However, some studies have provided conflicting results, demonstrating that specific subpopulations of dermal stem cells (MSCs) may increase inflammation and risk of hypertrophic scarring (Zhang et al. 2009a; van der Veer et al. 2009; Ding et al. 2013).

Furthermore, increasing evidence suggests the involvement of stem cells in keloid pathogenesis. For example, aberrant fibroblasts and profibrotic myofibroblasts may originate via epithelial-to-mesenchymal transition from MSCs, which in turn are derived from embryonic stem cells (ESCs) (Lee et al. 2015). In turn, keloid dermis-derived stem cells that express ESCs-specific markers OCT4, NANOG, Sox2, and pSTAT3 (ESC-like cells) promote aberrant fibroblasts and profibrotic myofibroblasts through an MSCs intermediate (Lim et al. 2019; Grant et al. 2016; Bagabir et al. 2012; Zhang et al. 2009b). Likely, establishment of a local inflammatory environment increases the number of keloid-derived precursor stem cells with a distinct MSCs-specific marker expression profile from normal skin precursor cells. The inflammatory niche induces TGFb, epidermal growth factor (EGF), FGF, and insulin-like growth factor (IGF) secretion by keloid-associated stem cells, which in turn results in excessive collagen production and ECM deposition, further recruitment of inflammatory cells and production of inflammatory mediator interleukins (IL) (e.g., IL1a, IL6), and scar formation (Smith et al. 1998; van der Veer et al. 2009). Taken together, studies suggest that the immune system and post-trauma-inflammatory period have an integral role in scarring, which likely occurs via local stem cell dysregulation. In the subsequent section, we will discuss the specifics of the various stem cell populations involved in wound healing.

Stem Cell Subtypes in Skin Regeneration

Stem cells have an integral role in physiologic, impaired, and excessive healing. Given their general prohealing effect, stem cells can putatively be harnessed therapeutically. Here, we discuss the various stem cell subtypes involved in skin regeneration.

Embryonic Stem Sells

ESCs, which are isolated from the inner cell mass of blastocysts, express the cell surface antigens, including stage-specific embryonic antigen (SSEA) SSEA3, SSEA4, T cell receptor alpha locus (TRA) TRA-1-60, and TRA-1-81 and transcription factors OCT4, NANOG, and Sox2 (Thompson et al. 1998; Reubinoff et al. 2000; Clark et al. 2004). The latter transcription factors promote self-renewal genes

while inhibiting differentiation genes, establishing ESCs' pluripotency and the potential to differentiate into any germ layers – endoderm, mesoderm, or ectoderm from which skin develops (Thomas et al. 1998). ESCs can form all somatic tissues and express high levels of telomerase, hence preventing cellular senescence. Depending on the growth factor milieu, ESCs can differentiate into keratinocytes and generate epidermal layers, besides showing proangiogenic properties, thus making them an attractive option for bioengineered skin substitutes (Aberdam 2004; Rufaihah et al. 2010). However, further research is needed before an efficient, controlled expansion and differentiation to particular cell types is feasible. Additionally, studies are required on how to deliver cells in a manner in which they can survive and integrate effectively in patients (de Wert and Mummery 2003).

While these challenges occur in ESCs and adult stem cells, ESCs have additional considerations to adult stem cells. For example, ESCs use is still controversial due to ethical concerns regarding harvesting cells from live embryos (de Wert and Mummery 2003). There are also concerns for potential immune rejection and teratoma formation (Hentze et al. 2009). The latter is likely since ESCs harbor qualities reminiscent of cancerous cells, including self-renewal, persistent proliferation, lack of contact inhibition, and proangiogenic features (Burdon et al. 2002). ESCs also have reduced CpG island methylation in specific genes, allowing for increased gene expression compared to differentiated cells (Altun et al. 2010). This is coupled with hypermethylation and silencing of tumor-suppressor genes, a phenomenon also seen in cancerous cells (Altun et al. 2010). Given that ESCs are potentially tumorigenic, further work is needed before they can be implemented clinically. In the meantime, adult stem cells have garnered greater interest as an alternative source of stem cells for the treatment of diseases.

Induced Pluripotent Stem Cells

While not an endogenous stem cell population, induced pluripotent stem cells (iPSCs) produced from adult-derived cells have significant therapeutic potential and merit an in-depth discussion (Ibrahim et al. 2016). iPSCs are programmed in vitro via induction of Oct4/Sox2/c-Myc/KLF4 or Oct4/Sox2/NANOG/LIN28 (Takahashi et al. 2007; Takahashi and Yamanaka 2006; Yu et al. 2007). They are pluripotent cells with the capacity for self-renewal and the ability to differentiate into any adult cell type, similar to ESCs (Ibrahim et al. 2016). As they are derived from adult somatic cells, iPSCs circumvent potential ethical issues faced with ESCs. Furthermore, iPSCs can easily be derived from the adult tissue harvested from multiple sources, including, bone marrow, skeletal muscle, and skin, thus providing a renewable source of pluripotent stem cells (Ahmed et al. 2011a; Buccini et al. 2012; Gorecka et al. 2019). They are also being used for disease modeling (Cagavi et al. 2018).

Due to this ability, iPSCs-derived cells are potentially able to target each phase of wound healing. During the inflammatory phase, they can ameliorate impaired growth factor and cytokine secretion, promoting macrophage, fibroblast, and

keratinocyte secretions lacking in chronic wounds (Casqueiro et al. 2012; Clayton et al. 2018; Kim et al. 2013; Açikgoz et al. 2004). During the proliferative phase, iPSC-derived cells promote angiogenesis and collagen deposition and include endothelial cells, smooth muscle cells, fibroblasts, keratinocytes, etc. (Tepper et al. 2005). Finally, the recruitment of cells such as fibroblasts and myofibroblasts during the proliferative phase impacts the remodeling phase of healing (Grenier et al. 2007).

Interestingly, iPSCs can be induced to produce other stem cell populations such as MSCs, which are multipotent stem cells capable of differentiating into various cell types (discussed in the subsequent section). MSCs obtained from models of poor healing (e.g., diabetic wounds) exhibit impaired proliferation, differentiation, and production of proangiogenic factors (Aasen et al. 2008). IPSCs-derived MSCs may have a better wound-healing potential, and we later discuss iPSCs-based treatment in conditions of poor healing. However, while iPSCs may have a prohealing advantage over MSCs, several potential issues are associated with their implementation. Like ESCs, iPSCs exhibit tumorigenic potential and can form teratomas when undifferentiated (Ahmed et al. 2011b; Gledhill et al. 2015; Krause et al. 2001). Currently, there are strategies to minimize teratoma risk, including differentiation before cell transplantation (Bedel et al. 2017). Another potential issue is that initial production required retroviral transfection with the risk of viral integration into the host genome and insertional mutagenesis. However, more recent techniques are nonintegrative, circumventing potential safety issues (Haridhasapavalan et al. 2019; Malik et al. 2013; Deng et al. 2015). Taken together, iPSCs have a potential application in wound healing, although further studies regarding their safety profile and improvements in iPSCs' generation are needed at this point.

Mesenchymal Stem Cells

MSCs are progenitor cells for connective tissue found in multiple sites, including AT, bone marrow, and nerves (Danisovic et al. 2009). To classify as an MSC, cells should exhibit plastic adherence, express specific cell surface markers (CD73, CD90, and CD105), and lack CD14, CD34, CD45, and HLA-DR, and be able to differentiate in vitro into either adipocytes, chondrocytes, or osteoblasts (Dominici et al. 2006). While the aforementioned characteristics apply to all MSCs, slight variations are depending on the tissue of isolation. Here, we focus on adipose tissue-derived MSCs (ADMSCs), which express the previous factors plus CD29, CD44, CD71, CD13, CD166, and STRO-1 (Ullah et al. 2015).

Akin to ESCs, MSCs have beneficial features for skin regeneration applications, including self-renewal, the ability to home toward wounds, rapid proliferation, and the capacity to differentiate into a myriad of cell types (Sackstein 2004). Their prohealing effects can be attributed in part to the release of growth, cell recruitment, and immunoregulatory factors in response to inflammatory mediators that accumulate at the site of injury (Prockop and Oh 2012). An added advantage over ESCs is that MSCs are not immunologically active due to low MHC1 and lack of MHCII and costimulatory CD80, CD40, and CD86, which protects MSCs from natural killer

(NK) cell lysis (Rasmusson et al. 2003). Furthermore, MSCs can inhibit NK and cytotoxic T-cells via various pathways, such as secretion of human leukocyte antigen G5, leukemia inhibitor factor (LIF), and interferon (IFN) (Selmani et al. 2008; Nasef et al. 2008; Sheng et al. 2008). More specifically, MSCs induce T-cell apoptosis, which enables macrophages to produce TGFb, thus promoting the generation of regulatory T-cells and macrophage phenotype switching to anti-inflammatory subtypes (Ohe et al. 2015; Barrandon and Green 1987; Green 2008). These immunomodulatory effects depend on the quantity and type of cytokines present and diminish the risk of immune rejection, making MSCs a viable option in inflammatory conditions and other clinical applications (Mansilla et al. 2005; Falanga et al. 2007). However, the intensity of inflammation regulates MSC-mediated immunomodulation, necessitating a healthy patient inflammatory status for optimal efficacy (Wang et al. 2014).

Recent research identified ADMSCs within subcutaneous tissue, purporting a skin regeneration role (Marfia et al. 2015). In this context, ADMSCs have several advantages, including ease of harvesting and enhanced proliferative and immunosuppressive properties (Jacobs et al. 2013; Pachón-Peña et al. 2011). The ability for ADMSCs to proliferate, differentiate, and migrate is inherently dependent on the local milieu. ADMSCs home in on the injury site via enhanced expression of CXCR-4, which modifies local immune cell (i.e., macrophages, T-cells, B-cells, and dendritic cells) inflammatory phenotypes to a healing, anti-inflammatory one likely via TGFb or growth differentiation factor (GDF) GDF11-mediated activation (Baharlou et al. 2017; Hyldig et al. 2017; Mazini et al. 2019). Production of TGF-b and GDF11, growth factors (i.e., FGF, VEGF), and cytokines, i.e., IL6, tumor necrosis factor-a (TNF-a), is likely induced by local IL6 production during the inflammatory phase (Mazini et al. 2020). Taken together, ADMSCs interact with dermal fibroblasts via cytokine and growth factor production to regulate their microenvironment. ADMSC secretome stimulates the migration and proliferation of dermal fibroblasts and keratinocytes, besides collagen and elastin deposition (Choi et al. 2018; Ferreira and Gomes 2018). Thus, preconditioning ADMSCs with a particular cytokine and growth factor combinations can enhance therapeutic benefits, which is an essential consideration for clinical applications.

Epithelial (Epidermal) Stem Cells

Studies suggest that the epidermis comprises a basal layer containing 2–7% of stem cells (Potten et al. 1979). Although integrins, which are responsible for attaching the epidermal basal layer to the basement membrane, may be a potential candidate, these stem cells lack specific markers. Evidence suggests that epithelial stem cells, including epidermal interfollicular, sebaceous gland, and hair follicle bulge stem cells, have slightly different characteristics. For example, interfollicular stem cells are less potent than bulge stem cells, possibly suggesting that they are the progeny of bulge cells (Alonso and Fuchs 2003). Interfollicular cells lack a distinct niche and are more easily induced to proliferate, although injuries that destroy the interfollicular

epidermis (i.e., superficial burns) but leave hair follicles intact can regrow epithelium and do not need grafting (Alonso and Fuchs 2003; Green 1991). Hair follicle bulge cells are multipotent cells capable of differentiating into all skin epithelial lineages (e.g., hair follicles, keratinocytes) and forming a stratified epidermis in vitro (Rochat et al. 1994). Taken together, this suggests that epithelial stem cells have different functions and importance, which has implications in skin regeneration and necessitates a greater understanding of the underlying signaling pathways.

In particular, Wnt/beta-catenin signaling is associated with the ability of epithelial cells to exhibit multipotency features (Zhou et al. 1995; Gat et al. 1998; Andl et al. 2002). While only bulge cells are considered multipotent, stabilization of skin beta-catenin induces adult interfollicular epidermal cells to behave similarly to embryonic skin. That is, they can differentiate into epidermal cells or hair follicles. Wnt signaling in embryonic skin epithelial cells results in beta-catenin-mediated activation of the DNA-binding protein family Lef/Tcf (Nusse 1999). When skin MSCs inhibit the BMP pathway, multipotent epithelial stem cells express Lef1 and commit to hair follicle formation (Jamora et al. 2003). The extent of Lef1/Tcf activation is essential in stem cell lineage commitment, and overexpression of Lef1 in skin epithelium results in inappropriate hair follicle formation, while interfering with Lef1/beta-catenin association results in hair follicles adopting a sebaceous cell fate (Zhou et al. 1995; Merrill et al. 2001; Niemann et al. 2001). Interestingly, despite consistently elevated stabilized beta-catenin levels and, hence, epithelial bulge stem cell commitment to hair follicle morphogenesis, the overall size of the stem cell niche does not change (Lowry et al. 2005). This suggests a balance between beta-catenin-mediated self-renewal of bulge stem cells and their efflux from the niche.

Under physiologic conditions, hair follicle and other epidermal cells function as distinct lineage niches. However, injury to the epidermis results in the recruitment of stem cells from different epidermal compartments, allowing for repopulation of cells in other epidermal compartments and expediting wound closure. Given endogenous stem cells' role in wound healing, we subsequently assessed stem cells in defective and excessive healing, highlighting the pros and cons of different stem cell types.

Applications in Defective Wound Healing

Chronic wounds, frequently associated with impaired stem cell function, can be managed with clinical approaches involving stem cell application. Several stem cell subtypes have potential in wound-healing management, including ESCs, EPCs, iPSCs, and MSCs (bone marrow and AD). Initially, ESCs were identified for their ability to differentiate into any of the three primary germ layers and, thus, their potential application in wound healing; however, ESCs can generate tumors and are controversial, as discussed earlier (Kanji and Das 2017). Therefore, focus has been shifted to adult stem cells as alternative treatment options. Here, we discuss current stem cell treatments and their effect on various physiologic events involved in wound healing: inflammation, angiogenesis, and fibrosis.

Endogenous bone marrow-derived EPCs have a crucial role in promoting wound healing via angiogenesis. However, migration to the injury site occurs in response to hypoxic factors, which are impaired in conditions such as diabetes (Tepper et al. 2005; Ceradini et al. 2004). Exogenous stem cell transplant is an alternative strategy to circumvent this issue. A study utilizing diabetic murine models demonstrated that injecting CD34+ EPCs into ischemic wounds enhances vascular density and minimizes healing time (Sivan-Loukianova et al. 2003). Furthermore, injection of CD34+ hematopoietic progenitor cells into human chronic sacral ulcers decreased wound volume by 60% within 3 weeks of administration (Wettstein et al. 2014). Although the sample size was small (three patients), this study provided evidence of efficacy with stem cell treatment and, in this case, no tumorigenicity, paving the way for additional human clinical studies utilizing stem cells.

An alternate source of stem cells is differentiated adult somatic cells, which can be de-differentiated to pluripotent iPSCs. For example, murine fibroblasts or keratinocytes treated with a combination of Oct3/4, Sox2, c-Myc, and Klf4 can revert to iPSCs, which in turn differentiate into tissue from all three germ layers (Takahashi and Yamanaka 2006; Aasen et al. 2008). In addition to the ability to induce pluripotency, directing differentiation into particular cell types is critical. In this regard, iPSCs can be selectively differentiated into fibroblasts and keratinocytes and, as an added advantage, elicit an anti-inflammatory response (Lu et al. 2014). Taken together, these characteristics render iPSCs an attractive option for treating chronic wounds and skin conditions (Zhang et al. 2015a). Indeed, iPSCs-derived cells obtained from patients promote healing and enhance collagen secretion (Gorecka et al. 2019). In murine models, iPSCs-derived MSCs injected into the wound site secrete type-VII collagen at the dermal-epidermal junction and improve epithelialization (Nakayama et al. 2018). These iPSCs can be obtained from donors with preexisting conditions (e.g., diabetes, epidermolysis bullosa), allowing autologous treatment and minimizing rejection (Tolar et al. 2011). This is coupled with a proangiogenic potential, allowing for potential applications in ischemic injury (e.g., myocardial infarction, peripheral arterial disease, and retinopathy). However, further studies regarding the safety-enhancement of iPSCs' reprogramming protocols are needed to assure minimal risk of mutagenesis and teratogenicity (Okita et al. 2007).

Similar to iPSCs, MSCs also lack immunological reactivity and are capable of rapidly proliferating and differentiating into a wide range of cell types (Nakagawa et al. 2005; Krause et al. 2001). MSCs express high levels of VEGF and angiopoietin-1 or may function as pericytes, indicating that prohealing effects are due in part to enhanced angiogenesis and stabilization of blood vessels in normal and impaired healing models (Dai et al. 2007; Shumakov et al. 2003; Kwon et al. 2008). Clinically, MSCs-based therapy has also shown to improve healing by improving angiogenesis and dermal vascularity and thickness, increasing reepithelialization and granulation tissue formation, and, more importantly, modulating the immune response (Badiavas et al. 2003; Vojtassak et al. 2006; Cha and Falanga 2007). Irrespective of the source, MSCs-based cell therapy lowers inflammatory cell numbers and proinflammatory cytokines (e.g., IL1, TNFa) and enhances IL10 at the site of injury in animal wound-healing models (Liu et al. 2014a). Furthermore, MSC-based treatment influences macrophage polarization, promoting an anti-inflammatory M2 macrophage

profile in murine wounds (Zhang et al. 2010). Since macrophage profile and inflammation also regulate fibrosis, the immunomodulatory effect putatively attenuates excessive ECM deposition and abnormal scarring, which will be discussed in-depth in the subsequent section.

Stem Cells in Overscarring

MSCs administration increased the tensile strength of wounds and reduces wound contracture and scarring due to (1) anti-inflammatory effects, (2) paracrine signaling, and (3) modified collagen deposition and ECM remodeling (Hu et al. 2018). Prolonged inflammation can induce fibrosis, and the anti-inflammatory effect of MSCs in part accounts for reduced fibrosis. MSCs upregulate prostaglandin E_2 (PGE2) that inhibits IL2 expression and diminishes T cell proliferation in the wound (Németh et al. 2009; Jarvinen et al. 2008; Djouad et al. 2007). PGE2 also facilitates the transition from T_H1 to T_H2 cells, which corresponds with a reduction in IFN expression and upregulation of IL4 (Zanone et al. 2010; Aggarwal and Pittenger 2005). Decreased IFN relative to IL4 favors anti-inflammatory M2 macrophages, which results in decreased proinflammatory signaling (Stout 2010; Varin and Gordon 2009). This is accompanied by the secretion of various factors that promote tissue regeneration.

MSCs secrete various antifibrotic cytokines and growth factors including hepatocyte growth factor (HGF), FGF2, VEGF, IL10, and adrenomedullin (Li et al. 2008, 2009; Chen et al. 2008; Du et al. 2016). In particular, fibroblasts respond to HGF secretion by downregulating collagen I/III and TGFb1 expression via nuclear exclusion of SMAD3, a transcriptional factor associated with several profibrotic genes (Mou et al. 2009; Schievenbusch et al. 2009; Inagaki et al. 2008). In addition to enhanced HGF and VEGF, TGFb1/b2 neutralization or addition of TGFb3 is also associated with the scar-free repair, and MSCs maintain a higher ratio of TGFb3/TGFb1 protecting against abnormal scar formation (Ono et al. 2004; Shah et al. 1995).

MSCs contribute to collagen type III secretion, and a higher type III: Type I ratio is characteristic of scar-free fetal tissue healing (Longaker et al. 1990; Fathke et al. 2004). In addition to targeting collagen deposition, MSCs-secreted factors, such as HGF, upregulate the matrix metalloproteinases MMP-1, MMP-3, and MMP-13 in fibroblasts, and promoting ECM turnover (Kanemura et al. 2008). Interestingly, MSCs may inhibit profibrotic myofibroblast differentiation via HGF secretion (Shukla et al. 2009; Abe et al. 2001). While myofibroblast differentiation may be needed in normal healing, these cells produce excessive ECM compared to dermal fibroblast and may contribute to scar formation (Bucala et al. 1994). Elevated TGFb1, observed in conditions characterized by a prolonged acute inflammatory response, mediates myofibroblast differentiation and, as a result, contributes to the excessive ECM deposition, the formation of tight collagen bundles, and wound contraction resulting in scarring. Downstream effects of MSCs-mediated inhibition of myofibroblasts yield less scar tissue, as witnessed in oral epithelial healing that is characterized by high HGF levels and lack of significant myofibroblast differentiation (Shannon et al. 2006).

Interestingly, ESC-like populations are implicated in fibrosis in models of aberrant healing (i.e., keloids). While MSCs attenuate inflammation and collagen remodeling, MSC intermediates may differentiate into keloid myofibroblasts (Lee et al. 2015). Keloid dermis contains a population of cells that express elevated ESCs-specific markers OCT4, NANOG, SOX2, and pSTAT3 in perivascular cells within keloid-associated lymphoid tissue, serving as a source of aberrant fibroblasts (Lee et al. 2015). This potentially occurs via the previously mentioned MSC intermediate, generated by the endothelial-to-mesenchymal transition (EMT). Interestingly, while MSCs-based treatment may have an actual clinical application in wound healing and scar prevention, endogenous dermal keloid-associated stem cells contribute to keloid pathogenesis. Thus, further studies regarding the complex signaling pathways involved in wound healing and the contribution of stem cells in the process are needed at this time to further enhance our understanding of the molecular mechanisms involved therein.

Stem Cell Therapy in Pathological Scarring

Several studies demonstrated the use of stem cell-based therapy for hypertrophic scar and keloid treatment. For example, iPSCs-conditioned medium (CM) may suppress hypertrophic fibroblast activation, collagen I, as well as, alpha-smooth muscle actin, a marker for myofibroblasts (Ren et al. 2015). Furthermore, iPSCs-CM-secreted factors block inflammatory cell recruitment, decrease adhesion, and mitigate the contractile ability of dermal fibroblasts (Ren et al. 2015).

In addition to multipotent iPSCs, MSCs also could be harnessed for scar treatment. An example of this is Wharton's jelly MSCs (WJ-MSCs), which exhibit antifibrotic properties, and no teratoma formation or rejection (Gauthaman et al. 2012; Bongso and Fong 2013). In addition to preventing fibrosis, WJ-MSCs enhance healing in immunodeficient mice and diminish scarring in other animal models (Sabapathy et al. 2014; Azari et al. 2011). Bone marrow-derived MSCs similarly have been used to treat hypertrophic scars in rabbit models and murine skin fibrosis, facilitating the formation of uniform, basket-weave collagen organization analogous to normal skin with minimal inflammatory cells (Liu et al. 2014b; Wu et al. 2014). This is combined with a marked decrease in profibrotic TGFb1 and upregulation of MMPs (e.g., MMP-2/9/13) (Wu et al. 2014). Alternatively, injection of ADSCs in a rabbit-hypertrophic scar model led to the normal-appearing scars with a reduced scar elevation index (Zhang et al. 2015b). Likely, ADSCs modify the local host microenvironment via the production of antioxidants, free radical scavengers, and heat shock proteins, promoting normal wound healing (Gimble et al. 2007).

Conclusion

In this chapter, we highlight the mechanisms underlying normal and aberrant post-trauma healing and the role of stem cells in these processes. In particular, we discuss how endogenous stem cells can impact all the phases of wound healing:

inflammatory, proliferative, and remodeling. Currently, the studies suggest that application of stem cells may benefit dermal wound healing by accelerating reepithelialization, improving the tensile strength of new tissue, promote healing in chronic wounds, and minimize excessive scarring. However, further work regarding safety and regulation, clinical translatability, ability to scale up production, and efficient means of stem cell delivery is needed before widespread clinical use.

Abstract

Since Friedenstein and co-workers first reported bone marrow-derived mesenchymal stem cells (MSCs) during the early 1970s, several researchers have focused on their biology and in vitro and in vivo characterization in experimental animal models. After their initial isolation from the bone marrow, MSCs have also been isolated from almost every tissue including the adipose tissue, liver, skeletal muscle, amniotic fluid, umbilical cord blood, and dental pulp. Following the minimum criteria recommended by the International Society for Cellular Therapy, human MSCs show preferred plastic adherence in culture, can undergo trilineage differentiation (i.e., adipogenic, chondrogenic, and adipogenic), besides the expression of CD44, CD71, CD90, CD105, and lack of CD34 and CD45 expression. Other important markers include Stro-1, SSEA-4, CD146, and CD271. This identification criterion has gone a long way in comparing the findings from independent research labs involved in MSCs research. MSCs show remarkable immunomodulatory and anti-inflammatory properties besides their ability to undergo transdifferentiation and paracrine activity. These characteristics make them ideal candidates for cell therapy and for this reason; there are numerous clinical trials worldwide that use MSCs to treat various pathologies including myocardial infarction for which they have entered into Phase III trials. They also secrete exosomes as part of their paracrine activity, which has led to the emergence of "cell therapy without cells" approach. Several studies have suggested that exosomes, small extracellular vesicles, derived from MSCs could serve as a novel therapeutic tool in the field of regenerative medicine. This book chapter discusses in-depth the advancements in the field of MSCs-based cell therapy and cell-free therapy using their derivative exosomes with a special focus on the clinical perspective.

Introduction

Mesenchymal Stem Cells: Fist Description in Bone Marrow

The term mesenchymal stem cell (MSCs) is widely accepted today. The existence of cells in various tissues with the ability to differentiate into diverse cell types is assumed. But, when does this concept arise? We go back to the end of the nineteenth century when Goujon (1869) demonstrated that transplanted bone marrow (BM) in a heterotopic site generated bone and marrow de novo (Goujon 1869). A century later, Tavassoli and Crosby advanced knowledge of the potential of BM with their experiments published in a prestigious scientific journal (Tavassoli and Crosby 1968). These authors observed that autologous transplanted marrow fragments survived in various extramedullary sites in the rat, rabbit, and dog. These pioneering works revealed some cellular elements with proliferation and differentiation capacity in the BM. Based on their work, Friedenstein and collaborators would be the first to suggest a cell type in the BM with the ability for differentiation; it would be a different cell type to hematopoietic progenitors. They demonstrated that BM contains a population of cells with a high proliferative capacity that adhered to plastic and that presented a morphology characteristic fibroblast-like. These authors were also the first to propose the ability of these cells to form colonies from a single cell (the fibroblast-colony forming unit (F-CFU)) (Friedenstein et al. 1970). But it would not be until the beginning of the 1990s when the term MSCs was coined. Caplan proposes this name in analogy with "hematopoietic stem cells (HSCs)" (Caplan 1991). The concept of non-HSCs and their presence in BM was reinforced by Pittenger and co-workers' pioneering data published in 1999 (Pittenger et al. 1999).

The abstract published in a prestigious journal says,

> Human mesenchymal stem cells are thought to be multipotent cells, which are present in adult marrow, that can replicate as undifferentiated cells and that have the potential to differentiate to lineages of mesenchymal tissues, including bone, cartilage, fat, tendon, muscle, and marrow stroma. Cells that have the characteristics of human mesenchymal

> stem cells were isolated from marrow aspirates of volunteer donors. These cells displayed a stable phenotype and remained as a monolayer in vitro. These adult stem cells could be induced to differentiate exclusively into the adipocytic, chondrocytic, or osteocytic lineages. Individual stem cells were identified that, when expanded to colonies, retained their multilineage potential.

This text has already summarized two decades ago what has now been widely accepted as MSCs. Numerous laboratories worldwide became interested in this cell type, and many works began to be published from here onwards. However, there was no defined approach to characterize MSCs due to the lack of specific surface markers. Moreover, they constitute a heterogeneous group of subpopulations and possess a distinct expression of surface proteins and differentiation potential besides showing source-specific transcriptome under a given set of culture conditions (Elahi et al. 2016). Hence, various methods of cell isolation, expansion, and characterization protocols have been reported in the literature to ensure a uniform/homogeneous population of cells.

Their low propensity in the BM, lack of surface markers, and diversity in the methods and protocols of isolation, purification, and expansion protocols rendered it difficult to compare the findings originating from independent research laboratories worldwide. To address this critical issue and standardize MSCs preparations for experimental and clinical usage, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy has established standard criteria to fully define and characterize human MSCs preparations (Haider 2018). The minimal criteria include plastic-adherence when maintained in standard culture conditions; they must express specific surface antigens, that is, CD44, CD73, CD90, and CD105 and absence of CD11b, CD14, CD19, CD34, and CD45. Besides, they should undergo trilineage (i.e., adipogenic, chondrogenic, and osteogenic) differentiation in vitro (Dominici et al. 2006). Some additional surface markers expressed by MSCs include, CD9, Cd10, CD13, CD29, CD51, CD54, CD117, CD166, and Stro-1. These criteria facilitated the work of many groups involved in experimental and clinical research with this cell type.

The favorable characteristics of MSCs, availability without any moral and ethical issues, ease of availability, simple isolation and undifferentiated in vitro expansion protocols, multilineage differentiation potential, inherent paracrine activity, and robust nature to carry exogenous genetic material for genetic therapy, etc., have made them attractive candidates for clinical application (Haider and Ashraf 2005).

Bone Marrow-Derived MSCs

Currently, obtaining MSCs from BM is well-established in various laboratories around the world. Usually, spinal aspirates are obtained by aspiration of the iliac crest. Mononuclear cells are isolated from the BM aspirate on a Ficoll-density gradient by centrifuging. After washing twice the cells are re-suspended in culture medium and finally seeded into adequate flasks. Thereafter, the medium must be changed every 2–3 days and wait a time that may vary, but it may be around 2 weeks

to obtain the confluence of the cells. To check the quality of the culture-expanded cells, the three parameters indicated above must be fulfilled – adherence to plastic, presence of specific surface antigens, and the ability to undergo multilineage differentiation (Dominici et al. 2006).

Although BM remains the most used, and well-studied and characterized tissue source of MSCs, obtaining MSCs from BM has many drawbacks such as invasiveness of the process, pain and discomfort for the donor, morbidity, due to high proliferative capacity and resistance to apoptosis (Musiał-Wysocka et al. 2019). Moreover, availability in low cell numbers (only 0.001–0.00001 percent of the total cell population) necessitates in vitro expansion, making them immunogenic and may induce genetic instability and chromosomal abrasions (Haider 2006). This searches for alternative tissues to obtain this cell type with the capacity for self-renewal and differentiation.

Isolation of MSCs from Different Sources

Until recently, MSCs have been isolated from almost every tissue in the body. Some tissue sources and their derivative MSCs have been discussed in the following sections. Our focus will be only on some of these tissue sources for MSCs due to their interest in clinical applications.

Adipose Tissue

Adipose tissue, like BM, is derived from the mesenchyme. It is a connective tissue present in all mammals that serve as simple protection of the viscera. It is currently well-supported by the published data that adipose tissue has an endocrine function. It is responsible for controlling of energy metabolism through the storage of lipids (Scheja and Heeren 2019). This endocrine function is attributed to the adipocytes, which are a rich source of endocrine hormones, that is, adipokines and lipokines released in response to metabolic stresses and physiological cues and have their specific targets in the biological system for action (Booth et al. 2016). Since the publication of the early reports showing the presence of stem cells and their characterization as MSCs by Zuk and colleagues (Zuk et al. 2001), adipose tissue-derived stem cells (ASCs) have been extensively characterized and studied for differentiation capacity (Bunnell et al. 2008; Mizuno et al. 2012).

The protocol for harvesting adipose tissue is accessing a concentrated pool of MSCs in the tissue, simple, minimally invasive, and can be performed under local anesthesia that makes adipose tissue ideal for obtaining cells for clinical use in the cellular therapy context (Vallée et al. 2009). ASCs are isolated either by the suction of adipose tissue (SVF) or from the excised human fat by enzymatic digestion followed by purification (Minteer et al. 2013; Alstrup et al. 2019). The quality attributes of the cell preparation depend upon the isolation and purification technique (enzymatic digestion and nonenzymatic) (Gentile et al. 2019). Similarly, the

harvested cells' yield is significantly determined by whether these methods were used singly or combined (Alstrup et al. 2020). Adipose tissue-derived stromal vascular fraction SVF is an attractive therapeutic product obtained in an operating room using an automated device in 60–90 min with prospective clinical utility and efficacy (Han et al. 2015). It is pertinent to mention that collagen digestion requires more time, technical and procedural know-how of culturing the derived cells, a qualified clean room, and working under good manufacturing practices (GMP). In contrast, while SVF requires a less restrictive regulatory pathway. Studies are underway to ascertain whether the cells obtained without enzymatic digestion are identical to those subjected to this process (Chaput et al. 2016; Kokai and Rubin 2016). Researchers are awaiting advances in nonenzymatic separation due to the advantages that this would bring, including eliminating collagenase digestion with the implications that it entails. A review of literature has concluded that subcutaneous human adipose tissue is an accessible and abundant cell source for clinical applications (Kapur et al. 2015). Numerous studies using both ASC and SVF can be found in the clinical trials.org database in this context.

Umbilical Cord

The umbilical cord (UC) connects the fetus to the placenta. The two arteries and a vein in the UC are wrapped in Wharton's jelly (WJ), a gelatinous connective tissue. The UC has characteristics ideal for procuring stem/progenitor cells as it provides abundant stem cells. Their clinical use would not generate ethical conflicts, they are easily obtainable, display low immunogenicity, and have the potential for use in autologous cell therapy (Moreira et al. 2019). Besides Wharton's jelly, MSCs are also isolated from umbilical cord blood (UCB).

Umbilical Cord Blood

Once considered biological waste, UCB contains different subpopulations of stem cells, a unique feature not shared with peripheral blood. They have been isolated and characterized from fetuses/infants of various ages at 19–40 weeks (Iwatani et al. 2019).

Besides being a source of cells for hematopoietic stem cells (HSCs), they are under extensive investigation and characterization as an alternative source of MSCs to the BM-derived MSCs for use in cell-based therapy (Weiss and Troyer 2006). From the ease of availability and simple collection/processing protocols to a lower rejection rate and a higher rate of acceptance, UCB stem cells are considered at par or even superior to the BM-derived stem cells. Given their low immunogenic nature, they have also been used from the allogenic source, which incidentally helps overcome their limited availability from the autologous source. However, the quality and quantity of UCB-derived cells are influenced by various methodological-related parameters, the greatest being the sample volume

(Vasaghi et al. 2013). Some authors have proposed that UCB-derived MSCs show high morphological and molecular similarities with the BM-derived MSCs, including the lack of hematopoietic surface antigens (Erices et al. 2000). Similar to BM cells, UCB-cells constitute a heterogeneous population of cells. In a recently published study, two distinct subpopulations of MSCs were reported and named as short- and long-living cells based on their growth capacity and colony-forming efficiency (Amati et al. 2017). Besides revealing a differential trilineage differentiation potential, the study's immunophenotyping results showed intense surface marker expression of CD90, CD105, CD44, CD13, and HLA-DRA while lacking in HSCs-specific markers, that is, CD31, CD34, and CD45. The cells were also negative CD271. There are reports about the presence of UCB-derived MSCs co-expressing neuronal markers, which show spontaneous neuronal differentiation (Divya et al. 2012). A recently published study has used a combinatorial expression pattern of CD105, CD90, and CD73 (Mishra et al. 2020). They observed that UCB-derived MSCs double-positive for CD105 +CD90+ were CD45+CD34+ immediately after isolation but started to reduce CD45 and CD34 markers during in vitro expansion. The authors also reported that umbilical cord tissues were a much rich source of MSCs than the UCB.

Molecular profiling for stemness-related markers revealed little difference between MSCs derived from UCB, BM, and adipose tissues (Heo et al. 2016). A direct comparison of UCB-derived MSCs and BM-derived MSCs revealed that the former showed more robust chondrogenic differentiation. Bioinformatic analysis revealed donor-to-donor variations in their inherent genetic expression profile pertaining to the pro-angiogenic gene under hypoxic culture conditions (Kang et al. 2018). The presence or absence of MSCs in UCB has remained controversial for some time. For example, Yu et al. (2004) reported that early fetal blood was rich in MSCs; however, full-term UCB was devoid of these cells (Yu et al. 2004). Alternatively, several authors have proposed that the difficulty of obtaining MSCs from UCB was due to their low propensity, as low as 1–2 clones per 10^8 mononuclear cells of UCB (Martins et al. 2009; Bieback et al. 2004; Kern et al. 2006). These data seriously argue against the possibility of considering the UCB as a resource for acquiring MSCs. However, several authors have successfully differentiated UCB-MSCs in vitro to osteogenic, chondrogenic, neural, and hepatic lineages (Liu et al. 2011; Tio et al. 2010; Zhang et al. 2011). Although well-studied and well-characterized, up until now, UCB is not unanimously accepted as a source of MSCs for routine clinical applications.

Wharton's Jelly

Thomas Wharton was the first to describe WJ in 1656, a gelatinous substance composed of various isoforms of collagen and proteoglycans with the principal function to protect the arteries and veins from compression and torsion. They provide a bidirectional flow, delivering oxygen and nutrients that contribute to the adequate development of the fetus and moreover eliminating the waste and carbon dioxide. Human WJ-derived MSCs are emerging as an efficient and advantageous

source of stem cells for experimental and clinical application. Their comparison with MSCs derived from other compartments of the umbilical cord revealed that they are a better choice of cells for clinical application (Subramanian et al. 2015). They exhibit a high degree of self-renewal capacity and multi-lineage differentiation potential, similar to that of MSCs derived from BM (Kern et al. 2006). The ease of availability and noninvasive collection protocols adds up to these advantages. Phenotypically and genetically, they show close resemblance with the embryonic stem cells, but their use and availability are without ethical or moral issues (Marino et al. 2019). Transcriptome profiling of WJ-derived stem cells revealed very low-level expression of pluripotency markers akin to the embryonic stem cells, that is, Nanog, Sox2, Lin28, and POUF1, thus providing a reason for their safety in terms of teratogenicity (Fong et al. 2011). Besides, they also express genes associated with immunomodulation, apoptosis, and chemotaxis. They also release a plethora of growth factors, cytokines, and extracellular vesicles as part of their paracrine activity contributing to their beneficial effects (Puig-Pijuan et al. 2020). There are two popular protocols for the isolation of WJ-derived MSCs, including the one based on the explant technique and the enzymatic digestion method. The enzymatic digestion protocol offers better results because the cell populations obtained are more uniform and homogeneous (Ding et al. 2015). WJ-derived MSCs are attractive cells due to their capacity for proliferation and other characteristics of MSCs like immunomodulatory properties and because the UC is an easy resource to obtain.

Placenta

The human placenta plays a fundamental and essential role in fetal development, nutrition. The placenta's fetal part originates from the blastocyst, whereas the maternal component (decidua) is derived from the endometrium. It is generally believed that it might be a source of primitive cells with immunomodulatory characteristics that render these cells worthwhile for use in regenerative medicine (Evangelista et al. 2008). Besides other types of cells, various studies have demonstrated that the human term placenta is a rich source of MSCs as it is considered one of the structures developed during the earliest stages of embryogenesis (Battula et al. 2008). Considering the complexity of the structure of the placenta, Parolini and coworkers published a paper to show the origin and define a protocol for the isolation of cells from the placenta. One of the main characteristic features of the placenta is its four regions, including the amniotic epithelial, amniotic mesenchymal, chorionic mesenchymal, and chorionic trophoblastic, each one of which respectively offers the following cell populations: amniotic epithelial cells, amniotic mesenchymal stromal cells, chorionic mesenchymal stromal cells, chorionic trophoblastic stromal cells (Parolini et al. 2008). A direct comparison of MSCs derived from these tissues has revealed that MSCs from fetal tissue had higher expansion potential than those derived from the maternal tissue, but they all had different levels of paracrine activity (Wu et al. 2018a). Soncini et al. achieved the isolation of amniotic and chorionic mesenchymal cells. These MSCs were isolated by a mechanical

separation followed by enzymatic digestion (Soncini et al. 2007). Both show MSCs' characteristics, such as fibroblastic morphology, adherence to plastic, and the capacity to form colonies. Both cell types, when analyzed by flow cytometry, showed phenotypes similar to BM MSCs. Diaz-Prado reported the isolation of amniotic membrane MSCs from human placenta by two different protocols for comparison and successfully isolated and in vitro expanded their derived cells for further characterization; however, the cell yield was much higher by Soncini's protocol (Díaz-Prado et al. 2011). These amniotic MSCs are identified by the expression of CD105, CD90, and CD73, plastic adherence ability, and trilineage differentiation and showed excellent osteointegration and bone regeneration potential post engraftment in a rabbit model (Yin et al. 2019). Despite these encouraging data, the discrepancy in their characterization makes it difficult for their progress to regular use in the clinic (Ghamari et al. 2020).

Characterization MSCs Before Culture

As discussed earlier, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy in 2006 proposed minimal criteria to define human MSCs that included preferential adherence to a plastic surface; specific surface antigen expression, that is, CD105, CD73, and CD90, among others, and a simultaneous lack of expression of hematopoietic and endothelial cell-specific surface antigens, that is, CD45, CD34, CD14 or CD11b and HLA-DR); and multilineage differentiation potential to adopt phenotypes similar to osteoblasts, adipocytes, and chondrocytes. These criteria define the minimal requirements to ascertain the purity of MSCs preparation in culture. However, the in vivo identification of MSCs in their "natural habitat" before ex vivo culture has not been well established by any such criterion. They are generally accepted to have a fibroblastic or pericytic origin (de Souza et al. 2016; Soundararajan and Kannan 2018). It would be exciting to establish an appropriate optimized protocol of cell selection that allows the employment of MSCs before their in vitro expansion. A standard protocol to define pre-culture identification markers would guarantee higher purity of the cell preparations than that obtained with selection based on plastic adherence. Many investigators direct their efforts to find a marker to ensure their selection. In an exciting review, Lv and co-workers (Lv et al. 2014) have in-depth reviewed several molecules proposed as markers to identify MSCs before culturing (Lv et al. 2014). The authors have primarily focused on four markers, that is, Stro-1, CD271, SSEA-4 (stage embryonic antigen-4), and CD146 for consideration.

STRO-1

STRO-1 is a cell membrane 75 kd endothelial antigen expressed on MSCs membrane (Ning et al. 2011). It is highly expressed on MSCs. It moves out from the endoplasmic reticulum in response to a decrease in intracellular calcium (Lv et al. 2014). In 1991,

Simmons and Torok-Storb demonstrated Stro-1 enriched F-CFU from human BM with multipotency (Simmons and Torok-Storb 1991). However, this marker's use as an in vivo MSCs "enricher" did not work with the various tissues tested for its expression. Lv et al. (2014) reviewed that Stro-1 is not universally expressed in all reported types of MSCs. Adipose tissue-derived stem cells highly express STRO-1 in culture when differentiated into endothelial lineage (Ning et al. 2011). Its expression is lost from MSCs when the cells are cultured for a longer time in vitro (Gronthos et al. 2003). Various research groups have attempted to establish a relationship between STRO-1 expressions with the MSCs functionality. STRO-1 expression has been related to the immunosuppressive properties of the MSCs (Francois et al. 2005). STRO-1+ cells could stimulate T-cell proliferation more than STRO-1- MSCs. Similarly, another study has attributed the expression of STRO-1 positivity with the paracrine activity of the cells (Psaltis et al. 2010). Pekozer and colleagues have recently shown that STRO-1 positivity is related to trilineage differentiation potential (except for osteogenesis, which was similar to STRO-1- cells) of the cells besides higher clonogenicity and proliferation (Pekozer et al. 2014). Despite these sporadic data, the exact relationship between STRO-1 expression and MSCs functions has not yet been fully established; its expression is related to the primitive status of MSCs.

CD271

CD271 is one of the most specific and prolific markers for the purification of MSCs from the human BM besides UCB. However, CD217+ MSCs derived from UCB were slow in proliferation compared to the ones derived from the BM (Watson et al. 2013). CD271 is also referred to as the low-affinity nerve growth factor receptor (LNGFR), nerve growth factor receptor (NGFR), or p75NTR (neurotrophin receptor). It has been included as a member of the tumor necrosis factor (TNF) superfamily (Thomson et al. 1988). A review performed by Alvarez Viejo and colleagues concluded that CD271 would not be regarded as a universal marker to identify MSCs before culture in vitro. In the BM or adipose tissue, CD271 could be considered a quite suitable marker to isolate MSCs. However, CD271 is inadequate for MSCs' isolation from other tissues such as UC or UCB. Moreover, in the placenta, contradictory results have been obtained by different groups (Álvarez-Viejo et al. 2015). MSCs isolated based on CD271 are highly immunosuppressive and possess lymphohematopoietic engraftment promoting properties. Kuci and colleagues have reported a functional heterogeneity between CD271+ MSCs subpopulations compared with the plastic adherent MSCs. They have shown that both MSCs populations showed differential proliferation and differentiation potentials besides allosuppression but following different mechanisms (Kuçi et al. 2013). Within their derivative clones, the cells were monopotent, bipotent, and tripotent, while their immunosuppressive properties were not consistent with their proliferation or differentiation capacity. A recently published study has reported that CD271-selected MSCs were less angiogenic than their counterparts isolated based on preferential

plastic adherence, although both cell types could populate the scaffolds equally (Kohli et al. 2019).

SSEA-4

SSEA-4 is an early embryonic glycolipid antigen and one of the panels of reliable markers for identification of the undifferentiated human ESCs and cleavage to blastocyst stage embryos (Wright and Andrews 2009). Gang et al. identified the adult BM-MSCs population using SSEA4 (Gang et al. 2007). Conversely, other authors reported no detection of SSEA-4 expressing cells in the unsorted BM (Tormin et al. 2011; Wagner et al. 2005). Therefore, these data suggest that this marker would not be considered an excellent marker to isolate MSCs before culture. A recent study has isolated SSEA-4 expressing cell population from WJ that was also positive for CD90, CD105, CD70, Nanog, and Sox2 (Li et al. 2017). These cells could spontaneously differentiate cells of all three germ layers in vitro. Moreover, they were able to undergo adipogenic and osteogenic differentiation much easier than SSEA4- cells. Maddox and colleagues have reported the presence of stromal cells expressing SSEA-4 in the breast and abdominal adipose tissue and showed the higher potential of osteogenic and adipogenic differentiation potential (Maddox et al. 2012). It is pertinent to mention that breast adipose tissue contained only 0.48% SSEA-4 positive cells sub-population against the 12% propensity of their counterparts in abdominal fat tissue. It is also expressed by some of the cancer cells identifying their malignant character and resistance to chemotherapy (Aloia et al. 2015; Nakamura et al. 2019). Given its association with disease progression in cancers, SSEA-4 expression results in the loosening of the cell-to-cell interaction, loss of epithelial phenotype, and adoption of the mesenchymal phenotype. These cellular and molecular changes are important for the cells to attain migratory capacity, thus contributing to their metastasis (Sivasubramaniyan et al. 2015).

CD146

CD146, also known as Mel-CAM, MUC18, A32 antigen, is a 113 kDa melanoma cell adhesion molecule (CAM) (Wang and Yan 2013). This is primarily expressed at the intercellular junction of endothelial cells. A more recently published study has reported that CD146 is more than merely an adhesion molecule to serve as a receptor for various signaling molecules, thus participating in diverse physiological and pathological processes encompassing angiogenesis to lymphogenesis (Wang et al. 2020c). The soluble form of CD146 derived from endothelial cells is being considered a reliable marker of neuroinflammatory disease (Wang et al. 2020a). Moreover, it mediates FAK activation to help melanoma cells to traverse vessel walls during metastasis in response to VEGF signaling (Jouve et al. 2015). Harkness et al. (2016) published a study showing that CD146 defines a subpopulation of human MSCs capable of bone formation and in vivo trans-endothelial migration. They also

showed that the CD146 sub-population of the BM cells was ideal for use in clinical protocols of bone tissue regeneration (Harkness et al. 2016). The expression of CD146 was found in human MSCs and other sources of MSCs such as adipose tissue, placenta, or dermis, among others (Lv et al. 2014). CD146 expression on MSCs has been attributed to their better therapeutic potential than the cells lacking in CD146 expression (Wu et al. 2016). It is also considered a surrogate marker for MSCs cultured in vitro to predict their differentiation potential. MSCs in the confluent cultures downregulate CD146 expression with concomitant decrease in differentiation potential. Therefore, a moderate rate of medium addition during MSCs culture may ensure their confluence good enough to maintain their differentiation capacity (Jones et al. 2018).

MSCs in the Clinical Perspective

Given their remarkable reparability, immunomodulatory, and anti-inflammatory properties generally attributed to their paracrine behavior and differentiation potential, MSCs have entered into advanced phases of clinical trials for the treatment of various diseases. As discussed earlier, their near ideal characteristics, as discussed in the previous sections, make them best candidates for cell-based therapy. Currently, they are part of numerous clinical trials worldwide that use MSCs to treat various pathologies some of which will be discussed in the following sections of the chapter (Table 1).

MSCs-Based Therapy for Cardiovascular Pathologies

Since the pioneering work of Hamano et al. in a group of five patients in 2001 that the BM cell transplantation for myocardial repair is safe (Hamano et al. 2001), they have been extensively studied in both the small and large experimental animal models of myocardial infarction and heart failure for the repair and regeneration of the injured myocardium (Haider et al. 2008a; Kim et al. 2012; Van der Spoel et al. 2015; Cai et al. 2016). There is mounting evidence in the literature that transplantation of MSCs (both native, genetically modified, and physiologically or pharmacologically preconditioned) in the experimentally injured heart results in decreased infarction size, reduced area of fibrosis, attenuated remodeling, and preserved global heart function (Haider et al. 2008a, b, 2010, 2012; Afzal et al. 2010; Lai et al. 2012; Kim et al. 2012; Haider and Aziz 2017). MSCs have also combined with other cell types to enhance their survival and differentiation potential (Hosseini et al. 2018). BM-derive MSCs have also been reprogrammed to achieve pluripotency status and their derived cells have been successfully using for myocardial repair in experimental animal models (Buccini et al. 2012). These therapeutic benefits have been attributed to a multifactorial mechanism wherein cardiogenesis and vasculogenesis due to cardiac differentiation and paracrine activity of the transplanted cells. Based

Table 1 Summary of the studies involving MSCs from different tissue sources for various disease conditions

Disease	MSCs source	Results	References
Acute graft-versus-host disease	BM-MSC	BM-MSCs was considered second-line treatment for GvHD	Le Blanc et al. 2004, 2008
Inflammatory bowel disease: Perianal Crohn's disease	ASC	Results phase III clinical trial, improved results as compared with placebo, after 1 year of follow-up	Panés et al. 2018
Crohn's Disease	UC-MSC	UC-MSCs were effective in the treatment of Crohn's Disease and produced mild side effects	Zhang et al. 2018
Ulcerative colitis	BM-MSC	Studied the efficacy and safety of BM-MSCs for patients with ulcerative colitis. Two-year follow-up showed immunomodulatory effects and reduction in inflammation and decreased risk of recurrence	Lazebnik et al. 2010
Knee osteoarthritis	ASC	Evaluated the efficacy of autologous ASCs therapy on pain, function, and disease modification in knee osteoarthritis. Results showed that the therapy was safe and effective	Freitag et al. 2019
Knee osteoarthritis	ASC	Satisfactory functional improvement and pain relief for patients that received this ASCs treatment	Lee et al. 2019
Knee osteoarthritis	BM-MSC	Compared the results of MSC with hyaluronic acid, after a year better results were observed with MSCs	Kim et al. 2020
Multiple Sclerosis	BM-MSC	Observed that transplantation of BM-MSCs in patients with multiple sclerosis is a clinically feasible and relatively safe procedure and induces immediate immunomodulatory effect	Karussis et al. 2010
Multiple Sclerosis	BM-MSC	The administration of the cells was intrathecal and the results in some of the patients were encouraging enough for Phase II	Harris et al. 2018
Rheumatoid arthritis	BM-MSC	Suitable safety profile of autologous MSCs therapy in rheumatoid arthritis patients with promising trend for clinical efficacy	Ra et al. 2011
Rheumatoid arthritis	ASC	Observed that the intravenous dose of ASCs in patients was well-tolerated, recommended it appropriate to carry out one more phase of this clinical trial	Álvaro-Gracia et al. 2017
Rheumatoid arthritis	UC-MSC	Authors indicated that the intravenous infusion of was safe	Park et al. 2018

(continued)

Table 1 (continued)

Disease	MSCs source	Results	References
Heart failure	BM-MSC	Intramyocardial injection of autologous MSCs into akinetic non-revascularized segments produced comprehensive regional functional restitution, which in turn improved global LV function	Karantalis et al. 2014
Heart failure	BM-MSC	Successfully reported the safety and feasibility of allogenic MSCs in patients with dilated cardiomyopathy	Hare et al. 2017
Heart failure	BM-MSC	The intracoronary infusion of human BM-derived MSCs at 1 month was tolerable and safe with modest improvement in LVE	Lee et al. 2014
Heart failure	BM-MSC	Intracoronary BMC therapy improved ventricular performance, quality of life, and survival in patients with heart failure	
Heart failure	UC-MSC	Assessed the safety and efficacy in patients with chronic stable heart failure and reduced LV-ejection fraction	Bartolucci et al. 2017
Heart failure	ASC	ASC treatment was safe but did not improve exercise capacity compared to placebo	

on these data, and encouraged by the favorable data in Phase-I and Phase-II trials (Karantalis et al. 2014; **PROMETHEUS trial** (**P**rospective **R**andomized Study **O**f **M**esenchymal Stem Cell **The**rapy in Patients **U**ndergoing Cardiac **S**urgery; Clinical trial identifier: NCT00587990), MSCs-based studies have currently advanced to multiple Phase III clinical trials worldwide, that is, **RELIEF trials** (Clinical trials identifier: NCT01652209; **R**andomized, Open lab**E**led, mu**L**ticenter Trial for Safety and Efficacy of Intracoronary Adult Human MSCs AMI).

Allogenic MSCs have also been assessed to overcome the problem of autologous cells from the aging and diseased donors. A phase I/II pilot clinical study **POSEIDON** (Percutaneous Stem Cell Injection Delivery Effects on Neomyogenesis; Clinical trials Identifier: NCT01087996) was performed to ascertain a dose-range comparison between autologous and allogenic BM-derived MSCs in 31 randomized patients (1:1) between the two cell type treatment with escalating doses (Hare et al. 2012). Other research groups have also reported similar clinical trials to ascertain the use of allogeneic MSCs (Perin et al. 2015; Jansen of Lorkeers et al. 2015). Hare et al. have successfully reported the safety and feasibility of allogenic MSCs in patients with dilated cardiomyopathy (Hare et al. 2017).

Some of the other trials using TENDO I/M delivery of MSCs include **ESTIMATION trial** (Clinical trial identifier: NCT01394432); **CEP-41750** (Clinical trial Identifier: NCT02032004; Allogeneic Mesenchymal Precursor Cells) for the Treatment of Chronic Heart Failure; **CHART-1 trials** (Clinical trial identifier: NCT01768702); and **CHART-2 trial** (Clinical trial identifier: NCT02317458).

A randomized, open-label, multicenter, Phase-II/III **SEED-MSC** (Clinical trial identifier: NCT01392105) pilot trial assessed the safety and efficacy of BM-derived MSCs (Lee et al. 2014). The cells were delivered by I/C infusion at 1 month after successful revascularization of the infarct-related artery in 58 acute myocardial infarction (AMI) patients.

Similarly, Dr. Timothy Henry is leading another Phase-II clinical study **AMICI** to assess the safety of **A**llogeneic **M**esenchymal Precursor Cell **I**nfusion in Myo**C**ardial **I**nfarction (Clinical trial identifier: NCT01781390). The research involves 105 AMI patients and is expected to complete and release its findings very soon. Some other on-going Phase-II/III clinical trials including **RELIEF** (Clinical trial identifier: NCT0165209), **CIRCULATE** (Clinical trials identifier: NCT03404063), **SEED-MSCs** (Clinical trial identifier: NCT01392105; Safety and Efficacy of Intracoronary Adult Human Mesenchymal Stem Cells After Acute Myocardial Infarction), etc. have also opted for I/C delivery of MSCs in patients with AMI.

I/C route of cell delivery has also been used for myocardial cell therapy using cells other than BM-derived MSCs, that is, CSCs (**CAREMI trial**; Clinical trial identifier: NCT02439398), BM-derived CD133+ (**COMPARE-AMI**; ACTRN12609001045202), and BM-derived AC133+ cells (**STAR**; **S**tem cell **T**ransplantation in patients with chronic he**ARt failure**) which is incidentally one of the most extensive clinical trials using I/C route for BM cell delivery. Interesting use of the I/C route has been the delivery of CDCs in children with hypoplastic left heart syndrome (HLHS) after staged surgery (Clinical trial identifier: NCT01273857).

More recently, Bartolucci and colleagues assessed the safety and efficacy of the UC-MSCs in 15 patients with chronic stable heart failure and reduced LV-ejection fraction and compared them with placebo treated patients (Bartolucci et al. 2017). They reported that intravenous infusion of 1 × 106 cells/kg UC-MSCs was safe. Moreover, they also observed significant improvement in LV-function, and quality of life in patients treated with UC-MSCs during 3, 6, and 12 months of follow-up.

Other than BM, MSCs-derived from other human tissues have been used to assess their efficacy in the patients which include ASC (Clinical trial Identifier: NCT01449032; MesenchYmal STROMAL CELL Therapy in Patients With Chronic Myocardial Ischemia; **MyStromalCell Trial**), and UC-MSCs (Clinical trial Identifier: NCT01739777; **RIMECARD Trial** (Randomized Clinical Trial of Intravenous Infusion UC Mesenchymal Stem Cells on Cardiopathy).

MSCs-Based Therapy for Acute Graft-Versus-Host Disease

Graft-versus-host disease (GvHD) is a severe and sometimes life-threatening complication due to interaction between donor-derived immunocompetent T cells and recipient tissue antigens. Acute GvHD reaction severity is graded from I (mild) to IV (very severe) after allogenic HSCs transplantation that maybe even fatal in some cases (Moreno and Cid 2019; Nassereddine et al. 2017). Although GvHD offers diverse therapeutic targets during its progression, the use of MSCs with

immunomodulatory has been extensively studied as a potential therapeutic option. In 2004, substantial research in *The Lancet* was published, which provided a leap forward in the treatment of GvHD using BM-MSCs (Le Blanc et al. 2004). The study successfully exploited the immunomodulatory properties of haploidentical BM MSCs in patients with treatment-resistant grade IV acute GvHD. Since the publication of these data, Le Blanc and colleagues besides many other research groups have been part of various clinical trials which have advanced to Phase III trials, and in some countries, MSCs-based intervention has achieved a status of second-line treatment for GvHD (Le Blanc et al. 2008; Martin et al. 2010; Galipeau 2013; Wu et al. 2013; Szabolcs et al. 2010). These data provide evidence that the use of BM-MSCs for the treatment of GvHD is safe and feasible (Cheung et al. 2020).

On the contrary, the authors of a recently published systematic review based on 12 studies and 13 on-going clinical trials have concluded that the published literature well supports the safety of MSCs-based treatment for GvHD. Still, it could only provide low-quality evidence that MSCs reduce the risk of chronic GvHD (Fisher et al. 2019). The systematic review results also suggested future studies to optimize the therapeutic intervention's protocol. The systematic review findings can also be interpreted that the outcome of the studies and clinical trials is influenced by various factors (Wang et al. 2017). For example, it is now generally perceived that not all MSCs' preparations are equally effective, necessitating the optimization of MSCs isolation and purification protocols, besides optimizing the dose and injection route (Elgaz et al. 2019). The pro-inflammatory immune profile in the gut of the recipient at the time of MSCs treatment is one of the primary determinants of the therapeutic outcome (Gavin et al. 2019).

MSCs-Based Therapy for Crohn's Disease

Inflammatory bowel disease (IBD) includes two chronic inflammatory idiopathies: ulcerative colitis and Crohn's disease that severely affect the quality of life. Crohn's disease is characterized by the presence of perianal fistulas, treatment of which remains a challenge for therapy with the contemporary therapeutic options. The merging of cell-based therapies using MSCs has reasonable success thus far in the clinical trials to treat IBD via systemic and local delivery (perianal Crohn's disease) (Adak et al. 2017). Lazebnik et al. (2010) studied the safety and feasibility of BM-MSCs in patients with ulcerative colitis (Lazebnik et al. 2010). A 2-year follow-up of the patients revealed the significant immunomodulatory potential of MSCs, leading to a reduction in inflammation and a decrease in the risk of recurrence. These data were substantiated by a recently published meta-analysis that supported the use of MSCs for treating ulcerative colitis (Shi et al. 2019). Similarly, a previously published meta-analysis by Dave et al. had suggested a promising role for MSCs in cell-based therapy in IBD patients despite many challenges in their routine clinical use (Dave et al. 2015).

Searching Clinicaltrials.org, 62 clinical trials for Crohn's disease have either been completed or in progress using cell-based therapy, mostly using MSCs (https://clinicaltrials.gov/ct2/results?cond=Crohn+Disease&term=stem+cells&cntry).

Panés et al. (2018) have proposed the allogeneic ASCs to treat complex perianal fistulas in patients with Crohn's Disease (Panés et al. 2018). The authors published a double-blind phase III clinical trial reporting encouraging data compared to the placebo-treated patients during the 1-year follow-up. They concluded that ASCs provided a safe and effective option in closing fistulas. Although its etiology is unclear, most researchers believe that Crohn's disease is associated with autoimmune response. Considering this hypothesis, Zhang et al. proposed UC-MSCs to treat this disease in 82 patients with confirmed Crohn's disease (Zhang et al. 2018). During a randomized controlled clinical trial, the patients received a weekly dose of 1×10^6 cells/kg for 4 weeks. During the 12-month follow-up, they observed UC-MSCs were effective in reducing Crohn's disease index, Harvey-Bradshaw index, and steroid therapy. Only four patients showed mild signs of the ill-effects relevant to the treatment.

Although the use of MSCs has progressed to Phase-III clinical trials, the underlying mechanism remains elusive. A recent study in an experimental mice model of dextran sulfate sodium (DSS)-induced colitis has revealed that ASCs induce an innate immune memory response in the MSCs-treated animals (Lopez-Santalla et al. 2020b). Cell therapy-treated animals, which received MSCs during the acute phase after DDS treatment, showed sustained protection against inflammation when re-challenged after 12 weeks. The authors concluded that MSCs treatment incurs long-term benefits as they change the regulatory to inflammatory macrophage ratio in *lamina propria* of the colon. Future studies are warranted to have a head-to-head comparison of the safety and effectiveness of MSCs from different tissue sources, although their use in individual studies has generated encouraging data.

MSCs-Based Therapy for Multiple Sclerosis

Multiple sclerosis is an autoimmune disease involving the appearance of focal inflammatory lesions in the substance white matter of the brain characterized by demyelination of the nerve fibers. Karussis et al. 2010 observed that transplantation of BM-derived MSCs in patients with multiple sclerosis is a clinically feasible and relatively safe procedure and induces immediate immunomodulatory effects (Karussis et al. 2010). MSCs also release biologically active secretome due to their paracrine activity that adds to the therapeutic benefits (Gugliandolo et al. 2020). On the same note, MSCs from tissue sources other than BM have also shown encouraging results (Giacoppo et al. 2017; Riordan et al. 2018). These results have been corroborated among many research groups as reviewed by Lotfy et al. (2020).

In 2018, a study was published showing the results from a Phase I clinical trial (ClinicalTrials ID: NCT01933802) that used MSCs-derived neural progenitor cells to treat multiple sclerosis (Harris et al. 2018). The cells' administration was via intrathecal injection, and the results in some of the patients were encouraging enough to propose the execution of Phase II. The safety and efficacy of autologous MSCs to treat multiple sclerosis were further assessed in a Phase I/II clinical study

MEsenchymal StEm cells for Multiple Sclerosis (MESEMS) (Uccelli et al. 2019). MESEMS study has been designed to merge partially independent clinical trials, following harmonized protocols and sharing some critical centralized procedures, including data collection and analyses. With this model, where various clinical trials are grouped, the authors suggest that the results will provide patients and the scientific community with data on the safety and efficacy of MSC for multiple sclerosis. Although not assessed against all forms of multiple sclerosis, treatment with MSCs is a future hope for the patients.

MSCs-Based Therapy for Rheumatoid Arthritis and Osteoarthritis

Encouraged by the experimental animal data that revealed the safety and effectiveness of cell-based therapy for rheumatoid arthritis, the cell-based therapy approach has progressed to the clinical phase of assessment. A direct comparison of MSCs from various sources, including BM, UC, and human deciduous tooth revealed superior outcomes from UC-derived MSCs (Zhang et al. 2019). A recently published meta-analysis of the preclinical studies has demonstrated consistent therapeutic benefits of cell-based therapy in the experimental animal models (Liu et al. 2019b). Although the mechanism of action and beneficial therapeutic outcome is considered multifactorial, it has been reported that the transplanted MSCs control the memory T-cell response (Noymar et al. 2019).

The first pilot clinical study with MSCs therapy autoimmune disorders including rheumatoid arthritis was conducted in 2010 by the Stem Cell Research Centre in Korea. The results were published in almost a decade later (Ra et al. 2011). This study involved the use of ASC. It was considered the first proof-of-concept clinical study that has reported a suitable safety profile of autologous MSCs therapy in 10 patients with various autoimmune disorders, including rheumatoid arthritis patients with promising clinical outcomes' efficacy. Tested in Balb/c nude mice for tumorigenicity even at larger doses, the cell therapy was safe in the patients. Among several studies published in this line, Álvaro-Gracia et al. evaluated the safety and tolerability of the intravenous administration of allogenic ASC in patients with refractory rheumatoid arthritis as a part of Phase Ib/IIb trials including 53 patients (Álvaro-Gracia et al. 2017). They observed that the intravenous dose of adipose tissue-derived stem cells in these patients was well-tolerated. These results agree with the data published by Park et al. (2018), who reported a phase I, uncontrolled, open clinical trial to treat patients with moderate intensity rheumatoid arthritis using UC- MSCs (Park et al. 2018). The authors noted that the intravenous infusion of UC-derived MSCs showed a similar safety profile to BM-derived MSCs. Lopez-Santalla et al. have recently published a comprehensive review of literature documenting both active and closed clinical trials that have focused on using MSCs in rheumatoid arthritis (Lopez-Santalla et al. 2020a). The authors have concluded that a toxicity-free and adverse effects-free use of MSCs in rheumatoid arthritis patients during all the reported clinical trials conducted. However, insufficient data on efficacy have been obtained from the completed clinical trials, most

likely because a large majority of the rheumatoid arthritis patients enrolled in the studies were refractory to conventional rheumatoid arthritis treatments with a long history of the disease.

It is pertinent to mention that only a few examples of the clinical trials published until today wherein a regeneration of the tissue is necessary to treat autoimmune disorders (Lopez-Santalla et al. 2020a). Moreover, there are still concerns about the use of cells from the autologous tissue sources. For example, it has been reported that autologous MSCs obtained from patients with rheumatoid arthritis were functionally impaired, as was observed by their failure to inhibit Th17 (Sun et al. 2015). These data are significant in optimizing the protocols for future cell therapy clinical trials to harness maximum therapeutic benefits from MSCs-based treatment.

Knee osteoarthritis is one of the most commonly diagnosed forms of arthritis, especially in elderly patients after age 65. The underlying cause is the slow but progressive degeneration of the cartilage that protects the knee joint due to physiological aging. Freitag et al. evaluate the efficacy of ASC-based therapy on pain, function, and disease modification in knee osteoarthritis (Freitag et al. 2019). Upon completing the clinical trial, the authors concluded that the therapy was a safe and effective therapy for knee osteoarthritis. These results were substantiated by Lee et al., who used an intra-articular injection of autologous ASC to treat knee osteoarthritis (Lee et al. 2019). They described satisfactory functional improvement and pain relief for patients that received cell therapy. Given that intra-articular injection of hyaluronic acid is a medical option for knee osteoarthritis, Kim et al. (2020) conducted a comparative study between the MSCs and hyaluronic acid-based treatment (Kim et al. 2020). They observed that the MSCs group showed better results during 1-year post-treatment follow-up than the hyaluronic acid group.

Exosomes-Based Therapeutic Intervention

Despite encouraging data emanating from the clinical studies using the cell-based therapy approach, the underlying mechanism of the therapeutic benefits is only partly understood. In addition to undergoing fusion with the host cells and differentiation to adopt morphofunctional phenotype post engraftment to participate in the regeneration process, the paracrine hypothesis has gained wide-spread acceptance amongst the researchers in the field (Haider and Aziz 2017). These proposed mechanisms are correct and supported by substantial data; however, they are not exclusive (Álvarez-Viejo 2020). It is widely accepted that MSCs produce a plethora of bioactive molecules, including cytokines, growth factors, and extracellular vesicles (EVs) containing specific payload (Altanerova et al. 2017). Almost every cell type, including MSCs, releases exosomes as part of intercellular signaling, and given their specific payload, they could serve as a novel cell-free therapeutic tool in the field of regenerative medicine (Haider and Aramini 2020; Nikfarjam et al. 2020). However, there is little headway made in exosomal use in the clinical perspective as is evident from the literature search which did not fetch any records of clinical trials

at least for the diseases included in our chapter. This limited progress of exosomes from bench to the clinic is attributed to the challenges faced in this regard (Forsberg et al. 2020).

MSCs-Derived Exosome for Therapy "Without Cells"

The term EVs includes microvesicles, nanoparticles, vesicles, apoptotic bodies, and exosomes (Pinheiro et al. 2018). The difference between these terms is the size of the vesicles released. Due to the size-heterogeneity between these particles, it was imperative to develop guidelines for their definition. In this regard, The International Society for Extracellular Vesicles proposed the minimum criteria to characterize extracellular vesicles, which requires *EVs as the generic term for particles naturally released from the cell that is determined by a lipid bilayer and cannot replicate,* i.e*., do not contains a functional nucleus* (Théry et al. 2018). The size of exosomes is 60–100 nm with a diverse protein composition between cells, but they share some proteins, such as CD9, CD63, or CD81, for use as exosome markers (Yamashita et al. 2018). Similar to exosomes derived from other cell types, MSCs-derived exosomes participate in intercellular communication and carry proteins, mRNA, and microRNA (miRNA) for delivery to the target cells to facilitate intercellular signaling (Mendt et al. 2019).

The use of exosomes offers several advantages, such as the aversion of introducing exogenous cells, thus avoidance to bring in mutated or damaged genetic material that could harmfully affect the recipient. They are low in immunogenicity (Elahi et al. 2019), but given their inability to divide or replicate, they are static, thus restricting their therapeutic benefits for time duration until they get eliminated from the biological system post-delivery (Phinney and Pittenger 2017). Currently, there are nearly a hundred clinical trials registered in *Clinicaltrial.gov* fetched by the term exosomes. On the same note, there are nearly a thousand trials that include MSCs. The novelty of exosome-based "cell-free" therapy, however, still require optimization of GMP grade exosome production protocols (Chen et al. 2019), their standard markers, ideal donor cells, standardization of their payload, indicated dose, route of administration, etc., and sufficient preclinical data to support their routine clinical use.

MSCs-Derived Exosomes and Acute Graft-Versus-Host Disease

Given the paracrine hypothesis's wide-spread acceptance that the therapeutic benefits of MSC-based cell therapy are mediated via paracrine release of immunosuppressive and immunomodulating factors, cell-free therapy using MSCs-derived exosomes is now fast-emerging as a treatment option for refractory GvHD in an increasingly standardized way (Zhou et al. 2020). Several preclinical studies have reported that MSCs-derived exosomes could be as effective as MSCs-based cell therapy. For example, using a mice model of acute GvHD (aGvHD), Fujii et al. have

shown that systemic infusion of BM MSCs-derived exosomes prolonged the survival of mice with aGvHD, besides alleviating pathologic damage to aGvHD targeted organs via suppression of CD4+ and CD8+ cells (Fujii et al. 2018). The authors attributed the therapeutic benefits of exosomal treatment to the unique miRNA profile of the MSC-derived exosome preparation used for treatment. Similarly, Wang et al. reported that human UC-MSCs derived exosomes could prevent aGvHD in a mouse model after allogeneic HSCs transplantation (Wang et al. 2016). The authors noted that EVs derived from UC-MSC could prevent life-threatening a GvHD by modulating the immune response. Moreover, they could represent a prophylactic method to prevent aGvHD as well. On the other hand, working with a chronic mouse model of GvHD, Lai et al. studied the efficacy and safety of MSCs-derived exosomes to treat this disease. They suggested that MSCs-derived exosomes could improve survival and ameliorate the pathologic damage of chronic GvHD (Lai et al. 2018). A recently published meta-analysis of four studies involving the use of MSCs-derived exosomes for the treatment and prevention (two studies each) of GvHD showed that exosomes were an effective treatment tool as well as for prophylactic application (Gupta et al. 2020). The authors concluded that the use of MSCs-derived exosomes successfully enhanced survival and attenuated histologic findings of GvHD in all four studies.

Supported by the preclinical data, the cell-free therapy approach has progressed to clinical assessment of MSC-derived exosome to treat the GvHD patients but only very cautiously. There is only one Phase I clinical study registered at ClinicalTrials.gov entitle "Effect of UM-MSCs-derived exosomes on dry eyes in patients with GvHD" (Clinicaltrials.gov Identifier: NTC04213248). The study will enroll 27 patients who will receive UC-MSCs derived exodrops (UM-exo). However, the study results are still awaited. Also, we have only found a letter to the Editor in which their use to treat graft GvHD is described. In one patient, Kordelas et al. used an exosome-enriched fraction processed from collected MSCs supernatants instead of administering the MSCs themselves (Kordelas et al. 2014). The patient was stable for several months of post-exosome application. Although the patient died of pneumonia 7 months after treatment, the authors concluded that BM MSC exosomes could be a potentially new and safe tool to treat therapy-refractory GvHD, and most likely other inflammation-associated diseases. Despite encouraging data, there is slow progress for the use of MSCs-derived exosomes for clinical applications, which may be due to the technical and methodological hindrances involved therein.

MSCs-Derived Exosomes for Inflammatory Bowel Disease

The role of MSCs-derived exosomes for the treatment of IBD in general and Crohn's disease, in particular, has been extensively studied in the experimental animal models (Ocansey et al. 2020). Mao et al. investigated the effects of exosomes derived from UC-MSCs in a model of induced inflammatory bowel disease (Mao et al. 2017). According to their findings, UC-MSCs exosomes could substantially alleviate experimentally induced inflammatory bowel disease in a mice model.

While elucidating the underlying mechanism, IL-10 expression was elevated while pro-inflammatory TNFa, IL-1b, IL-6, IL-7, and iNOS were significantly downregulated in the colonic tissue and spleen of exosome-treated animals. Besides, ubiquitination played a significant role in UC-MSCs derived-exosome treated experimental animals (Wu et al. 2018b). The exosome-treated animals were able to better recover tissue structural integrity. These results agree with those published by Liu et al., who demonstrated that systemic administration of exosomes from human BM-MSCs substantially mitigated colitis in various models of inflammatory bowel disease (Liu et al. 2019a). Mechanistically speaking, the colonic macrophages were pivotal in alleviating the disease process as was observed by abrogation of the beneficial effects of exosome treatment by macrophage depletion. They also agreed with Yang et al., who investigated the potential alleviating effects of BM-MSCs EVs in the colitis model (Yang et al. 2015). The authors concluded that the beneficial effects of exosomes from the BM-MSCs were due to the downregulation of the pro-inflammatory cytokines, inhibition of NF-κBp65 signal transduction pathways, modulation of antioxidant/oxidant balance, and moderation of the occurrence of apoptosis, as the possible underlying mechanism. Despite finding several papers published in the preclinical phase, there are no clinical trials registered in clinicaltrials.gov, although their diagnostic use has been attempted (Larabi et al. 2020). The possible explanation for the lack of exosome-based clinical data is the unavailability of standardized protocols for isolation, large-scale reproducible exosome preparations to their protocols for optimum clinical use (Harrell et al. 2020).

MSCs-Derived Exosomes for Rheumatoid Arthritis and Knee Osteoarthritis

Continuing the success story of MSCs-based cell therapy for rheumatoid arthritis and knee arthritis, Chen et al. investigated the therapeutic effects of MSCs-derived exosomes on joint destruction in rheumatoid arthritis (Chen et al. 2018). After treatment with experimentally induced arthritis in the mice model, the authors showed the safety and feasibility of exosome derived from MSC overexpressing miRNA-150. The authors observed a reduction in joint destruction with concomitant inhibition of synoviocyte hyperplasia and angiogenesis. From the analysis of the results, they conclude exosomes facilitate the direct intracellular transfer of miRNAs between cells. Given the pivotal role of miRNAs and their regulatory network in the pathogenesis of rheumatoid arthritis (Zakeri et al. 2019), many other research groups have adopted a similar approach for their use as biomarkers as well as therapeutic targets (Huang et al. 2019). The recently published study by Zheng et al. substantiates these data (Zheng et al. 2020). They also proposed that exosomes derived from BM-MSCs, and more specifically, BM-MSCs secreted exosomal miR-192-5p could delay the inflammatory response events in rheumatoid arthritis. Meng et al. have used exosomes derived from miRNA-320a-loaded MSCs to regulate fibroblasts-like synoviocytes activity by interacting with CXCl9, which are mechanistically involved in rheumatoid arthritis pathology (Meng and Qiu 2020). Cosenza et al. compared the

anti-inflammatory and immunosuppressive properties of MSCs-derived exosomes and microparticles in a mice model of collagen-induced rheumatoid arthritis (Cosenza et al. 2018). The authors observed that both exosomes and microparticles were equally effective in suppressing the inflammatory response, but exosomes were more efficient in anti-inflammatory activity in vivo.

The role of MSCs-derived exosomes and their mechanism remains an area of intense investigation wherein most researchers have used them for both diagnostic and therapeutic purpose, as summarized by Ni et al. and Mianehsaz et al. in their recently published literature reviews (Ni et al. 2020; Mianehsaz et al. 2019). Tofiño-Vian et al. investigated chondroprotective action of exosomes from adipose tissue-derived MSCs from healthy volunteers in vitro using chondrocytes from arthritic patients (Tofiño-Vian et al. 2018). Treatment with exosomes significantly reduced MMP activity and MMP13 expression besides upregulation of anti-inflammatory IL10 in the treated chondrocytes. Their results support the interest of MSCs-derived EVs to develop new therapeutic approaches in arthritic joint conditions. These in vitro results were reinforced by He and colleagues, who investigated the effect of exosome derived from BM-MSCs on damaged cartilage repair and pain in an experimental animal model of osteoarthritis (He et al. 2020). They used a rat model of osteoarthritis established by injection of sodium iodoacetate. After analyzing these results, the authors concluded that exosomes successfully promoted cartilage repair and extracellular matrix synthesis, as well as relieve knee pain in rats with osteoarthritis. A recently published systematic review analyzing 20 published in vivo and in vitro studies revealed positive findings in reduced inflammation, downregulation of catabolic processes, and increased anabolic studies D'Arrigo et al. 2019). However, for optimal benefits of this approach, it is essential that exosome production protocols and identification of patients who could benefit from this novel approach must be identified.

As with most of the diseases discussed in this chapter, rheumatoid arthritis and knee arthritis treatment with exosomes have not yet progressed to the clinical trials.

MSCs-Derived Exosomes for the Heart

Exosomes from various stem cells, that is, ESCs, iPSCs and their derivative progenitors and cardiomyocytes (Khan et al. 2015; Arslan et al. 2013; Kervadec et al. 2016; El Harane et al. 2018), cardiosphere-derived progenitors (Xiao et al. 2016), and MSCs-derived exosomes (Zhang et al. 2016), have been studied for their reparability of the injured myocardium. Exosomes derived from MSCs have also been used to precondition other cells to enhance their survival post-engraftment and promote angiogenesis and reduce cardiac fibrosis in the experimentally induced cardiac fibrosis with concomitantly improved cardiac function (Zhang et al. 2016). Lai et al. (2010) used purified exosomes from MSCs to treat a mouse model of ischemia-reperfusion injury (Lai et al. 2010). The authors reported a successful reduction in infarct size. These data also strengthened the paracrine hypothesis according to which the cardioprotective effects of stem cell-based therapy were

related to paracrine secretions of stem cells that also included exosomes (Haider and Aziz 2017). These conclusions were later supported by Wang et al., who tested EVs secreted by BM-MSC secreted EVs for their pro-angiogenic activity in the infarcted heart (Wang et al. 2017). They concluded that exosome-derived MSCs are sufficient to improve angiogenesis and exerted therapeutic benefits in the experimental myocardial infarction model. Study of the mechanisms involved in exosome-mediated cytoprotection showed AMPK/Akt signaling in the H2C9 cells treated with MSCs-derived exosomes after subjecting the cells to oxidative stress. On the same note, treatment with UC-MSCs-derived exosome was protective for cardiomyocytes in the infarcted myocardium by transferring miR-19a, targeting SOX6, activating Akt, and inhibiting JNK3/caspase-3 activation (Huang et al. 2020). The exosomal payload's role of miRNAs has been eloquently reviewed for their role in myocardial repair Haider and Aramini (2020). Despite extensive studies in the small animal model and encouraging data from large animal models with clinical relevance, there are still no studies registered for their clinical use (Gallet et al. 2017; de Couto et al. 2017).

Multiple Sclerosis

Given the immunomodulatory role of MSCs, their exosomes are being assessed extensively in experimental animal models of multiple sclerosis to impede autoimmune diseases' progression (Baharlooi et al. 2020). Employing an experimental rat model of autoimmune encephalomyelitis, Li and colleagues investigated the effect of exosomes derived from BM-MSCs on microglia polarization and inflammation in the central nervous system (Li et al. 2019). They observed that exosome treatment significantly decreased neural behavioral scores, reduced the infiltration of inflammatory cells into the central nervous system, and reduced demyelination compared to untreated experimental model rats. At molecular levels, there was a significant increase in M2-related and TGF-b IL-10, whereas M1-related TNF-a and IL-12 decreased significantly in exosome treatment. Based on these data, they proposed that therapy using exosomes derived from BM-MSCs could be an interesting alternative for treating multiple sclerosis. On the same note, experiments are underway to exploit exosomes' ability to cross the blood–brain barrier using aptamer bio-conjugated exosomes to enhance oligodendroglia cell line in vitro and reduce demyelinated lesions in the brain of experimental mice model (Hosseini et al. 2019). Intravenous administration of MSCs-exosomes also helped improve recovery in experimental mice with progressive multiple sclerosis (Laso-García et al. 2018). Despite these encouraging data, no clinical trials have been designed to assess their safety and feasibility in human patients as yet.

Conclusion

In conclusion, in this chapter, we have focused only on a few of the diseases treated with MSCs in the clinical studies after extensive characterization in experimental animal models. More recently, the same conditions are being investigated to treat

with exosomes derived from MSCs as part of the emerging cell-free therapy. Despite encouraging data from the experimental animal studies, little progress has been made using exosomes in the clinics. Most of the clinical trials with exosomes are relevant to cancer, that is, Metastatic pancreatic cancer (NCT03608631), Colon cancer (NCT01294072), Malignant ascites and pleural effusion (NCT01854866), Type 1 diabetes, that is, (NCT02138331) and acute ischemic stroke, that is, (NCT03384433).

Abstract

Despite the titanic efforts of health systems worldwide through the implementation of severe public health measures, the number of patients with the current coronavirus disease 2019 (COVID-19) has been dramatically increasing since December 2019. COVID-19 is a real threat that is currently becoming a major concern worldwide. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has a virulent infection leading to a high mortality rate. Although, the emergency use authorization of COVID vaccines has brought hope to mitigate pandemic of COVID-19, there remains a need for additional effective vaccines to deal with SARS-CoV-2, a virus characterized by its unpredictable nature, high morbidity, and rapid ability to spread and to meet the global demand and address the potential new viral variants. Still there is a significantly increased demand for the development of new therapeutic alternatives to palliate the ongoing pandemic. Actually, treating critical COVID-19 patients is challenging as no specific treatment options against SARS-CoV-2 are available. The main pathologic features of critical COVID-19 were consistent with acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). Therefore, regenerative, immunomodulatory, and anti-inflammatory properties of mesenchymal stromal cells (MSCs) can reduce the manifestation of cytokine storm and can restore ARDS and ALI, exhibiting an important option to be applied to critical COVID-19 patients. Here we propose MSCs as a potential alternative therapy for COVID-19 patients and discussed specific aspects of this proposed cell therapy.

Keywords

ARDS · CAR-T cells · Cell therapy · COVID-19 · Cytokine storm · Immunomodulation · Inflammation · Mesenchymal stromal cells · Organoids · SARS-CoV-2 · Stem cells

List of Abbreviations

3D	Three-dimensional
ACE2	Angiotensin-converting enzyme 2
ALI	Acute lung injuries
Ang-1	Angiopoietin-1
ARB	Angiotensin receptor blocker

ARDS	Acute respiratory distress syndrome
AT2s	Type 2 alveolar epithelial cells
CAR-T	Chimeric antigen receptor T cells
CCN1	CCN family number 1
CFTR	Cystic fibrosis transmembrane conductance regulator
CLDN1	Claudin1
COVID-19	Coronavirus disease 2019
CPE	Cytopathologic effect
Cyr61	Cysteine-rich protein 61
DEX	Dexamethasone
ECM	Extracellular matrix
EMMPRIN	Extracellular matrix metalloproteinase inhibitor (or CD147)
FDA	Food and Drug Administration
GFP	Green fluorescent protein
GI	Gastrointestinal
Gsis	γ-Secretase inhibitors
HACE2	Human angiotensin-converting enzyme 2
HCQ	Hydroxychloroquine
HE	Heme agglutinin esterase
HESCs	Human embryonic stem cells
HiPSCs	Human-induced pluripotent stem cells
HPSC	Human pluripotent stem cell
Hrsace2	Human recombinant soluble ACE2
Hs-cTnI	Highly sensitive troponin-I
HSV1	Herpes simplex virus-1
ICU	Intensive care units
IFN	Interferon
$Ifnar1^{-/-}$	C57BL/6 mice with a genetic ablation of their type I interferon receptors
IL-1α	Interleukin-alpha
IL1-β	Interleukin-beta
IL-2	Interleukin-2
$Il28r^{-/-}$	C57BL/6 mice with a genetic ablation of their type III interferon receptors
Il2rg	Interleukin-2 receptor gamma chain
Isgs	Interferon-stimulated genes
KGF	Keratinocyte growth factor
KRT18	Cytokeratin 18
LPS	Lipopolysaccharide
MAS	Macrophage activation syndrome
Mascp6	Mouse-adapted strain at passage 6
MERS	Middle East respiratory syndrome
MODS	Multiple organ dysfunction syndromes
MPA	Mycophenolic acid
MSCs	Mesenchymal stem cells
NPC	Neural progenitor cells

NSCs:	Neural stem cells
NSG mouse	NOD-SCID with null mutation in the gene encoding the il2rgl
PAMPs	Pathogen-associated molecular patterns
PDGFb	Platelet-derived growth factor subunit b
PMN	Polymorphonuclear
QNHC	Quinacrine dihydrochloride
RIG-I	Retinoic acid-inducible gene-I-like
RLU	Relative luciferase units
RM	Regenerative medicine
SARS-cov-2	Severe acute respiratory syndrome coronavirus-2
SFTPC	Surfactant protein-C
SLC10A2	Solute carrier family 10 member 2
SOS	Sinusoidal obstructive syndrome
S-protein	Spike protein
TF	Tissue factor (or CD142)
TMPRSS2	Transmembrane serine protease 2
TNFα	Tumor necrosis factor alpha
WHO	World Health Organization
WT	Wild type

Introduction

Late in December 2019, an outbreak of atypical pneumonia of unknown etiology was described in Wuhan Province in China. A novel coronavirus named "severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)" was then identified as the etiologic agent (Gorbalenya et al. 2020; Wu et al. 2010). Later, the disease was designated **CO**rona **VI**rus **D**isease 2019 (COVID-19) (World Health Organization 2020). The rapid expansion of COVID-19 cases in number and geographic distribution prompted the World Health Organization (WHO) to declare a global health emergency. Containment of the disease was hindered by the lack of antiviral treatment, lack of vaccines, and asymptomatic carriers. On March 11, 2020, COVID-19 was officially classified by the WHO as a pandemic.

The WHO has declared coronavirus disease 2019 (COVID-19) a pandemic due to the rapid increase in infections worldwide. The initial outbreak occurred in Wuhan City of Hubei Province of the People's Republic of China in December 2019 and has since spread to nearly every country and territory globally. As of April 24, 2021, there have been more than 145 million confirmed cases of COVID-19 in the world, including about 3 million deaths, reported to WHO (WHO 2020). However, despite strict worldwide containment strategies and national closures in many countries, prevalence rates continue to increase with significant mortality.

Since COVID-19 affects different people in different ways, most infected people develop mild-to-moderate disease and recover without hospitalization, but a subset of patients progresses to severe illness, with a high mortality rate and limited treatment options. The clinical feature of COVID-19 varies from asymptomatic

forms to conditions involving multiorgan and systemic manifestations in terms of septic shock and multiple organ dysfunction syndromes (MODS). The primary pathologic features of critical COVID-19 were consistent with acute lung injuries (ALI) and acute respiratory distress syndrome (ARDS). The majority of infected persons is usually asymptomatic or has mild symptoms, and about 15% are affected by ARDS, of which 5% progress to multiple organ dysfunction syndromes or failure. From the point of view of prevention, evasive carriers still in the early stage of infection, and that therefore do not show any clinical manifestation of the disease, are the most infectious and the least tractable.

This pathology involves direct attacks by the virus on the cells and secondary attacks on the body after activating the immune system. This means that both the virus and the immune response can cause damage to the body, and common complications or secondary infection can occur. At the cellular level, the spike protein (S-protein) of SARS-CoV-2 interacts with cell receptors to infect target cells. SARS-CoV-2 binds to angiotensin-converting enzyme 2 (ACE2), triggering the endocytosis of virus particles. Consequently, ACE2 receptor would represent a potential therapeutic candidate to study SARS-CoV-2 infection mechanisms. Treating COVID-19 patients is challenging as no specific treatment options against SARS-CoV-2 are available. The current supportive but not curative treatments consist of the use of experimental medication. These include remdesivir, hydroxychloroquine, abidol, lopinavir/ritonavir, plasma from convalescent patients, antibody, and other nonspecific vaccines (Haider and Hyder 2020). Currently, remdesivir appears to be the most promising pharmacological intervention for the treatment of pneumonia caused by COVID-19.

The exact pathogenesis of the virus and the dynamics of the disease are not yet fully understood; therefore, the available treatment options are limited. These consist mainly of supportive therapies for symptomatic treatment. Several antiviral drugs (Grein et al. 2020), corticosteroids (Wang et al. 2020b; Al-Rasheed et al. 2021), convalescent plasma (Shen et al. 2020; Verma et al. 2020), and neutralizing monoclonal antibodies (Shanmugaraj et al. 2020) have been tested and have undergone different phases of clinical trials, but none have been approved explicitly for COVID-19. Another alarming fact is the report from some countries of recurrence of infection in recovered as well as vaccinated individuals, which calls into question the efficacy of available treatments (Lan et al. 2020). In the absence of a recommended treatment, observance of general principle of resorting to take preventive measures, including social distancing, hygienic precautions, and use of face masks, remains the preferred strategy (Hyder and Haider 2020).

Within this scenario, investigations have been conducted at a dizzying speed to achieve a vaccine. The pioneering manufacturer's platforms of vaccines (BioNTech-Pfizer, University of Oxford-AstraZeneca, Moderna, Johnson & Johnson, Sanofi-GlaxoSmithKline, CanSino Biologics, Inovio, Sinovac, Novavax, Gamaleya Research Institute, CureVac, Clover Biopharmaceuticals, Merck & Co.) have been able to ensure their historic and rapid development. According to WHO, as of February 18, 2021, at least seven different vaccines across three platforms have been rolled out in countries. Vulnerable populations in all countries are the highest priority for vaccination. At the same time, more than 200 additional vaccine

candidates are in development, of which more than 60 are in clinical development (García-Montero et al. 2021; Yan et al. 2021a).

The first mass vaccination program was initiated in early December 2020, and as of February 15, 2021, 175.3 million vaccine doses have been administered (Hasan et al. 2021). At least seven different vaccines (three platforms) have been developed and administered as part of the worldwide vaccination program. WHO issued an Emergency Use Listing (EUL) for the Pfizer COVID-19 vaccine (BNT162b2) on December 31, 2020. On February 15, 2021, WHO issued EUL for two versions of the AstraZeneca/Oxford COVID-19 vaccine, manufactured by the Serum Institute of India and SKBio. On March 12, 2021, WHO issued an EUL for the COVID-19 vaccine Ad26.COV2.S, developed by Janssen (Johnson & Johnson). WHO is on track to EUL other vaccine products through June.

Although many biotechnology companies have developed different vaccines and millions of people have been vaccinated to date, the complete process of safety evaluation, manufacturing, and scale-up are still under question, and longer follow-up is needed (Yan et al. 2021b; Kadkhoda 2021). As such, the development of feasible, safe, and effective therapies is extremely urgent. Therefore, increasing experimental and clinical evidence has given credibility to the claim that advanced therapies research could change the future of COVID-19 and the forthcoming emergence of virulent viruses. Notably, cell-based therapies will impact, not yet foreseen, on the present and future sequels of COVID-19. In this regard, mesenchymal stem cells (MSCs) have long been associated with the repairing and rejuvenating damaged tissues due to their broad pharmacological effects, including anti-inflammation, immunomodulation, anti-apoptosis, angiogenesis, and trans-differentiation to specific cell types. They also secrete a myriad of soluble factors and vesicles altogether involved in restoring tissue homeostasis and functionality. The efficacy of MSCs and their secretory factors has been proven in successfully reducing inflammation, dampening immune responses, and repairing lung damage in various preclinical and clinical models (Hmadcha et al. 2009). Therefore, the potential of MSC-based therapy as an option for severe or critically ill COVID-19 patients is being explored in the current scenario (Leng et al. 2020; Sánchez-Guijo et al. 2020) (Table 1).

On the one hand, recent studies focus on regenerative, immunomodulatory, and anti-inflammatory properties of mesenchymal stromal cells (MSCs) to reduce the manifestation of cytokine storm and to restore ARDS and ALI, exhibiting an important option to be applied to critical COVID-19 patients, or on MSCs secretome to treat COVID-19 pneumonia (Tang et al. 2020; Meng et al. 2020; Li et al. 2020b; Liang et al. 2020; Lanzoni et al. 2021). Other research includes the use of hematopoietic stem cells derived from umbilical cord blood, bone marrow, or mobilized peripheral blood, as well as immune chimeric antigen receptor T cell (CAR-T cell). On the other hand, the understanding of the mechanism of infection and pathogenesis are still limited. In this regard, the use of human pluripotent stem cells, both embryonic stem cells (hESCs) and induced stem cells (hiPSCs), to generate tissue-specific human organoids (lung, intestinal, liver, vascular, heart, and kidney

Table 1 Registered clinical trials using MSC-based therapy to COVID-19 (NIH-*ClinicalTrial.gov*)

organoids) may provide a next-generation cellular model for investigating viral infection and drug screening. Altogether, the ultimate goal of all these strategies is to achieve a definitive and efficient therapy for COVID-19.

Mechanism of Infection and Immune Response

Several types of coronavirus are known to have the potential for human infection; only six are known to cause disease in humans: HCoV-229E, HCoV-OC43, HCoV-NL63, HCoV-HKU1, Middle East respiratory syndrome coronavirus (MERS-CoV), and SARS-CoV (Skariyachan et al. 2019; Bonilla-Aldana et al. 2020). The 2019-nCoV, a single-stranded RNA virus, is closely related to SARS-CoV that emerged in 2003–2004 and caused an epidemic disease (Racaniello 2016). The virus was provisionally designated 2019-nCoV and later given the official name SARS-CoV-2 (Gorbalenya et al. 2020). SARS-CoV-2 was characterized as a beta-coronavirus

and recognized as the seventh discrete coronavirus species capable of causing human disease (Zhu et al. 2020a). The virion nucleocapsid consists of an RNA genome complexed with a nucleoprotein and is enveloped by a phospholipid bilayer. This bilayer is covered by two types of spike proteins: protein S, which is present in all known coronaviruses and forms peplomers on the surface, which gives it a corona solar appearance, and protein hemagglutinin esterase (HE), which is present in only a few types of coronaviruses. The spike S protein interacts with the host angiotensin-converting enzyme 2 (ACE2) receptor protein, resulting in membrane fusion with subsequent release of the viral genome into the cell, or clathrin-dependent and clathrin-independent endocytosis of the virus (Li et al. 2020a).

Moreover, the ACE2 receptor is widely expressed by human cells, particularly in the lungs by type 2 alveolar epithelial cells (AT2s) and capillary epithelial cells, and cells of the heart, kidney, and intestine. In addition, two proteases, transmembrane serine protease 2 (TMPRSS2) and extracellular matrix metalloproteinase inhibitor (EMMPRIN or CD147), have been reported to be essential for virus entry into the host cell (Chen et al. 2020). The damage to the lungs is caused by the virus either directly, by the destruction of AT2s and capillary endothelial cells, which disrupts the renin-angiotensin system, or indirectly, by dampening the immune response (Jin et al. 2020). The precise pathogenesis of this particular virus remains unknown. Most of the information on the cycle of infection and subsequent immune response is primarily derived from the SARS and MERS coronaviruses due to the correlation in the clinical features of patients with COVID-19 with these viral infections (Guan et al. 2020; Huang et al. 2020).

Upon infection, the virus is recognized by the innate immune system through pathogen-associated molecular patterns (PAMPs), which in this case is the genomic RNA of the virion. This leads to activation of the NFkB pathway and the IRF3 pathway, which results in the expression of type I interferon (IFN). IFN then activates the JAK/STAT pathway and induces the expression of IFN-stimulated genes (ISGs) that have antiviral activity (Prompetchara et al. 2020).

Successful viral clearance and amelioration of the clinical manifestations of the disease depend on this effective immune response. However, the virus can evade IFN- and ISG-mediated killing and often results in a delayed IFN response. This results in the infiltration of hyper-inflammatory neutrophils and macrophages into the lung site, along with pro-inflammatory cytokines, mainly IL-1b, IL-2, IL-6, IL-7, IL-8, IL-17, G-CSF, GM-CSF, CCL3, MCP1, and TNF (Cao 2020). This so-called cytokine storm is a result of the innate response (neutrophils and macrophages). Moreover, hyperactivation of T lymphocytes (especially the Th1 response) is actually responsible for pulmonary dysfunction and abnormalities such as pneumonitis, ARDS, respiratory failure, viral sepsis, and organ failure. Elevated pro-inflammatory cytokines also induce the synthesis of hyaluronan synthase 2, which produces hyaluronan in the lungs, leading to the characteristic opacity or fluid accumulation in the lungs (Shi et al. 2020).

In critical cases, the virus can also enter the peripheral blood (viremia) and translocate to other target organs expressing the ACE2 receptor, such as the heart, kidney, and intestines, resulting in multiple organ dysfunctions. Thus, there is a great

need to discover the specific virulence mechanisms during which cell and tissue injury occurs. As it is not always possible to capture the underlying mechanisms of pathophysiology in humans, several modeling methods have been developed, including 3D-engineered organoids derived from pluripotent stem cells (ESCs and iPSCs), different types of stem cells, and animals (Sun et al. 2020; Yang et al. 2020; Youk et al. 2020; Zheng et al. 2021; Boudewijns et al. 2020).

The Rationale for the Clinical Use of MSCs for COVID-19 Patients

MSCs administration tends to unbalance the pro-inflammatory cytokines, immune cells, and tissue damage toward an anti-inflammatory and regenerative microenvironment. MSCs have been widely used in cell-based therapy, from basic research to clinical trials (Acosta et al. 2013; Capilla-González et al. 2018; Soria-Juan et al. 2019). Safety and efficacy have been avidly documented in many clinical trials, especially in both systemic and local immune-mediated inflammatory diseases, such as GvHD, Crohn's complex fistula, and type 2 diabetes complications (Soria-Juan et al. 2019; García-Gómez et al. 2010; Herreros et al. 2012). MSCs play a positive role mainly in two ways: immunomodulatory effects and anti-inflammatory abilities both linked to regeneration (Pacienza et al. 2017; Lee and Kang 2020). MSCs, when activated, can secrete many types of cytokines by paracrine secretion or make direct interactions with immune cells (Leng et al. 2020).

MSCs may act as suppressors of the cytokine storm, specifically through IL-1 blockade. Recent data support that IL-1 receptor antagonist, a naturally occurring antagonist of IL-1α/IL1-β signaling pathways, has been attributed to the immunosuppressive effects of MSCs (Harrell et al. 2020). So, IL-1 blockade seems to activate MSCs toward anti-inflammatory phenotype able of releasing anti-inflammatory cytokines, of increasing Treg, and of favoring polarization of M1 (pro-inflammatory) macrophages into M2 (anti-inflammatory), which could contribute to revascularization and regeneration of lung tissue (Varghese et al. 2017).

In summary, MSCs tend to unbalance the pro-inflammatory cytokines, immune cells, and tissue damage toward an anti-inflammatory and regenerative microenvironment (Fig. 1).

This is why these cells have been proposed for use in pulmonary sepsis and cystic fibrosis. They are safe when used for ARDS (Wilson et al. 2015). The intravenous route is the most appropriate for the current intensive care unit (ICU) setting. Additionally, MSCs of any origin injected intravenously are rapidly located in the pulmonary microcirculation network because the cells are significant than the diameter of the capillaries, based on previous data in preclinical animal models. They can also be captured by local macrophages, which subsequently stimulate MSCs to produce IL-10, indirectly providing a source of immunosuppressive cytokines (Argibay et al. 2017). Altogether, MSCs have been successfully tested in other inflammatory diseases. Preclinical data suggest that they may be beneficial in patients with COVID-19 with severe pulmonary inflammation and oxygen therapy (mechanical ventilation) without excluding their use in earlier stages of the disease.

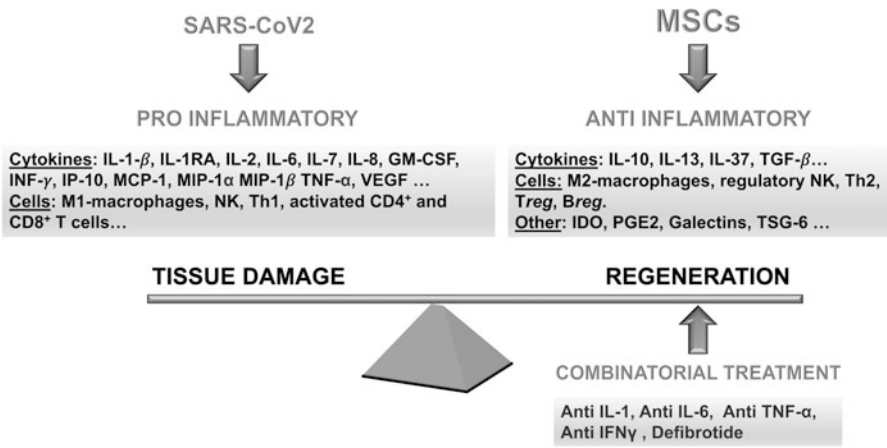

Fig. 1 Schematic of the anti-inflammatory effects of mesenchymal stem cells-derived exosomes, secretome, and combinatory treatment on lung inflammation and tissue damage caused by COVID-19. **Abbreviations:** Breg, regulatory B cell; GM-CSF, granulocyte-macrophage colony-stimulating factor; IDO, indoleamine-pyrrole 2,3-dioxygenase; IFNγ, interferon gamma; IL-1RA, interleukin-1 receptor antagonist; IL, interleukin; IP-10, interferon gamma-induced protein 10 (or CXCL10, C-X-C motif chemokine ligand 10); M1-macrophages, classically activated macrophages; M2-macrophages, alternatively activated macrophages; MCP, monocyte chemoattractant protein; MIP-1, macrophage inflammatory protein 1; NK, natural killer; PGE2, prostaglandin E2; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; Treg, regulatory T cell; TGF-β, transforming growth factor-beta; Th1, T helper type 1; Th2, T helper type 2; TNFα, tumor necrosis factor-alpha; TSG-6, stimulated gene-6; VEGF, vascular endothelial growth factor

Progress in MSC-Based Therapy for COVID-19

MSCs have been widely used for their capacity to differentiate into diverse cell lineages, migration, and secretion of cellular regulators (secretome), together with their immunosuppressive and immunomodulatory potential. Moreover, their isolation is almost easy and presents no major ethical problems, making them the most suitable stem cells among many others (Larijani et al. 2015).

On the one hand, adipose tissue, umbilical cord, bone marrow, and blood are some important sources of MSCs. Although adipose tissue-derived MSCs have been shown to have more exciting results initially, the best source of stem cells still needs to be found (Gentile and Sterodimas 2020; Song et al. 2021). On the other hand, through their impacts on T and B cells, macrophages, and dendritic cells, they help establish a tolerogenic environment leading to an optimal therapeutic condition (Wang et al. 2018; Lee and Song 2018). Consequently, by inhibiting T- and B-cell proliferation and successfully regulating pro-inflammatory cytokines to optimize the microenvironment for intrinsic recovery, MSCs can reduce the cytokine storm. Moreover, MSCs can restrict the infiltration of innate immune system cells, consequently decreasing the secretion of inflammatory cytokines, which may indirectly

attenuate the cytokine storm (Zhu et al. 2020b; Ellison-Hughes et al. 2020; Song et al. 2021; Jeyaraman et al. 2021).

Under COVID conditions, a few days after infusion of MSCs, immune cells related to the cytokine storm are shown to decrease. Increased levels of lymphocytes and regulatory dendritic cells along with decreased levels of CRP, IL-1, IL-6, IL-12, IFN-γ, and TNF are also other results of this type of MSC-based therapy. MSCs can also deliver antimicrobial peptides and anti-inflammatory cytokines (Rajarshi et al. 2020; Wang et al. 2020a; Leng et al. 2020). In addition to these anti-inflammatory characteristics, the secretion of IL-10 and some growth factors, together with their regenerative and repair capacity, renders MSCs a potent therapeutic tool for lung repair and treatment of ARDS (Azmi et al. 2020). Administration of MSCs has also been shown to have beneficial effects in conditions like sepsis and septic shock due to their ability to normalize inflammatory biomarkers, oxygen saturation, and pulmonary improvements. For sepsis condition, umbilical cord Wharton's jelly-derived MSCs are mentioned as the best source of MSCs due to their effectiveness and acceptability (Laroye et al. 2020).

Furthermore, the gene expression profile showed that MSCs were negatively expressed angiotensin-converting enzyme 2 (ACE2-), an essential protein for viral infection along with transmembrane serine protease 2 (TMPRSS2-), which indicated that MSCs are free from COVID-19 infection (Leng et al. 2020; Hernandez et al. 2021). In this regard, the FDA has confirmed the safety and efficacy of MSCs for widespread application for COVID-19 cases (Choudhery and Harris 2020; Kavianpour et al. 2020). Despite the aforementioned benefits on the administration of MSCs, there are still some challenges; MSCs-related characteristics regarding their dosage, route of administration, frequency, and location of MSCs in the damaged sites have posed some limitations. Ethical concerns that remain, along with the lack of standardized protocols in the preparation and isolation processes, are other challenges.

Another primary concern about MSCs therapy is their side effect of increased hypercoagulability (Jeyaraman et al. 2021). Therefore, in accordance with the increased risk of thrombosis, cell-free therapies, including MSCs secretome and MSCs extracellular vesicles, appear to be an interesting treatment approach for COVID-19 having no risk of mutagenesis and/or tumorigenicity. Exosomes harbor different types of microRNAs and mRNAs and various protein components and have a lower risk of escort and lower transmission of infection. However, a clearer understanding of the dose, timing, and route of administration of the cells is needed. Their ability for nebulized administration (Hmadcha et al. 2020; Aguilera et al. 2021) and more extended storage periods also make them promising alternative therapeutic approaches (Maron-Gutierrez and Rocco 2020; Kheirkhah et al. 2021).

One of the first clinical trials to study the efficacy of intravenous infusion of MSCs in ten patients with confirmed moderate, severe, or critical forms of COVID-19 aged 45–75 years was conducted in China (Chinese Clinical Trial Registry – ChiCTR2000029990). Seven patients (one with the critical, four with the severe, and two with the moderate form of the disease) received an intravenous infusion of MSCs; three patients with the severe disease received a placebo. Two days after

MSCs infusion, all seven patients showed a significant improvement in lung function and a decrease in the expression of disease symptoms. All seven patients who received MSCs recovered and were discharged 10 days after the procedure. Due to the immunosuppressive properties of MSCs, after infusion, they contributed to a significant decrease in the level of pro-inflammatory cytokines and chemokines in serum, which attracted a lower number of mononuclear cells/macrophages to the damaged lungs. At the same time, MSCs promoted the recruitment of many regulatory dendritic cells (DCs) to the site of inflammation. In addition, there was an increase in IL-10 and vascular endothelial growth factor (VEGF) levels in this trial, which may contribute to lung recovery. Among the three patients in the control group (who received a placebo), one died, the second developed ARDS, and the third remained in severe condition (Leng et al. 2020). Since then and over a year, many clinical trials have been launched with different types of MSCs to treat COVID-19 disease.

Other Cell-Based Innovation for COVID-19

Cell therapy is emerging as one of the most promising strategies for regenerating damaged or failed tissues and organs in the healthcare system. In this regard, in addition to the extensive use of MSCs of both autologous and allogeneic origin, there is a wide range of treatments using various cell types (e.g., T cells, NK lymphocytes, and different stem cells). In this context, the adoptive T-cell therapy approach or CAR-T cell therapy as a type of immunotherapy has proven effective against some infections and diseases. In this case, T cells are extracted from the patient's immune system (autologous source) and sent to the laboratory for genetic modification. The modified cells are then reinfused into the patient (Bonifant et al. 2016; Maus and Levine 2016; Seif et al. 2019). Despite the impressive efficacy of CAR-T cell therapy in treatment, it has several serious side effects, including cytokine release syndrome (CRS) and neurological difficulties. Immediate-onset CRS tends to be a cytokine storm (Chen et al. 2019; Hong et al. 2021). Currently, T-cell therapy has also shown promise in immunosuppressed individuals as a preventive measure against COVID-19. Thus, peripheral blood cells from convalescent subjects who had been at risk for the virus were used (Keller et al. 2020).

Regulatory T-cell-related strategies have also been suggested as treatment approaches for disease management based on their ability to inactivate innate/adaptive immunity through inhibitory molecules (Stephen-Victor et al. 2020). In addition, antigen-specific modified/unmodified T-cell transfer has shown promising results in treating different disorders by reconstituting T-cell subsets (effector/memory cells). In this context, it is mentioned that adoptive T-cell therapy by transferring immune subsets of T cells has therapeutic benefits that may be the same as the characteristics of adult tissue stem cells. However, the required high maintenance of memory T cells and engraftment processes may create some limitations (Busch et al. 2016). In this regard, specific COVID-19-related T cells (within CD45RA memory T cells) have been recognized that can be feasibly received by depleting CD45RA

from convalescent donors. These cells can provide a cell population for the condition of lymphopenia along with rapid reactions to infection. Memory T cells can respond quickly to infection and provide long-term immune protection to reduce the severity of COVID-19 symptoms. Also, CD45RA memory T cells confer protection from other pathogens encountered by the donors throughout their life (Ferreras et al. 2021). CD45RA memory T cells also provide immunity against probable secondary infections that may be found in COVID-19 hospitalized individuals (Ferreras et al. 2021). HLA-matched cytotoxic T cells isolated from convalescent patients are other promising approaches for treating COVID-19, as are EBV-specific cytotoxic T cells used for EBV^{+}-related lymphomas (Hanley et al. 2020).

Another promising candidate for a significant advance has been natural killer (NK) cell therapy. In this case, autologous or allogeneic origins can be used to create pure populations of NK cells. The use of allogeneic NK cells as a platform for CAR engineering has been augmented by the limitations of autologous NK cells (such as a diminished effector role and the requirement for a patient-specific stock) (Veluchamy et al. 2017; Daher and Rezvani 2018). Given that the decrease in NK cell numbers may be related to the severity of COVID-19 infection, some clinical trials used engineered NK cells to help combat COVID-19 (Market et al. 2020; van Eeden et al. 2020). However, the use of NK cells also has many drawbacks that may clinically hinder their efficacy. Their short lifespan (due to the lack of cytokine support), low cell number, and vulnerability to immunosuppressed status could limit their trafficking and function (Nayyar et al. 2019; Liu et al. 2021).

Side Effects of Mesenchymal Stem Cell-Based Therapy

Although the safety and efficacy of MSCs infusion have been demonstrated in hundreds of clinical trials, this treatment can lead to potential complications (Acosta et al. 2013; Capilla-González et al. 2018; Soria-Juan et al. 2019), and possibly it is the time for combinatory therapies. Preclinical studies have shown that the lungs act as a filter that retains most of the cells injected intravenously (Zhang et al. 2020). Numerous critically ill COVID-19 patients are in a hypercoagulable procoagulant state. Hence, they are at high risk for disseminated intravascular coagulation, thromboembolism, and thrombotic multiorgan failure, another cause of high lethality of the infection. It remains unclear whether intravenous (IV) infusion is a safe and effective route of MSCs infusion for COVID-19 patients. This information is important as MSC-based products express variable levels of highly procoagulant tissue factor (TF or CD142), which compromises the hemocompatibility and safety profile of the cells. Of potential concern is that intravenous infusions of poorly characterized MSC products with uncontrolled (high) TF (CD142) expression may trigger blood clotting in COVID-19 subjects and other vulnerable patient populations and further promote the risk of thromboembolism.

By contrast, well-characterized products with robust manufacturing procedures and optimized clinical delivery modes hold great promise for improving COVID-19 patients by exerting their beneficial immunomodulatory effects, inducing tissue

repair and organ protection. While the need for MSCs therapy for COVID-19 subjects is evident, integrating innate and adaptive immune compatibility testing into current cell, tissue, and organ transplantation guidelines is critical for safe and effective therapies. Thus, it is essential to use only well-characterized and safe MSCs for even the most urgent and experimental treatments (Moll et al. 2020). Because the COVID-19 patients suffer a prothrombotic state, concomitant use of heparin and defibrotide, a drug used in sinusoidal obstructive syndrome (SOS) after hematopoietic stem cell transplantation, has been proposed. Defibrotide is a mixture of single-stranded oligonucleotide aptamers with multi-target pharmacology limiting endothelial cell activation (Pescador et al. 2013). Given its antithrombotic, anti-TNFα, anti-atherosclerotic, etc., the US Food and Drug Administration (FDA) approved its use in SOS. It will be consistent both to block the cytokine storm and prevent pulmonary thromboembolism. With HIV infections, we learned that combinatorial therapies show higher effectiveness in controlling the disease. Case reports, pilot studies, and well-designed clinical trials are needed to fight this pandemic. Now and when it comes back.

Unmet Challenges of Adoptive MSCs Therapy

Despite the promising preliminary results, specific challenges demand attention before MSCs can be adopted at a larger scale in treating coronaviruses-induced infections. These challenges include the study design, source of MSCs, route of administration, dosage requirements, and their laboratory preparation and manipulation (Escacena et al. 2015; Soria-Juan et al. 2019; García-Bernal et al. 2021).

Study Design

We believe that most of the trials that have been registered utilizing MSCs or their derived products do not have any appropriate control to conclusively determine the efficacy of cellular or cell-free therapy (Table 1). In most of these cases, MSCs are used in combination with adjunct antiviral drugs and supportive therapy. In such cases, it would become almost impossible to determine if the observed clinical improvements are actually attributed to MSCs or not. Therefore, a strategy including an appropriate control should be included in the design of such trials along with a greater sample size to validate the clinical efficacy of stem cells technology fully.

Source of Cells

Different tissue sources, whether adult- or fetus-associated tissues, like adipose tissue, umbilical cord, dental pulp, and bone marrow, vary in their capacity to generate MSCs. Therefore, choosing an ideal source for harvesting MSCs and subsequently generating cell-free products is equally important as cell-free therapy

is fast emerging as a therapeutic option (Haider and Aslam 2018). MSCs tissue sources, like umbilical cord and adipose tissue, are easily accessible without discomfort to the donor and generate a greater amount of MSCs with equivalent differentiation potential from the same amount of tissue in comparison to bone marrow, which incidentally is more invasive.

Route of Cell Administration

Another major factor to consider here is their route of administration. MSCs and their products can either be systemically or locally injected. There are only limited studies that have compared the different routes of MSCs administration and have reported different outcomes. Therefore, it is difficult to conclude which route can be considered as the safest and most effective (Antunes et al. 2014; Cardenes et al. 2019). For COVID-19 disease, MSCs can be administered both systemically and locally with equal efficacy as both of these routes would result in their delivery first to the lungs only. However, in the case of cell-free products, like exosomes, delivery directly to the lungs via intranasal or intratracheal route is a more tenable option as systemic delivery often leads to a substantial loss in the amount of these products, mainly due to the activity of circulatory proteases and their distribution to the liver and spleen first, thus calling for booster doses (Gardin et al. 2020; Mahajan and Bhattacharyya 2021).

Dosage Strategies

The number of MSCs required per dose and the total number of doses required are quite crucial in determining the treatment outcome. Based on the previous studies, it is estimated that approximately 4×10^8 MSCs are required for every patient regardless of the clinical indication (Olsen et al. 2018). The trials registered for COVID-19 have reported varied dosages, with an average of 1×10^6 cells/kg body weight up to 2–5 times to this average dose, but the actual number of MSCs required to produce such doses is not mentioned in any report, which needs to be optimized. Furthermore, while MSCs can be injected directly, the products like exosomes need to be prepared into stable formulations for their delivery to the patients (Gardin et al. 2020; Mahajan and Bhattacharyya 2021).

Risks Associated with Stem Cell Therapy

While MSCs and their products have proven beneficial in the current scenario, we should not overlook the risks associated with stem cell therapy. Many stem cells clinics have opened up in recent years, marketing unethical and unauthorized stem cell treatment for various ailments, including COVID-19, by feeding on people's fears and anxieties (Turner 2020). These less than clinical-grade stem cells and unlicensed stem cell treatments are potentially dangerous to the general public and undermine the efforts at determining stem cells efficacy in clinical trials. Undoubtedly, the use of

MSCs and their factors has proven to be quite promising in the current scenario but is mainly dependent on the functional quality and integrity of stem cells. Therefore, stringent regulatory control should be maintained for the manufacturing and distribution of these products (see ▶ Chap. 3, "Considerations for Clinical Use of Mesenchymal Stromal Cells" of this book for review on clinical use of MSCs).

Concluding Remarks

Considering the prevalence of COVID-19 and its complications, such as cytokine storm, which is followed by ARDS and death of patients, finding a way to treat and improve patients is of great importance. As previously mentioned, currently available vaccines are not a cure for COVID-19; there is no specific therapy for this virus, and supportive therapies as well as nonspecific antiviral drugs are mainly used for this purpose. Cell-based therapy is a modern method to treat various diseases. Recently, a number of studies have been conducted to treat COVID-19 using stem cells, suggesting the application of MSCs or immune cells such as T, CAR-T, or NK cells. Accordingly, the safety and immunomodulatory role of MSCs in ARDS has been approved. The MSCs can secrete factors that improve the pulmonary microenvironment, inhibit immune system over-activation, promote tissue repair, rejuvenate alveolar epithelial cells, inhibit counteract pulmonary fibrosis, or improve function in lung tissue damaged by SARS-CoV-2 infection.

Nonetheless, many issues related to the application of MSCs, such as the ideal dose and optimal timing of administration, need further study. Of note, in several animal models of human disease, the use of MSC-secreting exosomes has been claimed to mimic the beneficial effects of MSCs in antiviral therapy against the influenza virus by reducing virus replication in the lungs and virus-induced release of pro-inflammatory cytokines, which highlights the great potential of cell-free-based therapies. In addition, considering the impossibility of studying the detailed mechanism of pathogenicity and the sequence of suggested drugs or vaccine candidates in human beings, these significant steps toward cell-based therapies in the SARS-CoV-2 field of study should be continued. Ongoing experimental studies and randomized trials will play an essential role in elucidating the therapeutic potential of MSCs, leading to a better understanding of how MSCs interact with SARS-CoV-2-infected lung tissue. Although current progress on COVID-19 vaccinations is promising, the world population will have to continue to adapt to the "new normal" and practice social distancing and hygienic measures, at least until an effective cure is available to the general public.

Abstract

Inflammatory bowel disease (IBD) belongs to the group of diseases characterized by idiopathic inflammation of the gastrointestinal organs. Two basic IBD types are distinguished: ulcerative colitis and Crohn's disease. The IBD symptoms including vomiting and diarrhea, abdominal pain, rectal hemorrhage, and anemia have a significant negative impact on the general patient's state of health. More than four million people in the USA and Europe suffer from IBD, while the general incidence of this disease in the developed countries exceeds 0.5% of the population. Besides, IBD is associated with a significant risk of colitis-associated malignancy. In the last decades, considerable progress has been achieved in the IBD therapy due to application of drugs suppressing the local gastrointestinal tract inflammation, such as antibodies to TNF-α (infliximab and adalimumab), corticosteroids, salicylates, etc. At the same time, this strategy, unfortunately, does not result in the repair of the damaged tissues, primarily ulcers of the colon, in many IBD patients. To achieve the mucosa healing and stable remission in IBD patients, novel approaches are required, cell therapy, actively used since the beginning of 2000s, being one of them. In our book chapter, we discuss the advantages and problems of application of mesenchymal stem cells (MSCs) which are most actively used in the cell therapy of IBD. The results of the most important preclinical and clinical studies are covered.

Keywords

Abbreviations

5-ASA	5-Aminosalicylic acid
APC	Antigen-presenting cells
ASC	Adipose tissue–derived stem cells
AZA	Azathioprine
BM	Bone marrow
CCL-2	C-C-chemokine ligand 2
CD	Crohn's disease
CDAI	Crohn' Disease Activity Index
CI	Confidence interval
DC	Dendritic cells
DSS	Dextran sodium sulfate
GCS	Glucocorticosteroids

GI	Gastrointestinal
HBI	Harvey-Bradshaw Index
HGF	Hepatocyte growth factor
HLA-G	Human leukocyte antigen-G
hUC	Human umbilical cord
I/A	Intra-arterial
I/V	Intravenous
IBD	Inflammatory bowel disease
IBDQ	Inflammatory Bowel Disease Questionnaire
ICG	Lindocyanine green
IDO	Indoleamine-2,3-dioxygenase
IFN	Interferon
IL	Interleukin
iNOS	Inducible nitric oxide synthase
LPS	Lipopolysaccharide
MHC	Major histocompatibility complex
miR	MicroRNA
MMP	Matrix metalloproteinases
MSCs	Mesenchymal stem cells
NK-cells	Natural killer cells
PDAI	Perianal Disease Activity Index
PGE2	Prostaglandin E2
PSC	Primary sclerosing cholangitis
RR	Relative risk
SMA	Smooth muscle actin
SVF	Stromal vascular fraction
TGF-β	β-transforming growth factor
TNBS	Trinitrobenzenesulfonic acid
TNF	Tumor necrosis factor
UC	Ulcerative colitis

Introduction

Inflammatory bowel disease (IBD) is a group of chronic inflammatory conditions of the gastrointestinal (GI) tract characterized by the augmented immune response of the mucosa. Crohn's disease (CD) and ulcerative colitis (UC) are the two basic types of IBD. Long-lasting IBD results in GI tract damage. CD may affect any part of the GI tract from the mouth to the anus. The terminal part of the small intestine (ileum) is most frequently affected near the place where it joins the large intestine. CD may manifest itself in the form of "patches," involving some parts of the GI tract and leaving the other parts intact. The inflammation in CD may spread through the whole colon wall thickness (Sairenji et al. 2017). In UC, only the colon and rectum are affected. The inflammation appears only in the innermost layer of the colon mucosa. It usually starts in the rectum and lower parts of the colon, but may also spread

continuously and affect the entire large intestine. IBD shares some symptoms such as persistent diarrhea, abdominal pain, rectal bleeding/bloody stool, weight loss, and fatigue. In some cases, it is difficult to determine whether a patient has CD or UC. Such cases are classified as indeterminate colitis (Guindi and Riddell 2004).

The exact cause of IBD is unknown, but there is an assumption that it results from a defective immune system. The immune system of an IBD patient wrongly reacts to the environmental triggers that cause the GI tract inflammation. Such a wrong reaction of the immune system arises, supposedly, in people with a corresponding family history who inherited genes determining the susceptibility to IBD (Khor et al. 2011).

More than four million people in the USA and Europe suffer from IBD, while the general incidence of this disease in the developed countries exceeds 0.5% of the population. Seventy thousand new IBD cases are diagnosed yearly in the USA only, and in general, the yearly financial burden of IBD in the USA exceeds 31 billion dollars (CCFA 2014; GBD 2020). The majority of patients receive the diagnosis of IBD at the age of less than 35 years. In particular, 80,000 children suffer from IBD in the USA. These lifelong chronic conditions essentially affect the quality of life and medical expenses of patients. Besides, IBD patients are susceptible to the risk of developing of other serious diseases such as colon cancer, thrombosis, and primary sclerosing cholangitis (PSC).

In some cases, surgical removal of the damaged GI parts is required for the therapy of severe IBD forms. However, due to the achieved success of the drug therapy of IBD, it has been generally used in the last decades, with five basic types of drugs (CCFA 2014).

Aminosalicylates such as sulfasalazine, balsalazide, mesalamine, and olsalazine administered per os or rectally reduce the colon wall inflammation and are applied primarily for the UC treatment. At the same time, they are less efficient in the CD treatment.

Corticosteroids, such as prednisone, prednisolone, and budesonide, keep the immune system under control. Therefore, they are efficient in the short-term management of exacerbations. But unfortunately, their side effects include infections, weight gain, sleep disorders, etc.

Immunomodulators, such as azathioprine, 6-mercaptopurine, and methotrexate, influence the immune system activity; they are toxic and usually used to sustain the remission in those patients who do not respond to other drugs, or respond to steroids only.

Antibiotics, such as ciprofloxacin and metronidazole, are of moderate use in treating CD patients with the affected colon or perianal region. In particular, antibiotics are administered in the case of infections, e.g., abscesses.

TNF inhibitors include adalimumab, certolizumab pegol, golimumab, and infliximab. These drugs have a pronounced anti-inflammatory effect and are used in the therapy of patients suffering from severe forms of IBD in the absence of a satisfactory and sound effect from the standard treatment. However, the application of these drugs, regretfully, is not always efficient, as well. In particular, the long-term infliximab administration has shown that up to one-third of patients do not respond

to the anti-cytokine therapy, either due to primary resistance to the drug or the development of secondary resistance (Magro and Portela 2010). Besides, severe complications may occasionally emerge, including bacterial, viral, and fungal infections, increased risk of lymphoma, colorectal cancer, and other oncological diseases.

IBD Therapy with MSCs

According to estimates, application of contemporary methods of IBD therapy leads to a 20–30% rate of remission, with a maximum of 50% when using a combinatorial therapy approach (Ocansey et al. 2020). Furthermore, cell therapy has shown to be very effective and extremely promising in treating IBD (Cassinotti et al. 2012; Irhimeh and Cooney 2016; Lopez-Santalla et al. 2020). Therefore, the use of mesenchymal stem cells (MSCs) is of particular interest regarding this approach.

MSCs Properties

MSCs are multipotent stromal cells which may be derived from the bone marrow, adipose tissue, dental pulp, skeletal muscle, etc. (Lei et al. 2006; Tolar et al. 2010; Williams et al. 1999; Zuk et al. 2001; Gronthos et al. 2011). MSCs express molecules of the major histocompatibility complex (MHC) class I at a low level and do not express molecules of MHC class II, hence they may be used in allogeneic transplantation (Prockop 2009; Haider et al. 2011). They constitute a heterogeneous population of cells and are characterized by the expression of specific surface markers including CD73, CD90, and CD105 markers, while lacking the expression of CD14, CD11b, CD79 and Cd19, CD34 and CD45 hemopoietic stem cell–specific markers, as well as CD31 endothelial markers (Lv et al. 2014; Haider 2018). Besides surface marker expression, they show specific adherence to the plastic surface and possess trilineage differentiation potential to adopt adipocyte, osteoblast, and chondrocyte phenotypes (Caplan and Correa 2011; Wang et al. 2018). This criterion of characterization has been set forth by the International Society of Cell Therapy (ISCT) which has significantly helped in harmonizing the nomenclature and biological characterization of the cell preparations being used in the experimental and clinical studies. Their autologous availability and robust nature, therefore, can be genetically manipulated to delivery genes of interest to the target organ for angiomyogenic repair as well as to enhance their therapeutic potential (Jiang et al. 2006; Haider et al. 2008) and reprogramming in to pluripotency (Buccini et al. 2012). They have also been combined with other stem cell types for combinatorial cell therapy approach (Hosseini et al. 2018).

Mechanisms of MSCs' Action

The first and the primary mechanism of MSCs' action is their transdifferentiation into morphofunctionally competent cell types and achieve the phenotype of interest,

which allows the replacement of damaged cells and contribute to the repair and restoration of damaged tissues (cartilage, bones, etc.). The second mechanism of MSCs' action is associated with the ability of MSCs to move to the sites of damage and inflammation, and secrete cytokines and growth factors, and lipid vesicles rich in bioactive cargo of proteins, lipids, and RNA as part of their paracrine activity to reduce inflammation and restore the damaged tissues (Caplan and Correa 2011; Caplan 2016; Bernardo and Fibbe 2013) (Fig. 1). Besides the abovementioned two primary mechanisms, MSCs also have immunosuppressive and anti-inflammatory effects via the suppression of proliferation and differentiation of T cells (CD4+ and CD8+ lymphocytes), reducing the activity of NK cells and activating T regulatory cells. In addition, MSCs reduce the secretion of pro-inflammatory cytokines (IL-1β, IL-6, TNFα, and IFN-γ) and boost the secretion of anti-inflammatory IL-4 and IL-10 (Spaggiari et al. 2008; Ghannam et al. 2010). More recently, MSCs surface markers including PDL1, Gal-9, CXCR4 etc., have been implicated as part of the immunosuppressive activity of MSCs (Siyu et al. 2020). Concomitantly, proangiogenic activity of MSCs induces neovascularization regionally at the site of engraftment to restore regional blood flow (Maacha et al. 2020), while apoptosis and oxidative stress are inhibited (Terai and Tsuchiya 2017). Put together, the mechanism of MSCs' therapeutic benefits is multifactorial as summarized in Fig. 1.

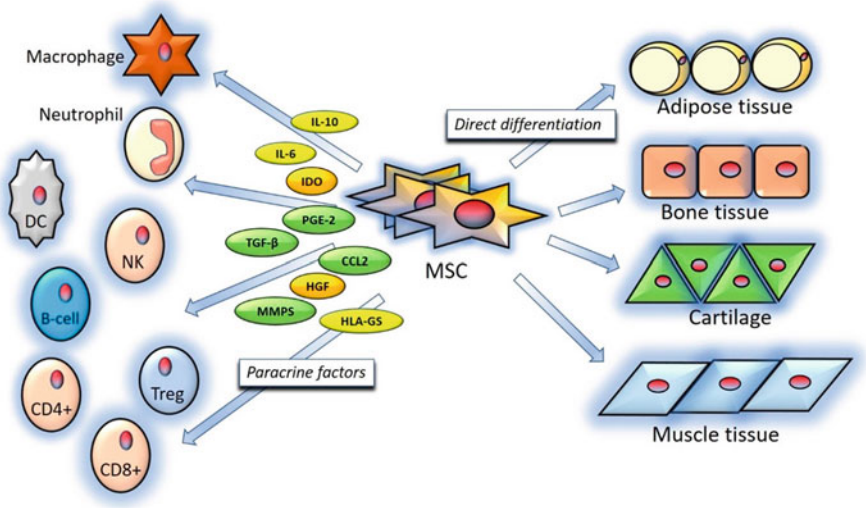

Fig. 1 General MSCs' effects grouped by the two fundamental mechanisms: (1) direct transdifferentiation of the transplanted MSCs (into cells of adipose, bone, cartilage, and muscle tissues) to replace damaged cells and (2) induction of cytokines secreted by MSCs as a part of their paracrine activity into the inflammatory medium, affecting the recipient's immune system. **Abbreviations**: (IL-6: Interleukin-6; PGE2: Prostaglandin E2; TGF-β: β-transforming growth factor; IDO: Indoleamine-2,3-dioxygenase; CCL-2: C-C-chemokine ligand 2; IL-10: Interleukin −10; HGF: Hepatocyte growth factor; MMP: Matrix metalloproteinases; HLA-G: Human leukocyte antigen-G)

Preclinical Studies

Yabana et al. demonstrated that in rats with dextran sodium sulfate (DSS)-induced colitis, MSCs, administered intravenously to the animals, migrated to the lamina propria of the damaged colon, where they activated the expression of alpha-smooth muscle actin (α-SMA), which facilitated the restoration of the epithelium (Yabana et al. 2009). It was also shown that MSCs participated in sustaining the epithelial barrier function by the repeated assembly of claudins, apical proteins of tight junctions.

The most critical role in the IBD pathogenesis is evidently played by enhanced proliferation and defective apoptosis of immune cells, which is likely related to the imbalance of Bcl-2 and Bax, essential proteins controlling apoptosis (Dias et al. 2014).

Akiyama et al. showed that systemic infusion of bone marrow–derived MSCs (BM-MSCs) induced apoptosis of T cells via the Fas-ligand (FasL)-dependent pathway and could improve the disease course in experimental murine DSS-induced colitis (Akiyama et al. 2012). However, FasL/MSCs did not induce apoptosis of recipients' T -cells and could not positively influence the colitis course. It was shown that Fas-regulated secretion of MCP-1 protein by BM-MSCs recruited T cells for FasL-mediated apoptosis. Apoptosis of T cells, in turn, leads to the induction of macrophages producing a high level of TGFβ. This results in an increased number of T-regulatory cells and, finally, in the immune tolerance of the organism.

IBD is also associated with the imbalance in subpopulations of T cells. As a result, the pro-inflammatory cytokines level grows: in CD – due to differentiation of Th1 and Th17 cells, and in UC – due to differentiation of Th2 cells. In contrast, the level of T-regulatory (Treg) cells is depressed in the peripheral blood of IBD patients (Sisakhtnezhad et al. 2017). Among Treg cells, the crucial role in the immune system suppression and sustaining the tolerance belongs to CD4+CD25+FoxP3+ cells (Akiyama et al. 2012).

Chen et al. demonstrated that intravenous MSCs administration significantly reduced the clinical severity of murine UC (weight loss, diarrhea, and inflammation) induced by trinitrobenzene sulfonic acid (TNBS) and enhanced the survival of animals (Chen et al. 2013). It was shown that MSCs reached the damaged colon and facilitated the proliferation of intestinal epithelial cells and differentiation of intestinal stem cells (determined by detecting Lgr5+-cells). Furthermore, it was mediated by suppressing both Th1 and Th17 cell–induced autoimmune and inflammatory reactions (IL-2, TNF-α, IFN-γ, T-bet; IL-6, IL-17, RORγt), as well as by enhanced activity of Th2 cells (IL-4, IL-10, and GATA-3). Besides, it was shown that MSCs induced activated CD4+CD25+Foxp3+ T-regulatory cells (TGF-β, IL-10, Foxp3).

Macrophages, dendritic cells, and B cells, known as antigen-presenting cells (APC), are also involved in the IBD pathogenesis due to their specialization in presenting an antigen to T cells and the subsequent generation of the T cell response. Macrophages play a critical role in sustaining normal intestinal homeostasis, but they

may also participate in the IBD pathogenesis (Han et al. 2021). In a healthy colon, resident macrophages exhibit an M2 phenotype, while inflammatory M1 macrophages dominate in the inflamed intestinal mucosa. In this regard, changing the balance of macrophage population to the M2 phenotype is being adopted as a novel approach in IBD therapy (Ahluwalia et al. 2018). Numerous preclinical studies have shown that MSCs can induce immunomodulating macrophages and macrophages mediate their therapeutic efficiency in experimental UC with an M2-like phenotype (Hidalgo-Garcia et al. 2018).

Jo et al. cocultured immature dendritic cells and lipopolysaccharide (LPS)-treated mature dendritic cells with MSCs for 48 h, and then analyzed the profiles of surface markers and cytokines and the regulatory role of those DC for primary splenocytes (Jo et al. 2018). Besides, the therapeutic effects of MSCs and DC cocultured with MSCs were compared for UC-affected mice. The authors demonstrated that following the coculture of MSCs with immature dendritic cells (MSCs-DC) or LPS-treated mature dendritic cells (LPS + MSCs-DC), the expression of CD11c, CD80, CD86, IL-6, TNF-α, and IFN-γ was significantly decreased. In contrast, the expression of CD11b, IL-10, and TGF-β was elevated. Besides, MSCs-DC and LPS + MSCs-DC induced CD4, CD25, and Foxp3 in primary mice-derived splenocytes. In mice with DSS-induced UC, MSCs and MSCs-DC increased the length of the colon, body weight, and survival, and caused a histological improvement. Moreover, in the MSCs and MSCs-DC groups, the expression of IL-6, TNF-α, and IFN-γ in the colon tissues was also inhibited, while the expression of IL-10, TGF-β, and Foxp3 was elevated. These data assumed that MSCs stimulate differentiation of dendritic cells into regulatory dendritic cells leading to improved chronic colitis therapy.

It was also shown that administration of MSCs could suppress activation and proliferation of B cells secreting IgG and, oppositely, stimulate the formation of CD5 + regulatory B cells (Bregs) producing IL-10. Besides, it was shown that MSCs could depress the proliferation of NK cells secreting pro-inflammatory cytokines (Liu et al. 2020).

MSCs-Derived Exosomes for Experimental IBD Therapy

MSCs-derived exosomes – extracellular vesicles obtained from MSCs – contain a large number of essential factors (Haider and Aramini 2020). In intercellular communication, exosomes are identified as efficient carriers for nucleic acids, functional proteins, lipids, mRNA, and microRNA (Samoylova et al. 2017). Thus, MSCs-derived exosomes, similar to MSCs themselves, have a potent physiological action affecting the damaged tissue repair (Zhao et al. 2019; Haider and Aramini 2020). At the same time, exosomes are more stable than MSCs and in principle are nonimmunogenic.

It was demonstrated earlier by several research groups that exosomes secreted by MSCs had a pronounced regenerative effect in the therapy of many diseases causing tissue damage, including IBD (Mianehsaz et al. 2019; Mendt et al. 2019; Mao et al. 2017). For instance, Mao et al. showed that exosomes released from human

umbilical cord–derived MSCs (hUC-MSCs) positively influenced the treatment of DSS-induced colitis and studied the primary mechanism of their effect (Mao et al. 2017). Similarly, exosomes labeled with indocyanine green (ICG) reached the colon tissue of IBD-affected mice 12 h after the injection. The IL-10 gene expression was increased, while the expression of TNF-α, IL-1β, IL-6, iNOS, and IL-7 genes was decreased in the colon and spleen tissues of mice treated with MSCs-derived exosomes. Besides, macrophages infiltration in the colon tissues was significantly reduced. It was also shown that coculturing in vitro with exosomes suppressed the expression of iNOS and IL-7 in macrophages isolated from the peritoneal cavity of normal mice. In addition, the researchers found that IL-7 expression in the colon tissue was higher for colitis patients than healthy participants of the control group. In general, the data obtained have demonstrated a potent effect of hUC-MSCs-derived exosomes on the relief of DSS-induced experimental IBD. The observed effects may be mechanistically mediated via the modulation of IL-7 expression in macrophages at molecular levels.

In a study by Yang et al., exosomes derived from MSCs preconditioned with IFN-γ were transplanted in an experimental mice model of DSS-induced colitis that essentially improved the index of activity and histological assessment of colitis, as well as reduced the fraction of Th17 cells and augmented the fraction of Treg cells (Yang et al. 2020). Molecular studies revealed that the administration of exosomes markedly inhibited the expression of Stat3 and p-Stat3, suppressing differentiation of Th17 cells. Interestingly, treatment with exosomes derived from MSCs preconditioned with IFN-γ showed the highest inhibition. Furthermore, the preliminary treatment with IFN-γ increased the level of miR-125a and miR-125b in MSCs-derived exosomes, which directly targeted Stat3, suppressing differentiation of Th17 cells. Moreover, concomitant infusion of miR-125a and miR-125b also demonstrated a therapeutic effect in colitis, accompanied by a simultaneous decrease in the Th17 cell fraction. In general, this study demonstrated that the IFN-γ treatment enhanced the efficiency of MSCs-derived exosomes in the relief of colitis, owing to increasing the level of miR-125a and miR-125b, which are bound to 3′-UTR of Stat3, to suppress differentiation of Th17 cells.

Clinical Studies

Completed Clinical Studies

Due to their therapeutic properties, MSCs (obtained mainly from the bone marrow and adipose tissue) have been actively used in numerous clinical trials on IBD therapy, with both local injections of cells and intravenous (systemic) infusions (Table 1).

Local MSCs Injections

Local administration of MSCs is used primarily for the therapy of fistulizing (extraluminal) form of CD (Ko et al. 2021). For example, Panes et al. have conducted a

Table 1 Results of major completed clinical trials on the MSCs therapy of IBD

No	Disease	Patients	Cells	Cell dose/delivery	Key findings	Study location
1.	Perianal CD	212	Allogeneic ASC	120×10^6 ($n = 107$) vs placebo ($n = 105$)/local injection	At week 52, a significantly larger part of patients receiving ASC reached the combined remission (56.3%, as compared to the control group with 38.6%) and the clinical remission (59.2% vs. 41.6% of the control group). In 1 year, no serious adverse events were observed	Forty-nine hospitals in Europe and Israel; NCT01541579 (ADMIRE-CD) (Panes 2018)
2.	Perianal CD	18 (45 total)	Allogeneic ASC, autologous ASC, and stromal vascular fraction (SVF)	$40–42 \times 10^6$ ASC, $6.5–15 \times 10^6$ SVF/local injection	Healing achieved: 40% of CD patients who received SVF, 66.6% of CD patients who received auto-ASCs, and 55.5% of CD patients who received allo-ASCs	University Hospital Fundación Jiménez Díaz, Madrid, Spain (Herreros 2019)
3.	Perianal CD	36	Autologous ASC	$3–6 \times 10^7$/local injection	At 24 months, complete healing was observed in 27 out of 36 patients (75.0%). No adverse events related to ASC administration were observed	University of Ulsan College of Medicine and Asan Medical Center, Seoul, Republic of Korea; NCT01011244 and NCT01314079 (Cho 2015)
4.	Perianal CD	24	Allogeneic ASC	$20–40 \times 10^6$/local injection	At week 24, 69.2% of the patients showed reduction in the number of draining fistulas, 56.3% of the patients achieved complete closure of the treated fistula, and 30% of the cases presented complete closure of all existing fistula tracts	Virgen del Rocio University Hospital, Seville, Spain (de la Portilla 2013)

5.	Perianal CD	21	Allogeneic BM-MSCs	1×10^7 ($n = 5$, group 1), 3×10^7 ($n = 5$, group 2), or 9×10^7 ($n = 5$, group 3) MSCs, or placebo ($n = 6$)/local injection	Thirteen out of fifteen patients (87%) treated with BM-MSCs were available for a long-term follow-up (4 years). No adverse events were associated with local injection of any dose of MSCs. In group 2 [$n = 4$], all fistulas were closed 4 years after BM-MSCs therapy. In group 1 [$n = 4$] 63%, and in group 3 [$n = 5$] 43% of the fistulas were closed, respectively. Pelvic MRI showed significantly smaller fistula tracts after 4 years	Leiden University Medical Center, Leiden, The Netherlands (Barnhoorn 2020)
6.	UC	70	Allogeneic hUC-MSCs	Group I ($n = 34$): I/V injection of 0.5×10^6 cells/kg, followed by intra-arterial injection of 1.5×10^7 MSCs 1 week later. Group II ($n = 36$): placebo (normal saline)	One month after therapy, 30/36 patients in group I showed a good response, and diffuse and deep ulcer formation and severe inflammatory mucosa were improved markedly. During the follow-up, the median Mayo score and histology score in group I were decreased while IBDQ scores were significantly improved compared with before treatment and group II ($P < 0.05$). Compared with	Qingdao University, Qingdao, Shandong, China; NCT01221428 (Hu 2016)

(continued)

Table 1 (continued)

No	Disease	Patients	Cells	Cell dose/delivery	Key findings	Study location
					group II, there were no evident adverse reactions after MSCs infusion in any of the patients in group I, and no chronic side effects or lingering effects appeared during the follow-up period	
7.	Luminal CD	82	Allogeneic hUC-MSCs	Group I ($n = 41$): 1×10^6 cells/kg once a week, four times in total. Group II ($n = 41$): placebo (normal saline)/I/V infusion	Twelve months after treatment, the CDAI, HBI, and corticosteroid dosage had decreased by 62.5 ± 23.2, 3.4 ± 1.2, and 4.2 ± 0.84 mg/day, respectively, in the UC-MSCs group and by 23.6 ± 12.4, 1.2 ± 0.58, and 1.2 ± 0.35 mg/day, respectively, in the control group ($p < 0.01$, $p < 0.05$, and $p < 0.05$ for UC-MSCs vs. control, respectively). Four patients developed a fever after cell infusion. No serious adverse events were observed	Shaanxi Provincial People's Hospital, Xi'an, China (Zhang 2018)
8.	UC and luminal CD	90 (69 UC and 21 CD)	Allogeneic BM-MSCs	$150–200 \times 10^6$ ($n = 39$ with UC and $n = 11$ with CD) vs control group ($n = 30$ with UC and $n = 10$ with CD)/I/V infusion	In MSCs group: statistically significant decrease in the indices of the clinical and morphological activities of an inflammatory process; clinical remission occurred in	Moscow Clinical Research Center, Moscow, Russia (Lazebnik 2010)

					40 patients (80%); discontinuing corticosteroids in 34 of the 50 patients (68%)	
9.	Luminal CD	34	Allogeneic BM-MSCs	Group 1 (15 patients): 2×10^6 MSCs/kg (at months 0, 1, and 6), with AZA 2–2.5 mg/kg. Group 2 (19 patients): 2×10^6 MSCs/kg (at months 0, 1, 6)/ IV infusion	Clinical remission (CDAI <150) was demonstrated in both groups in 12 months (average CDAI was 99.9 in group 1, 100.6 in group 2)	Moscow Clinical Research Center, Moscow, Russia (Knyazev 2018a)
10.	Perianal CD	22	Allogeneic BM-MSCs	2×10^6 MSCs/kg I/V infusion and 10–20 $\times 10^6$ local injection	According to the study results, in 12 weeks the cure of simple fistulas was noted in 8 patients (66.6%) of group I, in 6 patients (60%) of group II, and in 1 patient (7.14%) of group III. In 6 months, the simple fistulas were still healed in 8 patients (66.6%) of group I, in 6 patients (60%) of group II, and in 1 patient (7.14%) of group III. In 12 months, the healing was sustained in 7 patients (58.3%) of group I, in 6 patients (60%) of group II, and in 2 patients (14.3%) of group III. In 24 months, the closure of fistulas was sustained in 5 patients (41.6%) of group I, in 4 patients (40%) of group II, and in 0 patients (0%) in group	Moscow Clinical Research Center, Moscow, Russia (Knyazev 2018b)

					III. In conclusion, it was demonstrated that combined cell and anti-cytokine therapy of CD with perianal lesions reliably provided more frequent and prolonged closure of simple fistulas, as compared to antibiotic and immunosuppressive therapy, and reduction of the relapse incidence, as well	

Abbreviations: *CD* Crohn's disease, *UC* ulcerative colitis, *ASC* adipose tissue–derived stem cells, *SVF* stromal vascular fraction, *MSCs* mesenchymal stem cells, *BM-MSCs* bone marrow–derived mesenchymal stem cells, *hUC* human umbilical cord, *CDAI* Crohn's Disease Activity Index, *HBI* Harvey-Bradshaw Index, *AZA* azathioprine

double-blind, randomized, placebo-controlled study (ADMIRE CD Study) to establish the safety and study the long-term efficiency of a single local administration of allogeneic adipose tissue–derived MSCs (Cx601), for the treatment of CD patients with hard-to-treat draining complicated perianal fistulas (Panés et al. 2018). The study was conducted in 49 clinical centers of Europe and Israel. The trials enrolled a total of 212 patients (ClinicalTrials.gov: NCT01541579). The patients were randomly distributed (1:1) into groups, which received either a single local injection of Cx601 (120×10^6 cells) or placebo (control group) in addition to the standard care. The final indices of efficiency, estimated in the modified population of intended to treat (randomly assigned, receiving the treatment, with one or several efficiency estimations after the basic level) at week 52, including a combined remission (closure of all the treated external fistula tracts, draining at the initial level in the absence of accumulations of >2 cm, confirmed by magnetic resonance imaging; MRI) and clinical remission (absence of draining fistulas). Earlier, the same researchers reported a primary endpoint of a study at week 24 (combined remission in 51.5% patients receiving Cx601, compared to 35.6% in the control group, the difference being 15.8%; 97.5% confidence interval 0.5–31.2; $P = 0.021$) (Panés et al. 2016). At week 52, a significantly larger section of the patients receiving Cx601 reached the combined remission (56.3%, as compared to the control group with 38.6%, 17.7%difference; 95% confidence interval 4.2–31.2; P = 0.010) and the clinical remission (59.2% vs. 41.6% of the control group with the 17.6% difference; 95% confidence interval 4.1–31.1; $P = 0.013$). The safety was sustained for 52 weeks; side effects were observed in 76.7% of group Cx601 patients and 72.5% of the control group patients.

The researchers concluded that according to the results of the phase 3 study of CD patients with treatment-resistant perianal fistulas, the researchers have concluded that Cx601 is safe and efficient for closures of external fistulas, compared to placebo, in one year of the study. Based on the ADMIRE CD Study results, Darvadstrocel (Alofisel), a medication based on MSCs derived from the adipose tissue, has been developed (Scott 2018). This is the first MSCs-based cell preparation approved in the EU to treat complicated perianal fistulas in adult patients with nonactive/moderately active luminal CD when fistulas do not respond to one or more standard therapies.

Herreros et al. have published the data of a clinical study that assessed 45 patients with 52 surgically resistant anal fistulas of various etiology (of them 18 patients with perianal fistulas caused by CD) (Herreros et al. 2019). The patients' response to MSCs therapy of different types was monitored, with cells, including allogeneic MSCs from the adipose tissue (ASCs), autologous ASCs, and a stromal vascular fraction (SVF), which were believed to contain ASCs with a minimal addition of adipocytes and erythrocytes.

In 40 out of 42 cases of perianal fistulas (95.2%), either healing or improvement was shown in 6.6 weeks on average (in the observation time of 2–36 weeks). The cure occurred in 22 out of 42 cases (52.4%). Most of the patients were cured in 5.8 months on average (in the observation time of 0.5–24 months). The disease course in the 42 patients was assessed depending upon the applied cell preparations.

The degree of cure reached 13/23 (56.5%) for SVF, 3/9 (33.3%) for autologous ASCs, and 6/10 (60%) for allogeneic ASCs. The administered cell dose was also analyzed, with the average value of 43.9 million (in the range of 3–210 million cells) for the cases of cure.

If to focus on perianal fistulas caused by CD, 18/18 patients (100%) demonstrated healing or improvement/partial response, beginning from 5.3 weeks on average (in the observation time of 2–12 weeks). The cure occurred in 10/18 (55.5%) cases. Most of the patients were cured in 6.5 months (in the observation time of 0.5–24 months).

The disease course in those 18 patients was also assessed depending on the cell preparations used. The degree of cure reached 40% for SVF, 66.6% for autologous ASCs, and 55.5% for allogeneic ASCs. The mean administered dose in the cure cases was 43.9 million (in the range of 3–210 million cells). In all the cases of CD-associated perianal fistulas, the surgical technique was applied: the curettage, closing of the fistula tract, and injection of cells (Herreros et al. 2019).

The phase 2 clinical trial on the application of autologous ASCs for CD-associated perianal fistulas with a high rate of recurrence has shown their safety and therapeutic potential with a stable response for 2 years (Cho et al. 2015). In this phase 2 study, 41 patients initially participated. In 24 months, the complete cure was observed in 27 out of 36 patients (75.0%) (the data from 5 patients were absent in 24 months). No ASCs-based treatment-related adverse effects were observed. Moreover, the complete closure of the fistula was stable after the initial treatment. These results also testified that autologous ASCs were efficient in the treatment of CD-associated fistulas.

De la Portilla et al. have conducted an open-label, single-arm clinical trial which included 24 CD patients with perianal fistulas from six hospitals in Spain (de la Portilla et al. 2013). Twenty million ASCs were administered locally in one draining fistula tract. At week 12, if the fistula had not completely closed, 40 million more ASCs were administered. The patients were monitored up to week 24 after the first treatment.

During 6 months of follow-up, no serious adverse events were observed, attesting the treatment as sufficiently safe. At week 24, the number of fistulas was reduced in 69.2% of patients, the complete closure of treated fistulas was observed in 56.3% of the patients, and in 30% of the cases all the fistulas were completely closed. The criteria used to grade the extent of closure were the following: absence of draining and complete re-epithelization, and the MRI-confirmed absence of accumulations. The MRI Score of Severity showed a noticeable reduction at week 24. Thus, the applied ASCs-based therapy appeared safe and fairly efficient for CD-associated perianal fistulas.

A double-blind dose-finding study on the allogeneic BM-MSCs treatment of refractory perianal fistulizing CD was conducted at Leiden University Medical Center in 2012–2014 (Barnhoorn et al. 2020). The study involved 21 patients; three regimes of local MSCs administrations were applied: cohort 1 – five patients, 1×10^7 cells, cohort 2 – five patients, 3×10^7 cells, and cohort 3 – five patients, 9×10^7 cells. The patients were assessed for 4 years, with the registration of

clinical events, monitoring the fistula closure, and measuring the level of anti-HLA antibodies, pelvic MRI, and rectoscopy.

The long-term follow-up was performed in 13 patients (four from cohort 1, four from cohort 2, and five from cohort 3). No serious side effects of the therapy were observed. In two patients, malignancies were observed; however, these were reported as unrelated to the cell-based therapy. During 4 years of follow-up, the closure of fistulas was observed in all the cohort 2 patients, in 63% of cohort 1 patients, and in 43% of cohort 3 patients. No anti-HLA antibodies were detected in 24 weeks and 4 years of posttreatment follow-up. The fistula tracts became notably smaller, according to the MRI data. This study demonstrated that local application of BM-MSCs was safe and efficient for fistula closures.

A promising variation of the MSCs treatment for perianal fistulas is the use of a bioabsorbable matrix as a carrier for the cells. A Gore BioA Fistula Plug based on a bioabsorbable material was earlier tried in a multicenter study of high anal fistulas, including those in CD patients (Ommer et al. 2012). The study showed a rather high efficiency of such plugs in the treatment of fistulas; in particular, two out of four study participants with CD had complete healing in 6 months. Another development of the plug technique was its combined use with MSCs. A six-months-long study at Mayo Clinic (ClinicalTrials.gov Identifier: NCT01915927), including 12 patients, was dedicated to the treatment of fistulas with autologous ASCs deposited onto a Gore BioA Fistula Plug (Dietz et al. 2017). ASCs were harvested from the patients for autologous transplantation, and 6 weeks later the fistula plug loaded with autologous ASCs (named MSCs-MATRIX) was placed during a surgical intervention. Before the surgical procedure, ASCs were thawed and cultured on a Gore Bio-A Fistula Plug for 3–6 days in a polypropylene bioreactor. Each plug contained about 20×10^6 cells.

The primary study objective was to establish the safety and efficacy of autologous MSCs-MATRIX in the treatment of recurrent anal fistulas. The criteria for the secondary endpoint of the study were both clinical and radiographical. The former included: (1) partial response, when the drainage and symptoms reported by a patient were notably reduced, and (2) complete healing, when the drainage was not seen either without any action or with a mild pressure in 6 months after the treatment. The latter criterion included the narrowing and shortening of the fistula tract, as well as the absence of an abscess, as visualized by MRI (T2-weighted hyperintense fistula tract on a T2-weighted fast spin echo image). Quantitatively, the MRI results were presented in percent difference from the baseline and using the Van Assche perianal fistula severity score.

The applied MSCs-MATRIX plug for a fistula did not cause any serious effects during the 6 months of observation. Ten of the twelve patients (83%) in 6 months had clinical and radiographic signs of the complete healing. Thus, the bioabsorbable plugs containing MSCs proved themselves safe and efficient for chronic perianal fistulas.

A recently published systematic review and meta-analysis by Cao et al. have estimated the efficiency of stem cells (MSCs derived from the bone marrow and adipose tissue) in the treatment of CD-associated fistulas of any form (Cao et al. 2021).

In total, a total of 29 clinical studies involving 1252 patients were included in the review and analyzed. It was shown that the group of patients with CD-associated fistulas, to whom stem cells were transplanted, demonstrated a higher degree of fistula healing as compared to the placebo-treatment group (61.75% vs. 40.46%, or 2.21, 95% CI 1.19–4.11, $P < 0.05$). The group of patients who received stem cells in the dose of 3×10^7 cells/mL had a 71.0% acceleration of fistula healing vs. the groups of stem cell treatment with other doses (RR 1.3, 95% CI 0.76–2.22). The percentage of cured patients with perianal and trans-sphincteric fistulas was higher than patients with rectovaginal fistulas (77.95% vs. 76.41%). It is of interest that Crohn's Disease Activity Index (CDAI) and Perianal Disease Activity Index (PDAI) temporarily increased 1 month after stem cell–based therapy; however, they returned to the initial level 3 months after the treatment. Moreover, the incidence of side effects related to the treatment was significantly lower in the MSCs-treated group than in the placebo-treatment group (RR 0.58, 95% CI 0.30–1.14). The conducted study has shown that the application of stem cells, especially ASC, is a promising approach in the treatment of CD-associated fistulas, based on its higher efficiency and lower incidence of adverse events.

Intravenous MSCs Administration

Systemic (intravenous) administration of MSCs is used mainly in the therapy of luminal (inflammatory) forms of IBD (Ko et al. 2021).

In a randomized placebo-controlled clinical trial (ClinicalTrials.gov: NCT01221428), Hu et al. studied the safety and efficiency of hUC-MSCs in treating moderate and severe UC (Hu et al. 2016). Thirty-four UC patients were included in group I and received an MSCs infusion in addition to the basic treatment, while 36 patients in group II received saline in addition to the basic treatment. One-month post-treatment, the incidence of diffuse and deep ulcers and severe inflammatory processes in the mucosa was essentially reduced in 30 patients of group I. During the following observation, the average score of the Mayo scale and the histological score were decreased in group I, while the IBDQ score was significantly improved as compared to before the treatment and group II ($P < 0.05$). Furthermore, in comparison with group II, no apparent adverse reactions were observed after MSCs infusion in group I patients. Again, no chronic or long-lasting side effects were observed during the entire observation period. Thus the authors demonstrated that MSCs infusion was a safe and efficient strategy to treat UC.

Zhang et al. studied the safety and efficiency of hUC-MSCs to treat CD (Zhang et al. 2018). Eighty-two patients with diagnosed CD who had received the supporting steroid therapy for more than 6 months were included in the study. Forty-one patients were randomly assigned for administering four peripheral intravenous infusions of 1×10^6 hUC-MSCs/kg, one infusion per week. The patients were observed in the dynamics for up to 12 months. CDAI, Harvey-Bradshaw Index (HBI), and the dosage of corticosteroids were evaluated. As a result of the treatment, CDAI, HBI, and the dosage of corticosteroids decreased by 62.5 ± 23.2, 3.4 ± 1.2, and 4.2 ± 0.84 mg/day, respectively, in the hUC-MSCs group, and by 23.6 ± 12.4, 1.2 ± 0.58, and 1.2 ± 0.35 mg/day, respectively, as compared to the control group

($p < 0.01$, $p < 0.05$, and $p < 0.05$ for the hUC-MSCs group vs. the control, respectively). Four patients developed fever after the cell-based infusion. No serious adverse events were observed. The researchers concluded that hUC-MSCs were efficient in CD treatment, though occasionally may cause mild side effects.

In one of our studies, 22 patients with exacerbation of moderate and severe UC were treated with allogeneic BM-MSCs (Knyazev et al. 2016). The patients were divided into two groups. Patients of group I ($n = 12$), in addition to the standard anti-inflammatory therapy, received MSCs according to the following protocol: 0 (first infusion), week 1, and week 26, followed by every 6 months for the subsequent years of observation. Patients of group 2 ($n = 10$) received the standard anti-inflammatory therapy with 5-aminosalicylic acid (5-ASA) and glucocorticosteroids (GCS). Of group I patients, 58.3% had a severe UC exacerbation, and 41.7% had moderate UC exacerbation; in group II, the severe and moderate UC patients constituted 60% and 40%, respectively. Total colitis was established in 33.3% of group I patients and in 40% of group II patients; left-sided colitis was observed in 66.7% and 60% patients, respectively. The efficiency criterion for the therapy was a no-relapse course of the disease for 12 months. The UC clinical activity was estimated by the Rahmilevich score, endoscopic activity – by the Mayo score. The control over the dynamics of clinical, laboratory, and endoscopic indices was performed in 2, 6, and 12 months, then yearly for 3 years. During the first year of observations, in group I, a UC relapse occurred in two patients (16.7%), in group II – in three patients (30%). The relative risk (RR) was 0.3 (95% CI 0.08–1.36; $p = 0.2$; $\chi^2 = 1.47$). The Rahmilevich Clinical Activity Index was 3.33 ± 0.54 points in group I, 4.4 ± 1.13 points in group 2 ($p = 0.81$), the Mayo score was 3.1 ± 0.85 and 3.9 ± 1.06, respectively ($p = 0.66$). In 2 years of observation, the risk of a UC relapse in group I was three times lower than that in group 2 ($p = 0.03$). The average duration of remission in group I was 22 months, in group II – 17 months ($p = 0.049$). In 3 years of observation, the duration of remission was 22 and 20 months, respectively ($p = 0.66$). The Rahmilevich Clinical Activity Index was 4.75 ± 1.13 points in group I, 8.1 ± 1.1 points in group II ($p = 0.001$). In conclusion, the study reliably demonstrated that MSCs infusions enhanced the efficiency of anti-inflammatory therapy in patients with the acute UC.

In another study (Lazebnik et al. 2010), we used intravenous administration of allogeneic BM-MSCs to treat 39 UC patients and 11 CD patients (with the control groups of 30 UC patients and 10 CD patients). A statistically significant decrease in the indices of the clinical and morphological activities of the inflammatory process was noted after the MSCs transplantation in 39 patients with UC and in 11 patients with CD as compared to the control groups. A clinico-morphological remission occurred in 40 patients (80%). In addition, the use of MSCs made it possible to discontinue GCS in 34 out of 50 patients (68%) with the hormone-dependent and hormone-resistant forms of UC and CD and reduced the dose of prednisolone to 5 mg/day in 7 patients, with administering 5-ASA only.

Our later study estimated the efficiency of BM-MSCs therapy of CD patients receiving azathioprine (AZA) (Knyazev 2018a). The study included 34 patients with the inflammatory (luminal) CD form. Group I ($n = 15$) received an anti-inflammatory

therapy with the use of MSCs culture in combination with AZA. Group II ($n = 19$) received MSCs without AZA. The severity of attack was estimated in CDAI points. The blood serum was studied, including immunoglobulins (IgA, IgG, IgM), interleukins (IL) 1β, 4, and 10, tumor necrosis factor-α (TNF-α), interferon-γ (INF-γ), transforming growth factor-1β (TGF-1β), C-reactive protein (CRP), thrombocytes, and erythrocyte sedimentation rate (ESR) in 2, 6, and 12 months from the MSCs therapy beginning. The initial mean CDAI was 337.6 ± 17.1 points in group I and 332.7 ± 11.0 points in group II ($p = 0.3$). In both groups, a significant decrease in CDAI was noted in two and 6 months from the therapy beginning: in 2 months – to 118.9 ± 12.4 in group I and to 120.3 ± 14.1 in group II ($p = 0.7$), in 6 months – to 110.3 ± 11.1 in group I and to 114.3 ± 11.8 in group II ($p = 0.8$). In 12 months, the CDAI was 99.9 ± 10.8 in group I and 100.6 ± 12.1 in group II ($p = 0.8$); in 24 months – 133.2 ± 28.3 in group I and 120.8 ± 15.5 in group II ($p = 0.2$); in 36 months – 139.9 ± 23.4 and 141.7 ± 20.8 ($p = 0.9$) in group I and II, respectively. The IgA, IgG, and IgM levels were significantly lower in the group of patients with a more extended history of the disease and prolonged use of AZA. After the MSCs infusions, in both groups, we observed a tendency to the increase in the pro- and anti-inflammatory cytokines, with a significantly lower level of pro-inflammatory cytokines (INF-γ, TNF-α, and IL-1β) in group I. The latter indicates potentiation of the immunosuppressive effect of MSCs and AZA, which provides a more pronounced anti-inflammatory effect. Moreover, it has been demonstrated that MSCs transplantation stimulates elevation of the initially reduced concentration of immunoglobulins and cytokines in the blood serum and restoring their balance with the setting-in of the clinical remission.

Interesting results were obtained when comparing the effects of combined (local and systemic) administration of BM-MSCs, anti-cytokine therapy (infliximab, IFL) and antibiotic, and immunosuppressive therapy on the healing of CD-associated simple perianal fistulas (Knyazev 2018b). The first group of CD patients aged from 19–58 years (Me – 29; $n = 12$) received MSCs systemically according to a scheme and locally. The second group aged from 20–68 years (Me – 36, $n = 10$) received IFL according to a scheme. The third group aged from 20–62 years (Me – 28, $n = 14$) received antibiotics and immunosuppressants. According to the study results, in 12 weeks the cure of simple fistulas was noted in eight patients (66.6%) of group I, in six patients (60%) of group II, and in one patient (7.14%) of group III. In 6 months, the simple fistulas were still healed in eight patients (66.6%) of group I, in six patients (60%) of group II, and in one patient (7.14%) of group III. In 12 months, the healing was sustained in seven patients (58.3%) of group I, in six patients (60%) of group II, and in two patients (14.3%) of group III. During 24 months follow-up, the closure of fistulas was sustained in five patients (41.6%) of group I, in four patients (40%) of group II, and no patient (0%) in group III. In conclusion, it was demonstrated that combined cell and anti-cytokine therapy of CD with perianal lesions reliably provided more frequent, sustained, and prolonged closure of simple fistulas, as compared to antibiotic and immunosuppressive therapy, and reduction of the relapse incidence as well (Fig. 2).

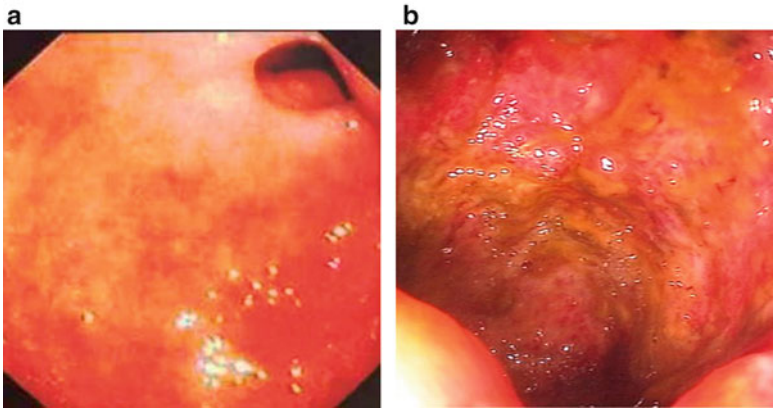

Fig. 2 Colonoscopy of a 38-year-old female patient with CD, before and after MSCs-based cell therapy [50]. (**a**) The internal opening of the fistulous tract in the lower part of the rectum ampulla before the treatment; (**b**) Twelve weeks post-treatment, healed fistula

In their recent publication, Ko et al. have provided an extensive analysis of the safety and efficiency of MSCs-based cell therapy of IBD involving on 24 studies, in 17 of which MSCs were administered locally while in the remaining 7 studies MSCs were administered systemically (Ko et al. 2021). The authors concluded that local MSCs injection-based protocol for fistulizing (extra-luminal) CD form demonstrated long-term efficiency, with the good safety level. However, regarding the efficiency of systemic MSCs infusion, the evidence was ambiguous, in the authors' opinion. They noted the marked methodological heterogeneity of the studies (first of all, due to different MSCs sources), along with the absence of facts confirming that MSCs reach the colon after an intravenous injection, and found that the safety profile was not always clearly demonstrated. At the same time, in our studies mentioned above, unequivocal pieces of evidence have been obtained for the efficiency of systemic allogeneic MSCs infusions in the IBD therapy (Lazebnik et al. 2010; Knyazev et al. 2016; Knyazev et al. 2018a, b).

In a larger and a more extensive study with a 5-year follow-up, we compared the safety profile of BM-MSCs and a standard treatment using 5-ASA, GCS, and immunosuppressive agents (Knyazev et al. 2015). The study included 103 IBD patients (56 UC patients and 47 CD patients) who received the MSCs therapy and 208 patients receiving the standard anti-inflammatory therapy (but not anti-TNF therapy). All the participants were similar in their demographic characteristics and disease features. No differences were found in the development of acute posttransfusion toxicity, infectious complications, exacerbation of chronic inflammatory diseases, serious infectious complications, malignancy, and death, with the exception of fever in some patients treated with MSCs. Thus, cell-based therapy was considered safe for the clinical practice.

Proceeding Clinical Studies

Currently (by March 2021), 14 proceeding clinical trials involving MSCs-based cell therapy for the IBD treatment have been registered at Clinicaltrials.gov (Table 2). Included in these clinical studies are autologous MSCs-based cell therapy (two studies) and allogeneic MSCs-based cell therapy (12 studies). BM-MSCs are used in seven studies, MSCs derived from the adipose tissue will be used in five studies, one study will use MSCs derived from the umbilical cord blood, while one study will use Wharton's jelly–derived cells. Ten clinical trials are dedicated to the treatment of CD, while the other four trials will focus UC treatment. Local MSCs administration protocol will be used in 12 studies while systemic administration will be used in the other two studies.

The mentioned above Mayo Clinic study of MSCs-impregnated plugs for perianal fistulas (Dietz et al. 2017) has a very promising development with young patients (Pediatric MSCs-AFP Sub-Study for Crohn's Fistula, NCT03449069). A single dose of 20 million autologous MSCs is suggested to use in five pediatric patients aged from 12–17 with CD-associated perianal fistulas. The treatment will begin with a standard therapy of infection drainage and placement of a draining seton. In 6 weeks after the placement of a draining seton, it will be removed and replaced with a fistula plug (MSCs-coated Gore Bio-A Fistula Plug). The follow-up period will be 24 months, with the treatment safety and the fistula response being monitored.

Table 2 The ongoing clinical trials on the MSCs therapy of IBD (according to clinicaltrials.gov by March, 2021)

No.	Title, ClinicalTrials.gov ID	Disease	Cell type and source	Delivery	Location
1.	Use of Mesenchymal Stem Cells in Inflammatory Bowel Disease; NCT03299413	UC	Allogeneic MSCs, Wharton's jelly	Intravenous	Cell Therapy Center, Amman, Jordan

Conclusion

The numerous open and randomized clinical studies on MSCs in the IBD therapy have unequivocally shown the safety of this approach and its potential efficiency, including the traditional treatment-resistant cases. The therapeutic action of MSCs originates from the potent immunomodulating effect resulting in the reduction of the autoimmune inflammation and stimulation of reparative processes in the intestinal mucosa. In turn, it prolongs the duration of remission, decreases the risk of relapses, and the frequency of hospital admissions. Based on the conducted clinical trials, a first medication based on allogeneic MSCs derived from the adipose tissue, Darvadstrocel (Alofisel, Takeda), has been approved in the EU for the therapy of complicated perianal fistulas in patients with luminal CD. A promising approach in the treatment of fistulizing CD is the use of biomaterials as carriers for MSCs (fistula plugs coated with MSCs). Firstly, the donor cell survival is higher on a biomaterial. Secondly, the application of autologous MSCs enhances the therapeutic effect of fistula plugs.

However, presently there is no single established optimal protocol for MSCs transplantation in IBD therapy. Additional studies are warranted on the optimal MSCs source, dosage, delivery method, and optimal treatment frequency. Despite the achievement of positive results, further preclinical and clinical studies are

required to enhance the efficiency of both local and systemic MSCs transplantation. Along with BM-MSCs and ASC, the use of MSCs from the placenta appears promising. With the techniques enhancing the efficacy of MSCs production, such as 3D culturing and application of large-volume bioreactors, it may essentially lower the price of MSCs production and make this unique therapy available for a wide circle of patients.

Abstract

The substantial worldwide burden of liver diseases and related complications is in line with the regular developments of innovative therapeutic strategies that could alleviate the number of patients requiring liver transplantation, the gold standard of care approved so far. Cell transplantation has brought new perspectives to treat those patients while keeping their own livers. The concept was simple as the transplanted cells were used to promote parenchymal regeneration and/or repairing. Isolated hepatocytes were initially applied and demonstrate the proof of concept of this approach at the clinical level. Stem cells, second-generation advanced therapy medicinal products, have provided many technological and logistical solutions to improve the wide clinical use of cell therapy. Mesenchymal stem cells were extensively developed to this end and show a significant ability to migrate in the recipient diseased liver, to differentiate in situ, and to exhibit

interesting immunomodulatory, immunosuppressive, and anti-fibrotic features. Most of those paracrine effects were mediated by potent bioactive molecules secreted by those stem cells. Extracellular vesicles represent a significant part of this secretome and display several interesting characteristics that support their development for liver-cell-free therapy. This chapter summarizes and discusses the significant advances related to cell-based and cell-free therapies currently achieved for the treatment of liver diseases. It also addresses the current challenges that extracellular vesicles-based therapy is dealing with before a future clinical use.

Introduction

The heart and the liver, together with the lungs, constitute the central trio of organs that critically manage the primary physiological activities of the human body and also control the activities of other organ systems. Any defects impacting one or the other organ can consequently be fatal.

Due to its contractile function, the heart distributes oxygenated and nutrient-rich blood to all the body tissues and organs besides preserving body temperature (Yilmaz et al. 2013). Since antiquity, much interest has been focused on heart-related research. It has been described as a hot and dry organ and a center of intelligence and vitality in the human body. The structural and functional development of the heart is critical from birth to weaning as its increased activity has to be perfectly aligned with growing locomotor activity and thermoregulation (Rakusan et al. 1984; MacLellan and Schneider 2000). Such proliferative growth will completely stop after the end of this critical period (Rumyantsev 1977; Brodsky 1990; MacLellan and Schneider 2000).

On the other hand, the liver is the largest gland in the human body and concomitantly manages a broad range of high-level physiological and complex functions such as detoxification, protein synthesis, and biochemical production, and any alteration of which significantly impacts the physiological functioning of other body organs (Gebhardt and Matz-Soja 2014). Galen A. has considered the liver the primary organ of the human body because it is the source of the veins and the

principal instrument of sanguification (Temkin and Straus 1946). Contrary to the heart, the critical period for the liver is from weaning to maturation (Wheatley 1972; Alison 1986; Brodsky 1990) primarily due to dietary changes (Wheatley 1972; Brodsky 1990; Vinogradov et al. 2001).

For many years, an established intimate interaction between both vital organs has been extensively reported as in the theoretical system of traditional Chinese and modern-day medicines (Zhang and Fang 2021). Avicenna also pointed out the functional interaction between the two vital organs in his famous book *The Canon of Medicine*.

The blood circulation between the liver and heart is primarily supporting such essential interorgan communication. Indeed, the hepatic artery and portal vein together allow 25% of cardiac output to reach the liver (Silvestre et al. 2014), while hepatic veins and the inferior vena cava are involved in the venous drainage toward the liver (Silvestre et al. 2014). Furthermore, such an interaction has also been described earlier during development (El-Hadi et al. 2020). The determination of the hepatic lineage is dependent on the pre-cardiac mesoderm. Indeed, it is well-accepted that the emerging ventral endoderm should be spatially close with the pre-cardiac splanchnic mesoderm to follow a hepatic fate (Fukuda 1979; Fukuda-Taira 1981). The invagination of the foregut will lead the ventral wall of the endoderm abutting the developing heart. The septum transversum, which gives rise to the epicardium of the heart and the diaphragm, also plays a significant role in modulating the differentiation of hepatocytes that constitute metabolically highly active cell population of the liver. The mesenchyme compartment of the septum transversum collaborates with the developing heart to modulate the hepatic lineage specification in a paracrine manner (Rossi et al. 2001).

Liver and Heart Connected and Non-connected Defects

Structural and/or functional defects of one or the other organ will seriously impact health by negatively altering the quality of life and decreasing its expectancy. Hence, scientists and clinicians have shown a great interest in consistently developing novel and improving the existing therapeutic strategies dedicated to treating any defects of organs, the heart and liver. Irrespective of the etiology of the disease, perturbation of the functionality of the cells remains the primary cause of various pathologies. Thus, replacing, repairing, and/or reactivating the functionally perturbed cells remains the primary focus of all the innovative therapies currently being developed to address the root cause of the problem and restore the normal function of these organs.

Heart diseases are also associated with partial or complete disruption of blood flow to the heart muscle (coronary heart diseases) and altered contractile function, which will also negatively impact the blood flow to other organs like the brain (cerebrovascular diseases) (Ren et al. 2021). Cardiovascular diseases are the leading cause of morbidity and death worldwide, affecting nearly 17.9 million people as reported in 2019. Indeed, acute events, including heart attack and stroke, may be induced due to perturbed blood flow toward the brain, or the heart, due to the

deposition of fatty plaques in the vessels, blood clots, or bleeding. Deaths related to heart attack and stroke represent 85% of cardiovascular diseases (WHO). Congenital or acquired structural abnormalities of the heart, including the valves or the heart muscle (rheumatic heart disease), as well as inherited disorders, are the other reported defects (Dimmeler 2011). Therefore, damaged or weakened organ will lead to heart failure that may be triggered by a heart attack or abnormally increased high blood pressure.

Cardiovascular diseases may be fatal for which no cure is available; however, they mostly remain preventable. Depending on the type and the severity of the illness, rigorous lifestyle changes, early start of proper medication according to the published guidelines, and surgery may ensure these patients have improved quality of life and live longer, with reduced hospitalization occurrences.

Akin to cardiovascular diseases, pathologies of the liver may lead to significantly altered liver functions. Such compromised liver function may happen at any age in life and may be caused by several internal and/or extraneous factors. Liver defects may be genetically inherited or acquired after viral infection, excessive alcohol consumption, and obesity. Inborn errors of liver metabolism happen as early as the neonatal stage and cause more than 300 different human diseases (Najimi, 2016). Although presenting features are specific for each genetic alteration, clinical disease manifestations include lethargy, vomiting, seizure, etc. Early diagnosis and appropriate treatment should limit critical extrahepatic impairments, including those occurring at the brain level. Therapeutic solutions applied so far include pharmacological, dietary, and surgical intervention (Najimi 2016). When conventional treatments fail to alleviate the disease symptoms, orthotropic liver transplantation (OLT) remains the gold standard and clinically most validated therapeutic approach to treat liver diseases (Wallot et al. 2002). However, donor shortage limits its widespread use worldwide (Kamath et al. 2001; Struecker et al. 2014; Najimi 2021).

Notably, there is mounting evidence in the literature that acute and chronic heart diseases might directly lead to reversible or irreversible deterioration of liver functions or vice versa (Poelzl and Auer 2015). This is well-supported by the existence of heart-liver and liver-heart axes primarily mediated by organokines specifically synthesized and secreted by the endocrine heart (16 cardiokines) and liver (Chiba et al. 2018; Jensen-Cody and Potthoff 2020; Meex and Watt 2017; Stephan and Haring 2013; Cannone et al. 2019). This means that the heart can modulate the liver metabolic functions, while heart diseases significantly affect the liver, an observation made since the nineteenth century (Komatsu et al. 2019). For example, heat failure may induce hypoxic hepatitis, and atrial fibrillation (arrhythmia) obviously induces hyper-coagulation. Heart failure, a general consequence of the cardiac pump dysfunction at the systolic (reduced contractility) or diastolic (altered relaxation and consequent ventricular filling) levels, is associated with severe hepatic congestion, which induces acute hepatocellular necrosis and raises liver enzyme blood concentrations, and direct or indirect serum bilirubin elevation.

The diseases of the liver also affect the functional status of the heart, including the role of nonalcoholic fatty liver disease in promoting the development of cardiovascular diseases (i.e., coronary artery disease, structural myocardial

alterations, and cardiac arrhythmias). Still, the pathophysiological mechanisms involved therein are not yet deciphered, although insulin resistance, visceral adiposity, subclinical generalized inflammation, dyslipidemia, and oxidative stress are potentially related pathways (Tana et al. 2019). End-stage liver diseases are also implicated in developing cirrhotic cardiomyopathies. In an animal model of liver cirrhosis, an abnormally increased expression of collagen isoforms was reported in the ventricular myocardial tissue that led to a raised cardiac stiffness and diastolic dysfunction (Glenn et al. 2011). Hence, sustained hemodynamic variations are behind both bridging fibrosis and cardiac cirrhosis. The consequent dysregulation of hepatic functions will lead to the impairment of the metabolism of cardiovascular drugs and potential, which can lead to an undesirable toxicity.

The functional liver-heart connection was also reported in genetic diseases. The best example is Alagille syndrome, a genetic disorder caused by abnormal bile ducts, in which subsequent perturbed bile flow induces significant scarring that prevents the liver from eliminating bloodstream wastes. Alagille syndrome is interestingly linked to an impaired blood flow from the heart to the lungs (pulmonic stenosis) (Tretter and McElhinney 2018).

The heart-liver interorgan connection is supported by the nature of the major risk factors of the heart disease (i.e., alcohol intake, unhealthy diet, etc.), whose processing and metabolism are managed primarily by the liver. Inversely, perturbation in the liver functionality (like raised blood lipids, obesity) will influence the quality of heart activity. Therefore, broadening our knowledge on both heart and liver physiopathology is mandatory for the design and dosage of preventive and therapeutic strategies dedicated to one or the other organ.

Status on Cell-Based Therapy for Liver Diseases

Although OLT remains the gold standard therapeutic option for treating liver diseases, the significantly increased donor shortage and the consequently enhanced mortality due to long waiting time limit its application worldwide (Kamath et al. 2001; Struecker et al. 2014; Najimi 2021). The more extended living grafts are unfortunately associated with posttransplantation complications and morbidity, including long-term exposure to high levels of immunosuppression regimens, deficits, or delays in development (Moreno and Berenguer 2006). This has prompted the development of innovative strategies that may restore liver function, especially for indications where liver transplantation is not the ultimate treatment, or at least support the patient while waiting for a graft to be transplanted. From the early experiment involving hepatocyte transplantation in a rat model of Crigler-Najjar syndrome by Groth et al. (1977), cell-based therapy has progressed a long way to involve stem cell and progenitor cell engraftment for liver diseases treatment (Sun et al. 2014). The cells are generally infused as a cell suspension via the vascular system without compromising or alteration of the structural integrity of the diseased liver (Najimi et al. 2016; Forbes et al. 2015). The portal vein system remains the optimal injection site from which the suspended cell will be delivered

(Regmi et al. 2019). The aim is to allow transplanted cells to reach the liver parenchyma, where the transplanted cells can function after engraftment as well as in a paracrine manner (Iansante et al. 2018). Cell-based therapy preserves the recipient's liver, and it may be repeatedly applied with no significant complications (Wang et al. 2019).

The proof of concept of cell-based therapy for treating liver diseases has been demonstrated by using hepatocytes isolated from cadaveric donors (Ibars et al. 2016). Ibars and colleagues at Hepatic Cell Therapy Unit, Valencia, have shared their experience of working with five adults and four children with inborn metabolic diseases and have reported hepatocyte transplantation as a safe and viable option to generate metabolically functioning hepatocyte post engraftment. The transplanted hepatocytes were shown to display an ability to migrate from the injection site, replace the dead cells in the recipient hepatic parenchyma, and function in situ leading to vital restoration of deficient metabolic defects. Those data have also been confirmed by using stem/progenitor cells of intrahepatic and extrahepatic origins that can be expanded and differentiated into hepatocyte-like cells in vitro before transplantation.

Some of the important parameters that significantly impact the efficacy and prognosis after cell-based liver therapy include the quality of the source organ from which the cells will be isolated, the quality and yield of cell suspension post-isolation and expansion, or post-cryopreservation and thawing, as well as the nature and severity of the targeted disease, etc. (Zhu et al. 2020). Understanding of these impacting factors will not only streamline, optimize, and standardize the protocols, but it will have practical value in terms of the fast-emerging concept of individualized treatment of the patients.

Experimental Animal Studies

Cell-based therapy dedicated to treating liver diseases has been firstly assessed on surgical animal models in which liver regeneration can be physiologically induced like after partial and total hepatectomy (Alwahsh et al. 2018; Forbes et al. 2015). Animal models of inherited metabolic diseases with single specific liver enzymatic defects have also been widely used. Mostly genetically modified, those animal models exhibit significant liver damage and hepatocyte structural and functional perturbations. These conditions provide a high advantage for transplanted healthy cells to survive, engraft, and proliferate in situ. The best example is the mouse model overexpressing the urokinase-type plasminogen activator gene within the liver as albumin promoter drove its expression. This experimental mouse model displays a severe hepatic injury, while transplanted hepatocytes are able to effectively reconstitute the whole liver mass (Sandgren et al. 1991). Crossed with the (SCID = Severe Combined Immunodeficient) mice , those genetically modified animal models did allow the deep study of human cells behavior after transplantation like in fumarylacetoacetate hydrolase knockout *Fah*−/−, *Rag2*−/−*Il2rg*−/− mice (Ohshita and Tateno 2017; He et al. 2010).

Animal models in which liver diseases were pharmacologically induced and mimicked did allow the evaluation of cell-based therapy efficacy in acquired defect settings, i.e., nonalcoholic steatohepatitis, fibrosis/cirrhosis, etc. (Al-wahsh et al. 2018), but also under acute liver failure conditions like by using acetaminophen (APAP). Although animal models have demonstrated the potential of transplanted healthy cells to integrate into recipient's livers and to correct hepatic defects and even animal improved rate of survival, the higher number of combinations involving animal models and types of transplanted cells is not yet supporting the establishment of a standardized application of cell-based therapy and its translation to the clinic. Accordingly, preclinical models deeply recapitulating human diseases at the cellular and molecular levels are still lacking although trials using large transgenic or genetically deficient animals, i.e., macaques and pigs, have been reported. On the same note, despite the use of stem cells from different tissue sources, there is an obvious lack of consensus among the stem cell researchers about the ideal cell choice (Gounder et al. 2017). From among the different cell types, mesenchymal stem cells have been extensively studied for cell-based therapy of liver diseases and have progressed to the clinical phase studies more than any other cell type (de Miguel et al. 2019).

Clinical Studies

Encouraging preclinical data of liver cell therapy have supported the exploration of its usefulness at the clinical level, primarily when no other therapeutic option can be applied. This also has been supported by the reduced invasiveness of cell delivery intervention, the repeatability of cell infusions, and safety posttransplantation (Najimi et al. 2016). After successfully recovering good quality and significantly high yield of clinically approved human liver cell suspensions, hepatocyte transplantation, under the proof of concept and first in man configurations, has been applied in several centers worldwide, and data from patients with different etiologies have been reported. Indeed, the durability of the effect posttransplantation as shown on several patients with inborn errors of liver metabolism was quite variable and dependent on several factors including the yield of cells infused, the type of the analyses performed, as well as the severity of the disease. The lack of appropriate clinical trials reporting deep investigations on safety and efficacy (only very few were reported so far) makes it very difficult to formulate any conclusions on the definitive clinical use of isolated hepatocytes. Furthermore, although hepatocyte transplantation did show its ability to be used at least as a bridge to transplantation, still limitations are hampering the rapid clinical development of such therapeutic option, including the significant scarcity of good-quality raw material and the inability to long-term preserve the isolated cells due to their poor ability to survive and proliferate in vitro as well as post-cryopreservation/thawing.

Recent advances in studying stem/progenitor cells have highlighted their potential in providing several solutions to the limitations encountered when isolated hepatocytes were used, such as self-renewal, plasticity, and paracrine potency. Stem/progenitor cells have been looked for and isolated from different tissues and organs at any age including the liver itself. Although with exciting preclinical results

like those reported on embryonic stem cells (ESCs) (Woo et al. 2012; Asahina et al. 2006) and FIRST MENTIONED HERE human-induced pluripotent stem cells (iPSCs) (Corbett and Duncan 2019; Sekine et al. 2020; Takeishi et al. 2020), only MSCs are considered one of the most well-studied and extensively characterized cell types currently applied for clinical evaluation on liver diseases (Luan et al. 2021; Zhang et al. 2020). Their use in the humans has also been supported by the excellent safety profile and tolerance reported in the translational experimental studies and the ongoing trials. Fifty-nine clinical studies are registered so far in which both allogeneic and autologous MSCs isolated from different tissues were used to target various acute and chronic liver defects. A recently published pooled analysis of 39 published studies involving MSCs for various liver defects has reported that compared with the conventional treatment, MSC therapy significantly improves liver function in terms of the model of end-stage liver disease score; albumin, alanine aminotransferase, and total bilirubin levels; and prothrombin time, up to 6 months after administration (Zhao et al. 2018). Interestingly, subgroup analysis showed that single injection via hepatic artery of MSCs was more effective than peripheral intravenous injections. Moreover, bone marrow-derived MSCs were more effective than umbilical cord-derived MSCs. Recent technological advances did allow knowing and learning more on the optimal conditions for banking, large-scale production and cryopreservation, stability of MSCs, and treatment methodology/approach, which would ultimately lead to provide the best-quality cell suspension to the patient.

Liver cells of mesenchymal phenotype and stem/progenitor profile have also been described in both mice and humans. While directly isolated from mouse livers, those cells were obtained after primary culture of human liver parenchymal cell suspensions and displayed variable levels of plasticity (Herrera et al. 2006; Najimi et al. 2007; El-Kehdy et al. 2016). Those cells isolated from the adult human liver are currently developed under industrial settings (GMP large-scale expansion) to be clinically tested as advanced therapy medicinal products to treat liver diseases. For instance, HepaStem® has been successfully used in patients with urea cycle defects and Crigler-Najjar syndrome in a phase I/II clinical study in Europe aiming at evaluating its safety and preliminary efficacy at 6 and 12 months post-infusion. In parallel to their safety profile, transplantation of those cells was associated with de novo urea synthesis in most urea cycle diseased patients. It also decreased bilirubin level only in some of the Crigler-Najjar patients (Smets et al. 2019). Both metabolic effects were reported at 6 months post-HepaStem® transplantation. Advances in understanding the behavior of MSCs in targeting liver diseases have also highlighted their potent paracrine features. Indeed, this has been revealed by both in vitro analyses in which the secretome of those cells was shown to contain several bioactive molecules and in vivo, in which many described positive effects were not associated with the engraftment of transplanted cells in the recipients' livers. HepaStem has been recently applied on cirrhotic patients with acute on chronic liver failure (ACLF) or with acute decompensation at risk of developing ACLF and has been shown to significantly improve the altered liver functions in parallel to systemic inflammation and survival rate of the transplanted patients (Nevens et al. 2021).

Cell-Free Therapy Approaches for the Liver

Thanks to the information recovered from advanced clinical trials, it becomes more consistent that the beneficial clinical effects of transplanted cells were more related to their paracrine potential and aligned with their reported low engraftment (Haider and Aziz 2017). Other lessons learned from those clinical trials are the cell expansion culture timing and costs, the high procoagulant activity of the transplanted cells, their entrapment in the lung tissue when peripherally infused which may reduce their potency, and the cytogenetic abnormalities that may happen during large-scale production and/or long-term culture in vitro that may render the cell tumorigenic post engraftment (Prockop et al. 2010; Nikitina et al. 2018). On the same note, maintenance of the quality of the cell preparation and avoidance of batch-to-batch variations remains one of the major hurdles to achieve optimal prognosis (Haider, 2018). Similarly, survival of the donor cells post engraftment significantly reduces the feasibility, although various strategies, such as transient immunosuppression and preconditioning of donor cells, have been adopted successfully (Haider et al. 2004, Xiao et al. 2004, Haider and Ashraf 2012).

The fast-emerging strategy of cell-free therapy using both soluble and particulate components of stem cell paracrine secretions has given encouraging data which is comparable with the cell-based therapy (Haider and Aslam 2018). Extracellular vesicles (EVs), one of the insoluble components of cellular paracrine secretion, have been considered to be a significant component of the MSCs' secretome that could be delivered precisely and that could have influential paracrine and endocrine contribution toward the intercellular communications (Raposo and Stahl 2019; Devaraj et al. 2021). Significant technological advancements have led to the isolation and purification of these nano-sized entities from the soluble factors of the cell secretome, and they have been extensively characterized for yield and contents – under different physiopathological conditions (Borgovan et al. 2019). EVs have also been proposed to discriminate between stem cell populations depending upon their tissue of origin, which will help in categorizing and characterizing them to reduce batch-to-batch variation in their preparation (Hur et al. 2020).

Accordingly, their potential use as a therapeutic alternative to cell transplantation may bring interesting solutions for easy and widespread clinical use. Indeed, infusion of EVs could be safer as many cell-related posttransplantation reactions, like procoagulant activity, thrombogenic effect, ectopic cell migration, and differentiation, might not be considered. The simple recovery and purification of the cell supernatant containing EVs will make the production process much cheaper while following the same production and storage paths as the small molecules. Furthermore, the structural aspects of the EVs are essential to protect the cargo contents for a smooth "physiological" transfer to the target cells after fusion with the cell membrane (Haider and Aramini 2020). This latter feature is quite interesting as it will allow the manipulation of their internal and/or membranous contents for targeted tissue and material delivery.

The diverse parenchymal and non-parenchymal cell composition of the liver should be perfectly aligned with a high level of coordinated intercellular

communication to ensure the complex vital functions that such organ manages (Devaraj et al. 2021). EVs secreted by liver cells may be critical tools for the establishment of a fine-tuned crosstalk between neighboring and distant cells at the physiological as well as pathological levels. The content of EVs has been reported to be involved in the alteration of acute and chronic immune-inflammatory responses associated with several liver diseases, including those chemically or virally induced. Such alteration is due to a perturbed communication between the various liver cell types and between the liver and other organs (Babuta and Szabo 2021). As shown in the normal liver, quiescent hepatic stellate cells (HSCs) can modulate parenchymal regeneration via cell migration and immune responses and facilitate tissue remodeling after damage. Therefore, the EVs of each liver cell type may adapt the content and yield of their cargo depending on the liver defect. Many consider the circulating pools of such entities as noninvasive diagnosis biomarkers and exploit them as potential targets for developing innovative treatments.

An increasing number of preclinical studies dealing with evaluating the therapeutic potential of EVs in liver diseases are noticed. Diverse strategies, using both native and modified EVs, have been investigated to target many aspects of liver defects, including inflammation (inhibition of infiltrating cells or potentiation of the intrahepatic immune response), tissue regeneration (inhibiting the injury and/or promoting hepatocyte proliferation), viral intrahepatic infection, fibrosis/cirrhosis, and liver cancer (Driscoll et al. 2021). Transplantation of EVs is associated with an improvement of liver defects. It has confirmed the multiple modes of action of these entities, including inhibition of inflammation, hepatocyte apoptosis, autophagy and HSCs activation, the fundamental cell event behind the initiation, and sustaining of liver fibrosis (Lee et al. 2021).

In acute liver failure or injury, the therapeutic effects of EVs have been studied posttransplantation in different appropriate animal models. MSCs derived from bone marrow, umbilical cord, and adipose tissue were mainly used and did show significant mitigation of inflammation, autophagy, and apoptosis in parallel to stimulation of hepatocyte proliferation and activation of the adaptive immune system (Jin et al. 2018; Jiao et al. 2019; Haga et al. 2017; Yao et al. 2019). Such modifications have significantly attenuated the levels of circulating inflammatory markers and the necrotic parenchymal areas and accordingly restored the altered liver functions. Those data have been associated with the presence of noncoding RNAs, like H19, miR-17, and miR-455-3p.

In the ischemia/reperfusion animal model, EVs from MSCs fuse with the membranes of the hepatocytes and stimulate their proliferation, which further significantly decreases transaminases levels and histopathological scores (Du et al. 2017). Transplantation of exosomes and their migration to the liver are followed by a significant inhibition of the ALF induced by D-GalN/LPS treatment in mice due to an inhibition of hepatic mononuclear cells and cell apoptosis (Chen et al. 2017). In addition, anti-fibrotic effects of EVs have been reported posttransplantation in the widely used CCl4-treated animal model as demonstrated by the inhibition of epithelial-to-mesenchymal transition, intrahepatic inflammation, and hepatocyte apoptosis (Li et al. 2013; Devaraj et al. 2021).

iPSCs have also been used to generate MSCs as they display higher survival and proliferation than their adult stem cell counterparts (La Greca et al. 2018). When transplanted in ALF animal models, EVs from those cells display the same therapeutic effects as restoration of normal transaminases levels, thanks to significant inhibition of hepatocellular necrosis and sinusoidal congestion (Povero et al., 2019; Chen et al., 2017). EVs from the iPSCs-derived MSCs effectively protect hepatocytes and stimulate their proliferation via the sphingosine-1-phosphate pathway (Du et al. 2017). In chronic liver disease settings, EVs from MSCs of adult (bone marrow, umbilical cord, adipose tissue, and amniotic fluid) or embryonic origin (ESC, iPSCs) can improve fibrosis as experimentally shown both in vitro and in vivo (Povero et al. 2019; Li et al. 2013; Rong et al. 2019; Mardpour et al. 2018). Several features have improved following EVs transplantation, including the expression of ECM-specific disorganization markers, of activated HSCs and infiltrated immune cells, and hepatocyte survival. So far, EVs-derived MSCs from the bone marrow, adipose tissue, and liver were studied under Hepatocellular carcinoma (HCC) settings both in vitro and in vivo (Weng et al. 2021; Bruno et al. 2013; Ko et al. 2015; Webber et al. 2015; Fonsato et al. 2018). The data reported the potential of those EVs to decrease the expression of HCC markers and inflammatory cytokines as well as the number of altered parenchymal cells (both by inducing apoptosis and decreasing proliferation) which leads to an improvement of liver functions.

Furthermore, an increase in the level and activity of circulating NKT cells and their recruitment to the diseased liver have been reported (Lou et al. 2015; Ko et al. 2015). Both coding and noncoding RNAs are implicated in those reported effects (Fonsato et al., 2018). This has led to assess the efficiency of EVs for which the cargo was modified to improve their migration (membrane engineering) as well as the targeted delivery (content engineering) of specific molecules related to the tissue and disease configurations (Tan et al. 2013; Lai et al. 2013; Ishiguro et al. 2020; Psaraki et al. 2021). Advances that may arise from studies using naïve EVs should help in addressing the molecules/pathways that would improve the therapeutic value of these entities. Accordingly, additional information is mandatory to know more on the appropriate EV doses to be applied; their quality, safety, potency; and durability of the effects posttransplantation, with the vision to implement their use at the clinical level.

Diagnostic and Therapeutic Role of EVs in Liver Diseases

Intercellular communication is not only crucial for maintaining liver homeostasis but is actively involved in initiating the disease and sustaining its progression. Under pathological conditions, the yield, the size, and the content of EVs are modulated depending on the disease severity (structural intra- and extra-organ alterations) and chronicity. Therefore, the circulating EVs will reach the target cells to deliver their encapsulated content after membrane fusion and/or to modulate the activity of specific signaling pathways consequently to membranous

protein-protein interactions. The detection of EVs in blood or other fluid samples and their longer half-life support their development as a very attractive diagnostic tool that could deliver important cellular and molecular information to the diseased organ (Newman et al. 2020). Although circulating noncoding RNAs like miRNAs are reported to be concentrated in EVs, the diagnostic potential of EVs in liver diseases is still not well demonstrated due to the very limited data available so far. Ongoing investigations should potentially lead to improve (i) the selection and purity of hepatic EVs derived from the normal and diseased livers mainly at the cellular level and (ii) the discovery of altered biomarkers specific to each hepatic defect and in fine to address a highly sensitive diagnosis of those different and complex liver defects. While the simplest view of one EV type-one disease is difficultly supported, one could expect several layers of complex combination as for instance, of EVs and/or specific contents. Therefore, extensive investigations are mandatory to address several still raised questions before EVs can be applied at the clinical level, as for instance, the determination of (i) the best source of EVs to be applied for each of liver disease type, (ii) the optimal production process, and (iii) the efficient dose of EVs (fresh, cryopreserved, single and/or repeated injection, etc.) to be infused for each specific liver disease indication. Multi-omics analyses may certainly help in compiling and exploiting information related to their biogenesis, cargo, and function (Chitoiu et al. 2020).

Conclusion and Future Perspectives

Although OLT remains the gold standard therapeutic option to treat liver diseases, many patients do not have access to it. Furthermore, the waiting time for a graft often increases, while long-term posttransplantation follow-up highlights significant liver graft hepatitis and fibrosis posttransplantation as reported in the pediatric population (Kelly et al. 2016). Liver cell and stem cell transplantation has been developed as an alternative to OLT or a bridge to transplantation. Several successes and achievements of cell-based therapy have been reported both at the preclinical and clinical levels. Cell-based therapy was initially proposed to provide healthy and highly functional cells that will participate in repairing and regenerating the recipient's diseased liver. Advances in manipulating the trialed stem cells and evaluating their effects post-transplantation have instead revealed their potent paracrine effects in mitigating liver inflammation, fibrosis, and cancer. Thus, cell-free therapy is positioned as an alternative therapeutic approach able to overcome many limitations reported with cell-based therapy. The effects observed with EVs for the MSCs field are equal to those reported with MSC-based therapies. Still, extensive knowledge and investigations are mandatory before this approach can be fully considered at the clinical level. Indeed, more efforts are needed to understand the EVs-based communication between same and different cells under normal and pathological conditions knowing the complex cell composition of the liver. This means that we have to learn more about the identity of the bioactive molecules involved as well as on their respective

mode(s) of action (direct and/or indirect) both at the cellular and molecular levels, knowing the heterogeneity of cells and factors causing liver defects. Once addressed, the logistical aspect is another milestone to achieve, in terms of cell material used for large-scale production, considering the heterogeneous aspect of MSC cultures, standardized characterization and quantification, and potency evaluation. At the in vivo level, much information is mandatory to determine the optimal formulation (fresh and/or cryopreserved), route of administration, and injection dose that should be aligned with an optimal safety profile of the transplanted patients.

cardiomyocytes will decrease, the number of senescent cells will increase, the cardiac tissue will become thicker, and the contractility will diminish. Besides, heart diseases such as myocardial infarction and heart failure also will reduce the functionality of the heart. Currently, heart disease is normally treated with medication and surgery. In severe conditions, the patient will be recommended to opt for a heart transplant. However, medication and surgery cannot reverse the pathological changes in the heart, and it is very difficult to find a suitable heart for transplantation. Stem cell therapy offers a glimpse of hope to these patients as the cells can stimulate the proliferation of cardiac progenitor cells and cardiomyocytes as well as secrete the paracrine factors which modulate the tissue environment to promote regeneration. Even though stem cells, e.g., mesenchymal stem cells (MSCs) and embryonic stem cells (ESCs), have been shown to differentiate into cardiomyocytes in vitro, however, there is a lack of evidence to prove that the transplanted cells can reconstitute the myocardium in vivo. The number of clinical trials using stem cells to treat heart disease is still very limited. Results from these trials suggested that stem cell therapy is safe and provides certain benefits to the patients. Nonetheless, there is still a long way to go for the researchers to identify the ideal cell source and therapy protocol to achieve a greater therapeutic effect.

Introduction

A lively heart is vital to keep the body healthy and to maintain the body's homeostasis. The heart, together with the vascular system, is responsible for delivering blood throughout the body. Nowadays, the world population is growing older rapidly as people live longer due to better healthcare. Aging leads to progressive

changes in heart structure and deterioration of heart function**.** As a result, aging is the dominant risk factor for the heart disease. The incidence and prevalence of heart disease increase with age, and heart disease is one of the leading causes of death worldwide (Yazdanyar and Newman 2009).

Proper management of the aging heart and prompt treatment of heart disease are vital to extend the healthy lifespan of older adults and patients with heart disease, respectively. Unfortunately, there is no definitive aging heart therapy. On the same note, pharmacological and surgical interventions can achieve limited results in mending the ailing heart as these therapies primarily help to control the signs and symptoms, but fail to reverse the pathological changes and structural damage. The long waiting list is hindering the patients with advanced heart disease from getting a heart transplant.

Despite a significant reduction in cardiovascular mortality over the last decades, especially in the developed countries, cardiovascular disease remains the leading cause of death in many parts of the world (Mc Namara et al. 2019). Thus, stem cell therapists have focused on the developing novel cell-based treatment strategy for a wide range of heart diseases. Mesenchymal stem cells (MSCs) and mononuclear cells isolated from the bone marrow and cord blood are more commonly used to treat heart disease. In fewer studies, cardiac stem cells (CSCs), embryonic stem cell (ESC)-derived cardiac progenitor cells, and skeletal myoblasts also have been trialed to treat heart disease.

Stem cells modulate cardiac regeneration primarily through paracrine signaling (Gallina et al. 2015). The stem cell secretome consists of two major components, i.e., soluble proteins and extracellular vesicles (Maacha et al. 2020). However, there is inadequate evidence showing that the transplanted cells differentiate into cardiomyocytes to ameliorate the ailing heart, as indicated by the poor survival of transplanted cells (Abdelwahid et al. 2016). Furthermore, the wound environment with intense inflammation, hypoxic, and nutrient deprivation is hostile to the transplanted cells which are not prepared for such condition.

In this book chapter, we have discussed the effects of aging on the heart, the pathophysiology of heart diseases, and the contemporary treatment strategies with emphasis on the clinical evidence of using stem cell therapy to repair the damaged heart.

Aging of the Heart

Aging leads to progressive decline in body physiological function, eventually causing various diseases and health complications. For example, aging significantly affects the health of the heart, causing more inferior cardiac function and contributing to the development of heart failure and atrial fibrillation (AF) (Strait and Lakatta 2012; Steenman et al. 2017). Characteristics of the aging heart include alteration in left ventricular diastolic function, left ventricular hypertrophy, reduction of left ventricular systolic reserve, reduction of myocardial contractility, decrease in

maximum heart rate, and decrease in maximum left ventricular ejection fraction (LVEF) (Steenman and Lande 2017; Christou and Seals 2008; Chiao and Rabinovitch 2015).

Reduction of left ventricular diastolic filling rate is the first physiological modification observed at the early stage of aging. The reduction of left ventricular diastolic filling rate is compensated by increasing the atrial contraction in order to sustain the stroke volume and to maintain the LVEF (Fleg and Strait 2012). An increase in atrial contraction is associated with atrial hypertrophy and dilation. In addition, the adrenergic signaling will change to reduce the maximum heart rate to permit a longer filling time (Strait and Lakatta 2012). However, left ventricular contractility and response to β-adrenergic receptor activation reduced with age (Lakatta and Levy 2003). Hence, the myocardial mass will increase to compensate for the reduction in cardiac output. Ventricular hypertrophy is the result of an increase in the size and number of cardiomyocytes. Ventricular hypertrophy is reversible when caused by physiological changes such as in healthy athletes and pregnant women or irreversible when the modification is induced by pathology such as heart disease (Marketou et al. 2016). Although ventricular hypertrophy may provide temporary improvement in cardiac output, however, it will lead to deterioration of cardiac function, i.e., defective ventricular relaxation and filling and even heart failure, in the long term (Tardiff 2006).

The heart undergoes complex changes at the cellular and molecular level during aging. With age, there will be alteration in cellular composition resulting in a reduction of cardiomyocyte population as more cells undergo apoptosis, necrosis, and a decrease in CSC reservoir (Daniele et al. 2004; Chiong et al. 2011). These are due to the aging cardiomyocytes that are more susceptible to stress, including oxidative stress. Therefore, an increase in reactive oxygen species (ROS) production due to aging often results in stimulation of cardiomyocyte death. During cardiomyocyte necrosis, various toxic cellular components that can affect the survival of neighboring cardiomyocytes are released (North and Sinclair 2012). The remaining cardiomyocytes will become hypertrophic to compensate for the reduction in cell number. In addition, there will be changes in the collagen composition with a shift toward type I collagen and increased tissue fibrosis. Fibrotic tissue is linked with poorer myocardial contractility. The accumulation of amyloid protein in the aging myocardium is also related to reducing myocardial contractility (Steenman and Lande 2017).

Cardiac aging is also associated with mitochondrial dysfunction. Tocchi et al. have mentioned that aging mitochondria have inferior functionality, higher production of ROS, higher mitochondrial DNA mutation, higher respiratory chain dysfunction, dysregulation of mitochondrial fission and fusion, as well as suppressed mitophagy (Tocchi et al. 2015). All these lead to the accumulation of dysfunctional mitochondria. Furthermore, dysregulation in calcium signaling, neurohormonal signaling, and nutrient and growth signaling are also related to the impaired cardiac function (Steenman and Lande 2017; Chiao and Rabinovitch 2015). Figure 1 shows the changes in the aging heart at the cellular and tissue level.

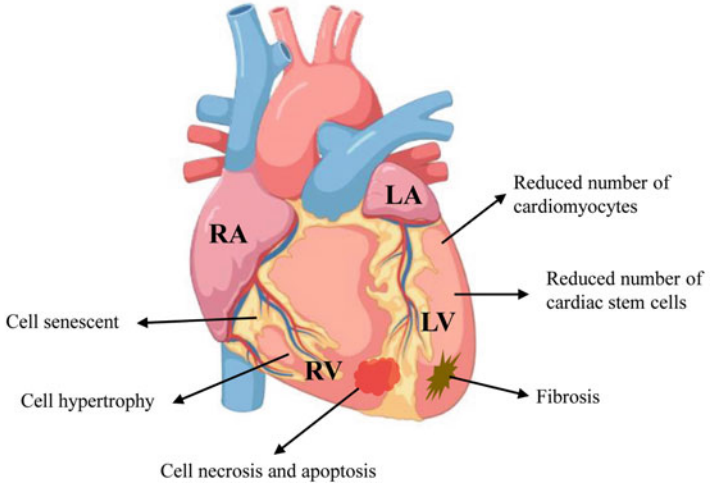

Fig. 1 Changes in aging heart at the cellular and tissue level. With age, the cardiomyocytes will undergo senescence, and the number of cardiomyocytes will reduce as the number of apoptotic and necrotic cells increases. The heart tissue also will become hypertrophic, ischemic, and fibrotic. These pathophysiological changes to the heart tissue are closely related to the changes in aging vascular system whereby the lumen is narrowed by the atherosclerotic plague, leading to poorer perfusion to the heart tissue

Heart Disease

Heart disease is prevalent and is one of the leading causes of death worldwide. There are many types of heart disease, e.g., myocardial infarction (MI) and heart failure, which affect a different part of the organ. MI, commonly known as heart attack, is caused by a sudden disruption in blood supply to the myocardium. The lack of oxygen leads to irreversible damage to the cardiomyocytes. At the cellular and tissue levels, prolonged ischemia causes cardiomyocyte apoptosis and necrosis, inflammation, loss of cellular glycogen, mitochondrial dysfunction, myofibril relaxation, and sarcolemmal disruption. Most of the affected cardiomyocyte cell death took place within the first 24 h of injury. Tissue inflammation following the injury will lead to the second wave of cardiomyocyte cell death. The human heart has inadequate regenerative capacity. Thus, the infarcted tissue will be replaced with fibrous scar tissue. Replacement of functional myocardium with nonfunctional fibrotic scar alters the cardiac contraction and impulse conduction and subsequently increases the prevalence of diastolic and systolic dysfunction, arrhythmia, and heart failure (Thygesen et al. 2018; Frangogiannis 2015).

Heart failure is a clinical syndrome characterized by the inability of the heart to pump sufficient blood to meet the body's metabolic demand. Many factors, including MI, can cause heart failure. Other etiologies include cardiomyopathies, valvular disease, hypertension, diabetes mellitus, myocarditis, infections, systemic toxins,

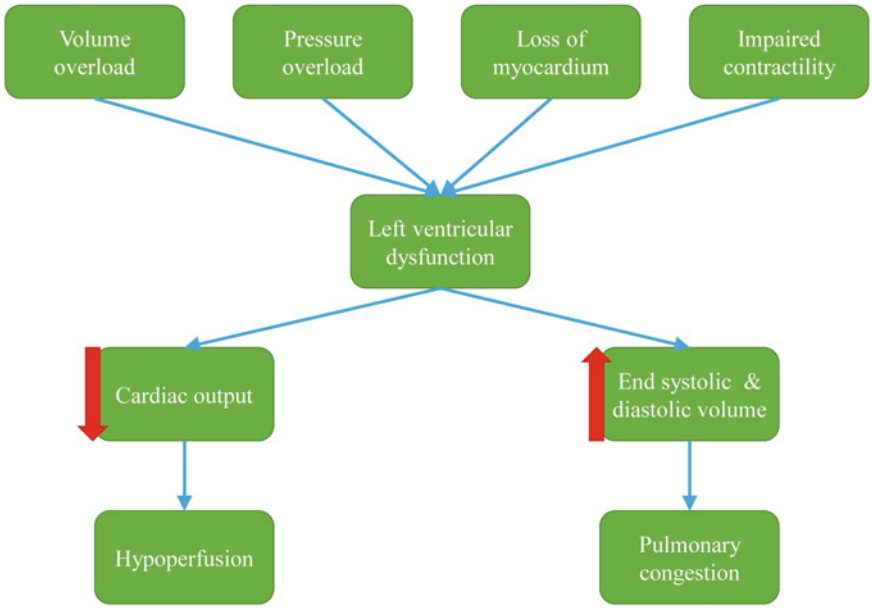

Fig. 2 Pathophysiology of aged and diseased heart. Aging and heart disease will lead to volume overload, pressure overload, loss of myocardium, and reduced contractility which in turn cause left ventricular dysfunction. Left ventricular dysfunction will reduce cardiac output and increase end-systolic and end-diastolic volume which eventually resulted in hypoperfusion and pulmonary congestion, respectively

and cardiotoxic drugs. Generally, the initial insult induced a destructive cycle that causes metabolic and morphological changes in the remaining cardiomyocytes. These cellular changes progressively lead to structural remodeling of the ventricle. Although remodeling initially occurs as a compensation mechanism or adaptive response to sustain cardiac performance, however, over time, the response becomes counterproductive and leads to ultrastructure abnormality, e.g., including hypertrophy and fibrosis, finally causing heart failure. In addition, with time, diastolic dysfunction and subsequent systolic dysfunction resulted in an enlarged, dilated, and low contracting ventricle (Kemp and Conte 2012; Johnson 2014). Figure 2 shows the pathophysiology of an aged and diseased heart.

Conventional Therapies for Heart Disease

Nowadays, treatment for heart disease depends on the type, etiology, symptoms, and severity of the disease. The treatment of ischemic heart disease starts from lifestyle modifications such as regular exercise, smoking cessation, and lipid control. Antiplatelet and antianginal medications are routinely used in those with established diagnosis via coronary angiogram or CT imaging of the heart. Ultimately such a

domain might require percutaneous coronary intervention (stenting) or coronary artery bypass surgery to tackle the blocked native coronary vessels (Dababneh and Goldstein 2020).

Structural heart disease and valvular heart disease deliberately warranted surgical intervention. The progressive valve defect can lead to ventricular dilatation and subsequently dilated cardiomyopathy because of the lengthening and destruction of muscle fibers (Frank-Starling law) (Epstein and Davis 2003). Therefore, cardiothoracic surgeon referral is paramount to address the underlying valve pathology, and valve repair or replacement is mandatory to delineate the structural defect.

Another subgroup of patients commonly seen is those with heart failure due to varying pathology. These patients require medications, e.g., angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), beta-blockers, diuretics, aldosterone antagonists, vasodilators, digoxin, I(f) inhibitor, and angiotensin receptor-neprilysin inhibitor, to control the disease progression and achieve symptom control (Shah et al. 2017). Surgery might have limited benefits for these patients. However, advancements in technologies, such as left ventricular assist devices (LVAD), provide certain advantages in controlling heart failure (Hunt and Ross 2002; Birati and Jessup 2015). Eventually, a heart transplant is the only chance for them. However, there is a critical shortage of donor's hearts worldwide to meet the current demand for heart transplantation.

Mechanisms of Action of Stem Cells in Restoring the Heart Function

Stem cells are multipotent cells that reside in embryos and adult tissues. Stem cells are categorized either by their potency (e.g., totipotent, pluripotent, multipotent, or unipotent) or their source of origin (e.g., embryo, bone marrow, adipose tissue, Wharton's jelly, etc.) (Los et al. 2018). The most widely studied stem cells are MSCs that could be isolated from many adult tissues, e.g., bone marrow, adipose tissue, peripheral blood, skin, and heart. Researchers considered MSCs as the most attractive stem cells because it is easily obtainable from many adult tissues and can be expanded with ease in the laboratory to fetch many cells (Ding et al. 2011; Haider 2018). According to the characterization guideline proposed by the International Society for Cell & Gene Therapy (ISCT), MSCs are cells that (i) are plastic adherent in vitro; (ii) are more than 95% positive of CD105, CD73, and CD90, while less than 2% positive for surface antigen markers CD34, CD45, CD79/CD19, CD14/CD11b, and HLA-DR; and (iii) have in vitro tri-lineage, i.e., chondrogenic, osteogenic, and adipogenic differentiation capability (Horwitz et al. 2005).

Stem cells have been reported to restore heart function via several mechanisms. Generally, the transplanted cells will stimulate proliferation of native cells in the heart and secrete paracrine factors which favor heart repair and regeneration (Fig. 3). Additionally, MSCs can differentiate into cardiomyocytes to repopulate the injured heart tissue (Hafez et al. 2016). However, based on the results from in vivo study, researchers have found that the benefits of MSCs-based therapy do not rely on its

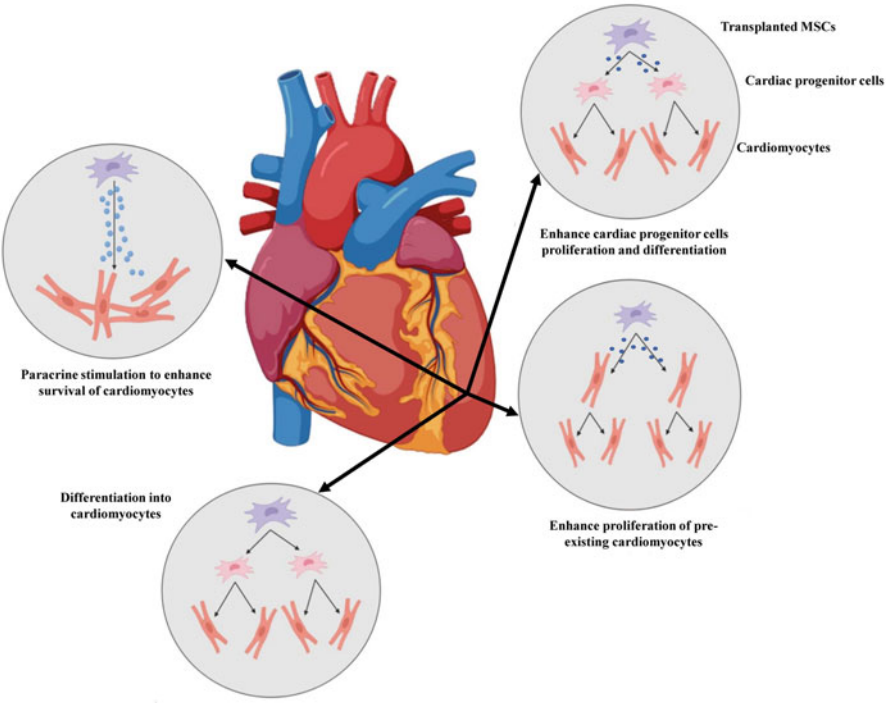

Fig. 3 Functions of stem cell therapy. Transplanted cells secrete paracrine factors and extracellular vesicles that stimulate the proliferation of cardiac progenitor cells and cardiomyocytes and modulate the tissue environment to enhance the survival and function of preexisting cardiomyocytes

ability to repopulate the infarcted heart but more on its secretion of paracrine factors, which possess the immunomodulatory ability and support tissue regeneration. This is evidenced by the poor MSC retention in the infarcted area (Luger et al. 2017).

Despite the poor cell homing in the infarcted area, delivery of MSCs resulted in improved left ventricular function. This improvement has been attributed to the anti-inflammatory effect of MSCs, whereby delivery of MSCs reduces the number of NK cells and neutrophils after MI, subsequently improving left ventricular function (Luger et al. 2017).

The body reacts to injury by producing pro-inflammatory factors such as tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1), interleukin-6 (IL-6), interleukin-12 (IL-12), interleukin-17 (IL-17), and interferon-gamma (IFN-γ) (Chaplin 2010). These factors are produced by both innate and adaptive immune cells and attract the migration of MSCs to the injury site. Thus, regardless of the origin, whether exogenously introduced or endogenously recruited, MSCs will be activated by these pro-inflammatory cytokines and polarized to the immunosuppressive phenotype. Upon activation, MSCs will modulate the innate and adaptive immune response by influencing the function of macrophages, natural killer cells, B cells, T cells, mast cells, neutrophils, and dendritic cells (Liau et al. 2020b; Wang et al. 2014).

MSCs mediate immunomodulation through paracrine secretion and cell-to-cell contact (Liau et al. 2020a).

MSCs have been reported to secrete a myriad of anti-inflammatory factors, including galectin-1, interleukin-10 (IL-10), interleukin-13 (IL-13), prostaglandin E2 (PGE2), nitric oxide (NO), transforming growth factor-beta (TGF-β), and indoleamine-2,3-dioxygenase (IDO) (Lim et al. 2018; Kyurkchiev 2014; Haider and Aziz 2017). Even though inflammation is indispensable in wound healing, an overwhelming inflammation upon heart injury is detrimental for the remaining cardiomyocytes. Thus, stem cell therapy, particularly MSCs, can act as a potent modulator of inflammation response to promote heart regeneration. Immunomodulatory role of MSCs is apparent in restoring heart function during heart disease progression.

The paracrine effects of MSCs are not limited to the immune-related cells but including the resident cells, i.e., injured cardiomyocytes and cardiac progenitor cells (CPCs). Exosomes secreted by MSCs contain miR-221 and miR-19a that are involved in apoptosis suppression and activation of PI3K-Akt signaling pathway to promote cardiomyocyte survival and growth (Ward et al. 2018; Yu et al. 2015). The paracrine effects of MSCs are studied via conditioned media exposure in vitro or injection in vivo. Conditioned media are spent media or used media collected from cultured cells. In vitro study showed increased migration and proliferation of CPCs when cultured with MSCs-derived conditioned media. MSCs-derived conditioned media also exert protective effect against serum starvation and hypoxia-induced apoptosis (Nakanishi et al. 2008). On the other hand, in vivo study found that MSCs-derived conditioned media injected in a porcine MI model significantly reduced tissue infarct size and improved systolic function (Timmers et al. 2011). These were achieved by abrogation of TGF-β signaling and apoptosis resulting from phospho-SMAD2 suppression and activation of caspase 3 by the conditioned media (Timmers et al. 2008).

MSCs also improve the myocardial angiogenesis after injury. In a preclinical study using experimental rat model of MI, transplanted MSCs differentiated into endothelial cells and improved the myocardium angiogenesis (Siamak et al. 2003). Nonetheless, most of the studies found that MSCs promote angiogenesis mainly through paracrine signaling (Teng et al. 2015; Cai et al. 2009). MSCs secrete several proangiogenic factors, such as IL-6, TGF-β, basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), angiopoietin-1 (Ang-1), placental growth factor (PGF), hepatocyte growth factor (HGF), and monocyte chemotactic protein-1 (MCP-1) (Maacha et al. 2020; Tao et al. 2016). Moreover, MSCs-derived exosomes are also rich in miRNAs, e.g., miR-210, miR-199-5p, miR-423-5p, miR-939, and miR-21-3p, that are proangiogenic (Baruah and Wary 2020).

Clinical Evidence of Cell-Based Intervention in Ameliorating Heart Disease

Several clinical trials have published their findings, while many more trials are underway and have been registered in the ClinicalTrials.gov database (Table 1) (Rajab et al. 2019). Worth mentioning is the BAMI trial that will recruit 3000 MI

Table 1 List of clinical trials using stem cells to treat cardiac diseases listed in ClinicalTrials.gov database

ClinicalTrials.gov identifier	Phase	Disease	Patients number	Cell source	Cell delivery
NCT00869024	I/II	End-stage HF patients undergoing LVAD implantation	25	Autologous BM-MNCs	10 I/M injections (20×10^6 cells)
NCT01759212	II/III	End-stage HF patients undergoing LVAD implantation	5	Allogeneic BM-MNCs	I/M transplantation
NCT01758406	II	Ischemic HF	50	Autologous CSCs	I/C infusion
NCT02387723	I	Ischemic HF	10	Allogeneic AT-MSCs	I/M transplantation (100×10^6 cells)
NCT01883076	I	HLHS	30	Autologous UC-blood MNCs	I/M transplantation (3×10^6 cells per kg)
NCT01829750	II	HLHS	34	Autologous CPCs	I/C infusion (0.3×10^6 cells per kg)
NCT03406884	I	HLHS	32	Autologous c-kit+ cells derived from the right atrial tissue	6–10 I/M injections (up to 12,500 cells/kg)
NCT03431480	I	HLHS	12	Autologous placenta cord blood MNCs	I/C infusion
NCT03092284	II	HF	81	Allogeneic AT-stem cells	I/M transplantation
NCT03145402	I/II	HF	5	Autologous BM-MNCs	I/C infusion (cells collected from 100–150 ml of BM)
NCT03227198	I/II	HF	5	Autologous BM-MNCs	I/M transplantation
NCT03180450	I/II	HF	60	Allogeneic UC-derived MSCs	Intravenous infusion
NCT02057900	I	HF	10	ESCs-derived CD15+ IsI-1+ progenitors	Fibrin patch transplanted at the epicardium
NCT03763136	-	HF	5	Allogeneic iPSCs-derived CMs	I/M transplantation (100×10^6 cells)
NCT01693042	II/III	Chronic post-MI HF	81	Autologous BM-MNCs	1 or 2 I/C infusions
NCT00644410	1/II	Congestive HF	59	Autologous BMSCs	I/M transplantation
NCT00526253	II/III	Congestive HF post-MI	170	Autologous SkMs	I/M transplantation
NCT02032004	III	Chronic HF due to systolic dysfunction	566	Allogeneic BM-MPCs	T/E transplantation

(continued)

Table 1 (continued)

ClinicalTrials.gov identifier	Phase	Disease	Patients number	Cell source	Cell delivery
NCT02467387	II	Nonischemic HF	23	Allogeneic BMSCs	I/V infusion (1.5×10^6 cells /kg)
NCT03043742	I	Chronic ischemic heart disease patients with laser revascularization surgery	10	Autologous BM-CD133+ cells	Injection into laser channels during trans-myocardial revascularization
NCT04236479	I	Congenital heart disease	36	Allogeneic BMSCs	Cardiopulmonary bypass (1×10^6, 10×10^6, 20×10^6, 40×10^6, 80×10^6 cells/kg)
NCT02501811	II	Ischemic cardiomyopathy	144	Autologous BMSCs or c-kit+ cells or both	15 T/E injections (150×10^6 MSCs, 5×10^6 c-kit+ cells)
NCT00313339	I	MI	31	Autologous BM-CD34+ cells	I/C infusion
NCT00384982	II	MI	116	BM-MNCs	I/C infusion or I/C infusion+ I/M transplantation
NCT02672267	III	MI	50	Allogeneic ischemia-tolerant BMSCs	I/V infusion
NCT01291329	II	MI	160	Allogeneic Wharton's jelly-MSCs	I/C infusion
NCT01392105	II/III	MI	80	Autologous BMSCs	I/C infusion (1×10^6 cells/kg)
NCT02439398	I/II	MI	55	Allogeneic CSCs	I/C infusion (35×10^6 cells)
NCT00313339	I	MI	31	Autologous BM-CD34+ cells	I/C infusion
NCT01187654	II/III	MI	80	BM-AC 133+ or MNCs	I/C infusion
NCT01569178	III	MI	350	Autologous BM-MNCs	I/C infusion
NCT00936819	II	MI	47	Autologous EPCs or EPCs overexpressing eNOS	I/C infusion (20×10^6 cells)

Abbreviations: BM, bone marrow; BMSCs, bone marrow-derived mesenchymal stem cells; EPCs, endothelial progenitor cells; HLHS, hypoplastic left heart syndrome; I/C, intracoronary; I/V, intravenous; LVAD, left ventricular assist device; MI, myocardial infarction; MNCs, mononuclear cells; MSCs, mesenchymal stem cells; eNOS, human endothelial nitric oxide synthase; T/E, transendocardial

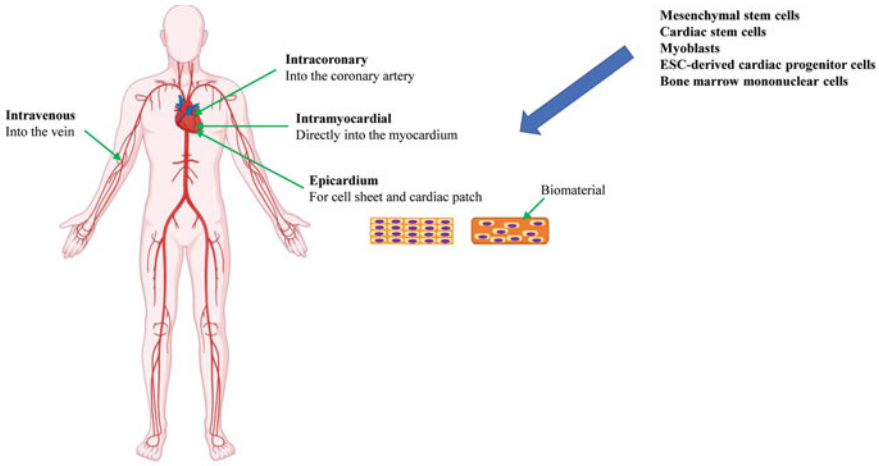

Fig. 4 Stem cell therapy for heart diseases. Mesenchymal stem cells, cardiac stem cells, skeletal myoblasts, embryonic stem cell-derived cardiac progenitor cells, and bone marrow mononuclear cells have been used to treat heart disease. The cells can be administered directly through the intravenous, intracoronary, and intramyocardial routes or assembled as cell sheet and cardiac patch to be transplanted at the epicardium

patients (Mathur et al. 2017). The patients will be divided equally into the stem cell treatment group, which would receive an intracoronary infusion of autologous bone marrow mononuclear cells (BMMCs), and a control group patient who would be given only the standard therapy. The trial aims to determine if BMMC treatment can reduce all-cause mortality in acute MI (AMI) patients with an LVEF of $\leq$45% after successful reperfusion. Another interesting study is the ENACT-AMI trial that applied autologous endothelial progenitor cells overexpressing human endothelial nitric oxide synthase (eNOS) to treat MI patients (Taljaard et al. 2010). This is the first trial combining cell and gene therapy to treat heart disease.

Multiple types of stem cells, e.g., MSCs and mononuclear cells isolated from different tissue sources, cardiac stem cells, skeletal myoblasts, and ESCs-derived CPCs, have been tested clinically to treat heart disease (Haider 2006). The cells were administered via different route, most commonly via direct transplantation to the myocardium or through the intracoronary infusion. Furthermore, the cells also can be injected intravenously and transplanted as a cell sheet or cardiac patch (Fig. 4) (Guo et al. 2020).

Acute Myocardial Infraction

Bone marrow cells in different forms have been tested in multiple randomized clinical trials to treat AMI. Most of the studies used the heterogeneous cell population, i.e., BMMCs, while some applied specific cell population such as bone marrow-derived mesenchymal stem cells (BMSCs), CD133+ bone marrow progenitor cells, and $CD34^{+}$ $CXCR4^{+}$ bone marrow cells.

Strauer et al. reported the intracoronary infusion of autologous BMMCs in ten AMI patients. They found that cell therapy is safe and effective in reducing the size of the infarcted region and improving cardiac function (Strauer et al. 2002). In another study that also administered autologous BMMCs via intracoronary route, the authors found no changes in left ventricular end-diastolic volume (LVEDV), significant improvement in left ventricular end-systolic volume (LVESV) and LVEF, and better regional contractility in the patients who received cell therapy compared to the patients who received standard therapy (Francisco et al. 2004).

Lipiec et al. infused autologous BMMCs via intracoronary route to 26 AMI patients and found no significant changes in LVEF, LVEDV, LVESV, and left ventricular-wall motion score index (WMSI) compared to the 13 patients in the control group after 6 months (Lipiec et al. 2009). However, the infarct area WMSI, perfusion defect extent, left ventricular perfusion score index (PSI), and infarct area PSI improved significantly in the stem cell group.

The FINCELL trial divided 80 AMI patients equally to the treatment group that received intracoronary BMMC injection and the placebo group that received media without cells (Huikuri et al. 2008). After 6 months, the treatment group showed more considerable improvement in LVEF compared to the placebo group. Ge et al. infused autologous BMMCs into the infarct-related coronary artery of ten AMI patients and found that LVEF increased while left ventricular end-diastolic internal diameter (LVDd) remained unchanged and myocardial perfusion defect scores decreased. This was compared with ten AMI patients who received bone marrow supernatant and showed no changes in LVEF and myocardial perfusion defect scores as well as larger LVDd (Ge et al. 2006). Cao et al. delivered autologous BMMCs via intracoronary route to 41 AMI patients as compared to normal saline solution without cells to 45 AMI patients in the control group (Cao et al. 2009). After 6 months, the LVEF improved significantly in the stem cell treatment group compared to the control treatment group. The improvement persisted for up to 4 years of follow-up.

The HEBE trial recruited 200 AMI patients and randomly assigned them to receive either an intracoronary infusion of BMMCs, peripheral blood mononuclear cells, or standard therapy (Hirsch et al. 2010). The researchers observed no significant difference in the percentage of dysfunctional left ventricular segments that improved after treatment. Similarly, there was no observed difference between the cell treatment groups in terms of improvement in LVEF and changes in left ventricle mass, volume, and infarct size at 4 months after treatment as compared with the control group. The ASTANI trial treated 50 AMI patients with an intracoronary infusion of autologous BMMCs and found that stem cell therapy significantly increases the exercise time, peak heart rate, and percentage of heart rate reserves compared to the control group (50 patients) 6 months after the treatment (Lunde et al. 2007). However, no significant differences were detected for the changes in LVEF, LVEDV, WMSI, and infarct size between the two groups at 6 and 12 months (Lunde et al. 2006, Lunde et al. 2008). The REGENT trial involved intracoronary infusion of BMMCs and CD34+ CXCR4+ bone marrow cells to 80 AMI patients each (Tendera et al. 2009). At 6 months, the LVEF increased by 3% in both stem cell therapy

groups but remained unchanged in the 40 control group patients. However, the observed improvement was statistically insignificant. Also, no significant changes were observed in LVESV and LVEDV. Nonetheless, the authors reported that stem cell therapy gave better results in patients with extremely poor LVEF.

In a study examining the effect of BMMC dosage, 66 MI patients were divided equally into 3 treatment groups, high-dose group (100×10^6 cells), low-dose group (10×10^6), and a control group (without cell transplantation) (Meluzín et al.2006). All the three groups had intravenous administration of their respective treatment. The results showed that the high-dose group demonstrated significantly higher improvement in the peak systolic velocity of longitudinal contraction of the infarction wall compared to the low-dose group, and only the high-dose group showed considerable enhancement in LVEF compared to the control group after 3 months of follow-up. The significant improvement in LVEF persisted for up to 12 months (Meluzín et al. 2008). In a study that compared the effectiveness of intracoronary and intravenous administration of BMMCs, the authors reported no significant differences in the changes in echocardiographic parameters, i.e., LVEF, LVEDV, LVESV, and WMSI, at 6 months between the intravenous group, intracoronary group, and control group (Nogueira et al. 2009).

Many have raised the question regarding the optimal timing for stem cell therapy in post-MI patients. Thus, the TIME trial was designed to examine the safety and efficacy of intracoronary infusion of 150×10^6 autologous BMMCs at day 3 or 7 post-MI on 120 patients (Traverse et al. 2012). After 6 months, it was found that the timing of cell infusion does not affect the improvement in global and regional left ventricular function, whereby no significant differences were observed between the stem cell-based treatment groups. Furthermore, no significant differences were detected between the stem cell groups and the placebo group at 6 months and 2 years (Traverse et al. 2012, Traverse et al. 2018). The LateTIME trial used a similar treatment protocol; however, the cells were administered 2–3 weeks post-MI (Traverse et al. 2010). Similarly, results showed no differences in global and regional left ventricular function between the groups after 6 months (Traverse et al. 2011). The SWISS-AMI trial randomized 200 AMI patients in ratio 1:1:1 to receive early (5–7 days after AMI) administration of BMMCs, late (3–4 weeks after AMI) administration of BMMCs, and standard therapy (control group). At 4-month follow-up, there was no real difference in left ventricular function improvement between the two treatment groups and the control group (Sürder et al. 2013). Similarly, no improvement was observed during 12-month follow-up (Sürder et al. 2016). Thus, the timing of cell transplantation might be less important when using bone marrow cells to treat AMI.

The BONAMI trial recruited 101 AMI patients divided into the stem cell therapy group (52 patients) who received an intracoronary infusion of autologous bone marrow cells ($98.3 \pm 8.7 \times 10^6$ cells) and control treatment group (49 patients) who received the sham infusion without cells (Roncalli et al. 2010). The authors reported that cell therapy significantly improved myocardial viability after 3 months. However, no differences were detected for the LVEF, global WMSI, and infarct size. The REGENERATE-AMI trial investigated intracoronary infusion of autologous

bone marrow cells to 55 AMI patients. Another 45 AMI patients in the placebo treatment group received normal saline without cells (Choudry et al. 2016). The results showed that the stem cell therapy group had greater improvement in LVEF and significantly higher myocardial salvage index than the placebo treatment group. In the BOOST trial that treated 30 AMI patients with an intracoronary infusion of autologous bone marrow cells, the researchers found that cell therapy is safe and helped to improve the diastolic function and LVEF compared to the control patients (30 patients) (Schaefer et al. 2006, Wollert et al. 2004). However, the follow-up study found that the significant improvement in LVEF diminished after 18 months (Meyer et al. 2006, Meyer et al. 2009). Nonetheless, the improvement in LVEF was maintained in the subgroup of patients with more transmural infarcts. In the multiple-arm BOOST-2 trials, the researchers found that intracoronary infusion of high dose and low dose of autologous bone marrow cells, γ-irradiated or not, did not significantly improve the LVEF (Wollert et al. 2017).

The LEUVINE-AMI trial applied autologous bone marrow-derived stem cells in 33 AMI patients, and another 34 patients in the control group received the placebo (Janssens et al. 2006). Stem cell-based treatment significantly reduced the myocardial infarct size and improved the regional systolic function compared to the placebo treatment group after 4 months. However, no significant differences were detected in LVEF, LVEDV, and LVESV. Grajek et al. intravenously infused bone marrow stem cells to 31 AMI patients. The authors found that it did not result in any significant improvement in LVEF, LVEDV, and LVESV compared to the 14 patients in the control group during 1-year follow-up (Grajek et al. 2009).

In the multicenter REPAIR-AMI trial, 101 patients received bone marrow-derived progenitor cell infusion into the infarct-related coronary artery, and another 103 patients received placebo treatment (Schächinger et al. 2006). The progenitor cell-based therapy significantly improved LVEF, LVESV, and regional contractility compared to the placebo treatment at 4 months. Furthermore, at 2 years, the progenitor cell-based therapy group demonstrated a lower incidence of recurring MI, rehospitalization for heart failure, and death as well as higher improvement in LVEF compared to the placebo-treated group (Assmus et al. 2010). In the TOPCARE-AMI trial, 59 patients with AMI received an intracoronary infusion of circulating progenitor cells or bone marrow-derived progenitor cells and are followed of up to 5 years (Leistner et al. 2011; Schächinger et al. 2004). The results showed the long-term safety of intracoronary delivery of autologous circulating progenitor cells and bone marrow-derived progenitor cells in AMI patients. In addition, the patients also showed a sustained improvement in LVEF for 5 years without any significant difference between the two treatment groups.

Chen et al. examined the potential of using autologous BMSCs to treat AMI by intracoronary administrating the cells to 34 AMI patients with another 35 AMI patients in the control group receiving only the saline (Chen et al. 2004). Patients who received the stem cell-based therapy demonstrated significant improvement in LVEF, wall movement velocity over the infarcted region, LVEDV, and LVESV after 3 months compared to those in the control group.

Bartunek et al. reported that intracoronary infusion of CD133+ bone marrow progenitor cells in 19 AMI patients significantly improved the LVEF, left ventricular regional chordae shortening, and reduction of the perfusion defect compared to the 16 AMI patients without the stem cell therapy (Bartunek et al. 2005). However, it also increased the incidence of coronary events. In another study, the researchers compared intracoronary infusion of CD133+ cells from bone marrow and peripheral blood with the standard therapy (five patients each group) (Colombo et al. 2011). It was found that LVEF and wall motion score index remained stable for all groups, but the infarct-related myocardial blood flow was only increased in the bone morrow group after 1 year. In addition, infarct size and summed rest score decreased most significantly in the bone marrow-treated group.

Overall, some studies such as BOOST, TOCARE-AMI, FINCELL, REGENERATE-AMI, and REPAIR-AMI demonstrated improvement in global and regional left ventricular function after the bone marrow cell therapy. Nonetheless, there are also many trials, i.e., BONAMI, LEUVEN-AMI, HEBE, ASTAMI, BOOST-2, TIME, LateTIME, SWISS-AMI, and REGENT, which failed to detect significant functional improvement. Furthermore, in the systematic review and meta-analysis conducted by Fisher et al. in 2015, the authors recovered 41 randomized controlled trials (RCT) that compared the safety and efficacy of autologous bone marrow cells with no cell therapy group and found that there is insufficient evidence to prove the advantages of applying autologous bone marrow cells in MI patients (Fisher et al. 2015). These discrepancies might be due to the differences in the cell preparation technique, the number of cells administered, cell composition, and timing of cell administration.

Heart Failure

The FOCUS-CCTRN trial studied the safety of transendocardial injection of autologous BMMCs in end-stage ischemic heart disease patients (Perin et al. 2012). Results indicated that the mononuclear cells were well-tolerated, and the treatment showed a positive effect on myocardial perfusion and contractility. The investigators reported that the cell therapy resulted in a slight improvement in patients' LVEF but did not reduce LVESV or increase maximal oxygen consumption. In addition, the clinical trial also showed a positive correlation between the degree of LVEF improvement and the percentage of $CD34^+$ and $CD133^+$ cells. Specifically, every 3% increase in CD34 or CD133 cells was associated with an increase in LVEF of 3–5.9%. These critical findings suggested that the cellular composition does affect the clinical effectiveness of stem cell therapy. In 2016, Fisher et al. published a systematic review and meta-analysis that included 38 randomized controlled trials (RCTs) and 1907 participants. The authors concluded that BMSCs therapy could reduce mortality and improve the cardiac function of patients with chronic ischemic heart disease and heart failure, albeit with the low quality of the collected evidence (Fisher et al. 2016). The BMSCs used in these RCTs included BMSCs, BMMCs, $CD133^+$ cells, $CD34^+$ cells, aldehyde dehydrogenase-bright cells, bone marrow aspirate

concentrate, and G-CSF mobilized and cultured circulating mononuclear pro-angiogenic cells.

Interestingly, bone marrow stem cells have been cardiomyogenically induced for the treatment of heart failure clinically. The C-CURE trial used cardiopoietic stem cells (cardiomyogenic differentiated BMSCs) to treat patients with chronic heart failure (Bartunek et al. 2013). The 2-year follow-up showed that cell therapy is safe. In addition, the efficacy measurement at 6 months showed that LVEF increased, LVESV decreased, and 6-min walk distance improved significantly compared to the control group. Instead of expanding the cells in normoxic conditions like most studies, Butler et al. cultured the allogeneic BMSCs in hypoxic condition and used the cell to treat nonischemic cardiomyopathy (Javed et al. 2017). Treatment with ischemia-tolerant BMSCs is safe and significantly improved the 6-minute walking distance and Kansas City Cardiomyopathy Questionnaire clinical summary score compared to the control group.

Apart from bone marrow stem cells, umbilical cord-derived mesenchymal stem cells (UC-MSCs) also have been used to treat heart failure. The RIMECARD trial applied allogeneic UC-MSCs to treat 15 patients with heart failure (Bartolucci et al. 2017). The cell therapy group demonstrated significant improvement in LVEF, New York Heart Association (NYHA) functional class, and Minnesota Living with Heart Failure Questionnaire (MLHFQ) score. In a separate study, Zhao et al. administered UC-MSCs to treat chronic systolic heart failure. The authors reported improved 6-minute walk distance and LVEF improved besides significantly reduced mortality rate compared to the control group (Zhao et al. 2015).

In 2015, Menasché et al. reported the first clinical case of using human embryonic stem cell (ESC)-derived CPCs to treat severe heart failure (Menasche et al. 2015). The patient showed improvement in NYHA functional class and LVEF. More importantly, no adverse event was reported.

Refractory Angina

Refractory angina (RA) is a chronic condition ($\geq$3 months) characterized by angina in the setting of coronary artery disease (CAD). Currently, RA cannot be controlled by conventional therapeutic interventions, angioplasty, coronary artery bypass surgery, or a combination of the two methods mentioned above. Hence, Losordo et al. conducted a phase II, randomized, controlled clinical trial involving 26 centers (167 patients) in the United States to treat patients with chronic RA with autologous stem cells (Losordo et al. 2011). In this study, patients received either low dose (1×10^5 cells/kg) or high dose (5×10^5 cells/kg) of G-CSF mobilized autologous $CD34^+$ stem cells through the intramyocardial route. The 6-month and 12-month follow-up showed that only the low-dose group recorded a significant reduction in angina frequency and improvement in exercise tolerance. Similarly, the RENEW trial and clinical trial by Wang et al. that also administered autologous $CD34^+$ stem cells showed a reduction in angina frequency, improvement in exercise tolerance, and improvement in the Canadian Cardiovascular Society (CCS) class compared to the placebo group (Povsic et al. 2016, Wang et al. 2010).

Mathiasen et al. found benefit in treating patients with CAD and RA using BMSCs (Mathiasen et al. 2013; Haack-Sorensen et al. 2013). The results from the 3-year observation period showed that the cell therapy reduced the frequency of hospital admission, improved the exercise time, lowered the CCS class, increased the Seattle Angina Questionnaire (SAQ) scores, and exhibited long-term safety with no adverse effect. Other investigators assessing the use of bone marrow-derived stem cells to treat RA also reported encouraging results (Beeres et al. 2006; Vicario et al. 2004; Tse et al. 2007; van Ramshorst et al. 2009; Pokushalov et al. 2010).

The PROGENITOR trial and REGENT-VSEL trial applied transendocardial administration of autologous bone marrow $CD133^{+}$ cells to treat patients with RA (Wojciech et al. 2017, Pilar et al. 2014). The results showed that cell therapy reduced frequency of angina and improved the CCS class in the PROGENITOR trial. Still, fewer promising findings were reported in the REGENT-VSEL trial that found no significant difference in single-photon emission computed tomography (SPECT) score, left ventricular function, and CCS class compared to the control group.

In a recent clinical trial (MyStromalCell trial), Qayyum et al. reported the intramyocardial administration of autologous adipose-derived stromal cells (ASCs) to treat 40 patients with RA with another 20 patients in the control group receiving normal saline (Qayyum et al. 2019). Patients treated with ASCs demonstrated improved metabolic equivalents, CCS class, and NYHA class compared to the control group during the 3-year observation period. In addition, the ASCs-treated group was able to maintain the exercise capacity, while deterioration was recorded in the control group. In the ATHENA trial that also used ASCs to treat RA, the authors found that more patients demonstrated improvement in HYHA class and CSS class than the placebo group (Henry et al. 2017).

Limitations of Stem Cell Therapy

Despite significant progress in clinical translation of cell therapy in heart disease over the past decade, many uncertainties remain regarding the most efficacious cell type, cell dosage, and route and timing of cell administration (Haider and Ashraf 2005). Adding to the complexity, there is growing evidence showing that stem cells harvested from elderly patients do not produce the same benefits from healthy donors (Haider et al. 2018). Collectively, these issues highlighted the need to investigate further the mechanisms underlying stem cell survival, plasticity, and functionality.

The most critical question yet to be answered is to find an ideal type of stem cells to treat heart diseases. For this purpose, it is crucial to understand the mechanisms of each type of stem cells in affecting the myocardial performance and also in modulating different cardiac pathologies. Different types of cells might be needed for diverse cardiac pathologies. Thus far, bone marrow-derived stem cells have been widely used clinically, and they have been proven safe and beneficial under certain circumstances. However, the cells' regeneration potential is controversial. CSCs can

be patient-specific, but the tissue collection procedure is highly invasive, and the culture procedure needs further optimization, especially the upscaling process. An alternative option is to use the cardiomyogenic differentiated MSCs. In fact, the C-CURE trial has used the cardiomyogenic differentiated BMSCs to treat heart failure (Bartunek et al. 2013).

Another key factor for successful cell-based therapy is determining the optimal route of delivery. Cells can be injected intravenously, intracoronary, or directly into the myocardium, each with distinct pros and cons. Cell engraftment at the injury site majorly depends on the delivery strategy. Generally, cell engraftment improved through intramyocardial injection under direct vision at the injury site. Scaffold-based cell delivery strategy is gaining popularity as it promotes the rate of cell survival and integration of transplanted cells in the hostile host environment besides ensuring site-specific delivery (Kc et al. 2019). In addition, the cells also can be expanded and transplanted as a monolayer or multilayer cell sheet (Guo et al. 2020). This method of cell delivery reduces the need for the transplanted cells to migrate long distance to home into the injured myocardium to participate in the repair process (Meluzin et al. 2006; Nogueira et al. 2009). Kanelidis et al. in their meta-analysis of preclinical and clinical studies found that intramyocardial injection of stem cells through catheter-based transendocardial stem cell injection provided more benefits than the intravenous route in terms of infarct size reduction and LVEF improvement (Kanelidis et al. 2017).

A few clinical trials have examined the effects of different cell dosages for cardiac regeneration (Meluzin et al. 2006). Averse to the findings of Meluzín et al. that found that the high-dose treatment is more effective in treating MI, Losordo et al. reported that the low-dose cell therapy gave better results in a patient with RA. The discrepancy could be due to their use in different cardiac pathologies and diverging routes of cell administration. For example, more cells are needed when using the intravenous and intracoronary routes of cell delivery compared to intramyocardial transplantation due to lower cell engraftment and vast distribution in nontargeted organs besides massive cell death post engraftment. Pre-conditioning protocols are being developed and optimized to support donor cell survival (Haider and Ashraf 2012) via various mechanisms including induction of pro-survival microRNAs (Kim et al. 2009).

Lastly, stem cells isolated from different individuals might vary in cellular composition, characteristics, and functionality. These variations contributed to the outcome disparity. Quality of the cell preparation remains an ultimate determinant of the outcome and success of cell-based therapy (Haider 2017). It is well known that human stem cells become less viable and dysfunctional with age and individuals with chronic diseases (Efimenko et al. 2015; Shahid and Haider 2016). Such conditions may alter the effectiveness of stem cell therapy. Therefore, the efficacy of autologous stem cells used in previous studies to treat older patients with heart disease may be inconsistent. Thus, the considerations mentioned earlier should be taken into account while interpreting the data of previous studies and designing future research for heart diseases besides developing strategies to restore reparability characteristics of the aging cells (Igura et al. 2011).

Future Perspectives

Supported by the advancement and introduction of new technology, various pharmacologic and genetic strategies are being developed to improve the currently available cell-based therapy for heart disease. These efforts include combination with gene therapy and biomaterial as well as application of stem cell-derived extracellular vesicles.

Combination with Gene Therapy

Recent advancements in high-precision genome-engineering CRISPR/Cas9 system have allowed the researchers to design gene therapy to up- or downregulate the expression of cardiac, vascular, or immune system-relevant gene(s) which is/are abnormally expressed and permanently correct disease-causing mutations in the adult cardiomyocytes. However, despite the tremendous promise, most studies encountered difficulties translating gene therapy to the clinical setting. For example, the recent CUPID2 trial that applied gene therapy (AAV1/SERCA2a) showed low efficacy in heart failure patients despite having encouraging results during the experimental preclinical studies (Greenberg et al. 2016). Discouraging results were also reported in the STOP-HF trial (Chung et al. 2015). Other gene-based innovations such as lineage reprogramming sound promising in theory. However, such intervention could introduce ectopic cardiomyocyte formation, and the activity of the transferred genes is not well-established.

Thus, a novel combinatorial approach of gene therapy and stem cell treatment may prove to be most feasible and efficacious (Haider et al. 2011). The combination therapy offers the advantage that cells can be genetically engineered ex vivo before transplantation, offering a safer alternative and more precise control of gene expression than gene therapy alone (Jiang et al. 2006; Haider et al. 2008). Another potential strategy involves genetically engineered cell grafting using a mixture of physiologically relevant cell types, including stem cells, cardiomyocytes, and neuronal, vascular, and immune cells (Hosseini et al. 2018). These cells serve as vehicles to deliver the gene(s) or even microRNAs of interest to the heart and provide a more comprehensive regenerative strategy compared to each cell type without genetic modulation (Kim et al. 2012a, b).

Exosomes

Exosomes are membrane-bound vesicles produced by cells and contain a variety of factors, including nucleic acids, lipids, and proteins which are considered to be primarily responsible for intercellular transfer of bioactive molecules. More recently, exosomes-based research has gained intense interest as a fast-emerging cell-free therapy approach for many diseases, including heart disease (Haider and Aslam 2018).

The systematic review and meta-analysis conducted by Zhang et al. found that MSCs-secreted exosomes improved the heart function in experimental animal model of myocardial ischemia-reperfusion injury (Zhang et al. 2016). Similarly, CSC-secreted exosomes were also reported to promote heart regeneration in experimental mouse model of MI (Ibrahim et al. 2014). Adamiak et al. reported that induced pluripotent stem cell (iPSC)-secreted exosomes are more potent than iPSCs in myocardial reparability in vivo (Adamiak et al. 2018). Besides being equal or better than the original cells in cardiac protection, the use of exosomes is also safer by mitigating the risk of potential adverse effects observed in cell therapy, such as host immune rejection and tumor formation (Haider and Aramini 2020). These exciting results await future comprehensive clinical evaluations as most of the current findings are still at the preclinical stage.

Biomaterials

Retention and engraftment of transplanted cells at the injury site are crucial to maintaining the therapeutic effects. Unfortunately, regardless of the route of administration, the majority of the cells do not reach (intravenous and intracoronary injection) or engraft (intramyocardial injection) at the damaged myocardium. The poor cell engraftment limited the therapeutic benefits of stem cell therapy. Therefore, scaffolds, either in the form of nanofibers, cell sheets, biodegradable hydrogels, or decellularized tissues, have been utilized to deliver and promote cell retention in the infarcted myocardium. The scaffolds can be made from various biodegradable biomaterials, such as the natural alginate, collagen, and Matrigel, as well as synthetic polycaprolactone (PCL) and poly-L-lactic acid (PLLA) (Reis et al. 2016). An ideal scaffold should be biodegradable and biocompatible having appropriate thickness and could provide mechanical support, besides being easy to handle and permitting precise placement. Currently, research is focused to develop an ideal scaffold for cardiac tissue engineering.

Conclusion

The contemporary treatment options show limited success for the treatment of heart diseases. Stem cell-based therapy has emerged as a novel approach. Even though the quality and quantity of the available data, especially the clinical data, are still limited, the results reported thus far are promising. Further in-depth mechanistic studies are warranted in the future to understand how stem cells work and to optimize the treatment protocol to improve the safety and efficacy of stem cell-based therapy. A combination of stem cells with gene therapy and biomaterial might be able to create a synergistic effect and is an area that needs to be further explored. Also, more efforts are needed to develop the cell-free exosome therapy to ensure its safety and efficacy before being used clinically as an alternative for stem cell therapy.

Abstract

Cardiovascular diseases (CVDs), particularly acute and chronic ischemic heart disease (IHD), are the primary cause of morbidity and mortality worldwide. The contemporary pharmacological and invasive revascularization strategies, i.e., percutaneous coronary angiography (PCA) and coronary artery bypass grafting (CABG), reduce mortality and could only provide symptomatic relief. Cell-based therapy has emerged as a novel breakthrough strategy to ensure angiomyogenic repair of the ischemically damaged heart via the generation of neomyocytes and biological bypassing to restore regional blood flow. In this regard, bone marrow (BM)-derived mesenchymal stem cells (MSCs) have shown promise and progressed to advanced phases of clinical assessment. MSCs are one of the well-

studied and characterized cell types in vitro and various small experimental animal models and during the translational animal models for safety and reparability. They are currently the most used cells for cell-based cardiovascular therapy with excellent safety profiles, immunomodulatory properties, paracrine action, and differentiation potential. With overwhelming success, researchers have advanced their efforts to bring MSCs a step closer to their eventual routine use in the clinics. This chapter summarizes the advancement of MSCs from in vitro characterization to the clinical phase and discusses their future perspective.

TGF-b	Transforming growth factor-b
TUNEL	Terminal deoxynucleotidyl transferase dUTP nick-end labeling

VEGF	Vascular endothelial growth factor
WNT	Homologous of wingless and Int-1

Introduction

Cardiovascular diseases (CVDs) are the leading cause of mortality globally (WHO 2017) as they account for nearly 836,546 deaths in the USA alone, which is equivalent to one out of every three deaths (AHA-2018 Statistics at a glance). Among the CVDs, ischemic heart disease (IHD) is a major clinical challenge that causes morbidity and mortality in patients in acute and chronic forms. Thrombotic coronary occlusion due to atherosclerotic rupture leads to acute myocardial infarction (AMI) due to compromised blood supply to the affected region of the heart, thus causing massive cardiomyocyte death (Falk et al. 1995). Although the number of surviving patients, their quality of life post-AMI, and the rate of rehospitalization due to recurrence of AMI episodes improved due to advancements in contemporary revascularization techniques and better pharmacological management, these interventions only provide symptomatic relief to the patients. The infarcted myocardium undergoes a series of detrimental events as part of the intrinsic repair process. This involves forming a noncontractile cicatricle tissue to replace the damaged myocardium besides undergoing geometrical changes in the myocardium to accommodate altered pressure-volume needs and overstretching of viable cardiomyocytes, especially in the peri-infarct region to sustain near-normal contractile function (Taggart 2012; Maron et al. 2006).

Standard heart failure medical therapies suffer from a lack of potential to replenish the dead cardiomyocytes. Hence, the emerging strategy of cell-based therapy for myocardial repair and regeneration is revolutionary and exploits the exclusive reparability and differentiation potential of stem cells into structurally and functionally competent neomyocytes and neovascular structures to restore the lost myocardial function (Kwon et al. 2010; Haider et al. 2010a). Given their optimal characteristics and ease of availability, bone marrow (BM)-derived mesenchymal stem cells (MSCs) indeed provide an attractive source of cells for heart cell therapy. This chapter gives an overview of the progress of BM-derived MSCs from in vitro (Table 1) to preclinical studies in small and large animal models focusing on their safety and efficacy leading to the published randomized placebo-controlled clinical trials in the human subjects.

BM-Derived MSCs

BM comprises two main lineages of stem/progenitor cells, i.e., hematopoietic stem cells (HSCs) and MSCs (Haider and Ashraf 2005). MSCs were first described by Friedenstein et al. in 1968 as the fibroblast-like colony-forming units (Friedenstein et al. 1968) and later substantiated and characterized by many other research groups (Bobis et al. 2006; Deng et al. 2008; Luu et al. 2007; Bhat et al. 2021). Such characterization is of great significance to ensure uniformity of cell characteristic prepared from various labs (Stroncek et al. 2020) and to ensure quality preparation

Table 1 Summary of some of the studies reporting in vitro differentiation of BM-derived MSCs

Author/year	Cell type	Method of differentiation	Main findings
Wakitani et al. (1995)	Rat BM-derived MSCs	5-Azacytidin treatment	5-Azacytidine treatment at 24 h after seeding of twice-passaged MSCs in vitro culture. After an exposure of 24 h, long, multinucleated myotubes developed in some of the dishes on days 7–11 after treatment
Makino et al. (1999)	Murine BM-derived MSCs	5-Azacytidin treatment	Nearly 30% of the cells connected with adjoining cells after 1 week, formed myotube-like structures, began spontaneously beating after 2 weeks, and beat synchronously after 3 weeks. Expressed ANP and BNP, stained positive for anti-myosin, anti-desmin, and anti-actinin. Revealed a cardiomyocyte-like ultrastructure. Also expressed MEF-2A and MEF-2D
Rangappa et al. (2003)	Human MSCs	Human MSCs and human cardiomyocytes were mixed at a 1:1 ratio in smooth muscle 2 media	Differentiated hMSCs from the coculture expressed myosin heavy chain, beta-actin, and cTnT detected by PCR. Immunostaining also showed myosin heavy chain and cTnT. Only beta-actin expression was observed in the hMSCs incubated with conditioned media without serum
Antonitsis et al. (2007)	Human BM-derived MSCs	Second passaged cells were treated with 10 microM 5-azacytidine for 24 h	MSCs treated with 5-azacytidine became stick-like morphology, connecting with adjoining cells forming myotube-like structures, running in a parallel fashion. Immunohistochemically positive for myosin

(continued)

Table 1 (continued)

Author/year	Cell type	Method of differentiation	Main findings
			heavy chain and vimentin. The mRNAs of alpha-cardiac actin, beta-myosin heavy chain, and cTn-T were also expressed
Ramkisoensing et al. (2012)	Human adipose tissue MSCs and amniotic membrane MSCs with or without Cx-43	Ten-day coculture with neonatal rat ventricular cardiomyocytes	Functional cardiomyogenic differentiation, based on action potential recordings, occurred only in control fetal AM hMSCs. Cx45 overexpression in Cx43 knockdown fetal AM hMSCs restored their ability to undergo cardiomyogenesis (1.6% ± 0.4%, n = 2500) in coculture with neonatal myocytes. Gap junctional coupling is required for differentiation of fetal AM hMSCs into functional CMs
Hou et al. (2013)	Rat BM-derived MSCs	BMP-2 and 5-azacytidine treatment	Combined treatment with BMP-2 and 5-AZA significantly improved the cardiac differentiation with fewer cell damage effects as compared to either of the them alone, and combined treatment was safer and effective method of induction in vitro. Expression of cTnI and Cx-43 was used as differentiation markers
Liu et al. (2013)	Rat BM-derived MScs	Combined treatment with 5-AZA (10 μmol/L), Ang-II (0.1 μmol/L), PFT-α (20 μmol/L), and BMP-2 (10 μg/L)	Development of cardiomyocyte-like cells expressing cTnT, cTnI, and Cx43 suggesting that the combination of inductors improved rate of differentiation. Total potassium current level

(continued)

Table 1 (continued)

Author/year	Cell type	Method of differentiation	Main findings
			and calcium transient in PFT-α cardiomyocyte-like cells was also higher in the differentiated cells
Szaraz et al. (2017)	BM-derived MSCs and UC-perivascular cell MSCs	Coculture on feeder layer	Increased expression of cardiomyocyte markers (i.e., MEF2C, cardiac troponin T, heavy chain cardiac myosin, signal regulatory protein α, and connexin 43) showed aggregate-based contracting cells in vitro

ANP atrial natriuretic peptide, *BNP* brain natriuretic peptide, *BM* bone marrow, *CMCs* cardiomyocytes, *cTnT* cardiac troponin T, *Cx-43* connexin 43, *MEF2c* myocyte enhancer factor 2C, *FACS* fluorescence-activated cell sorting, *MSCs* mesenchymal stem cells.

for clinical use of the cells (Trivedi et al. 2019). In the published data, MSCs have also been reported as mesenchymal stromal cells, mesenchymal progenitor cells, multipotent mesenchymal stromal cells, BM stromal cells, BM-derived MSCs, multipotent stromal cells, mesenchymal precursor cells, and medicinal signaling cells (Caplan 1991; Bobis et al. 2006; von't Hof et al. 2007; Deng et al. 2008; Samsonraj et al. 2017).

MSCs are a heterogeneous group of cells that constitute only 0.001–0.01% of the stem/progenitor population in the BM (Haider 2006; Wilson et al. 2019). They, therefore, necessitate extensive amplification in vitro culture to achieve a sufficient number for cell therapy applications (Lennon and Caplan 2006). Although MSCs were first isolated from the BM more than 50 years ago (Friedenstein et al. 1970), there are no unique surface markers for their definite identification from other cells (Haider 2018). More recently, the International Society for Cell Therapy (ISCT) has suggested standardized criteria to define human MSCs, which includes (1) adherence to the plastic surface under standard culture conditions; (2) the expression of CD73, CD90, and CD105 and lack of CD34, CD45, HLA-DR, CD14 or CD11b, and CD79a or CD19 membrane surface molecules; and (3) tri-lineage differentiation potential to adopt osteoblasts, adipocytes, and chondroblasts under a defined set of culture conditions in vitro. The ISCT standardized norms for the characterization of MSCs have been instrumental in removing the inconsistencies regarding the nomenclature as well as biological characteristics of MSCs. It is important to mention that MSCs from different species and even from various tissue sources cultured under a different set of conditions may differ in the expression of surface markers (Boxall and Jones 2012; Jones and Schäfer 2015) as well as in the number of isolated cells (Sullivan et al. 2015; Yoshimura et al. 2007) and their efficacy (Shariatzadeh et al. 2019). Moreover, the innate expression levels of a set of surface markers are not a guarantee of MSC homogeneity.

Besides other cell types, MSCs are an integral part of the HSC niche in the BM and essentially instrumental in offering a unique microenvironment for the HSCs

(Morrison and Scadden 2014). Together with the endothelial cells and megakaryocytes, MSCs provide proximity to the HSCs and contribute to the maintenance of niche homeostasis by providing instructive cues for their quiescence and functional activity (Schepers et al. 2015; Asada et al. 2017). These MSCs have been identified as CD45-Nestin+, contain all CFU-fibroblastic activity associated with HSCs, and respond to adrenergic stimulation (Méndez-Ferrer et al. 2010).

Isolation and Characterization of MSCs

Other than the BM, MSCs have been isolated from many other adult- as well as fetus-associated tissues, including adipose tissue, peripheral blood, lung, marrow spaces of a long bone, synovial fluids, muscle, placenta, umbilical cord, cord blood, periodontal ligaments, and dental pulp (Aust et al. 2004; Smiler et al. 2008; He et al. 2007; Griffiths et al. 2005; Tuli et al. 2003; Fan et al. 2009; Gay et al. 2007; Jackson et al. 2010; Anker et al. 2004; Miao et al. 2006; Corrao et al. 2013; Ong et al. 2014; Erices et al. 2000; Mareschi et al. 2001; Camilleri et al. 2016) (Fig. 1).

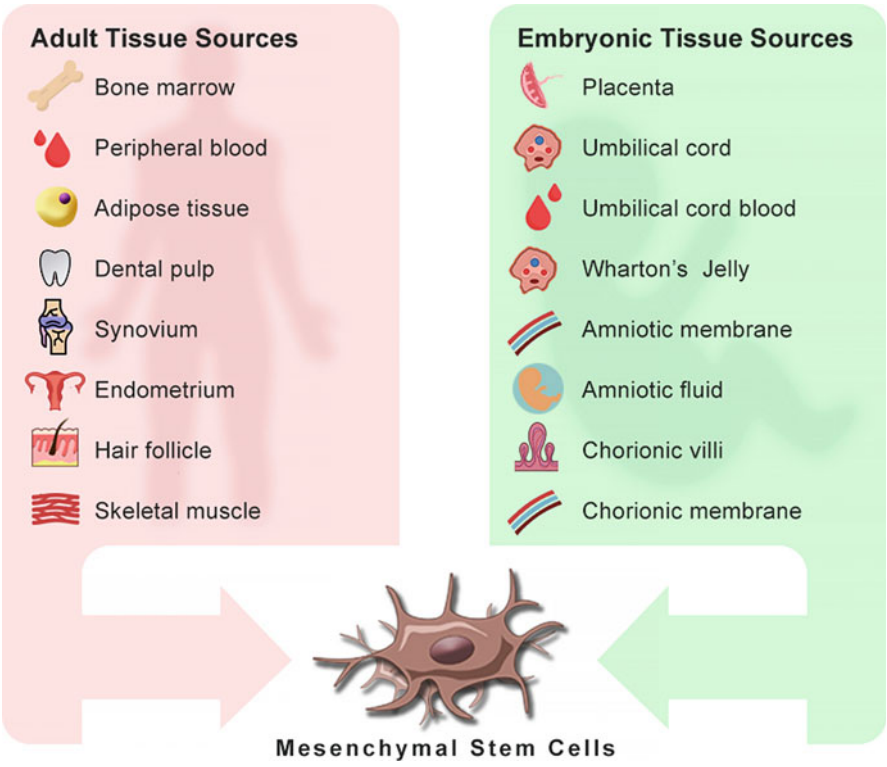

Fig. 1 Some of the adult- and fetus-associated tissue sources of MSCs used in experimental or clinical studies

The lineage-tracing studies strongly propose that progenitor cells of the MSCs come from around the blood vessels (capillaries, arteries, and veins), thus pointing their perivascular origin (Seo et al. 2004; Corselli et al. 2010).

Besides other parameters, the quality of MSC preparation is determined by their isolation procedure and expansion in the culture conditions (Haider 2018). The three steps needed for isolation and purification of MSCs from the BM include their separation from the nonnucleated RBCs by density gradient centrifugation, adherence to the plastic surface, and removal of monocytes by trypsinization. Generally, mechanical and enzymatic dissociation of the tissue has their respective advantages, but combining both of the approaches may enhance the yield of MSCs as compared to the enzymatic digestion alone as it results in loss of extracellular matrix that increases their time of adherence and low yield (Mushahary et al. 2018). Expansion of plastic adherence is the most employed way of obtaining and expanding the MSCs. Given their 3D habitat in the niche, the 2D in vitro culture expansion of MSCs may lead to loss of their progenitor potency and function. A paradigm shift in MSC culture in vitro uses 3D culture conditions that closely mimic their natural habitat (Hoch and Leach 2014).

Besides improving their proliferation rate, paracrine activity, and differentiation potential, more recent studies have shown that 3D culture conditions promote the expression of pluripotency genes (Zhou et al. 2017). Elucidating the underlying mechanism, it has been attributed to the relaxation of the cytoskeleton due to more conducive culture conditions. The commonly employed 3D methods include the hanging-drop approach, scaffold-free method, spin or rotate wall vessels, and fabricated membrane culture methods (Bartosh et al. 2010; Zhang et al. 2015; Miyagawa et al. 2011).

As discussed earlier, MSCs are generally characterized by their capacity to form colonies, renew themselves, express surface markers, and differentiate into multilineages (Friedenstein et al. 1974). The MSC colonies show heterogeneous morphological characteristics ranging from fibroblastoid- to spindle-shaped or from large-flattened to small-round cells. The first recognized multipotent stromal precursor cells from the BM were the colony-forming unit-fibroblastic (CFU-F), which are mainly composed of primary BM-derived MSCs. After further proliferative expansion in culture, they constitute MSCs/stromal cells, and in vitro they give rise to colonies during their initial growth (Pittenger et al. 1999). CFU-F is the efficiency of self-renewal assessed by the rate of colony formation that is a routinely employed standard approach to characterize MSCs.

Additionally, research labs from all over the world have diverse sets of antigens for characterization, and there is no consistency in the use of cell surface antigens for the isolation of MSCs. There is no one universal marker that precisely identifies MSCs. This divergence in surface marker expression besides extremely low-frequency presence in the tissues renders it challenging to identify MSCs in vivo. From among the wide array of surface antigens expressed by MSCs, CD105, CD73, and CD90 are reckoned as the primary markers, which are expressed on more than 95% of MSCs, while the expression of CD105, CD90, and CD73 is not completely specific to undifferentiated multipotent MSCs as some of these markers are also expressed by vascular cells, smooth muscle cells, and mature stromal cells

such as fibroblasts (Dominici et al. 2006). On the contrary, cultured MSCs do not express CD45, CD34, CD14, CD11b, CD19, and HLA-DR. Additionally, MSCs expressing STRO-1, CD146, SSEA-4, CD271 (NGFR), and MSC antigen 1 (MSCA-1) have been identified but with little significance as markers of identification and purification (Andersen et al. 2011; Jones et al. 2006). Nestin, a neural stem cell marker, has also been reported as a selective marker for BM-MSCs (Nombela-Arrieta et al. 2011; Méndez-Ferrer et al. 2009, 2010).

Important Characteristics of MSCs

Differentiation Potential of MSCs

Friedenstein was the first researcher who described that MSCs could differentiate into mesodermally derived cells (Friedenstein et al. 1974). Henceforth, it was shown that MSCs can cross lineage restriction and transform into morph functionally competent osteogenic, adipogenic, chondrogenic, vasculogenic, and myogenic phenotypes (Piersma et al. 1985; Caplan 1986; Wakitani et al. 1995; Kopen et al. 1999). This inherent property of multipotentiality may be accentuated in the presence of various factors such as ascorbic acid, dexamethasone, bone morphogenetic proteins (BMPs), WNTs, fibroblast growth factors (FGFs) besides other heparin sulfate-sensitive morphogens, and growth factors (Bhakta et al. 2012; Bramono et al. 2012; Dombrowski et al. 2013; Helledie et al. 2012; Ling et al. 2010; Teplyuk et al. 2009). While dexamethasone, indomethacin, insulin, and isobutylmethylxanthine generally support adipogenic differentiation (Scott et al. 2011), the presence of ascorbate, insulin, transferrin, selenic acid, and TGF-β promotes chondrogenesis (Johnstone et al. 1998; Mackay et al. 1998; Barry et al. 2001). Similarly, treatment with 5-azacytidine induces the cardiomyogenic differentiation of BM-derived MSC in vitro (Makino et al. 1999; Fukuda 2001; Antonitsis et al. 2007; Ullah et al. 2021). Please refer to summary of studies reporting in vitro differentiation of MSCs (Table 1).

Other factors included in the culture medium, i.e., antibiotics, serum, and growth supplements, to support cell stability and proliferation may significantly interfere with the undifferentiated expansion of MSCs (Riis et al. 2016; Pountos et al. 2014; Gharibi and Hughes 2012; Lee et al. 2001). On the same note, cellular and subcellular level preconditioning approaches have been developed to promote survival signaling, cell proliferation, differentiation, and paracrine activity of the preconditioned cells (Haider et al. 2010b; Lu et al. 2010, 2012; Suzuki et al. 2010; Haider and Ashraf 2010; Kim et al. 2009; Afzal et al. 2010). More recently, the focus has shifted to the use of pharmaceutical-grade human plasma derivatives and platelet lysate to promote MSC proliferation (Diez et al. 2015; Haider 2017). In vitro expansion of MSCs is also imperative during the use of autologous cell therapy due to the limited availability from the tissue source, especially from the aging patients as aging impairs their proliferation and differentiation potential (Kretlow et al. 2008).

Haider and colleagues have already reported that the doubling time of BM-derived MSCs from aging rats (24 months of age) was significantly higher than the young donor MSCs (Jiang et al. 2007, 2008; Haider et al. 2008). The harvest of MSCs was meager, and it took a significantly more extended time for the aging BM cells to adhere to the plastic surface. Moreover, when the cells got adhered to the plastic surface, they were stickier and required longer time to get dislodged from the tissue culture plates during trypsinization. In an attempt to support their proliferation in vitro culture, Igura and colleagues have reported that transgenic overexpression of neuropeptide Y (NPY) receptors and subsequent treatment with NPY5 significantly enhances MSCs' rate of proliferation (Igura et al. 2011). Other strategies to enhance MSC proliferation include concomitant transgenic overexpression of Ang-1 and Akt with downstream involvement of miR-143, a critical regulator of cell proliferation (Lai et al. 2012). One needs to understand that culture-expanded colonies of MSCs show limited differentiation potential that ranges from bi-potency (osteogenic and chondrogenic lineages) to monopotency (Muraglia et al. 2000; Pevsner-Fischer et al. 2011; Russell et al. 2010). The reason for this variation is not well understood, but it may be due to the epigenetic adaptations to the culture conditions.

Trophic Functions of MSCs

Various stem cell research groups now support the "paracrine hypothesis" and attribute the therapeutic benefits of MSCs with their capability to release trophic factors with or without their ability to undergo differentiation (Lei and Haider 2017). MSCs are also capable of generating a reparative microenvironment with their paracrine secretions rich in bioactive molecules, including chemokines, cytokines, morphogens, growth factors, microvesicles, and microRNAs (Kordelas et al. 2014; Lai et al. 2010; Amable et al. 2014; Eirin et al. 2014, 2016; Haider and Aramini 2020). Besides vasculogenic and myogenic differentiation potential and immune-regulatory properties, paracrine activity is an essential characteristic of MSCs that tips them as one of the choice cells for cell-based therapy.

Various research groups have provided evidence that the MSCs can maintain the growth, viability, and multipotent status of HSCs in long-term cocultures which lacked growth factor supplementation by secreting these trophic factors (Spees et al. 2016; Dexter et al. 1977; Dexter and Spooncer 1987; Queensberry et al. 1989; Wu et al. 2013). Although the paracrine hypothesis has gained popularity and acceptance as one of the important underlying mechanisms of cell therapy and has led to the novel strategy of cell-free therapy (Haider and Aziz 2017), there is no comprehensive uniform list of paracrine factors released from MSCs. The paracrine activity of MSCs is sensitive to the signals from their microenvironment. Hence, the composition of the paracrine secretions is influenced by a multitude of factors, including physical factors, i.e., hypoxia, stretch, pulsed focused ultrasound, electrical stimulation, and heat-shock treatment (Kusuma et al. 2017; Lei and Haider 2017; Antebi et al. 2018; Razavi et al. 2020; Parate et al. 2020), and chemical cues, i.e., vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), and IL-6

(Jeanmonod et al. 2018; Wei et al. 2013). Haider and colleagues have already reported that exposure to intermittent cycles of anoxia-reperfusion during preconditioning of the cells significantly altered their paracrine activity (Kim et al. 2009, 2012a). A marked upregulation of various growth factors and HIF-1α-related miRs including miR-107 and miR-210 in the preconditioned cells was observed (Kim et al. 2012b). Besides physical and chemical manipulation, MSCs have also been genetically modulated to accentuate their paracrine activity (Jiang et al. 2006; Haider et al. 2008; Ahmed et al. 2010; Haider et al. 2011).

Immunomodulatory Characters of MSCs

Bartholomew and colleagues were the first to describe the ability of allogenic MSCs to modulate immune responses in a baboon model of skin allograft (Bartholomew et al. 2002). Immunomodulatory characters of MSCs may be due to their hypoimmunogenic nature, ability to alter the T-cell response, and immunosuppression of the local microenvironment while modulating angiogenesis, apoptosis, and cell proliferation (Atoui and Chiu 2012; Faiella and Atoui 2016; Hong et al. 2012; Marfy-Smith and Clarkin 2017). Although the immune-regulatory properties of MSCs remain less well defined, the general perception is that MSCs can modulate immune cells' functions by cell-to-cell contact and by secretory mechanisms involving the paracrine release of bioactive molecule factors. Moreover, MSCs express low levels of major histocompatibility complex (MHC) class I and lack MHC class II and co-stimulatory molecule B7 and CD40 ligand (Devine and Hoffman 2000; Majumdar et al. 2003; Tse et al. 2003). They can also interfere with the normal B-cell function by the T-cell suppression (Castro-Manrreza and Montesinos 2015). Besides their anti-apoptotic and anti-inflammatory functions, MSCs interact with tumor cells via paracrine signaling to increase the risk of metastasis (Costanza et al. 2017; Lacerda et al. 2015; Ye et al. 2012; Ridge et al. 2017).

Preclinical Studies with MSCs

Small Experimental Animal Studies

MSCs are genetically stable and less susceptible to malignant transformation (Izadpanah et al. 2006). They have been extensively characterized in various small and large experimental animal models for safety and reparability. Since the early report of heart cell therapy using lineage-negative (Lin-) BMCs expressing enhanced green fluorescent protein (eGFP) in a mice model of coronary artery ligation, it was observed that the transplanted cells repopulated the infarcted myocardium with neomyocytes by 9 days after treatment. The neomyocytes were also interspersed by vascular structures, a which contributed to the recovery of global cardiac function (Orlic et al. 2001). Similar observations were later reported in a study which used human BM-derived MSCs for transplantation in an adult

murine heart (Toma et al. 2002). These encouraging data lead to a plethora of experimental studies in vitro as well as in the preclinical settings to support the safety and effectiveness of BM-derived MSCs for myocardial repair and paved the way for their further investigations in the human patients.

A direct comparison of BM-derived MSCs and MNCs in a porcine model of chronic IHD showed superiority of the former over the latter cells in terms of improvement of systolic function (van der Spoel et al. 2015). A meta-analysis of the translational studies shows that BM-derived MSC-based cell therapy is safe and effective in preserving ischemic heart function including LVEF (van der Spoel et al. 2011). The proposed mechanism is multifactorial and involves stimulation of angiogenesis and neovascularization (Psaltis et al. 2008; Haider et al. 2008), neomyogenesis (Nagaya et al. 2004; Haider 2006), paracrine effects (Mirotsou et al. 2007), reduction of fibrosis (Molina et al. 2009; Jin et al. 2020), immunomodulation (Van den Akker et al. 2013; Hamid and Prabhu 2017), and stimulation of endogenous cardiac stem cells (CSCs) to proliferate and participate in the repair process (Hatzistergos et al. 2010; Table 2).

Large Animal Experimental Models: Translational Studies

Large experimental animal studies are considered a critical step forward in establishing novel treatment approaches for diseases. The data generated from these studies are more relevant for translation to humans and hence greatly influence the advancement of novel treatments to the clinical phase of assessment. Given that stem cell-based therapy has already entered into the clinical phase of evaluation for cardiovascular applications, the support from the large experimental animal models is of utmost significance in translating the continuum of safety and efficacy data for a rationale designing the clinical trials (Harding et al. 2013). However, the need for large animal models has been generally ignored by the researchers due to their high cost, complexity, labor-intensive nature, and less suitability for the mechanistic understanding of cell-based therapy. Amid these challenges, which have restricted them to less than optimal usage to treat specific cardiac pathologies, the debate for an ideal translational model for modeling of cardiac pathologies continues unabated. However, as a fundamental principle, the body-to-heart weight ratio of the experimental animal should be comparable to that of humans to yield reliable simulation besides giving due consideration to other factors such as age appropriateness, etc. (Milani-Nejad and Janssen 2014; Haider 2018).

A wide array of large experimental animal models, i.e., pigs, dogs, sheep, monkeys, etc., have been developed to model CVDs in general and assess stem cells' safety and regenerative potential. However, experimental pig models of myocardial injury have been preferred over the other models and are primarily classified as open and closed-chest models with their respective advantages and limitations (Munz et al. 2011). Some of the typical translational studies using stem cells for myocardial repair and regeneration and their outcome have been summarized in Table 3.

Table 2 Summary of preclinical trials utilizing BM-derived MSCs in the small animal models of heart diseases

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
Wang et al. (2006)	Allogenic BM-MSCs with or without VEGF overexpression (^{VEFG}MSCs)	Intramyocardial injection of ^{VEGF}MSCs and cytokine therapy	48	AMI	Mice	Extensive regeneration and survival of ^{VEGF}MSCs in and around the infarcted heart. Blood vessel density significantly increased in ^{VEGF}MSCs as compared to other groups in peri-infarct area. Fibrosis was significantly reduced with improved LV contractile function. LV systolic and diastolic functions were well preserved in ^{VEGF}MSCs as indicated by +dP/dt, -dP/dt, and Tau (glantz)
Noiseux et al. (2006)	Allogeneic	Intramyocardial injection	12	AMI	Mice	MSC engraftment within infarcted myocardium was transient but significantly enhanced by Akt-MSCs fusion with CMs and was observed but was infrequent. Also a low rate of cardiomyogenic differentiation of MSCs was observed. MSC-Akt decreased infarct size at 3 days and restored early cardiac function. These observations confirmed that paracrine mechanisms mediated by MSC are responsible for CM survival and Akt could alter the secretion of various cytokines and growth factors

(continued)

Table 2 (continued)

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
Boomsma et al. (2007)	Syngeneic	Intravenous injection	25	AMI	Mice	Two weeks after coronary occlusion, there was a significant drop in LV systolic pressure, dP/dt (max), dP/dt(min), ESPVR, and E (max) and a significant increase in end-diastolic volume in vivo. Femoral vein injection of MSCs 1 h after occlusion attenuated the cardiac dysfunction without altering infarct size or end-diastolic volume. Injected MSCs pre-labeled with fluorescent paramagnetic microspheres were observed scattered in non-infarcted myocardium. Flow cytometry of whole heart digests after intravenous injection of MSCs labeled with either fluorescent microspheres or fluorescent PKH26 dye showed that infarcted hearts from mice that received MSC injections contained significantly more cells that integrated into the heart than those from non-infarcted controls
Derval et al. (2008)	Allogeneic	Patch system	107	Chronic	Murinae	This study showed that cell therapy improved angiogenesis and cell survival in the scar but only MSCs exhibited the capacity to invade the

						scar. No evidence of myocardial or vascular regeneration from progenitor cells. Engraftment of the progenitors/unfractionated BMC mix increased repopulation and thickness of the scar
Dai et al. (2008)	GCSF mobilization of and intramyocardial injection of BM-MPCs	GCSF mobilization of BM cells	96	AMI	Mice	LVEF and LVFS improved in MPC-treated animals as compared to control animals which received the medium. The infarcted area was also significantly smaller in MPC transplanted hearts than that in control hearts. MPC injection significantly promoted GFP+ cells homing from BM
Jin et al. (2011)	First and fifth passage naïve BM MSCs	Intramyocardial injection	45	AMI	Mice	LacZ or β-gal in the hearts from the MI + first passage MSC group was greater, leading to increased LV wall thickness, significant reduction in fibrotic area, and significantly improved LVEF than MI + fifth passage BM-MSC group on week 6 after cell transplantation
Huang et al. (2013)	BM-MSCs overexpressing Mir-1, naïve, or null vector transduce MSCs	Intramyocardial injection	80	AMI	Mice	The transplanted MSCs were able to differentiate into cardiomyocytes in the infarcted zone. Cardiac function in the MSCs, MSCs-null, and MSCs-miR-1 groups was significantly improved compared to the PBS group ($p < 0.01$ or $p < 0.001$).

(continued)

Table 2 (continued)

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
						However, most significant improvement highest rate of myocyte differentiation was observed in miR-I-expressing MSCs
Liao et al. (2017)	Allogenic	Intravenous injection	54	N/A safety study	Mice	Clinical doses of BM-derived MSCs induced mild and reversible coagulation, which increased BM-derived MSC lung embolism and clearance. Anticoagulation treatment by heparin (400 U/kg) prevented BM-derived MSC-induced coagulation and the acute adverse effects of large-dose BM-derived MSC infusion efficiently. Heparin treatment decreased BM-derived MSC lung embolism and enhanced migration and maintenance of BM-derived MSCs to target organs in cell therapy. Based on an experimental colitis model, it was confirmed that heparin treatment enhanced the effect of BM-derived MSC therapy efficiently to reduce mortality, prevented weight loss, suppressed inflammation reaction, and alleviated tissue injury

Chen et al. (2020)	AD-MSCs	Tailorable hydrogel (ColT gel) or intramyocardial	150	AMI	Mice	The Col-Tgel created a suitable microenvironment for long-term retention of ADSCs in an ischemic area and enhanced their cardioprotective effects, significantly increased LVEF at 4 weeks after MI, and decreased LV end-systolic diameter but did not significantly decrease the LV end-diastolic diameter at 4 weeks after MI compared to PBS treatment
Barbash et al. (2003)	99mTc-exametazime labeled allogenic rat BM-MSCs	Intra-left ventricular injection vs. intravenous injection	39	2, 10, and 14 days after transient coronary artery occlusion	Rat	Comparison of intra-left ventricle, right ventricle, and intravenous routes. Drastically low uptake of the intra-left ventricular injected cells in the lungs and high uptake in the heart compared to intravenous injected cells. Histological evidence of cells in the infarct and peri-infarct regions on day 7 after intra-LV injection of cells
Davani et al. (2003)	Syngeneic	Intramyocardial injection	16	AMI	Rat	Thirty days after implantation, immunofluorescence studies showed engrafted cells expressing a smooth muscle phenotype (alpha SM actin+), as similarly observed in culture. Other engrafted cells lost their smooth muscle phenotype and acquired an endothelial phenotype (CD31+). Furthermore, vessel density was augmented in the MPC

(continued)

Table 2 (continued)

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
						group compared to the control group. After 30 days, echocardiography showed an improvement in LV performance in MPCs than the control group
Nagaya et al. (2004)	Syngeneic	Intravenous injection	70	AMI	Rat	The engrafted MSCs were positive for cardiac markers: Desmin, cTn-T, and connexin43. Some of the transplanted MSCs were positive for von Willebrand factor and vascular structures. Capillary density increased after MSC transplantation. Infarct size was significantly smaller in MSC group than control group (24+/−2 vs. 33 +/− 2%, $P < 0.05$). MSCs decreased LV end-diastolic pressure and increased LV maximum dP/dt (both $P < 0.05$ and control)
Imanishi et al. (2008)	Allogenic vs. syngeneic MSCs	Intramyocardial injection	119	AMI	Rat	Both syngeneic and allogeneic MSC transplantations were useful for AMI, increased VEGF, and blood vessel density. The donor MSCs disappeared rapidly but became a trigger of VEGF paracrine effect. One day after cell transplantation, transient increase in IL-1 beta and MCP-1 in recipient

						hearts were enhanced in allogenic MSCs, with macrophage infiltration at the injection site
Atoui et al. (2008)	Xenogeneic BM-MSCS or fibroblasts	Intramyocardial injection	90	AMI	Rat	Xenogeneic transplanted human BM-derived MSCs survived in the rat heart for more than 8 weeks without the use of immunosuppressants. The implanted MSCs significantly contributed to the improvement in ventricular function and attenuated LV remodeling. No immune cell infiltration, characteristic of immune rejection, was noted in MSC transplanted cells
Haider et al. (2008)	Allogenic rat MSCs with or without IGF-1 overexpression ($^{IGF\text{-}1}$MSC)	Intramyocardial injection	78	LAD ligation//AMI	Rat	Elevated myocardial IGF-1, pAkt, and SDF-1 in $^{IGF\text{-}1}$MSCs. Massive mobilization and homing of ckit+, MDR1+, CD31+, and CD34+ in $^{IGF\text{-}1}$MSCs. Extensive angiomyogenesis in the infarcted heart with significantly improved LVEF and LVFS
Enoki et al. (2010)	Allogeneic	Intramyocardial injection	40	Chronic	Rat	One month after MI, rat hearts were injected with MCs in the presence or absence of 10 μg/ml IGF-1 with or without PI3K inhibitor, 5 μM LY294002. IGF-1 significantly increased engraftment of MSCs between 6 h and 3 days after transplantation associated with the increase in stromal cell-derived

(continued)

Table 2 (continued)

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
						factor-1α in the infracted LV. IGF-1-MSCs significantly increased neovascularization and inhibited CM apoptosis 3 days and 1 month after MSC transplantation. This improved LV function 1 month after MSC transplantation. LY294002 abrogated all of the beneficial effects of MSC transplantation with IGF-1
Kim et al. (2012a)	Allogenic MSC overexpressing mir-210 or preconditioned	Intramyocardial injection	48	AMI	Rat	Induction of miR-210 in MSCs, preconditioned or transfected, promoted cell survival post-engraftment in the infarcted heart. Moreover, direct transfer of pro-survival miR-210 from miR-MSCs to host cardiomyocytes led to functional recovery of the ischemic heart. Improved LVEF, attenuated infarct size, and reduced fibrosis
Armiñán et al. (2010)	Human cells (xenogenic engraftment)	Intramyocardial injection	90	AMI	Rat	Both cell types induced an improvement in LV cardiac function and increased tissue cell proliferation in myocardial tissue and neoangiogenesis. However, MSCs were more effective for the reduction of infarct size and prevention of ventricular

						remodeling. Scar tissue was 17.48 +/− 1.29% in the CD34 group and 10.36 +/− 1.07% in the MSCs group ($p < 0.001$ in MSCs vs. CD34). Moreover, unlike MSC, CD34 (+)-treated animals showed local inflammatory infiltrates in LV wall that persisted until 4 weeks after transplantation
Li et al. (2012)	Allogeneic	Intramyocardial injection/intravenous injection	36	AMI	Rat	The cardiac function of the intramyocardial group increased significantly compared to the intravenous and control groups at day 7. In intramyocardial group, labeled cells were visualized in the infracted heart by serial MRI, and the intensity by OI was significantly higher on day 1. In the intravenous group, the heart signals were significantly attenuated by dual-modal tracking at two time points
Wang et al. (2012)	Allogenic	Intramyocardial injection	18	AMI	Rat	Every week for 6 weeks, hearts from three rats injected with MSCs were harvested to observe single CMs. Although each week numerous round MSCs were found in the hearts of animals treated with MSCs, beating CM-like cells labeled with PKH26 were observed by the sixth week of observation. The contractility of CM-like cells

(continued)

Table 2 (continued)

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
						was the same to that of the unlabeled contractile native CMs at the sixth week and that of the normal group (10.71 ± 1.59 vs. 11.09 ± 3.42 vs. 11.21 ± 2.16, $p > 0.05$). The contractility of CM-like cells was greater than cells both from the first week (10.71 ± 1.59 vs. 7.37 ± 3.47, $p < 0.01$) and the second week (10.71 ± 1.59 vs. 8.08 ± 3.11, $p < 0.05$) which was associated with significantly increased LVEF
Flynn et al. (2012)	Allogenic	Intramyocardial injection	17	AMI	Rat	Assessed 28 days after MI, the delivery of MSCs 24 h post-MI did not improve LVEF ($p = 0.19$) and did not prevent the decline in LVEF observed in the absence of cell therapy ($p = 0.17$). The administration of unrestricted somatic stem cells also did not improve LVEF ($p = 0.11$) but prevented a further decline in LVEF ($p = 0.001$). The infarct area ($p = 0.2$), apoptosis ($p = 0.07$), and angiogenesis ($p = 0.09$) did not differ between groups

Chen et al. (2019)	Allogenic	Intramyocardial injection	14	AMI	Rat	Coculture showed that IL33-MSCs reduced T-cell proliferation and enhanced CD206+ macrophage polarization. Echocardiography showed LVEF was enhanced in IL33-MSC-injected rats compared with vector-MSC-injected rats. Postmortem analysis of rat heart tissue showed reduced fibrosis and less inflammation in IL33-MSC-injected rats
Zhu et al. (2009)	Skeletal myoblasts or BM-MSCs	Intra-arterial (LAD)	45	AMI	Rabbit	Four weeks after the cell transplantation, LVEF was significantly improved in all cell treatment groups compared to control. Neovascularization was observed in both of the treatment groups. There was no significant difference between the two cell types
Xu et al. (2010)	Allogeneic	Intravenous	46	AMI	Rabbit	The cardiac improved significantly in the US + microbubble + MSC treatment group. The number of capillaries stained by HE in US + microbubble + MSC group was much greater than that of the other groups. US + microbubble-mediated supply of MSCs increased the level of VEGF in ischemic myocardium

(continued)

Table 2 (continued)

Author/year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
Rahbarghazi et al. (2014)	Autologous	Intramyocardial	42	AMI	Rabbit	Transplanted GFP-positive MSCs were enriched with time in the peri-infarct border zone with differentiation potential into three major cell types of the heart, including cardiomyocytes, endothelial cells, and smooth muscle cells, and there was significant augmentation of microvascular density
Tanaka et al. (2016)	BM autologous preconditioned (2% oxygen culture) MSCs	Cell sheet-based delivery	N = 5 per group	Chronic MI	Rabbit	Preconditioned autologous BM-derived MSC sheets were implanted into a rabbit old MI model. Implantation of BM-derived MSC sheets increased angiogenesis in the peri-infarcted area and decreased the infarcted area, leading to LVEF improvement. Importantly, the therapeutic efficacy of the preconditioned BM-derived MSC sheets was higher than that of standardly cultured sheets

ADSC adipose-derived stem cells, *AMI* acute myocardial infarction, *BM* bone marrow, *BMC* bone marrow concentrate, *CMs* cardiomyocytes, *ESPVR* end-systolic pressure-volume relationship, *GCSF* granulocyte colony-stimulating factor, *LV* Left ventricle, *LVEF* left ventricular ejection fraction, *LVFS* left ventricular fractional shortening, *MPC* mesangiogenic progenitor cells, *MSCs* mesenchymal stem cells, *VEFG* vascular endothelial growth factor

Table 3 Summary of preclinical trials utilizing BM-derived MSCs in the large animal models of heart diseases

Author/ year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
Shake et al. (2002)	Autologous MSCs	Intramyocardial injection	14	Chronic	Porcine	Extensive survival and engraftment of MSCs at the site of cell graft. Expression of muscle-specific proteins after 2 weeks. Contractile dysfunction attenuated at 4 weeks in cell-treated animals as compared to controls. Attenuation of LV remodeling
Amado et al. (2005)	Allogenic MSCs	Intramyocardial injection	14	Acute	Porcine	Significant long-term retention of the injected cells at 2 months after delivery. Gross pathology showed significant reduction in fibrosis and near normalization of systolic and diastolic cardiac function as compared to the placebo-treated animals
Quevedo et al. (2009)	Allogenic	Transendocardial injection	10	Chronic	Porcine	Long-term MSC survival, engraftment, and tri-lineage differentiation after transplantation into chronically scarred myocardium. MSCs showed capacity for cardiomyogenesis and vasculogenesis which contribute, at least in part, to their ability to repair chronically scarred myocardium
Schuleri et al. (2009)	Autogenic	Surgical-anterior thoracotomy	15	Chronic	Porcine	Autologous MSCs' safety and efficacy in a heart failure model. Showed substantial structural and functional reversal remodeling. Support clinical trials of MSC therapy

(continued)

Table 3 (continued)

Author/ year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
						in patients with chronic ischemic cardiomyopathy
Schuleri et al. (2011)	Allogeneic	Myocardial injections	22	Chronic	Porcine	MSC-based therapy led to reduction in infarct size, whereas infarct size increased in non-treated animals
Cai et al. (2016)	Autologous	Intramyocardial injection	24	Acute	Mini-swine	Twenty animals survived full length of experiment. PET-CT showed better 18F-FDG uptake in the cell-transplanted LV segments. Improved global cardiac function. Molecular studies showed mTOR activation signaling and improved LV function due to paracrine activity
van der Spoel et al. (2012)	Autologous	Intracoronary, NOGA-guided transendocardial, or surgical	19	Acute	Porcine	Direct comparison of MSCs with BM-derived mononuclear cells and effect of repetitive injections. At 4 weeks, LVEF improved in MSC-treated animals, but endpoint analysis showed no significant difference in efficiency after surgical injections at 8 weeks
de Jong et al. (2014)	Allogenic	Intracoronary infusion	36 with moderate and 33 with severe infarct	Acute	Porcine	Encapsulated MSCs (eMSCs) transduced to express glucagon-like protein-1. Three incremental doses of eMSCs or Ringer's solution without cells. LVEF increased more (9.3%) in

						animals with severe infarction. Vessel density increased threefold in the infarct zone 30% more in the border zone
Sheu et al. (2015)	Autologous	Surgical	25	Acute MI	Porcine	Baseline LV injection fraction and LV chamber size did not differ among the five groups. By day 60, LVEF was highest in group 1 and lowest in group 2, significantly higher in group 5 than that in groups 3 and 4, and significantly higher in group 4 than that in group 3
Guadalupe et al. (2016)	Adipose tissue allogeneic MSCs overexpressing IGF/HGF	Intramyocardial injection	14	Acute MI	Porcine	Treatment with paMSC-IGF-1/HGF (1:1) vs. the other groups had a reduced inflammation in some sections analyzed. This also enhanced angiogenesis in ischemic myocardium. Although indices of cardiac function did not show significant improvement, cell retention and IGF-1 overexpression were confirmed within the myocardium
Lim et al. (2006)	Allogenic naïve or Akt-transduced MSCs	Intracoronary infusion	36	Acute MI	Porcine	Highest LV systolic function improvement and reduction in infarct size were observed by M-SPECT in Akt-transduced MSCs than naïve MSC- or vehicle-treated animals. Akt-MSCs survived better in the peri-infarct zone observed by FISH

Table 3 (continued)

Author/ year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
Silva et al. (2005)	Allogeneic	Intramyocardial injection	20	Chronic	Canine	Mean LVEF was significantly higher in treated dogs at 60 days. WBC and CRP levels were similar in both groups. CK-MB and troponin-I increased from baseline to 48 h and then returned to baseline. There was a trend toward reduced fibrosis and more vascular density in treated group. MSCs co-localized with endothelial and smooth muscle cells but not with myocytes
Bartunek et al. (2007)	Autologous Pre-treated MSCs	Intramyocardial injection	30	Chronic	Canine	Pre-treated MSCs with cardiomyogenic factors significantly increased their myogenic differentiation and increased LV wall thickness by week 12. The biological ex vivo cardiomyogenic specification of adult MSCs is feasible and increases in vivo cardiac differentiation as well as the functional recovery
Mathieu et al. (2009)	Autologous	Intramyocardial injection	24	Chronic	Canine	Direct comparison of BM-derived MSCs and mononuclear cells. Treatment with latter were superior in giving sustained improvement in wall motion score index, reduction in infarct size, improved end-systolic elastance, and improved regional systolic function. VEGF-3 levels

						increased in border zone leading to more vascular density in mononuclear cell-treated animals
Wang et al. (2015)	Allogenic MSCs +bFGF	Retrograde coronary infusion	32	Subacute	Canine	Retrograde coronary venous bFGF infusion enhanced engraftment and differentiation capacity of MSCs, recovery cardiac function, improved LVEF, attenuated remodeling, and increased vascular density
Zhao et al. (2012)	Autologous	Surgical	10	Acute	Ovine	Significant attenuation of CM hypertrophy with the normalization of the hypertrophy-related signaling proteins PI3Kα, PI3Kγ, extracellular signal-regulated kinase (ERK), and phosphorylated ERK (p-ERK) in the adjacent zone of the MSC-treated group versus the MI-alone group
Locatelli et al. (2015)	Allogenic male donor naïve or VEGF-expressing BM-MSCs	Intramyocardial injection	24	AMI	Ovine	One month posttreatment with MSCs overexpressing VEGF, infarct size (magnetic resonance) decreased by 31% vs. pre-treatment. LVEF recovered to almost its baseline value and marked decrease in end-systolic volume. Moreover, the treatment induced significant capillary and arteriolar proliferation, which reduced subendocardial fibrosis. These data were in comparison with naïve MSC-injected animals

Table 3 (continued)

Author/ year	Cell type	Mode of delivery	Sample size	Model type	Animal	Main findings
Rabbani et al. (2017)	Autologous	Intramyocardial injection	18	Acute	Ovine	Echocardiography revealed a significant improvement in the LVEF compared with the control group (p value <0.05). Vascular density increased in cell therapy groups. The electron microscopic evaluation of the infracted areas revealed cardiomyocytes in variable stages of development in the border zone
Hu et al. (2016)	Allogenic hypoxia cultured	Intramyocardial injection	49	Acute	Cynomolgus monkey	Direct comparison naïve and hypoxia-treated allogenic MSCs for long-term effects. Insignificant functional improvement between the two cell-treated groups. However, hypoxia-MSC transplantation was also associated with increases in cardiomyocyte proliferation, vascular density, myocardial glucose uptake, and engraftment of the transplanted

Quevedo and colleagues investigated the regenerative potential of BM-derived MSCs after long-term engraftment in a chronic myocardial infarction (MI) model (Quevedo et al. 2009). The cells were harvested through an iliac crest BM aspiration from a healthy male landrace pig, expanded in vitro, and labeled with 5-bromodeoxyuridine (BrdU). The experimental animal model of chronic MI was developed in female pigs by left anterior descending (LAD) occlusion for 150 min using an over-the-wire balloon catheter. The pattern of induced MI was consistently antero-apical in all of the experimental animals included in the study. Twelve weeks following the induction of MI, the animals were allocated to receive either a catheter-based transendocardial injection of placebo ($n = 4$) or male allogeneic BM-derived MSCs ($n = 6$). A noticeable decline in the LVEF, transmural extension of myocardial scar, and left ventricular remodeling was observed on a cardiac MRI scan at 12 weeks after the induction of MI. MSC-treated hearts showed almost one-third decrease in the infarct size (29%) 8 weeks after the intervention compared to the placebo-treated animals. Eulerian circumferential shortening (Ecc) was used to estimate the contractile function of the regenerated myocardium, which showed significant improvement in the border and infarct zones for up to 3 months of observation compared to the placebo-controlled group. Furthermore, a significant increase in the basal blood flow was observed as early as 4 weeks after BM-derived MSC therapy in the cell treatment group.

Schuleri and colleagues investigated the dose-response effects exerted by BM-derived MSCs on the infarcted myocardium (Schuleri et al. 2009). The experimental porcine model was developed by a temporary balloon occlusion of the LAD, similar to the approach described earlier by Quevedo et al. (2009). Ischemia was sustained for 120 min, followed by reperfusion by deflating the balloon. The BM-derived MSCs were harvested from the iliac crest of each animal and expanded in vitro for four to seven passages before transplantation. The cells were phenotypically characterized for CD45− and CD90+ expression besides the assessment for CFU-F. A total of 15 pigs were randomly assigned to one of the three arms of high-dose, low-dose, and placebo (saline) treatment. The cells were delivered by direct intramyocardial injections through an anterior thoracotomy into areas of severe hypo- and/ or akinesia at a rate of 15–25 injections per animal. A series of cardiac MRIs were obtained at different time intervals to assess the outcomes of the study. The study data revealed no observable safety and tolerability concerns (including neoplasms and arrhythmias) in all of the intervention groups. However, infarct size decreased significantly in both cell treatment groups (i.e., high and low dose) with a concomitant remodeling reversal when compared to the placebo-treated animals. Furthermore, the cell-treated animals had a significant enhancement in their cardiac contractile function and improved post-MI coronary basal flow and adenosine-dependent coronary flow reserve (CFR).

Building on these findings, Schuleri et al. conducted another study to investigate the usefulness of multi-detector computed tomography (MDCT) in assessing the therapeutic effects of myocardial regenerative cell therapies (Schuleri et al. 2011). They reported a massive 27.9% reduction in infarct size and a significant 13%

increase in LVEF. The authors concluded that MDCT was a valuable tool in evaluating infarct size and LVEF after intramyocardial cell delivery.

Cai et al. used an open-chest model of acute MI in mini-Chinese swine to elucidate the mechanism of stem cell-based improved cardiac function (Cai et al. 2016). Using PET-CT, the authors observed a significant increase in mean signal intensity (MSI) in the cell-transplanted hearts at 4 weeks as compared to their baseline levels at 1 week after cell transplantation. Gene expression of glucose transporters Glut1 and Glut4 and glucose metabolism-related enzyme phosphofructokinase was significantly increased in the cell-transplanted segments. The authors inferred that these molecular changes leading to global and regional left ventricular function resulted from the transplanted cells' paracrine.

Lim et al. previously used either naïve or genetically modified BM-derived MSCs overexpressing Akt (Lim et al. 2006). The sex-mismatched cells were delivered via intracoronary infusion 3 days after the development of experimental porcine model of MI developed by balloon occlusion for 30 min. Myocardial single-photon emission tomography (M-SPECT) revealed the highest LVEF improvement and reduced infarct size in Akt-MSC-treated animal hearts. Fluorescence in situ hybridization (FISH) for Y-chromosome revealed the highest survival of male donor cells in the peri-infarct zone in the female recipient animals. The authors observed the most significant cardiac function improvement in the Akt-MSC-treated animals and attributed it to the better donor cell survival. On the same note, de Jong et al. used genetically modified MSCs expressing glucagon-like peptide-1 (GLP-1) and microencapsulated them before transplantation in a porcine model of AMI (de Jong et al. 2014). One hundred animals were divided into posterolateral (moderate MI, $n = 36$) and anterior MI (severe MI $n = 33$) groups. The most significant LVEF improvement was observed in the GLP-1 eluting microencapsulated cells transplanted in severe MI animals. The microencapsulated cells served as a continuous source of GLP-1, an incretin hormone with cardioprotective effects. Moreover, there was a significant increase in vascular density in the infarct and peri-infarct areas in the animals treated with GLP-1-expressing MSCs.

Some of the other exciting studies in the porcine model include comparison of different routes of administration (Moscosoa et al. 2009; Gathier et al. 2019), percutaneous intramyocardial delivery of MSCs (Tao et al. 2015), validation of the use of contrast-enhanced MRI to monitor the efficacy of cell therapy (Malliaras et al. 2013), study of the effect of dose on the outcome of myocardial repair (Crisostomo et al. 2019), etc.

Despite their overwhelming abundance in the literature, the promising performance of BM-derived MSCs on improving the myocardial function in chronic ischemic models did not stop with swine models. For example, Silva et al. investigated the effectiveness of BM-derived MSCs in a canine model of chronic myocardial ischemia (Silva et al. 2005). Diverging from using an autologous source of the cells, Silva et al. utilized allogeneic canine cells. The cells were isolated and cultured using almost a similar protocol previously discussed and labeled with the cross-linkable membrane dye CM-DiI and the nuclear stain DAPI before transplantation. The chronic myocardial ischemia model was developed through a left thoracotomy

and placement of an ameroid constrictor over LAD. One month after ameroid constrictor placement, the animals were randomly divided to receive intramyocardial injection of allogeneic MSCs (treatment group, n = 6) or saline (control group, n = 6). Overall, the procedure was highly safe without any observed arrhythmias or pericardial effusions. Transthoracic echocardiography revealed a mean 10% reduction of LVEF in the control group. In comparison, it showed a significant 5% increase in the treatment group, with a concomitant reduction in fibrotic changes in the infarct area. Furthermore, a noticeable increase in the vascular density was detected in the BM-derived MSC treatment group. The authors claimed differentiation of Dil- and DAPI-positive cells into actin-positive neomyocytes leading to increased LV wall thickness.

On the same note, Zhao et al. investigated the effectiveness of allogenic BM-derived MSCs on cardiac remodeling using an ovine model of acute myocardial ischemia (Zhao et al. 2012). The cell preparation process followed a similar protocol as described earlier, and the purified cells were characterized by tri-lineage differentiation and flow cytometric analysis for surface marker expression to ascertain the purity of MSC preparation. Experimental MI was developed in ten male sheep through a surgical ligation of LAD and second diagonal coronary arteries, while another four healthy sheep were assigned to a sham group. The sham-treated group's hearts were not infarcted and did not receive any stem cell therapy. Terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) assay was used to detect apoptotic cells. The total number of TUNEL staining nuclei was later used to estimate the nuclei undergoing apoptosis. Furthermore, hypertrophy-related signal proteins (e.g., PI3Kα, PI3Kγ, and p-ERK/ERK) were upregulated in the infarction zone in the animals that only received MI as compared to the sham group. Nonetheless, analysis of the identical zones in the BM-derived MSC treatment group revealed a normalized expression, almost indistinguishable from that of the sham group. Sonomicrometric analysis revealed a considerable decline in regional contractile function and remodeling strains in both cell treatment and control groups.

Throughout the years, various strategies have been adopted to enhance the efficacy of BM-derived MSCs. For example, van der Spoel et al. investigated the efficiency of different cell delivery methods in donor cell survival and therapeutic benefits (van der Spoel et al. 20,212). They compared intracoronary and transendocardial routes of delivery with the well-established surgical delivery in a chronic porcine model of ischemic cardiomyopathy. The BM-derived MSCs were radiolabeled with indium-111 (^{111}In) for later quantitative analysis of cell survival. The experimental animal model of MI was developed by median sternotomy induced in 24 healthy pigs by temporary ligation of the left circumflex artery for 75 min. The authors did not observe any significant difference in hemodynamic and echocardiographic parameters at the start of the trial and 1 month after the induction of MI. In addition, cell-related characteristics such as viability and count did not differ between the groups. However, intracoronary delivery showed more consistent results concerning the delivery efficiency, while higher levels of local retention (i.e., at the mid-papillary level) were observed in the animals receiving

transendocardial delivery. Noticeably, a high level (up to 45%) of ^{111}In-labelled cell retention was observed in extra-cardiac organs in all of the groups.

To enhance donor cell survival, various strategies have been adopted. In this regard, Sheu and colleagues investigated the effects of combining shockwave therapy and autologous BM-derived MSCs to improve the clinical outcome of the left ventricular failure (Sheu et al. 2015). Twenty-five male mini-pigs were equally divided into sham control (group 1), acute MI (AMI, group 2), AMI + shock wave (shockwave, group 3), AMI + autologous BM-derived MSCs (group 4), and AMI + shockwave + autologous BM-derived MSCs (group 5). The experimental animal model was developed by LAD ligation, and 1 hour later the animals received their respective treatment by intramyocardial injections. The trial results showed that dual therapy group receiving shockwave therapy and BM-derived MSCs showed a significantly higher LVEF improvement with a significant reduction in the infarct size and most wall thickness. Immunohistochemical staining revealed that the number of inflammatory indicators was also significantly lower in this group. Neovascularization in the infarct and peri-infarct area, as evident by the number of arterioles, was by far the highest in the AMI-shockwave BM-derived MSC group. These findings support the essential regenerative role of BM-derived MSCs and signify the anti-inflammatory role of shockwave therapy.

Although the use of BM-derived MSCs has already reached the veterinary clinics for various applications (Gomes et al. 2017), some other important studies using the canine model for myocardial repair include assessment of the efficiency of pre-treated MSCs with cardiomyogenic factors (Bartunek et al. 2007), comparison of BM-derived MSCs and mononuclear cells (Mathieu et al. 2009), histological evidence of the efficacy of allogenic MSCs in myocardial repair (Vela et al. 2009), combining cell delivery with growth factor treatment for myocardial repair (Wang et al. 2015), comparison of routes of administration for MSC delivery, using dual-isotope simultaneous acquisition (DISA) of SPECT for assessment (Perin et al. 2008; Hao et al. 2015), etc. Besides canine models, monkeys are also considered an excellent surrogate cardiac model (Yang et al. 2011) for translational assessment of stem cells for myocardial repair (Hu et al. 2016).

It is pertinent to add that that there is a wide array of experimental animal models, dominated by porcine models (Hotham and Henson 2020), which are available to study the safety and efficacy of stem cell-based therapy of heart diseases, and each one of these models has specific features (Ou et al. 2010; van der Spoel et al. 2011). These specific features could be exploited to add to the relevance of the study to achieve desired results for translation to humans and hence should be given due consideration before opting for a particular model (Gandolfi et al. 2011). For example, the presence of well-developed collateral circulation in the canine hearts is useful to study vascular adaptation to ischemic myocardial injuries and, therefore, may have an effect on the long-term benefits of stem cell therapy. Similarly, the ovine and porcine hearts, similar to humans', lack these adaptations, making them more suitable in studies where human-like anatomy is a required feature. However, the difficulties brought by the unique thoracic anatomy of ovine have limited its use due to technical challenges encountered during cardiac

imaging (e.g., transesophageal echocardiography). Moreover, ovine and porcine models may not be feasible for mechanistic understanding at molecular-level interplay involved in cell-based therapy. Despite its shortcomings, porcine models have gained huge popularity among researchers modeling heart disease for translational studies because of the many similarities swine heart shares with humans' in the aspects of gross anatomy, coronary circulation, and immunological and physiological responses (Cui et al. 2005; Milani-Nejad and Janssen 2014).

MSCs in the Clinical Perspective

Stem cell-based therapy has emerged as novel science that should be considered for the routine treatment of cardiac damage. MSCs are currently the most used cells for cell-based cardiovascular therapy (Rajab et al. 2020). Based on the safety and efficacy data from the preclinical and translational studies and given their ease of ability and biological characteristics, they have progressed to advanced phases of clinical assessment including several randomized placebo-controlled phase II and even phase III trials for different diseases (refer to Chapter-5, section 4 & Table-1 in this book). Despite the dominance of autologous MSCs in these clinical studies, the use of allogeneic MSCs has also gained popularity with encouraging results in general and for cardiovascular applications (Table 4). Irrespective of the tissue source for MSCs, the primary efficacy endpoint in these clinical trials has been to investigate if MSC transplantation could successfully improve the indices of LV structure and function in patients with IHD. The following section summarizes some of the randomized clinical trials involving BM-derived MSCs from autologous and allogenic sources to discuss the advantages and limitations of the cells from each source of cell in the clinic.

Randomized Clinical Trials with Autologous or Allogenic BM-Derived MSCs

The POSEIDON Trial

The significance of the POSEIDON trial (Clinicaltrials.gov Identifier: NCT01087996) is that it compares the safety and efficacy of autologous vs. allogenic BM-derived MSC-based cell therapy in treating myocardial damage (Hare et al. 2012). A total of 30 patients with ischemic cardiomyopathy were included in the study. Cardiac CT screening was done at 13-month follow-up for detecting LV function and volumes besides quality of life, physical health, LVEF, and other related cardiac measurements. Only one participant from each treatment group had SAE during 30-day follow-up after treatment and needed emergent hospitalization for heart failure. The 1-year incidence of SAE was 33.3% ($n = 5$) vs. 53.3% ($n = 8$) in the allogeneic vs. autologous groups ($p = 0.46$). Four patients suffered ventricular arrhythmias in the autologous group, while no ventricular arrhythmias were observed in the allogenic group. The trial data concluded safety and efficacy of stem cell therapy in cardiac patients in terms of functional status and

Table 4 Summary of clinical trials utilizing BM-derived MSCs in the management of heart failure

Author/year	Cell type	Mode of delivery	Sample size	Trial phase	Placebo	Primary outcomes	Findings
Mathiasen et al. (2020)	Autologous	I/M injection	60	2	Phosphate-buffered saline	Change in LVESV by MRI or CT	Significant reduction of LVESV in MSC group
Butler et al. (2017)	Allogenic	IV	22	2	Ringer's lactate	Safety and efficacy	Nonsignificant
Karantalis et al. (2014) (PROMETHIUS)	Both	I/M injection	9	Suspended (1 and 2)	No placebo group	12 months adverse events	Insufficient results
Heldman et al. (2014)	Both	Intraventricular injection with infusion catheter	65	1 and 2	Vehicle placebo	30-day adverse composite event	None (0% events)
Hare et al. (2012) (POSEIDON)	Both	Transendocardial stem cell injection	30	1 and 2	None	30-day emergent serious adverse events	6.7% rate (1 patient in each group)

quality of life improvement. However, there was no significant improvement in 6-min walk test (6MWT) in the allogenic group compared to the baseline, while no significant LVEF and LV end-diastolic volume changes were observed in the autologous group. Interestingly, low-dose allogenic MSC (20 million cells) treatment led to highest reduction in LV end-diastolic volumes. Lack of placebo arm is a limitation of this study, along with a small size of participants.

The same research group registered another trial POSEIDON-DCM (ClinicalTrials identifier: NCT01392625) comparing allogenic vs. autologous BM-derived MSCs in patients with dilated cardiomyopathy. A total of 37 patients were randomized in a ratio of 1:1 to transendocardially (TESI) receive 100 million autologous or allogenic MSCs using NOGA catheter (Mushtaq et al. 2014). For baseline, the patients were followed up on day 30, 3, 6, and 12 months for safety and efficacy endpoints including serious adverse events (SAE), LVEF, 6MWT, MACE, and immune-biomarkers. The authors did not observe any treatment-related SAE in both the treatment groups until day 30 but observed SAEs 28% (95% CI: 12.8, 55.1) in allogenic treatment group vs. 63.5% (95% CI: 40.8, 85.7; $p = 0.1004$) in autologous treatment group (Hare et al. 2017). LVEF was up by 8 units (95% Cl: 2.8, 13.2; $p = 0.004$) vs. 5.4 (95% Cl: −1.4, 12.1; $p = 0.116$, allogenic vs. autologous treatment $p = 0.4887$) units in allogenic vs. autologous treatment groups, respectively. Interestingly, MACE rate was also lower in allogenic treatment group ($p = 0.0186$ vs. autologous group) besides a significant decrease in tumor necrosis factor-alpha ($p = 0.00001$). These findings clearly showed the superiority of allogenic MSCs in the clinical perspective.

The PROMETHEUS Clinical Trial

Researchers at the University of Miami and Johns Hopkins University conducted a **Pro**spective Randomized Study of Mesenchymal Stem Cell Therapy in Patients Undergoing Cardiac Surgery (PROMETHEUS; ClinicalTrials.gov Identifier: NCT00587990) (Karantalis et al. 2014). During the phase I/II randomized, double-blind, placebo-controlled study, a total of six patients received intramyocardial injections of autologous MSCs as an adjunct to coronary artery bypass grafting (CABG). The cells were injected in the akinetic/hypokinetic myocardium, which were not receiving bypass graft and assessed by cardiac MRI during follow-up at intervals of 3, 6, and 18 months. All the patients enrolled in this study had a known history of chronic ischemic LV dysfunction after a MI. Cardiac MRI at 18 month revealed increased LVEF ($9.4\% + 1.7$, $p = 0.0002$) and decreased scar mass($-47.5 + 8.1$, $p = 0.0001$) as compared with the baseline values. Interestingly, reduction in the scar volume, perfusion, and contractile function improvement was observed in the cell-transplanted regions. In addition to increased stroke volume, there was significantly increased ventricular wall thickening due to revascularization. It is important to mention that there was no control patient group in the study and results were compared to previously obtained data of post-CABG patients; hence, results should be viewed in scope of this important limitation of the PROMETHUS trial. However, these data favor MSC-based therapy in patients who require surgical intervention, as combining both approaches could lead to interesting outcomes.

The TAC-HTF Clinical Trial

Heldman and colleagues conducted TAC-HTF trial (ClinicalTrials.gov Identifier: NCT00768066), a phase I/II randomized, double-blind, placebo-controlled study (Heldman et al. 2014). Led by Joshua Hare at the University of Miami Miller School of Medicine, the trial was intended to study the safety and efficacy of trans-endocardial injection (TESI) of autologous human BM-derived mononuclear cells or MSCs in patients with chronic ischemic LV dysfunction and heart failure after MI. A total of 65 patients with confirmed ischemic cardiomyopathy and LVEF less than 50% were randomized to receive MSCs or mononuclear cells into ten different sites in the LV endocardially using an infusion catheter. No treatment-related SAEs were observed with statistical significance between the different arms of the study within 1 month, which was reassuring regarding the safety of the procedure. The study, however, recorded two unfortunate deaths due to cardiac adverse events, one patient each from the MSC- and placebo-treated groups at 239 and 115 days after respective treatment. A total of 16 patients were hospitalized, five patients each from the cell therapy groups and six patients from the placebo group. Six-MWT distance increased and infarct size decreased significantly within the group only in MSC-treated patients. The authors did not observe any significant change in LVEF and LV chamber volumes. The findings of this trial reassured the safety of TESI-based stem cell therapy in patients with chronic ischemic cardiomyopathy for larger future studies.

Mesenchymal Stromal Cell for IHD

Mathiasen and colleagues have reported a single center, randomized controlled study (ClinicalTrials.gov Identifier: NCT00644410). Led by Jens Kastrup at Rigs Hospitalet, Denmark, the trials were designed to study the effect of NOGA-guided direct intramyocardial injection of in vitro expanded MSCs on the development of new myocardium and blood vessels in patients with heart failure using saline-treated patient group as control (Mathiasen et al. 2012). A total of 60 patients (aged 30–80 years) with ischemic heart failure, LVEF <45%, and NYHA class II or III were randomized (2:1) to receive their respective treatment of cell therapy and placebo. Six-month follow-up revealed significant improvements in LVEF of 6.2% ($p = 0.0001$), stroke volume of 18.4 mL ($p = 0.0001$), and myocardial mass of 5.7 g (p ¼ 0.001) in cell therapy group vs placebo group (Mathiasen et al. 2015). The authors also observed reduced LVESV in MSC group, −7.6 (95% CI -11.8 to −3.4) mL ($p = 0.001$), which was increased in the placebo group, 5.4 (95% CI -0.4 to 11.2) mL ($p = 0.07$). However, no differences were observed in NYHA class, 6-MWT. The improvement was consistent and sustained even 1 year after treatment. Unfortunately, mortality was present in both intervention and control groups, but the mortality rate was less in MSC-treated group (35%) after 4 years of treatment than the control group (27.5%) (Mathiasen et al. 2020). A similar trend was seen in SAE as they were considerably lower in the treatment group, with fewer hospitalizations for angina. These data show the safety TESI and therapeutic benefits of autologous MSCs in patients with ischemic heart failure.

Intravenous Allogenic MSC Nonischemic Cardiomyopathy

Butler and colleagues have reported the results of a phase 2a, single-blind, placebo-controlled, randomized study that evaluated the safety and preliminary efficacy of intravenously administered allogenic BM-MSCs (Clinicaltrials.gov identifier: NCT02467387). A total of 22 patients with nonischemic heart failure were randomized to intravenously receive 1.5 million cells/kg ($n = 10$) or placebo control ($n = 12$) (Greene et al. 2017). The cells were expanded in vitro under chronic hypoxic conditions before transplantation to render them ischemia tolerant. The patients enrolled in this study had the specific characteristics of having chronic nonischemic cardiomyopathy with a LVEF 40% or less but without a prior history of MI and NYHA class II/III. After their respective treatment, the patients were followed up at regular of intervals of 30 days for the first 180 days, 9 months, and 15 months. There was no difference between the incidences of SAE in either cell therapy or control groups (Butler et al. 2017). There was one reported bruising at the site of intravenous infusion but no deaths or hospitalization in either group. Change in LVEF compared to the baseline was observed but insignificant. There was a finding of reductions in LV diastolic and systolic volumes. However, compared with placebo, cell therapy group showed an increased 6MWT distance (+36.47 m, 95% CI 5.98–66.97; $p = 0.02$). The authors attributed the functional improvement to the systemic anti-inflammatory and immunomodulatory effect of hypoxia-stimulated allogenic MSCs via the systemic release of bioactive molecules. Although the study was limited by the sample size and lacked a comparator group for hypoxia cultured cells using normoxia cultured cells, overall, intravenous administration of hypoxia preconditioned allogenic MSCs was safe and well tolerated intravenously and led to noticeable improvement in health status of the patients.

Conclusions and Future Perspective

Although the ongoing and already completed clinical trials diverge in the inclusion and exclusion criteria used for patient enrolment, the quality of the cell preparation, the number of cells injected, route of administration, number of injection sites for cell delivery, time of injection after ischemic episode, study endpoints and method of assessment, etc., the apparent divergence in all these parameters renders it challenging to reach to a consensus outcome in terms of MSC efficacy (Kallu et al. 2021). However, the current evidence stemming from these trials supports the safety and modest ability of MSCs to attenuate myocardial fibrosis after ischemia, besides neovascularization and tissue regeneration. A recently published systematic review and meta-analysis by Jeong et al. involved 950 patients from 14 randomized placebo-controlled trials that showed mechanical, regenerative, and clinical benefits of cell-based therapy using MSCs (Jeong et al. 2018). They observed 3.84% (95% CI: 2.3 ~ 5.35) increase in LEVF in MSC treatment group that was sustained until 24 months, while scar mass was reduced −1.13 (95% CI = −1.8 to −0.46). These observations comply with the outcome of a systematic review and meta-analysis published based on 23 preclinical studies in experimental animal models of AMI and

ischemic heart failure (Lalu et al. 2018). The observed therapeutic efficacy of stem cells may be improved further if certain requirements pertaining to the abovementioned parameters have been met and optimized.

One of these requirements, and possibly the primary one, is the quality of the cell preparation which is now being considered as responsible for modest outcome of the clinical trials (Haider 2018; Shahid et al. 2016). In this regard, the genetic constitution of the donor cells to ensure its acceptance by the recipient immune system is an important determinant to ensure that the transplanted cells survive and their derived tissue is sustained for a long time. Apparently, autologous MSCs seem an obvious choice as they inherently avoid any immunologic effects, but in the clinical perspective, this may not be true. For cardiovascular applications, patients who were candidates for cell therapy may not have the option of waiting for long enough that their autologous MSCs could be expanded in vitro to achieve them in sufficient number needed for transplantation. Similarly, aging and diseased autologous cells from the patient for engraftment in elderly patient may not be the best option in the clinic (Haider 2018). As the safety and efficacy of allogenic MSCs are comparable with autologous (Jansen of Lorkeers et al. 2015) and even better in some cases than the autologous cells, the use of allogenic MSCs has logistic superiority. Please refer to ► Chap. 1, "Human Mesenchymal Stem Cells: The Art to Use Them in the Treatment of Previously Untreatable," in this book for further discussion where a case for allogenic MSCs has been discussed in depth.

Abstract

Mesenchymal stem cells (MSC) are specific cell types that enable tissue renewal within the body and are activated during the regeneration processes in response to injury. These cells are present in all human and animal tissues. In medical and biological research, MSCs are isolated and purified from the donor organism and cultured in vitro before use in the treatment of a variety of diseases and conditions associated with tissue damage and cell loss, including ocular lesions. This approach is called cell-based therapy or regenerative medicine. Despite the many existing therapeutic strategies in the area of cell therapy in relation to curing ocular diseases in recent years, advances and new regenerative therapy

methods have also been developed and consolidated, giving us a new perspective. Therefore, it is necessary to implement standardization and comparison of cell therapy results. Experimentation using animal models has played a central role in biomedical research. The safety and efficacy of new drugs are usually tested in animal models of human diseases prior to entering human clinical trials. Nevertheless, the pathophysiological mechanisms of eye diseases are complex and multifactorial; hence it is crucial that experimental animal models with clinical relevance provide adequate information and sufficiently replicate the eye diseases being assessed and demonstrate the effects of MSC therapy.

Keywords

Abbreviations

ADMSC	Adipose-derived mesenchymal stem cells
AMD	Age-related macular degeneration
BDNF	Brain-derived neurotrophic factor
BMSC	Bone marrow stromal cells
CNV	Choroidal neovascularization
DR	Diabetic retinopathy
ES	Embryonic stem cells
GCL	Ganglion cell layer
GFP	Green fluorescent protein
PVPC	Multipotent perivascular progenitor cells derived from human
hESC	Embryonic stem cells
hRPC	Human retinal progenitor cells
LEC	Lens epithelial cells
LHON	Leber's hereditary optic neuropathy
MSC	Mesenchymal stem cells
NF1	Neurofibromatosis type 1
POAG	Primary open-angle glaucoma
RCS	Retinal dystrophy of Royal College of Surgeons rats
RGC	Retinal ganglion cells
RP	Retinitis pigmentosa
RPE	Retinal pigment epithelial cells
SC	Stem cells
UMSC	Umbilical cord mesenchymal stem cells

Introduction

Dysfunction of the visual system can significantly reduce the quality of human life, as the brain receives more than 80% of the incoming information via the eyes. According to the World Health Organization (WHO), in 2020, there were more than

1.3 billion people with visual impairments; 217 million people within this group had poor vision, and 36 million were blind. The leading causes of visual impairment are uncorrected refractive errors, cataracts, age-related macular degeneration, glaucoma, diabetic retinopathy, and corneal opacity (Lancet Global Health 2019).

Despite the availability of various medications and therapies available for use in ophthalmic practice presently, not all ocular diseases are treatable. Therefore, stem cell (SC) therapy has recently become more widespread. Many publications indicate its effectiveness in treating intractable eye diseases for both humans and animals (Zakirova et al. 2015, 2019).

The role of experimental animal models for obtaining information about the effectiveness and safety of cell therapy, including SC therapy, has significantly increased. Most studies are currently conducted on rodents, and on large animals, such as rabbits, dogs, pigs, sheep, goats, and non-human primates (Harding et al. 2013).

There is presently a wide range of potential SC-based drugs that can be used for medical purposes. Currently, embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs) somatic stem cells, as well as differentiated cells derived from SC, mesenchymal stem cells (MSCs) from adipose tissue (ADMSCs), MSCs from bone marrow (BM-MSCs), neural stem cells, endogenous retinal stem cells, and stem cells derived from ciliary, retinal pigment epithelium, and umbilical cords (UMSCs) are used for therapy (Harding et al. 2013).

Currently, preclinical animal models are used to develop methods for treating eye surface diseases, glaucoma, retinal diseases, diabetic retinopathy, and age-related macular degeneration. Many experimental animal models imitate eye diseases, but none of them reflect the incredible complexity that the human disease possesses. Therefore, to replicate or emulate different aspects of human pathology, several experimental models of the same disease are usually required. Some of the important and commonly used experimental animal models used for testing cellular technologies in ophthalmology are summarized in Table 1.

Models of Corneal Diseases

The cornea is a piece of transparent tissue in the anterior aspect of the eye. It is a protective physical and biological barrier against the external environment and provides a refractive force for the concentration of light on the retina (Lewis et al. 2010).

The cornea comprises three main cell types: stratified surface epithelium, stromal keratocytes, and the innermost single-layered endothelial cells, which are neuroepithelial in nature (Sagizade et al. 2017). Surface epithelial cells are essential for corneal transparency and visual acuity. Corneal epithelial cells are continuously enhanced by a population of SC or progenitor cells, which are located in the corneal limb. However, severe corneal damage caused by chemical or mechanical exposure, and immune or hereditary diseases, can lead to corneal inflammation, ulceration, neovascularization, and deficiency of limbal SC. All of these situations can result in loss of vision.

Corneal transplantation is currently a reasonably effective method for managing corneal damage. However, the main problem with this treatment is the rejection of the transplants following this therapeutic technique. The use of allogeneic or autologous limbal cell transplantation is also limited due to the significant risk of systemic immunosuppression. Autologous transplantation can also lead to damage in the contralateral normal eye. Therefore, the search for a safe and adequate source of cells to create a bioengineered corneal epithelium is still ongoing, and one which is under active research at the present.

Numerous experimental studies have attempted to use mesenchymal stem cells (MSCs) as a bioengineered corneal epithelium. Research has also confirmed that epithelial-like corneal cells can be formed from mesenchymal and embryonic stem cells (ESCs) extracted from bone marrow. The numerous potential advantages of adipose tissue-derived MSCs (ADMSC), including easy availability, low immunogenicity, high pluripotency, lack of ethical controversy, and reduced risk of infection, have made them a particularly attractive cell source for bioengineered corneal epithelium (Sun et al. 2018).

MSCs can treat both congenital corneal diseases and various types of injuries and damages (Joe and Gregory-Evans 2010). Additionally, there are many animal models designed to reproduce inherited diseases and injuries affecting the cornea. Therefore, the therapeutic efficacy of MSCs has been tested on various animals (mice, rats, rabbits, dogs, and primates).

In addition to different species, different model types have been used, including transgenic animals, experimental animals with natural spontaneous corneal diseases, and induced models.

Liu and colleagues used knockout mice as model animals for the Lumican gene (Liu et al. 2010). The mice received UMMC transplantations to facilitate studying their potential use as a therapy for congenital corneal diseases caused by genetic mutations. As a result, it was found that transplantation into the UMMC corneal stroma increases the thickness of the stroma and reduces corneal opacity. The turbidity of the corneal stroma was determined by measuring the total pixel intensity of light scattering through a three-dimensional volume, while the thickness of the corneal stroma was calculated by measuring the axial distance from the anterior to posterior stroma (Liu et al. 2010).

Coulson-Thomas and Caterson used genetically modified MPS VII mice with type VII mucopolysaccharidosis as a model to study the therapeutic properties of mesenchymal stem cells (Coulson-Thomas and Caterson 2013). Their study was aimed to establish cell therapy effectiveness in mucopolysaraidosis VII (Sly syndrome). The researchers used UMSCs, which were transplanted into the corneal stroma. A significant number of the UMSCs delivered to the cornea survived the transplant process and remained in the cornea throughout the treatment period. The data obtained showed that human UMSCS transplanted into the murine cornea with MPS VII prevented the accumulation of glycosaminoglycans in the corneal stroma and keratocytes. There was also a lack of corneal opacity, which showed that UMSCs could prevent the disease progression (Coulson-Thomas et al. 2013).

Shukla and Mittal (2019) used a mechanical approach to damage the cornea. The corneal epithelium and anterior stroma, which account for approximately one-third of the total thickness of the cornea, were mechanically removed using an Algerbrush brush. The study was conducted to determine the effectiveness of BMSCs on damaged cornea and conjunctiva within the eye. The cells were injected subconjunctivally, intravenously, and intraperitoneally for an hour after the injury had been induced. Studies have shown that subconjunctival or intravenous administration of BMSCs has higher therapeutic efficacy compared to local or intraperitoneal administration following corneal damage. The authors noted a decrease in corneal opacity, tissue fibrosis, and the expression of pro-inflammatory cytokines (Shukla et al. 2019).

In a laser-induced model of corneal damage in mice, ADMSC administration had significantly smaller defects of corneal epithelial (Zeppieri et al. 2017). In a thermal moxibustion murine model of corneal damage, the ability of MSCs to penetrate into damaged tissue and promote repair of corneal was investigated (Lan et al. 2012). BMSCs were administered intravenously following injury, and the outcomes were evaluated using epifluorescence microscopy whereas the epithelial regeneration was evaluated via corneal fluorescein staining. Studies have shown that the systemic administration of MSCs affected the damaged cornea and showed their long-term survival. The researchers also noted that after the cornea had been damaged, the introduction of BMSCs resulted in a significant and rapid regeneration of the corneal epithelium (Lan et al. 2012).

The effectiveness of human BMSCs in treating chemical burns in the corneal epithelium of rats has also been investigated. BMSCs were cultured on the human amniotic membrane, and 7 days after a chemical burn had been administered, amniotic membranes with BMSCs were transplanted onto rodent corneas. The

anatomical effects and vision of these rodents were measured once a week with a slit lamp and optokinetic head tracking response, respectively. The resulting data showed that BMSCs successfully repaired damaged corneal surfaces in rats (Ma et al. 2006).

Faruk et al. (2017) induced corneal damage using an alkali solution in rats. Studies have shown that systemic injection of autologous MSCs leads to regeneration of the corneal epithelium and inhibits neovascularization in the induced chemical burn of the cornea. The authors showed that MSCs had a therapeutic effect and inhibited early inflammatory responses in local corneal cells (Faruk et al. 2017). This method of corneal damage has also been used in rats. A model of corneal burn, using an alkali, was created by placing a 3 mm diameter piece of NaOH-soaked filter paper onto the right eyes of rats. Immediately after the injury, and 3 days later, the rats were given a subconjunctival injection containing a 2×10^6 MSCs suspension. Studies have shown that subconjunctival injection of MSCs reduces inflammation of the locally burned cornea by inhibiting the infiltration of inflammatory cells and the production of pro-inflammatory cytokines (Yao et al. 2012).

The therapeutic effects of MSCs have also been tested in a model where 100% ethanol was applied to the eye's surface. Afterward, a reservoir with a hollow tube pre-filled with MSCs and culture medium was placed on the cornea and left in situ for 2 h. The reservoir was then removed and the eyes sutured. In this study, the authors demonstrated that MSCs reduced corneal inflammation and neovascularization and this was associated with IL-10 and TGF-beta1, IL-6, and TSP-1 upregulation, and IL-2, IFN-gamma, and MMP-2 downregulation, as well as decreased tissue infiltration by CD4 + cells (Oh et al. 2008). The same researchers also applied the same rat model of 100% ethanol chemical damage where BMSCs and human corneal epithelial cells were directly injected into the cornea. This technique resulted in upregulated expression of IL-6, VEGF, TGFbeta1, MMP-2, and thrombospondin-1, and suppression of MMP-9 secretion by the damaged epithelial cells (Oh et al. 2009).

One study investigated surgical corneal damage with ADMSC with PAX6 therapy. The research revealed that PAX6 induces differentiation of ADMSCs into epithelial-like corneal cells in vitro. ADMSCS reprogrammed with PAX6 also repaired damaged corneal surfaces in vivo (Joe and Gregory-Evans 2010).

The therapeutic efficacy of systemic administration of BMSCs after applying an alkaline burn to the experimental rats was investigated. Efficacy was assessed by corneal reepithelization, corneal opacification, and neovascularization. In the publication, the authors concluded that systemically transplanted BMSCs can take root in the damaged cornea, promoting wound healing through differentiation, proliferation, and synergy with hematopoietic stem cells (Li et al. 2014).

The therapeutic efficacy of topically applied MSCs for dry eye syndrome has been extensively reported (Hirayama 2018; Villatoro et al. 2017). The effectiveness of topical application of MSCs was assessed to treat dry eye syndrome (keratoconjunctivitis sicca; KCS) caused by benzalkonium chloride (BAC) in an experimental rat model. Eye drops containing ADMSC were applied topically every day for a week. The effectiveness of the treatment was evaluated using the Schirmer test, evaluation of the time of destruction, assessment of the eye surface, the index of

corneal inflammation, and histological and electron microscopic analysis. Studies have shown that topical application of ADMSC can be a safe and effective treatment for dry eye syndrome (Beyazyıldız et al. 2014).

Mesenchymal stem cells (MSCs) are also known to promote the engraftment of cell and organ transplants due to their immunotherapeutic and immunomodulatory characteristics (Beeken et al. 2021). Indeed subconjunctival injection of MSCs to rats was effective in increasing the survival rate of corneal allografts. This effect was due to the inhibition of inflammatory and immune responses (Jia et al. 2018).

The possibility of using MSC systemic administration to accelerate the healing of corneal wounds after the alkaline burn of rabbits has been investigated. The clinical outcomes were evaluated using corneal reepithelization, corneal opacification, neovascularization, and immunohistochemical studies. The experiments conducted showed that systemically transplanted MSCs could engraft the damaged cornea, stimulating wound healing by differentiation, proliferation, and synergy with hematopoietic stem cells (Ye et al. 2006).

Gu and Xing (2009) studied the efficacy of MSCs in rabbits concerning whether BMSCs can differentiate into corneal epithelial cells. Corneal damage in rabbits was caused by contact with 1 N NaOH-soaked filter paper for 30 s. Twenty-eight days after corneal injury, fibrin gels were transplanted onto the rabbit cornea. The corneas of the rabbits were observed each day for follow-up with a slit-lamp microscope system (SL-1600; Nidek Co., Ltd., Aichi, Japan) to assess reepithelization, neovascularization, and transparency. The data showed that following BMSC transplantation, the damaged surface of the rabbit cornea was successfully reconstructed, and some of the transplanted cells directly participated in the healing process of the damaged corneal epithelium (Gu et al. 2009).

The effects of human ADMSCs on surgically damaged cornea have also been investigated. Studies have shown that ADMSCs transplanted to the surface of the eye migrated to the inflamed tissues, reduced inflammation, restrained the development of neovascularization and corneal opacification, and partially restored the phenotypes of the limbal and corneal epithelium (Galindo et al. 2017). Molecular profiling revealed partial restoration of corneal epithelial cell markers CK3 and E-Cadherin and the limbal epithelial cell markers CK15 and p63, that was lost during experimental corneal failure. The same research group has reported that subconjunctival injection of MSCs is less invasive and allows high-dose administration of MSCs besides being more efficacious (Galindo et al. 2021).

Evaluation of autologous BMSCs for the treatment of corneal stroma defects in rabbits showed interesting preliminary results. Animals were subjected to deep lamellar corneal dissections, and clinical outcomes were assessed via corneal reepithelization, corneal opacity, corneal thickness, and histology. Studies have shown that the use of BMSCs did not achieve complete transparency in the cornea. It has been suggested that remodeling the corneal stroma to fully restore the original optical qualities requires a longer time ranging from several months to several years. The authors noted that locally transplanted BMSCs could be a valuable source of corneal stroma regeneration (Then et al. 2017).

The beneficial therapeutic effect of isolated primary human corneal endothelial cell transplantation on a preclinical model of bullous keratopathy in rabbits has shown promising results. Primary corneal endothelial cell transplantation gradually reduces the thickness of the cornea during the first 2 weeks. It completely restores it to a thickness of approximately 400 microns by the third week of transplantation. In contrast, the cornea of control rabbits remained significantly thicker, more than 1000 microns ($p < 0.05$) throughout the study. This study data showed that the use of primary human corneal endothelial cells opens up excellent prospects in the clinic (Peh et al. 2017).

In addition to experimental animal models, it has been highlighted that veterinary patients, such as dogs, are increasingly recognized as critical translational models of human diseases. For example, the etiopathogenesis of canine diseases is similar to that of humans (Brown 2016). Therefore studies of keratoconjunctivitis in dogs can help to develop therapeutic approaches which may also benefit people. Researchers have evaluated the intralacrimal transplantation of allogeneic MSCs in dogs with mild, moderate, and severe dry conjunctivitis. The data retrieved showed that allogeneic transplantation of MSCs on dogs was safe as no side-effects were observed with allogenic MSCs. The authors also showed improvements in the condition of the treated eyes. Experiments have shown that the use of MSCs is effective and safe for experimental dogs and, therefore, this type of treatment may be used in clinics after additional tests (Bittencourt et al. 2016).

In another canine study, this time in corneal wounds, the therapeutic efficacy of MSCs was tested in dogs. Previously, the experimental animals had been diagnosed with deep corneal ulcers, and for the duration of the experiment, the animals did not receive any immunomodulatory drugs. The researchers noted that all dog owners had signed written consent before this experimental procedure was started. Moreover, all owners were fully informed that the safety, complications, and effectiveness of cell implantation in corneal ulcers were unknown and not very well-established. The effectiveness of the treatment was evaluated using ophthalmological examination on three occasions, once prior to MSC therapy, then on days seven and 14 following their respective treatment. The tests included criteria such as clinical signs and the size and depth of the ulcers. MSCs were administered sub-conjunctively at a dose of three million cells. Studies have shown that the effectiveness of treatment was 84.6%, that is, the healing was observed in 22 of the 26 experimental dogs (Falcão et al. 2019).

Keratoconjunctivitis, or dry eye syndrome, is mainly an immuno-mediated degenerative disease directly affecting patients' vision and quality of life; it is one of the leading causes of ocular diseases in both dogs and humans. Dogs are excellent animal models for facilitating the understanding of this disease. One trial used 22 animals that were already unwell to study the effectiveness of MSCs. MSCs were administered locally and the treatment effectiveness was evaluated based on clinical signs, ophthalmological tests, histology, and immunohistochemistry. The work showed that the introduction of MSCs improved the condition of the cornea in experimental dogs, and relapses were only observed in seven of the 22 treated dogs (Sgrignoli et al. 2019).

Models of Lens Diseases

The structure of the human lens is reflected in Fig. 1.

A cataract is a pathological condition associated with the opacity of the eye lens which causes varying degrees of visual impairment up to complete loss of vision. A cataract is one of the problems that affect the clarity of vision and can be caused by a number of factors, including aging, eye injuries, inflammation, and other circumstances. According to the latest estimate, cataract occurrence is responsible for 51% of the world's blindness, affecting around 20 million people. An effective way to treat a cataract is surgery; the natural lens of the eye is removed and replaced with an artificial lens (Snellingen et al. 2002).

Maleki (2015) induced lens damage in rats and rabbits via administration of sodium selenite. They conducted research to identify the therapeutic properties of SCs derived from Wharton's jelly by introducing SCs into the lens via surgical manipulation. The effectiveness of this treatment was evaluated by determining the expression of βB1 and βB3-crystallin genes and by evaluating the lens' morphological ultrastructure by electron microscopy. Studies have shown that the SCs obtained from Wharton's jelly, differentiated into the lens fibers and then restored lens structure within the capsule. The authors suggested that this method of cataract treatment could be applied in clinical practice following additional safety parameter studies (Maleki 2015).

To evaluate the complications associated with the development of type 2 diabetes pathologies, the effectiveness of ADMSC was investigated. This work illustrated the positive effects on various body systems in the experimental rats, including the lens of the eye. In the group of animals that received ADMSC intravenously, lens opacification was not observed, results which contrasted to those observed in the control group (Yu et al. 2019).

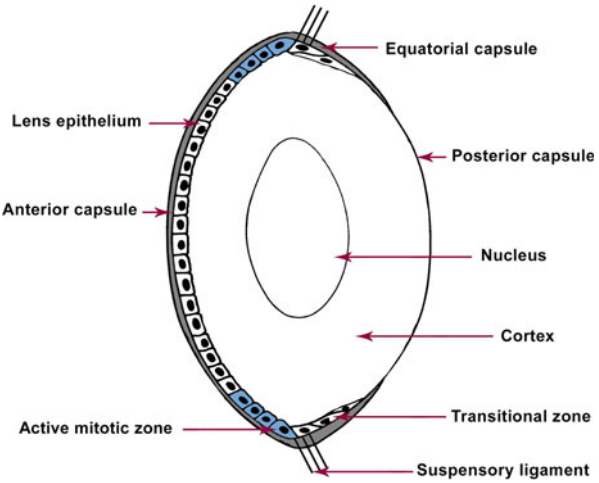

Fig. 1 Diagram showing the structure of the human lens

A new surgical method for the treatment of cataracts, which consisted of preserving endogenous lens progenitor cells (LEC), was developed as it was thought that the cells might provide functional regeneration of the lens in rabbit and macaque models. Although this method is conceptually different from modern practice, since it preserves the endogenous LEC and their natural environment as much as possible, it also restores the functionality of the lens (Haotian et al. 2016).

Retinal Models

Retinal diseases are one of the leading causes of blindness in the modern world. Previous research has shown that many retinal diseases observed in animals are similar to those seen in people. This work has primarily led to an improved understanding of the pathogenesis of retinal diseases and has also provided the means to test possible treatments, including cell therapy.

In the diseases of the external retina, such as age-related macular degeneration (AMD) and diabetic retinopathy (DR), two of the most common causes of blindness in the developed countries, the main body of in vivo models are those showing abnormal retinal angiogenesis or damage to the retinal pigment epithelium (RPE) (Liu et al. 2017).

One model with induced choroid neovascularization (CNV) caused by a laser was used to study the therapeutic effect of bone marrow-derived cells. The intravenously administered MSCs penetrated the damaged area and differentiated into several cell types and participated in the development of neovascularization without stagnation in other organs, thereby suppressing the growth of choroid neovascularization (Hou et al. 2010). Li and colleagues also used laser photocoagulation to induce CNV to investigate whether subretinal transplantation of RPE expressing Fbln5 could suppress CNV in vivo. One week after laser-induced CNV, RPE cells were transplanted into the subretinal space, with the pZlen-Fbln5-IRES-GFP vector placed in the right eye and the pZlen-IRES-GFP vector in the left eye. CNV was then evaluated using fundus photography, fundus fluorescence angiography, and hematoxylin and eosin staining. CNV appeared 1 week after photocoagulation and reached a peak of activity after 3 weeks. The transplanted RPE cells survived for at least 4 weeks and migrated to the retina. Subretinal transplantation of RPE cells, with Fbln5 expression, resulted in a significant reduction in the total lesion area. The researchers concluded that subretinal transplantation of RPE cells with Fbln5 expression inhibited laser-induced CNV in rats and therefore, represented a promising therapy for this condition (Li et al. 2015).

Neovascularization has been reproduced in a diabetes model induced by the administration of STZ in rodents. It was hypothesized that multipotent perivascular progenitor cells derived from human embryonic stem cells (hESC-PVPC) would improve the damaged retinal vasculature. Indeed a single intravitreal injection into Brown Norway diabetic rats caused the localization of cells in distinct perivascular areas of the retinal vasculature and stabilized the rupture of the hemato-retinal barrier. This study shows the therapeutic potential of hESC-PVPCs in diabetic

retinopathy by imitating the role of pericytes in vascular stabilization. The researchers highlighted that this study represents a simple method for creating perivascular progenitor cells from human embryonic stem cells. These cells have common functional characteristics with pericytes, which are irreparably lost at the onset of diabetic retinopathy. Animal studies have shown that replenishing damaged pericytes with perivascular progenitor cells can restore the integrity of retinal vessels and prevent loss of vitreous fluid. These data provide promising and compelling evidence that perivascular progenitor cells could be used as a novel therapeutic agent to treat patients with diabetic retinopathy (Kim et al. 2016).

The effectiveness of BMSCs in diabetic retinopathy was studied in a streptozotocin (STZ) model in male albino Wistar rats. After 3 months of induced diabetes, the right eye was intravitreally injected with green protein-labeled guidelines and the left eye was injected with a balanced saline solution. The introduction of BMSCs increased retinal gliosis in the diabetic group compared to the control group of animals. Immunofluorescence analysis revealed that BMSCs mainly integrated into the inner retina. Overall, this study showed that intravitreal administration of BMSCs improved visual function (Çerman et al. 2016). Attention is currently being paid to models with photoreceptor damage from retinitis pigmentosa and various hereditary disorders of central vision. It should be noted that these animal models are a target for the transplantation of early photoreceptors or RPE cells because RPE cells are responsible for protecting the function of photoreceptors.

The efficacy and safety of human retinal progenitor cells (hRPCs) in experimental RCS rats with dystrophy have also been researched. The hRPCs have been tested to maintain visual function and evaluation was undertaken using optokinetic head tracking and retinal structure studies. The safety of the NPHR was evaluated by subretinal cell transplantation into rats and wild-type mice of the bodily lower-III stages with analysis at 3, 6, and 9 months after transplantation, respectively. Studies have shown that the optimal dose of hRPCs for preserving visual function and retinal structure in dystrophic rats was between 50,000 and 100,000 cells. The human retinal progenitor cells integrated and survived in the retinas of dystrophic and wild-type rats up to 6 months after transplantation. No signs of tumors were detected. Therefore human retinal progenitor cells appear to be safe and effective in this preclinical model. It has been shown that they can be used in the early stages of retinal degeneration and the areas of intact retina without the risk of adverse effects on visual function (Semo et al. 2016).

Qu, Linghui et al. (2017) studied the effects of both hRPCs and BMSCs in a different disorder, retinitis pigmentosa (RP). The researchers have noted that both hRPCs and human BMSCs (hBMSCs) are widely and practically used for transplantation. In this study, the possibility of using combined transplantation of the above cells was tested. The researchers transplanted hRPCs and hBMSCs into the subretinal space of RCS rats. Studies have shown that combined hRPCs/hBMSCs transplants supported electroretinogram results much better than single transplants. The thickness of the outer nuclear layer also showed the best results during combined transplantation. It was also recorded that the cells in the combination treatment migrated better than single transplantation. Photoreceptor differentiation of cells in

the retina rats treated with combined cell transplantation also showed a higher ratio than those treated with a single type cell transplant. Finally, microglial activation and Muller cell gliosis were more effectively suppressed following a combined transplantation protocol, indicating better immunomodulatory and anti-glial effects. The researchers stated that the combination of hRPC and hBMSC transplantation was a more effective strategy for treating SC-based retinal degenerative diseases (Qu et al. 2017).

Substitution therapy in degenerative diseases such as age-related macular degeneration has also been investigated. A modified trans-scleral injection method has been developed that uses specific angles and needle depth to successfully and consistently deliver retinal pigment epithelial cells into the rat's subretinal space and prevent excessive retinal damage. Efficacy was demonstrated in RCS rats sustaining for 2 months (Zhao et al. 2017).

The efficacy of RPE cells obtained under xenon-free conditions from clinical and xenon-free human embryonic stem cells (OpRegen) after transplantation into the subretinal space of the RCS rats has also been characterized. The rats received a single subretinal injection of xeno-free RPE cells, whereas a physiological saline solution and non-operated eyes served as a control. Optomotor behavior tracking was used to evaluate functional effectiveness and recovery of photoreceptors, and survival of the transplanted cells was assessed using histology and immunohistochemistry. The subsequent studies showed that the outer nuclear layer (ONL) was significantly thicker in the eyes treated with the cells than in the controls. Transplanted RPE cells were identified in the subretinal space, and integration into the RPE monolayer was also revealed. It was proven that the OpRegen RPE cells survived and restored visual function and preserved rod and cone photoreceptors for an extended time period (McGill et al. 2017).

During subretinal transplantation of RPE-derived stem cells (RPESCs) and RPE cells (RPESCs-RPE), the preserved vision was observed in a model of RPE cell dysfunction in RCS rats. The researchers noted that the stage of differentiation that the RPESCs-RPE had acquired before transplantation significantly affected the effectiveness of vision restoration. While the cells at all tested stages of differentiation protected photoreceptor layer morphology, the intermediate stage of RPESCs-RPE differentiation, obtained after 4 weeks of culture, was more consistent in protecting vision than the subsequent generation that differentiated during culture weeks 2 or 8 (Davis et al. 2017).

Park and colleagues used an experimental rat model of retinal degeneration developed by an intravenous injection of sodium iodate. Human embryonic stem cells (hESCs) as a therapeutic agent for treating degenerative retinal diseases and proposed to differentiate the cells into retinal pigment epithelium (RPE) using particular culture conditions. The putative RPE cells (10^5 cells/5 μl) were transplanted into the subretinal space. The animals were killed at either 1, 2, or 3 weeks after transplantation for immunohistochemistry to check transplanted cell survival and their fate. The putative RPE cells derived from hESCs had the morphological characteristics of human RPE cells. The implanted RPE cells survived in the subretinal space for up to 4 weeks post-transplantation, and the expression of RPE

markers was confirmed via immunohistochemistry. Thus, the researchers showed the potential of using hESC-derived RPE cells for cellular therapy of retinal degenerative disease (Park et al. 2011).

In another model of retinal degeneration, Rd1 mice were used to replicate rapid progressive retinitis pigmentosa with end-stage retinal degeneration. Development of a structured outer nuclear layer with internal and external segments during the transplantation and integration of three-dimensional retinal tissue derived from mouse embryonic stem cells or induced pluripotent stem cells were investigated. The resulting retinal sheets were transplanted into the subretinal space of mice aged 6–8 weeks and sacrificed from 2 weeks to 6 months after transplantation. The transplanted retinal sheets obtained from both mESCs and iPSCs survived and matured in the highly degenerated retinas of the experimental animals. This study is a "proof-of-concept" for retinal transplantation in late retinal degenerative diseases (Assawachananont et al. 2014).

The therapeutic potential of photoreceptor precursors derived from human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs) have been studied to confirm their potential in retinal degeneration. ESCs and iPSCs were cultured in four stages under certain conditions, resulting in a somewhat homogeneous population of photoreceptor-like progenitors. After transplantation into the experimental mice model of end-stage retinal degeneration, these cells differentiated into photoreceptors and formed a cell layer associated with the host retinal neurons. Visual function in the animals of the experimental group was partially restored, as evidenced by visual behavioral tests. In addition, the degree of functional improvement was positively correlated with the number of implanted cells. The data obtained confirmed the potential of ESCs and iPSCs for photoreceptor replacement therapy aimed at photoreceptor regeneration in retinal diseases (Barnea-Cramer et al. 2016).

An experimental mouse model of severe human retinitis pigmentosa at a stage of loss native cells showed that transplanted rod precursors could transform an anatomically distinct and appropriately polarized outer nuclear layer. The three-layer organization was returned to rd1 mice that had only two retinal layers before treatment. The transplanted progenitors could integrate and develop in the degenerated retina and transformed into mature rods with light-sensitive outer segments connected to neurons. The visual function in these experimental animals was also restored after cell transplantation. Studies have shown that cell therapy can restore the light-sensitive cell layer de novo and, consequently, restore the structurally damaged visual contour (Singh 2013).

Diseases of the internal retina, such as glaucoma and various forms of optical neuropathy (ischemic, traumatic, and compression), have common characteristics of retinal ganglion cell loss (RGC). Experimental animal models that focus directly on RGC damage do not necessarily reproduce the pathogenesis of individual conditions; however, they are widely used because of their ability to demonstrate dramatic changes in RGC function in many different animal types. Damage to the optic nerve is one of the frequently used preclinical methods to reproduce the loss of RGCs. This model was used to study RGC stimulation as a way to regenerate

axons along the entire length of the visual pathway and further in the lateral geniculate nucleus, the upper mound, and other visual centers. Notably, regeneration partially restored the optomotor response, demonstrating the possibility of restoring the central vision circuit after optic nerve damage in adult mammals (de Lima et al. 2012).

The therapeutic potential of MSCs injected into the vitreous body, also on a model of optic nerve damage, has been demonstrated. Adult (three to five-month old) Lister hooded rats underwent unilateral optic nerve crushing followed by an injection of MSCs into the vitreous. Before injection, MSCs were labeled with a fluorescent dye or superparamagnetic iron oxide nanoparticles, which enabled cell tracking and their post-engraftment fate determination in vivo using magnetic resonance imaging. Retinal ganglion cell survival was evaluated at 16 and 28 days after the injury. The researchers noted that the transplanted MSCs remained in the vitreous body and were detected in the eye for several weeks. The MSCs-based therapy's success was further explained by an increase in FGF-2 expression in the retinal ganglion cell layer, and the concomitant expression of interleukin-1β. Thus, studies have shown that MSCs protect RGCs and stimulate axon regeneration following optic nerve damage (Mesentier-Louro et al. 2014).

Evaluation of human UMSCS to protect and promote the regeneration of axotomized neurons in the rat optical system "UMSK" has also been undertaken. The cells survived well up to 2 weeks post-transplantation; however, they did not significantly migrate significantly or differentiate. In the presence of UMMC grafts, it was found that the axonal processes of the host were present at the site of the lesion, and there was a stimulation of the population of endogenous neural progenitors. Four weeks after the transplant, UMMC was shown to have a neuroprotective effect, protecting a significant percentage of axotomized retinal ganglion cells. Further experiments showed that UMSCS could also promote the re-growth of axotomized RGCs (Zwart et al. 2009).

Model Damage to the *N*-methyl-d-aspartate Receptor (NMDA)

Glutamate excitotoxicity is a critical component of selective neuronal cell death in ischemic retinopathy and glaucoma. This process is associated with excessive stimulation of NMDA receptors in retinal ganglion cells, which leads to an intracellular influx of calcium ions, and this, in turn, leads to the activation of the apoptotic cascade. Experimental animal models using glutamate excitotoxicity focus on NMDA receptor stimulation have been developed and optimized (Casson 2006). This was used to study a constructed eye-like structure derived from ESCs consisting of retinal neural clone cells, RPEs, and lens cells to determine whether they could differentiate into retinal ganglion cells (RGC) during retinal transplantation into the vitreous body of a damaged adult mouse (Aoki et al. 2008). Prior to this, it was shown that the cells of these eye-like structures could integrate into the developing visual bubble of chickens. ESCs were induced to differentiate into

eye-like structures in vitro for 6 or 11 days. NMDA was then injected into the eyes of the mouse recipients to damage the RGC before transplantation. Cell material for transplantation was extracted from eye-like structures and transplanted into the vitreous body of both the damaged and control eyes. During the follow-up, the eyes were analyzed both qualitatively and quantitatively by immunohistochemistry 10 days or 8 weeks after transplantation. Studies showed that cells from eye-like structures derived from ESCs had integrated into the RGC layer and differentiated into neurons when transplanted into control (non-NMDA-treated) eyes; however, they rarely expressed RGC markers. Once transplanted into NMDA-treated eyes, the cells spread across the surface of the retina and covered a relatively large area of the host's RGC layer, which was damaged by NMDA. Eye cells derived from ECU often differentiated into cells expressing RGC -specific markers and formed a new layer of RGC. In addition, it was observed that a small number of these cells, originating from the ESC, expanded the axon-like processes in the direction of the optic disc. However, visually induced responses could not be recorded from the visual cortex (Aoki et al. 2008).

Transplantation of neural progenitors, derived from ECU (Es-NP) into *N*-methyl-D-aspartate (NMDA)-injected mouse models, ablated RGA in mouse models, and preclinical glaucoma (dBA/2D) models with consistently higher intraocular pressure (IOP). Visual acuity and functional integration were assessed using behavioral tests and immunohistochemistry, respectively. Studies have shown that ES-NP, GP-expressing, transplanted into mice with depleted RGA, which were injected with NMDA, differentiated into a clone of RGA. Improvement in visual acuity was observed 2 months after transplantation (Divya et al. 2017).

The effects of allogeneic Muller cat glia transplantation (fMGSC) with the ability to differentiate into cells expressing RGC markers after RGC removal using *N*-methyl-d-aspartate (NMDA) have also been investigated. In contrast to previous observations in rats, transplantation of hMGSC-derived RGCs into the vitreous body of cats formed aggregates and caused a severe inflammatory response without improving visual function. In contrast, allogeneic transplantation of feline MGSC (fMGSC)-derived RGC into the vitrectomized eye improved the threshold scotopic response (STR) of the electroretinogram (ERG). Despite the functional improvement, the cells did not attach to the retina. Also they did not form aggregates on the peripheral remains of the vitreous, suggesting that the vitreous may represent a barrier to cell attachment to the retina. This has been confirmed by observations that cell scaffolds of compressed collagen and enriched RGC preparations derived from fMGSC facilitate cell attachment. Although the cells did not migrate to the RGC layer of the optic nerve, they significantly improved the STR and photopic negative ERG response, suggesting enhanced RGC function. These results suggest that fMGSCS have a neuroprotective ability that promotes partial restoration of impaired RGC function and indicate that cell attachment to the retina may be necessary for transplanted cells to provide retinal neuroprotection (Becker et al. 2016).

Models of Transient Ischemia

Transient ischemia models cause loss of RGC by occlusion or functional inhibition of the blood vessels supporting the optic nerve and retina, often followed by reperfusion of these vessels – hence named "transient" ischemia. One such model induced retinal ischemia in adult Wistar rats by increasing IOP to 130–135 mmHg for 55 min. Twenty-four hours after the induction of ischemia, BMSCs were injected into the vitreous body. Functional recovery was assessed after 7 days using electroretinography (ERG) measurements of a-wave, b-wave, P2, scotopic threshold response (STR), and oscillatory potentials (OP). Retinal damage and anti-ischemic effects were quantified by measuring apoptosis, autophagy, inflammatory markers, and the permeability of the blood-brain barrier of the retinal. BMSC distribution was qualitatively investigated using real-time fundus images. The introduction of the guiding compound into the vitreous body significantly improved the recovery of ERG a-and b-waves, OP of negative STR and P2, and also reduced apoptosis, as evidenced by a decrease in the levels of TUNEL protein and caspase-3. BMSCs significantly increased autophagy, reduced inflammatory mediators (TNF-α, IL-1β, IL-6), and retinal vascular permeability. BMSCs were preserved in the vitreous and were also observed in the ischemic retina. The results showed that intravitreal injection of PCRS protected the retina from ischemic damage in a rat model. (Mathew et al. 2017).

Li and Zhao (2014) used this model to study the effect of retinal progenitor cell (RPC) transplantation into the subretinal space (SRS) and the superior colliculus (SC) in rats (Li et al. 2014). For transplantation, cultured postnatal rat NPCs were used for 1 day, transfected with an adeno-associated virus-containing cDNA encoding enhanced green fluorescence protein (EGFP). The damage was caused by an increase in intraocular pressure to 110 mmHg for 60 min. The effectiveness of transplantation was evaluated using ERG immunohistochemistry. The transplanted cells survived for at least 8 weeks, migrated to surrounding tissues, and improved ERG responses in the rats with ECP damage. The data obtained showed that RPC transplantation in SRS and SC may be a possible method of cell replacement therapy for retinal diseases (Li et al. 2014).

Transgenic RGC Loss Models

Although they are more challenging to maintain and breed than traditional models, transgenic mouse models using the Cre-Lox system can provide an animal with pure RGC depletion for stem cell research. One example is the Pou4f2 knockout mouse (Brn3b). Pou4f2 is a critical gene for RGC differentiation and is expressed throughout life (Cho et al. 2012). This research group developed a mouse model in which RGC is genetically removed in adult mice. These mice were transplanted with a GFP-labeled progenitors of the embryo's retina. These retinal cells were injected into

the vitreous body of one eye of mice between the ages of 2 and 6 months. Gene expression analysis using an immune tag and the morphology of the optic nerves both visually and using histology were evaluated. The embryonic GFP-labeled RPCs were successfully introduced into the eyes of transgenic mice. Many transplanted RPCs penetrate the ganglion cell layer, and several GFP-labeled cells were found within the optic nerves. At the same time, a significant increase in optic nerve thickness was noted and more connected axons were observed in the retina following RPC injection. The results suggest a new approach to the regeneration of damaged optic nerves. They indicate that a significant number of RPCs toxin differentiate into RGC in the alien environment of the adult retina (Cho et al. 2012).

Model of Experimental Autoimmune Encephalopathy (EAE)

The EAE model primarily models the diseases that cause autoimmune demyelination in the central nervous system, namely multiple sclerosis (MS). Loss of RGC precedes inflammation of the optic nerve in rat models of chronic EAE, whereas, in mice, optic neuritis comes first, and loss of RGC follows. The typical induction time is 1–2 weeks. Current stem cell research on EAE models has focused on neuroprotection via neural or mesenchymal stem cells rather than directly replacing RGCs or their precursors (Pluchino et al. 2009; Lanza et al. 2009).

Models of Hereditary Diseases Associated with Optic Nerve Damage

Retinal degeneration resulting from hereditary diseases such as Leber's hereditary optic neuropathy (LHON) and type I neurofibromatosis (NF1) has no definitive treatment options to date. There are animal models of LHON (Yu et al. 2015). One rotenone-induced LHON model was applied to investigate the protection of visual function in stem cells. Photoreceptor progenitor cells were used, which, according to research, integrate into the ganglion cell layer (GCL). The results of the work were evaluated using magnetic resonance imaging with manganese enhancement, optokinetic responses, and ganglion cell counting. The cultured progenitor cells integrated into the GCL and positive affected maintaining retinal function (Mansergh et al. 2014).

Glaucoma Models

Open-angle glaucoma is the most common glaucoma subtype (Weinreb et al. 2016). It is characterized by an imbalance between the production of water from the ciliary body and its outflow through the trabecular network and uveoscleral pathways. This discrepancy can lead to increased intraocular pressure, resulting in damage to the RGC, as evidenced by pathological changes. Hao and co-authors (2013) studied the

therapeutic effects of executive staff transplantation on vision loss in older rats with glaucoma caused by laser ocular hypertension. The BMSCs contributed to the survival of retinal ganglion cells in the transplanted eyes compared to control eyes. In addition, in swimming tests based on visual cues, rats with a leadership graft performed significantly better. The overall results of the study showed that BMSC transplantation therapy is effective in the treatment of older rats with glaucoma (Hao et al. 2013). An experimental model of photocoagulation of episcleral veins and limbal plexus with an argon laser has been used to study the possibility of retinal stem cell (RSC) transplantation and immunization with glatiramer acetate copolymer-1 (COP-1) copolymer. Rats were immunized with (COP-1) on the same day as glaucoma induction by photocoagulation. RSCs were cultured and transplanted intravitreally a week after laser treatment. The effectiveness of treatment was evaluated based on the expression of brain neurotrophic factor (BDNF), insulin-like growth factor I (IGF-I), and immunohistochemical studies, RT-PCR, and Western blotting were also performed. RGC survival was assessed by TUNEL staining and RGC counts. Their studies showed that the expression of BDNF neurotrophic factors in the IRF-I and RSC/COP-1 group was significantly higher than in the other groups ($P < 0.05$). In addition, the number of apoptotic RGS in the RSC/COP-1 group was markedly lower and the number of RGS in the RSC/COP-1 group was higher. Thus, the researchers concluded that the combined action of RSC and immunization with COP-1 protect RGC against apoptosis in a rat glaucoma model (Zhou et al. 2013).

Harper et al. (2011) used an experimental rat model of chronic ocular hypertension induced by laser cauterization of the trabecular network and episcleral veins in the eyes to study the ability of engineered MSCs to produce and secrete brain neurotrophic factor (BDNF) to protect retinal function and structure after intravitreal transplantation. MSCs expressing BDNF (BDNF-MSC) were transplanted intravitreally. The function of the optic nerve and retina was evaluated using computer pupillometry and ERG; quantitative assessment of optic nerve damage was performed by RGCs counts and by evaluating cross-sections of the optic nerve. After BDNF-MSC transplantation, the eyes retained significantly more retinal and optic nerve functions and showed higher RGC preservation. Interestingly the neurotrophic factors BDNF b-MSCs, transduced by lentiviruses, could persist in the eyes with chronic hypertension and provide functional and structural protection of the retina and optic nerve (Harper et al. 2011).

An ocular hypertension model for the induction of glaucoma, which was performed by cauterizing three episcleral veins (EVC) of the eyes of male Long-Evans rats, has also been utilized. One study investigated the potential of MSCs therapy in this model and deciphered the in vitro effects of MSCs on primary cells within the human trabecular network. BMSCs were labeled with nanocrystals of quantum dots for post engraftment tracing of the cells' fate. The cells were injected in the anterior chamber of the eye for 20 days, with eye pressure monitored twice a week for 4 weeks. At the end of the experiment, the cell distribution in the anterior segment was examined by confocal microscopy on flat corneas. In addition, the effects of the BMSCs-conditioned medium on the primary cells of the trabecular

network were tested in vitro. The work showed a long-lasting and rapid effect obtained following BMSCs transplantation in vivo. Injection of BMSCs into the anterior chamber of the eye in a rat model provides a neuroprotective effect in the pathophysiology of glaucoma. These results demonstrate that BMSCs represent a promising tool to treat ocular hypertension and retinal cell degeneration (Roubeix et al. 2015).

In ocular hypertension induced by an intra-chamber injection of hyaluronic acid into the anterior chamber of rats, the neuroprotective effects of BMSCs and ADMSCs, which were transplanted intravitreally, were investigated. MSCs labeled with green fluorescent protein were transplanted intravitreally 1 week after induction. At the end of the second and fourth weeks, retinal ganglion cells were visualized using the flat retinal attachment method and evaluated using immunofluorescence staining. The results of these studies showed that the number of retinal ganglion cells present was significantly higher when compared to untreated animals. The results of the immunohistochemical analysis showed that a limited number of SCS were integrated into the ganglion cell layer and the inner nuclear layer. The number of cells expressing pro-inflammatory cytokines (interferon-γ and tumor necrosis factor-α) in the group receiving MSCs decreased. On the other hand, the expression of Il-1Ra and prostaglandin E2 receptors had increased. It was concluded that intravitreal MSC transplantation had a neuroprotective effect when the experimental model was reproduced in rats (Emre et al. 2015).

Animal Models of Primary Angle-Closure Glaucoma (PACG)

Primary angle-closure glaucoma, in most cases, is a chronic disease with the gradual appearance of visual symptoms, which differs from open-angle glaucoma only in the degree of angle closure. Possible improvements in visual function by transplanting neural progenitors derived from ESCs were evaluated in a mouse model with glaucoma. Neural progenitors originating from ESCs (ES-NP) were transplanted in a model of preclinical glaucoma (DBA/2 J) with a persistently higher intraocular pressure (IOP). Transplantation experiments in dBA/2D mice showed no significant improvements in visual function, possibly due to the death of both host and transplanted retinal cells, which could be associated with high intraocular pressure. The results showed that strategies for controlling intraocular pressure are necessary for the enhanced survival of transplanted cells in glaucoma (Divya et al. 2017).

This chapter has given an overview of the past and present preclinical research undertaken into MSC-based therapies for ocular diseases. The potential future research directions, complications observed to date, and exciting lines of research have been explored. Several studies have shown the efficacy and safety of MSC therapies in a number of ocular disorders and highlighted the mechanisms of action present within much of the in vitro and in vivo work conducted to date. The eye is a complex organ; replicating human ocular disorders remains a challenge and developing potential therapies is a complex and one of the most intricate and multifaceted challenges, but the one wherein progress is being made.

Acknowledgments This work was funded by the subsidy allocated to KFU for the state assignment 0671-2020-0058 in the sphere of scientific activities. This work is part of the Kazan Federal University Strategic Academic Leadership Program.

Abstract

Several of the age-related joint diseases such as osteoarthritis lead to chondrocyte degeneration and loss of articular cartilage. Chondrocyte after an injury has restricted capacity to repair. The contemporary clinical treatments such as osteochondral transplantation and arthroplasty procedures have shown serious limitations especially for the treatment of extensive full-thickness cartilage defects. Therefore, alternative therapeutic approaches are warranted. Thus, several cell-based therapies using different stem cells have been proposed as a novel treatment approach for cartilage regeneration and repair. During organogenesis in the embryonic period, chondrocytes originate from mesenchymal progenitor cells. Several studies have reported that treatment using stem cells, especially mesenchymal stem cells, is an optimal intervention for cartilage repair rather than implantation of terminally differentiated cells such as chondrocytes. In this chapter, we have highlighted the use of cell-based therapies for the treatment of injured cartilage and discuss advantages and limitations of different stem cells. We also discuss stem cell-based cartilage tissue engineering as a novel therapeutic strategy for the damaged articular cartilage and discussed in-depth the main components of cartilage tissue engineering such as stem cell source, scaffolds used for their seeding and culture, and types of the bioreactors.

Keywords

Bioreactor · Cartilage · Chondrocytes · Mesenchymal stem cells · Stem cell · Tissue engineering · Transplantation

Abbreviations

AC	Acryloyl chloride
ACI	Autologous chondrocyte implantation
ADSCs	Adipose tissue-derived stem cells
BMDCs	Bone marrow-derived cells
CH	Chitosan
COL	Collagen
CS	Chondroitin sulfate
CSMA	Methacrylated chondroitin sulfate
DJDs	Degenerative-related joint diseases
ECM	Extracellular matrix
GO	Graphene oxide
HA	Hyaluronic acid
OA	Osteoarthritis
OAT	Osteochondral autologous transplantation
OCA	Osteochondral allograft transplantation
OCT	Osteochondral transplantation
PACI	Particulated articular cartilage implantation
PBPCs	Peripheral blood progenitor cells

PC	Pectin-based
PCEC	Polycaprolactone-polyethylene glycol
PCL	Polycaprolactone
PDS	Poly-p-dioxanone
PECA	Poly(ethylene glycol) methyl ether-”-caprolactone-acryloyl chloride
PEG	Poly(ethylene glycol)
PES	Polyethersulfone
PGA	Poly(glycolic acid)
PLA	Polylactic acid
PLCL	Poly(L-lactide-co-”-caprolactone)
PLGA	Polylactic-co-glycolic acid
PLLA	Poly(L-lactide)
PU	Polyurethane
RA	Rheumatoid arthritis
RWVs	Rotating wall vessels
SCPL	Solvent casting and particulate leaching method
SFs	Spinner flasks
SMSCs/SF-MSCs	Synovium fluid-derived mesenchymal stem cells
UCB-MSCs	Umbilical cord blood-derived mesenchymal stem cells
WJ-MSCs	Umbilical cord Wharton’s jelly-derived mesenchymal stem cells

Introduction

Cartilage

Articular cartilage is found at the end of a large area of lining bones in the joint bones. This tissue has important properties, including load-bearing, low-friction, and wear-resistant surface to facilitate joint movement. In terms of structure and composition, the joint cartilage can be divided into three surfaces: The thin superficial (tangential) zone represents approximately 10% to 20% of articular cartilage thickness. The middle with about 40% to 60% of the total cartilage volume contains proteoglycans and thicker collagen fibrils. The deep zone represents approximately 30% of the articular cartilage volume. When articular cartilage is damaged, patients will experience severe pain, inflammation, and some degree of disability (Athanasiou et al. 2010).

Chondrocyte

Articular chondrocytes constitute about 1–10% of the total cartilage volume. They are contained in cavities in the matrix, called cartilage lacunae. Chondrocytes secrete extracellular matrix containing collagen fibers to maintain and sustain the cartilage.

Chondrocytes are separated by a cartilage extracellular matrix consisting of a dense network of collagen and proteoglycan.

Collagen accounts for about 10 to 30% of the dry weight of adult articular cartilage. Proteoglycans, as one of the main components of the cartilage extracellular matrix, bind water and provide the basis for absorbing high compressive loads. Collagen and proteoglycan provide skeletal structure for the articular cartilage and determine cartilage's biochemical and functional properties. Other compounds present in cartilage include salts and little lipid, glycoprotein, and proteins (Darling and Athanasiou 2003; Guilak et al. 2000; Wu et al. 2002).

Collagen

Collagen is the main structural protein in the extracellular matrix found in the articular cartilage. Over 90% of the collagen in the articular cartilage is type I collagen. The arrangement of collagen fibers differs in the layers of articular cartilage; the surface layer is arranged parallel to the cartilage surface. They are oriented almost perpendicular to the bone and cartilage surfaces with a radial arrangement in the inner layers. The articular cartilage also contains other types of collagen fibrillar and globular, such as collagen VI, IX, and V. However, their role does not appear significant in molecular interaction and articular structure (Clark 1990; Deshmukh and Nimni 1973; Eyre and Wu 1995).

Fluid

Water is the most abundant component of articular cartilage; approximately 80% wet weight of cartilage is fluidly associated with the intrafibrillar space within the collagen, in the intracellular space, and pore space of the matrix. Inorganic ions such as sodium, calcium, chloride, and potassium are dissolved in the tissue water. Cartilage is avascular and aneural and receives nutrition by diffusion through the matrix gel. Therefore, fluid plays an essential role in the transport of nutrients and wastes through cartilaginous tissues. It also plays a vital mechanical role (Hardingham et al. 1994).

Chondrocyte Degeneration and Loss of Articular Cartilage

Because articular cartilage, once synthesized, lacks lymphatic or blood supply, several degenerative and age-related joint diseases (DJDs), such as osteoarthritis (OA) and rheumatoid arthritis (RA), lead to chondrocyte degeneration and loss of articular cartilage. Chondrocyte after an injury has restricted capacity to repair. Treatment strategies for DJDs are major challenges of the twenty-first century and vary depending on both cartilage defect and patient factors. At present, both reparative and restorative procedures have been developed for the patients who suffered

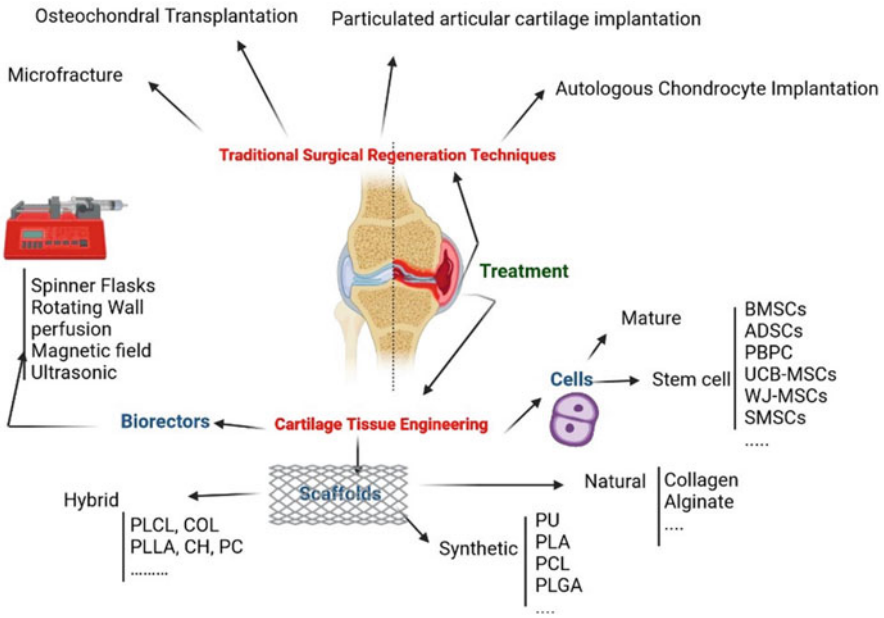

Fig. 1 The articular cartilage defects treatments. Bone marrow-derived cells (BMDCs), adipose tissue-derived stem cells (ADSCs), peripheral blood progenitor cells (PBPCs), umbilical cord blood-derived mesenchymal stem cells (UCB-MSCs), umbilical cord Wharton's jelly-derived mesenchymal stem cells (WJ-MSCs), synovium fluid-derived mesenchymal stem cells (SMSCs/SF-MSCs), CH (chitosan), COL (collagen), PLA (polylactic acid; PU, polyurethane), PLLA (poly(L-lactide)), PLGA (polylactic-co-glycolic acid), PC (pectin-based), PLCL (poly(L-lactide-co-"-caprolactone))

from either partial-thickness or full-thickness cartilage lesions, including microfracture as a reparative technique and osteochondral autografts and allografts in addition to autologous chondrocyte implantation as restorative techniques. In this chapter, we have also highlighted the use of cell-based therapies to treat injured cartilage and discuss the advantages and limitations of different stem cells (Fig. 1). We have also discussed stem cell-based cartilage tissue engineering as a novel therapeutic strategy for damaged articular cartilage and the main components of cartilage tissue engineering, including stem cell source, scaffolds used for cell seeding and culture, and types of the bioreactors.

The Articular Cartilage Defects Treatments

There are several reparative and restorative procedures for patients suffering from partial-thickness or full-thickness cartilage lesions, including microfracture, osteochondral autografts, and allografts, in addition to autologous chondrocyte implantation. Table 1 summarizes the different cartilage defects and the available treatments with their respective advantages and limitations.

Table 1 Advantages and limitations of the articular cartilage defects treatments

Traditional surgical regeneration techniques		Advantages	Limitations
Microfracture		Cost-effective for small ($\leq$6 cm^2) focal defects Reproducible techniques	Limited hyaline repair tissue Fibrocartilage formation Variable repair cartilage volume Partial defect filling Functional deterioration
Osteochondral transplantation (OCT)	Osteochondral autologous transplantation (OAT)	Reproducible and primary treatment strategy Good clinical results at medium long-term follow-up Cost-effective for small focal defects Restoration of hyaline cartilage articulating surface Good chondrocyte survival rate	For younger patients Morbidity in donor site Limited number and graft size and tissue availability Potential chondrocyte apoptosis during graft Lack of cartilage integration Poor matching of graft and host cartilage Congruency
	Osteochondral allograft transplantation (OCA)	Cost-effective Good chondrocyte survival rate Treat large defect Using fully mature articular cartilage Reproducible and primary treatment strategy Good clinical results at medium long-term follow-up Restoration of hyaline cartilage articulating surface	Limited tissue availability Potential chondrocyte apoptosis during graft Risk of disease transmission Potential immunological response Potential chondrocyte apoptosis during graft impaction
Particulated articular cartilage implantation (PACI)	Autologous PACI	Single-stage procedure Treatment of full-thickness cartilage and osteochondral defects medium (10–15 mm) to large (>15 mm) chondral defect Chondrocyte migration into a biomaterial and synthesize new ECM	Active infection at surgical site Diffuse osteoarthritis Malalignment Morbid obesity Patient noncompliance Patients (up to 40 years of age)
	Allogeneic PACI	Overcome the limitations of ACI Immature chondrocytes can better regenerate hyaline-like tissue	Lack long-term follow-up data Risk of disease transmission Limited hyaline repair

(continued)

Table 1 (continued)

Traditional surgical regeneration techniques		Advantages	Limitations
			tissue Potential immunological response
Autologous chondrocyte implantation (ACI)		Arthroscopic or minimally invasive Potential for hyaline cartilage repair tissue Use of autologous cells	Expensive and two-stage procedure Variable repair tissue type: hyaline-like, fibrocartilage, and mixed Limited defect filling and integration Donor-site complications
Tissue-engineered articular cartilage	"Cell-scaffold construct" strategies	High biocompatibility and nontoxicity Provides surface, 3D space, and seed cell support Gradual degradation	Require in vitro expansion of autologous chondrocytes Fibrocartilage formation
	Cell-free strategies	Avoids problems of iatrogenic trauma due to autologous chondrocytes or MSCs harvest Time and expense of cell culture and expansion in vitro	Still in the animal test stage Not in large-scale clinical trials No long-term follow-up data Difficulty in removal of the subchondral bone before implantation
	Scaffold-free strategies	Overcome scaffold-related problems Preserves the chondrocyte phenotypes Provides a natural matrix component Reduce loss of chondrocytes and maintain the defect for a long time	Preclinical, experimental stage A few scaffold-free products available Expensive and no ideal scaffold Requiring a long culture time Complex culturing procedure Expensive

Traditional Surgical Regeneration Techniques

Microfracture

Microfracture is a bone marrow stimulation surgery by making multiple small holes (spaced at 3–4 mm) in the surface of the joint. This is commonly performed for cartilage repair and induces fibrocartilage growth. The procedure basically involves

creating multiple holes in the subchondral region to generate a blood clot containing precursor cell populations derived from the subchondral bone marrow. An important element of the microfracture technique, which is single-stage and technically simple, is the proper preparation of the damaged area. Firstly, a layer of calcified cartilage is removed from the bottom of the lesion and then its edges are evened out. Previous investigations revealed that microfracture has a definite short-term efficacy although it is cost-effective and easy to perform than other methods. However, its sustained treatment benefits are uncertain. The published data show several retrograde changes may occur after microfracture in the subchondral region, including osteophyte formation, cysts, and excessive bone growth which will limit microfracture applications (Galperin et al. 2013; Gudas et al. 2005; Knutsen et al. 2007; Kraeutler et al. 2020; Mithoefer et al. 2006; Polat et al. 2016).

Osteochondral Transplantation (OCT)

Osteochondral transplantation, which is especially useful in active young patients, involves the removal of osteochondral columns (both bone and cartilage obtained from the healthy articular surface) from the non-weight-bearing articular surfaces, such as the femoral trochlear, and their transplantation into repaired articular cartilage defects (Ansah et al. 2007). The goal of OCT is to improve articular function, relieve symptoms, and delay arthroplasty by restoring the articular surface through a biologically active implant. OCT has been shown to be effective in the treatment of medium-sized defects (up to approximately 3–4 cm) (Taşkiran and Ozçelik 2007; Yamashita et al. 1985). There are two types of OCT procedures: osteochondral autologous transplantation and osteochondral allograft transplantation.

Osteochondral Autologous Transplantation (OAT)

In osteochondral autologous transplantation, one or more osteochondral plugs from less weight-bearing joint areas are transplanted as a treatment strategy for small- and medium-sized focal articular cartilage defects (Vogt et al. 2011; Weigelt et al. 2015). This procedure is usually performed in young patients. The scheme of this procedure is to harvest normal cartilage and bone from a nonarticular part of the joint and transplant it into the affected area. The collected cylinders in OAT procedures are larger in size. Therefore, for a typical defect with a diameter up to 9 mm, only one or two of the collected cylinders are sufficient. Consequently, filling the defect with actual articular cartilage and recreating the natural barrier between synovia and subchondral bone may be achieved (Andrade et al. 2016; Hangody and Füles 2003; Sherman et al. 2017; Shimozono et al. 2018).

Osteochondral Allograft Transplantation (OCA)

Osteochondral allograft transplantation (OCA) is a tissue-based articular cartilage and bone reconstruction or replacement method, which comprises the preparation of the cartilage defect, including the debridement of the damaged cartilage for stable healthy borders and fitting and implantation of the osteochondral allograft. An osteochondral allograft is a piece of tissue containing bone and cartilage that is taken from a deceased donor to replace damaged cartilage. This method has emerged

as an important and versatile option in the restoration of articular cartilage, particularly for lesions with both an osseous and a chondral component. The procedure is highly cost-effective (Mistry et al. 2019). Because of the low immunogenicity of articular cartilage, this method of treating cartilage is clinically applicable and does not require immunosuppression. This technique is used primarily in the treatment of large chondral defects (Cook et al. 2014; de Sousa et al. 2015; Langer and Gross 1974; Mankin et al. 1987; McCulloch et al. 2007; Nuelle et al. 2017).

Particulated Articular Cartilage Implantation (PACI)

PACI is a novel treatment modality, which involves autograft and off-the-shelf allogenic juvenile grafts (Riboh et al. 2015; Wixted et al. 2020). By this method, autologous or allogeneic cartilage fragments crushed into small-sized particles are implanted into articular cartilage defects to stimulate chondrocytes' migration and home into the cartilage chips from the extracellular matrix and promote cartilage regeneration (Christensen et al. 2020). Advancement in this regard is the use of PACI to treat chondral and osteochondral defects using platelet-rich plasma scaffolds (Cugat et al. 2021). In this novel approach, platelet-rich plasma scaffold serves as a bioactive component, which induces migration, proliferation, and differentiation of chondrocytes as part of the repair and regeneration process. It is pertinent to mention that given the bioactive molecule-rich composition of platelet-rich plasma, its use may significantly contribute to the ongoing intrinsic repair process (Haider 2017).

Autologous PACI: This procedure is performed by simply cutting autologous cartilage fragments into small size (0.25 to 0.5 mm^3) chips using a scalpel. These pieces are later embedded in scaffold glue before placing them in the debrided defect. Autologous PACI stimulates chondrocyte migration and promotes cartilage regeneration. A commercial product of DePuy company is the cartilage autologous implantation system (CAIS) that results in significantly better international knee documentation committee (IKDC) scores and knee injury and OA outcome scores (KOOS) (Cole et al. 2011; Lu et al. 2006).

Allogeneic PACI: Allogenic PACI involves implanting particulated articular cartilage from a donor as a treatment option for focal articular cartilage defects. Currently, Zimmer's DeNovo NT system as a commercial product derived from allogeneic juvenile cartilage particles results in an extended retention period of up to 45 days in vitro. The repair effect (mixture of hyaline cartilage and fibrocartilage) is reported for 2 years after implantation (Farr et al. 2014; Tompkins et al. 2013).

Autologous Chondrocyte Implantation (ACI): This surgical treatment method involves harvesting chondrocytes from the non-weight-bearing autologous articular surface to treat isolated full-thickness (down to the bone) articular cartilage defects. Autologous chondrocyte implantation (ACI) or mosaicplasty is a two-stage treatment procedure in which chondrocytes are harvested from a patient's joint, expanded in culture, amplified in vitro, and reimplanted over an articular cartilage defect. The American Food and Drug Administration (FDA) has officially approved ACI only as a reparative articular cartilage procedure to treatments of large, grade 3 and 4 chondral defects, up to 10 cm^2. There are three generations of ACI. The first-generation ACI (PACI) involves suturing the autologous periosteum onto the edge of

the cartilage defect and injecting chondrocytes into the defect lacunas. On the other hand, the second generation of ACI (C-ACI) involves the replacement of periosteal tissue with a type I/III collagen membrane, while the third generation of ACI is matrix-induced autologous chondrocyte implantation (MACI) (Brittberg et al. 1994; Giannoni et al. 2005; Kino-oka et al. 2009; McNickle et al. 2009; Peterson et al. 2000, 2002; Rogers et al. 2010; Steinwachs and Kreuz 2007).

Tissue-Engineered Articular Cartilage

The contemporary clinical treatments, such as osteochondral transplantation procedures, have shown severe limitations, especially for extensive full-thickness cartilage defects. Therefore, alternative therapeutic approaches are warranted. Thus, several cell-based therapies using different stem cells have been proposed as a novel treatment approach for cartilage regeneration and repair. There are three categories of cartilage tissue engineering: cell-scaffold constructs, cell-free procedures, and scaffold-free strategies (Caplan and Correa 2011; Harrell et al. 2019; Huang et al. 2016).

"Cell-Scaffold Construct" Strategies

The "cell-scaffold construct" strategy is one of the most commonly used methods in cartilage tissue engineering. Several tissue-engineered articular cartilage technologies based on the "cell-scaffold construct" strategy have been introduced, such as matrix-induced autologous chondrocyte implantation (MACI), BioSeed, Hyalograft, CaReS, NeoCart.

MACI: MACI is a typical tissue engineering procedure, which is a two-part procedure of articular cartilage technology. During MACI, the patient's cells are used to regrow new cartilage. At first, a cartilage biopsy is performed arthroscopically and then planted into a scaffold. Then the construct is implanted into the cartilage defect (Bartlett et al. 2005; Basad et al. 2010; Benthien et al. 2011).

BioSeed®-C: A unit of **BioSeed®-C** is a second-generation implant consisting of approximately 28.8 million patient's autologous chondrocytes embedded in a 3D bioabsorbable gel polymer scaffold. Given that BioSeed®-C employs fibrin glue as the cell carrier to grow the cells on the polyglactin 910/poly-p-dioxanone fleece scaffold. This graft is ideal for 3D homogenous chondrocyte distribution since the chondrocyte phenotype remains differentiated (Huang et al. 2016; Kreuz et al. 2011; Ossendorf et al. 2007).

Hyalograft: Hyalograft is a hyaluronan-based material based on a "cell-scaffold construct" strategy in cartilage tissue engineering. Hyalograft C autograft is an implant consisting of autologous chondrocytes derived from the patient and planted on 2-cm x 2-cm square inserts. The positive clinical results of Hyalograft have shown that it may be a viable therapeutic option for the treatment of acute cartilage lesions (Huang et al. 2016; Nehrer et al. 2009; Schneider et al. 2011).

The Cartilage Regeneration System (CaReS): CaReS uses collagen type I hydrogels as scaffolds for seeding primary autologous chondrocytes. This product has resulted in significantly lower adverse events when compared with ACI in patients during 30-month follow-up after CaReS surgery (Schneider et al. 2011).

NeoCart. NeoCart is an autologous cartilage tissue implant containing autologous chondrocytes embedded in a three-dimensional type I collagen scaffold, resulted similar to that of microfracture surgery, and is associated with greater clinical efficacy (Anderson et al. 2017; Crawford et al. 2012).

NOVOCART® 3D. It is a type I/III collagen biphasic scaffold. The previous investigation revealed that NOVOCART ®3D is an effective method for repairing articular cartilage defects, for treating children and adolescents (Niethammer et al. 2017).

The "cell-scaffold construct" strategy was performed using many types of MSCs with clinical applications, such as bone marrow-derived mesenchymal stem cells (BM-MSCs), adipose tissue-derived stem cells (ADSCs), peripheral blood progenitor cells (PBPCs) and peripheral blood-derived mesenchymal stem cells (PB-MSCs), umbilical cord blood-derived mesenchymal stem cells (UCB-MSCs) and umbilical cord Wharton's jelly-derived mesenchymal stem cells (WJ-MSCs), and synovium/synovial fluid-derived mesenchymal stem cells (SMSCs/SF-MSCs).

Cell-Free Strategies

Paracrine release of bioactive molecules and exosomes rich in bioactive molecules constitutes an integral part of the mechanism of MSCs' reparability post-transplantation (Haider and Aziz 2017; Haider and Aramini 2020). Hence, in the recent years, cell-free therapy based on MSCs-derived paracrine factors is now a fast emerging strategy due to its advantages, i.e., avoidance of tumorigenicity, rejection of cell graft, undesired differentiation, etc. (Haider and Aslam 2018). Cell-free procedures for cartilage tissue attempt to repair and regenerate the injured cartilage tissues by recruiting endogenous stem/progenitor cells to participate in the repair (Schüttler et al. 2019). Cell-free strategy can be performed with two methods.

In the first procedure, induction of cartilage regeneration is carried out by in situ endogenous BMSCs using synthetic degradable scaffolds combined with bone marrow stimulation. In the second procedure, to build composite scaffolds of the derivatives secreted by MSCs (i.e., extracellular vesicles, cytokines, and various RNAs) implanted in the cartilage defect areas. Currently, the representative products of cell-free strategies are TruFit scaffolds and MaioRegen scaffolds.

TruFit Scaffolds: The TruFit osteochondral scaffold plug implant is commercially available composed of a poly(lactide-co-glycolide) copolymer, 10% calcium sulfate, polyglycolide fibers, and surfactant for the treatment of chondral and osteochondral defects. Investigations indicated a clear improvement of the clinical symptoms and slowing joint degeneration in the case of focal osteochondral (Azam et al. 2018; Barber and Dockery 2011; Bugelli et al. 2018; Joshi et al. 2012).

MaioRegen Scaffold: The MaioRegen scaffold is a three-layer biomimetic scaffold consisting of collagen I and hydroxyapatite. Studies have shown that it has a reliable medium-term effect on repairing articular cartilage defects. MaioRegen scaffold has been proposed for in situ cartilage regeneration. MaioRegen, with a porous composite structure, mimics the whole osteochondral anatomy. It is a nanostructured biomimetic and bioresorbable implant, which has three different layers (superficial, intermediate, and lower). In the superficial layer with only type I

collagen (100% type I collagen) mimicking smooth surface, it reproduces the articular surface. The intermediate layer has collagen type I and 40% hydroxyapatite composite (60% type I collagen and 40% hydroxyapatite), while the lower layer has 30% collagen type I and 70% hydroxyapatite that reproduces the composition of the subchondral bone (Berruto et al. 2014; D'Ambrosi et al. 2019).

Scaffold-Free Strategies

In recent year, the scaffold-free strategies and products have gained popularity for use in the clinic as the process is similar to the native cartilage development. These novel products can completely regenerate continuous, homogeneous, and healthy cartilage layers, because it mimics the elements of developmental processes underlying these tissues. This method needs important consideration, such as cell sourcing, stimulation of tissue-specific extracellular matrix (ECM) production, and tissue organization (Park et al. 2019; Yamashita et al. 2015). A few scaffold-free products are currently being used in clinical applications.

Chondrosphere (Spherox): Chondrosphere is a 3D autologous chondrocyte transplantation product that comprises spheroids in suspension developed from autologous chondrocytes, which indicated for the repair of symptomatic articular cartilage defects. The spheroids are formed from the patient's undamaged articular condyles. Human chondrocytes undergo three steps for the production of spheroids harvesting from healthy articular cartilage, cultivation for 8–10 weeks in vitro, and condensing into spheroids (chondrospheres). The three-dimensional spheroids are then transplanted into the defect. In literature, the recommended dose of spheroids of human autologous matrix-associated chondrocytes was 10–70 spheroids/cm^2 (Armoiry et al. 2019; Becher et al. 2017).

Common Cell Types for Articular Cartilage Regeneration

During organogenesis in the embryonic period, chondrocytes originate from mesenchymal progenitor cells. Several studies have reported that treatment using stem cells, especially MSCs, is an optimal intervention for cartilage repair rather than implanting terminally differentiated cells such as chondrocytes. Various cell types from diverse tissue sources have been characterized as possible candidates for cartilage repair (Ma et al. 2018). The reparability of these cells has been assessed with or without manipulation using various scaffolds for the delivery, as discussed in the following sections (Huang et al. 2018a). Table 2 summarizes the advantages and limitations of the use of common cell types for articular cartilage regeneration.

Mature Cells

Autologous chondrocytes were one of the first tissue cells for tissue engineering applications to regenerate the articular cartilage surface. Autologous chondrocytes can be used for larger chondral lesions, where the subchondral bone plate remains

Table 2 Advantages and limitations of the use of common cell types for articular cartilage regeneration

Cell types		Advantages and limitations

intact. The previous investigation revealed indications of autologous chondrocyte implantation for larger and full-thickness defects (e.g., 2–10 cm^2) in younger patients, to treat injuries that have failed debridement or other cartilage repairs after a preceding bone graft for deeper lesions. But in the patient with inflammatory arthritic condition, kissing lesions (in particular, outer bridge grades 3–4 on the opposing surface) and reluctance to cooperate with postoperative rehabilitation should be avoided. Although several investigations showed that autologous chondrocytes have potential in cartilage tissue engineering applications, many restrictions limit the application of autologous chondrocytes, such as limited number of cells (Brittberg et al. 1994; Giannoni et al. 2005; Kino-oka et al. 2009; McNickle et al. 2009; Peterson et al. 2000, 2002; Rogers et al. 2010; Steinwachs and Kreuz 2007).

Stem Cells

Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) constitute the heterogeneous stromal multipotent adult stem cells compartment of the bone marrow (BM) with diverse properties, including plastic adherence, clonal expansion by self-renewal, and tri-lineage differentiation potential. MSCs have capacity multipotentiality, and under a conducive set of conditions, MSCs can transdifferentiate into at least three cell lineages, adipocytes, osteoblasts, and chondrocytes, besides others, i.e., myofibroblasts. MSCs can be isolated from several body tissues, such as the placenta, umbilical cord, skeletal muscle, synovium, synovial fluid, and adipose tissue (Bianco and Robey 2015; Frisbie and Stewart 2011; Kim et al. 2014; Lee et al. 2007; Li et al. 2016). There are currently many types of MSCs with underexplored and even unexplored potential of clinical utility. However, some of these cells have already progressed to advanced stages of clinical trials for the treatment of various diseases, i.e., bone marrow-derived MSCs, adipose tissue-derived MSCs (AD-MSCs), peripheral blood-derived stem/progenitor cells, umbilical cord blood-derived mesenchymal stem cells (UCB-MSCs), umbilical cord Wharton's jelly-derived mesenchymal stem cells (WJ-MSCs), and synovium/synovial fluid-derived mesenchymal stem cells (SMSCs/SF-MSCs) (Le et al. 2020).

BM-MSCs

BM-derived MSCs are an integral part of the HSCs' niche in vivo. Based on their surface marker expression, they are positive for CD90, CD44, CD70, etc., but negative for the expression of hematopoietic stem cell-specific markers, i.e., CD34, CD45, etc. (Haider and Ashraf 2005). The International Society for Cell Therapy (ISCT) has suggested standardized criteria to define human MSCs which include (1) adherence to plastic surface under standard culture conditions; (2) expression of CD73, CD90, and CD105 and lack of CD34, CD45, HLA-DR, CD14 or CD11b, CD79a, or CD19 membrane surface molecules; and (3) tri-lineage differentiation potential to adopt osteoblasts, adipocytes, and chondroblasts under a defined

set of culture conditions in vitro (Haider 2018). Although they are available in small numbers in the BM, BM-MSCs are easy to harvest and expand in vitro undifferentiated to achieve a relatively high concentration that is enough for use. Given their robust nature, they can be genetically manipulated or preconditioned to enhance their paracrine activity as well as survival and differentiation potential (Haider et al. 2008, 2010; Kim et al. 2009, 2012). Hence, BM-MSCs are the most well-characterized, better studied, and commonly used in the field of articular cartilage regeneration.

Published data have demonstrated that BM-MSCs possess the capability of differentiating into cartilage and, hence, repair articular cartilage defects. These data have been reported in numerous preclinical as well as clinical studies and showed that BM-MSCs significantly improved patients' quality of life after treatment (Li et al. 2018; Nejadnik et al. 2010; Park et al. 2015; Wakitani et al. 2007).

Various research groups have demonstrated that autologous BM-MSCs seeded on a collagen gel or combined with platelet-rich fibrin glue scaffolds could significantly improve the symptoms of cartilage defects (Jung et al. 2009; Berninger et al. 2013; Araki et al. 2015). No adverse events have been reported, demonstrating the safety of and efficacy of scaffold-based delivery of BM-MSCs. Several investigations have reported the effects of bioactive factors on BM-MSCs' chondrogenic differentiation (Fortier et al. 2011; Patel et al. 2019). For example, TGF-β3 activated the downstream TGF-β3/Smad signaling pathway and promoted MSCs' chondrogenic differentiation (Ng et al. 2008). Bian et al. have designed an implantable construct by co-encapsulating MSCs and TGF-β3 containing alginate microspheres in HA hydrogel for cartilage repair (Bian et al. 2011). Subcutaneous implantation of the construct into nude mice resulted in a superior cartilage matrix formation, attributed to controlled local delivery of TGF-β3. In another study, TGF-β3, through the activation of MAPK and Wnt signaling pathway, induced gene expression of SOX9, COL II, and ACAN and proteoglycan synthesis (Tuli et al. 2003). Although the role of TGF-β3 in chondrogenic differentiation of MSCs is well-established, the approach is not without its drawback that includes inefficiency of the protocol and instability of chondrogenic phenotype.

Besides TGF-β3, bone morphogenetic proteins (BMPs) superfamily, including BMP-2, BMP-4, BMP-6, and BMP-7, have shown to significantly enhance MSCs' chondrogenic differentiation (Taipaleenmäki et al. 2008; Scarfì 2016). BMPs function by the activation of Smad-dependent and Smad-independent signaling pathways that involve activation of mitogen-activated protein kinases (ERK, p38MAPK, JNK) (Carreira et al. 2015). On the same note, another TGF superfamily, the addition of FGF-2 during the expansion of BMSCs, alters MSCs' surface marker distribution and chondrogenic differentiation potential and increased GAG/DNA contents (Hagmann et al. 2013).

Bioactive melatonin attenuates IL-1β-induced activation of NF-kB pathway and rescued interleukin 1b-impaired chondrogenic potential of BM-MSCs. In similar studies, melatonin increased gene expression of SOX9, RUNX2, SERPINB2, and SERPINA9 and enhanced the accumulation of GAG, COL II, and COL X (Gao et al. 2014; Granados-Montiel and Cruz-Lemini 2021; Hu and Li 2019). Treatment with

chondroitin sulfate promoted BM-MSCs' chondrogenic differentiation and also inhibited chondrocyte hypertrophy (Varghese et al. 2008), while ghrelin treatment upregulated COL II, SOX9, and ACAN expression and enhanced the collagen and GAG accumulation in vitro through activation phosphorylation of ERK1/2 and DMNT3A pathway. These molecular changes improved the cartilage repair effect of BMSCs in vivo through SHH pathway activation (Li et al. 2012). Atractylenolides increase SOX9, COL II, and ACAN gene expression (Li et al. 2012).

Several investigations have also reported the effects of physical stimulation of BMSCs in terms of supporting chondrogenic differentiation, such as vibration and compression. These methods of physical stimulation include mechanical methods (i.e., cyclic strain, fluid shear stress), electrical and magnetic field exposure, ultrasound and shock-wave treatment, and substrate stimuli (Huang et al. 2018). Vibration through activation of Wnt/b-catenin pathway promoted BM-MSCs' chondrogenic differentiation and inhibited hypertrophic differentiation. Tensile stimulation improved chondrogenic phenotype of MSCs (Hou et al. 2020; Xie et al. 2019).

Compression stimulation functions by TGF-β/activin/nodal pathway and suppresses BMP/GDP and integrin/FAK/ERK pathways. These molecular changes enhanced BM-MSCs' chondrogenic differentiation and suppressed chondrocyte hypertrophy and fibrocartilage formation (Xie et al. 2019). Microgravity suppressed IHH and SHH pathways and attenuated their chondrogenic differentiation and chondrocyte hypertrophy as well as aging of MSCs by increasing the expression of COL II and SOX9 (Xie et al. 2019; Zhang et al. 2015).

WJ-MSCs

Similar to BM-MSCs, WJ-MSCs have multi-lineage differentiation potential. Investigations have demonstrated that WJ-MSCs can sustain undifferentiated self-renewal in vitro for more than ten generations. WJ-MSCs express surface markers similar to the phenotype of BM-MSCs. Although WJ-MSCs are allogenically sourced, they are weakly immunogenic; they resemble BM-MSCs in terms of paracrine activity (Marino et al. 2019), and hence, they are considered an excellent cell source in tissue engineering, especially when cells have to be allogenically sourced (Voisin et al. 2020). Interestingly, studies have demonstrated that immune-related molecules (i.e., B7-H3/CD276 and HLA-E) characterized in undifferentiated MSCs were also expressed in the differentiated progeny of WJ-MSCs and suggest that WJ-MSCs-derived cells may maintain their immunoprivileged status post differentiation (La Rocca et al. 2013). Similar observations have also been reported recently by Voisin et al., who have demonstrated that hypo-immunogenicity is sustained and remains unchanged during the process of differentiation. A head-to-head comparison of BM-MSCs and WJ-MSCs has shown that the latter's immunoprivileged properties and stemness were much superior as compared to BM-MSCs (Li et al. 2017).

Human WJ-MSCs co-cultured with primary cartilage cells on an acellular cartilage ECM scaffold significantly enhance the biomechanics and composition of the neo-tissue post engraftment into the articular cartilage defect area in a caprine

experimental model (Zhang et al. 2020). The differentiated WJ-MSCs showed a stable chondrogenic phenotype in the biomimetic cartilage microenvironment. More interestingly, the neo-tissue was more similar to native cartilage during 9 months of follow-up.

Various strategies have been adopted to enhance the rate of differentiation. One such strategy combines WJ-MSCs and pulsed electromagnetic field (PEMF), which induce an early and higher rate of WJ-MSCs differentiation toward cartilaginous tissue (Esposito et al. 2013). On the same note, a study aimed to evaluate the usefulness of two commercially available hyaluronic acid (HA)-based hydrogels, HyStem and HyStem-C, for the cultivation and chondrogenic differentiation of WJ-MSCs showed that the cells had some degree of chondrogenic potential in both the hydrogels (Aleksander-Konert et al. 2016). The use of advanced hydrogels with tailored properties has been excellently reviewed by Wei et al. (Wei et al. 2021).

UCB-MSCs

Human UCB-MSCs (hUCB-MSCs) offer a promising cell source for in vivo repair of cartilage defects. Cord blood is collected from the umbilical cord, and placenta UCB-MSCs have several advantages over BM-MSCs and AD-MSCs, including noninvasive availability, high proliferative potential, presence of pluripotent cell population, low immunogenicity, and chondrogenic potential. In recent years, the co-culture of hUCB-MSCs and chondrocytes in vitro has been shown to promote hUCB-MSC chondrogenesis (Zheng et al. 2013). A direct comparison between BM-MSCs, AD-MSCs, and UCB-MSCs revealed that UCB-MSCs had the highest proliferation capacity, clonality paracrine activity, and tolerance to aging (Jin et al. 2013). It was observed that the ratio of co-cultured cells and the presence of IGF-1 in the differentiation culture significantly enhanced their chondrogenic potential. More interestingly, the defined ratio between the two cell types resulted in the expression of the cartilaginous cellular matrix (Zheng et al. 2013).

Besides co-culture, various strategies have been developed to enhance the rate of chondrogenic differentiation. Thrombospondin-2 secreted by UCB-MSCs as part of paracrine activity triggers chondrogenic differentiation of chondroprogenitor cells (Jeong et al. 2013). Molecular studies showed autocrine activation of the Notch signaling pathway during chondrogenic differentiation of UCB-MSCs and attenuated their hypertrophic differentiation (Jeong et al. 2015). In a recent study, Jing et al. have exploited the preconditioning approach during which the authors treated UCB-MSCs with kartogenin before TGF-β3 induction. The authors observed activation of the JNK/RUNX1 signaling pathway with concomitant suppression of the β-catenin/RUNX2 pathway. The preconditioned cells showed accumulation of extracellular matrix and chondrogenic gene expression of SOX9, COL II, and ACAN (Jing et al. 2019). Similar data have also been reported by Zhao et al. that have also shown the superiority of concomitant use of kartogenin preconditioning and TGF-b3 induction for chondrogenesis in UCB-MSCs (Zhao et al. 2020). Some recent advances in the use of kartogenin for chondrogenic differentiation of UCB-MSCs are their use with hydrogels and collagen nanofibers (Yin et al. 2017; Fan et al. 2020). Another study has reported that a combination of allogeneic UCB-MSCs and

HA hydrogel is a safe and effective treatment option for large osteochondral defects (Park et al. 2017).

SMSCs/SF-MSCs

The synovial fluid (SF) is a novel source of MSCs (SF-MSCs) for cartilage repair (Li et al. 2020). SF-MSCs can be harvested during arthrocentesis, arthroscopy, or knee surgery with chondrogenic potential. Like BM-MSCs and UCB-MSCs, SF-MSCs have shown significant chondrogenic differentiation capacity (Neybecker et al. 2020). A recently published systemic review including 20 studies (4 using human- and 16 using animal-sourced SF-MSCs) has concluded that irrespective of the source, harvesting protocol, delivery method, etc., SF-MSCs successfully and effectively repaired focal cartilage damage/defects (Kendrick et al. 2019). There is mounting evidence in the published data that SF-MSCs may have superior chondrogenic potential compared with MSCs from other tissue sources (Bami et al. 2020). Molecular studies have revealed the activation of RhoA/ROCK involved in TGF-β3-induced chondrogenic differentiation of rat SF-MSCs through interaction with the Smad pathway (Xu et al. 2012). A study conducted on bovine synovium-derived progenitor cells cultured in 3D alginate hydrogel demonstrated that BMP-2 could induce these cells to express chondrocyte-specific genes, Sox9, type II collagen, and aggrecan (Park et al. 2005). In vitro cartilage formation of composites of SF-MSCs with collagen gel effectively induced chondroitin sulfate and mRNA expression for cartilage-related genes that demonstrated cartilage maturation (Yokoyama et al. 2005). Also, addition of dexamethasone in the combination of TGF-β and BMP2 significantly enhanced in vitro chondrogenesis of SF-MSCs (Shirasawa et al. 2006).

Adipose Tissue-Derived MSCs

Adipose tissue contains stem cells that have the capacity to differentiate into cartilage. ADSCs' effective reparability and regeneration potential of cartilage have been reported in a variety of animal models. Therefore, they represent a promising, minimally invasive, nonsurgical source of cells for cell-based therapy of cartilage defects. ADSCs obtained from lipoaspirates have immunosuppressive properties and low immunogenicity (Simona et al. 2020; Huaman et al. 2019). Moreover, they actively secrete trophic factors as part of their paracrine activity that actively contributes to the therapeutic and regenerative potential of the cells in a wide range of applications (Linero and Chaparro 2014; Dabrowski et al. 2017).

Treatment with bioactive factors of BMPs family, such as BMP-2, BMP-4, BMP-6, and BMP-7, enhances ADSCs' chondrogenic differentiation (Taipaleenmäki et al. 2008). However, a recent study has reported that BMP-2 outperforms BMP-6 in promoting chondrogenesis using canine adipose tissue-derived MSCs (Teunissen et al. 2021). The authors also reported a direct comparison of canine AD-MSCs with BM-MSCs to demonstrate the former were inferior in chondrogenic differentiation. However, both the cell types expressed common surface markers. An earlier study has reported that this weakness of AD-MSCs may be compensated by higher dose treatment of pro-chondrogenic growth factors to achieve a comparable rate of chondrogenic differentiation rate (Kim and Im, 2009). On the same note, kartogenin

treatment significantly promotes chondrogenic differentiation, suppresses chondrocyte hypertrophy in ADSCs' fibrin scaffold (Valiani et al. 2017), and enhances the expression of chondrocyte redifferentiation markers (Zhang et al. 2021). In another interesting study to enhance their chondrogenic differentiation, ADSCs from adipose were transduced for ectopic expression of Sox-9 with a retroviral vector encoding the Sox-9 gene in vitro. The transduced cells were engineered for the chondrocyte-like cell differentiation by 3D culturing in alginate beads and TGF-β treatment. Ectopic expression significantly increased the chondrogenic potential of the cells (Yang et al. 2011). These studies provide strong evidence that AD-MSCs can be strong candidates for use in the clinical perspective.

PB-MSCs

Peripheral blood (PB) is yet another potential source of chondrostem/progenitor cells that can be used for cartilage repair and regeneration. PB-derived stem/progenitor cells can be obtained by a minimally invasive procedure without general invasiveness and complications associated with MSCs harvesting from many other tissues, such as hemorrhage, chronic pain, neurovascular injury, etc. PB-derived stem/progenitor cells secrete circulating cytokines, which puts them at par with MSCs from other tissue sources for autologous cell-based therapy. It is generally perceived that PB-derived stem/progenitor cells positively influence MSCs' emigration from the BM. A direct comparison of PB-derived MSCs and BM-MSCs has revealed that the two cell types were similar in their biological characteristics, but the chondrogenic potential of BM-MSCs was superior to PB-MSCs (Lotfy et al. 2019).

Several studies conducted with PB-derived stem/progenitor cells for cartilage repair and regeneration have reported that autologous PB-derived stem/progenitor cells are safe for use in vivo. In a recent study, it has been demonstrated that quality of life improvements measured by WOMAC and KOO scores increased after successful regeneration of articular cartilage during early osteoarthritic disease (Turajane et al. 2013). Cells derived from mobilized peripheral blood showed similar biological characteristics in chondrogenesis as MSCs from the NM. In some studies, PB-derived stem/progenitor cells have shown even better chondrogenic differentiation potential than BM-MSCs in vitro (Fu et al. 2014). Hypoxic culture of PB-derived stem/progenitor cells seeded on HA and collagen scaffolds significantly enhanced the expression of pro-chondrogenic cells in the seeded cells (Bornes et al. 2015).

Scaffolds for Cartilage Treatment

A recent systematic review has shown that cellular scaffolds are undoubtedly more effective than the noncellular scaffolds (Pot et al. 2017). However, the nature of the scaffold material remains a significant determinant of the outcome because the scaffold type and biomaterials in cartilage tissue engineering should provide a suitable and conducive microenvironment mimicking the natural microenvironment in the articular cartilage. This is important for the cells to sustain their biological and differentiation characteristics during culture and post engraftment in the tissue

regeneration process. Therefore, ideal scaffolds for cartilage tissue engineering should have the following essential features that include but are not restricted to improved cell attachment behavior, biodegradable, noncytotoxic, biocompatible, highly porous, support proliferation and differentiation, flexible and elastic, and nonantigenic. Currently, matrix materials suitable for chondrocytes can be made using synthetic or natural polymers or both (hybrid scaffolds). Table 3 summarizes natural scaffolds approved for cartilage tissue engineering for medical use, while Table 4 summarizes the synthetic and hybrid scaffolds for cartilage tissue engineering.

Commercially available natural polymers, i.e., chitosan, collagen, alginate, silk fibroin, hyaluronan, and gelatin, exhibit excellent tissue compatibility, little toxicity, and facile biodegradation (Jiang et al. 2020; Li et al. 2020). Despite these advantages, however, some of the common drawbacks of natural materials include their weak mechanical properties and unstable degradation rate, which significantly limit their application in cartilage tissue engineering (Xia et al. 2021). To overcome these limitations of the natural polymers, synthetic materials such as polyurethane (PU), polylactic

Table 3 Natural scaffolds approved for medical use for cartilage tissue engineering

Base	Scaffold	Product (company)	Properties
Collagen	**Bovine type I collagen**	NeoCart® (Histogenics)	Two-step procedure Expanding chondrocytes into scaffolds Incubation in the tissue engineering processor
	Type I/III	Chondro-Gide (Geistlich)	One-step procedure The first described matrix for the ACI method
	Type I/III	ACI-Maix™ (MACI)	Two-step procedure Expanding chondrocytes into scaffolds Implantation into the patient
	Type I collagen, chondroitin sulfate	NOVOCART® 3D—Aesculap Orthopaedics (BBraun)	Two-step procedure A sponge form
	Type I collagen gel	CaReS® (Arthrokinetics)	Two-step clinical procedure Mixing of isolated autologous chondrocytes Fluid matrix A fibrin glue
Agarose and alginate	**Agarose and alginate**	Cartipatch® (Xizia Biotech)	Two-step method The cylindrical scaffold of a single layer of hydrogel with expanded cartilage cells
Hyaluronic acid	**Benzyl ester of hyaluronic acid**	Hyalofast® (Anika)	One-step procedure bioresorbable Nonwoven structure
	Hyaluronic acid	CARTISTEM® (Medipost)	Allogeneic human umbilical cord blood (hUCB)-derived MSCs and HA hydrogel

Table 4 Synthetic hybrid scaffolds for cartilage tissue engineering. (Kreuz et al. 2011; Christensen et al. 2012; Theodoridis et al. 2019a; Tsai et al. 2015)

Type	Base	Scaffold	Source/animal model	Properties
Synthetic	PGA	Chondrotissue® (Bio-Tissue)	Platelet-rich plasma and bone marrow concentrate	Provide one-step cartilage repair method
	PU	Spongy PU scaffold	Chondrocytes, human MSC	Biodegradable
	PCL	NSP-PCL scaffold	Rabbit articular chondrocytes	In vitro and in vivo studies results
	PES	Polysulfonic scaffold	Rabbit model and human articular chondrocytes	Effective in repairing articular cartilage defects
	PLLA	PLLA-100 scaffolds	Human articular chondrocytes	Promote the secretion of chondrogenic genes
	PLCL	PLCL-2 scaffold	Rabbit articular chondrocytes and mice model	Maintain mechanical integrity of chondrocyte
Hybrid	PGA, HA	Chondrotissue® (Bio-Tissue)	Platelet-rich plasma and BM concentrate	For the one-step cartilage repair method
	PLGA, COL	IC scaffold	Bovine articular chondrocytes (BACs) and mice model	Promote gene expression, chondrocyte proliferation, and regeneration of cartilage tissue with high mechanical properties
	Gelatin, PCEC, TGF_1	Gel/PCEC-TGF_1 hydrogel scaffold	Human adipose tissue (AD)-MSCs	The potential for the growth and differentiation of h-AD-MSCs
	PLCL, COL	PLCL-COLI	Rabbit articular chondrocytes	Controlled structure, good biocompatibility, elasticity, and mechanical properties
	C2C1H scaffold	PLA, COL, CH	Bovine articular cartilage chondrocytes	High porosity, good mechanical strength, and interconnected pore network
	PLGA, ECM	ECM-PLGA scaffold	Rat mesenchymal stem cells (MSCs) and rat model	Improve attachment, proliferation, and differentiation of the MSCs
	PCL, COL	PCL/COL1	Pig articular chondrocytes and nude mice model	High porosity and repetitive pore structure
	PLLA, CH, PC	CH/PLLA/PC scaffold	Rabbit articular chondrocytes	Suitable for cartilage tissue regeneration

(continued)

Table 4 (continued)

Type	Base	Scaffold	Source/animal model	Properties
	PLCL, CH	Chitosan-modified PLCL scaffold	Pig articular chondrocytes	Biodegradable, with high porosity, good mechanical strength, and interconnected pore structure
	CSMA, GO MPEG-PCL-AC (PECA)	CSMA/PECA/GO (S2) scaffold	Rabbit articular chondrocytes	Scaffold with an appropriate structure with biological components

List of Abbreviations: AC, acryloyl chloride; CH, chitosan; COL, collagen; CS, chondroitin sulfate; CSMA, methacrylated chondroitin sulfate; ECM, extracellular matrix; GO, graphene oxide; HA, hyaluronic acid; PC, pectin-based; PCEC, polycaprolactone-polyethylene glycol; PCL, polycaprolactone; PDS, poly-p-dioxanone; PECA, poly(ethylene glycol) methyl ether-"-caprolactone-acryloyl chloride PEG—poly(ethylene glycol); PES, polyethersulfone; PGA, poly(glycolic acid); PLA, polylactic acid; PLCL, poly(L-lactide-co-"-caprolactone); PLGA, polylactic-co-glycolic acid; PLLA, poly(L-lactide); PU, polyurethane; SCPL, solvent casting and particulate leaching method

acid (PLA), polycaprolactones (PCL), and poly(lactide-co-glycolide) (PLGA) with unique properties including plasticity, degradation rate, and mechanical characteristics have been introduced. Synthetic materials allow forming into desired shapes and improved control over mechanical and structural features besides having resorbable properties (Joshi et al. 2012). However, synthetic materials are very costly and have weak cell-adhesive ability (Wei and Dai, 2021). Therefore, in-depth investigations are currently underway to develop hybrid materials such as gelatin/polycaprolactone-polyethylene glycol (Gel/PCEC-TGF1) (Huang et al. 2016; Irawan et al. 2018; Wasyłeczko et al. 2020).

Bioreactors

Currently, the most common types of cartilage tissue bioreactors are the spinner flasks, rotating wall vessels, and perfusion systems, which have been developed in an attempt to provide necessary features, such as enhancing the expansion of seeded cells, promoting the exchange of nutrients and oxygen, and providing appropriate physicochemical stimuli (Mabvuure et al. 2012; Silva Couto et al. 2020). Table 5 summarizes common types of bioreactors for cartilage tissue engineering.

Spinner Flasks

Spinner flask is a cylindrical culture system that can create fluid convection and hydrodynamics to enhance the efficiency of nutrient delivery and seeding of cells in the scaffold that result in chondrogenic differentiation in vitro and subsequent

Table 5 Common types of bioreactors for cartilage tissue engineering

Type of bioreactor	Cell source	Study design	Results
Spinner flasks (SF)	Chondrocytes	Alginate gel beads with chondrocytes	Improvement of the GAG quantification and relevant gene expression
	hADSCs	Cellular metabolic response to dynamic loading	Enhancing chondrogenic differentiation of hADSCs
Rotating wall vessels (RWVs)	hADSCs	Chitosan/gelatin hybrid hydrogel and subsequent dynamic loading	Enhancing proliferation and matrix secretion
	RCS	Culture of cell pellets	Influence the expression of LRP4/5/6 in chondrocytes
Perfusion bioreactors (PB)	hADSCs	D-printed PCL scaffold-seeded cells	Uniform distribution of the cells within the scaffold
	hBM-MSCs	hBM-MSCs cultured in the perfusion bioreactor	Generated a homogeneous hypertrophic cartilage
Magnetic field bioreactors (MFB)	hBM-MSCs	Scaffold-free hBM-MSCs sheets in response to variable magnetic fields	Did not affect cartilage formation
Ultrasonic bioreactors (USBs)	Chondrocytes	Chondrocyte-seeded scaffolds	Impacted cell proliferation and depth-independent cell population density
	Chondrocytes	Studying the response of cells to ultrasonic stimulation	Influence cell proliferation, viability, and gene expression

List of Abbreviations: *hAD-MSCs* Human adipose tissue-derived MSCs, *hBM-MSCs* human bone marrow-derived MSCs, *MSCs* mesenchymal stem cells, *PB* perfusion bioreactors, *MFB* magnetic field bioreactors, *RWVs* rotating wall vessels, *SFs* spinner flasks, *USBs* ultrasonic bioreactors

chondrogenic formation in vivo (Mabvuure et al. 2012; Rauh et al. 2011; Yoon et al. 2012).

Rotating Wall Vessels

These vessels consist of a pair of concentric cylinders: rotating outer and inner cylinders that are static and used to exchange gases that create a microgravity environment and provide controlled oxygen transport, as well as low shear forces and turbulence (Nordberg et al. 2019; Zhu et al. 2017).

Perfusion Bioreactors

The perfusion bioreactors consist of a pump, culture media reservoir, tubing circuit, and a perfusion cartridge that holds the scaffolds and effectively infuses the medium into the scaffold. Perfusion bioreactors use a pumping system to feed the medium

directly to the scaffolds (Gharravi 2019; Gharravi et al. 2012, 2014, 2016; Pigeot et al. 2020; Sharifi and Gharravi 2019; Theodoridis et al. 2019b).

Magnetic Field Bioreactors

The magnetic field bioreactors (MFB) can meet the requirement of sterile culture conditions by contactless culture. Most of them consist of one group of permanent magnets that influence the behavior of cells through static or dynamic magnetic field strengths (Brady et al. 2014; De Mattei et al. 2004; Dikina et al. 2017; Dobson et al. 2006; Jaberi et al. 2011).

Ultrasonic Bioreactors

Low-intensity continuous ultrasound (US) has been shown to influence cell growth and modulate the expression of chondrocyte-specific genes. The traditional ultrasonic bioreactor (USB) is realized by adding an ultrasonic processing system (Guha Thakurta et al. 2014; Subramanian et al. 2013; Whitney et al. 2012).

Conclusion

None of the currently available methods, microfracture as reparative technique and osteochondral autografts and allografts, in addition to autologous chondrocyte implantation as restorative techniques, can be said not to have any disadvantages. Stem cell-based cartilage tissue engineering is considered the most promising strategy for the complete regeneration of hyaline cartilage. Unfortunately, optimal seed cell and scaffold material have not yet been found. Therefore, searching for new therapeutic methods with a cartilage regenerative potential is a major goal in cartilage sciences in the future. Limitations and advantages of abovementioned methods should be considered when designing a novel protocol or improvement in the existing procedures.

Abstract

Cell transplantation is an attractive therapeutic avenue for injuries of the central nervous system (CNS) and neurodegenerative disorders. Transplanted cells are able to restore the cells that are lost in the injury process, including neurons, oligodendrocytes, and astrocytes. Various clinically relevant cell types and sources have been explored thus far, including induced pluripotent stem cells (iPSCs), which can be used for autologous transplantation. Despite this advantage, differentiation of iPSCs remains time consuming, which may be a limitation in urgent clinical cases. Additionally, the intermediate pluripotent state increases the risk of tumorigenicity when transplanting iPSCs. In this regard, research efforts have shifted toward the transdifferentiation of somatic cells into a variety of neural cell types, including neurons, astrocytes, and oligodendrocytes or their progenitors. This method bypasses the pluripotent stage to reduce the risk of tumorigenicity, thus reducing the induction timeline while still maintaining the patient-specific capacity of the cells. Neural cells or their progenitors can be differentiated in vitro using a number of methods, including transient expression or suppression of certain transcription and chromatin remodeling factors through gene manipulation, or miRNA and small molecule treatment. Recently, research efforts have also focused on in vivo transdifferentiation, in which endogenous cells are targeted for conversion into cell types of interest. The following chapter will focus on the general principles of direct neural lineage conversion, the methods used to derive particular cell types, and their application to injuries of the CNS.

Keywords

Cell source · Cell transplantation · Direct reprogramming · High-throughput screening · Neurodegeneration · Transcription factors · Traumatic CNS injury

Abbreviations

6-OHDA	6-hydroxydopamine
AD	Alzheimer's disease
BMA	Ascl1, Brn2, Mytl1
CNS	Central nervous system
CPZ	Cuprizone

CRISPRa	CRISPR activation
DCas9	Dead form of Cas9
DCX	Doublecortin
DRNPCs	Directly reprogrammed neural progenitor cells
HDAC	Histone deacetylase
FACS	Fluorescent activated cell sorting
IPSCs	Induced pluripotent stem cell
INSCs	Induced neural stem cells
miRNA	Micro-RNA
MACS	Magnetic-activated cell sorting
MBD2	Methyl-CpG-binding domain protein 2
MS	Multiple sclerosis
MSI1	Musashi
Ngn2	Neurogenin-1
NSCs	Neural stem/progenitor cells
OPC	Oligodendrocyte precursor cell
ORF	Open reading frame
PD	Parkinson's disease
RA	Retinoic acid
SCI	Spinal cord injury
SCRNASeq	Single-cell RNA sequencing
SGRNA	Single guide RNA
SHH	Sonic hedgehog
TBI	Traumatic brain injury
TF	Transcription factor

Introduction

Initially, it was thought that terminally differentiated cells could not be converted to other cell types from other lineages. However, the pioneering finding that described how fibroblasts could be converted to myoblasts via overexpression of the transcription factor (TF) MyoD demonstrated that different cell lineages could be converted to one another (Davis et al. 1987). This finding has opened a new path for research in developmental biology and regenerative medicine, holding great potential for replacing postmitotic cells lost to disease. Further research has shown that converted cells can bypass the principal developmental stages of differentiation through other routes that are not developmentally defined. This process, called transdifferentiation or direct lineage reprogramming, does not follow developmental differentiation routes and is completed without transitioning through an intermediary pluripotent state. Direct reprogramming can generally be achieved by treating cells with defined cell reprogramming factors (Ibrahim et al. 2016). Therefore, determining the reprogramming factors that can be used for direct reprogramming towards a neural lineage is of high importance.

Throughout this chapter, we will discuss the methods by which cells can be directly reprogrammed to a neural fate. As there is a myriad of synthetic molecules

and gene regulatory elements that could possibly promote a neural fate, screening methods are needed to identify the essential factors that would be able to contribute to high-throughput reprogramming. Importantly, direct reprogramming techniques have been applied in the context of injury by reprogramming the cells in vitro and subsequently transplanting them into animal models, or by promoting endogenous conversion of resident cells in vivo. Nonetheless, considerations related to the cell sources as well as the resulting cellular identity must be addressed to derive a directly reprogrammed cell therapy that can appropriately replace the lost cells.

Direct Neural Reprogramming Strategies

Direct reprogramming of nonneural lineage cells to neural cell types or their progenitors is essential for human applications, as the accessibility to human neural cells is limited. Conventional methods, such as embryonic stem cell and induced pluripotent stem cell (iPSC) differentiation, typically mimic the developmental stages via applying different growth factors or small molecules to cultured cells. However, recapitulating the developmental stages for differentiation of human neural cells is very time consuming because the production of specific human neural cell types takes place over months and years during human brain and spinal cord development. In contrast, the direct reprogramming of fibroblasts or other cell types into neural cells uses alternate, non-developmental routes, ensuring the quick and reproducible generation of these cells that look more like mature neurons or neural subtypes born later. This is completed by screening for different genetic and chemical factors that can convert somatic cells along the neural lineage (Tsunemoto et al. 2015). To identify the minimal and optimal combinations of these factors, different screening methods have been developed. In this section, we discuss these approaches.

Reprogramming Factors

There are three main unique classes of reprogramming factors that have been utilized for the conversion of somatic cells to neural cells: (i) TFs, (ii) microRNAs, and (iii) chemical small molecules. Each of these classes can be used alone or in combination with others.

Transcription Factors

TFs are the key players among the reprogramming factors in lineage conversion. During development, cells become increasingly specialized until they reach a terminally differentiated state, which is mainly controlled by the expression of TFs that form specific expression networks to ensure stable cell identity. In humans, there are ~1500 different TFs, but not all of them are involved in cell, or more specifically, neural differentiation. Thus, only small subsets of TFs that are involved in differentiation are potential candidates to be used for direct reprogramming. However, groundbreaking work from the Wernig lab has shown that the TFs used for lineage

conversion are not necessarily those involved in cell differentiation during normal development (Vierbuchen et al. 2010). Sometimes a not easily predictable combination and sequential expression of TFs can change the lineage of cells from one terminal differentiated identity to another. Some of these TFs are "pioneer TFs," which can bind and open closed chromatin to enable the binding of other canonical TFs that are important for direct neural conversion. For example, Ascl1 is one of the pro-neural pioneer factors that, through ectopic expression, can initialize cells to exit the cell cycle and enter the neuralization route (Vierbuchen et al. 2010). Downstream of Ascl1, Zfp238, Sox8, and Dlx3 are the key canonical TFs that promote the expression of neural-fate specific genes (Wapinski et al. 2017).

Over the past decade, there have been advancements in identifying key TFs that can directly reprogram a somatic cell's fate. TFs can be overexpressed in somatic cells using different delivery methods. Integrating viral approaches (e.g., lentiviral or retroviral) is efficient but risks oncogenic insertion-mutagenesis due to random integration into the genome. Non-integrating viral (e.g., adenoviral or Sendai-virus) or nonviral (e.g. episomal plasmids) approaches have reduced risks but the trade-off results in considerably lower efficiency.

miRNA

miRNAs (or micro-RNAs) are short noncoding RNAs that are mainly demonstrated to mediate downregulation of expression via translational repression or decay of mRNA (Haider et al. 2015). However, miRNAs can indirectly stimulate gene expression. miRNAs have been shown to target the expression of TFs (Shibata et al. 2008) and epigenetic regulators (Gu et al. 2018), the two main contributors in cell fate reprogramming. Viral and nonviral approaches can be used to deliver miRNAs to cells both in vitro and in vivo. Recently, miRNAs received attention as reprogramming factors because of their relatively small size and ability to be administered systemically or locally by nanoparticle-based delivery systems, avoiding the use of viral vectors (Xue et al. 2013). Supporting their functionality for transdifferentiation of neural cells, brain-enriched miRNAs, miR-9/9∗ and miR-124, can convert human fibroblasts into neurons (Yoo et al. 2011). However, miRNAs do not typically function alone, but synergistically with different master TFs. For example, Ambasudhan et al. have reported that miR-124 needs to be supplemented with two TFs, Myt1l and Brn2 to directly reprogram postnatal and adult human primary fibroblasts to functional neurons in vitro (Ambasudhan et al. 2011). In another study, miR-338 has been used to transdifferentiate human stromal cells to pre-oligodendrocytes (Ebrahimi-Barough et al. 2013, p. 338).

Small Molecules

Small molecules are chemical compounds with a low molecular weight that function as agonists or antagonists of proteins and enzymes in signaling pathways or metabolic processes. The small molecules that manipulate signaling pathways controlling cell differentiation (e.g., Wnt, Notch, Smad, or GSK3b pathways) are widely used in approaches to directly reprogram somatic cells (Xie et al. 2017). Also, small

molecules that target epigenetic modifiers have been shown to play an essential role in the transdifferentiation process. Lineage conversion of one cell type to another needs to overcome the epigenetic barriers established during development (Qin et al. 2016). Histone deacetylase (HDAC) inhibitors and DNA methyltransferase inhibitors were among the earliest discovered compounds used for lineage conversion.

Large chemical libraries of compounds (in the order of a million compounds) are currently being used to screen reprogramming factors (Xie et al. 2017). Since small molecule treatment induces cell-lineage reprogramming in a transgene-free manner, the application of small molecules may potentially be easier to translate into therapeutic applications.

Approaches for Determining the Optimal Combination of Reprogramming Factors

Comparative Gene Expression Analyses

One of the approaches to determine the TFs that can be used for direct reprogramming of somatic cells to terminal neural cells is based on systematic comparative genome-wide gene expression analyses between somatic cells and the neural cells of interest or their progenitors, to use TFs that are highly expressed in neural cells compared to somatic cells (D'Alessio et al. 2015). This approach may not be efficient because most of the TFs that exhibit efficacy in direct lineage conversion are not necessarily the most differentially expressed between cell types. Therefore, this method is mainly useful as a starting point to identify potential TFs and is usually combined with alternative methods (discussed below) to determine an ideal cocktail of reprogramming factors for neural conversion.

Trial and Error Screening of Libraries

One alternative approach is random trial and error to screen pooled libraries of differentiation factors. In this approach, the candidate factors are not known a priori. These pools of differentiation factors can be either expression libraries of TFs/miRNAs, chemical small molecules, or a combination of both (Fig. 1). Pools of multiple factors or group of factors are applied to the cells, where one factor or a group of factors is eliminated to find those essential for that specific lineage conversion. However, performing this type of random screening of factors is a slow and tedious process if it is not combined with high-throughput automated readout approaches to identify reprogrammed cells. One of the most common readout approaches is inserting a fluorescent protein reporter under cell type-specific promoters in the initial cells. After applying the library of pooled factors to cells, only the cells that have received the right combination of factors will express the reporter protein.

This strategy enables fluorescence-activated cell sorting (FACS) of cells expressing the fluorescent protein. The common promoters that have been used for cells differentiated to neurons are Tubb3 and Mpa2. For oligodendrocyte and astrocytes, Olig2 and GFAP are the specific promoters that have been used. Deep sequencing approaches employing single-cell RNA sequencing (scRNA-seq) are

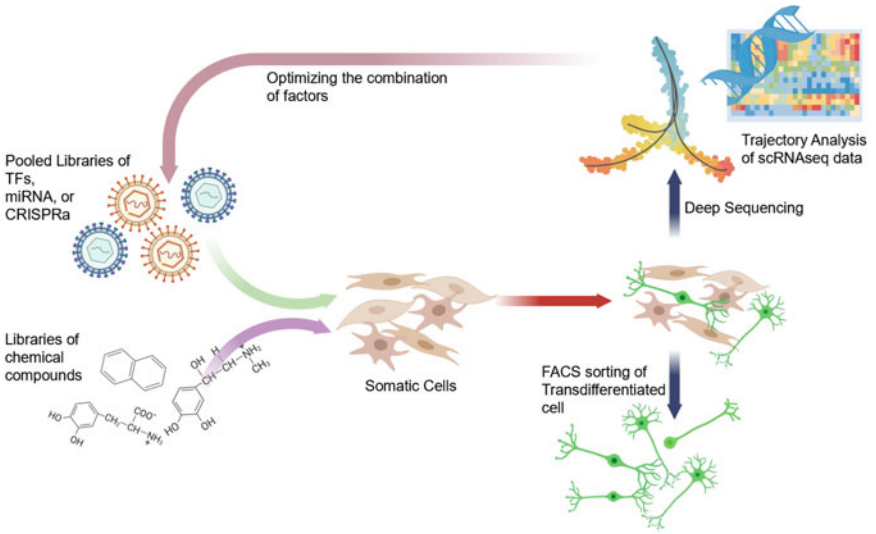

Fig. 1 Determining the optimal combination of reprogramming factors. In most situations, a combination of different approaches are used to screen for the optimal combination of factors to directly reprogram different somatic cells to neural cell types. Genetic screening includes libraries for overexpression of TFs via expressing their open reading frames (ORFs) or activation of their promoters by CRISPRa. Libraries of chemical compounds are used to screen for small molecules. After treating the cells with libraries of reprogramming factors, cells are screened for the target cell phenotype. FACS or deep sequencing are used to identify the factors in genetic screening. Computational approaches are helpful to fine-tune and optimize the combination of identified factors

being used to identify the optimal combination of TFs or miRNAs required to reprogram cells and induce transdifferentiation.

Using this trial and error approach, the Wernig lab identified three TFs: Ascl1, Brn2, and Myt1l (BAM) for direct lineage conversion of mouse fibroblasts to neurons. This was completed within 2–3 weeks, at an efficiency of up to 20% (Vierbuchen et al. 2010). Here, Ascl1 acts as a pioneer factor by immediately occupying most cognate genomic sites in fibroblasts to open the chromatin structure and allows the recruitment of Brn2 and Myt1l to target sites genome-wide. Several other groups have screened for different TF combinations, and notably, almost all successful cocktails contain Ascl (Pfisterer et al. 2011; Yoo et al. 2011; Ambasudhan et al. 2011; Caiazzo et al. 2011). However, the conversion of human fibroblasts to neural cells was more challenging. Developmentally, mouse and human cells have different temporal requirements for neural development involving distinct regulatory strategies. The Wernig lab has found that the addition of NeuroD1 to original BAM factors is necessary to convert human fibroblasts to neurons, but still with lower efficiency (2–4%) than that of mice (20%) (Pang et al. 2011). Several other attempts have been made to improve the transdifferentiation efficiency of human fibroblasts to neurons. In one of these studies, the addition of small molecules to inhibit GSK3β and Smad signaling in the TF cocktail was shown to increase the efficiency to more

than 80% (Ladewig et al. 2012). Later on, Pfisterer et al. identified six small molecules that could increase the neural conversion of human fibroblasts induced by BAM TFs. The six small molecules contain inhibitors of GSK3β and Src kinase pathways, forskolin to activate cAMP-induced pathways, and a balanced combination of an inhibitor and activator of histone deacetylases (Pfisterer et al. 2016).

In a screen to find the optimal factors to convert mouse fibroblasts into neuronal cells, a combination of a priori approaches have been used (Li et al. 2015). In this approach, a library of chemical small molecules is first applied to Ascl1-overexpressing fibroblasts. Ascl1, as a pioneering TF for conversion of somatic cells to neurons, helps to narrow down the screen to small molecules that are only complementary to Asl1. In this screen, forskolin plus three small molecules that inhibit signaling pathways under GSK3β, TGFβ, and noncanonical Wnt were identified. In the next step, researchers sought to determine if Asl1 can also be replaced with small molecules. Ascl1 was omitted and a subsequent small molecule library was screened to replace Ascl1. In this screen, the compound I-BET151 was identified (Li et al. 2015). I-BET151 targets an extensive range of diverse signaling pathways like cyclooxygenase, Aurora kinase, PI3 kinase, and GSK3β pathways. The most probable mechanism for I-BET151 replacing Ascl1 is mediation through affecting the abovementioned pathways.

To convert human fibroblasts into neurons, another screen of chemical compounds identified the inhibitors of MEK and p53 pathways as being required, in addition to forskolin and inhibitors of GSK3β and dual-Smad (TGFβ and BMP) pathways (Dai et al. 2015; Toyokuni 2015).

By comparing different small molecule screens to convert somatic cells to neurons, cAMP activation and GSK3b inhibition (cAMP/GSK3β/sSmad pathway) were deemed canonical for this process. However, depending on the developmental stage of the starting somatic cells, alternative pathways may also need to be targeted. For example, in a screen examining conversion of human adult fibroblasts to neurons, inhibition of TGFβ, PKC, and JNK pathways was found to be required in addition to canonical cAMP/GSK3β/sSmad pathways (Hu et al. 2015). Conversely, conversion of human astrocytes to neurons required activation of retinoid and smoothened pathways in addition to that canonical cocktail (Zhang et al. 2015a).

CRISPR Activation-Based Screening

CRISPR activation (CRISPRa) is a technique that uses the dead form of Cas9 (dCas9) without endonuclease activity fused to transcriptional activators, such as VP64, to induce gene expression. Using this technique, it is possible to activate the expression of any gene of interest by designing a “single guide RNA” (sgRNA) against their promoter regions (Gilbert et al. 2013). Libraries of CRISPRa are popular screening tools due to the relative ease in developing large sgRNA libraries, allowing for potential genome-wide screening. CRISPRa has excellent compatibility with high-throughput screening techniques, making it more attractive for screening of novel TFs involved in direct reprogramming (Fig. 1).

Liu and colleagues of the Qi group at Stanford University have applied the CRISPRa method to screen for TFs that can be used to convert fibroblasts to neurons

(Liu et al. 2018). Specifically, a library of CRISPRa was created against 2428 TFs, which were predicted in silico and applied to mouse fibroblasts. To identify and isolate differentiated neurons, they inserted a human CD8 antigen sequence into the neuronal gene Tubb3. This strategy enabled magnetic-activated cell sorting (MACS) of cells expressing the neuronal marker. Differentiated neurons were isolated by cell sorting and next-generation sequencing was performed to examine which sgRNAs were most efficient for generating neurons. They validated several previously identified TFs, as well as discovered new TFs, such as Ezh2. Ezh2 was identified to promote direct fibroblast to neuron reprogramming in combination with TFs such as Ngn1, Brn2, or Mecom. Furthermore, Ezh2 co-expression with Ngn1 resulted in an increased efficiency of transdifferentiation of fibroblasts to neurons (around 50%) (Liu et al. 2018).

Employing Single-Cell RNAseq and Computational Analysis

Most of the direct reprogramming cocktails discovered thus far for direct reprogramming are generally inefficient, producing incompletely converted and developmentally immature cells that fail to fully recapitulate target cell identity. Incomplete conversion results in heterogeneity among reprogrammed cells during reprogramming. However, the nature of the intermediate states that drive the reprogramming trajectory toward distinct neural types is largely unknown. Understanding the intermediate stages that initial cells undergo to get to the transdifferentiated neuronal fate is key to optimizing the directly reprogramming cocktails. scRNAseq analysis is useful for deconstructing the considerable heterogeneity that emerges during lineage conversion and enables us to distinguish fully converted cells from partially reprogrammed intermediates (Fig. 1). Therefore, cellular reprogramming strategies aimed at generating neural cells have begun to incorporate scRNAseq, alongside computational approaches, to find lineage relationships among intermediate steps that can be used to fine-tune the differentiation processes.

There are several computational frameworks and algorithms that have been developed to predict the combinations of factors that can be used for the transdifferentiation of various cell combinations. For example, Mogrify (http://www.mogrify.net) is a network-based algorithm designed to find TFs crucial for lineage conversion. Mogrify combines gene expression data with regulatory network information to predict the reprogramming factors necessary to induce cell conversion. This algorithm allows for exploring possible reprogramming factors and examining changes in regulatory networks (Rackham et al. 2016).

Implications of the Cell Source

Significant methodological variations exist for the derivation of neural cells depending on the somatic cell source, the germ layer that they are derived from (i.e., mesoderm, ectoderm, endoderm), or the cells' developmental state (Fig. 2). The variant extent of conversion may discredit the use of similar reprogramming factors for different somatic sources. As such, this may hinder a directly reprogrammed

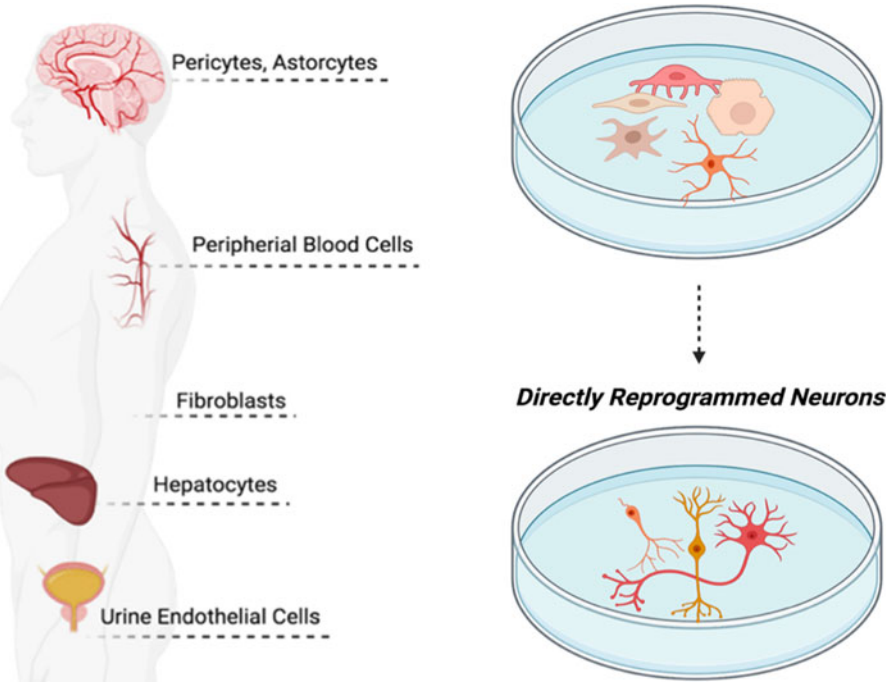

Fig. 2 Schematic of primary-derived cell sources used in the current literature for direct programming

Table 1 Summary of somatic cell sources and their confounding variables in CNS-injury environments if improperly reprogrammed

Somatic source	Germ layer	Potential adverse effects if reprogramming is incomplete
Fibroblast	Ectoderm	Contribute to fibrosis Excrete ECM molecules
Astrocyte	Ectoderm	Possibly become reactive in injury/degenerative environment
Hepatocyte	Endoderm	Secrete albumin
Brain-pericyte	Ectoderm	Contribute to fibrosis by sealing glial scar cavity
Urine tubular epithelial	Mesoderm	Possibly contribute to fibrosis (renal tubular epithelia)

cell's ability to promote an optimal cell replacement therapy. Outlined below are the contexts in which somatic cells are directly reprogrammed towards a neural lineage, as well as implications for their functions if they were not differentiated to a full neural extent (Table 1). This is an important consideration, as the extent of functional conversion in somatic cells is rarely described, making it unclear whether the reprogrammed cells retain unwanted properties from the original cell source. Thus, future work should thoroughly investigate transcriptomic changes, alongside several

other parameters, including but not limited to: functional loss of the original somatic tissues used for reprogramming, electrical activity, their neurotransmitter phenotype, as well as which endogenous targets integrated with the donor neuronal cells in vivo.

Fibroblasts

Fibroblasts are the primary cell type present in the dermis and present vast diversity of structure and function based on their anatomical site of origin. Fibroblasts are frequently used for reprogramming studies as they can be obtained from multiple sources with less invasive procedures. They can be easily expanded in vitro. At site-specific regions, fibroblasts differ in terms of their ability to regulate cell migration, extracellular matrix synthesis and secretion, as well as cell fate specification. The segmentation dictating these regional differences exists on the anterior-posterior (head vs. toe), proximal-distal (torso vs. outer appendages), and internal-external (stroma of organs vs. dermis) axis (Rinn et al. 2008). Thus, fibroblasts are notably heterogeneous and even contain derivatives of the neural crest/neuroectoderm, making them well suited to be converted to functional neural cells. Notably, they are the most widely used source for transdifferentiated and directly reprogrammed cells towards a neural lineage (Marro et al. 2011; Cassady et al. 2014; Tsunemoto et al. 2018; Thier et al. 2019). The extent of conversion towards a neural lineage, however, is crucial when considering their application to the injured brain and spinal cord. For example, the glial scar is present in neural tissue following injury. It comprises dense layers of fibroblasts, infiltrating macrophages, and reactive glial cells that secrete extracellular matrix molecules (Wang et al. 2018). Once transplanted, the functionally incomplete induced neural cells may accumulate and physically impede axonal outgrowth at the glial scar. Moreover, fibroblasts release extracellular matrix molecules, which may further exacerbate the formation of the glial scar. Thus, retention of fibroblast-like structures and functions may impede the regeneration the transplanted cells are attempting to correct.

Astrocytes

Reprogramming of astrocytes towards another neural cell type in vivo presents a potential strategy to overcome the reactive astroglial response following ischemic and traumatic injury. However, the exogenous transplantation of directly reprogrammed astrocytes in vitro would not be clinically relevant because astrocytes are not a readily available cell source, compared to other somatic cells such as fibroblasts. As such, the following discussion refers to astrocyte reprogramming in vivo.

As extensively reviewed elsewhere (Tai et al. 2020), reprogramming of astrocytes or NG2+ astroglia can promote the formation of neurons that are electrophysiological active and promote functional recovery in a variety of trauma and degenerative contexts (Tai et al. 2020). However, the primary issue of in vivo conversion appears

to be the lack of specificity in targetting the desired cells. Remarkably, several studies have evaluated reprogramming efficiency from NG2+ glia (Heinrich et al. 2014, p. 2; Torper et al. 2015; Pereira et al. 2017). However, NG+ glia contains heterogenous cells (astrocytes, oligodendrocytes, and oligodendrocyte precursor cells (OPCs)), which present a variety of somatic cell sources. As such, this results in the mistargeted reprogramming of non-astroglial cells, which leads to different reprogramming efficiencies. Moreover, the heterogeneity of OPCs during trauma further complicates reprogramming efficiencies. Specifically, OPCs rapidly proliferate and contribute to glial scar formation, and provide a new source of astrocytes and oligodendrocytes (Fernandez-Castaneda and Gaultier 2016). This brings into question whether another marker, aside from NG2+ can specifically target reactive astrocytes once they have begun to hyper-proliferate and contribute to glial scar formation.

Although clear benefits can be observed from studies using small molecule treatment (Ma et al. 2021), methods used to induce reprogramming via common TFs (Neurod1, Sox 2, Ascl1) needs further clarification in order to target and reprogram the appropriate cells. This was recently exemplified in a study evaluating the reprogramming effects of Neurod1. Using lineage tracing and a retrograde labelling method, Wang et al. determined that their once presumably reprogrammed astrocytes were actually Neurod1+ expressing endogenous neurons (Wang et al. 2020). Ultimately, this valuable study highlights the need for lineage tracing during in vivo reprogramming of astrocytes to confirm that the conversion of a cell population of interest, and not just overexpression of a particular TF, promotes a therapeutic effect.

Hepatocytes

Hepatocytes are a terminally differentiated cell type of the liver, derived from the endodermal lineage. Directly converted hepatocytes to neurons interestingly exhibit similar reprogramming efficiencies compared to fibroblasts, despite not being derived from the ectodermal developmental lineage. Hepatocytes are another common source of somatic tissue used for direct neural conversion and exhibit comparable differentiation efficiency compared to fibroblasts (Marro et al. 2011). The extent of neural conversion is also a potential issue when applying hepatocytes as a somatic cell source. Interestingly, however, incomplete differentiation of hepatocytes to neural cells may exhibit some utility. Functional neural tissue that exhibits some hepatocyte-like properties (i.e., albumin secretion) may suppress excessive excitotoxicity, a feature of early experimental spinal cord injury (Yildirim et al. 2018). This may peak interest in using hepatocytes as a cell source, as partial retention of function in converted neural cells from hepatocytes may exhibit a neuroprotective strategy. However, global transcriptomic changes following reprogramming are coupled with a loss of hepatocyte function, including albumin secretion and urea production (Marro et al. 2011). Thus, current evidence suggests typical reprogramming strategies are sufficient to restrict the function of hepatocytic

cell sources. The fact that cells that differ greatly from neural tissue can still be converted to the same extent is crucial because this suggests a variety of cell sources can be used for reprogramming. However, hepatocytes are not as easily accessible for exogenous reprogramming, nor do they reside within the CNS. As such, they are not a promising cell source for cell therapies within the CNS.

Pericytes

Pericytes represent an alternative resident cell type of interest within the central nervous system (CNS). In the context of injury states, they proliferate to mediate the intrusion of peripheral leukocytes, where they eventually migrate and contribute to vascularized sealing of the glial scar (Laredo et al. 2019). Moreover, experimentally attenuating their function can promote endogenous corticospinal tract regeneration across the site of injury (Dias et al. 2018). Thus, pericytes represent a potential cell source that can be reprogrammed in vivo following injury. However, the extent of direct pericyte reprogramming to a neural lineage is not commonly described. Pericytes can be reprogrammed into neuronal subtypes, as identified by cholinergic (Liang et al. 2018) and GABAergic (Karow et al. 2012) phenotypes. Although similar programming techniques suggest these cells enter a transient neural stem cell-like fate (Karow et al. 2018), their behavior in an injured transplant environment has yet to be described. Similar to the possible incomplete differentiation of fibroblast cells, their fibrotic/vascularization function in injury contexts may confound their use as an exogenous source of reprogrammed neurons. Moreover, if the extent of conversion is restricted to a neural progenitor-like fate, their differentiation in a transplant environment would likely be astrocytic.

Urine Epithelial Cells

Urine epithelial cells have been used as a cell source for reprogramming because they are a relatively abundant and easily accessible source of autologous tissue. For example, epithelial-like tissue from human urine can be converted to tripotent neural progenitors (Wang et al. 2013). Notably, these cells were synaptically active and expressed a variety of neuronal subtypes markers indicating the presence of GABAergic, glutamatergic, and dopaminergic neurons (Wang et al. 2013, p.; Zhang et al. 2015b). However, there is a heterogeneous population of three major epithelial cells present in urine: renal tubular, transitional, and squamous epithelium (Ringsrud 2001). It remains undescribed in these reprogramming methods whether one epithelial subtype may be more efficiently reprogrammed over another, or if a distinction was made to separate any of these cell types. Notably, incomplete differentiation and retention of epithelial-like characteristics of renal tubular cells could be particularly troubling, as they are prominent contributors to renal fibrosis and rapidly respond and aggravate this pathophysiological process (Qi and Yang 2018).

Generation of Distinct Neural Cell Subtypes

There are several neuronal subtypes present in various brain and spinal cord regions, which relay region-specific functions such as fine motor control, cognition and memory, and even respiration. Even glial function varies significantly between the compartments of the CNS. Thus, direct reprogramming protocols must begin to derive neurons, astrocytes, and oligodendrocytes that can replace distinct cell identities lost due to injury. The developmental origin of a cell is a crucial factor that dictates subtype specification during primary cell derivation (Mothe et al. 2011; Wuttke et al. 2018) and iPSC culturing protocols (Strano et al. 2020). Thus, variations in direct reprogramming methods *between* different somatic tissues (e.g., fibroblast, hepatocyte), as well as *within* a somatic cell type (brain-astrocyte vs. spinal-astrocyte) are likely required to produce the same terminal cell type of interest. Considerations for region-specific differences in these cell types will be discussed below.

Different Subtypes of Astrocytes

Notably, in both the developmental and adult stages, the spinal cord exhibits an enhanced expression of conventional astrocytic markers, such as GFAP and ALDH1L1, compared to whole-brain structures (Yoon et al. 2017). When directly comparing the ability to convert heterogeneous astrocytes derived from a rostral/caudal axis to a neural lineage, reprogramming efficiency was nearly 50% for cortex-derived astrocytes, but only 20% for spinal cord-derived astrocytes (Hu et al. 2019) (visualized in Fig. 3). However, converted astrocytes did not produce different proportions of neuronal subtypes (Hu et al. 2019). This suggests regionally distinct astrocytes are differentially competent to neural conversion but not neuronal subtype specification when using similar reprogramming protocols in vitro. In addition to discrepant reprogramming competency in the context of regional source, in vivo healthy and injury microenvironments present an additional layer of complexity. Notably, the TF *Sox2* can robustly convert various spatially derived astrocytes into induced neurons in vitro (Heinrich et al. 2014; Niu et al. 2015, p. 2), in various injury environments, and the healthy adult striatum (Niu et al. 2013), but cannot exhibit the same competency in the healthy cerebral cortex (Heinrich et al. 2014) (Fig. 4). This highlights critical differences in the intrinsic properties of cells during direct neuronal reprogramming. Future work should highlight the mechanistic variances in reprogramming efficiencies in various brain compartments and different segments of the spinal cord. For example, astrocytes may exhibit functional differences and conversion efficiencies when comparing between a cervical and lumbar-derived astrocyte. Such research can provide a

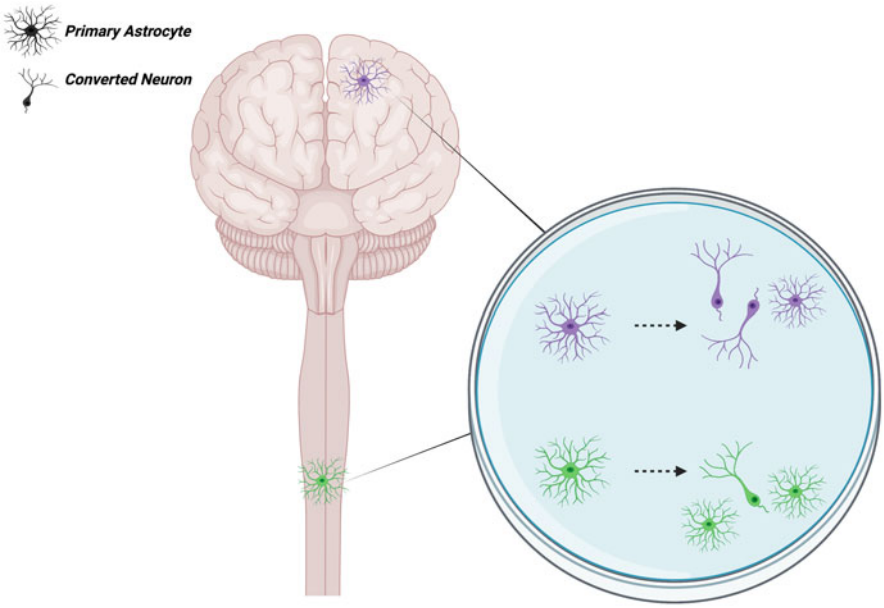

Fig. 3 Visual outline of in vitro reprogramming efficiency of astrocytes to neurons. Regional source of the primary astrocyte may affect reprogramming efficiency in vitro, while using similar reprogramming methods. Variation may include the efficiency or number of neurons produced from regionally distinct astrocyte cultures. Purple = brain-derived cells; green = spinal-derived cells

template for region-specific, directly reprogrammed cellular technologies towards region-specific degeneration/injuries in the CNS.

Different Subtypes of Oligodendrocytes

Regional characterization may be crucial for directly reprogrammed oligodendrocytes, as the brain and spinal cord contain a heterogeneous population of oligodendrocytes with varying functional properties. At a molecular level, there are discrepancies in the endocannabinoid receptor and ligand expression between oligodendrocytes from the brain and spinal cord, highlighting key differences in their migratory and myelination potential (Moreno-Luna et al. 2021). Functionally, spinal-derived oligodendrocytes can form longer myelin sheaths than cortical-derived oligodendrocytes, which mirrors internodal length in vivo (Bechler et al. 2015). Spinal-derived OPCs also exhibit opposite responses compared to forebrain-derived OPCs, in terms of proliferation capacity and response to excitotoxicity (Horiuchi et al. 2017). In response to demyelinating pathophysiology in vivo, the extent of remyelination is more significant in the forebrain

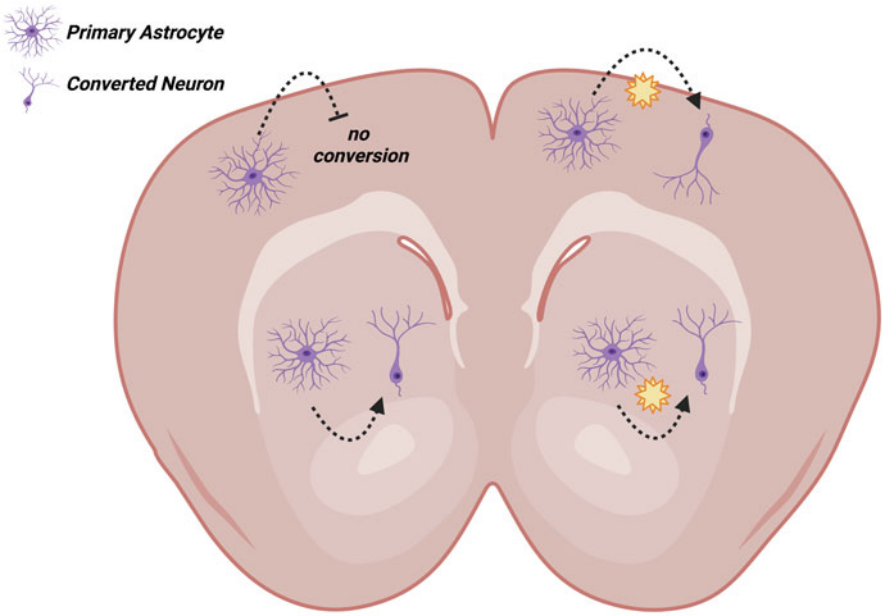

Fig. 4 Visual outline of in vivo reprogramming efficiency of astrocytes to neurons based on spatial region. Similar reprogramming methods in vivo may vary based on spatial region, as well as environmental context. Schematic highlights the necessity of specific-reprogramming paradigms for regional and context-dependent microenvironments (yellow/orange stars indicate injury/degeneration)

compared to the spinal cord (Bradl and Lassmann 2010). These critical functional differences highlight the necessity to derive directly reprogrammed NSCs, or even OPCs that exhibit similar functional properties, to the region they are attempting to restore.

Potential Pitfalls in Autologous Cell Transplantation

Autologous transplants can overcome several ethical and practical issues involving exogenous cell therapy, particularly the enhanced survival of cell grafts due to the reduced risk of host-rejection (Mandai et al. 2017; Song et al. 2020). However, a notable critique of exogenous cell therapy and the use of autologous transplants is the considerable time it takes to culture iPSCs. Once iPSCs have been aptly differentiated into pure NSCs, the therapeutic window in neural injury would have been long passed. Directly reprogrammed neural tissue is an exciting option to circumvent the timely iPSC culturing process. Yet, there are still translational barriers that must be investigated, particularly the age of cell donors.

Directly reprogramming somatic tissues from an older patient population to the neural lineage results in the maintenance of transcriptomic signatures that are age-dependent. These signatures translate to functional losses of cytoplasmic compartmentalization (Mertens et al. 2015) and DNA damage resulting from dysregulated heterochromatin and nuclear organization (Tang et al. 2017). Although these findings promote the use of directly reprogrammed cells for modelling and understanding the pathogenesis of late-onset diseases in culture (Rowe and Daley 2019), it presents several limitations to their use as a source of exogenous transplant therapies. Thus, an "older" autologous cell may retain these aging hallmarks upon direct reprogamming. Moreover, various neurological disorders have some extent of genetic etiology, such as Schizophrenia, Parkinson's disease, and Alzheimer's disease. These disorders, in particular, are often exacerbated with cellular senescence. In the rare case that a patient may be genetically predisposed to a neurological disorder, their genetic abnormalities may be translated into reprogrammed autologous cell grafts. Thus, neural cells prone to dysfunction and death could further confound the state of injury when applied as a transplant therapy. In theory, age and genetic predisposition may impair a directly reprogrammed cells' function. Still, the extent of dysfunction that an "older" reprogrammed cell may present when applied as a therapy requires further experimental investigation.

Treating CNS Disorders Using Transdifferentiated Neural Cells

Despite the advantages that direct reprogramming strategies present over other cellular methods, it is crucial to confirm that the cells contribute to meaningful therapeutic benefits in the context of disease. These cell therapies aim to address CNS pathologies by targeting a wide range of pathophysiological processes including inflammation, demyelination, neuronal disruption, and gliosis. Ultimately, their broad applications make them useful in a number of CNS disorders, which will be described in the following section and are summarized in Table 2.

Spinal Cord Injury

Spinal cord injury (SCI) involves a primary injury caused by mechanical trauma, which induces neural cell disruption, ionic imbalance, and vascular changes. As the injury progresses, the secondary injury ensues, further contributing to neuronal death, demyelination, ionic imbalance, excitotoxicity, and the formation of a glial scar in the chronic phases of SCI (Alizadeh et al. 2019). Various cell sources have been used for the derivation of neural cells that can be transplanted to target SCI. Human adipose-derived stem cells have been successfully directly reprogrammed into neuron/motor neuron-like cells via small molecule treatment with retinoic acid (RA), sonic hedgehog (Shh), and neurotrophic factors. Upon transplantation into injured mice, these cells synaptically integrated and facilitated motor improvements.

Table 2 Summary of direct reprogramming strategies that have been investigated in the context of CNS injuries and disorders

Spinal cord injury			
Source	**Method**	**Final cell type**	**Functional outcome**
Human adipose-derived stem cells (Gao et al. 2019)	• In vitro reprogramming • Small molecule treatment with RA, Shh, and neurotrophic factors	Neuron/motor neuron-like cells	• Motor improvements
Rat mesenchymal stem cells(Qiu et al. 2015)	• In vitro reprogramming • Adenoviral transfection with NT-3 and Trk-C	Neural-like cells and myelin-forming cells	• Motor improvements
Human bone marrow somatic cells (Nagoshi et al. 2018)	• In vitro reprogramming • Transfection with Msi1, Ngn2, and MBD2 • Small molecule treatment with RA, Shh, PDGF, and thyroxine	Oligodendrogenically biased neural progenitor cells	• Motor improvements
Endogenous astrocytes (Su et al. 2014)	• In vivo reprogramming • Lentiviral transfection with SOX2 under the GFAP promoter	Neurons	• Behavioral outcomes were not assessed
Traumatic brain injury			
Source	**Method**	**Final cell type**	**Functional outcome**
Endogenous glia (astroglial conversion was not observed) (Heinrich et al. 2014)	• In vivo reprogramming • Retroviral transfection with Ascl1 and Sox2	Neurons	• Behavioral outcomes were not assessed
Endogenous glia (Guo et al. 2014)	• In vivo reprogramming • Retroviral transfection with NeuroD1 under the GFAP promoter	Neurons	• Behavioral outcomes were not assessed
Ischemic stroke			
Source	**Method**	**Final cell type**	**Functional outcome**
Human bone marrow somatic cells (Vonderwalde et al. 2020)	• In vitro reprogramming • Transfection with Msi1, Ngn2, and MBD2	Neural progenitor cells	• Sensorimotor improvements
Endogenous astrocytes (Chen et al. 2020)	• In vivo reprogramming • Adenoviral transfection with NeuroD1 under the GFAP promoter	Neurons	• Motor and cognitive improvements
Multiple sclerosis			
Source	**Method**	**Final cell type**	**Functional outcome**
Human bone marrow somatic cells, fibroblasts, and keratinocytes (Ahlfors et al. 2019)	• In vitro reprogramming • Transfection with Msi1, Ngn2, and MBD2	Neural progenitor cells	• Behavioral outcomes were not assessed

(continued)

Table 2 (continued)

Spinal cord injury			
Mouse embryonic fibroblasts (Sullivan et al. 2020)	• In vitro reprogramming • Lentiviral transfection with Klf4, Sox2, c-Myc, and Oct4	Neural stem cells	• Motor improvements
Human bone marrow-derived mesenchymal stem cells (Ben-Zwi et al. 2019)	• Small molecule treatment using a patented method	Neuralized mesenchymal stem cells and neurons	• Motor improvements
Endogenous mouse astrocytes (Ghasemi-Kasman et al. 2018)	• In vivo reprogramming • Lentiviral transfection with miR-302/367 • Small molecule treatment with valproate	Oligodendrocyte progenitor cells and oligodendrocytes	• Cognitive improvements
Parkinson's disease			
Source	**Method**	**Final cell type**	**Functional outcome**
Human spermatogonial stem cells (Yang et al. 2019)	• In vitro reprogramming • Small molecule treatment with a series of factors	Dopaminergic neurons	• Motor improvements
Fetal liver mesenchymal stromal-like cells (Kumar et al. 2016)	• In vitro reprogramming • Small molecule treatment with B27, vitamin c, FGF2, Shh, FGF8, TGFβ3, BDNF, and GDNF	Dopaminergic neuron-like cells	• Motor improvements
Mouse embryonic fibroblasts (Dell'Anno et al. 2014)	• In vitro reprogramming • Lentiviral transfection with Ascl1, Nurr1, and Lmx1a	Dopaminergic neurons	• Motor improvements
Mouse Sertoli cells (Wu et al. 2015)	• In vitro reprogramming • Retroviral transfection with Ascl1, Ngn2, Hes1, Id1, Pax6, Brn2, Sox2, c-Myc, and Klf4 followed by lentiviral transfection with Lmx1a	Dopaminergic neurons	• Motor improvements
Endogenous mouse astrocytes (Rivetti di Val Cervo et al. 2017)	• In vivo reprogramming • Lentiviral transfection with NeuroD1, Ascl1, Lmx1a, and miR218 under the GFAP promoter	Dopaminergic neurons	• Motor improvements
Alzheimer's disease			
Source	**Method**	**Final cell type**	**Functional outcome**
Endogenous mouse astrocytes (Guo et al. 2014)	• In vivo reprogramming • Retroviral transfection with NeuroD1 under the GFAP promoter	Neurons	• Behavioral outcomes were not assessed

Additionally, the cells also reduced the inflammatory response, as indicated by increased levels of anti-inflammatory markers (Gao et al. 2019). Comparably, mesenchymal stem cells have also been used as a source of neural-like cells through genetic modification with NT-3 and TrkC. After transplantation, these cells acquired a myelin-forming phenotype and improved cortical motor evoked potential and hind-limb locomotion (Qiu et al. 2015). Moreover, human bone marrow somatic cells have been used for the generation of neural progenitor cells, which were further biased into an oligodendrogenic fate. Briefly, the somatic cells were transiently transfected with Musashi-1 (Msi1), Neurogenin-2 (Ngn2), and methyl-CpG-binding domain protein 2 (MBD2), and subsequently treated with RA, SHH agonist, PDGF, and thyroxine in vitro. When transplanted, these cells contributed to remyelination and axonal sparing, which correlated to improved motor function (Nagoshi et al. 2018). As such, in vitro reprogramming methods and subsequent cell transplantation have proven to be a promising therapeutic strategy for SCI. However, the integration of these cells is often limited due to the glial scar that forms surrounding the lesion. As such, since SCI is followed by reactive astrogliosis, a potentially useful application of direct reprogramming techniques is for endogenous cells to be used as a source to generate novel neurons, thereby indirectly reducing the number of scar-forming reactive astrocytes that surround the lesion. In this regard, in vivo reprogramming is limited in SCI; however, SOX2-mediated conversion of astrocytes to neurons has been reported. This was achieved by delivering a lentivirus that expressed SOX2 under the astrocyte GFAP promoter immediately after a hemisection injury. Notably, the infected cells began expressing neuronal markers, TUBB3 and MAP2, by 4 and 5 weeks post-injury, respectively. The infected cells also co-stained for the synapse marker, synapsin-1, suggesting that they could form synapses. Although no functional outcomes were tested in this paper, neuronal differentiation and synapse formation suggest circuit-specific functions can be recovered. Thus, future studies investigating the causal effects of vivo conversion of resident astroglial on functional recovery are warranted (Su et al. 2014).

Traumatic Brain Injury

Traumatic brain injury (TBI) is followed by a series of maladaptive processes, including immune cell infiltration, inflammation, excitotoxicity, vascular disruption, neuronal death, myelin disruption, and reactive gliosis (McGinn and Povlishock 2016). Animal models of TBI have demonstrated that the targeted delivery of pro-neuronal genes to endogenous glial cells facilitates their conversion into neurons. In one study, a retrovirus containing Ascl1, or a combination of Ascl1 and Sox2, was delivered following a stab wound injury in the upper layers of the cerebral cortex in mice. These constructs facilitated the reprogramming of NG2+ glia along the neuronal lineage, as marked by the immature neuron marker, doublecortin (DCX). Over time, these cells matured into NeuN+ neurons. Most importantly, electrophysiological techniques demonstrated that these cells were forming synapses with the surrounding cells, demonstrating that in vivo direct reprogramming

methods can generate functional neurons (Heinrich et al. 2014). However, it is important to acknowledge that the retroviral delivery method targets dividing cells, which involve astroglial and oligodendroglial cells. Yet, gliosis can be an adaptive process through the generation of novel oligodendrocytes, which can contribute to remyelination. Therefore, the reprogramming of these oligodendroglial cells may be counterproductive in that it may impede subsequent endogenous remyelination efforts by reducing the numbers of myelinating oligodendrocytes. Instead, it may be more helpful and prudent to focus on reprogramming the maladaptive astroglial cells that surround the injury site and limit regeneration.

Nonetheless, evidence demonstrating that astrocytes can be reprogrammed into neurons in the context of TBI has also been reported. In this study, a retrovirus delivery method was used to deliver NeuroD1, a basic helix loop helix TF involved in neurogenesis, into the mouse somatosensory cortex following a stab wound injury. This report demonstrated the conversion of the resident glial GFAP+ and NG2+ cells into novel DCX+ and NeuN+ neurons. Importantly, it was found that astrocytes were the source of newly generated glutamatergic neurons, which were electrophysiologically active (Guo et al. 2014). Therefore, the novel population of dividing glial cells provides a cell source that can be converted into functional neurons. However, future studies should aim to determine the behavioral changes that are associated with these strategies.

Ischemic Stroke

Ischemic stroke occurs when blood flow to the brain is impaired, thus reducing oxygen supply at the site of injury. Like TBI and SCI, this process is followed by several pathophysiological processes including excitotoxicity, inflammation, oxidative stress, and gliosis, all of which contribute to neuronal death and circuit disruption (Kuriakose and Xiao 2020). Therefore, the generation of new neurons is a plausible method by which novel circuitry can be established. Notably, transplantation of directly reprogrammed cells has shown promise in a endothelin-1 mouse model of focal ischemic stroke. Before transplantation, human bone marrow cells were converted into directly reprogrammed neural progenitor cells (drNPCs) by introducing Msi1, Ngn2, and MBD2. Four days after injury, reprogrammed drNPCs were transplanted into the lesion site. Importantly, behavioral tests, including both the foot fault task (assesses sensory and motor function) and the cylinder test (assesses locomotor function), revealed that drNPC transplantation was associated with improved functional outcomes. The authors hypothesized that this recovery was mediated through synaptic plasticity, as immunostaining revealed that drNPC transplantation was associated with an increase in synaptophysin expression (Vonderwalde et al. 2020). In addition, in vivo direct reprogramming has been investigated in the context of ischemic stroke. In this report, an adeno-associated viral construct carrying the pro-neurogenic gene NeuroD1 under the GFAP promoter was injected into the lesion site 10 days following ET-1-induced ischemia. This method facilitated the conversion of reactive astrocytes to electrophysiologically

functional neurons. Importantly, this astrocyte-to-neuron conversion was associated with improvements in motor deficits as assessed using food pellet retrieval, grid walk, and cylinder tests. Cognitive improvements were also observed in these animals, marked by improved fear conditioning memory (Chen et al. 2020). Overall, these preliminary reports demonstrate that directly reprogrammed cells can contribute to meaningful functional benefits following ischemic stroke.

Multiple Sclerosis

Multiple sclerosis (MS) is a neurodegenerative condition in which the immune system targets myelin for degradation. This results in axonal damage to the demyelinated neurons (Faissner et al. 2019). Several reports have described the transplantation of transdifferentiated cells into MS animal models to replenish the lost neurons and myelinating oligodendrocytes. Notably, bone-marrow cells, human fibroblasts and keratinocytes have been used for drNPC reprogramming by using Msi1, Ngn2, and MBD2. Upon transplantation into shiverer mice, which lack compact myelin, drNPCs have been shown to differentiate into oligodendrocytes (Ahlfors et al. 2019). Nonetheless, further analysis of these cells should assess functional improvements. In this regard, several other reports have assessed functional outcomes in MS animal models. For example, mouse embryonic fibroblasts were converted to induced NSCs through the continuous expression of Klf4, Sox2, and c-Myc, combined with the early temporal expression of Oct4. Upon transplantation into the corpus callosum of mice treated with cuprizone (CPZ), an agent that induces demyelination, these cells were associated with motor improvements as demonstrated using running misstep wheels. Moreover, there was an increase in oligodendrogenesis, showing that this is a plausible strategy for oligodendrocyte replacement (Sullivan et al. 2020). While these cell transplantation methods aim to address the neural deficits seen in MS, they have minimal affect on inflammatory-associated pathology. Notably, Ben-Zwi et al. generated neuralized MSCs, which were uniquely suited to address the neural deficits in conjunction with the inflammatory response. These cells contributed to myelin and neuronal sparing, as well as reduced inflammation following transplantation into mice with experimental autoimmune encephalomyelitis – a model of MS – in comparison to non-neuralized control MSCs. More importantly, the neuralized MSCs promoted motor function (Ben-Zwi et al. 2019). As such, transplantation of directly reprogrammed cells has been shown to contribute to functional benefits in MS. In vivo reprogramming has also been shown to promote recovery in the context of MS. Specifically; miR-302/367 and valproate treatment has been shown to convert endogenous astrocytes to OPCs and oligodendrocytes in CPZ-treated mice. Behavioral testing revealed that this in vivo conversion correlated with improvements in cognitive function (Ghasemi-Kasman et al. 2018). Overall, the evidence shows that both in vitro and in vivo cell reprogramming techniques can help generate new cells capable of promoting behavioral and cognitive benefits in MS.

Parkinson's Disease

Parkinson's disease (PD) is a neurodegenerative disorder marked by an accumulation of Lewy bodies, comprised of α-synuclein, which contributes to the progressive loss of dopaminergic neurons in the substantia nigra (Simon et al. 2020). Several reports have directly converted non-neuronal cells into dopaminergic neurons for transplantation into PD models. One paper reported the conversion of human spermatogonial stem cells into dopaminergic neurons by small molecule treatment in vitro. When transplanted into the MPTP PD model in mice, these cells contributed to synapse formation, electrophysiological activity, and most importantly, they facilitated improvements in gait (Yang et al. 2019). In another report, fetal liver mesenchymal stromal-like cells were converted into dopaminergic neurons through chemical treatment with neurotrophic factors. Upon transplantation into the 6-hydroxydopamine (6-OHDA)-lesioned striatum, these cells contributed to enhanced behavior compared to non-converted MSC control cells in mice 2 months post-transplantation (Kumar et al. 2016).

Moreover, mouse embryonic fibroblasts have also been used as a source of cells for conversion into dopaminergic neurons. These cells were also capable of contributing to electrical activity, synaptic activity, and ultimately promoted functions in a PD model (Dell'Anno et al. 2014). Another report converted Sertoli cells into induced NSCs (iNSCs) and further biased them toward the dopaminergic neuron lineage through the forced expression of Lmx1a. These biased cells exhibited increased motor recovery upon transplantation into mouse PD models (Wu et al. 2015). This shows that a plethora of studies that aim to generate functional dopaminergic neurons for transplantation into PD exist. However, in vivo neuronal conversion is less described in the context of PD. In a single paper, the combination of three TFs, NeuroD1, Ascl1, and Lmx1a, as well as the microRNA miR218, was used to target endogenous mouse astrocytes into dopaminergic neurons. Importantly, this astrocyte-to-neuron conversion was associated with an improvement in gait (Rivetti di Val Cervo et al. 2017). Ultimately, directly reprogrammed dopaminergic neurons show promise in ameliorating PD.

Alzheimer's Disease

Alzheimer's disease is characterized by an accumulation of amyloid-β plaques and neurofibrillary tangles, which contribute to neurodegeneration. Moreover, it involves the death of cholinergic neurons in the forebrain (Hampel et al. 2018). As such, neuronal replacement is thought to be one method that could promote the regeneration of this condition. A single paper has utilized direct conversion techniques in this disease, whereby a retroviral construct expressing NeuroD1 under the GFAP promoter was used to infect astrocytes in vivo in an experimental transgenic mouse model of AD. This facilitated the conversion of astrocytes into NeuN+ neurons, which formed glutamatergic synapses. Notably, the cells were electrophysiologically active. However, further analysis of the potential

therapeutic benefits is warranted to determine whether in vivo reprogramming can drive cognitive benefits (Guo et al. 2014).

Moreover, it is important to acknowledge that cholinergic cells are implicated in processes such as memory and learning (Hampel et al. 2018). Therefore, optimal cognitive recovery will likely rely on the replacement of this particular subtype of neurons. As such, future research should focus on the cholinergic specification of reprogrammed neurons.

Conclusions

Cell replacement is an important therapeutic strategy in a variety of CNS disorders. This can be facilitated through direct reprogramming technologies, which generate neural cells both in vitro and in vivo. Direct reprogramming of somatic cells into the desired cells without the intermediate pluripotent state remains a less explored strategy but would be a major step toward the generation of cells without tumorigenic potential (Ahmed et al. 2012). To date, several reprogramming strategies have been described, including the use of TFs, microRNAs, and the TF-free use of small molecules for direct reprogramming (Ullah et al. 2021). Nonetheless, several questions remain surrounding the ideal cell source and resulting cell identity (Heng et al. 2005). Future investigations will be needed to optimize these reprogramming techniques.

Abstract

Due to their multilineage differentiation capability and their potent immunosuppressive and proangiogenic characteristics, mesenchymal stem cells (MSCs) have been considered as new therapeutic agents for the treatment of inflammatory and degenerative diseases of the central nervous system. In vitro, MSCs may differentiate into neuron-like cells. In vivo, MSCs, in a juxtacrine and paracrine manner, suppress detrimental immune responses in the brain and spinal cord, attenuate

neuroinflammation, and promote the repair and regeneration of injured neural tissue. MSCs produce a large number of trophic and growth factors, induce neovascularization, and prevent apoptotic loss of injured neural cells. Alzheimer's disease (AD) is a neurodegenerative disease that is incurable and characterized by progressive cognitive dysfunction and memory loss. Since the incidence of AD has been continuously increasing in the past decade, new therapeutic agents for the treatment of AD are urgently needed. Several recently published experimental studies revealed that MSCs, through the delivery of neuroprotective and immunomodulatory microRNAs (miRNA), neural growth factors, and anti-inflammatory cytokines, significantly reduced neuronal loss, increased neurogenesis and synaptogenesis, and efficiently improved cognitive impairment. In this chapter, we summarized current knowledge about molecular and cellular mechanisms that were responsible for the MSC-based improvement of cognitive function in experimental animals, and we emphasized issues that should be addressed before MSCs and their secretome could be offered as a new human remedy for the treatment of AD.

Keywords

Alzheimer's disease · Cognitive impairment · Mesenchymal stem cells · Therapy

Abbreviations

AD	Alzheimer's disease
AF	Amniotic fluid
AF-MSCs	Amniotic-fluid-derived mesenchymal stem cells
ALS	Amyotrophic lateral sclerosis
ASDs	Autism spectrum disorders
AT	Adipose tissue
BACE1	β-site amyloid precursor protein cleaving enzyme 1
BDGF	Brain-derived growth factor
bFGF	Basic fibroblast growth factor
BM	Bone marrow
BM-MSCs	Bone-marrow-derived MSCs
CB	Cord blood
CD	Cluster of differentiation
CDNF	Cerebral dopamine neurotrophic factor
CTLs	Cytotoxic CD8 + T cells
CXCR4	Chemokine receptor
DCs	Dendritic cells
d-MAPPS	Derived Multiple Allogeneic Proteins Paracrine Signaling
DP	Dental pulp
EGF	Epidermal growth factor
FGF-21	Fibroblast growth factor 21
HD	Huntington's disease
HGF	Hepatocyte growth factor
HO-1	Hemeoxygenase-1
IDO	MSC-derived indolamine 2,3-dioxygenase

IFN-γ	Interferon gamma
IL	Interleukin
iNOS	Inducible nitric oxide synthase
IRAK1	Interleukin-1-receptor-associated kinase
ISCT	International Society for Cellular Therapy
MCP	Monocyte chemotactic protein-1
MHC	Major histocompatibility complex
miRNA	MicroRNA
MSC-Exos	Mesenchymal-stem cell-derived exosomes
MSCs	Mesenchymal stem cells
MWM	Morris water maze
NeuN	Neuronal nuclear protein
NK	Natural killer
NKT	Natural killer T
NO	Nitric oxide
NOR	Novel object recognition
NSC	Neural stem cell
PD	Parkinson's disease
PDGF	Platelet-derived growth factor
PFC	Prefrontal cortex
PGE2	Prostaglandin E2
PGF	Placental growth factor
PL	Placenta
PL-MSCs	Placenta-derived MSCs
RORγT	Retinoic-acid-receptor-related orphan receptor gamma T
RVG	Neurotropic rabies virus glycoprotein
S1K	Sphingosine kinase
S1P	Sphingosine-1-phosphate
SSEA-3	Stage-specific embryonic antigen 3
SSEA-4	Stage-specific embryonic antigen 4
STAT	Signal transducer and activator of transcription
T-bet	T-box protein expressed in T cells
TGF-β	Transforming growth factor beta
TNF-α	Tumor necrosis factor alpha
TRAF6	TNF-receptor-associated factor 6
UC	Umbilical cord
UC-MSCs	Umbilical-cord-derived mesenchymal stem cells
VEGF	Vascular endothelial growth factor

Introduction

Neurocognitive disorders belong to the group of organic brain syndrome caused by neurodegenerative processes, which lead to impaired cognitive functioning, memory problems, difficulties in the perception of language, and various behavioral changes (He et al. 2021). Neurodegenerative processes also lead to neuronal deterioration and

gradual loss of cognitive and neurological functions (Lilamand et al. 2020). The type of disorder and its cause determine, in the first place, which age group will be affected. Diseases like Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD) usually affect the elderly population. However, drug and alcohol abuse can cause these processes in the younger population as well (Luck et al. 2017). Vitamin deficiency, meningitis, encephalitis, and traumatic brain injuries cause neurocognitive dysfunction independent of age. Cardiovascular problems, diabetes, alcohol, and drug abuse significantly increase the possibility of neurological dysfunction and are, therefore, considered risk factors for neurocognitive diseases (Khan et al. 2021).

Cognitive and behavioral dysfunctions, manifested by difficulties in thinking, remembering, and reasoning, are all symptoms of neurocognitive organic syndromes, which develop as a consequence of gradual neuronal loss and degeneration (He et al. 2021). Additionally, all neurocognitive disorders may be accompanied by other symptoms, such as anxiety, headaches, vision loss, attention problems, and difficulties in performing routine tasks. The long-term prognosis of neurocognitive diseases remains challenging and uncertain since a definite cure for these conditions does not exist and the symptoms tend to aggravate and worsen over time (He et al. 2021).

Neurodegeneration and neuroinflammation are the leading causes of neurocognitive dysfunction (Subramaniyan and Terrando 2019; Süβ et al. 2021; Hook et al. 2020). Progressive atrophy accompanied by the loss of neural cell function is observed in specified regions of the brains of patients suffering from neurodegenerative diseases (amyotrophic lateral sclerosis (ALS), PD, AD, HD, prion diseases) (Hook et al. 2020). Metabolic dysfunction and alteration in cell-death-related signaling pathways in neural cells is the main reason for global developmental delay, expressive language delay, and intellectual disability in early childhood (Hook et al. 2020). Later on, in adolescence or early adulthood, due to progressive neurological regression, these patients continue to deteriorate with worsening neurological symptoms and a significant cognitive function decline (Hook et al. 2020). Bradykinesia, rigidity, loss of expressive language skills, epilepsy, and dysfunctional sleep are frequently part of the clinical picture observed in patients suffering from neurodegenerative diseases, affecting their quality of life and functionality (Subramaniyan and Terrando 2019; Süβ et al. 2021; Hook et al. 2020).

In addition to neurodegeneration, chronic inflammation is the hallmark of neurocognitive diseases (Walker 2019) and is considered the main reason for the progressive and irreversible loss of neural cells (Süβ et al. 2021). Responding to microbial infections, innate immune cells (macrophages, dendritic cells (DCs), natural killer (NK) and natural killer T (NKT) cells) generate a variety of pro-inflammatory cytokines and chemokines that increase the permeability of the blood-brain barrier (Subramaniyan and Terrando 2019). Increased production of proinflammatory cytokines (interleukin (IL)-1β, IL-6, tumor necrosis factor alpha (TNF-α)) and chemokines induce enhanced expression of E and P selectins on endothelial cells, enabling the recruitment of circulating leukocytes in the inflamed brain region (Subramaniyan and Terrando 2019; Süβ et al. 2021). Recruited DCs and

macrophages capture and phagocyte microbes degrade microbial antigens and form small polypeptide fragments, which are, within major histocompatibility complex (MHC) molecules, presented to the naïve or effector T cells, respectively (Subramaniyan and Terrando 2019). Th1 and Th17 cell-driven immune responses are mainly responsible for the development of inflammation-induced loss of neural cells (Holley and Kielian 2012). Activated, proinflammatory DCs deliver microbial antigens to the regional lymph nodes and activate antigen-specific naïve CD4+ and CD8 + T cells, resulting in the generation of T-cell-dependent cellular immune response (Subramaniyan and Terrando 2019; Süβ et al. 2021). Driven by DC-derived cytokines, naïve CD4 + T cells differentiate into effector, inflammatory CD4 + Th1, and Th17 helper cells (Süβ et al. 2021). DC-derived IL-12 and NK cell-sourced interferon gamma (IFN-γ) activate T-box protein expressed in T cells (T-bet) and signal transducer and activator of transcription (STAT)-4 transcriptional factors in naïve T cells, resulting in the generation of CD4+ and CD8+ Th1 lymphocytes (Stojić-Vukanić et al. 2020). DC-sourced IL-1β, IL-6, IL-23, and TGF-β induce the generation and expansion of Th17 CD4+ and CD8+ T lymphocytes through the activation of retinoic-acid-receptor-related orphan receptor gamma T (RORγT) and STAT-3 transcriptional factors in naïve T cells (Süβ et al. 2021; Hook et al. 2020; Stojić-Vukanić et al. 2020).

Within the inflamed tissue, CD4 + Th1 and Th17 cells activate phagocytes and enhance their proinflammatory properties (Harry 2021). CD4 + Th1 cell-sourced IFN-γ activates inflammatory M1 macrophages and M1 microglia, while CD4 + Th17 cells produce IL-17 and IL-22, which activate inflammatory N1 neutrophils to produce reactive oxygen species and inflammatory cytokines (TNF-α, IL-1β), crucially contributing to the aggravation of ongoing inflammation (Süβ et al. 2021; Hook et al. 2020; Stojić-Vukanić et al. 2020).

In addition to innate immune cells, effector CD4 + Th1 and Th17 cells orchestrate antigen-specific antimicrobial immune responses as well (Stojić-Vukanić et al. 2020). Antigen-presenting DCs activate naïve CD8 + T cells, which proliferate and differentiate into effector, cytotoxic CD8 + T cells (CTLs) under the influence of CD4 + Th cell-derived IL-2 (Sallusto and Lanzavecchia 2002). At the same time, cross-talk between effector CD4 + Th cells and B cells is crucially important for optimal humoral immune response (Subramaniyan and Terrando 2019; Süβ et al. 2021). IFN-γ, derived from CD4 + Th1 cells, induces Immunoglobulin (Ig) M and IgG antibody class switching and promotes synthesis and the production of antigen-specific IgG antibodies, which in turn regulate the antibody-dependent activation of macrophages, microglia, NK cells, and complement systems (Hook et al. 2020; Stojić-Vukanić et al. 2020; Harry 2021). This "inflammatory loop" and cooperation between innate and acquired immunity crucially contribute to the efficient elimination of foreign pathogens in the central nervous system (Harry 2021). However, the uncontrolled activation of immune cells may result in the development of chronic inflammation in the brain, which leads to the irreversible injury of neural cells (Süβ et al. 2021; Hook et al. 2020; Stojić-Vukanić et al. 2020; Harry 2021).

In order to prevent excessive tissue injury, immunosuppressive immune cells (alternatively activated macrophages, tolerogenic DCs, and regulatory Treg cells)

produce neurotrophins and anti-inflammatory cytokines (IL-10, IL-35, and transforming growth factor beta (TGF-β)), which attenuate ongoing inflammation; provide neuroprotection; stimulate axonal regeneration; and maintain homeostasis in the central nervous system (Subramaniyan and Terrando 2019). Since a weakened immune response is incapable of eliminating pathogenic microorganisms while an excessive immune response aggravates neuroinflammation and neurodegeneration, a balance between proinflammatory and anti-inflammatory immune cells has to be achieved for the optimal treatment of neurocognitive disorders (Kim et al. 2019). The most effective anti-inflammatory and neuroprotective therapeutic agents should prevent progressive loss of neural cells, induce axonal regeneration, stimulate an antimicrobial immune response, and promote the generation and expansion of immunosuppressive cells in the central nervous system (He et al. 2021). Correspondingly, therapeutic agents, which are able to suppress a harmful immune response and simultaneously provide trophic support to injured neurons, could be considered new remedies for the treatment of neurocognitive diseases (He et al. 2021).

Results obtained in recently conducted experimental and clinical studies demonstrated the therapeutic potential of mesenchymal stem cells (MSCs) in the treatment of neurodegenerative, neuroinflammatory, and neurocognitive diseases (Castorina et al. 2015; Harrell et al. 2021b; Andrzejewska et al. 2021). In this chapter, we emphasized current knowledge about molecular and cellular mechanisms, which are responsible for the beneficial effects of MSCs in the therapy of neurocognitive disorders.

MSCs and Their Exosomes as New Therapeutic Agents in Regenerative Neurology and Neuroimmunology

MSCs are adult stem cells which promote tissue repair and regeneration of postnatal tissues (Shariati et al. 2020). MSCs could be derived from many adult as well as fetus-associated tissues, including bone marrow (BM), adipose tissue (AT), umbilical cord (UC), cord blood (CB), amniotic fluid (AF), dental pulp (DP), placenta, synovia, and peripheral blood (Pittenger et al. 2019; Gazdic et al. 2015).

MSCs are fibroblastic, rapidly proliferating, self-renewable, spindle-shaped, plastic adherent cells, which grow well in vitro (Gazdic et al. 2015). The absence of an MSC-specific marker enforced the International Society for Cellular Therapy (ISCT) to establish the basic criteria for phenotypic characterization of MSCs, which should be positive (≥95%) for at least three markers among CD29, CD44, CD73, CD90, and CD105 and negative for CD14 (expressed on monocytes), CD34 (expressed on hematopoietic cells), CD45 (pan-leukocyte marker), and CD79a and CD19 (markers of B lymphocytes) (Dominici et al. 2006). Importantly, MSCs do not express MHC class II proteins and costimulatory molecules, CD80 (B7–1), CD86 (B7–2), and CD40, suggesting their low immunogenicity and possibility for allogeneic transplantation in MHC-mismatched recipients (Gazdic et al. 2015; Volarevic et al. 2011).

One of the determining properties of MSCs is their capacity for spontaneous differentiation into osteocytes, chondrocytes, and adipocytes (Shariati et al. 2020). MSCs adopt different functional properties depending on their tissue source (Volarevic et al. 2011). Bone-marrow-derived MSCs have also been combined with neural stem cells to enhance their benefits for the treatment of spinal cord injury in an experimental animal model (Hosseini et al. 2018). AF-derived MSCs (AF-MSCs) exhibited a greater capacity for cell proliferation and self-renewal than BM-derived MSCs (BM-MSCs) (Harrell et al. 2018). AF-MSCs and PL-derived MSCs (PL-MSCs)) display *intracellular* and *extracellular markers* of pluripotent stem cells, such as octamer binding protein 3/4 (Oct-3/4), homeobox transcription factor Nanog, c-MYC, tumor-related antigen (TRA)-1–60, stage-specific embryonic antigen (SSEA)-3, and SSEA-4, and were capable of multilineage differentiation (Harrell et al. 2018). Several lines of evidence demonstrated that AF-MSCs and PL-MSCs might differentiate into functional neurons in vitro (Harrell et al. 2018). In comparison with BM-MSCs, AF-MSCs and PL-MSCs have a higher capacity for neural differentiation, more rapidly generate neurospheres, show higher expression of neural stemness markers (nestin, vimentin, Musashi), and produce a significantly higher amount of brain-derived growth factor (BDGF) and nerve growth factor (NGF), which enhance axonal regeneration (Harrell et al. 2018). Additionally, AF-MSCs and PL-MSCs may be a valuable cellular source of neural stem cells (NSCs) (Harrell et al. 2018).

NSCs derived from AF-MSCs showed better neuroregenerative properties than NSCs, which were differentiated from BM-MSCs (Harrell et al. 2018). Upon cultivation in a neuronal differentiation medium, AF-MSC-sourced NSCs generate more functional neurons than NSCs derived from BM-MSCs. Importantly, AF-MSCs and AF-MSC-derived NSCs maintained a normal karyotype in long-term cultures and were not tumorigenic in vivo after transplantation in immunodeficient mice and, accordingly, could be used in clinical settings (Harrell et al. 2018). AF-MSC-based biological product "derived Multiple Allogeneic Proteins Paracrine Signaling" (d-MAPPS) restored meibomian gland structure and function, improved tear stability, induced the regeneration of epithelial cells, and enhanced the repair of the ocular surface epithelial barrier in patients suffering from dry eye disease, meibomian gland dysfunction, and epithelial basement membrane dystrophy with recurrent corneal erosion syndrome (Harrell et al. 2018).

In addition to their potential for multilineage differentiation, MSCs are immunoregulatory cells that may inhibit activated immune cells, attenuate ongoing neuroinflammation, and create an immunosuppressive microenvironment, enabling the efficient repair and regeneration of injured and inflamed neural tissue (Shariati et al. 2020). MSCs, in a juxtacrine (cell-to-cell-contact-dependent manner) or paracrine manner (through the secretion of soluble and insoluble immunomodulatory factors), regulate the phenotype and function of all immune cells. This also includes the cells that play a crucially important pathogenic role in the development and progression of neurocognitive diseases (Harrell et al. 2021b; Andrzejewska et al. 2021; Shariati et al. 2020). MSC-sourced TGF-β, hepatic growth factor (HGF), and nitric oxide (NO) inhibit the proliferation and activation of T lymphocytes, NK cells,

and NKT cells. At the same time, MSC-derived indolamine 2,3-dioxygenase (IDO) promotes the generation and expansion of immunosuppressive CD4 + FoxP3 + Tregs by inducing the transdifferentiation of inflammatory Th17 cells in Tregs (Volarevic et al. 2017). By producing hemeoxygenase-1 (HO-1), prostaglandin E2 (PGE2), and anti-inflammatory cytokines (IL-10, IL-35, and IL-1 receptor antagonist (IL-1Ra)), MSCs generate a tolerogenic phenotype in DCs and induce the alternative activation of macrophages (Harrell et al. 2019a). Tolerogenic DCs inter-react with naïve T cells and promote their differentiation toward Tregs, while alternatively activated macrophages produce immunosuppressive cytokines, which create an anti-inflammatory environment and inhibit ongoing inflammation in neural tissue (Harrell et al. 2019b).

As part of their paracrine activity, MSCs produce various proangiogenic factors (basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), angiopoietin-1, placental growth factor (PGF), IL-6, monocyte chemotactic protein-1 (MCP-1), epidermal growth factor (EGF), HGF, and vascular endothelial growth factor (VEGF)), which induce neovascularization and provide trophic support to injured neurons (Volarevic et al. 2017; Haider and Aslam 2018).

Animal studies showed that MSCs may engraft in injured neural tissue and produce various bioactive factors suppressing the detrimental immune response and promoting neural regeneration and repopulation (Lv et al. 2021; Schweizer et al. 2020; Cooney et al. 2016). Importantly, the transplantation of allogeneic MSCs evoked little or no immune reactivity in MHC-mismatched recipient animals (Harrell et al. 2021a). Nevertheless, although MSCs, due to their regenerative, proangiogenic, and immunomodulatory properties, offer new hope in regenerative neurology, a variety of safety concerns have been raised regarding their clinical use (Volarevic et al. 2018).

Results from several clinical studies showed that MSC-based immunosuppressive effects were not noticed in all MSC-treated patients. Some MSC-treated patients did not respond to MSCs regardless of identical medical conditions to MSCs' responders. Even more, inflammation was aggravated in some of the MSC-treated patients (Volarevic et al. 2018). This phenomenon could be explained by the fact that MSCs are not strictly immunosuppressive cells and their immunoregulatory properties depend on the concentration of inflammatory cytokines (particularly TNF-α and IFN-γ) in the tissue in which they have been engrafted (Shariati et al. 2020). MSCs obtain an immunosuppressive or proinflammatory phenotype according to the inflammatory milieu to which they are exposed (Shariati et al. 2020). When MSCs are transplanted in the tissue with high levels of inflammatory cytokines, MSCs develop an immunosuppressive phenotype and induce the generation of tolerogenic phenotype in DCs, the alternative activation of macrophages, and the expansion of regulatory T lymphocytes, NK cells, and NKT cells (Shariati et al. 2020). When MSCs are engrafted in the microenvironment with low levels of TNF-α and IFN-γ, they obtain proinflammatory characteristics, produce large amounts of inflammatory mediators, and induce the activation of inflammatory immune cells (M1 macrophages, N1 neutrophils, Th1 and Th17 lymphocytes) (Shariati et al. 2020).

Additionally, MSCs' therapeutic potential is influenced by the donor's age (Haider 2018). When MSCs are considered for autologous clinical applications in the elderly, the possible age-related alterations in their phenotype and function, such as loss of proliferation and differentiation capacity and reduced therapeutic effectiveness, should be considered (Nurkovic et al. 2016).

Serious safety concerns are related to the possible unwanted differentiation of MSCs upon their engraftment in inflamed and injured tissues (Musiał-Wysocka et al. 2019). Encapsulated formations, such as calcifications and ossifications, were detected in the tissue in which MSCs were transplanted, suggesting an unintended osteogenic and chondrogenic differentiation of engrafted MSCs under the influence of the local microenvironment (Volarevic et al. 2018). Furthermore, when MSCs had been given, together with immunosuppressive medications (which have been used as standard therapy for autoimmune and neuroinflammatory diseases), several patients developed severe, life-threatening respiratory and gastrointestinal infections. These observations provide evidence that MSCs could not be used along with other immunosuppressive drugs. Additionally, many chromosomal abnormalities were observed in some cultures of long-lived MSCs, indicating that a detailed genetic analysis of MSCs has to be done before their transplantation into patients (Volarevic et al. 2018).

Since numerous experimental and clinical trials showed that the majority of the immunoregulatory and angiomodulatory effects of MSCs in the treatment of neurocognitive disorders were dependent on the activity of MSC-sourced bioactive factors (lipids, proteins (enzymes, cytokines, chemokines, immunoregulatory proteins, trophic and growth factors, and microRNAs (miRNAs)), the therapeutic use of these soluble mediators (either alone or within exosomes (Exos)) hold a great promise in cell-free therapy of neurocognitive diseases (Harrell et al. 2019a; Haider and Aramini 2020). MSC-derived exosomes (MSC-Exos) contain all of MSC-sourced neuroprotective and immunomodulatory factors and, thanks to their nano-sized dimension and lipid envelope, may easily penetrate the blood-brain barrier and brain tissue and reach target cells (Harrell et al. 2021a). As cell-free therapeutic agents, MSC-Exos avoid all safety concerns related to the transplantation of MSCs, including unwanted differentiation, undesired immunoregulation, and malignant transformation (Harrell et al. 2021a; Volarevic et al. 2018). Accordingly, a large number of recently published experimental studies showed advantageous benefits of MSC-Exos over MSCs in the treatment of AD, PD, posttraumatic and ischemic brain injury, schizophrenia, and autism spectrum disorders (ASDs) (Harrell et al. 2021).

Therapeutic Effects of MSCs and Their Exosomes in the Treatment of Alzheimer's Disease

Alzheimer's disease (AD) is a neurological disorder that provokes memory loss, cognitive dysfunction, abnormal behavior, and reduced daily functions of patients suffering from it (Nurkovic et al. 2016). Patients with advanced AD often enter a

coma and pass away due to exhaustion and incapacitation (Joe and Ringman 2019). The main neuropathological characteristics of AD are the formation of neurofibrillary tangles (hyperphosphorylated microtubule-associated protein tau-intraneuronal aggregates) and the deposition of amyloid plaques (insoluble deposits of amyloid peptide) (Jellinger 2020). They are commonly detected in the medial temporal lobe and hippocampus of the brain. The intraneuronal aggregation of hyperphosphorylated tau proteins leads to microtubule disintegration, causing cell death in affected neurons, while amyloid peptides accumulate and inhibit synaptic signal transmission (Jellinger 2020).

Results obtained in a large number of preclinical studies showed that MSCs efficiently alleviate AD-related symptoms in experimental animals by decreasing the deposition of amyloid β protein and increasing the levels of acetylcholine in the brain, which led to the better survival of neuronal cells and, consequently, resulted in an improved spatial learning memory of AD animals (Harrell et al. 2021b; Andrzejewska et al. 2021; Si and Wang 2021; Shariati et al. 2020; Qin et al. 2020). MSCs reduce the deposition of amyloid β protein by inducing the autophagy of pathological neurons, which had increased the accumulation of this protein (Harrell et al. 2021b). Additionally, MSCs improve the neurogenesis and synaptogenesis of hippocampal neurons in AD animals by producing a large number of neurotrophins and growth factors (BDGF, nerve growth factor (NGF), VEGF) (Andrzejewska et al. 2021). MSCs reduced synaptic protein loss by restoring the levels of synaptotagmin-1, synaptophysin, and glutamic acid decarboxylase-65 in the hippocampus of AD rats. Additionally, by modulating the expression and activity of choline acetyltransferase and acetylcholinesterase, MSCs increase levels of acetylcholine in the hippocampus, which is followed by a significant improvement in the learning abilities and cognitive function of AD animals (Andrzejewska et al. 2021).

In addition to their direct effect on pathological neurons, MSCs prevent AD progression by suppressing ongoing inflammation by inhibiting inflammatory M1 microglia cells (Andrzejewska et al. 2021). MSCs inhibit the secretion of inflammatory cytokines and chemokines (TNF-α, IL-1β, IL-6, macrophage chemotactic protein (MCP)) and induce the production of immunosuppressive cytokines (TGF-β, IL-10) in microglia cells, favoring their transdifferentiation from inflammatory (M1) into anti-inflammatory (M2) cells (Andrzejewska et al. 2021). Accordingly, a cross-talk between MSCs and microglia cells resulted in the alleviation of inflammatory and the upregulation of immunosuppressive cytokines in the brains of AD animals, which was manifested by the significant improvement in cognitive functions (Bagheri-Mohammadi 2021).

Results obtained in various experimental trials demonstrated that exosomes are responsible for the interneuronal transfer of hazardous chemicals within the brain of AD patients, playing an essential role in the progression and aggravation of AD (Beatriz et al. 2021). In line with these findings, several research groups investigated whether MSC-Exos may use the same pathways (gap junctions, synaptic transmission, endosomal/lysosomal secretion system) to deliver MSC-derived neuroprotective and trophic chemicals to injured neurons, resulting in the alleviation of AD-related symptoms (Harrell et al. 2021b; Nakano and Fujimiya 2021;

Guo et al. 2020; Yang et al. 2020b; Yin et al. 2020; Chakari-Khiavi et al. 2019). As expected, MSC-Exos are effective in treating AD in a large number of animal studies (Harrell et al. 2021; Nakano and Fujimiya 2021; Guo et al. 2020, Yang et al. 2020b; Yin et al. 2020; Chakari-Khiavi et al. 2019).

Wang and Yang demonstrated that intravenously injected BM-MSC-Exos significantly reduced inflammation and the accumulation of amyloid peptides and restored synaptic signal transmission in the brains of APP/PS1 transgenic mice, a well-established animal model of AD (Wang and Yang 2020). The administration of BM-MSC-Exos significantly improved cognitive function in experimental mice by stimulating the sphingosine kinase (S1K)/sphingosine-1-phosphate (S1P) signaling pathway in the central nervous system (Wang and Yang 2020). S1K and S1P regulate sphingomyelin metabolism, maintain vascular solidity, and encourage the development of blood vessels in the brain, enabling a more efficient transfer of neurotrophins to the injured neurons (Jellinger 2020). Since a downregulated expression of S1K and/or S1P was noticed in the brain tissue samples of APP/S1 mice and AD patients (Jellinger 2020), BM-MSC-Exo-induced restoration of S1K/S1P signaling led to the significant improvement of cognitive function and the alleviation of AD-related symptoms in APP/S1 animals (Wang and Yang 2020). Increased S1K and S1P expression was fully prevented by the intraperitoneal injection of S1K or S1P inhibitors, implying that the therapeutic effects of BM-MSC-Exos in AD were dependent on the activation of S1/S1P signaling pathways in the brain of APP/S1 mice (Wang and Yang 2020).

In addition to the modulation of S1K/S1P signaling, MSC-Exo-based neuroprotection in APP/PS1 mice was also based on MSC-Exo-dependent activation of the amyloid-peptide-degrading enzyme neprilysin (Ding et al. 2018; Elia et al. 2019). Intracerebral injection of BM-MSC-Exos increased neprilysin expression and activity, which reduced amyloid protein accumulation in APP/PS1 animals (Ding et al. 2018). BM-MSC-Exos also reduced the activity of the β-site amyloid precursor protein cleaving enzyme 1 (BACE1) and downregulated the expression of presenilin-1 (PS1), both of which are required for the synthesis and degradation of amyloid precursor proteins (Harrell et al. 2021b; Elia et al. 2019). Additionally, BM-MSC-Exo-based therapy significantly increased the expression of NeuN (a neuronal cell biomarker). It also led to the increased accumulation of NeuN in the cortex and hippocampus of APP/S1 mice (Harrell et al. 2021b; Elia et al. 2019). As a result of MSC-Exo-based therapy, the total number of dystrophic neurites in the cortex and hippocampus of BM-MSC-Exo-treated APP/PS1 mice was considerably lower than in untreated animals (Elia et al. 2019).

Notably, according to Reza-Zaldivar and colleagues, MSC-Exos restored cognitive performance in AD mice in the same way that parental MSCs did (Reza-Zaldivar et al. 2019). The Morris water maze (MWM) and novel object recognition (NOR) tests revealed that injecting either MSC-Exos or MSCs into AD rats effectively reduced cognitive impairment (Reza-Zaldivar et al. 2019). There was no difference in the benefits achieved by MSCs and MSC-Exos in terms of learning ability and memory loss (Harrell et al. 2021b; Andrzejewska et al. 2021; Reza-Zaldivar et al. 2019). The MWM test revealed that both MSC-Exos and MSCs

dramatically improved learning ability in AD animals. The NOR test revealed that MSC-Exo-treated and MSC-treated mice had equivalent increases in the percentage of interaction time when compared to untreated mice, implying that MSCs restored learning ability and memory in AD mice in a paracrine manner by delivering immunomodulatory and trophic factors into the injured neurons of the affected brain via exosomes (Reza-Zaldivar et al. 2019). Accordingly, Reza-Zaldivar and colleagues concluded that MSC-Exos were mainly responsible for the beneficial effects of MSCs in AD, particularly for MSC-dependent improvement of cognitive function (Reza-Zaldivar et al. 2019).

Similarly, as observed after the injection of BM-MSC-Exos, AT-derived MSC-Exos (AT-MSC-Exos) could efficiently provide neuroprotection, stimulate neurogenesis, and alleviate cognitive impairment in APP/PS1 mice (Ma et al. 2020). AT-MSC-Exos reach the brain quickly after intranasal delivery, accumulating in neurons and glial cells. AT-MSC-Exo-treated APP/PS1 mice showed significantly reduced amyloid β protein accumulation and decreased microglia activation (Ma et al. 2020). Importantly, the proteomic analysis of AT-MSC-Exos revealed the presence of neurotrophins (filamin A, vinculin, neuropilin-1, neuroplastin, glia-derived nexin, flotillin-1, drebrin, teneurin-4), which induced neurogenesis and myelin formation, stimulated axonal growth and regeneration, and provided neuroprotection to injured neurons. In AT-MSC-Exo-treated neurons, 1094 genes were upregulated, while 267 genes were downregulated (Ma et al. 2020). Raised expression of PCLO, TENM1, and NEXMIF genes, which regulated synaptic function and improved memory in experimental mice and reduced the expression of the BAD gene, which caused the cell death of injured neurons, were found in AT-MSC-Exos. As a result, the injection of AT-MSC-Exos reduced neurologic damage, increased the total number of newly produced neurons, and effectively corrected memory deficits in APP/PS1 mice (Ma et al. 2020).

The accumulation of amyloid protein is aggravated by microglia-driven neuroinflammation, which plays a key role in the genesis and progression of AD (Subramaniyan and Terrando 2019). Several research groups demonstrated that the main mechanism for MSC-Exo-based reduction of cognitive impairment in APP/PS1 mice is the suppression of microglia's proinflammatory characteristics (Harrell et al. 2021; Andrzejewska et al. 2021; Bagheri-Mohammadi 2021; Ding et al. 2018). By using APP/PS1 mice as a model for AD, Ding and colleagues showed that the administration of umbilical-cord-derived MSC-Exos (UC-MSC-Exos) inhibited the generation of inflammatory phenotypes in activated microglia, which, consequently, resulted in alleviated inflammation in the brain and was manifested by improved learning ability and memory of experimental animals (Ding et al. 2018). UC-MSC-Exo-treated APP/PS1 mice had a significantly shorter mean escape latency, a greater number of platform location crossing times, and a longer time spent in the target quadrant than MSC-Exo-untreated mice, implying that UC-MSC-Exos improved APP/PS1 mice's behavioral performance by improving spatial learning and memory function (Ding et al. 2018). Additionally, UC-MSC-Exos considerably increased the activity of amyloid-β-degrading enzymes (neprilysin- and insulin-degrading enzymes) in the brains of experimental mice, resulting in a considerable

reduction in amyloid β deposition (Ding et al. 2018). The immunostaining of the brains of APP/S1 mice revealed a significantly reduced number of Iba-1-positive inflammatory microglia cells in the brains of UC-MSC-Exo-treated mice (Ding et al. 2018). The cellular makeup of microglial cells revealed that most microglia cells were polarized toward the immunosuppressive M2 phenotype (Ding et al. 2018). Significantly increased number of chitinase 3-like 3 (YM-1), arginase-1 (Arg-1), mannose receptors C type 1 (MRC1), and haptoglobin/hemoglobin scavenger receptor (CD163)-expressing M2 microglia cells were noticed in the brains of UC-MSC-Exo-treated APP/S1 mice compared to the UC-MSC-Exo-untreated animals (Harrell et al. 2021b; Ding et al. 2018). As a result, levels of M2 microglia-derived immunosuppressive cytokines (TGF-β and IL-10) increased in the peripheral blood and brains of UC-MSC-Exo-treated APP/PS1 mice, while levels of M1 microglia-sourced pro-inflammatory cytokines (TNF-α and IL-1β) decreased, confirming that the significant improvement of cognitive function in UC-MSC-Exo-treated APP/S1 mice was mainly a consequence of UC-MSC-Exo-based alleviation of microglia-driven neuroinflammation (Harrell et al. 2021; Ding et al. 2018).

Results obtained by Nakano and colleagues, who emphasized the crucial role of MSC-sourced miRNA-146 for MSC-Exo-dependent reduction of microglia and neuroinflammation in AD mice (Nakano et al. 2020), were consistent with these findings. MiRNA-146 is a noncoding RNA molecule that regulates microglia inflammatory characteristics (Nakano and Fujimiya 2021). In microglia, MSC-Exos suppressed TNF-receptor-associated factor 6 (TRAF6) and IL-1-receptor-associated kinase 1 (IRAK1) in a miRNA-146-dependent way, resulting in decreased phosphorylation of transcriptional factor NF-kB (Nakano and Fujimiya 2021).

In MSC-Exo-treated microglia, the inhibition of the NF-kB signaling pathway reduced the production of inducible nitric oxide synthase (iNOS), TNF-α, IL-1β, and IL-6 genes. It prevented the inflammatory M1 phenotype (Nakano et al. 2020). M1 microglia release NO and proinflammatory cytokines (TNF-α, IL-1β) that alter synaptogenesis and decrease cognitive function, leading to the progression of AD (Subramaniyan and Terrando 2019). Intracerebroventricularly injected BM-MSC-Exos alleviated neuroinflammation and improved spatial learning and memory function in APP/PS1 mice by suppressing M1 microglia activation and promoting their differentiation into M2 immunosuppressive cells in a miRNA-146-dependent manner (Nakano et al. 2020; Wang et al. 2018).

MSC-derived miRNA-21, in addition to miRNA-146, was also responsible for MSC-Exo-based immunomodulation in the inflamed brains of APP/PS1 mice (Cui et al. 2018). Exosomes derived from hypoxia-preconditioned MSCs, in a miRNA-21-dependent way, suppressed microglial cell activation in APP/PS1 mice and prevented memory impairments (Cui et al. 2018). Significantly increased miRNA-21 corresponded to reduced amyloid β protein deposition, downregulated concentrations of inflammatory cytokines, reduced activation of transcriptional factors (signal transducer and activator of transcription 3 (STAT3) and NF-kB), and increased levels of anti-inflammatory cytokine IL-10 in the brains of MSC-Exo-treated APP/PS1 mice (Cui et al. 2018).

Even though MSC-Exos can cross the blood-brain barrier, most intravenously injected MSC-Exos end up in the spleen and liver (Offen et al. 2019; Morishita et al. 2017). Cui and colleagues used MSC-Exos conjugated with the neurotropic rabies virus glycoprotein (RVG; RVG-tagged MSC-Exos) to target intravenously injected MSC-Exos into the brains of APP/PS1 mice (Cui et al. 2019). RVG-tagged MSC-Exos showed enhanced tropism for the cortex and hippocampus compared to RVG-untagged MSC-Exos. Accordingly, a higher presence of MSC-Exos was observed in the brains of APP/PS1 animals that received RVG-tagged MSC-Exos (Cui et al. 2019). The injection of RVG-tagged MSC-Exo dramatically reduced the serum levels of inflammatory cytokines (TNF-α, IL-β, and IL-6) and increased the serum concentration of immunosuppressive IL-10 in APP/PS1 mice. As a result, the behavioral and cognitive skills of APP/PS1 mice that received RVG-tagged MSC-Exos were much better than the learning and memory abilities of animals that were treated with RVG-untagged MSC-Exos (Cui et al. 2019).

The encouraging results of experimental studies raised hope for an efficient clinical application of MSCs in AD therapy (Andrzejewska et al. 2021). Initially, in 2011, scientists from South Korea conducted a Phase I clinical trial in which nine patients with mild to moderate AD underwent stereotactic brain infusion of allogeneic MSCs (ClinicalTrials identifier: NCT01547689). The transplanted MSCs were well tolerated without any significant side effects related to their administration. Subsequently, Phase I/II clinical trials in which AD patients received allogeneic MSCs in the hippocampal region were also reported to be safe since no patients reported serious complications during 18–24 months of follow-up (ClinicalTrials identifier: NCT01696591 and ClinicalTrials identifier: NCT02054208) (Andrzejewska et al. 2021). The first Phase II clinical trial that investigated the therapeutic potential of MSCs in the treatment of 40 AD patients was conducted in the United States in 2015 (ClinicalTrials identifier: NCT02833792) (Andrzejewska et al. 2021). Similar trials have been elicited in Europe and Asia, but results proving the therapeutic efficacy of MSCs in the alleviation of AD-related signs and symptoms are still waiting to be published.

Improvement of Cognitive Impairment Following Brain Damage and Ischemia in MSC-Treated Mice

The hippocampus is required for memory, spatial learning, and cognition (Shetty 2014). Accordingly, due to hippocampus injury, cognitive impairment and memory loss emerge (Shetty 2014). Traumatic injury and ischemia cause temporary neurogenesis, a compensatory response that should help injured neurons recover their function. However, the injured brain's regenerating ability is severely restricted (Chen et al. 2020b).

Intrathecal, intravenous, and intra-arterial infusion of MSCs significantly improved the cognitive deficit in experimental animals suffering from ischemia or traumatic brain injury (TBI) (Andrzejewska et al. 2021). MSCs, delivered directly into the injured or ischemic brains, engrafted in the inflamed microenvironment,

obtained an anti-inflammatory phenotype and produced large amounts of neurotrophins (neuropilin-1, neuroplastin, glia-derived nexin, flotillin-1), immunosuppressive cytokines (IL-10, IL-35, TGF-β), and proangiogenic factors (VEGF, hypoxia-inducible factor 1α (HIF-1 α)), which attenuated ongoing inflammation, promoted neovascularization, and finally led to the regeneration of injured neurons (Andrzejewska et al. 2021). Systemically injected MSCs usually engraft in lungs and liver (Volarevic et al. 2011). By releasing various neurotrophins, MSCs, in endocrine manner, modulate phenotype and function of injured neurons and microglial cells (Volarevic et al. 2011). Moreover, MSCs may, in a juxtacrine and paracrine manner, stimulate the microglial cells to secrete trophic factors, which will further promote neurogenesis, neuroprotection, and neural repair in ischemic and injured brains (Bagheri-Mohammadi 2021). MSCs generate the M2 phenotype in microglia, characterized by an increased capacity for enhanced production of neurotrophins and immunosuppressive cytokines (Andrzejewska et al. 2021; Bagheri-Mohammadi 2021). As a result, transplanted MSCs and M2 microglia create an immunosuppressive microenvironment with an increased concentration of neuroprotective molecules and growth factors that prevent the apoptosis of injured neurons and stimulate their regeneration (Andrzejewska et al. 2021; Bagheri-Mohammadi 2021).

The genetic modification of MSCs improves their therapeutic effects in neuroprotection and immunomodulation after transplantation in ischemic and injured brains (Andrzejewska et al. 2021). Genetically engineered MSCs that overexpress fibroblast growth factor 21 (FGF-21) or chemokine receptor CXCR4 enhanced cell homing to the site of brain injury and inflammation (Andrzejewska et al. 2021). A significant increase in engrafted MSCs resulted in increased neurogenesis in injured brains, particularly in the hippocampal region. As a result, significantly improved cognitive function and learning abilities were observed in TBI rats that received FGF-21 or CXCR4-overexpressing MSCs (Andrzejewska et al. 2021). Similarly, genetically engineered MSCs that overexpress IL-4 and IL-10 were superior in the inhibition of Th1 and Th17 cell-driven neuroinflammation, while HIF-1 α-overexpressing MSCs remarkably increased neo-angiogenesis in ischemic brains, contributing to the better restoration of cognitive function in MSC-treated TBI rats (Andrzejewska et al. 2021).

By using the same molecular mechanisms as their parental MSCs, MSC-Exos block harmful immune responses and enhance neurogenesis and neuritogenesis by delivering trophic, vasoactive, and immunomodulatory molecules to damaged neurons and microglia (Harrell et al. 2021a; Bagheri-Mohammadi 2021; Chen et al. 2020). Several lines of evidence showed that MSC-Exos effectively restored cognition, learning disabilities, and memory loss in injured and ischemic hippocampal neurons (Harrell et al. 2021b; Chen et al. 2020c; Niu et al. 2020; Kim et al. 2016; Zhang et al. 2015, 2020; Gao et al. 2020; Yang et al. 2020a).

By using an experimental murine model of acute brain injury, Niu and colleagues demonstrated that the intravenous injection of UC-MSC-Exos improved cognitive performance in experimental animals by modulating metabolism in hippocampal neurons (Niu et al. 2020). Proteomic analysis showed that UC-MSC-Exos contain 67 proteins that are able to alter metabolic function in damaged neurons

(Niu et al. 2020). Among these MSC-derived proteins, adiponectin was considered the most important regulator of metabolism. Accordingly, adiponectin levels in the hippocampus and serum samples of UC-MSC-Exo-treated mice were found to be higher, and an increase in adiponectin levels was linked to the better cognitive function of UC-MSC-Exo-treated animals (Niu et al. 2020).

Kim and coworkers used an experimental murine model of TBI to demonstrate the therapeutic potential of MSC-Exos in the restoration of cognitive function after TBI (Kim et al. 2016). They showed that only a few days after their intravenous injection, MSC-Exos significantly corrected pattern separation and spatial learning defects in experimental animals (Kim et al. 2016).

A single intravenous injection of MSC-Exos dramatically restored sensorimotor and cognitive performance in rats with unilateral mild cortical contusion (Zhang et al. 2020). There was a remarkable reduction in hippocampus neuronal cell death, alleviated neuroinflammation, and a significant rise in the number of newly produced blood vessels and neurons in the brains of MSC-Exo-treated rats. MSC-Exos improved animals' cognitive function by regulating microglia activation and preventing reactive astrogliosis, which led to a significant reduction in the inflammation-induced injury of neurons (Zhang et al. 2020). Additionally, MSC-Exos were able to correct myelination deficiencies and abnormalities of white matter. All of these MSC-Exo-based improvements in neural cells' morphology and function were followed by restored cognition and learning abilities of experimental animals (Zhang et al. 2020).

Similar to these findings are the results reported by Zhang and colleagues, who found that a systemic injection of MSC-Exos managed to significantly improve cognitive function in rats with TBI by encouraging functional recovery and neurovascular remodeling (Zhang et al. 2015). The MWM test showed that MSC-Exos-treated TBI rats had considerable improvement in spatial learning when compared to saline-treated animals (Zhang et al. 2015). Additionally, a significant increase in the number of newly formed immature and mature neurons in the dentate gyrus of MSC-Exo-treated TBI rats was accompanied by an alleviated concentration of inflammatory cytokines and an increased number of newly generated blood vessels in the brains, indicating that MSC-Exo-induced improvement in the cognitive function of TBI rats was due to the activity of MSC-Exo-sourced immunosuppressive, neurotrophic, and proangiogenic factors (Zhang et al. 2015).

Gao and colleagues suggested that miRNA-21, already reported for its anti-apoptotic activity (Haider et al. 2010), was mostly responsible for MSC-Exos' positive effects in the restoration of cognitive function following brain injury. In experimental rats, MSC-Exo-delivered miRNA-21 protected neurons from apoptosis and reduced subarachnoid hemorrhage (SAH)-induced cognitive impairment (Gao et al. 2020). MSC-Exo-delivered miRNA-21 inhibited apoptosis in damaged neurons by activating the PTEN/Akt signaling pathway (Gao et al. 2020). The knockdown of miRNA-21 as well as the administration of a PTEN/Akt inhibitor completely diminished MSC-Exo-dependent neuroprotection, demonstrating a critical role of miRNA-21/PTEN/Akt signaling for MSC-Exo-based restoration of cognitive function following SAH (Gao et al. 2020).

By delivering proangiogenic and trophic factors to the ischemic regions of injured brains, MSC-Exos prevented ischemia-induced apoptosis of hippocampal neurons and significantly reduced the cognitive impairment of experimental animals (Yang et al. 2020). MSC-Exos reduced the overall number of dead neurons and increased neuronal density in the ischemia boundary zone by downregulating the expression of proapoptotic proteins Bax, caspase-3, and caspase-9 and by increasing the expression of antiapoptotic protein Bcl-2 (Yang et al. 2020a).

Hippocampal brain injury and cognitive impairment are caused by ischemic injury, oxidative stress, glucose metabolism abnormalities (hyper- or hypoglycemia), alterations in glutamate neurotransmission, and impaired hippocampal synaptic plasticity in diabetic individuals (Hamed 2017).

Since MSC-Exos contain a large number of neurotrophins, proangiogenic factors, and molecules that control metabolism in ischemic neurons, several research groups analyzed the therapeutic potential of MSC-Exos in the treatment of diabetes-induced cognitive dysfunction (Nakano et al. 2016; Zhao et al. 2019; Kubota et al. 2018). Zhao and colleagues discovered that diabetic mice treated with BM-MSC had a practically complete recovery of cognition. In the hippocampus of diabetic mice, the intracerebroventricular injection of BM-MSC-Exos dramatically reduced the degeneration and synaptic loss of neurons (Zhao et al. 2019). MSC-Exos decreased inflammation-induced damage of hippocampal neurons by downregulating the expression of IRAK1 kinase in a miRNA-146-dependent manner (Zhao et al. 2019). By delivering immunoregulatory miRNA-146 in astrocytes, MSC-Exos suppressed the activation of IRAK1 kinase and altered the inflammatory phenotype and function of astrocytes. The inhibition of IRAK1 prevented the activation of transcriptional factor NF-kB, which resulted in the alleviated production of proinflammatory cytokines (TNF-α and IL-1β) in astrocytes and, consequently, led to the alleviation of ongoing inflammation (Zhao et al. 2019). Attenuated inflammation resulted in a decreased loss of hippocampal neurons, manifested by the significantly improved cognitive function and learning abilities of MSC-Exo-treated animals (Zhao et al. 2019).

Therapeutic Effects of MSCs and MSC-Exos in the Treatment of Parkinson's Disease, Schizophrenia, and Autism

Parkinson's disease (PD) is a progressive neurocognitive disease characterized by a loss of dopaminergic neurons (McDermott et al. 2018; Kubota et al. 2018). MSCs are effective in the treatment of PD in various experimental studies (Hwang et al. 2018; Chen et al. 2020a). The intracerebral injection of MSCs significantly improved locomotor activity and enhanced neurogenesis in PD animals (Andrzejewska et al. 2021). A remarkably increased number of tyrosine hydroxylase (TH)-positive dopaminergic neurons and elevated dopamine levels in the striatum were observed in MSC-treated PD animals. MSC transplantation promoted the survival of dopaminergic neurons by inducing the enhanced expression of antiapoptotic Bcl-2 protein and suppressing the activity of proapoptotic Bax protein in these cells (Andrzejewska et al. 2021; Chen et al. 2020a). Additionally, MSCs

delivered several neurotrophic factors (brain-derived neurotrophic factor (BDNF), cerebral dopamine neurotrophic factor (CDNF), HGF, and neurotrophin-3) to the dopaminergic neurons, enhancing their viability and regeneration (Chen et al. 2020b). Finally, an increased number of immunosuppressive M2 and the reduced presence of inflammatory M1 microglial cells were observed in the brains of MSC-treated PD mice, indicating that the beneficial effects of MSCs in the alleviation of PD-related symptoms were, at least partially, relied on in the MSC-dependent suppression of microglia-driven inflammation (Andrzejewska et al. 2021; Bagheri-Mohammadi 2021; Chen et al. 2020c).

Since a majority of MSC-based beneficial effects of PD treatment relied on the activity of MSC-sourced bioactive molecules (Harrell et al. 2021b; Andrzejewska et al. 2021), Chen and colleagues investigated whether intravenously given MSC-Exos may cause the regeneration of dopaminergic neurons in the same manner as their parental cells (Chen et al. 2020b). Systemically infused MSC-Exos easily crossed the blood-brain barrier and reached dopaminergic neurons in the substantia nigra of PD rats (Chen et al. 2020b). The histological examination of brain tissue samples revealed that MSC-Exos prevented the apoptosis of dopaminergic neurons (Chen et al. 2020b). Importantly, MSC-Exos dramatically increased levels of dopamine and its metabolites (dihydroxyphenylacetic acid and homovanillic acid) in the striatum, implying that MSC-Exo-based therapy managed to significantly improve dopaminergic neuron activity in PD mice.

Autism spectrum disorders (ASDs) represent a group of neurodevelopmental diseases characterized by cognitive impairment, increased repetitive behaviors, and difficulties in communication and social interaction (Hodges et al. 2020). The therapeutic potential of MSC-Exos in the therapy of ASD has been explored in BTBR T + tf/J mice, which have a behavioral phenotype comparable to human ASD (reduced social approach, low reciprocal social interactions, and impaired juvenile play) (Perets et al. 2018). Perets and colleagues demonstrated that the intranasal injection of MSC-Exos considerably reduced autism-like behavior and ASD-related symptoms in BTBR T + tf/J mice (Perets et al. 2018). Significantly enhanced male-to-male social interaction and reduced repetitive behaviors during social interaction were found in MSC-Exo-treated BTBR T + tf/J mice (61). Additionally, MSC-Exo-treated BTBR T + tf/J mice had more sophisticated and longer male-to-female ultrasonic vocalization, making them more similar to the healthy mice of the control group (Perets et al. 2018).

The pup retrieval behavior of female BTBR T + tf/J mice was also greatly improved by MSC-Exos. While saline-treated BTBR T + tf/J females returned just 2 of 24 pups to the nest, MSC-Exo-treated BTBR T + tf/J females returned all (18/18) pups, suggesting a considerable increase in maternal behavior (Perets et al. 2018).

The intranasal injection of MSC-Exos significantly improved the cognitive function of phencyclidine (PCP)-treated mice, used as a well-established murine model of schizophrenia. Tsivion-Visbord and colleagues found that MSC-Exos reduced schizophrenia-like behaviors by improving the survival of gamma-aminobutyric acid (GABA)-producing neurons (Tsivion-Visbord et al. 2020). Immediately after intranasal injection, the majority of MSC-Exos were observed in the neurons of the

prefrontal cortex (PFC), the brain area most severely impaired in schizophrenia. A significantly higher presence of GABA-producing PFC neurons was accompanied by decreased levels of glutamate in the cerebrospinal fluid of MSC-Exo + PCP-treated animals. MSC-Exo-based reduction of schizophrenia-like behavior was evidenced by improved social interaction and disrupted prepulse inhibition in PCP-treated mice (Tsivion-Visbord et al. 2020). Since the intranasal delivery of MSC-Exos was well tolerated and no side effects were observed in MSC-Exo-treated mice (Perets et al. 2018; Tsivion-Visbord et al. 2020), the efficacy of this noninvasive therapeutic approach for the improvement of cognitive function should be further investigated during upcoming clinical trials.

MSC-Exos play a crucial role in the information transfer between MSCs and recipient cells (neurons and microglia) (Harrell et al. 2021b). MSC-sourced miRNAs, trophic factors, enzymes, and immunomodulatory and proangiogenic chemicals delivered by MSC-Exos into the neurons and microglia enhance neurogenesis and reduce inflammation-induced damage of hippocampal neurons, improving the cognitive function of MSC-Exo-treated animals (Harrell et al. 2021b). Importantly, the capacity for immunomodulation and neuroprotection of MSC-Exos was comparable to or even superior to that mediated by their parental MSCs (Harrell et al. 2021b; Andrzejewska et al. 2021). The effects of MSC-Exos were unaffected by the local tissue's microenvironment. Unlike MSCs, which may change their phenotype and function as a result of engraftment in diverse tissue microenvironments, MSC-Exos deliver their cargo (immunoregulatory molecules and growth factors) directly to the target cells, and their therapeutic potential is not affected by local tissue milieu (Harrell et al. 2021a; Andrzejewska et al. 2021). Moreover, the composition of exosomal cargo can be modified by the physical or genetic modification of MSCs to achieve the desired prognosis (Haider and Aramini 2020).

Nevertheless, despite these promising outcomes, it has to be noted that various concerns must be addressed before MSC-Exos can be widely used in clinical settings on a regular basis (Harrell et al. 2021a). Since a variety of antiapoptotic and immunosuppressive molecules have been hypothesized as critical for the MSC-Exo-based restoration of cognitive function, more experimental research is needed to prove those findings and to delineate which of these factors play a critical role in MSC-Exo-based immunomodulation and neuroregeneration. Moreover, before MSC-Exos could be offered as a universal human therapeutic agent, future experimental studies and clinical trials should identify the exact disease-specific therapeutic dose, route of administration, and schedule for MSC-Exos-based therapy (Harrell et al. 2021).

Conclusion

MSCs produce a large number of immunoregulatory, proangiogenic, and trophic factors, which may suppress detrimental immune responses, alleviate ongoing neuroinflammation, improve oxygen supply, and induce the regeneration of injured neurons (Harrell et al. 2021a; Andrzejewska et al. 2021). The transplantation of MSCs as well as the infusion of MSC-Exos enhance hippocampal neurogenesis,

stabilize synapses, and induce the generation of anti-inflammatory and immunosuppressive phenotypes in microglia cells within injured and inflamed brains. Accordingly, a significantly reduced loss of hippocampal neurons and a remarkable improvement in cognitive function was noticed in MSCs and MSC-Exo-treated animal models of AD, TBI, PD, ASDs, and schizophrenia (Harrell et al. 2021b; Andrzejewska et al. 2021). The encouraging results of experimental studies raised hope for an efficient clinical application of MSCs. The results obtained in already conducted clinical trials demonstrated that MSC-based therapy is a safe therapeutic approach that does not cause undesirable severe side effects (Andrzejewska et al. 2021). However, the therapeutic efficacy of MSCs or MSC-Exos in the treatment of neurocognitive diseases has not yet been confirmed in clinical settings, and results of upcoming clinical trials that analyze their therapeutic potential are expected with enthusiasm and sincere hope.

Abstract

Preconditioning (PC) affords the most potent cytoprotective effects ever known in the physiological system. Since the publication of the first report that preconditioning by cyclical exposure to intermittent sublethal ischemia-reperfusion episodes is cardioprotective, the strategy has been extrapolated to sustain its beneficial effects at cellular and subcellular levels. The underlying principle of preconditioning is that exposure to sublethal episodes of a noxious stimulus triggers survival signaling pathways that render the cells resistant to subsequent exposure to the lethal stimulus. Diverging from the classical protocol involving treatment with ischemia-reperfusion, various preconditioning strategies have been developed and optimized to include physical, chemical, genetic, and pharmacological manipulation of cells to mimic the effects of ischemic preconditioning. Besides survival signaling, such manipulations significantly impact the stemness characteristics, paracrine behavior, angiogenic and differentiation potential, and various other aspects of cellular biology. Primarily used as cholesterol-lowering drugs, statins constitute a group of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase inhibitors that have been effectively employed as preconditioning mimetics. Various members of the statin group, natural, semisynthetic, or synthetic, i.e., lovastatin, simvastatin, atorvastatin, rosuvastatin, etc., have been used to exploit their pleiotropic effects on the stem/progenitor cells as a part of the preconditioning strategy to enhance their stemness and functionality postengraftment. This book chapter provides a critical review of the advancements in pharmacological preconditioning of stem/progenitor cells in general and with the use of statin in particular. It highlights the mechanism that renders superiority in the use of statins as preconditioning mimetics.

Keywords

Angiogenesis · Heart · Pharmacological · Preconditioning · Statins · Stem cells · Survival

List of Abbreviations

AMI	Acute myocardial infarction
AMPK	Adenosine monophosphate-activated protein kinase
Bax	Blc2-associated X-protein
Bcl2	B-cell lymphoma 2
bFGF	Basic fibroblast growth factor 2
Bim	Bcl2 like 4
BM	Bone marrow

CRP	C-reactive protein
CSCs	Cardiac stem cells
CXCR4	CXC chemokine receptor 4
ECM	Extracellular matrix
eNOS	Endothelial nitric oxide synthase
ERK1/2	Extracellular signal-related kinase 1/2
ESCs	Embryonic stem cells
GFP	Green fluorescence protein
hESCs	Human embryonic stem cells
ICM	Inner cell mass
iPSCs	Induced pluripotent stem cells
JAK	Janus kinase
LDL	Low-density lipoprotein
LVEF	Left ventricular ejection fraction
MEK	Mitogen-activated protein/extracellular signal-regulated kinase
miR	microRNA
MRI	Magnetic resonance imaging
MSCs	Mesenchymal stem cells
MTPs	Microthrombotic particles
NO	Nitric oxide
OCN	Osteocalcin
OPN	Osteopontin
ROCK	Rho-associated coiled-coil-forming kinase
ROS	Reactive oxygen species
SDF-1α	Stromal cell-derived factor-1
SkMs	Skeletal myoblasts
SPECT	Single-photon emission computed tomography
STAT	Signal transducers and activators of transcription
STAT	Signal transducers and activators of transcription
STEMI	ST-elevation myocardial infarction
VEGF	Vascular endothelial growth factor

Introduction

One of the most promising areas in the current research and prediction for the future is in basic and translational research exploring the conceivable use of stem cells for cell-based and cell-free therapies. These unique cells can transform into and regenerate the different tissues that make up the human body. Moreover, they represent the basic building blocks of human development at various levels, whether therapeutic, convalescent, or others (Zakrzewski et al. 2019). Stem cells also release a plethora of bioactive molecules and lipid membrane-enclosed vesicles as part of their paracrine activity that also plays a significant role in the repair process (Haider and Aslam 2018). They are characterized by unlimited

undifferentiated self-renewal, clonogenicity, and transdifferentiation into different cell lineages with morphofunctional competence in response to different chemical cues and under a unique set of conditions. Hemopoietic stem cells (HSCs) were first recognized and displayed all these properties (Ng and Alexander 2017). Today, many types of tissue-specific resident stem/progenitor cells, i.e., bone marrow-derived mesenchymal stem cells (MSCs), adipose tissue derived stem cells, resident cardiac stem cells (CSCs), skeletal myoblasts (SkMs), umbilical cord blood-derived stem cells, peripheral blood-derived stem cells, etc., have been identified, isolated, and characterized from almost every body tissue (Bhartiya 2021). It is generally perceived that they are responsible for tissue repair and regeneration in the event of tissue injury. Incidentally, SkMs (Haider et al. 2004a), bone marrow-MSCs (Haider and Ashraf 2005), and CSCs (Leong et al. 2017) have already reached the clinical phase for safety and efficacy assessment in the human patients, and bone marrow-derived MSCs have advanced to phase III clinical trials (Rajab et al. 2019).

Essentially, stem cells are found in both embryonic and adult tissues, and hence, they are referred to as embryonic stem cells (ESCs) and adult tissue-derived stem cells, respectively. Developmental activity decreases the differentiation potential of stem cells with each step from pluripotency to terminal differentiation when the cells become specialized. Human embryonic stem cells (hESCs) are derived from the inner cell mass (ICM) (Pera et al. 2000). They can be propagated in vitro indefinitely in the primitive undifferentiated state while retaining their pluripotency status (Vazin and Freed 2010). During embryonic development, ESCs form multiple assemblies with distinct functions called germ layers, which ultimately lead to the emergence of differentiated cells and tissues of the embryo, and later the adult organism (Larijani et al. 2012). A new entrant to this long list is the induced pluripotent stem cells (iPSCs), which are considered as surrogate ESCs albeit without the problem of ethical and moral issues and provide a renewable source for theranostic applications (Lalit et al. 2014; Ibrahim et al. 2016; Cagavi et al. 2018). Takahashi and Yamanaka first reported them in 2006, who successfully reprogrammed mouse tail fibroblasts using a quartet of pluripotency determining transcription factors, i.e., Oct3/4, Sox2, Klf4, and cMyc. Since then, iPSCs have been extensively studied for tissue regeneration in experimental animal models, including myocardial repair (Ahmed et al. 2011a; Buccini et al. 2012), however not without the threat of tumorigenicity (Ahmed et al. 2011b).

One of the most severe and widespread cardiovascular ailments is ischemic heart disease (IHD), which is now considered as the leading cause of morbidity and mortality globally. According to the figures released by the American Heart Association, one out of every three deaths reportedly occurred due to cardiovascular issues and incurring heavy financial burden (AHA 2018; WHO 2017). IHD leads to an irreversible impairment of cardiac function, which is generally attributed to the terminal differentiation status of the cardiomyocytes that renders them incapable of entering into the cell cycle in the event of injury (Rosenstrauch et al. 2005). Although the presence of resident CSCs has been reported (Frati et al. 2011; Mayfield et al. 2014), besides the ability of cardiomyocytes to reenter into the

proliferative cycle (Torella et al. 2015; Miyawaki et al. 2017), both these findings could contribute little in the intrinsic repair process, especially if the ischemic myocardial injury is extensive and involves massive myocyte injury and death. The contemporary treatment methods are limited to symptomatic relief without addressing the underlying cause and mechanistic interference in the pathological process, which continues as an unabated vicious cycle. The limitations of the current treatments have led to the search for novel treatment strategies aimed to regenerate and repair the damaged heart muscle so that the treatment extends over long-term and stable benefits. Stem cell therapy has given encouraging results in experimental animal models and clinical settings (Rajab et al. 2019).

Recent advances in stem cell biology and tissue engineering have given further impetus to regenerative medicine and its applications for myocardial repair. Despite these encouraging results, there are various aspects of stem cell-based therapy, which significantly hamper its progress to the clinical settings as a routine therapeutic modality. One of these impediments is the extensive death of the donor cells posttransplantation in the hostile microenvironment of the ischemic myocardium due to infiltrating inflammatory cells and a plethora of secreted proinflammatory cytokines, i.e., TNF-α, IL-1β, IL-6, etc., in response to the ischemic insult (Khodayari et al. 2019). This chapter focuses on the problem of extensive donor stem cell death-related issues and the preconditioning strategy to enhance donor cell survival. The particular focus of the chapter is on statins as preconditioning mimetics from the standpoint of pharmacological manipulation of the cells as well as the infarcted myocardium to render it conducive and favorable for the transplanted cells.

Stem Cell-Based Therapy for Myocardial Repair

Under the right physiological conditions and in response to the appropriate microenvironmental cues, stem cells divide and differentiate to form specialized cells with well-defined functions (Carbone et al. 2021). Given that ischemic myocardial damage is increasing the incidence of heart failure worldwide (Jenča et al. 2021) and the limited intrinsic regenerative capacity of the heart, cell-based therapy offers a potential therapeutic modality for routine use in the clinical settings. The published data has clearly shown the safety and feasibility of stem-cell-based therapy during the experimental phase and in the clinical trials (► Chap. 10, "Mesenchymal Stem Cells for Cardiac Repair").

Stem cells used for myocardial repair and regeneration have been derived from various tissue sources that include adult tissue-derived stem cells, i.e., bone marrow-derived MSCs, SkMs, resident CSCs, etc., embryo and embryo-associated tissue-derived stem cells, i.e., ESCs, umbilical cord blood-derived stem cells, etc., and iPSCs; each one with unique biological characteristics and stemness features. For example, the primary advantage of human ESCs over adult stem cells is their pluripotency. However, the moral and ethical issues ascribed to their use, tumorigenicity, and immunogenicity as well as arrhythmogenicity of the donor cell graft-derived cardiomyocytes have hampered their progress to the clinic. On the same

note, iPSCs are being assessed in translational experimental animal models for myocardial repair and regeneration (Li et al. 2013; Ye et al. 2014; Patrick et al. 2014). Contrarily, adult tissue-derived stem cells are easily accessible without ethical or moral issues, but with limited differentiation potential as compared to their pluripotent counterparts. Given their robust nature and autologous availability, three of them, including bone marrow-derived MSCs, mononuclear cells, and CSCs, have successfully progressed to the clinical assessment for myocardial repair (▶ Chap. 10, "Mesenchymal Stem Cells for Cardiac Repair").

Mesenchymal Stem Cells in Myocardial Repair and Regeneration

MSCs are self-renewing clonal precursors for nonhematopoietic tissues. They are characterized by preferential adherence to the plastic surface, expression of specific membrane markers, and trilineage differentiation potential (▶ Chap. 10, "Mesenchymal Stem Cells for Cardiac Repair"). Available data suggest that bone marrow-derived MSCs are suitable for the regeneration of infarcted myocardium. After decades of characterization in vitro, in small and translational experimental animal models, bone marrow-derived MSCs are the only cell type that has entered the advanced phases of clinical assessment. Hence, the fields of cell-based therapy, cell-free therapy (using conditioned medium and exosomes), and tissue engineering have primarily focused on MSCs owing to their wide range of properties, i.e., ease of availability and in vitro expansion, multilineage differentiation potential, paracrine activity, immunomodulatory and anti-inflammatory properties, etc. (Carson et al. 2018). However, the failure of the transplanted cells to thrive post engraftment in the infarcted myocardium has been generally ascribed to short-term beneficial effects of the cell therapy in most cases, both in the experimental settings and clinical trials, as further discussed in the next section.

Poor Survival of Stem Cells Postengraftment

Irrespective of the cell type, cell survival remains an issue in cell-based heart therapy (Li et al. 2021a). Like any other stem/progenitor cells, MSCs present a significant limitation post engraftment as they have a low survival rate after being transplanted in or around the infarcted myocardium, with the majority lasting for no more than 1 day (Penicka et al. 2005). Only a meager percentage of the transplanted cells survive for 3 months post-transplantation in some cases (Han et al. 2019). The massive death of the donor cells primarily occurs during early phase transplantation after ischemic injury. In one of the studies using [^{14}C]-thymidine-labeled cells, it was observed that only 44% of cells were present 10 min after intramyocardial injection, which decreased to 14% by 24 h and 7% after 72 h (Suzuki et al. 2004). Gyöngyösi et al. used a trifusion protein lentiviral transduction of porcine bone marrow MSCs to label them and study their fate after intramyocardial delivery. The trifusion protein included luciferase, red fluorescent protein (RPF), and herpes simplex thymidine kinase. PET-computed tomographic

metabolic and perfusion imaging was performed after intravenous injection of 10 mCi [18F]-FHBG, which showed decreased cardiac uptake of the delivered cells which was confirmed by luciferase activity as well. On day ten after injection, histological evidence showed 5.8% of the transplanted cells to survive in a porcine ischemic heart with a concomitant reduction in the infarct size (Gyöngyösi et al. 2008). On the same note, as little as 0.44% of the transplanted human MSCs were reported to survive by day 4 postengraftment in the experimental immune-deficient mice heart (Toma et al. 2002). The cells were labeled with *lac-z* reporter gene for tracking the fate of the cells posttransplantation. Similar results regarding the poor survivability of donor cells have also been reported in the clinical settings. For example, intracoronary infusion of ^{18}F-FDG-labeled MSCs showed meager 1.3–2.6% retention of the delivered cells after an hour of delivery (Hofmann et al. 2005).

As poor donor cell survival remains one of the primary limitations of cell-based therapy (Van Nguyen et al. 2021), the two primary mechanisms underlying donor cell death include the following: first, myocardial tissue turns inhospitable for the donor cells due to its highly acidic, hypoxic, cytokine-rich environment with scarcity of nutrients and high-level oxidative stress, and infiltration by the inflammatory and immune cells. Together, the molecular and cellular events in the infarcted myocardium present a significant challenge for transplanted stem cells, especially during the acute phase after ischemic injury (Bonvini et al. 2005; Chen et al. 2012). Second, the donor cells are not conditioned generally to withstand the rigors of the infarcted myocardium, in addition to anoiksis due to poor adhesion with the recipient's cardiac tissue during acute phase after transplantation (Zvibel et al. 2002), that lead the donor cells to undergo apoptosis (Tu et al. 2019).

Various strategies have been proposed to address the problem of massive loss of donor cells post engraftment. However, for the most part, these strategies have given dismal results. Nonetheless, preconditioning and reprogramming of cells by physical, chemical, genetic, and pharmacological manipulations have given encouraging data at least in the experimental settings to be pursued for clinical applications in the future (Haider and Ashraf 2012). Each preconditioning strategy primes the cells to withstand the severity associated with fatal ischemia in vitro and posttransplant (Wei et al. 2017).

Strategies to Enhance Donor Cell Survival

Stem Cell Preconditioning

Preconditioning refers to the protection of tissues and cells from injury when subjected to a subsequent innocuous environment. Preconditioning offers the most potent known cytoprotective effects in the physiological systems. Since the pioneering work of Charles Murry, conditioning from cyclical exposure to periodic ischemia-reperfusion sublethal episodes is cardioprotective via slowing down the rate of ATP depletion during ischemia and washing out of the catabolites during reperfusion (Murry et al. 1986). This strategy has been extrapolated to maintain its beneficial effects at the cellular and subcellular levels (Lu et al. 2010; Gu et al. 2021).

The underlying rationale of transient exposure to sublethal episodes of a noxious stimulus triggers a survival-signaling pathway that renders cells resistant to a subsequent lethal stimulus. More recently, the preconditioning strategy has been successfully extrapolated to condition stem cells to enhance their stemness properties in general and post engraftment survival in particular (Haider and Ashraf 2012).

Besides the classical ischemia-reperfusion-based treatment protocol, various pretreatment strategies have been developed and optimized to prime the cells into a "state of readiness" to combat chronic lethal exposure, which includes physical, chemical, genetic, and pharmacological manipulation of cells to mimic effects of ischemic pretreatment (Haider and Ashraf 2010). Haider et al. have reported the novel strategy of ischemic preconditioning of bone marrow-derived (MSCs) using short intermittent cyclical exposure to anoxia/reoxygenation (Kim et al. 2009). Elucidating the underlying mechanism, they have shown that their ischemic preconditioning protocol activated Akt(ser473) and Erk1/2(Thr202/Tyr204) with a consequent HIF-1α nuclear translocation and a consequent involvement of hypoxamir-210. Furthermore, real-time PCR array for rat apoptotic genes, computational target gene analyses, and luciferase reporter assay identified FLICE-associated huge protein (FLASH)/caspase-8-associated protein-2 (Casp8ap2) suppression in the preconditioned cells as the downstream target gene of miR-210 that was involved in cytoprotection. A subsequent experimental study by Haider et al. also showed a significant role of hypoxamir-107 in cytoprotection, and its simultaneous induction or concomitant transgenic overexpression with miR-210 in MSCs could mimic the cytoprotective effects of ischemic preconditioning (Kim et al. 2012a). The authors also observed that MSCs overexpressing miR-210 had higher survival postengraftment in the infarcted myocardium in the experimental rat model and contributed to the angiomyogenic repair of the myocardium (Kim et al. 2012b). Encouraged by the data, the authors have reported the development and optimization for preconditioning of stem cells via subcellular mechanism (Lu et al. 2010, 2012b). Some of the other strategies reported by the same group of researchers include pharmacological treatment, i.e., diazoxide, tadalafil, etc., (Niagara et al. 2007; Afzal et al. 2010; Haider et al. 2010; Suzuki et al. 2010), treatment with growth factors (Elmadbouh et al. 2011; Lu et al. 2012a), genetic modification of cells for growth factor overexpression, IGF-1, Netrin, etc., (Haider et al. 2008; Durrani et al. 2012), or concomitant transgenic overexpression of angio-competent growth factor and survival-signaling molecules, i.e., angiopoietin-1 and Akt, etc., (Jiang et al. 2006), treatment with small molecules, i.e., nicorandil, sodium butyrate, etc., (Tabeshmehr et al. 2017; Hosseini et al. 2018), and lysate from pharmacologically preconditioned cells (Afzal et al. 2008).

Augmenting the Myocardial Microenvironment Favorable for Donor Cells

The interaction between the microenvironment of the infarcted myocardium and the transplanted cells is one of the primary determinants of the outcome of myocardial cell therapy (Farhudg et al. 2019). In the case of MSCs, although MSCs have potent

anti-inflammatory and immunomodulatory effects, augmentation of the hostile myocardial microenvironment to make it favorable for receiving the donor MSCs postengraftment has been studied as an alternative approach to the donor stem cell preconditioning (Ezquer et al. 2017). In this regard, various strategies based on physical, chemical, or pharmacological pretreatment of the heart have been explored. For example, transient immunosuppression starting a few days before cell therapy results in significantly enhancing survival and engraftment of the transplanted cells in the infarcted heart (Xiao et al. 2004; Haider et al. 2004b). Similarly, during concomitant administration of cells with growth factor treatment, the latter helped as a modifier of the local microenvironment of the myocardium for the transplanted cells (Li et al. 2014). However, given the short biological half-life of the immunomodulating and tissue-modifying growth factors, the use of biomaterials loaded with growth factors and cytokines together with cell therapy is gaining popularity (Smagul et al. 2020). Another approach adopted during cell therapy has been to genetically modify the cells to secrete a cocktail of growth factors, which besides initiating survival signaling in the cells also provide a source of extended release of growth factors that favorably modify the microenvironment of the cell in the infarcted heart (Konoplyannikov et al. 2013).

Besides, genetic modification and growth factor treatment-based combinatorial approaches, some protocols are based on physical manipulation of the myocardial microenvironment to enhance its receptivity for the donor cells. For example, the cell-wave therapy approach has been effectively applied to the experimental animal models of MI and myocardial ischemia (Gollmann-Tepekoylu et al. 2018; Holfeld et al. 2016). After successful and encouraging data, it has progressed to safety and feasibility assessment in clinical trials (Assmus et al. 2013). The underlying mechanism has been attributed to the induction of toll-like receptor signaling, increased cell proliferation, increased level of VEGF, and mobilization and homing-in of endothelial cells besides cardioprotection (Aicher et al. 2006, Tepekoylu et al. 2013; Holfeld et al. 2014, 2016). Recent advancements in physical manipulation include ultrasound target bubble destruction (UTBD) to enhance vascular perforation and extravasation of the cells.

Treatment with statins in this regard has emerged as an approach that could simultaneously prime the cells and enhance the receptivity of the infarcted myocardium for donor cells.

Statins as Preconditioning Mimetic and Modifier of Myocardial Microenvironment

Introduction to Statins

Developed in 1987, statins are pharmacological agents that act as β-hydroxy β-methylglutaryl-CoA (HMG-CoA) reductase inhibitors (Endo 2010). The first statin to receive approval for clinical use was lovastatin, which naturally occurs in low concentrations in oyster mushrooms, red yeast rice, and other foodstuffs (Ferri and Corsini 2020). Over the years, a wide range of statins have been synthesized,

including atorvastatin, simvastatin, pravastatin, rosuvastatin, fluvastatin, and pitavastatin, each one with unique pharmacological characteristics but a common mechanism of action (Althanoon et al. 2020). Statins are designed to prevent three major categories of health conditions. First of all, they have been successfully used to attenuate the likelihood of cardiovascular diseases, including heart attack and stroke, especially in at-risk individuals older than 40 years. They are considered primary preventive treatment (Zeiser 2018). Second, statins lower the probability of further cardiovascular conditions in individuals suffering from cardiovascular disease referred to as secondary prevention. Finally, statins can prevent the development of hyperlipidemia by decreasing excessively high levels of blood cholesterol (Xu et al. 2013). There is a correlation between heightened cholesterol levels and cardiovascular disease. As such, statins are intended to diminish the likelihood of heart attack and stroke in the long term by reducing dangerously high levels of low-density lipoprotein (LDL (cholesterol (Ferri and Corsini 2020).

Functional Mechanism of Statins

Statins work by suppressing the enzyme HMG-CoA reductase, which functions as a rate-limiting enzyme within the mevalonate pathway associated with the production of cholesterol. Statins lower the blood LDL levels through competitive inhibition of HMG-CoA reductase (Stroes 2005). Another role fulfilled by statins is to decrease the amount of cholesterol that is produced by the liver. Internal physiological processes are the primary source of cholesterol in the circulation. The level of cholesterol in the blood declines due to statin-induced reduction of cholesterol produced by the liver (Young and Fong 2012; Zeiser 2018). The decrease in the levels of cholesterol triggers two events: LDL receptors are produced more extensively by liver cells to enable extraction of cholesterol from the bloodstream, and second, lipoproteins of low and extremely low density (the so-called “bad cholesterol”) undergo extraction and eventual conversion to bile acids and additional by-products (Han et al. 2019). Therefore, the function of statins is not limited to decreasing the levels of LDL cholesterol; instead, it extends more than that (Andrzejewska et al. 2019).

There is mounting evidence in the published data that statins contribute to endothelial cohesion and modulate inflammatory processes that can cause atheroma to develop. Moreover, statins keep plaque stable and make it less likely for blood clots to form (Xu et al. 2013). Additionally, statins regulate the proliferation, migration, and survival of tumor cells by regulating Rho, Ras, and Rac proteins. Further, they can also inhibit cancer cell growth by modulating specific other pathways.

The Impact of Statins on Mesenchymal Stem Cells

According to the published data, statins significantly enhance the outcome of cell-based therapy using MSCs. Studies on cardiac tissue engineering and myocardial

infarction therapy have reported that treatment strategies integrating statins and MSCs helped the heart function better by enhancing the LVEF and end-systolic pressure of the left ventricle while also contributing to myocardial repair by promoting cardiomyocyte protection and proliferation at the site of myocardial injury (Zeiser 2018; Cianflone et al. 2020). In vitro studies have also shown that treatment of CSCs with rosuvastatin, simvastatin, and pravastatin significantly enhances their proliferation and myocardial differentiation (Cianflone et al. 2020). These data have prompted nanoparticle-based and polymer-based delivery of statins to manage cardiovascular diseases (Nenna et al. 2021). Meanwhile, it has been proven that atorvastatin can ameliorate scar hypertrophy by reducing the thickness of the dermis and epidermis and by intensifying the production of the prorepair cytokine C-X-C motif chemokine ligand 8 (CXCL8) from MSCs of adipose origin in skin counterparts (Andrzejewska et al. 2019).

Studies on cardiac tissue engineering and myocardial infarction therapy have reported that treatment strategies integrating statin administration with MSCs-based therapy helped the global heart function to improve by enhancing LVEF and LV end-systolic pressure while also contributing to the cardiac repair mechanisms by promoting cardiomyocytes proliferation at the site of myocardial injury (Zeiser 2018) and attenuate myocardial hypertrophy (Nakagami and Liao 2004).

The potential of MSCs to differentiate appears to be affected by statins (Zeiser 2018). This conclusion is supported by observations that MSCs' osteogenic differentiation was encouraged by the release of simvastatin from poly (lactic-co-glycolic acid) (PLGA) nanoparticles integrated into bone substitute based on commercial calcium phosphate (Chamani et al. 2021). Overall, the proteins related to MSC osteogenic differentiation, including core-binding factor α1 (CBFA1), HIF-1α, and bone sialoprotein, are highly expressed in the presence of statins (Potier et al. 2007; James 2013). Furthermore, statins also enhance osteocalcin (OCN) gene expression, which reflects terminal differentiation of osteoblasts, and osteopontin (OPN), which is a sialoprotein with a high degree of phosphorylation present in the mineralized extracellular matrix (ECM) of bones and teeth and participates during the late phase osteoblast differentiation (Zurick et al. 2013). Moreover, some statins intensify the action of the osteogenic marker called alkaline phosphatase (ALP) (Xue et al. 2019; Chapman and Tanner 2021) and the expression of collagen type-Iα 1 (COL1A1) (Ruiz-Gaspa et al. 2007), which is vital for the development of ECM and osteogenic differentiation and is a marker of osteoblast maturation.

Statins may double bone morphogenic protein-2 (BMP-2) levels, which induces osteoblasts to differentiate (Alam et al. 2009). BMP-2 has a very short half-life; hence it is impractical to add it to the differentiation media in culture, which is why it is highly significant that MSCs are primed to produce BMP-2 in greater quantities to make it cost-effective and achieve sustained presence in the culture. In some cases, statin treatment has been combined with BMP-2 treatment to enhance osteoprecursor cells' differentiation (Park 2012). Furthermore, MSCs have elevated expression of Runt-related transcription factor 2 (RUNX2) in the context of simvastatin treatment (Chen et al. 2010). The discharge of simvastatin from TiO2 nanotubes has also been

shown to promote osteoblast differentiation and inhibit osteoclast resorption (Lai et al. 2017).

Statins and Stem Cell Preconditioning

Statins and In Vitro Experimental Studies

MSCs are deficient in nutrients and oxygen during ex vivo expansion. Though feasible, the supplementation of trophic factors in the culture medium is insufficient to support their stem cell functions optimally. Moreover, MSCs isolated from unhealthy and aging individuals or those maintained over an extended period undergo apoptosis and senescence. Besides other factors, these changes are caused by an imbalance between ROS generation and antioxidant mechanisms in the cells, leading to the inactivation of cytoprotective NO production and apoptosis.

Treatment of stem cells with statins as preconditioning mimetics has been extensively studied during in vitro experimental studies to exploit their ability to abrogate ROS activity and enhance NO activity (Wassmann et al. 2002). For example, Dong et al. (2011) have shown the cytoprotective effects of atorvastatin treatment on porcine BM-derived MSCs cultured under serum-free and hypoxic culture conditions (Dong et al. 2011). Molecular studies revealed that atorvastatin pretreatment significantly enhanced antiapoptotic protein Bcl2 expression in the cells besides higher level phosphorylation of AMPK and eNOS, which was abrogated in the presence of compound C, an inhibitor of AMPK. A similar molecular mechanism of atorvastatin-induced cytoprotection in MSCs has also been reported by several other research groups (Sun et al. 2006; Song et al. 2011; Zhang et al. 2012). Lovastatin also protects MSCs against hypoxia/serum deprivation-induced apoptosis, focusing on the mitochondrial pathway (Xu et al. 2008). Preconditioning with lovastatin (0.01–1 uM) significantly abrogated cytochrome c release from mitochondria, thus preventing the executioner caspase 3 activation. The cytoprotective effects of lovastatin preconditioning were abrogated by PI3K inhibitor LY294002, which inhibited ERK1/2 activation. These data showed the significant involvement of PI3K/Akt and MEK/ERK1/2 signaling in the cytoprotective effects of lovastatin preconditioning of MSCs. Zhang et al. have reported the RhoA/ Rho-associated coiled-coil-forming kinase (ROCK)/ERK pathway role in protecting cells against hypoxia and serum deprivation in culture conditions (Zhang et al. 2014). Treatment with atorvastatin enhanced cell survival, which was mimicked by ROCK inhibitor fasudil. The involvement of RhoA/ROCK in cardiomyocyte protection has also been reported after fluvastatin treatment (Yi et al. 2020).

Izadpanah et al. studied the impact of statin treatment on MSCs' biological characteristics (Izadpanah et al. 2015). They treated ex vivo cultured MSCs with atorvastatin and pravastatin at clinically relevant concentrations and studied their rate of proliferation and differentiation potential. After statin treatment, the authors observed significantly increased doubling-time and colony-forming units in both young and old donor adipose tissue-derived MSCs. Moreover, statin treatment also

reduced MSCs' osteogenic and chondrogenic differentiation potential besides their macrophage differentiation. Molecular studies revealed upregulated expression of p16, p53, caspase 3, 6, and 9 in the statin-treated MSCs.

A recently published study by Nantavisai et al. has reported that simvastatin treatment enhanced the expression of pluripotency markers in canine bone marrow-derived MSCs besides increasing their proliferation (Nantavisai et al. 2019). Treating the cells with four different doses of simvastatin ranging from 0.1 nM to 100 nM, the authors observed a dose-dependent increase in the rate of cell proliferation on days five and seven after treatment. Molecular studies revealed increased cyclin D1 and D2, Ki67 and antiapoptotic protein Bcl2, and reduced caspase-8 and -9 expressions at higher doses. Low-dose treatment increased the propensity of Rex1 and Oct4 expression.

Statins and in vivo Experimental Animal Models

A systematic review and meta-analysis of 5 studies regarding the combined efficacy of atorvastatin and MSCs-based cell therapy for treating acute myocardial infarction (AMI) in experimental animal models clearly shows the superiority of the combinatorial therapeutic approach over either treatment alone (Dai et al. 2015). The pooled analysis of the studies showed a significantly improved LVEF in the combined treatment group than MSCs-treated group without atorvastatin. The systematic review concludes that combining MSCs-based cell with atorvastatin-based pharmacotherapy is a more effective therapeutic approach for further assessment in the clinical settings. On the same note, a systematic review of 38 studies, including 18 preclinical studies involving statin-treated MSCs-based cell therapy, has reported significantly improved biology and stemness characteristics of stem/ progenitor cells. The combined treatment approach using preconditioned MSCs with statin therapy led to improved organ function (Park et al. 2016).

Combined Statin and MSCs-Based Cell Therapy

Using a mini-swine experimental model of acute myocardial infarction, Dong et al. reported significant enhancement of the therapeutic efficacy of combining cell-based therapy with daily atorvastatin treatment (0.25 mg/kg) after intramyocardial delivery of the cells, with or without L-NNA treatment, an inhibitor of atorvastatin (5 mg/kg/day) (Song et al. 2013). Interestingly, atorvastatin treatment significantly enhanced the donor cell survival postengraftment. Single-photon emission-computed tomography (SPECT) revealed reduced areas of the perfusion defect. At the same time, MRI showed significantly improved LVEF 4 weeks after treatment with a concomitant reduction in infarct size, the extent of fibrosis, and the rate of apoptotic cells in the combined atorvastatin and MSCs-treated animals as compared to the control animal group. The authors attributed the beneficial effects to improved donor cell survival, reduction in inflammatory markers, i.e., CRP, and improved paracrine activity of MSCs in the presence of atorvastatin. Similar data have also been reported when simvastatin was administered after MSCs-based cell therapy as a part of the

combinatorial approach (Yang et al. 2009). At 6 weeks, MRI revealed significantly attenuated infarct size and the number of dyskinetic segments. Treatment with simvastatin also reduced the number of apoptotic cells in the myocardium.

Treatment with atorvastatin has been reported to accentuate SDF-1α expression in the infarcted myocardium via nitric oxide production, which is generally increased in response to ischemic injury (Qiu et al. 2012). Tian and colleagues have reported atorvastatin-induced activation of the SDF-1α/CXCR4 axis as the possible underlying mechanism for their observed improvement in cardiac function in a rodent model of acute myocardial infarction (Tian et al. 2019). The authors exploited the elevated SDF-1α release from cardiomyocytes in response to ischemic injury and induction of CXCR4 on MSCs in response to atorvastatin preconditioning. Transplantation of atorvastatin-preconditioned MSCs significantly reduced scar formation and improved indices of myocardial function at 4 weeks after treatment. Interestingly, transplantation of preconditioned MSCs combined with oral administration of atorvastatin (10 mg/kg/day) potentiated the efficacy of preconditioned cells which was blocked by AMD3100 (SDF-1/CXCR4 specific antagonist). The same research group has also reported enhanced expression of CXCR4 on endothelial cells and increased emigrational activity of MSCs in a rat heart model of ischemia-reperfusion injury (Chiang et al. 2015; Cai et al. 2013).

Li et al. 2015 have also reported increased CXCR4 expression in atorvastatin-preconditioned MSCs within 24 h after preconditioning as evidenced by flow cytometry and real-time PCR and confirmed by a transwell system, which revealed their enhanced emigrational activity in response to SDF-1α gradient (Li et al. 2015). Intravenously delivered atorvastatin-primed MSCs homed-in to the infarcted rat heart in significantly higher number than the naïve (nonpreconditioned) MSCs and showed significantly higher survival on day 30 after transplantation. Moreover, treatment with preconditioned MSCs preserved the infarcted heart function and significantly reduced fibrotic tissue in the infarcted rat heart. While elucidating the molecular mechanism underlying the improved emigrational activity of atorvastatin-treated MSCs, it was observed that the induction of the CXCR4 expression was regulated by miR-146a, thus establishing miR-146a as a potential target to modulate MSCs' emigrational activity (Li et al. 2021b).

Rosuvastatin is considered a "super statin" due to many of pharmacological functions, including strong anti-inflammatory and antioxidant properties. Akin to atorvastatin, rosuvastatin treatment has been reported to enhance MSCs survival postengraftment in the infarcted heart (Fu et al. 2016; Zhang et al. 2013). Fu et al. hypothesized that combining rosuvastatin with MSCs transplantation would enhance the survival of transplanted cells via attenuation of inflammatory response in the infarcted myocardium (Fu et al. 2016). Using an experimental rat model of coronary microembolization, using microthrombotic particles (MTPs), GFP-labeled allogenic MSCs were delivered by intracardiac injection (into the left ventricle) simultaneously with MTPs. Rosuvastatin was administered 7 days before the cell transplantation and continued until 7 days after cell delivery. The authors observed significant reduction in proinflammatory cytokines, i.e., TNF-α, IL-1β, as well as infiltration of inflammatory cells. Rosuvastatin treatment significantly enhanced the

transplanted MSCs' survival (~45 fold) with concomitant increase in proangiogenic factors, i.e., VEGF and bFGF. In another study combining rosuvastatin (10^{-6} mmol/L) treatment with MSCs engraftment, Zhang et al. used murine MSCs expressing luciferase and GFP (Zhang et al. 2013). Rosuvastatin treatment significantly enhanced transplanted cells' viability and reduced cardiomyocyte apoptosis rate in the infarcted myocardium with a significant reduction in the area of fibrosis. Molecular studies showed enhanced Akt and ERK activation and reduction in proapoptotic proteins, including Bim and Bax. Another important observation was improved paracrine activity of the transplanted cells, which were counted as an integral part of the underlying mechanism leading to the overall reduction in apoptosis and improved cardiac function.

The Janus kinase (JAK /Signal transducers and activators of transcription (STAT) signaling is another essential pathway activated during statin treatment of MSCs and majorly impacted the efficacy of preconditioned cells (Xu et al. 2011). JAK/STAT is well documented for its role in cell stress response and cardioprotection (Kurdi and Booz 2009; Kiu and Nicholson 2012). The combinatorial treatment approach involving MSCs-based cell therapy and concomitant treatment with rosuvastatin provides an alternative approach that helps to render the cardiac microenvironment conducive for the transplanted cells rather than directly preconditioning the cells. Xu et al. have reported significantly improved survival, engraftment, and differentiation of the sex-mismatched transplanted MSCs in an infarcted female rodent heart model (Xu et al. 2011). Starting 1 day before intramyocardial injection of $2x10^6$ MSCs, rosuvastatin administration (4 mg/kg/day) was continued until 5 weeks with or without AG-490 treatment (JAK/STAT inhibitor, CalBiochem). The authors provided histological evidence of significant angiomyogenic activity in and around the infarcted myocardium, clearly abrogated by AG-490. There was a substantial improvement in cardiac function indices, including LVEF and LVFS, and reduction in the fibrotic area at 4 weeks after combined MSCs and statin treatment. Western blot analysis showed accentuation of JAK-STAT phosphorylation in rosuvastatin treatment animal hearts. More specifically, phospho (p)JAK2/JAK2, pSTAT1/STAT, and pSTAT3/STAT3 were significantly higher in the combined treatment group than the MSCs alone treated animal hearts. Another significant signaling pathway reported in cytoprotection in response to atorvastatin treatment is RhoA/ Rho-associated coiled-coil-forming kinase (ROCK), reported in experimental female heart model with AMI after sex-mismatched MSCs transplantation (Zhang et al. 2014). The cells showed significantly enhanced survival but with little evidence of transdifferentiation. Moreover, atorvastatin treatment has significant immunomodulatory effects with a pronounced reduction in proinflammatory cytokines.

In summary, these studies provide mounting evidence that combined treatment with statin supported the reparability of the transplanted MSCs by rendering the myocardial milieu conducive for their survival and functioning. For example, at molecular and subcellular level, it has been reported that simvastatin and atorvastatin attenuate collagen and collagen-associated proteins expression in the infarcted myocardium, while simvastatin promotes exosome release from the cardiomyocytes,

which are rich in decorin and deficient in periostin contents (Zeng et al. 2019; Kuo et al. 2019).

Using Statin-Preconditioned MSCs to Treat AMI

For optimal therapeutic outcome, Xu et al. combined atorvastatin-preconditioned MSCs with atorvastatin therapy at three different time points after AMI and delivered one to three cell injections (Xu et al. 2019a). In their extensive experimentation divided into two parts, the authors first determined the time of peak level SDF-1α expression in the infarcted heart post ischemic episode. Based on their findings, the second half of the experiment was designed to assess the time of intravenous delivery of atorvastatin-preconditioned MSCs at early, mid, and late time-point delivery of single, double, and triple doses of the cells with or without intensive treatment with atorvastatin. A total of 215 female rats were randomized in 11 different treatment groups. Although therapeutic benefits were observed in all the cell treatment groups of animals, the highest therapeutic benefits were achieved in the late-treatment group of animals with triple injections, which showed significantly higher homing of the delivered cells into the infarcted myocardium as compared to the other treatment groups. These animals also had significantly reduced infarct size, attenuated fibrosis, and improved cardiac function; there was little evidence of cardiomyogenic differentiation of the preconditioned MSCs. Besides showing the therapeutic significance of the statin-based preconditioning approach, these data also showed the importance of a multiple cell delivery strategy.

The use of MSCs-derived exosomes is gaining popularity for the treatment of injured myocardium as it alleviates the unwanted effects of cell-based therapy (Haider and Aramini 2020; Haider and Aslam 2018). A recent advancement in the atorvastatin-based combinatorial approach is based on the use of atorvastatin and MSCs-derived exosomes as part of the fast-emerging cell-free therapy for the treatment of ischemic stroke for neurological recovery (Safakheil and Safakheil 2020).

A summary of the various experimental animal studies involving the use of atorvastatin preconditioned MSCs or MSCs-based cell therapy combined with atorvastatin treatment is given in Table 1.

Statin-Based Preconditioning of MSCs and Exosomes

Preconditioned stem/progenitor cells release exosomes with enormous therapeutic potential as compared to the exosomes derived from naïve MSCs (Panda et al. 2021). For example, atorvastatin-preconditioned MSCs-derived exosomes had significantly higher proangiogenic potential for diabetic wound healing than exosomes derived from naïve (nonpreconditioned) MSCs (Yu et al. 2020). Treatment of human umbilical vein endothelial cells (HUVEC) in vitro with atorvastatin-preconditioned MSCs-derived exosomes significantly enhanced their emigrational potential, tube formation, and VEGF expression with the possible involvement of Akt/eNOS signaling and downstream upregulation of miR-221-3p.

Besides other effects, priming the MSCs with atorvastatin prompted the cells to release exosomes with significantly higher cardioprotective effects than the

Table 1 Summary of the important experimental animal studies reported using MSCs-based cell therapy combined with statin treatment as a combinatorial approach or for preconditioning of MSCs before transplantation

Animal model	Cells and route of delivery	Statin used	Summary of results	Reference
Swine experimental model of AMI	3x 10^7 cells by intramyocardial injection of MSCs	Atorvastatin 0.25 mg/kg/day	The intramyocardial delivery of MSCs was carried out in a mini swine heart model of AMI immediately after reperfusion The animals were pretreated without or with atorvastatin 30 days later, significantly higher survival of transplanted cells was observed in the atorvastatin-pretreated animals. MRI and SPECT showed significantly improved cardiac function and myocardial perfusion. Also, combined treatment reduced cardiomyocyte apoptosis, oxidative stress, and the suppression of proinflammatory cytokines in the infarcted myocardium	Yang et al. 2008
Rat-experimental model of AMI	1x 10^6 cells by intramyocardial injection	Atorvastatin 10 mg/kg/day	MSCs were cocultured with cardiomyocytes in transwell system and showed GATA4 and cTn-I expression and were used for transplantation study using non-cocultured MSCs as a control. Atorvastatin or vehicle was administered starting 24 h after AMI Four week later, the rate of survival of the cells and differentiation	Cai et al. 2011

(continued)

Table 1 (continued)

Animal model	Cells and route of delivery	Statin used	Summary of results	Reference
			was significantly higher in atorvastatin-treated animals. Also, significantly reduced inflammatory cytokines (i.e., TNF, VCAM, and CRP), myeloperoxidase activity, and infiltrating cells were observed by day 28 after treatment	
Rabbit experimental model of AMI	4x107 cells by intramyocardial injection	Atorvastatin 1.5 mg/kg/day	Thirty rabbits equally divided to receive no treatment, MSCs, and combined MSCs with atorvastatin. The combined treatment acted synergistically to improve LVEF, decreased LV-systolic and diastolic dimensions, reduced area of fibrosis, and reduced the inflammatory cell infiltration into the infarct zone There was significant improvement in MSCs survival as well as reduction in cardiomyocyte apoptosis	Qu et al. 2013
Rat model of chronic MI (7 days after MI)	2x 10^6 sex-mismatched MSCs by intramyocardial injection	Combined MSCs and Rosuvastatin 4 mg/kg/day	Significantly higher level survival of sex-mismatched MSCs in the infarcted heart which showed higher level cardiogenic differentiation as well. There was significantly higher angiogenic response Molecular studies revealed JAK/STAT pathway activation which was abrogated	Xu et al. 2011

(continued)

Table 1 (continued)

Animal model	Cells and route of delivery	Statin used	Summary of results	Reference
			by AG-490. There was significant reduction in cardiomyocyte apoptosis, reduction in fibrosis, and better functional improvement	
Swine experimental model of AMI	3x 10^7 cells by intramyocardial injection	Atorvastatin 0.25 mg/kg/day	Forty-two swines with AMI were grouped to receive sham, AMI control, MSCs, MSCs+ statin, and MSCs+statin+L-NNA. Four weeks after treatment, decreased perfusion defect areas on SPECT and metabolism by PET, significantly increased LVEF by MRI, and reduced apoptosis and area of fibrosis. The benefits were partially blocked by L-NNA which showed the involvement of eNOS activation	Song et al. 2013
Rat heart model of coronary microembolization	2x 10^6 GFP-labeled MSCs by intramyocardial injection	Rosuvastatin 3 mg/kg/day starting 7 days earlier until 7 days after cell treatment	Rosuvastatin treatment significantly reduced proinflammatory cytokines, i.e., TNF-a and IL-1b in the embolized myocardium, besides reduced infiltration of inflammatory cells Transplanted cell survival was significantly higher in rosuvastatin-treated animal hearts. Proangiogenic growth factors, i.e., VEGF and bFGF, increased significantly leading	Fu et al. 2016

Table 1 (continued)

Animal model	Cells and route of delivery	Statin used	Summary of results	Reference
			to enhanced angiogenic response	
Rat model of experimental AMI	$5x10^6$ sex-mismatched MSCs by intramyocardial injection	Atorvastatin 10 mg/kg/day	Atorvastatin treatment combined with male donor MSCs transplantation in female recipient infarcted heart. Significantly higher survival of the donor cells; however, no trans differentiation was observed in the transplanted cells. However, significantly reduced proinflammatory cytokines with concomitant reduction in ROCK and ERK activities	Zhang et al. 2014
Rat model of experimental AMI	$2x10^6$ MSCs via tail vein injection	Combined atorvastatin 10 mg/kg/day or preconditioned MSCs	Atorvastatin pretreatment of MSCs significantly enhanced CXCR4 expression on the cells which enhanced their migration in response to SDF-1α in transwell system. Intravenous delivered preconditioned MSCs in a rodent heart model of AMI successfully homed-in to the infarcted myocardium, leading to improved cardiac function parameters as compared to the control animals and attenuated LV remodeling. The study proved the significance of SDF-1α/CXCR4 axis for homing and engraftment of	Li et al. 2015

(continued)

Table 1 (continued)

Animal model	Cells and route of delivery	Statin used	Summary of results	Reference
			intravenously delivered MSCs	
Rat model of experimental AMI	$2x10^6$ MSCs by intramyocardial injection	Combined atorvastatin 10 mg/kg/day or preconditioned MSCs	115 female rats with AMI divided into six groups of treatment (n = 15 per group). Atorvastatin preconditioned MSCs combined with atorvastatin therapy showed significant emigrational activity via activation of SDF-1α/CXCR4 signaling, the cells homed-in to the infarcted heart. Significant improvement in cardiac function parameters besides reduction in infarct size. The therapeutic benefits were abrogated by AMD3100 treatment	Tian et al. 2019
Rat model of experimental MI	$2x10^6$ MSCs via tail vein injection	Combined atorvastatin 10 mg/kg/day or preconditioned MSCs	First part of the experiment determined the time point at which SDF-1α level was maximum in the heart after MI (in 150 rats). In the second part, 215 female rats were randomized into 11 treatment groups ($n = 15$ rats per group) receiving preconditioned cells early, mid, and late time points using single dose, two doses, or three doses. All cell therapy groups showed significant homing-in of the transplanted cells; however, the	Xu et al. 2019a

Table 1 (continued)

Animal model	Cells and route of delivery	Statin used	Summary of results	Reference
			highest cell number was achieved in late treatment group with triple injections. This group also showed highest angiogenesis when combined with atorvastatin treatment, with significantly reduced infarct size and area of fibrosis. There was little evidence of myogenic differentiation of the preconditioned cells	
Rat model of experimental AMI	Exosome derived from atorvastatin-preconditioned MSCs		Treatment with exosomes promoted significantly higher angiogenesis in the infarcted myocardium. There was significant reduction in proinflammatory cytokines IL6 and TNF in the infarcted myocardium. The exosomes derived from preconditioned MSCs were rich in lncRNA H19 to regulate miR-675 and activation of VEGF and intracellular adhesion molecule-1. Moreover, there was significant reduction in cardiomyocyte apoptosis in and around the area of infarct	Huang et al. 2020

AMI, Acute myocardial infarction; ERK1/2, Extracellular regulated protein kinase; L-NNA, NG-nitrol-L-arginine; LV, Left ventricle; LVEF, Left ventricular ejection fraction; MRI, Magnetic resonance imaging; PET, Positron Emission Tomography; ROCK, Rho-associated coiled-coil-forming kinase; SDF-1α, Stromal cell-derived factor-1α; SPECT, Single-Photon Emission-Computed Tomography; VEGF, Vascular endothelial growth factor; lncRNA, Long noncoding RNA

exosomes derived from naïve MSCs without atorvastatin treatment (Huang et al. 2020). Exosomal lncRNA sequencing of atorvastatin-primed MSCs showed nearly 450 lncRNA with upregulated expression (more than 1.5-fold increases) compared to the exosomes from naïve MSCs. Exosomal lncRNA H19 was increased almost 13-fold and had significant participation in angiogenesis and cardiac protection. Treatment of experimentally infarcted rodent heart with atorvastatin-primed MSCs-derived exosomes was cardioprotective, reduced cardiomyocyte apoptosis, increased angiogenesis, and reduced proinflammatory IL6 and TNF expression in the infarcted myocardium, which was attributed to the immunomodulatory effects of statins.

Although statin treatment enhances the therapeutic efficacy of the stem cell-derived exosomes, pretreatment of MSCs has been shown to abrogate exosome generation by the stem cells. For example, pretreatment of bone marrow-derived MSCs with simvastatin significantly reduces exosome biogenesis by depleting the synthesis of proteins needed for the generation of exosome (Kulshreshtha et al. 2019).

In vitro studies with atorvastatin-primed MSCs-derived exosomes showed significantly enhanced endothelial cell survival, emigrational potential, and tubulogenesis.

Combined Statin and Cell-Based Therapy for AMI Patients

Based on the encouraging data from small experimental animal models and translational studies (Table 1), and cardioprotective effects of high-dose atorvastatin treatment in the clinical settings (Teshima et al. 2009; Kim et al. 2010; Barbarash et al. 2015), combined statin and cell-based therapy has progressed to the clinical phase to treat patient with myocardial infarction. Xu et al. have designed TEAM-AMI (ClinicalTrials.gov Identifier: NCT03047772), a randomized double-blind placebo-controlled multicenter clinical trial of transplantation efficacy of autologous bone marrow mesenchymal stem cells with intensive atorvastatin in acute myocardial infarction patients (Xu et al. 2019b). The study was designed to enhance the efficacy of MSCs via combined therapy with atorvastatin by promoting their survival post engraftment in patients with anterior St-segment elevation MI. The patients were randomized to receive either routine atorvastatin therapy (20 mg/day) with placebo or intravenous injection of MSCs, or 80 mg/day or placebo (1:1:1:1). The primary end point of the study was absolute change in LVEF while the secondary end points were global cardiac function, remodeling, and regeneration. The study is anticipated to enroll 124 patients, and no data from it has been published as yet although the study was to be completed in 2018.

The same research group has registered another similar study STEM-AMI with an official title "Strengthening transplantation effects of bone marrow mononuclear cells with atorvastatin in myocardial infarction" (ClinicalTrials.gov Identifier:

NCT00979758) (Yang et al. 2020). The study used intensive atorvastatin treatment in combination with bone marrow-derived mononuclear cells rather than MSCs. The Phase 2 study was intended to "precondition" the cardiac microenvironment to make it less harsh and conducive for the transplanted cells to support their survival and reparability. A total of 100 patients (30–80 years) having LVEF <45% were enrolled in the study to receive either normal (20 mg/day) or high (80 mg/day) doses of atorvastatin with intracoronary mononuclear cells or placebo injections 2–4 weeks after STEMI. One year follow-up studies revealed that cell transplantation significantly improved LVEF as compared to the total placebo-treated patients. Only atorvastatin + mononuclear cell-treated patient group showed significantly improved LVEF as compared with placebo + atorvastatin-treated patients. Similarly, PET revealed significantly decreased fibrosis and increased viable myocardium in atorvastatin + mononuclear cell-transplanted animals. These data supported the combined atorvastatin and mononuclear cell-based therapy as more efficacious as compared to either of the treatment approach alone. The augmented efficacy of mononuclear cell-based therapy was attributed to the cytoprotective effects of atorvastatin on the infarcted myocardium, thus rendering it favorable for the transplanted cells.

Some earlier clinical studies have also reported significant mobilization of endothelial progenitor cells and homing in to the heart in response to atorvastatin treatment from the bone marrow and home-in to the myocardium after myocardial infarction (ClinicalTrials.gov Identifier: NCT00536887) (Hong et al. 2010) and coronary artery bypass surgery (ClinicalTrials.gov number, NCT01096875) (Baran et al. 2012).

Conclusion and Future Perspective

The modest outcome of most clinical trials in regenerative medicine has been attributed to the quality of the cell preparation besides the cytokine-rich harsh microenvironment of the infarcted myocardium, both of which interject to the massive death of the transplanted cells post engraftment. Hence, preconditioning of the donor cells to develop "super cells" (Haider & Ashraf, 2007) that could withstand the rigors of the infarcted heart and "fertilizing" the cardiac milieu (Xu et al. 2019; Yang et al. 2020) to make it favorable for the transplanted cells, especially during acute phase after infarction episode, remains the cornerstone of the ongoing research in cardiovascular regenerative medicine. In this regard, pharmacological preconditioning approach has come a long way in addressing both cell quality-related as well as cardiac milieu-related issues to achieve optimal outcome of cell-based therapy. The primary advantage of pharmacological preconditioning approach is that the drug molecules used in there already have an established safety profile for human use.

As discussed earlier, statins are known for their significant cytoprotective effects on MSCs and cardiomyocytes during in vitro and in vivo experimental animal models and during clinical studies in myocardial damage repair. Preconditioning of MSCs with statins before transplantation and combined treatment of cell therapy

with statin therapy has given encouraging results in the translational as well as clinical settings. The synergy between the intrinsic antiapoptotic and immunomodulatory properties of MSCs and pleiotropic action of statins, i.e., endothelial protection, immunomodulation, reduction in antioxidant stress, etc., together renders the cardiac environment favorable for the transplanted cells and augments their reparability. The combinatorial approach also involves stem cells from the intrinsic pool to home-in to the myocardium to participate in the myocardial repair and regenerative processes. Looking into the future, it is imperative that more research into the application of the different types of statins for myocardial damage repair be conducted. With the recent emergence of cell-free therapy approach, further characterization of statin-preconditioned MSCs-derived exosomes and their payload, and profiling of the conditioned medium from statin-preconditioned cells (Nowak et al. 2019), may offer ample opportunities for cardiovascular application to reduce morbidity and mortality due to myocardial injury. The potential of translating this research into successful clinical application looks bright; however, the statin-preconditioning regime should be tailored quite significantly depending on the nature and properties of the ischemic event. A summary of statin-based combined treatment approach with MSCs-based therapy for myocardial repair is outlined in Fig. 1.

Abstract

Despite many advancements that have been made in the field of cardiovascular research, heart failure is still associated with a poor prognosis and high mortality worldwide. The discovery that adult cardiomyocytes have an extremely low turnover rate has prompted researchers to investigate stem cells as a therapeutic option for cardiac regeneration. With stem cell therapy now approaching its third decade, numerous clinical trials have been completed and questions surrounding stem cell therapy are starting to be answered. It is now fairly well established that stem cell therapy has a positive safety profile, but only has produced neutral to moderately positive clinical outcomes. It is also clear that current stem cell therapies lack a significant ability to engraft and remuscularize the myocardium, suggesting cardiac repair occurs primarily through paracrine signaling mechanisms. Innovative strategies involving cardiac bioengineering, cell-free biomolecules, and combination therapies likely hold the key to advancing the field to the next stage. Looking ahead, we remain cautiously optimistic that stem cell therapeutics will have a significant place in the future of cardiovascular treatments, but there are still many questions that need to be answered before routine clinical application is possible.

Keywords

LVEDV	Left ventricular end diastolic volume
LVEF	Left ventricular ejection volume
LVESV	Left ventricular end systolic volume
MI	Myocardial infarction
MLHFQ	Minnesota Living with HF Questionnaire
MPC	Mesenchymal precursor cell
MSC	Mesenchymal stem cell
NYHA	New York Heart Association
PCI	Percutaneous coronary intervention
PDGF-B	Platelet-derived growth factor B
PSC	Pluripotent stem cell
SDF-1	Stromal cell-derived factor-1
SM	Skeletal myoblast
VEGF	Vascular endothelial growth factor

Introduction

Cardiovascular disease is a significant worldwide health issue that consistently ranks among the leading causes of death and disability-adjusted life years lost (Abbafati et al. 2020). Cardiovascular disease is an umbrella term used for numerous cardiac and peripheral vascular pathologies including heart failure. Heart failure (HF) is a global epidemic that impacts the quality of life, life expectancy, and the economics of the health care system. In the USA and Europe, HF is the leading cause of hospitalization with over one million admissions as a primary diagnosis (Ambrosy et al. 2014). Moreover, it represents up to 2% of total hospitalizations in these regions, with minor improvements in post-discharge mortality rates. It is estimated that there are over six million people in the USA living with HF, and this number is expected to increase to over eight million by 2030 (Mozaffarian et al. 2016; Virani et al. 2021). Globally, HF affects 26 million people, imposing an immense burden on international health care systems and society as a whole (Cheung and Jahan 2020).

Heart Failure

Heart failure is a complex clinical syndrome characterized by structural and functional abnormalities which impair ventricular filling or ejection of blood

(Gaglianello et al. 2016). These changes in cardiac function are highly problematic as they result in inadequate perfusion of vital organs and peripheral tissues. This mechanical pump failure consequently results in an inability of the heart to meet the body's metabolic demands. Heart failure is commonly classified as HF with reduced ejection fraction (HFrEF) or HF with preserved ejection fraction (HFpEF). HFrEF is defined as a left ventricular ejection fraction (LVEF) of less than 40%. Conversely, HFpEF is defined as an LVEF greater than 50% (Gaglianello et al. 2016). These classifications are essential, as they provide the information necessary to determine the appropriate management strategy and prognosis of the disease. Another important point to consider is the clinical severity of HF, which is graded based on the New York Heart Association (NYHA) functional classification. It defines four functional classes of heart failure – from class 1 being the least severe to class IV being the most severe (Inamdar and Inamdar 2016). Patients can move between classes relatively quickly as this classification system focuses on symptoms only. Moreover, the American College of Cardiology and the American Heart Association (ACC/AHA) HF staging system was created to complement the NYHA functional classification. With the ACC/AHA classification, there is no moving backward to prior stages. Once symptoms have developed, the patient is in stage C HF and will never again be classified in stage B. Together, the NYHA functional classification and the ACC/AHA clinical tools are useful in estimating the progression and future outcome of the disease.

The causes of heart failure are numerous – coronary artery disease, diabetes, hypertension, idiopathic cardiomyopathies, pressure overload, volume overload, cardiotoxic drugs, metabolic conditions, and inflammatory and hereditary conditions are common culprits. Nonetheless, the most common etiology of HF remains myocardial infarction (MI) (Tanai and Frantz 2015). Myocardial infarction results in ischemia, necrosis of cardiomyocytes (CMs), and fibrotic scar tissue formation (Mouton et al. 2018). The extent of CM damage depends on the duration of ischemia and the size of the zone of infarction. If the MI is not treated on time, severe structural and functional impairments ensue. Following an MI, compensatory mechanisms such as activation of the sympathetic nervous system and the renin-angiotensin-aldosterone system work together to maintain adequate cardiac output and blood flow to vital organs (Gaglianello et al. 2016). Over time, these responses are often insufficient as they result in fluid retention and adverse remodeling of the chambers of the heart. Cardiac remodeling typically results in CM hypertrophy, resulting in decreased cardiac contractility. Following these changes, a progressive decline in cardiac function is observed until the heart ultimately fails to pump completely (Tables 1 and 2).

Table 1 New York Heart Association Functional Classification of Heart Failure

Class	Symptoms
I (Mild)	No symptoms[a] during normal physical activity (walking, stairs)
II (Mild)	Mild symptoms[a] and slight limitations during normal physical activity
III (Moderate)	Moderate symptoms[a] with significant limitations in physical activity. Comfortable only at rest
IV (Severe)	Severe symptoms[a] that markedly limits activity and are present even at rest

[a]Symptoms – fatigue, chest pain, palpitations, dyspnea, and syncope

Table 2 American College of Cardiology/American Heart Association Heart Failure Staging System

Stage A	Patients at high risk for heart failure who have not yet developed structural heart changes
Stage B	Patients with structural heart disease (i.e., reduced ejection fraction, left ventricular hypertrophy, and chamber enlargement) who have not yet developed symptoms of heart failure
Stage C	Patients who have structural heart disease and have developed symptoms of heart failure
Stage D	Patients with refractory heart failure requiring specialized intervention (transplantation and left ventricular assist device)

Due to the high quality of medical care and revascularization techniques such as coronary artery bypass grafting (CABG) and percutaneous coronary intervention (PCI), survival rates following MI have increased (Skinner and Cooper 2011; Ambrosy et al. 2014). However, as patient survival increases, cases of HF are rapidly growing. Symptoms of HF are frequently homogenous, yet the progression of the disease and the pathological processes are diverse, warranting a holistic approach to treatment. It is recommended that patients incorporate both pharmacological and nonpharmacologic therapies to improve the functional capacity of the heart – reducing its workload (Gaglianello et al. 2016). Triple therapy, consisting of diuretics, angiotensin-converting enzyme inhibitors (ACE inhibitors), and beta-blockers, are some of the most common symptom management strategies for HF patients and have been particularly beneficial in HFpEF. Moreover, implantable cardiac defibrillators and ventricular assist devices are options for more severe cases. Heart transplantation is considered the gold standard for treatment, yet it yields a high cost, immune reactions are common, and there remains a major discrepancy between the availability of donors and recipients (Rojas and Haverich 2019; Mohite et al. 2015; Liu et al. 2020). Despite many therapeutic options available, the prognosis of HF remains poor, with a 5-year mortality rate of around 50% and a 10-year survival rate of only 20% (Gaglianello et al. 2016). These statistics warrant a treatment that can stop the progressive nature of the disease while restoring cardiac function. Due to the limited endogenous regeneration potential of the heart, stem cells as a therapeutic option to treat HF have gained interest globally. In the last few decades, stem cells have been extensively studied to treat patients living with HF.

Regenerative Potential of Stem Cells

The use of stem cells to generate healthy cells or replace diseased cells is not a novel idea. Historically, doctors have performed stem cell transplants – also known as bone marrow transplants. In these transplants, stem cells replace cells that have been damaged by disease or chemotherapy and serve as a vehicle for the recipient of these cells to fight off various forms of hematological cancers – leukemia, lymphoma, and

multiple myeloma. In regenerative medicine, the unique potential of stem cells is based on two important qualities: the ability to self-replicate and the potential to differentiate into mature, functional cell phenotypes (Zakrzewski et al. 2019).

Stem cells can be divided into two broad categories – pluripotent stem cells (PSCs) and adult stem cells. Adult stem cells are more differentiated and are limited to give rise to only certain sets of cells or tissues of the body (Singh et al. 2016). These can be broken down into derivatives from the bone marrow, cardiac tissue, skeletal muscle, umbilical cord, and adipose tissue. Human ESCs are termed pluripotent, meaning that they can divide into any cell type found in the body. These cells are incredibly versatile and can be used to repair or regenerate damaged or diseased tissues and organs. However, they are limited by important ethical implications as they arise from the blastocyst of an embryo. Novel protocols have been developed to reprogram adult stem cells to have properties of embryonic stem cells (Takahashi and Yamanaka 2006). The cells termed induced pluripotent stem cells (iPSCs) were developed by genetic reprogramming techniques to alter the potency level of mature somatic cells.

When considering stem cells as an option for cardiac regeneration, some cells are more specialized than others. Also, they can secrete different levels or combinations of various bioactive messengers, and some have different functions altogether through the expression of various cell markers (Sobhani et al. 2017). Stem cells can be transplanted directly into the heart, allowing engraftment, direct differentiation, and replacement of diseased cells. Conversely, some stem cells trigger a paracrine effect, involving the secretion of various chemical messengers that stimulate the patient's nearby cells to repair damaged tissue. To recognize and compare the therapeutic potential of the various stem cell types, it is important to understand their therapeutic potential along with the mechanisms in which they work. To date, ESCs, iPSCs, and various adult stem cell lineages such as bone-marrow-derived stem cells (BMDCs), cardiac stem cells (CSCs), and skeletal myoblasts (SMs) have either been tested or are currently undergoing clinical trials in the treatment of cardiac disease (Fig. 1).

Endogenous Cardiac Regeneration

It is well known that the human heart lacks any significant regenerative capacity in response to myocardial injury or chronic disease. This explains why myocardial injury is so problematic. An acute left ventricular MI that kills over 25% of the CMs in the LV can ultimately lead to chronic heart failure (Murry et al. 2006). Although the heart may not adequately repair itself after injury, it is becoming increasingly clear that the heart is not a postmitotic organ. Research in the last couple of decades has revealed that CM renewal does occur, albeit at a very slow rate. The current consensus is that in a healthy, adult human heart, the CM turnover rate is approximately 0.5–1% per year, and this rate decreases over the life span (Eschenhagen et al. 2017). A study using carbon 14 dating techniques in human cardiomyocyte DNA demonstrated that adult CM turnover takes place at a rate of 1% annually at age 20 and 0.3% at age 75. This

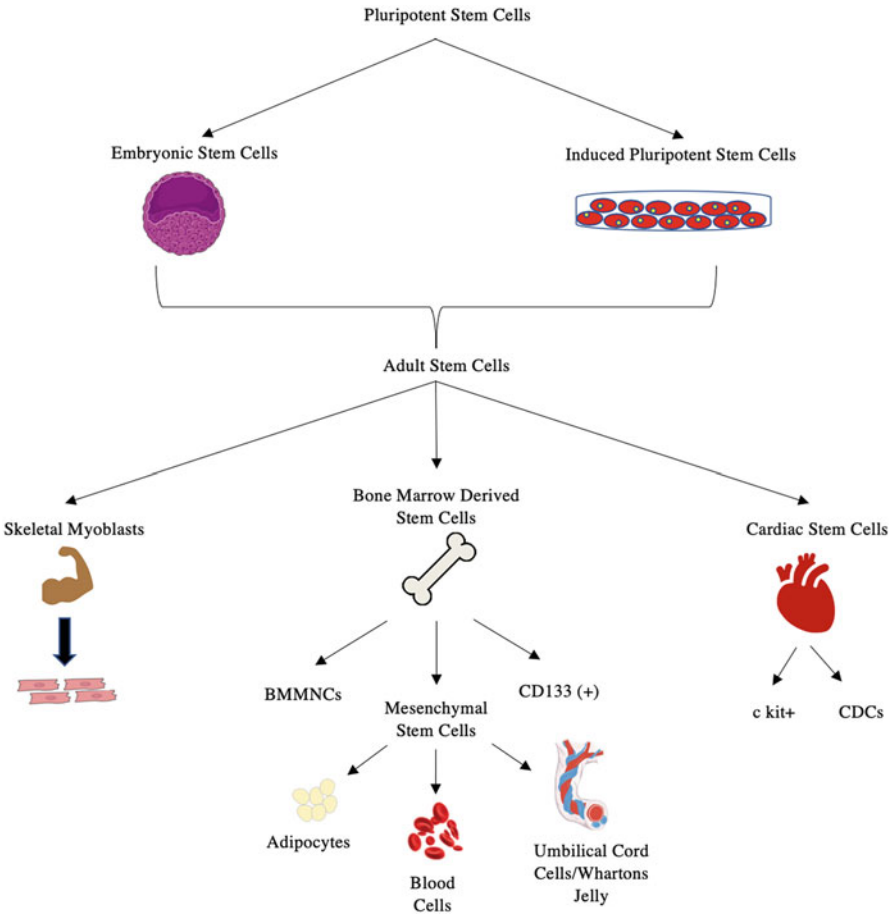

Fig. 1 Stem cell lineages utilized in regenerative medicine from least differentiated to most differentiated

equates to approximately 50% of the entire cell population being turned over in one's lifespan (Bergmann et al. 2009). This evidence was corroborated in a separate study that again demonstrated that CM renewal is greatest during the neonatal period and decreases in adulthood to less than 1% annually. Of note, turnover rates of cardiac endothelial cells and mesenchymal cells (MSCs) were slightly higher, at >15% and <4%, respectively (Bergmann et al. 2015).

Interestingly, anecdotal evidence supports the claim that cardiac regeneration in neonatal populations may be higher than initially thought. In 2015, a case report was published on a newborn child with thrombotic occlusion of the left anterior descending artery for >20 h, causing severe acute myocardial infarction. The myocardial damage was marked by elevated troponin levels, electrocardiogram, echocardiography, and cardiac angiography abnormalities. Miraculously, within

weeks the child's heart function began to recover, and at 1-year post-MI, there was no distinguishable difference in heart function or morphology compared to a healthy 1-year-old infant. A similar phenomenon of functional cardiac repair has been demonstrated in newborn murine models of severe MI and cardiac apex resection (Haubner et al. 2012; Porrello et al. 2011). This raises a pertinent question regarding the mechanism of new cardiomyocytes regeneration. Unfortunately, the answer remains elusive. Researchers hypothesize that new cardiomyocytes possibly originate from three potential sources: resident cardiac progenitor cells, proliferation of preexisting cardiomyocytes, or migration of extra-cardiac stem cells to the myocardium (Eschenhagen et al. 2017). We also do know that during embryonic development the heart enlarges primarily through CM proliferation. One month after birth, CM numbers are already at their highest and will remain constant across one's lifetime. In the second decade of life, cardiac growth occurs via cellular hypertrophy, and an increase of cardiomyocyte DNA content via polyploidization (Bergmann et al. 2015).

Determining the source and the extent of normal physiologic cardiac regeneration and renewal of CMs post-injury is a delicate but critical task. Identifying pathways that could be manipulated and amplified for therapeutic purposes remains a key goal for future research. Given that the endogenous turnover of CMs is relatively low, prevention of proapoptotic pathways immediately after cardiac injury and the stimulation of endogenous proliferative pathways may be the key to the cardiac regeneration puzzle. For example, researchers have recently begun investigating the Hippo-YAP pathway, with the hope of manipulating this intrinsic regenerative mechanism to influence cardiac regeneration.

Outcomes of Clinical Studies

Successful stem cell therapy depends on a multitude of outcomes that are observed in patients post-administration. Improvements in mortality, morbidity, and quality of life indexes such as the NYHA functional class, Minnesota Living with HF Questionnaire (MLHFQ), and distance on the six-min walk test with exercise capacity are commonly taken into consideration. In terms of heart function, stem cells should be able to improve left ventricular ejection fraction (LVEF), decrease end-systolic volume (ESV), end-diastolic volume (EDV), atrial natriuretic peptide (ANP), and brain natriuretic peptide (BNP). Lastly, the successful application of stem cells in HF relies heavily on the capacity for engraftment and survival of such cells into the host myocardium, the potential for revascularization and angiogenesis, and the capacity to electromechanically couple with resident CMs, allowing them to beat as a functional syncytium (Gerbin and Murry 2015). Most importantly, successful therapy needs to demonstrate a favorable safety profile, with minimal to no adverse events. Common concerns would be any cardiovascular events, cardiac arrhythmias, immune rejection, and teratoma formation. Past, present, and future clinical trials using various types of stem cells as a treatment for cardiac disease, and specifically HF, will be discussed in the following section in detail.

Pluripotent Stem Cells

In an attempt to regenerate the myocardium, some researchers have adopted an upstream approach to cellular-based therapies, using pluripotent stem cells (PSCs) and differentiating them into cardiac progenitors or functional CMs. The two basic approaches to creating PSC-derived CMs begin with either the extraction of human ESCs or the creation of iPSCs from mature somatic cell types. PSCs possess the unique ability of unlimited self-renewal and the ability to differentiate into functional progenitor cell types (Kadota and Shiba 2019). These two unique qualities allow researchers to differentiate a significant number of PSCs into functional CMs (Kadota and Shiba 2019). The newly generated CMs can then be implanted into the damaged tissue, with the ultimate goal of integration into the host myocardium. Recently, there has been increasing preclinical evidence accumulating on the efficacy of both iPSCs and human ESCs in the treatment of HF. Researchers have demonstrated that human PSCs can be successfully differentiated into functional CMs that display necessary electrophysiologic properties, calcium handling abilities, and contractile proteins (Kadota et al. 2013). Various animal models including rat, pig, and nonhuman primates have been used to show that human-ESC-derived-CMs can functionally engraft into the host myocardium and improve contractile function (Kadota et al. 2020).

To date, the phase I ESCORT trial (NCT02057900) conducted out of France is the only published clinical trial investigating human PSC-CMs in humans with HF (Menasché et al. 2018). This trial investigated the safety and feasibility of implanting human-ESC-derived CD15+ Isl-1+ cardiac progenitor cells (hESC-CP) in patients with severe ischemic left ventricular dysfunction. Six patients had a fibrin patch embedded with hESC-CPs transplanted epicardially as an adjunct to CABG. Safety was measured at 1-year follow-up for three primary endpoints: cardiac or off-target tumors assessed by CT and PET scan imaging, arrhythmias detected by serial interrogations of cardioverter-defibrillators, and alloimmunization assessed by detection of donor-specific antibodies. During 1-year follow-up, none of the patients exhibited any arrhythmias, and no tumors were detected in any of the patients included in the follow-up. Three patients developed low-level donor-specific antibodies; however, none of the patients had any clinically relevant complications due to the alloimmunization. Although efficacy was not a primary outcome in the study, all patients at the 1-year endpoint demonstrated symptomatic improvement from the baseline determined by a decrease in the NYHA functional class score and improvements in distance during the 6-min walk test. Patients also showed a modest increase in LVEF and a significantly improved left ventricular wall motion score measured via transthoracic echocardiogram. Although there is only one completed clinical trial using PSC-CMs in humans, there are currently two ongoing clinical trials utilizing iPSCs-CMs and likely several others in the near future. The first trial is an open-label clinical trial in China (HEAL-CHF, NCT03763136) assessing the safety and feasibility of direct epicardial injection of allogeneic human iPSCs-CMs in five patients with HF. The second clinical trial was launched in Japan in 2020 to implant cellular sheets of iPSCs-CMs into patients with ischemic cardiomyopathy. There are

relatively few known details about the trial, but it is enrolling ten patients over 3 years and aims to assess the efficacy and safety of iPSC-CMs in humans at the 1-year postoperative stage (Cyranoski 2018).

There remain some real concerns regarding the use of iPSC-CMs in clinical settings. Preclinical trials in porcine and nonhuman primate models demonstrated nonlethal transient ventricular arrhythmias posttransplantation assessed by electroanatomical mapping (Shiba et al. 2016; Romagnuolo et al. 2019). Incidentally, the arrhythmias were shown to be of graft-site origin. Two proposed mechanisms are believed to be contributing to the ectopic pacing: immaturity of the neomyocytes and automaticity (Kadota et al. 2020). No arrhythmias were observed in the human clinical trial. Besides arrhythmias, poor long-term engraftment of PSC-CMs remains a primary concern and this issue has been discussed in depth in a later section of the chapter. Lastly, immune rejection of the allogeneic donor cells is a potential problem that necessitates immunosuppression. However, Menasché et al. (2018) have demonstrated that three patients developed alloimmunization, but it was clinically silent.

Skeletal Myoblasts

Skeletal myoblasts (SMs) are harvested under the basal lamina of muscle fibers. This cell lineage is an attractive option for regenerative therapy as it provides an abundant source of readily available cells with myogenic differentiation potential (Haider et al. 2004a). Moreover, they can be easily expanded undifferentiated in culture to achieve the required number for cell-based therapy (Sim et al. 2003). Interestingly, SMs are immuno-privileged and need only transient immunosuppression for successful cross-species transplantation (Haider et al. 2004b). These data have led to first-in-man allogenic SMs transplantation in patients (Law et al. 2003). Preclinical trials found that SMs could improve cardiac function by differentiating into functional CMs in animal models (Taylor et al. 1998; Chiu et al. 1995; Ye et al. 2007). SMs are excellent carriers of therapeutic genes due to their robust nature. Hence, they have been genetically modulated for the angiomyogenic repair of the heart in experimental settings (Lei et al. 2007, 2011). They have also been preconditioned to enhance their post-engraftment survival and improve their reparability (Niagara et al. 2007; Elmadbouh et al. 2011). SMs have also been reprogrammed to develop induced pluripotent stem cells for myocardial repair, however, not without the possibility of myocardial tumorigenesis (Ahmed et al. 2011a, b).

Researchers quickly pushed SMs into human clinical trials with hopes to achieve similar results (Menasché et al. 2001; Sim et al. 2003; Siminiak et al. 2004). Unfortunately, researchers could not reproduce the successful findings in human clinical trials. The MARVEL study tested the intramyocardial (IM) injection of SMs in a sample of 14 patients, but ultimately resulted in an increased risk of developing ventricular tachycardia (Povsic et al. 2011). In addition, there were no significant improvements in LVEF or Minnesota Living with HF scores at the 6-month follow-up. The SEISMIC trial investigated the IM transplantation of autologous SMs in a cohort of 40 patients. It also found that LVEF and global heart function

improvements were not statistically significant at 6 months following administration (Duckers et al. 2011). Serious adverse events were common, yet there were no differences in incidence between the cell therapy group and the control group.

Similar to the MARVEL and SEISMIC studies, the MAGIC trial also administered SMs via IM route. In a sample of 120 patients, it was found that SMs did not improve LVEF or global cardiac function (Menasché et al. 2008). This was confirmed on a 5-year follow-up (Brickwedel et al. 2014). More significant risks of arrhythmias were noted upon administration of SMs and this was determined to be the primary concern regarding this cell lineage. Skeletal myoblasts are deprived of gap junctions and therefore lack electromechanical coupling potential, forming the basis of arrhythmia formation (Reinecke et al. 2002; Abraham et al. 2005). Though more studies with larger sample sizes could indicate whether or not SMs could be incorporated in HF treatment in the future, researchers have transitioned away from this phenotype due to their apparent lack of efficacy and safety concerns.

Bone Marrow-Derived Stem Cells

Bone marrow-derived stem cells are one of the most heavily tested cells in the treatment of cardiac disease to date. Researchers believe that autologous bone marrow mononuclear cells (BMMNCs) can improve heart function through angiogenesis and direct cardiomyocyte regeneration within the myocardium (Hu et al. 2011). The first ever published clinical trial using autologous (BMMNCs) included 21 patients with chronic HF who received the cells via transendocardial route. There were no safety concerns, and after 4 months, significant increases in LVEF, reductions in ESV, and improvements in perfusion and myocardial contractility were observed (Perin et al. 2003). Other clinical trials, such as the TOPCARE-CHD, showed significant improvements in global cardiac function, regional contractility, and mortality besides a decrease in ANP and BNP in response to transcoronary BMMNCs injection (Assmus et al. 2007). Similarly, improvements in LVEF, infarct zone, exercise capacity, NYHA functional class, and long-term mortality were observed up to 5 years after intracoronary (IC) administration of autologous bone marrow cells in the STAR-heart study (Strauer et al. 2010). The initial success of bone marrow-derived stem cells (BMDSCs) prompted the creation of more extensive phase II trials such as the FOCUS-CCTRN and the CELLWAVE, where autologous BMMNCs were administered via transendocardial and IC route, respectively. The initial excitement created by the smaller clinical trials data was short lived, as no significant improvements in LVEF, maximal oxygen consumption, infarct size, and reversibility of ischemia were observed in the larger phase II trials (Perin et al. 2012; Assmus et al. 2013). In the TAC-HFT trial, patients received either transendocardial injections of autologous BMMNCs, autologous MSCs, or placebo. Results showed that only MSC-based therapy decreased infarct size and improved the 6-min walk test distance and regional function of the heart (Heldman et al. 2014). No improvement was noted in LVEF. The Cardio133 clinical trial reported significant adverse events in patients receiving CD133(+) bone marrow cells delivered via

CABG. Although some improvements in scar size and perfusion were observed, it was found that the injection of CD133(+) cells had neither effect on clinical symptoms of HF nor global LV function (Nasseri et al. 2014).

A systematic review and meta-analysis including 1907 participants and a total of 38 randomized controlled trials found low-quality evidence that BMDSCs improved LVEF and mortality during short-term and long-term follow-up (Fisher et al. 2016a). Moreover, there was little evidence that BMDSCs improved NYHA functional class in HF patients. Though periprocedural adverse events were uncommon and serious adverse events were rare, there is no current consensus on whether or not this cell type is truly efficacious in improving outcomes. Fisher et al. applied the trial sequential analysis of two Cochrane reviews to overcome the limitations of meta-analyses (Fisher et al. 2016b). Randomized controlled trials using autologous BMDSCs to 2739 patients with acute MI and 1094 patients with HF were included in the analysis. It was found that although there is insufficient evidence to determine the treatment effect in acute MI, there is solid evidence that the administration of autologous BMDSCs reduced mortality and rehospitalization for those with HF. It was also found that BMDSCs did not improve LVEF by more than a mean difference of 4% in patients with acute MI or HF (Fisher et al. 2016b). Results of this analysis must be confirmed by an adequately powered double-blind phase III trial. Given these marginally positive findings, there is currently no consensus on whether or not BMDSCs will have a future role in treating HF patients. However, BMDSCs seem to have a favorable safety profile as there are generally few safety concerns.

Mesenchymal Stem Cells

Mesenchymal stem cells are a subtype of BMDSCs. Though found primarily in the bone marrow, they are also located in other areas of the body, including adipose tissue, blood, and the umbilical cord, commonly referred to as Wharton's jelly (Menasché 2018; Mathiasen et al. 2020; Zhao et al. 2015). Among the different BMDSCs types, MSCs primarily act via paracrine signaling mechanisms and, for this reason, seem to show great promise for regeneration of the myocardium (Menasché 2018). Paracrine signaling allows for pro-angiogenic effects by releasing vascular endothelial growth factor (VEGF), insulin growth factor-1 (IGF-1), and stem cell growth factor (Natsumeda et al. 2017; Liu et al. 2020). Moreover, the paracrine effect stimulates the proliferation and differentiation of endogenous cardiac progenitor cells (CPCs) (Natsumeda et al. 2017). These CPCs have pro-angiogenic capabilities and the potential to promote the differentiation of existing cardiac cells, though evidence of their long-term engraftment is lacking (Williams et al. 2013). In addition to paracrine signaling, MSCs can directly contribute to vascular proliferation and direct myocardial regeneration on a greater scale (Tehzeeb et al. 2019; Lalu et al. 2018). This cell lineage also has important repair properties through immunomodulation, anti-fibrotic, pro-angiogenic, and anti-oxidative effects (Turner et al. 2020). One unique characteristic of MSCs is

that they do not express major histocompatibility complex class II (MHC II) antigens. Hence, MSCs are good candidates for allogeneic sourcing, as they are nonimmunogenic (Nair and Gongora 2020). Together, these qualities make MSCs great contenders for treating chronic HF. A meta-analysis investigating 52 preclinical studies showed that MSCs were moderately associated with significant improvements in LVEF and showed that cardiac cell therapy is safe and not associated with increased mortality (van der Spoel et al. 2011). A recent systematic review investigated the impact of MSCs as a treatment for nonischemic dilated cardiomyopathy (Hoeeg et al. 2020). In total, 27 studies were included; however, most studies involved preclinical animal models (3 clinical and 24 preclinical trials). Of these, 21 of the included trials tested bone marrow-derived MSCs, 4 tested human umbilical cord MSCs, and 3 tested adipose tissue-derived MSCs. It was found that bone marrow, umbilical cord, and adipose tissue-derived MSC treatment can improve cardiac function in nonischemic dilated cardiomyopathy through main mechanisms of anti-fibrotic and anti-apoptotic effects, angiogenesis, and immunomodulation. This suggests that independent of the cell origin, all MSC types share synonymous mechanisms of action. All three clinical trials and 22 of the 24 preclinical trials reported improvements in cardiac function following administration of MSCs.

Thus far, human clinical trials utilizing MSCs in HF have yielded exciting results. The results of the first placebo-controlled trial, MSC-HF, indicated that the IM injection of autologous MSCs is safe, reduces hospital admissions, and improves myocardial function (Nigro et al. 2018). In addition, the TAC-HFT trial suggested that MSCs were superior to BMMNCs in reducing infarct size and improving regional heart function in patients with chronic HF (Heldman et al. 2014). Other studies like the POSEIDON trial compared the transendocardial delivery of autologous versus allogeneic MSCs in patients with HF. Interestingly, both autologous and allogeneic MSCs improved LV function while reducing infarct size and adverse cardiac remodeling without any safety concerns highlighted (Hare et al. 2012). Five years later, results of the POSEIDON-DCM trial were released. Overall, it was demonstrated that more significant improvements were observed in allogeneic MSCs versus autologous MSCs in patients with nonischemic dilated cardiomyopathy. There were more significant improvements in quality of life, functional capacity scores such as the NYHA functional class and MLHFQ, the 6-min walk test, and improvements in ejection fraction (Hare et al. 2017). Just like the POSEIDON trial, the transendocardial delivery of both autologous and allogeneic MSCs in the POSEIDON-DCM trial had no notable safety concerns. Though more extensive trials are required to determine which cell source is more favorable, evidence supports the superiority of allogeneic MSCs regarding the efficacy and endothelial function. Another trial led by Mathiasen et al. (2020) administering MSCs via IM injection resulted in improvements in LVEF, stroke volume, and myocardial mass in patients with HF. A larger trial, the DREAM-HF trial with 566 patients enrolled, was recently completed. It evaluated the efficacy of allogeneic mesenchymal precursor cells (MPCs) in patients with advanced chronic HF. Results are pending.

A systematic review and meta-analysis investigating the efficacy and safety of MSCs in ischemic and nonischemic cardiomyopathies determined that of the 29 clinical trials, the vast majority demonstrated improvements in LVEF, LVESV, NYHA functional class, and exercise capacity without significant safety concerns (Poulin et al. 2016). Patients who received stem cells as an adjunct to CABG had the most remarkable improvements in LVEF, which justifies the role of catheter-based revascularization. Based on this data, it seems that MSC therapy may be a feasible option in improving cardiac function while decreasing adverse cardiac remodeling in patients with HF. Another systematic review and meta-analysis reviewed the safety and efficacy of MSCs in 12 trials focused on ischemic HF. There were significant improvements in LVEF; however, there were no significant improvements in mortality. Additionally, several studies within the meta-analysis showed an increase in quality of life and physical performance. However, quality of life and performance status were inconsistently reported in studies, which limited the ability to provide conclusions (Lalu et al. 2018). Most importantly, there seems to be no association between treatment with MSCs and adverse events, suggesting a favorable safety profile.

Other descendants of MSCs such as cardiopoietic and umbilical cord MSCs have been studied in clinical trials. These are more specialized cells derived from a pure MSC lineage. Cardiopoietic stem cells are derived from MSCs in the bone marrow and are of particular interest in regenerative medicine. One of the first using cardiopoietic cells, the C-CURE trial, demonstrated significant improvements in LVEF, quality of life, and lower LVESV 2 years after administration into the heart with no safety concerns noted (Bartunek et al. 2013). This small-scale study catalyzed the formation of the CHART-1 trial, which had a greater sample size of 351 individuals. Interestingly, this study shared similar results to the C-CURE trial, indicating that cardiopoietic cells have the potential to provide long-lasting benefits toward cardiac function in those with HF (Teerlink et al. 2017; Bartunek et al. 2017). Wharton's jelly, a gelatinous substance present within the umbilical cord, is rich in MSCs, which have been tested in various clinical trials. Of these, a study led by Zhao et al. (2015) studied the delivery of umbilical cord MSCs via IC route in combination with various medications, such as ACE inhibitors or ARBs, beta-blockers, diuretics, and digoxin. Twenty-four hours after transplantation, symptoms of HF such as cough, dyspnea, and chest tightness were alleviated, though no improvements were noted in LVEF. There were some improvements in the 6-min walk test, NT-pro BNP levels were significantly lower than the control group, and improvements in mortality rates were observed. Given these positive results, it is crucial to link these improvements with the medications given in combination with the MSCs. In the RIMECARD trial, the intravenous (IV) infusion of umbilical cord MSCs were found to improve LVEF but did not reduce LVESV or LVEDV (Bartolucci et al. 2017). No significant safety concerns were noted.

Though MSCs have massive potential in regenerative medicine, there is a need for larger, international clinical trials to fully elucidate the field of MSC therapy in humans living with HF. The surge of incoming clinical trials, including the first phase III clinical trial, should help clarify the true therapeutic potential of MSCs in HF. Put together, the meta-analysis by Lalu et al. demonstrated that MSCs could

improve LVEF and enhance the quality of life and performance, that too without any major safety concerns (Lalu et al. 2018).

Cardiac Stem Cells

Cardiac stem cells (CSCs) were among the most heavily researched cells in cardiac regenerative medicine. Clinical research led by Dr. Piero Anversa showed great promise for the application of CSCs to treat heart failure. He claimed that CSCs produced functional myocardial changes and they were a viable option to treat heart failure. These claims sparked a great interest in the medical community and the public (Chien et al. 2019). Many researchers attempted to replicate Anversa's studies albeit without success. It was soon discovered that the field of CSCs was heavily compromised and Anversa and his group were accused of scientific misconduct. As a result, the Brigham and Women's Hospital along with the Harvard Medical School took action by launching an investigation on Anversa's work. In 2014, the SCIPIO clinical trial using c kit+ CSCs was retracted, and by 2018, the investigations revealed that 31 publications contained falsified or fabricated data (Ozkan 2019). The National Institute of Health also stepped in by suspending the CONCERT-HF trial due to its lack of scientific foundations (Bolli et al. 2018). This clinical trial was the first to evaluate the combination of CSCs and MSCs as a treatment of HF.

To date, c-kit+ CSCs and cardiosphere-derived cell (CDC) phenotypes have been studied in clinical trials. The CADUCEUS trial demonstrated that the IC injection of CDCs reduced scar tissue size and improve regional contractility and heart mass on MRI (Makkar et al. 2012). There were no differences in ESV, EDV, and LVEF. There were no significant adverse events, alluding to a favorable safety profile for CDCs. The TAC-HFT-II trial will soon compare therapy with autologous MSCs alone vs MSCs combined with c-kit+ CSCs (Bolli et al. 2018). Without question, the implications of Piero Anversa's 31 retracted studies will have a long-lasting effect on the field of CSCs. The findings of these investigations have created a significant distrust of the scientific community and discredited the current advancements made in this field. Although other clinical trials are currently investigating the feasibility and efficacy of CSCs and cardiac-derived stem cells, clinical benefit has yet to be demonstrated for patients. Moreover, CSC isolation is invasive as it requires a heart biopsy, and culture requires many days before injecting adequate numbers (Nigro et al. 2018). In the future, it is of utmost importance that rigorous scientific standards are followed when conducting clinical trials to protect the integrity of research and protect patients (Tables 3 and 4).

Understanding the Factors Affecting Cell-Based Therapy

Though the safety profile of stem cells appears to be satisfactory, their overall efficacy is, at best, modest. For successful cell therapy to treat HF, a greater understanding of the factors surrounding the application of cellular treatment is warranted.

Table 3 Summary of safety parameters in human clinical trials

Cell type	Safety parameters in human subjects	References
ESCs	• Positive safety profile in one human clinical trial • Silent alloimmunization in three of six patients • Larger trials are warranted	Menasché et al. (2018)
iPSCs	No published human clinical trials completed	Cyranoski (2018)
Skeletal myoblasts	• Risk of ventricular arrhythmias • Easy to harvest	Menasché et al. (2008), Povsic et al. (2011), and Brickwedel et al. (2014)
BMDSCs	• Positive safety profile demonstrated in allogeneic and autologous human clinical trials • Easy to harvest • Decrease in arrhythmogenic risk • Noteworthy increase in adverse events	Hu et al. (2011), Perin et al. (2003), Strauer et al. (2010), Assmus et al. (2013), and Hu et al. (2011) Strauer et al. (2010) Nasseri et al. (2014)
MSCs	• Positive safety profile demonstrated in multiple human clinical trials • Dyspnea, fatigue, and chest tightness 1-month post-transplantation, though small sample	Mathiasen et al. (2020), Hare et al. (2012, 2017), Bartunek et al. (2013), Bartolucci et al. (2017), Poulin et al. (2016), Lalu et al. (2018), and Zhao et al. (2015)
CSCs	• Heavily compromised field of research due to lack of scientific integrity • Isolation of cells is invasive • Suggested positive safety profile of CDCs	Ozkan (2019) Nigro et al. (2018) Makkar et al. (2012)

Engraftment, Survival, and Rejection

One of the most critical impediments in stem cell therapy is their ability to engraft and survive in the heart post-administration, while avoiding immune rejection from the recipient. Both preclinical and clinical trials show that cell retention in the heart 24 h post-administration does not exceed 10% (Hou et al. 2005; Aicher et al. 2003; Blocklet et al. 2006). This is likely due to a poor engraftment potential along with the rapid washout of cells once they are injected into the heart (Terrovitis et al. 2009). These shortcomings have prompted the development of improved cell retention approaches, such as plugging the injection site with a fibrin compound to prevent backflow of cells, and transplantation of constructed cell sheets besides the use of bioengineered natural or synthetic polymers (Chiu et al. 2012; Terrovitis et al. 2009). Autoimmune rejection of transplanted cells is another crucial risk to mitigate, mainly when the source is allogeneic. This has resulted in a push for cells that require minimal to no immunosuppression, such as ESC-derived cells, MSCs, and MPCs. Future research focusing on cell retention while decreasing the risk of immune rejection will continue to improve the efficacy and feasibility of stem cell therapy for HF.

Table 4 Landmark human clinical trials

Cell type	Clinical trial	Sample size	Results	References
ESCs	ESCORT	6	Improvement in NYHA functional class, 6-min walk test and heart wall motion	Menasché et al. (2018)
iPSCs	Cyranoski (2018)	10	Trial results pending	Cyranoski (2018)
	HEAL-CHF	2	Trial results pending	
Skeletal myoblasts	MAGIC MARVEL SEISMIC	120 23 40	No improvements in LVEF or global heart function No improvements in LV function Moderate improvements in 6-min walk test No improvements in LVEF at 6 months	Menasché et al. (2008) and Brickwedel et al. (2014) Povsic et al. (2011) Duckers et al. (2011)
BMMNCs BMMNCs and autologous MSCs CD133(+) BMDSCs	Perin et al. (2003) TOPCARE-CHD STAR-heart FOCUS-CCTRN Hu et al. (2011) TAC-HFT CARDIO33 Systematic review and meta-analysis Systematic review and meta-analysis	21 121 191 153 60 65 60 1907 1094	Improvements in LVEF, perfusion, and contractility Reductions in ESV Improvements in global cardiac function, contractility, and mortality Decreased ANP and BNP Improvements in LVEF, NYHA functional class, and long-term mortality Decreased LV preload, ESV, and infarct area No improvements in LVEF, maximal O_2 consumption, and infarct size Improvements in LVEF, LVESV, 6-min walk test, and exercise tolerance. Decreased BNP levels Decreased infarct size and improvements in 6-min walk test and regional function of the heart in MSC group only. MSCs better at improving myocardial function No improvements in LV function or clinical symptoms Improvements in mortality, LVEF, and NYHA functional class (low-quality evidence) Reductions in mortality and rehospitalization minimal improvements in LVEF	Perin et al. (2003) Assmus et al. (2007) Strauer et al. (2010) Perin et al. (2012) Hu et al. (2011) Heldman et al. (2014) Nasseri et al. (2014) Fisher et al. (2016a) Fisher et al. (2016b)
Autologous MSCs Autologous	MSC-HF POSEIDON POSEIDON-	60 31 37	Improvements in LVEF, stroke volume, and myocardial mass Improvements in LV functions with	Mathiasen et al. (2020) Hare et al. (2012)

(continued)

Table 4 (continued)

Cell type	Clinical trial	Sample size	Results	References
and allogeneic MSCs	DCM	36	reductions in adverse remodeling and infarct size	Hare et al. (2017)
Cardiopoietic	C-CURE	351		Bartunek et al. (2013)
Umbilical MSCs	CHART-1	30	Greater improvements seen in allogeneic MSCs regarding functional capacity, quality of life, EF, 6-min walk test, and the MLHFQ	Teerlink et al. (2017) and Bartunek et al. (2017)
Umbilical MSCs in collagen hydrogel	RIMECARD	59	Improvements in LVEF, quality of life, and decreased LVESV	Bartolucci et al. (2017)
Allogeneic MPCs	Zhao et al. (2015)	50	Decreased LVESV and LVEDV but no improvements in LVEF	He et al. (2020)
MSCs	He et al. (2020)	566	Improvements in LVEF but no improvements in LVESV or LVEDV	Borow et al. (2019)
	DREAM-HF	29 studies	No improvements in LVEF but some improvements in the 6-min walk test, mortality rate, and NT-pro BNP levels	Poulin et al. (2016)
	Systematic review and meta-analysis	12 studies	Improvements in LVEF, NYHA functional class, viable heart mass, and quality of life. Decreased LVESV and LVEDV	Lalu et al. (2018)
	Systematic review and meta-analysis		Trial results pending	
			Improvements in LVEF, LVESV, NYHA functional class, quality of life, and exercise capacity	
			Improvements in LVEF. No improvements in mortality or quality of life	
CSCs	CADUCEUS	31	Improvements in scar size, regional contractility, and heart mass; no differences in EDV, ESV, and LVEF between groups	Makkar et al. (2012)

Dosage

The optimal dosage of stem cells to reach therapeutic effect is still unknown, and the evidence is conflicting. Studies show large variations in dosing from 1×10^6 to 2×10^8 cells per dose administered per patient (Madonna et al. 2014). Though these include a large number of cells administered to a patient, it is not enough, as on average, one billion CMs are lost following an MI (Robey et al. 2008). There is a need for larger doses of stem cells to be administered if the goal is to replace lost CMs following MI. However, this may not be the case, as several clinical trials have demonstrated that smaller doses of stem cells are more effective than higher doses, possibly due to increased paracrine and cytoprotective factors release, activation of angiogenesis, and induced cardiomyocyte hypertrophy (Nigro et al. 2018). Whereas

large doses of stem cells may increase the potential for remuscularization, cell engraftment and survival are pretty low, and large doses may aggregate in areas of the heart, thus increasing the risk of arrhythmias (Prockop and Olson 2007). Also, the exact timing of cell administration has not been confirmed – though it is hypothesized that the longer the time interval between MI and administration of stem cells, the less the patient is likely to benefit. Current and future clinical trials will hopefully address these controversies and challenges.

Cell Type

Many different cell types have been tested in clinical trials, yet there is no current consensus on the type that is best suited for cardiac regeneration. In an ideal world, the perfect stem cell would be able to proliferate, engraft, and survive in ischemic areas, along with the ability to induce paracrine effects to stimulate endogenous cardiac regeneration. Moreover, it would have the potential to contract and electromechanically couple with the host CMs. At the moment, no cell has met all of these expectations in clinical trials (Gerbin and Murry 2015). The quality of the cell in question is also important to consider, as older age and preexisting comorbidities limit cell potency and regenerative potential (Nigro et al. 2018). Based on these findings, allogeneic sources of cells may present greater advantages over autologous sources. It is noteworthy that allogeneic cells can be cultivated and isolated from younger, healthy donors devoid of comorbidities and genetic defects. Allogeneic cells can be screened for quality and stored as an "off the shelf" product, making them readily available for acute applications. Lastly, allogeneic stem cells are more appealing in the eyes of the pharmaceutical industry as they provide superior profit margins versus autologous stem cells (Nigro et al. 2018). However, one must be wary of this conflict of interest, as we cannot sacrifice the quality of the product over the financial interests of external parties.

Currently, MSCs have been of particular interest in trials due to their ease of isolation and extraction, their multipotent differentiation potential, low immunogenicity, and their potential to trigger paracrine effects (Menasché et al. 2018; Nigro et al. 2018). Recent research has focused on more pure forms of stem cells, such as CSCs to increase the regenerative potential. Though CSCs have been shown to improve some aspects of cardiac function in patients with HF, the isolation of autologous CSCs is an invasive procedure, culture takes time, and the field of CSCs is heavily compromised (Nigro et al. 2018; Ozkan 2019). Some derivatives of iPSCs, such as cardiomyocyte-derived from human iPSCs, pose some risk of tumorigenicity (Nigro et al. 2018). For the moment, the most promising types of stem cells for cardiac regeneration appear to be iPSCs and ESCs. Alternatively, different approaches to cellular therapy may involve combining different cell types to increase efficacy. The rationale behind combining cells revolves around the activation of various regenerative pathways due to the underlying physiologic role of each cell type. Preclinical trials have shown promising results. It was found that the combination of MSCs and CPCs in the treatment of chronic HF improved cardiac

outcomes versus MSCs alone or placebo (Williams et al. 2013; Karantalis et al. 2015; Natsumeda et al. 2017). Though there were some differences between the three trials, there were improvements in EF, contractility, cell retention, and decreases in infarct size versus MSCs administered alone. Since MSCs alone act primarily via paracrine signaling, they stimulate angiogenesis and the proliferation, differentiation, and migration of endogenous CPCs to the heart (Natsumeda et al. 2017). However, the evidence on long-term engraftment is lacking (Williams et al. 2013). Other preclinical studies investigated the utility of epicardial patches containing human iPSC-derived CMs combined with human MSCs versus administering either of the cell type alone. It was found that the combination therapy group showed more significant improvements in EF, cardiac fibrosis, and capillary density (Park et al. 2019). Larger randomized, double-blind trials with more extended follow-up periods are warranted to determine which combination of cell types will yield the remarkable improvements and reduce safety concerns in HF patients. Alternatively, cardiac regeneration may not rely on stem cells after all. Current studies are now investigating the use of cell-free strategies due to concerns that the administration of stem cells results in poor cellular retention rate. This approach is discussed in greater detail in section "Cell-Free Strategies."

Route of Administration

An effective route of delivery is as important as the type of cell in question. It is one of the essential factors in successful stem cell treatment, as it can affect the potency of the cells, their retention, engraftment, and survival in the recipient's heart (Turner et al. 2020; Nigro et al. 2018). Successful delivery of cells will depend on the ability of the cells to migrate to the target area of the heart, their engraftment potential, and the ability to function in synchrony with the heart's natural rhythm without interference. Overall, an optimal delivery method should ensure the survival of the cells. It must be well tolerated by the patient, and the procedure should be relatively easy to perform by a clinician.

Preclinical studies have utilized various methods of delivery such as transendocardial, retrograde intracoronary sinus, open surgical epicardial injection, IM, IC, IV, and, more recently, 3D scaffolding with the help of cardiac patches (Bruyneel et al. 2016; Nakamura and Murry 2019; Mazzola and Di Pasquale 2020). The most common routes of administration include, IM, IC, IV, transendocardial, and 3D scaffolding.

Intramyocardial injection entails a direct injection of stem cells in a targeted area of the heart. These cells are usually injected along the borders of infarcted heart tissue as this provides better blood and oxygen supply for the cells to survive. This method ensures adequate blood supply to the cells, an essential component for their survival (Campbell and Suzuki 2012). This method of delivery provides the highest rate of retention, greatest engraftment, and remuscularization potential but fails to produce a significant paracrine effect (Nakamura and Murry 2019;

Campbell and Suzuki 2012). This technique is more invasive and risks myocardial perforation, vascular injury, arrhythmia, and embolism. Moreover, it can be challenging to distinguish between infarcted tissue and normal myocardium. For this reason, a skilled clinician is required.

The intracoronary infusion of stem cells is the most common and safer delivery method in clinical trials. This is primarily due to the central role of catheter-based revascularization of the heart in MI (Nakamura and Murry 2019; Tehzeeb et al. 2019). Clinical trials have deemed this method superior to the IM route as it promotes the paracrine effect, is less invasive, and ensures high cell survival rates due to the rich oxygen and nutrient content in the coronary circulation. The IC injection of cells is considered to decrease the risk of inflammation and damage to the myocardium post-transplantation, while allowing for a uniform distribution of cells in the target area (Campbell and Suzuki 2012). Given these slight advantages, IC injection is associated with long-term minimal cell retention due to rapid washout in humans, resulting in inefficient remuscularization of the heart (Nakamura and Murry 2019). Moreover, large doses of cells cannot be delivered via the IC route due to risk of obstruction of the coronary arteries, ultimately resulting in ischemia and myocardial cell death (Freyman et al. 2006; Goussetis et al. 2006; Nakamura and Murry 2019).

Although the IV approach has demonstrated positive safety parameters and is one of the least invasive methods, it is less efficacious than the IM and IC route (Freyman et al. 2006; Menasché 2018). This lack of efficacy is primarily due to a lack of cell retention, and engraftment and the majority of the cells remaining trapped in the lungs. Most of the cells are eliminated by phagocytic cells in the reticuloendothelial system (Freyman et al. 2006; Bruyneel et al. 2016; Turner et al. 2020). Moreover, there are concerns about vascular occlusion that can quickly occur with systemic delivery. To improve the effectiveness of the IV method, the approaches that will enhance the cellular homing mechanisms to the heart are essential.

The transendocardial route is the most challenging technique to execute, yet it can avoid the need for open-heart surgery – reducing periprocedural risks. It has shown tremendous potential for cell retention as it deposits stem cells directly into the myocardium (Tehzeeb et al. 2019; Turner et al. 2020). Like the IM route, there is a risk for ventricular rupture and arrhythmia formation. Though some small preclinical and clinical trials have shown the safety and efficacy of the transendocardial route, larger, more robust clinical trials are necessary to evaluate the long-term success of this method.

Bioengineering of cellular materials has recently entered the field of regenerative medicine. It involves culturing and implanting stem cells in a three-dimensional vehicle to improve the rate of cell differentiation and survival at the site of the cell graft. One of the current goals is to create a scaffold that mimics the microenvironment of the heart. This scaffold can be grafted with the cell type of choice and administered to the heart (Mazzola and Di Pasquale 2020). One of the first applications of fibrin patches was in the ESCORT trial, where patches embedded with human ESC-derived CPCs were implanted epicardially during CABG

(Menasché et al. 2018). This novel method of stem cell delivery has been validated in preclinical studies and yields high cell retention rates (Park et al. 2019). It was also reported that sheets containing MSCs could increase cell retention while amplifying paracrine effects to regenerate damaged heart tissue (Narita et al. 2013). Biomaterials such as collagen, hyaluronic acid, alginate, and a large variety of synthetic polymers have shown variable advantages and disadvantages (Mazzola and Di Pasquale 2020). Though the optimal combination of scaffolding materials and stem cells has yet to be confirmed in clinical trials, PSCs are better candidates in creating functional heart tissue since they have a more significant potential to integrate into the myocardium (Liu et al. 2018; Oikonomopoulos et al. 2018). MSCs combined with bioengineered materials will also hold a promising approach for heart repair. Currently, hydrogel-based scaffolds and cell sheet engineering are being studied (Oikonomopoulos et al. 2018). Cell sheets and scaffolds also avoid the risk of myocardial injury caused by direct injection.

Though many methods of delivery exist, the degree of cell retention within the myocardium remains very low. Though some preclinical studies have compared various routes of delivery, the results in human studies are pending. It is believed that the most effective method will likely be dependent on the type of cell in question, as all have their benefits and limitations (Turner et al. 2020). Intravenous delivery of stem cells is minimally invasive but has negligible cell retention potential. Intracoronary infusion of cells is the most commonly used method but presents a risk of coronary artery occlusion. The intramyocardial route has the greatest potential for cell retention, lacks paracrine effects, and requires skilled clinicians. The transendocardial route poses great potential for cell retention, yet is challenging to approach and requires skilled and experienced clinicians (Fig. 2). The type of stem cell, patient characteristics, and the degree of cardiac disease may all play a role in determining which route of administration is optimal for the patient in question (Nigro et al. 2018) (Table 5).

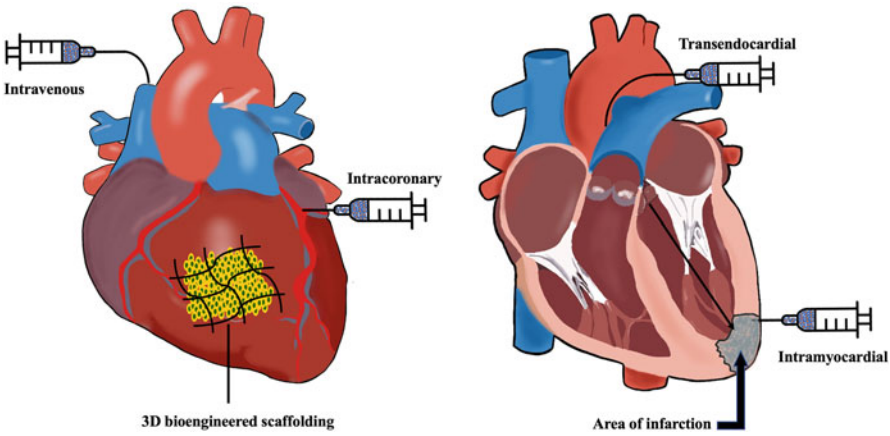

Fig. 2 Common routes of cell administration in humans

Table 5 Routes of administration: benefits and limitations

Route of administration	Benefits	Limitations
Intramyocardial	High rate of retention in the heart	• No significant paracrine effect • Invasive • Risk of perforation, arrhythmias, and emboli • Hard to distinguish between normal and infarcted tissue
Intracoronary	• Most common and safer method of delivery • Increased cell survival rates and paracrine effect	• Risk of MI with large doses • Rapid washout of cells
Intravenous	Least invasive with positive safety parameters	Lack of engraftment and retention potential
Transendocardial	• Great cell retention potential • Does not require open-heart surgery	• Difficult technique • Risk of perforation and arrhythmia formation
Bioengineering and 3D scaffolding	• High rate of cell retention • Prolongs paracrine effect • Many different biomaterials and synthetics are being tested	• Ideal combination of scaffolding and stem cells needs to be confirmed • Avoids risk of myocardial damage

Hippo-YAP Pathway

It is well established that the adult heart lacks significant endogenous regenerative potential. For this reason, researchers have focused on manipulating pathways that regulate CMs proliferation to amplify endogenous cardiac regeneration. Particular attention has been paid to the Hippo signaling pathway – an evolutionary homeostatic mechanism that controls organ size (Wang et al. 2018). The primary mechanism of this pathway is to restrict cardiomyocyte proliferation once the heart has fully developed to maintain its optimal size. This pathway also inhibits cardiac regeneration, which is problematic when tissue damage occurs. Research has focused on the Hippo-YAP (Yes-associated protein) pathway to reactivate cardiac regeneration by regulating cardiomyocyte proliferation and differentiation. YAP is a downstream effector of the Hippo pathway and is responsible for triggering transcription of cell-proliferating genes while suppressing apoptotic genes. These two characteristics are instrumental in determining regenerative potential (Xin et al. 2011). Normally, YAP is inhibited by the Hippo signaling pathway, restricting cellular growth and organ size (Wang et al. 2018). It is clear that manipulating the Hippo-YAP pathway effectively enhances fetal and neonatal cardiac proliferation and regeneration; however, the question remains if YAP activation can stimulate adult CMs' proliferation and mitigate cardiac cell death (Lin et al. 2014).

Researchers have shown that 28-day-old YAP transgenic mice post-MI had a 2.5-fold increase in cardiomyocyte proliferation, a decrease in scar size and an improvement in cardiac function compared to control mice (Xin et al. 2013). Similar results were found with the inactivation of the Hippo pathway, which led to increased DNA

synthesis and cytokinesis (Heallen et al. 2013). However, the 2.5-fold increase in CM proliferation is still 20-fold lower than the observed rate in wild-type mice. This suggests that alternative mechanisms, such as mitigation of fibrosis, reduction in apoptosis, and decreasing inflammation, may contribute a large portion of the therapeutic benefit (Xin et al. 2013). Notably, the Hippo-YAP pathway stands out from other paracrine growth factors as it promotes cardiomyocyte proliferation without the possibly deleterious effects of cardiac hypertrophy (Lin et al. 2014). More detailed studies are required to confirm the manipulation of the Hippo-YAP pathway. Nevertheless, it may be a feasible tool for treating cardiac injury and triggering endogenous cardiac regeneration in humans.

Ethical Issues in Regenerative Medicine

In an attempt to lower the global burden of cardiovascular diseases, stem cells have quickly gained momentum in research and are being explored at an unprecedented rate. However, their use generates various ethical and political issues not commonly seen in other treatment modalities. The most prominent ethical issue arises from the morality of using human embryonic stem cells in research. The creation of a human ESC line involves the extraction of the inner cell mass from the blastocyst during 5–7 days of fetal development, which results in the destruction of the human embryo and the potential for human life. This ethical dilemma begs the question of when does human life truly begin. Some believe that human life begins at conception, whereas others believe that it begins further into development or even at birth (Lo and Parham 2009). A current strategy to circumvent this issue involves only using embryos that have initially been produced for reproductive purposes. Although this may ease the ethical burden for some, it is a near-impossible task appeasing all the parties involved in the matter. Alternatively, the use of other stem cell types eliminates the ethical concerns regarding the destruction of potential human life. Currently, iPSCs are seen as an attractive alternative to ESCs. They are derived from adult stem cells and genetically programmed back to a higher state of potency, making them a strong contender to the ESC. Adult stem cells can also be viable options, but their use is limited, and they lack the level of potency seen in ESCs and iPSCs (Barile et al. 2007).

Another concern regarding the use of stem cells is the growing trend of "stem cell tourism," which describes the practice of patients seeking expensive, unproven stem cell treatments at private clinics around the world. These treatments are frequently promoted as a definite cure; however, they often lack sufficient data on clinical efficacy or safety (Ryan et al. 2010). This dangerous trend has resulted in the opening of unregulated clinics that exploit their patients for their profits, sometimes charging fees of $30,000 for unproven treatments (Regenberg et al. 2009). Unfortunately, the public is often ill-equipped to gauge whether or not treatments offered in clinics are safe and credible, and only 29% of clinics that offer stem cell treatments are accredited to do so (Connolly et al. 2014). Although the applications of stem cells are pretty exciting, cardiac regeneration is still a relatively novel concept.

Particularly for HF treatment, many variables must be accounted for before stem cells can make their way into medical practices. It is imperative that scientific standards and methodologies remain at the highest degree to avoid breaches of scientific integrity, as previously seen in the study of CSCs.

What Does the Future Hold for Cardiac Regenerative Medicine?

Cell-Free Strategies

Data from preclinical and clinical trials seems to come to a reasonably consistent conclusion that low cellular retention rates and the inability to generate new CMs adequately remain a concern with current cellular strategies (Maghin et al. 2020). In addition, it postulated that a large portion of the therapeutic benefit of stem cells is derived from the biological factors that they secrete rather than direct cellular differentiation (Park et al. 2018). Recently, much attention has been paid to utilizing a cell-free approach to cardiac regeneration via administering a "cocktail" of cardioprotective paracrine signaling molecules. This combination of factors secreted by progenitor or stem cell populations includes cytokines, growth factors, and miRNAs and has been termed the "secretome." Several strategies to deliver these paracrine factors include direct administration of individual growth factors, use of endogenous extracellular vesicles secreted by various cell types, delivery of cultured medium of stem cells, and the overexpression of proteins via modified mRNA (Liew et al. 2020).

One of the first studies that truly corroborated the validity of the paracrine hypothesis was the use of a conditioned medium of cultured human MSCs into a porcine model of acute MI (Timmers et al. 2007). It was demonstrated that a single IC injection of human MSC cultured medium into an ischemic porcine model was associated with a 60% reduction in infarct size and improvement in both systolic and diastolic cardiac function (Timmers et al. 2007). Precisely, it is thought that small EVs or exosomes may contribute a significant portion of the stem cell secretome's regenerative effects (Kishore and Khan 2016). EVs is a collective term that describes small phospholipid MVs secreted by cells and contain biologically active compounds such as proteins, growth factors, RNA, and biolipids (Simons and Raposo 2009). Although they may be used interchangeably in the literature, exosomes refer to a subclass of extracellular vesicles that range from 40 to 100 nm and originate as endosomes (Simons and Raposo 2009). However, the source of extracellular vesicles is not limited to MSCs. A study was published delivering exosomes derived from CDCs into a porcine model of acute MI (Gallet et al. 2017). The pigs received either IC or open-chest IM injection of either placebo vehicle or exosomes 4 weeks post-MI. They demonstrated that pigs receiving CDC-derived exosomes had a preserved LV volume and LVEF, as well as histologic improvements in vessel density and cardiomyocyte hypertrophy.

Interestingly, a separate study investigated the efficacy of a mixture of human iPSC-derived CMs, endothelial cells, and smooth muscle cells versus only exosomes

extracted from these PSC-derived cell types (Gao et al. 2018). It was found that cardiac outcomes such as LV function, angiogenesis, infarct size, and wall stress were similar in both the exosome group and cell group, and both were significantly improved compared to MI without treatment group. Moreover, exosome therapy did not increase the frequency of arrhythmia, a primary concern from studies investigating human iPSC-derived CMs in a primate model (Shiba et al. 2016; Romagnuolo et al. 2019). These findings suggest that exosomes alone could potentially be as effective as stem cells in the treatment of cardiac pathologies. However, human clinical trials will need to be completed on exosome use before these conclusions can be definitively made.

The direct administration of cellular growth factors appears to be the most simplistic strategy for delivering paracrine factors to the heart. Two standard strategies to induce growth factor gene expression include the direct injection of recombinant proteins or the administration of viral vectors or plasmids containing the growth factor encoded gene (Spannbauer et al. 2020). Most preclinical studies have focused on several key growth factors: vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF), although many others have also been investigated (Liew et al. 2020). A similar strategy revolves around using RNA, including coding messenger (mRNA) and noncoding RNA (ncRNA). One of the first studies that demonstrated this concept involved the epicardial or IC administration of VEGF and effectively improved myocardial blood flow and enhanced regional ventricular function in a porcine model of chronic ischemia (Lopez et al. 1998). In another study, porcine models of chronic ischemic heart disease were co-transfected with VEGF-A and platelet-derived growth factor B (PDGF-B) plasmids (Kupatt et al. 2010). The pigs co-transfected with VEGF-A and PDGF-B showed significant neovascularization and improved regional and global myocardial function. In gene therapy, there have been over 150 human clinical trials investigating the effects of various therapeutic molecules on cardiac angiogenesis (Cannatà et al. 2020).

However, there remains no gene therapy that has been proven to be successful in achieving clinical benefit. There have also been several landmark clinical trials that specifically investigated the use of gene therapy in the treatment of HF. The main targets in these trials were various components of the calcium handling system within CMs (Cannatà et al. 2020). The first key clinical trial was the phase 1/2 CUPID trial, which aimed to restore the sarcoplasmic Ca2+ ATPase (SERCA2a) in 39 patients with HF (Jaski et al. 2009; Jessup et al. 2011). The SERCA2a gene was delivered via cDNA in an adenovirus vector (AAV-1) during a single IC infusion. Patients were stratified into a low dose, medium dose, high dose, or placebo group. Initial results were promising, as a positive safety profile was confirmed, and there was a trend toward symptomatic improvement and a significant reduction in cardiovascular events at 12 months (Jessup et al. 2011). This prompted a follow-up with the much larger randomized, placebo-controlled phase II CUPID2 clinical trial, which enrolled 250 patients with HF (Greenberg et al. 2016). Unfortunately, results were disappointing as patients given AAV-1/SERCA2a did not have an improvement in cardiovascular events. A similar story can be told with a different target, the stromal cell-derived factor-1 (SDF-1). The SDF-1 growth factor promotes cell

survival and recruitment, triggers angiogenesis, and increases tissue repair (Chung et al. 2015).

Initial phase I clinical trials tested the safety and efficacy of an endomyocardial injection of a DNA plasmid encoding SDF-1 into 19 patients with ischemic cardiomyopathy (Penn et al. 2013). The trial demonstrated a positive safety profile and qualitative symptomatic improvement. However, the larger, randomized phase II STOP-HF trial fell short and could not reproduce the positive results seen in the earlier trials (Chung et al. 2015). However, this does not mean that all hope is lost as several other targets have either shown initial promise or are currently in clinical trials (Hulot et al. 2016). Interestingly, an ongoing phase I clinical trial investigates the combination of VEGF-A, SDF-1 alpha, and S100 calcium-binding protein A1 as triple gene therapy in patients with end-stage HF and an implantable left ventricular assist device (NCT03409627). The ongoing EPICCURE study will be the first clinical trial to administer mRNA into the human heart (NCT03370887). It aims to investigate the safety and efficacy of AZD8601, a VEGF-A mRNA formulated in an injectable saline solution. Twenty-four patients with moderately decreased EF will be given a round of 30 epicardial injections of either 30 mg, 3 mg AZD8061, or placebo during a CABG procedure and followed for 6 months.

Cell-free strategies appear to overcome potential concerns surrounding conventional stem cell therapies, particularly from a translational perspective. These include safety concerns such as immune compatibility and rejection, as well as practical concerns such as accessibility, cost-effectiveness, and time-consuming procedures (Maghin et al. 2020). The necessary next steps include determining the optimal route of administration of these factors. In summary, noncellular regenerative therapies such as single growth factors, RNAs, or combination therapies such as exosomes appear to have significant myocardial reparative capacity. Exosomes circumvent many practical issues such as cell retention and immunogenicity and could potentially serve as an alternative to the cell-based approach in the future.

Bioengineering

The lack of understanding of the optimal cell type, dosage, route of administration compounded by low cell retention and survival, poor engraftment, and ineffective differentiation of progenitor cells post-transplantation are some of the most significant barriers encountered in clinical trials. Tissue engineering may hold the key to improving cell delivery and retention. The extracellular matrix (ECM) is now understood to be a dynamic microenvironment that contains complex networks of various proteins and growth factors and provides physical and mechanical signals to modulate cell behavior and differentiation (Maghin et al. 2020). Two strategies to bioengineer a matrix include creating a synthetic microenvironment or extracting ECM from tissues and decellularizing the matrix to create a cell-free product (Domenech et al. 2016). Since the cell microenvironment plays such an essential role in cell behavior, researchers have aimed at creating constructs that mimic the environment to improve cell culture systems and improve effectiveness of stem cell

transplantation. In the last several years, 3D culture systems have improved differentiation techniques to create cell phenotypes similar to those in native tissues (Mazzola and Di Pasquale 2020). Several studies have demonstrated that differentiation of human PSCs or iPSCs-CMs in 3D culture systems improved the level of cell maturation (Ronaldson-Bouchard et al. 2018; Correia et al. 2018). Ronaldson-Bouchard et al. (2018) showed that early iPSCs-derived CMs cultured on a 3D hydrogel subjected to electrical and mechanical stimulation showed a similar gene expression profile, sarcomere length, density of mitochondria, and functional calcium handling similar to mature adult cells.

A separate strategy in tissue engineering revolves around implanting the bioengineered tissue construct with stem cells or biologically active molecules, which is believed to increase cellular retention rates and lengthen the duration of regenerative paracrine signaling (Micheu 2019). Tissue constructs known as cardiac patches were created by adding stem cells to natural or synthetic biomaterials such as fibrin, collagen, alginate, or even a natural decellularized ECM and mimicking the biomechanical or electrical signaling they would receive in vivo (Mazzola and Di Pasquale 2020). These cardiac patches can be directly transplanted onto the epicardial surface of the heart and serve as a temporary scaffold to enable cell engraftment into the host heart. Thus, the choice of biomaterial for the scaffold is important in determining the functional survival, engraftment, and proliferation of implanted cells (Mazzola and Di Pasquale 2020). Preclinical trials have shown that administration of cells embedded in patch construct improved cellular engraftment and decreased the number of cells needed for the same graft size and functional benefit by tenfold compared to cell injection studies (Weinberger and Eschenhagen 2021). Efficacy and safety have also been demonstrated in a porcine model of MI. Researchers showed that a cardiac muscle patch produced from human iPSC-derived CMs, smooth muscle cells, and endothelial cells loaded onto a fibrin scaffold induced significant improvements in LV function, infarct size, and protective effects on endogenous CMs (Gao et al. 2018). Since tissue engineering is a relatively novel concept in cardiac regeneration, there have been relatively few clinical trials investigating the use of cardiac scaffolds. The groundbreaking ESCORT trial discussed earlier demonstrated the effective and safe use of a fibrin patch embedded with human ESC-derived CPCs (Menasché et al. 2018).

Likewise, a recent clinical trial out of Japan compared the use of human umbilical cord mesenchymal stromal cells embedded in a collagen hydrogel versus cell treatment only in patients with chronic ischemic heart disease (NCT02635464). Fifty patients were randomized into either cell/hydrogel group, cell only, or placebo, and were given a single IM injection during a CABG procedure. Results showed that the collagen hydrogel treatment was a safe and feasible delivery option, and the collagen/cell combination decreased mean scar size at 12 months. However, results were not statistically significant (He et al. 2020). However, improvements in LVEF, NYHA functional class, viable heart mass, and quality of life measured by the MLHFQ were noted. Moreover, LVESV and LVEDV decreased. This study, to our knowledge, is the first ever to establish that the use of collagen hydrogel in humans is safe and feasible for cell delivery. These findings will provide a basis for future clinical trials in the future.

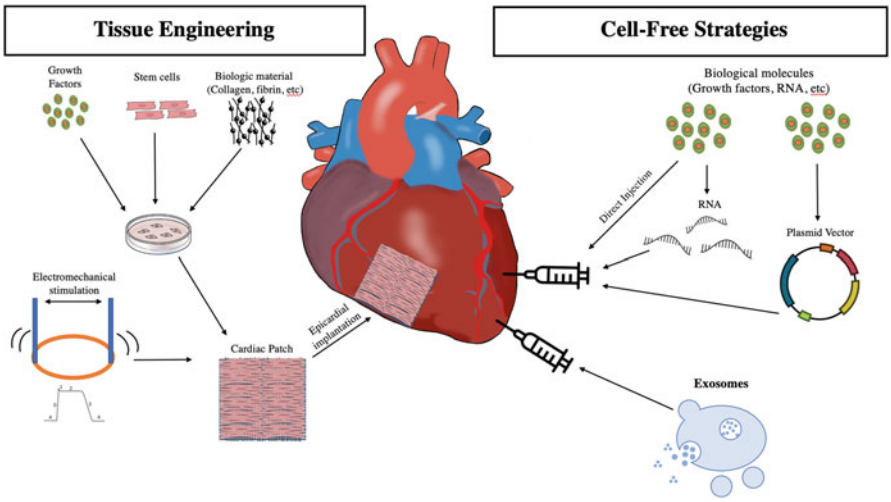

Fig. 3 Approaches to tissue engineering and cell-free strategies in cardiac regeneration

Recently, researchers have created scaffold-free cell sheets which can be directly implanted onto the myocardium without transplantation of a biomaterial in addition to the cells. This technology involves culturing a monolayer or multilayer of cells on a thermoresponsive polymer surface, and then removing the individual sheets of cells to combine them and create 3D cardiac grafts (Zhang 2015). However, this recent phenomenon has been well proven in various preclinical animal models but has yet to be tested in the clinical trial setting. Because of the low rates of cellular retention and cardiac remuscularization involved with direct cell injection, alternative methods needed to improve cardiac regeneration. Many believe that combination therapy holds the key to improving the efficacy of cardiac regeneration through enhanced cell engraftment and also improved paracrine factor signaling. This likely involves not only the combination of cells embedded in scaffolds, but also the involvement of biologically active molecules such as growth factors, RNAs, and exosomes. It seems inevitable that future research will investigate the implantation of a cardiac construct containing several different cell types and signaling molecules as a cell sheet or embedded in a biologically active scaffold (Fig. 3).

Conclusion and Future Perspectives

As the field of cardiac cell therapy approaches its third decade, we have yet to have a single stem cell type that the FDA approves for the treatment of heart disease (Cingolani 2019). However, it appears that we are finally gaining a greater understanding of the issues that have plagued the discipline for so long. Through a plethora of clinical trials, we have witnessed that it is incredibly difficult to remuscularize the failing heart. Cellular retention and survival rates have been

incredibly low in clinical trials. In response, the field has shifted its mechanistic hypothesis of how cardiac cell therapy provides the observed therapeutic benefits. Most researchers now believe that stem cells provide the vast majority of their cardiac benefit via paracrine signaling rather than directly producing new CMs to remuscularize the heart. However, there appears to be some variation between specific cell types and method of delivery.

Thus far, numerous clinical trials have shown that cardiac cell therapy generally has a favorable safety profile. The SafeCell Heart meta-analysis demonstrated no adverse events associated with the use of MSCs in heart disease (Lalu et al. 2018). There are concerns surrounding the arrhythmogenicity of stem cells primarily within the skeletal myoblast lineage. Nonetheless, all cell types should be thoroughly investigated for arrhythmogenic risk before applied in large-scale clinical settings (Chen et al. 2020).

Most clinical trials to date have demonstrated neutral to marginally positive results in terms of clinical efficacy. Interestingly, a trial sequential analysis in 2016 revealed that there is firm evidence supporting that bone marrow-derived stem cell therapies do reduce the risk of rehospitalization and mortality in patients with HF (Fisher et al. 2016b). The SafeCell Heart meta-analysis also demonstrated that patients who receive MSCs therapy have a significantly improved LVEF (Lalu et al. 2018). Nonetheless, there has only ever been one phase III clinical trial investigating cellular therapy in heart disease and the results are still pending. This does not imply that stem cells have no clinical value in heart disease. Rather, we have not found the optimal cell type or delivery system for these stem cells. Large comparative clinical trials will need to be performed before reaching any conclusions about the effectiveness of regenerative therapies compared to our conventional pharmacologic treatments currently used for HF.

Clinical research to date has set the foundations for a technological breakthrough in cardiac cell therapy. In particular, we believe that future research in three specific areas will produce a generational breakthrough in cardiac regeneration. First, cell-free sources of cardiac regeneration such as exosomes, growth factors, and RNAs may provide a potential therapeutic approach without some of the safety concerns associated with cellular therapies. A cell-free strategy may also have practical advantages in terms of scalability, availability, and reduced cost. Second, combining cell therapy with bioengineering scaffolds or tissue constructs may provide a way to increase cell engraftment rates and prolong the survival of cells so that their beneficial paracrine effects can be sustained for longer. Lastly, the use of pluripotent cells to derive cell phenotypes of choice could be an excellent strategy for creating functional CMs or endothelial cells that can directly engraft into the myocardium and synchronize with the host cells. In addition, combination therapy of multiple PSC-derived cells types has already been proven in clinical trials to provide successful cardiac outcomes.

In summary, future research must establish the optimal cell type, route of delivery, and dosage to improve the efficacy to levels needed for implementation at the clinical level. In addition, studies should have long-term follow-up periods to truly identify the therapeutic risks and potential of cardiac cell therapy. Tailoring the cell

therapy to the patient in question would be likely the most productive approach, as many differences exist between patients such as age, the severity of HF, immune status, and comorbidities. In addition, combination approaches consisting of pharmacological, cell-free paracrine strategies, and stem cell therapy will likely provide superior, sustainable results for patients. Regenerative therapies are still far from being implemented as a mainstay in the clinic; however, incredible progress has been in the field in the last several years. We remain cautiously optimistic that innovative techniques such as bioengineering, exosome therapy, and combination therapies will propel the field into unprecedented territory in the years to come.

Abstract

Heart failure is one of the leading causes of morbidity and mortality globally. Myocardial infarction remains one of the primary causes of chronic heart failure due to cardiac remodeling, including the formation of fibrotic scar tissue and cardiomyocyte necrosis. Despite myocardial infarction being recognized as a significant predisposing factor to heart failure, modern therapies such as pharmacological and surgical interventions are currently unable to treat the underlying

pathologies. Because of the limited intrinsic regenerative capacity within the heart, stem cell therapy has recently been touted as a potential option for the treatment of heart failure. Stem cells are characterized by two unique properties; the ability to self-renew and to differentiate into multiple lineages. Although the exact regenerative mechanism remains relatively unknown, it is believed that stem cells mediate myocardial repair primarily via activation of paracrine signaling pathways, with some cell types contributing to the direct replacement of functional cardiomyocytes. Pre-clinical and clinical studies have shown a range of predominantly neutral to moderately positive outcomes in terms of both safety and clinical efficacy. The following review will discuss what is currently known about stem cell-based treatment for heart failure, the various types of stem cells used in therapeutics, recent clinical trials, as well as current limitations and future directions of regenerative cell therapy.

Keywords

Adult stem cells · Bone marrow stem cells · Cardiomyocytes · Cardiovascular · Cell therapy · Chronic cardiomyopathy · Heart failure · Myocardial infarction · Pluripotent stem cells · Regenerative therapy · Stem cell

Abbreviations

ABMCs	Autologous bone marrow cells
AMI	Acute myocardial infarction
BMDSCs	Bone marrow derived stem cells
BMMNCs	Bone marrow mononuclear cells
CABG	Coronary artery bypass grafting
CPCs	Cardiac progenitor cells
CSCs	Cardiac stem cells
CVD	Cardiovascular disease
EDV	End diastolic volume
ESCs	Embryonic stem cells
ESV	End systolic volume
HF	Heart failure
HFpEF	HF with preserved ejection fraction
HFrEF	HF with reduced ejection fraction
IGF-1	Insulin-like growth factor-1
iPSCs	Induced pluripotent stem cells
LVEF	Left ventricular ejection fraction
MI	Myocardial infarction
MSCs	Mesenchymal stem cells
PSCs	Pluripotent stem cells
VEGF	Vascular endothelial growth factor
WHO	World Health Organization

Introduction

Cardiovascular disease (CVD) continues to be the leading cause of morbidity and mortality globally, with the World Health Organization (WHO) reporting an estimated 17.9 million deaths attributed to CVD in 2016 (World Health Organization 2021). Chronic heart failure (HF) is an important cardiovascular disease due to its high incidence, high mortality rate, and poor prognosis (Alpert et al. 2017; Hong-Mi et al. 2019). HF is a debilitating disease that leads to progressive cardiopulmonary symptoms and is strongly associated with a decreased quality of life (Merck Manuals Professional Edition 2020). HF currently affects 1.5% of Canadians (Tran et al. 2016) and these numbers are expected to increase due to the aging demographic and the increase in CV risk factors such as obesity. Canadians who are hospitalized with HF have a 1-year mortality rate of over 30% and these numbers have not improved over the last decade despite significant medical advancements (Ibid.).

Pathophysiology of Heart Failure

Heart failure is a complex syndrome of ventricular dysfunction that results from structural or functional impairment of ventricular filling or ejection of blood. This subsequently results in inadequate blood supply to the tissues for metabolic needs (Merck Manuals Professional Edition 2020). The most common underlying cause of HF is myocardial infarction (MI) (Cahill and Kharbanda 2017), which is defined as myocardial cell death due to prolonged ischemia (Thygesen et al. 2012). However, HF may also be caused by structural defects like congenital deformities, valvular disorders (i.e., aortic stenosis), high metabolic demand (i.e., thyrotoxicosis), myocarditis, arrhythmias and persistently high heart rate (Merck Manuals Professional Edition 2020). In MI, single or multiple coronary arteries are occluded persistently or intermittently, which impedes perfusion of the myocardium (Thygesen et al. 2012). After the onset of ischemia, cardiomyocyte death is observed and an intense inflammatory response is triggered (American College of Cardiology 2016). Besides, reperfusion of the myocardium causes the production of reactive oxygen species, release of vasoactive mediators, and plugging of inflammatory cells leading to further myocardial damage (Cahill and Kharbanda 2017). In the post-MI state, there is a progression from inflammation to cardiac repair, including the formation of fibrotic scar tissue, activation of the sympathetic nervous system and initiation of the renin-angiotensin-aldosterone system (Braunwald 2013). Cardiac remodeling results in structural and functional changes in the zone of infarction (Merck Manuals Professional Edition 2018) and can ultimately lead to HF. The most common classifications of HF are HF with reduced ejection fraction (HFrEF) and HF with preserved ejection fraction (HFpEF) (Yancy et al. 2013). HFrEF is defined by HF with left ventricular ejection fraction (LVEF) of $\leq$40%. In this type of HF, the ventricle fails to contract properly, leading to increased diastolic volume and

diastolic pressure with decreased ejection fraction. Over time, the ventricles are remodeled as a higher preload is required to maintain cardiac output. As the ventricle dilates and hypertrophies, increased stiffness of the ventricle and diastolic dysfunction ensues, compromising cardiac performance, and further contributing to adverse systemic venous congestion (Merck Manuals Professional Edition 2020). Conversely, HFpEF is defined as HF with LVEF ($\geq$ 50%). In this case, the ventricular filling is impaired as the heart is unable to relax and becomes stiff. Increased ventricular end-diastolic pressure and normal end-diastolic volume, ejection fraction, and contractility are observed (Yancy et al. 2013). HFrEF and HFpEF can affect both ventricles, though the left ventricle is most commonly affected. A deep understanding of the pathophysiology of HF is critical in producing an effective stem cell-based strategy that reverses underlying pathological processes.

Significance to the Research

Despite tremendous medical advancements in the past generation, the diagnosis of chronic heart failure still carries significant morbidity and mortality (Kostuk 2001). Current goals of HF treatment are aimed at alleviating symptoms, properly managing comorbidities, and enhancing the quality of life rather than reversing the underlying pathologic process. Standard pharmaceutical therapies involve medication such as diuretics, beta-adrenergic blockers, anti-hypertensives, inotropic agents, and anticoagulants (Inamdar and Inamdar 2016). HF caused by MI can be treated with surgical intervention to relieve obstructed arteries and reperfuse the myocardium (Briffa et al. 2009). Smoking cessation, healthy dietary patterns, regular physical activity, and maintaining a normal body mass index (BMI) are common risk reduction techniques (Fleg 2016) that serve to slow disease progression without reversing pre-existing damage to the heart (Faiella and Atoui 2016). Heart transplantation is generally used as a last resort for all-cause HF (Yamakawa et al. 2013) and carries a 10-year survival rate of over 50% (Anyanwu and Treasure 2003). However, there remains a major discrepancy between the availability of donors and recipients (Ibid.). Research is now focusing on promising alternative therapy to treat HF: stem cells. It is believed that stem cells can regenerate damaged cardiac tissue and restore its physiologic function (Fraser et al. 2004). The following review will discuss the advantages and limitations of various stem cell therapies, including current clinical trials, safety concerns, and how to optimize cell therapies.

Introduction to Stem Cells

Stem cells are characterized by two unique properties: the ability to self-renew and to differentiate into specialized cell types. Although first identified in the hematopoietic system, various subtypes are present in other tissues, which have led to the development of multiple system-specific therapies. They are gaining popularity and their roles have been evolving within the following three major applications in medicine.

1. Cell therapy to replace functional tissue
2. Targets of drug therapy
3. To generate differentiated tissue for in vitro study of disease models to develop drugs

Stem cells have varying differentiating potentials, known as potency. Potency is the capacity of the stem cell to differentiate into specialized cell types (Hima and Srilatha 2011) which will give rise to a mature cell type and, subsequently, the formation of tissues within the body. Once an egg is fertilized in the female, the cells that arise in the first few divisions are classified as totipotent, meaning that they can generate a viable embryo. However, within a matter of days, these totipotent cells transition to pluripotent, subsequently becoming embryonic stem cells (ESCs). The level of their potency decreases as stem cells differentiate further along their lineage pathways. Thus, stem cells can be classified into three clinically relevant categories based on their origin and level of potency: ESCs, induced pluripotent stem cells (iPSCs), and adult stem cells.

Embryonic Stem Cells

ESCs are a descendant of totipotent cells. These cells are derived from the inner cell mass of the blastocyst, a hollow ball of cells that forms 3–5 days after an egg is fertilized (Stem Cells 2020). ESCs are pluripotent, meaning that they have the ability to produce cells from all three germ layers (ectoderm, mesoderm, endoderm), but not the placenta or umbilical cord. These cells are a resource for studying normal development, disease, and for testing drugs and therapies (Ibid.). Current therapeutic strategies involve differentiating ESCs into the tissue-specific cell or progenitor before incorporation into the tissue of choice. When ESC lines are produced in the laboratory, they retain their proliferative properties indefinitely. These are invaluable since they have the highest differentiation potential but are subject to various ethical debates (Hima and Srilatha 2011) (discussed in Ethical Considerations of the Use of Stem Cells).

Induced Pluripotent Stem Cells

iPSCs- have been engineered in laboratories by converting tissue-specific somatic cells into stem cells that behave like ESCs (Stem Cells 2020). For example, isolating keratinocytes from the epithelium and engineering it into a pluripotent stem cell with the capacity to differentiate into all three germ layers. Like ESCs, these can help researchers to learn more about normal development, characterize the disease, and investigate novel therapeutics (Ibid.). Although these cells share many of the same characteristics of ESCs, several important differences distinguish them from ESCs. One of the major advantages of iPSCs is that they circumvent serious ethical concerns that come with ESCs. However, it is believed that iPSCs retain some

residual epigenetic memory of their specialized cell of origin (Kim et al. 2010), making it difficult to effectively reprogram to a fully pluripotent phenotype. As with ESCs, current strategies of cardiac therapeutics involve "instructing" iPSCs to differentiate into cardiac progenitor cells (CPCs) or cardiomyocytes before implantation into the myocardium.

Adult Stem Cells

Tissue-specific stem cells are commonly referred to as adult stem cells. These are more specialized stem cells (Hima and Srilatha 2011) and can only differentiate into a limited number of cell types within their tissue of origin. Tissue-specific stem cells are classified as multipotent, but their products are unipotent as they are of the lowest differentiation potential. For example, hematopoietic stem cells are multipotent, but red blood cells are unipotent as they are at their last stage of differentiation. The adult stem cells of interest in this discussion are cardiac stem cells (CSCs), bone marrow-derived stem cells (BMDSCs), and mesenchymal stem cells (MSCs). CSCs are isolated from the atria, ventricles, or the epicardium in biopsies (Faiella and Atoui 2016) and play an important role in clinical trials. Although they are harder to acquire and possess less impressive self-renewal capabilities, they have many attributes that improve cardiac function (Menasché 2018). The only CSCs used in clinical trials are KIT+ and cardiosphere-derived cells. Bone marrow-derived mononuclear stem cells (BMMNCs) are adult stem cells that contain various populations of hematopoietic and immune cells. Lastly, MSCs are commonly mentioned in stem cell research. Many tissues in the body contain these multipotent cells, the largest reservoir being in the bone marrow (International Society for Stem Cell Research). These fall under the category of adult stem cells, and although found in the bone marrow, they are classified under their subtype. These cells are capable of forming bone, cartilage, and fat cells (Ibid.). Although these fall under tissue-specific stem cells, they are classified under their own lineage.

Endogenous Regeneration of Cardiomyocytes

Heart regeneration has been a heavily investigated topic in a countless number of species. In the developing mammals and invertebrates, there is well-documented evidence showing vast myocardial regeneration (Laflamme and Murry 2011). Yet, the extent of endogenous myocardial regeneration in adult hearts is still up for debate. The vast majority of the growth of the human embryonic and fetal heart occurs due to the rapid proliferation and differentiation of CPCs and immature cardiomyocytes (Eschenhagen et al. 2017; Eldad et al. 2017). Throughout the postnatal life, the central mechanism for cardiac growth shifts from hyperplasia to cardiomyocyte hypertrophy (Eschenhagen et al. 2017). One current theory postulate that the polyploid genome found in adult human cardiomyocytes restricts regeneration. In contrast, animal cardiomyocytes such as amphibians and reptiles have an

almost entirely diploid genome (Marchianò and Murry 2019) allowing cells to divide more frequently. Further investigations suggest that polyploidy is strongly correlated with endothermy, the ability to regulate one's body temperature. As one's body temperature and metabolic rate increase, there is a decrease in diploid cardiomyocytes, leading researchers to think that there may have been an evolutionary trade-off between the ability of humans to regenerate cardiac tissue and the ability to regulate body temperature (Ibid.). Nonetheless, one thing is for certain: the human heart is not a completely post-mitotic organ (Bruyneel et al. 2016). Current evidence estimates that in a healthy human adult heart, the cardiomyocyte turnover rate appears to be around 1% per year, with a decline in turnover rate with age (Burridge et al. 2012; Bergmann et al. 2009). This equates to approximately 50% of cardiomyocytes being renewed across one's lifespan (Bergmann et al. 2009). This can become incredibly problematic, given that a severe myocardial infarction can destroy 25% of functional cardiomyocytes within only a few hours (Murry et al. 2006). Interestingly, several studies suggest that the myocardium may have some innate proliferative ability after a severe cardiac event. In 2001, Beltrami et al. discovered that there was an increase in human cardiomyocyte renewal post-myocardial infarction in the border regions of the infarct. However, it is uncertain if this provides any clinical benefit. The question remains as to where these cardiomyocytes arise. The majority of studies seem to suggest that the proliferation of existing cardiomyocytes provides the largest contribution to basal cardiomyocyte turnover, with differentiation of resident and extracardiac stem cells occurring at a higher rate after injury (Eschenhagen et al. 2017). A deeper understanding of the exact mechanisms underpinning endogenous cardiomyocyte regeneration after myocardial injury would be extremely beneficial for developing the most effective therapeutic strategy.

Landmark Clinical Trials

Adult Stem Cells

Cardiac Stem Cells

Until recently, it was controversial as to whether CSCs had the potential to regenerate the myocardium. However, it is now well established that CSCs express markers of cardiogenesis and can differentiate into cardiomyocytes and vascular endothelial cells (Faiella and Atoui 2016). To date, only c-KIT+ CSCs and cardiosphere-derived cell phenotypes have been utilized in clinical trials. The stem cell infusion in patients with ischemic cardiomyopathy (SCIPIO) is a phase 1 clinical trial (2011) administering KIT+ CSCs to patients with HF undergoing coronary artery bypass grafting (CABG). Interestingly, KIT+ cells are speculated to favor differentiation into vascular cells rather than cardiomyocytes (van Berlo et al. 2014). Preliminary results of the study demonstrated an increase in LVEF at 4- and 12-months post-infusion, in addition to a decrease in infarct size (Chugh et al. 2012). However, in 2014 the editors of The Lancet issued an "expression of

concern" (Menasché 2018) as the integrity of the data was questioned, leading to the retraction of the study. The intracoronary cardiosphere-derived cells for heart regeneration after myocardial infarction (CADUCEUS) trial is a published phase 1 clinical trial examining the use of autologous cardiosphere-derived CSCs. Six months post-administration, MRI findings showed a reduction in scar tissue size, along with improvements in regional contractility and viable heart mass. Although structural and functional changes were noted, changes in end-diastolic volume (EDV), end-systolic volume (ESV), and LVEF did not differ between groups (Makkar et al. 2012). There were no significant adverse effects noted in the SCIPIO and the CADUCEUS trials, alluding to a positive safety profile for CSCs. The CONCERT-HF trial is an ongoing trial including 144 patients with HF who are assigned randomly to receive KIT+ CSCs, bone marrow-derived MSCs, a combination of both cell types or a placebo. The premise of using both cell types together is based on animal models showing that the pairing works synergistically (Bolli et al. 2018) to improve structural and functional outcomes in chronic HF. Although this study was paused for a brief period, it is set to be completed by July 2020 (National Institute of Health, n.d.). Likewise, the TAC-HFT-II trial will soon compare therapy with autologous MSCs alone versus MSCs combined with KIT+ CSCs. The ALLSTAR phase 2 trial using cardiosphere-derived cells was stopped prematurely due to the futility of the data and the probability of not meeting the primary goal after 6 months follow-up (Menasché 2018).

Bone Marrow-Derived Cells

Bone marrow-derived stem cells (BMDSC) have been one of the most heavily tested cell types in the treatment of cardiovascular disease to date. However, many of these trials focus on acute myocardial infarction (AMI) rather than HF (Turner et al. 2020). While MSCs are often isolated from the bone marrow, this section will be focusing on BMMNCs and autologous bone marrow cells (ABMCs). The first-ever clinical trial using cellular therapeutics was published in 2003. It included 21 patients with chronic ischemic cardiomyopathy who received transendocardial injection of autologous BMMNCs. After 4 months, there was a significant increase in LVEF and a reduction in ESV (Perin et al. 2003). Similar results were found in the TOPCARE-CHD trial, which showed a significant decrease in brain natriuretic peptide and decreased mortality in response to intracoronary administration of BMMNCs (Assmus et al. 2007). The STAR-heart study demonstrated that up to 5 years after intracoronary administration, ABMCs improved long-term mortality and LVEF (Tehzeeb et al. 2019). Besides, a decreased left ventricular preload, end-systolic volume, systolic wall stress, occurrence of arrhythmias, and area of infarction was noted. To this point, all clinical trials had also demonstrated a positive safety profile for BMDSCs. This initial success set the stage for the larger phase 2, randomized, double-blind FOCUS-CCTRN trial. This trial enrolled 153 patients with chronic ischemic cardiomyopathy and aimed at administering autologous BMMNCs via transendocardial injection. Unfortunately, these positive results could not be replicated, as there were no significant improvements in LVEF,

maximal oxygen consumption, or infarct size (Perin et al. 2012). Additionally, In the TAC-HFT-I trial, patients were given either transendocardial injections of autologous BMMNCs, autologous MSCs, or placebo. Results showed that only MSC therapy decreased infarct size and improved regional function of the heart, and the distance walked during the 6-min walk test (Heldman et al. 2014). No improvements were noted in LVEF. After more than a decade of research, a trial sequential analysis of two Cochrane reviews was published, providing clarity as to the overall effectiveness of BMDSCs in the treatment of HF. They determined that there is firm evidence showing BMDSCs cause a reduction in both mortality and rehospitalization rates. However, they show that treatments do not provide more than a 4% increase in LVEF (Fisher et al. 2016a). There is also a large phase 3 clinical trial ongoing to assess if the intracoronary infusion of autologous BMMNCs is safe and can cause a reduction in mortality and LVEF. If positive data comes out of the ongoing BAMI trial, we may very well see a public push for autologous BMMNCs to transition from bench to bedside.

Mesenchymal Stem Cells

Preclinical and clinical evidence suggests that MSCs may provide benefit in the treatment of MI and HF (Lalu et al. 2018) due to a greater likelihood of vascular proliferation and regeneration (Tehzeeb et al. 2019). MSCs exhibit important reparative properties such as immunomodulation, along with antifibrotic, proangiogenic, and anti-oxidative effects (Turner et al. 2020) making them great contenders for treating cardiomyopathies such as HF. By March 2018, there were 17 clinical trials registered using MSC therapy in chronic HF. Among the different bone marrow-derived cells, MSCs seem to show the greatest promise for regeneration of myocardium (Menasché 2018), likely due to their strong paracrine effect. The POSEIDON randomized control trial compared autologous and allogeneic MSCs in HF patients. Results indicate that both types of cells reduced infarct size, adverse cardiac remodeling, and LV function after an MI (Hare et al. 2012). A recent systematic review and meta-analysis which included 23 studies in total, investigated the safety and efficacy of adult stem cell therapy for the treatment of acute myocardial infarction and HF. In total, 11 studies evaluated the efficacy of adult MSCs in acute myocardial infarction, while 12 studies evaluated their efficacy in ischemic HF. Post-treatment; there was a significant improvement in LVEF but no significant differences in mortality between groups (Lalu et al. 2018). However, upon further subgroup analysis, no significant LVEF improvements were observed in the treatment of HF, but rather only for the treatment of AMI. Positive results were observed in other clinical outcomes of HF, as there were significant improvements in quality of life and the 6-min walk test. Evidence suggests that MSC therapy seems to be safe, as there was no association between treatment and acute adverse outcomes for patients. An important limitation to consider is that MSCs are expected to lose some form of efficacy due to aging, warranting donations from healthy donors rather than obtaining autologous cells from older individuals who may have additional comorbidities (Tehzeeb et al. 2019). Cardiopoietic stem cells are more specialized

cells derived from a pure MSC population in the bone marrow. Although these are more developed than true MSCs, they have been of interest in HF studies. The C-CURE trial is one of the first using cardiopoietic cells in the treatment of HF. Findings demonstrated an increased LVEF, improved quality of life, and a lower left ESV after 2 years (Bartunek et al. 2013). The findings of the C-CURE trial catalyzed larger studies to take place such as the CHART-1 trial, which shared similar results as the latter. Both the C-CURE and CHART-1 trial indicate that stem cell therapy is safe and has potential to provide long-lasting benefits on cardiac function in those affected by HF (Bartunek et al. 2017). Larger randomized controlled trials, along with a comprehensive assessment of the impact of MSCs on cardiac function, would further establish a conclusive risk-benefit ratio for MSCs.

Skeletal Myoblasts

Early preclinical trials showed promise as skeletal myoblasts appeared to have the capabilities to differentiate into cardiomyocytes and improve cardiac function in animal models (Taylor et al. 1998; Chiu et al. 1995). Other preclinical studies were not able to successfully transdifferentiate skeletal myoblasts into cardiomyocytes after grafting, contradicting earlier evidence (Reinecke et al. 2002). Regardless, skeletal myoblasts were quickly rushed into clinical trials, and the results were disappointing. In the MAGIC trial, the intramyocardial injection of skeletal myoblasts did not improve LVEF and failed to improve regional and global heart function. In addition, patients receiving the skeletal myoblasts had a significantly greater risk of arrhythmias and embolic events compared to the placebo (Menasché et al. 2008). Similarly, the MARVEL trial did not demonstrate improvements in left ventricular function, although some moderate improvements in the distance for the 6-min walk test were noted (Povsic et al. 2011). The MARVEL trial also revealed that intramyocardial injection of skeletal myoblasts posed an increased risk of developing ventricular tachycardia. Since these landmark trials have come out, researchers have transitioned away from using skeletal myoblasts in hopes of finding a safer, more effective alternative cell type.

Pluripotent Stem Cells

Pluripotent stem cells include both ESCs and iPSCs and, by definition, are cells that can form all three germ layers of the embryo (Hackett and Fortier 2011). Although there are subtle differences in potency between the two cell types, the major distinction between the two comes from their difference in origin. Nonetheless, pluripotent stem cells (PSCs) have a unique advantage of being able to be differentiated in a tightly controlled, stepwise fashion. This allows researchers to create lineage-specific progenitors such as CPCs at their preferred level of differentiation (Menasché 2018).

Embryonic Stem Cells

There have been relatively few trials investigating the safety and efficacy of human ESCs in preclinical and human models. Of interest, two preclinical trials in non-human primates involved intramyocardial delivery of human ESC-derived

cardiomyocytes post-ischemia/reperfusion injury (Liu et al. 2018; Chong et al. 2014). In these studies, human ESCs derived cardiomyocytes were administered 2- and 4-weeks post-MI into immunocompromised Macaque monkeys. These studies produced some positive results: as hearts exhibited significant remuscularization within the infarcted area, ESC-grafts demonstrated successful reperfusion by the host vasculature, and engrafted cells demonstrated electromechanical coupling to host myocytes. There was also no sign of immune rejection or teratoma formation. However, there was no significant improvement in LVEF and non-fatal ventricular arrhythmias were seen in all monkeys (Liu et al. 2018; Chong et al. 2014) These findings were reproduced in a similar preclinical experiment administering human ESC derived cardiomyocytes into a post-MI porcine model (Romagnuolo et al. 2019). Together, these studies demonstrated the feasibility of producing and using human ESC derived cardiomyocytes on a clinical scale and opened the door for phase 1 clinical trials in humans.

The first human trial using human ESC derived CPCs to treat HF was completed and illustrated some promising preliminary results (Menasché et al. 2018). This trial incorporated 6 patients with left ventricular dysfunction (ejection fraction <35%) and a history of myocardial infarction. A fibrin patch embedded with human ESC derived CPCs was implanted epicardially during a coronary artery bypass procedure. At the endpoint of 1 year, there were no signs of teratoma formation or arrhythmias present in any of the patients. Interestingly, the four patients who were assessed at the 1-year follow up had functional and symptomatic improvements. Although statistically insignificant, they showed a modest increase in LVEF, a decrease in left ventricular volume, and a statistically significant improvement in heart wall motion within the cell treated segments. Patients also showed symptomatic improvement quantified by a decrease in the New York Heart Association Class and an increased 6-min walk test. Although these results regarding efficacy do appear quite exciting, they should be interpreted with caution as it was an extremely small sample size and there are various confounding variables involved, including the concomitant coronary artery bypass grafting. However, the principal discovery of this trial was successful in showing that human ESC derived CPCs can be produced on a clinical scale and show no major signs of adverse effects after implantation. This trial does display the potential for human ESCs to be used in the treatment of HF, and further clinical trials are warranted to investigate the full extent of their clinical usefulness.

Induced Pluripotent Stem Cells

Since the major discovery of Takahashi and Yamanaka in 2006, there has been great interest in the therapeutic potential of iPSCs. The first human clinical trial involving iPSCs occurred in 2014 and was aimed at treating age-related macular degeneration (Mandai et al. 2017). Although the trial didn't produce positive results in terms of clinical improvement, it demonstrated the feasibility of human iPSCs being produced on a clinical scale and administered to humans without major safety concerns. From there, iPSCs began being investigated for various diseases, including Parkinson's disease, immunotherapy for cancer, and now

heart disease (Bragança et al., 2019). Several pre-clinical studies have validated that iPSCs could play an important role in cardiac repair. Ye et al. (2014) demonstrated that intramyocardial administration of a fibrin patch embedded with human iPSC derived cardiomyocytes among other cells and growth factors produced a significant improvement in left ventricular function and decreased infarct size in a post-MI porcine model. In a recent study, extracellular vesicles secreted by murine iPSCs were shown to cause a significant improvement in left ventricular function and a decrease in infarct mass in a post-MI mouse model (Adamiak et al. 2018).

There are currently two clinical trials that have been approved for utilizing iPSCs in the treatment of chronic cardiomyopathy in humans. The world's first clinical trial was approved in Japan in 2018 and aims to administer a patch of human reprogrammed iPSC cardiomyocytes into the damaged myocardium (Cyranoski 2018). Details about the trial are scarce, but three initial patients with chronic ischemic cardiomyopathy have been treated and the clinical trial aims to involve 10 patients over 3 years. Follow up will occur at 1-year post-implantation and the primary endpoints investigated will be safety and efficacy. The second clinical trial (HEAL-CHF) is an open-label taking place in China. Five patients with HF will be treated with intramyocardial delivery of allogeneic human iPSC-derived cardiomyocytes and assessed for safety and efficacy. There are currently no published results from either trial, although these should be expected within the next year.

One of the major barriers that arose during preclinical trials is that cardiomyocytes derived from PSCs have an immature phenotype compared to human adult cardiomyocytes. The ideal transplant would involve cardiomyocytes integrating into the host myocardium, secreting factors to re-vascularize necrotic tissue, electromechanically coupling with the resident cardiomyocytes, and beating in synchrony (Gerbin and Murry 2015). Unfortunately, human PSC derived cardiomyocytes are functionally immature in terms of their sarcomere organization, calcium handling properties, and metabolism compared to adult cardiomyocytes (Mazzola and Di Pasquale 2020). This limits their ability to efficiently integrate with host cardiomyocytes and is believed to be the reason that ventricular arrhythmias can arise (Vagnozzi et al. 2018). The problem may not be with the potency of the cells themselves, but rather the differentiation techniques that are currently used to create the cardiomyocytes. Strategies that enhance the differentiation of PSC-derived cardiomyocytes include the use of bioengineered scaffolds, chemical factors, mechanical loading, and electrical stimulation (Ibid.). Since then, we have seen the emergence of the very first human clinical trials in both ESCs and iPSCs in the treatment of HF and more are likely to come (Menasché et al. 2018; Cyranoski 2018). Although data is still quite limited, initial results regarding safety are quite promising, suggesting that the challenges of cell integration surrounding the immature cardiomyocyte phenotype may not be as severe in humans. Future studies should shift toward confirming safety in larger cohorts and optimizing the efficacy of PSCs. A summary of some of the landmark clinical trial has been included in Table 1.

Table 1 Summary of landmark clinical trials

Clinical trial	Cell type	Study design	Efficacy	Safety	Conclusions
1. SCIPIO (2011)	Kit+ cardiac	Phase I randomized open label 23 patients total Intracoronary injection	Decrease in infarct size and increase in LVEF	Satisfactory safety profile	Improvements in ventricular function "Expression of concern" from *The Lancet,* 2014
2. CONCERT-HF (2015–present)	Kit+ cardiac and bone marrow-derived MSCs	Phase II randomized, placebo-controlled study 144 patients total Transendocardial injection	Awaiting results	Awaiting results	Awaiting results
3. TAC-HFT-II (estimated start date March 1, 2025)	Kit+ cardiac and bone-marrow derived MSCs	Phase I and II randomized, placebo-controlled trial 55 patients total	Awaiting results (2032 estimated completion date)	Awaiting results	Awaiting results
1. ALLSTAR (2017)	Cardiosphere-derived	Phase II randomized double-blind placebo-controlled 134 patients total Intracoronary injection	Study was stopped prematurely	Study was stopped prematurely	Study was stopped prematurely
2. CADUCEUS (2014)	Autologous cardiosphere-derived	Phase I randomized open label 25 patients total Intracoronary injection	Reduction in infarct size and improvements in contractility	Satisfactory safety profile	Structural improvements but no improvements in LVEF
1. FOCUS CCTRN (2012)	Autologous bone marrow-derived mononuclear	Phase II randomized double-blind placebo-controlled trial 92 patients total Transendocardial injection	No significant improvements in LVEF noted	No in-hospital events besides one aortic dissection No other safety concerns noted	Transendocardial injection of bone marrow cells versus placebo did not improve LV end systolic volume, maximal oxygen consumption, or perfusion defects

Clinical trial	Cell type	Study design	Efficacy	Safety	Conclusions
2. TAC-HFT-I (2009–2013)	Autologous bone marrow-derived mononuclear and MSCs	Phase I and II randomized blinded placebo-controlled trial 65 patients total Transendocardial injection of MSCs and placebo, and BMCs with placebo	Improvements in the MLHF score, 6-min walk distance, infarct size, and regional function with MSCs only	Transendocardial injection was not associated with an increased risk of side effects	Ejection fraction and left ventricular chamber volume did not change. Larger studies are warranted to provide definitive evidence about safety and assess efficacy
3. STAR-heart (2003–2005)	Autologous bone marrow-derived mononuclear	Prospective study 191 patients total Intracoronary injection	Improvements in NYHA functional class, decreased LV preload, end-systolic volume, wall stress, arrhythmias, and smaller area of infarction	No side effects were documented	Intracoronary injection of autologous bone marrow cells decrease long-term mortality and improve ventricular function
1. POSEIDON (2010–2011)	Mesenchymal	Phase I/II randomized comparison 30 patients total T.E. injection	Both allogeneic and autologous MSCs reduced infarct size, adverse cardiac remodeling and LV function	Satisfactory safety profile	Patients treated with both allogeneic and autologous MSCs had functional and structural improvements over time
2. MSC-HF (2015)	Mesenchymal	Phase I/II randomized double-blind placebo-controlled trial 60 patients total Intramyocardial	Improvements in LVEF, stroke volume, and myocardial mass	Satisfactory safety profile	Autologous MSCs improved myocardial function and myocardial mass in heart failure patients

3. CHART-1 (2017)	Cardiopoietic	Phase III prospective, randomized double blind placebo-controlled trial 271 patients total I.M. injection	Significant benefits with patients with severely dilated ventricles	Satisfactory safety profile	Neutral outcome with no significant difference between all-cause mortality, rehospitalization for MI, heart failure, and stroke at 12 months between groups
4. DREAM-HF (2014)	Allogeneic mesenchymal precursor cells	Phase III randomized double-blind placebo-controlled trial 566 patients total T.E. injection	Awaiting results	Awaiting results	Study is expected to be completed on May 29, 2020
1. MAGIC (2008)	Skeletal myoblasts	Randomized, placebo-controlled double-blind study in 120 patients Conducted in 21 hospitals in France, Italy, Germany, Belgium, UK, I.M. injection	No significant improvements in LVEF noted	Risk of arrhythmias	Unsafe and ineffective source of stem cells
2. MARVEL (2011)	Skeletal myoblasts	Randomized placebo-controlled trial 23 patients total I.M. injection	No improvements in LV function Moderate improvements in 6-min walk distance	Increased risk of ventricular tachycardia	Mere investigations are warranted to determine improvements in functional capacity
1. ESCORT (2018)	Embryonic	Open label interventional trial in 6 patients Epicardial delivery of human ESC derived cardiomyocytes embedded in a fibrin patch Primary endpoint at 1 year	Decrease in New York Heart Association functional class Modest decrease in LV volumes and an increase in LVEF Improved systolic wall segment motion	No signs of teratoma formation or arrhythmias at 1 year – 1 patient died postoperatively from unrelated comorbidities	Demonstrates feasibility of clinical grade human ESCs Demonstrated positive safety profile Moderate improvements in cardiac function and symptomatic improvement

(continued)

Table 1 (continued)

Clinical trial	Cell type	Study design	Efficacy	Safety	Conclusions
1. HEAL-CHF (ongoing)	Induced pluripotent	Open label interventional trial in 5 patients Direct epicardial injection of allogeneic iPSC derived cardiomyocytes	Awaiting results (estimated December 2020 completion)	Awaiting results	Awaiting results
2. Induced pluripotent trial Japan (initiated May 2018)	Induced pluripotent	Scarce details 7–10 patients total Administration of human iPSC derived cardiomyocytes	Awaiting results (2021 completed date)	Awaiting results	Awaiting results

Insights into Ccell-Based Therapy Approaches

What Is the Proposed Mechanism of Action?

In general, regulatory bodies such as the FDA and Health Canada require a clear and concise mechanism of action for most drugs and molecular therapies to be approved (Overington et al. 2006). However, the mechanism of action for stem cell therapy in the treatment of cardiovascular disease appears quite complex. It has still not yet been fully elucidated, creating a barrier for clinical trials. Initially, it was believed that transplanted stem cells differentiated into functional cardiomyocytes and replaced the damaged tissue within the myocardium. This was supported by evidence showing that transplanted BMDSCs engrafted into damaged myocardium of mice produced a substantial amount of proliferating myocytes and vasculature within the infarcted tissue 9 days post-injection (Orlic et al. 2001). There is also evidence suggesting the fusion of the transplanted stem cells with the resident cardiomyocytes (Nygren et al. 2004). However, in 2004 a landmark study showed that retention of transplanted hematopoietic stem cells into the recipients' hearts was extremely low, and there was a lack of significant differentiation into cardiomyocytes (Murry et al. 2004). This provided the first clue that direct cardiomyocyte replacement may not be the primary mechanism of repair. Since then, a study revealed that the administration of cultured medium from adult MSCs alone produced the same beneficial effects as MSCs in vitro and in vivo (Gnecchi et al. 2005). Although there has been convincing evidence that engraftment of transplanted stem cells does improve cardiac function, the small number of cells retained couldn't have solely produced the clinical benefits seen (Hatzistergos et al. 2010). The leading hypothesis then transitioned toward transplanted stem cells providing cellular support via the secretion of paracrine factors. Although the mechanism of action is likely multidimensional, it is now widely accepted that the vast majority of physiologic effects come from paracrine signaling (Bruyneel et al. 2016). However, the mechanism likely also varies with each cell type and the route of administration.

Paracrine Signaling

In the context of cardiac regeneration, paracrine signaling involves the release of various effector substances that directly cause cardioprotective effects or active endogenous regeneration mechanisms within the heart. These include various chemokines, cytokines, growth factors, and extracellular vesicles called exosomes that contain proteins and RNA (Bruyneel et al. 2016). Stem cells are believed to release these substances and alter the existing environment within the region they are transplanted in (Tang et al. 2018). Although the paracrine factors vary between stem cell types, it is believed that these factors activate endogenous repair mechanisms including neovascularization, inhibiting apoptosis, mitigating inflammation, and many others (Oikonomopoulos et al. 2018). For example, adult stem cells, including MSCs or BMDSCs, have been shown to secrete vascular endothelial growth factor (VEGF) and insulin-like growth factor-1 (IGF-1) (Gnecchi et al. 2008). IGF-1 is

believed to act as a cardio-protective factor to inhibit cardiomyocyte apoptosis via activation of the Akt pathway (Nagaya et al. 2005). VEGF, among other growth factors, is believed to be the key to stimulating the formation of new blood vessels (Guo et al. 2017). A comprehensive list of all the secreted paracrine factors and their mechanisms has yet to be determined, making it difficult to identify which combination of factors is most effective at promoting cellular regeneration. Regardless, transplanted stem cells are believed to release a large number of paracrine factors, which activate a network of pro-survival cascades, leading to an overall cardioprotective effect (Bruyneel et al. 2016).

Direct Regeneration

Although the paracrine signaling theory predominates most of the literature in the CSC field, recent advancements in pluripotent stem cell medicine have somewhat reignited the idea that direct engraftment may contribute to heart regeneration (Liu et al. 2018; Chong et al. 2014; Ye et al. 2014; Adamiak et al. 2018). Both ESCs and iPSCs have previously been shown to be successfully differentiated into cardiomyocytes (Kehat et al. 2001; Batalov and Feinberg 2015). However, only recently has there been evidence that PSC derived cardiomyocytes can successfully integrate into the host heart, form mature cardiac grafts and electromechanically couple with the host myocytes (Liu et al. 2018). Although this was in a non-human primate model, it still alludes to the fact that long term cellular integration of human PSC derived cells into a host heart is plausible. As transplantation and differentiation techniques improve, we may see an increase in the long-term cellular engraftment rates into the host heart and therefore, an increase in the overall efficacy of stem cell transplantation that is considered multifactorial as is depicted in Fig. 1.

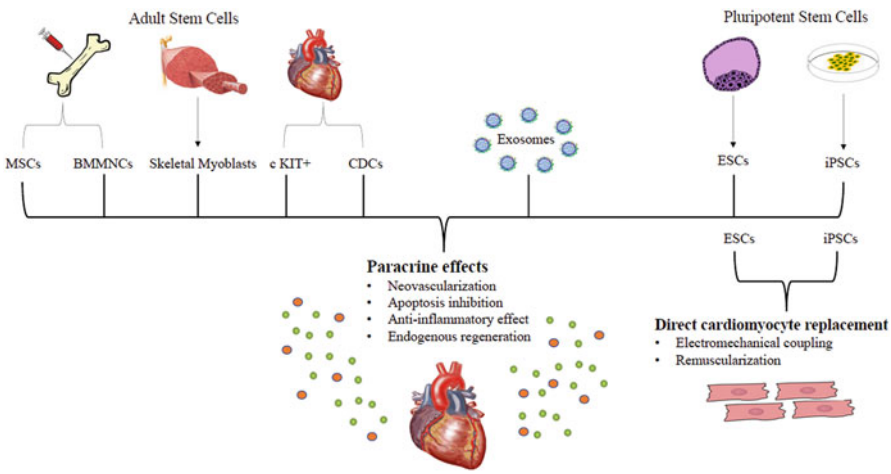

Fig. 1 Proposed mechanism of action for stem cells in the treatment of heart failure. This diagram shows various adult stem cell and pluripotent cell types and their contribution to cardiac regeneration

Optimizing Cardiac Stem Cell Therapy

In treating HF, successful therapy will depend on multiple factors: the type of stem cells, the route of administration, the timing of the therapy, and the characteristics of the patient.

What Is the Optimal Cell Type?

So far, multiple cell types have been proposed as the next generation of treatment for HF. These include various classes of adult CSCs, MSCs, non-selective bone marrow-derived stem cells, skeletal myoblasts, iPSCs, and ESCs. Unfortunately, determining the optimal cell type for the treatment of HF is not a straightforward endeavor. Many practical factors regarding the delivery of cells need to be considered before definitively crowning a superior cell type (Faiella and Atoui 2016). In addition to determining clinical efficacy, careful consideration of ethical concerns, simplicity of treatment, and patient preferences will also influence which cell type will predominate future treatment options (Raval et al. 2008). Determining the optimal cell type requires a comprehensive understanding of the mechanism of action of cell-based therapies. Currently, the proposed mechanism of myocardial repair involves either direct replacement of functional, contractile cardiomyocytes, or paracrine signaling to activate endogenous repair mechanisms within the heart (Nakamura and Murry 2019), although these events are not mutually exclusive. Thus, cellular therapies aim to achieve either one or both of goals, depending on the type of cell.

Skeletal myoblasts were one of the very first cells to be tested in the treatment of HF (Garbern and Lee 2013). There are many features that make skeletal myoblasts a viable option for cardiac repair such as their resistance to ischemia, high proliferative potential, and myogenic capabilities (Durrani et al. 2010). However, a significant challenge surrounds skeletal myoblasts, as they appear to remain electromechanically independent from the host myocardium (Ferreira-Cornwell et al. 2002). This was exhibited in the landmark MAGIC trial, where patients receiving skeletal myoblasts had a higher rate of arrhythmic events than those receiving the placebo. In addition, the skeletal myoblast administration did not improve heart function (Menasché et al. 2008). Since then, the interest in using skeletal myoblasts in cardiac cellular therapeutics has diminished, as more attractive cell candidates have emerged (Rikhtegar et al. 2019).

BMDSCs were also among the first cell types to be tested, with BMMNCs and MSCs being the most heavily investigated. Initially, it was shown that the infusion of BMDSCs could regenerate the myocardium (Beltrami et al. 2001). However, as time progressed, the primary hypothesis shifted toward paracrine signaling, as there is little evidence of long-term engraftment in the heart (Turner et al. 2020). After a decade of research, a trial sequential analysis reported mixed results. It demonstrated that the administration of BMMNCs caused a reduction in all-cause mortality and hospitalization from HF. The analysis also showed cell therapy did not improve LVEF by a value of more than 4% (Fisher et al. 2016b). In contrast, there have been mainly positive results published about MSCs. Three separate studies have demonstrated a robust safety profile surrounding MSCs and may have a clinical impact on LVEF, quality of life and cardiac remodeling (Hare et al. 2012; Rikhtegar et al. 2019; Mathiasen et al. 2020). Interestingly, the TAC-HFT trial compared BMMNCs versus

MSCs in a head-to-head randomized phase 2 trial. They demonstrated that bone marrow-derived MSCs produced significant improvements in quality of life, 6-minute walk test, and infarct size, while BMMNCs did not (Heldman et al. 2014). These findings suggest that MSCs may have superior capabilities in producing anti-fibrotic effects than BMMNCs (Banerjee et al. 2018). However, larger comparative studies are needed before we make definitive statements on efficacy.

C-kit+ CSCs and cardiosphere derived cells have been the two most heavily studied CSCs to date. Like MSCs, CPCs have minimal long-term engraftment, suggesting that their primary mechanism of action is through paracrine signaling (Tang et al. 2016). Landmark studies such as SCIPIO and CADUCEUS have demonstrated a positive safety profile for both C-Kit+ and CDCs. They have also shown varying degrees of cardiac recovery, with one study demonstrating structural improvements, one study exhibiting improvements in ventricular function, and both showing a decrease in infarct size (Chugh et al. 2012). However, it is difficult to conclude which cell type is superior to the other because there has yet to be a comparative trial completed. Despite the lack of a comparative trial, the initial clinical results surrounding CPCs are promising, and we remain optimistic that ongoing studies such as the CONCERT trial will produce positive results.

ESCs and iPSCs hold the highest level of potency, and therefore their primary advantage is the ability to effectively differentiate into functional cardiomyocytes or cardiovascular progenitors. In comparison to other cell types, PSCs also appear to hold a distinct advantage: the ability to integrate and electromechanically couple to the host myocardium (Liu et al. 2018). Theoretically, this means that PSCs can generate beneficial effects via both paracrine signaling and direct cardiac replacement. Perhaps this could be the underlying reason that ESCs see early success in preliminary clinical trials (Menasché et al. 2018). Nevertheless, there are still some safety concerns that arise when discussing PSCs, including ventricular arrhythmias, teratoma formation, and immune rejection (Gerbin and Murry 2015). We will need to see higher-powered clinical trials demonstrating a positive safety before we can make any definitive statements on the potential of pluripotent stem cells. Still, we believe that human ESCs and iPSCs are truly one of the top candidates to represent the next generation of cellular therapeutics.

Alternatively, there may not be one optimal cell type but rather an optimal combination of stem cells. This strategy could take advantage of the diverging mechanisms of action between cell types and synergistically (Turner et al. 2020). This theory has been validated in numerous preclinical studies, where the combination of CSCs and MSCs provided a significant improvement in cardiac function compared to either cell type alone (Natsumeda et al. 2017; Karantalis et al. 2015). Researchers applied this knowledge to create the first clinical trial comparing different types of stem cells in the treatment of chronic cardiomyopathy (Bolli et al. 2018). The CONCERT study is an ongoing phase 2 clinical trial assessing the head-to-head comparison of c-Kit+ CSCs alone, MSCs alone, and the combination of the two. Additionally, there was a recently published study demonstrating that concomitant administration of human iPSC derived cardiomyocytes and human MSCs loaded on a patch produced a synergistic effect on cardiac repair (Park et al. 2019).

Ultimately, we need randomized controlled trials comparing the efficacy of stem cell types before we can make any definitive recommendations on what the superior

cell type is. There is currently a lack of robust evidence assessing the superiority of one stem cell type versus another via human clinical trials. To date, the only published study directly comparing cell types in the treatment of HF has been the TAC-HFT trial. We will likely see an increase in comparative studies such as the CONCERT trial in the upcoming years as more evidence surrounding the optimal administration of stem cells is produced.

What Is the Optimal Method of Delivery?

One of the most important factors in successful cell therapy is the route of administration to the host (Turner et al. 2020). Though the idea may seem simple, there is a need for a method of delivery that will deliver the cells that we want into the correct area, which the cells delivered will engraft effectively while being able to function with the heart's natural rhythm without interference. Currently, there is no consensus on the most effective route, yet most studies suggest that the infusion, injection, or tissue-based implantation of cells can present therapeutic benefits to injured myocardium (Eschenhagen et al. 2017). Multiple routes have been studied preclinically: intravenous, intracoronary, intramyocardial, percutaneous transendocardial, transendocardial, retrograde intracoronary sinus, open surgical epicardial injection and scaffolding (Nakamura and Murry 2019; Bruyneel et al. 2016; Sudulaguntla et al. 2017) (Fig. 2).

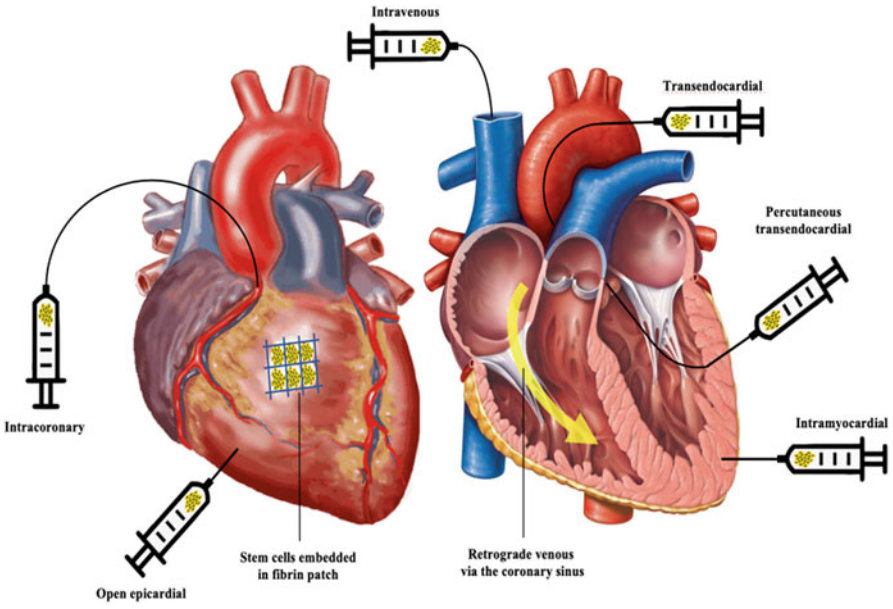

Fig. 2 Schematic depicting the various routes of delivery of stem cells. On the left, we see the intracoronary method, epicardial injection and cells embedded in a scaffold made of fibrin. On the right, we see the intravenous method, the retrograde venous route via the coronary sinus, the transendocardial method via the aorta, the percutaneous transendocardial method, and intramyocardial injection

The intravenous approach is attractive, as it is a straightforward procedure. It is currently the least invasive and has been demonstrated to have a positive safety profile (Menasché 2018). Intravenous injection has been found to attract cells to the site of injury, although there are concerns of poor cell implantation and retention (Turner et al. 2020). Intracoronary infusion of stem cells is the most common route of administration observed in studies and causes minimal inflammation. It is associated with some paracrine effects but, unfortunately, minimal cell retention and rapid washout in humans, resulting in inefficient re-muscularization (Nakamura and Murry 2019). The STAR-heart Study showed several benefits on cardiac function and minimal adverse effects with intracoronary infusion (Tehzeeb et al. 2019). Large doses of stem cells cannot be delivered by intracoronary infusion as these can obstruct coronary arteries and cause ischemia, leading to myocardial cell death (Nakamura and Murry 2019). Although there are potential risks involved, intracoronary administration of stem cells is one of the safer techniques of delivery (Tehzeeb et al. 2019). Since both intracoronary and IV administration do not confer high rates of long-term engraftment, stem cells that produce a strong paracrine effect should be selected. This means that adult stem cells such as MSCs and CSCs would be better candidates than PSCs in conjunction with this route of administration.

Intramyocardial injection of stem cells has a superior engraftment capability but has a greater arrhythmic potential, is more invasive, and increases the risk of perforating the myocardium (Nakamura and Murry 2019). The transendocardial route is minimally invasive, and the POSEIDON trial demonstrated a positive safety profile (Tehzeeb et al. 2019). Though this method carries a small risk of perforation and arrhythmias, cell retention is more successful versus other methods (Turner et al. 2020). It also permits the visualization of the target area, allowing greater accuracy injecting the target site. Currently, there are a limited number of studies and insufficient data on the safety profile of retrograde intracoronary sinus injections (Gathier et al. 2018). A small randomized control study with 20 patients with ischemic HF had autologous stem cells administered to the sub-epicardial regions of the heart plus CABG (Tehzeeb et al. 2019). Results showed a significant increase in LVEF and no adverse effects were observed.

Over the last few years, bioengineering has crept into the field of regenerative medicine. This involves culturing and implanting stem cells in 3D environments to improve both cell differentiation and survivability. One of the current goals is to create a scaffold that mimics the microenvironment of the heart and can be grafted with your cell type of choice into the heart (Mazzola and Di Pasquale 2020). The first application of cardiac patches was in a clinical trial instrumenting a fibrin scaffold embedded with human ESC-derived CPCs (Faiella and Atoui 2016). This method has been validated in preclinical models and appears to yield higher rates of cell retention (Park et al. 2019). In addition to fibrin, other biomaterials are used in scaffolding. Notably, natural materials like collagen, hyaluronic acid, and alginate, as well as a large variety of synthetic polymers have shown great variability in advantages and disadvantages (Mazzola and Di Pasquale 2020). Although the optimal combination of stem cell types and scaffolding materials has yet to be

confirmed, PSCs seem to be one of the better candidates for engineering functional heart tissue (Oikonomopoulos et al. 2018). This is because PSCs have a greater potential to integrate into the host myocardium than adult stem cells (Liu et al. 2018). Two main types of tissue engineering are currently being investigated: hydrogel-based and cell sheet engineering (Oikonomopoulos et al. 2018). Very few studies have directly compared therapeutic differences between routes of administration of stem cells. Clinical studies have yet to identify the optimal route of administration, and the most efficacious method is likely cell-type dependent (Turner et al. 2020).

What Is the Appropriate Timing of Administration?

This variable is also of great importance, as administering cells in the acute (less than 30 days), subacute (between 30 days and 1 year) or chronic phase (more than 1 year) post-MI is expected to work by different mechanisms and requires different cell properties (Nakamura and Murry 2019). Administration of cells in the acute phase aims to control inflammation and cardiomyocyte apoptosis while increasing vascularization. Conversely, in the subacute or chronic phase, therapy aims to augment repair of the myocardium and replace lost tissues. Multiple studies suggest that the administration of stem cells in 2–8 days post-MI is the most favorable window to modulate injury response and potentiate repair mechanisms. The exact dosing has yet to be confirmed and remains under investigation (Ibid.).

Patient Characteristics and Sourcing

Currently, patient characteristics that may improve or impede the success of cell therapy have not yet been studied systematically. Poor patient parameters such as diabetes, smoking, obesity, and older age can impair both autologous cell potency and the host's receptivity to stem cell treatments (Nakamura and Murry 2019). Studies are also comparing cells from autologous and allogeneic sources. Autologous cells have the benefit of immunocompatibility to the host, but their potency may be negatively impacted by poor patient parameters. In addition, autologous therapy is currently impractical for replacing billions of cells and for diseases that require treatment within a few weeks, such as a MI. Allogeneic cell therapy allows for increased availability, scalability, and quality-controlled product development (Ibid.). To receive allogeneic cardiomyocyte transplantation, patients are required to be chronically immunosuppressed, to which the degree is unknown at the moment (Pidala et al. 2011).

What Are Some Challenges that Remain?

Stem cells show exciting potential for the future, but several complexities must be addressed before widespread applications in the treatment of HF becomes feasible. We've seen varying levels of success for different cell types and the results have yet to be uniform and consistent in studies. Of the many challenges that remain, tissue integration is a key component to master, in order to produce myocardial tissue that acts as a functional syncytium. The ideal stem cell will have to effectively engraft into the heart to repair the damaged area, create new functional cardiac tissue and contract with the heart's natural rhythm in a coordinated fashion. So far, it seems like

iPSCs and ESCs-derived CPCs have the greatest potential to integrate mechanically and electrically into the myocardium (Liu et al. 2018). A direct comparison of the advantages and disadvantages of stem cells has been summarized in Table 2.

Table 2 Advantages and disadvantages of various stem cell types

Cell type	Advantages	Disadvantages
Cardiac stem cells	Autologous transplantation → decreased risk of immune rejection Low risk of carcinogenicity Moderate level of potency → can differentiate into various cardiac specific cell types	Difficult to isolate from myocardium → requires invasive biopsy Lack of consistency provided from clinical trials
Nonselective bone marrow-derived stem cells	Improves structural recovery of the heart and decreases infarct size Positive safety profile in multiple human clinical trials Autologous or allogeneic transplantation	Low quality evidence on efficacy in humans Minimal functional improvements on cardiac function Requires invasive biopsy
Mesenchymal stem cells	Positive safety profile demonstrated in multiple human clinical trials Autologous transplantation → lower risk of immune rejection Positive safety profile for allogeneic transplantation Exhibit strong paracrine effects	Difficult to isolate from bone marrow, although umbilical MSCs from Wharton's Jelly appear more accessible Quality of autologous cells may be affected by aging
Embryonic stem cells	High level of potency and controlled differentiation Well established cell lines Can produce cardiomyocyte progenitors on a clinical scale Minimal genetic manipulation of cells Indefinite self-renewal of cells	Has to be allogeneic → increased risk of immune rejection Ethical concerns about destruction of potential human life Risk of teratoma formation Risk of ventricular arrhythmias → in preclinical annual models Currently only 1 human clinical trial completed
Induced pluripotent stem cells	High level of potency and controlled differentiation Can be autologous transplantation → increased risk of immune rejection Less ethical concerns as they are derived from somatic cells Easily accessible source of cells	Increased risk of teratoma formation compared to ES cells due to use of viral vectors Variability in completeness of reprogramming No published human clinical trials completed
Skeletal myoblasts	Autologous transplantation → decreased risk of immune rejection Low ethical concerns Low risk of carcinogenicity	Low differentiation potential Unsuccessful in differentiating into functional cardiomyocytes after grafting Risk of ventricular arrhythmias → in human clinical trials Risk of embolism → shown in human clinical trials

PSCs also carry the potential for transplanted cells to form teratomas (Thomson et al. 1998; Takahashi et al. 2007). Thus, it is important to precisely differentiate cells pre-transplant to avoid the development of malignancies. However, the directed differentiation of PSCs is a challenge. Currently, techniques to completely differentiate PSCs into a fully functional, mature, cardiomyocyte phenotype have proven difficult. PSC derived cardiomyocytes appear functionally immature in terms of their sarcomere organization, calcium handling properties, and metabolism compared to adult cardiomyocytes (Mazzola and Di Pasquale 2020). This is believed to be the reason that ventricular arrhythmias were arising during preclinical trials (Vagnozzi et al. 2018).

Other challenges include the matching between patient and donor. A close match between parties is essential, as it reduces the risk of cell rejection and the need for lifelong immunosuppressants. This challenge may be mitigated by developing patient-specific iPS cell lines that could potentially avoid rejection and the need for immunosuppression (International Society for Stem Cell Research n.d.). Autologous cells are also an option, but the capacity of producing clinical-grade autologous cells during an acute time frame is currently not realistic. Additionally, potency may be impacted by poor patient parameters as previously explained. Lastly, we need an abundant source of stem cells available with hopes of treating many patients across the world. We need to identify, isolate, and grow the correct type of stem cell to have the therapy available and avoid shortages. ESCs and iPSCs are great candidates as they can be grown indefinitely in the laboratory, but this is a complex process that is tightly regulated (International Society for Stem Cell Research n.d.).

What Are Some Ethical Considerations in Using Stem Cells?

Stem cell research offers a novel solution for understanding and treating a variety of human diseases, including HF (National Research Council 2002). However, this research generates ethical, religious, and political controversies.

The most obvious controversy surrounding stem cells revolves around the morality of ESCs. Human ESCs are derived from the inner cell mass of the blastocyst from day 5–7 before implantation. This process involves the destruction of the human embryo and, thus, the potential for human life. This begs the question: When does human life begin? Some believe that human life begins as soon as fertilization occurs, and a zygote is formed. This view is often known as "pro-life" and believes human embryos have the same rights and interests of all humans. From this "pro-life" perspective, the destruction of the blastocyst pre-implantation is equal to murder (Lo and Parham 2009). Two solutions have been implemented by the Canadian Institutes of Health Research, which partially circumvent the morality issues associated with ESCs (Government of Canada and Interagency Advisory Panel on Research Ethics 2018). The first guideline strictly inhibits the creation of embryos for the sole purpose of research. The second guideline stipulates that the embryo must have been created for reproductive purposes. On the other hand, many others believe the embryo has a different moral status and is not considered a "person" until later on in development past fertilization. The Canadian Institutes of Health Research developed guidelines that attempt to respect the diversity of opinion

on the subject. Current guidelines state that "research involving embryos will take place only during the first 14 days after their formation by a combination of the gametes, excluding any time during which embryonic development has been suspended" (Ibid., p. 174). The final question comes down to: Is it morally acceptable to destroy the potential for human life to research new therapeutics to treat diseases? Since individuals will all have different moral beliefs on life, a definitive policy on the moral status of the embryo will likely never be globally accepted. Hence, iPSCs are increasing in popularity for research as there are fewer ethical considerations involved.

A fundamental principle in medicine is the process of containing informed and voluntary consent from patients before any medical procedure. This includes the ability to withdraw consent for a medical procedure at any time. This principle is implemented in general research by Canada's Tri-council policy, where research participants can withdraw consent at any time (Canadian Institutes of Health Research, Natural Sciences and Engineering Research Council of Canada, and Social Sciences and Humanities Research Council of Canada 2014). However, in research settings involving stem cell bio-specimens, the situation becomes more complex. Ethical norms would suggest that a donor is entitled to have control over any bodily tissue that has been removed from them, including gametes or embryologic tissue. This would also include any biological health information about the donor. After all, stem cells carry the complete genome of the donor and the privacy of the donor should be protected. However, from a researchers' or clinicians' perspective, this could be severely problematic. Well established human ESC lines are often distributed to hundreds of laboratories across the world. If the donor wished to withdraw consent from the use of their biologic tissue after it had been distributed globally, it would cause significant issues and could be detrimental to the field of stem cell research (Caulfield et al. 2007). This is a realistic possibility, as the moral beliefs of donors may change with time. If the withdrawal of consent occurs within the context of a therapeutic biobank used for analogous transplantation, it would have negative repercussions for patients who are stem cell recipients. This underlines the importance of creating a Canadian policy that both respects the donors' wishes and prevents an adverse impact on stem cell research and therapeutics. Canadian consent law has yet to specifically address issues about genetic and tissue information. However, in the absence of extenuating circumstances, regulations should lean toward individual human rights and not the goals of research (World Medical Association 2000).

False Claims

Stem cell therapeutics are advancing at an unprecedented rate, and significant discoveries have been made in the last decade. The idea of treating HF with stem cells may not seem completely out of reach in the future and if proven successful, it may save millions of lives. This scientific community has displayed much enthusiasm but, in some circumstances, overstepped their boundaries and generated falsified

or embellished results. This is true in the case of Dr. Piero Anversa, who claimed that stem cells did, in fact, produce viable and functional myocardium, despite scientific consensus stating otherwise. In total, 30 publications were retracted due to disproven hypotheses and irreproducibility in laboratories (Chien et al. 2019). Patients were provided false hope and were put at risk without reliable evidence for a period of 18 years, a truly unprecedented event. This had a major impact on cardiac cell therapeutics and was disheartening for those involved in such a field. To avoid cases like this one, the International Society for Stem Cell Research (ISSCR) recognizes and confronts science hype by assuring researchers and the public that the science that is put forward is sound and treatments have proven to be safe and effective (Caulfield et al. 2016). These obligations represent a commitment to patients that stem cell research is to be undertaken ethically by following a set of standards and that treatments are provided based on proven science (Ibid.). In addition, the ISSCR provides valuable information to the public regarding facts on stem cells, treatment options, and what to ask when considering stem cell trials or therapies. Implementing a set of standards in stem cell research not only protects patients but also allows researchers to compare the outcomes of clinical trials and enables the reproducibility of such studies in clinical settings. Enthusiasm and optimism are natural components of research. However, sustained hype with lack-of supporting evidence cannot be viewed positively. For this reason, the ISSCR urges stem cell researchers to "promote accurate, balanced and responsive public representations of stem cell research" (International Society for Stem Cell Research 2016, p. 28) to ensure that risks, benefits, and uncertainties are not misrepresented. These guidelines will reduce misinformation, facilitate the provision of accurate, credible information to the public, and improve transparency in the field of stem cell therapeutics.

Conclusion

Myocardial infarction is one of the leading causes of death worldwide, and HF is an important consequence associated with the event, which can lead to catastrophic outcomes for patients. Currently, therapeutic strategies rely on treating comorbidities and improving the quality of life for patients, which is why the regenerative capabilities of stem cells have created so much promise for the field. There has recently been a drastic shift from bench to bedside studies as we have seen a large increase in human clinical trials within the last decade. However, clinical trials to date have generally produced only moderately positive or even neutral clinical outcomes in terms of efficacy. This does not imply, however, that the cells have no therapeutic value but rather, it may reflect our limited knowledge about the optimal cell type, cell dosing, method of delivery, or even the endogenous cardiac repair mechanisms. Unfortunately, the lack of significant results has generated skepticism among the scientific community, which is likely due to the tremendous expectations that have been placed on the stem cell field. However, all hope is not lost. The therapeutic use of stem cells to treat HF is still a relatively novel concept and there is a plethora of clinical trials on the horizon, which will likely provide some clarity to

the field. There are also several positive results to report from clinical trials as well. A positive safety profile has been demonstrated for MSCs, ESCs, CSCs, and BMDSCs as various preliminary clinical trials have shown the absence of significant adverse events. However, many important questions still remain. Should we be focusing on techniques that involve activating endogenous repair mechanisms within the heart? Or should we be focusing on strategies that improve the engraftment of implanted cells? What is the most effective type of cell? What is the most efficient dose and route of administration? It currently appears that the field is diverging into two: One involves using 3D bioengineered scaffolds to improve retention rates of transplanted stem cells. The other involves using no cells at all, but instead delivering exosomes suspended with proteins, DNA, microRNAs, and various other growth factors. These questions will need to get addressed before we see cellular therapeutics become a staple in the clinic. All things considered, we remain cautiously optimistic that stem cells still represent the next generation of treatment for heart failure.

Abstract

Oromaxillofacial tissues are composite tissue containing teeth, bones, nerves, and blood vessels. It is a heterogeneous tissue rich in mesenchymal stem cells. So far, mesenchymal stem cells have been isolated from teeth and dental tissues, cranial bones and jaw bone marrow, and salivary glands. They have the potential to create a biological response by migrating to damaged dental tissues. However, in vitro culture conditions, reduced cell number (for periodontal ligament, gingiva tissue, buccal tissue, etc.), and unwanted differentiation mesenchymal stem cells

during frequent passages have limited the use of such cells in clinical cell therapy. Recently, studies have focused on the precondition strategies, effect of bacteria, and their components on proliferation and differentiation of mesenchymal stem cells.

Keywords

Dental pulp · *Lactobacillus rhamnosus* · Mesenchymal stem cell · Oromaxillofacial · Precondition · Probiotics · Stem cell

Abbreviations

AP-MSCs	Apical papilla mesenchymal stem cells
CB-MSCs	Cranial bone mesenchymal stem cells
DF-MSCs	Dental follicle mesenchymal stem cells
DP*-MSCS	Dental pulp mesenchymal stem cells
EOMSCs	Epithelial and oral mucosal stem cells
G-MSCs	Gingival mesenchymal stem cells
iBM-MSCs	Iliac bone marrow mesenchymal stem cells
MSCs	Mesenchymal stem cells
OMT	Oromaxillofacial tissue
PDL-MSCs	Periodontal ligament mesenchymal stem cells

Introduction

Within the framework of International Society for Cellular Therapy (ISCT) definition, mesenchymal stem cells have the ability to adhere to plastic surfaces; self-renew; differentiate into ectoderm, endoderm, and mesoderm germ layers; and express CD73, CD90, and CD105 surface markers, while hematopoietic stem cell markers include CD11b, CD19, CD79a, CD31, CD34, CD45, and HLA-DR-negative cells (Zhou et al. 2020). Along with these features, they can be effective in their environment with cell-cell contact or in the surrounding tissues with their paracrine effects, with their secretomes of immune, hormonal, and differentiation pathways. These activities are unfolded over the last many years to encompass remarkable modulatory effects in various autoimmune and inflammatory diseases, such as graft versus host, multiple sclerosis, acute lung injury, multiple sclerosis, Crohn's disease, depression, and osteoarthritis (Zhou et al. 2020).

Embryonic stem cells (ESCs), adult somatic SCs, mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs), and induced pluripotent stem cells (iPSCs) have all been identified (Ding et al. 2011; Herberts et al. 2011; Egusa et al. 2012; Naji et al. 2019). Adult SCs are the ideal choice for cell-based therapy since they are free of ethical problems. MSCs are regarded as one of the most promising cell types for regenerative therapy (Naji et al. 2019). MSCs were first discovered in the bone marrow as fibroblast-like cells. At clonal density, they looked like colony-forming unit fibroblasts (CFU-Fs). Mesenchymal stem cells have been

identified from the adipose tissue, synovial fluid, uterus, pancreas, and skeletal muscle, in addition to bone marrow (Ding et al. 2011; An et al. 2015; Chen et al. 2017, 28). Bone marrow and adipose tissue have been the most commonly employed tissue sources for MSC isolation in the past. However, because the tissue collection methodology involves highly intrusive procedures, the danger of morbidity in the patient procedure area has necessitated the identification of alternative tissue sources for research (Samsonraj et al. 2017; Ducret et al. 2015; Kang et al. 2016).

After Gronthos et al. (2000) reported the identification of MSCs from dental pulp tissue, oromaxillofacial tissue mesenchymal stem cells (OMT-MSCs) were isolated and identified by different researchers (Fukumoto et al. 2003; Tatullo et al. 2015). Easy surgical access made dental pulp-derived MSCs (DP-MSCs) a promising alternative tissue source of MSCs. The easy availability of DP-MSCs compared to other tissues provides a great advantage in tissue repair and regeneration studies. The fact that dental pulp tissue is a composite tissue consisting of fibroblast, endothelial cells, nerve cells, odontoblast, and osteoprogenitor and immune cells gives DP-MSCs a functional and unique feature (Ledesma-Martínez et al. 2016; Nuti et al. 2016). Ectodermal stem cells travel from the neural tube to the oral area during tooth formation, giving rise to OMT-MSCs. They eventually become mesenchymal cells at the end of the procedure (Aurrekoetxea et al. 2015). This distinguishes them from other neural crest cells in terms of biological features, making them ideal for therapeutic use.

In MSCs-based clinical therapies, strategies based on improving endogenous MSCs in the microenvironment have begun to emerge to ensure the engraftment and migration of transplanted cells (Grayson et al. 2015; Gao et al. 2017; Zhou et al. 2018). Since the huge efforts given to exogenous MSCs, it is critical to take use of endogenous MSCs, which dwell inside the tooth pulp and/or particular tissues and can self-renew and differentiate into different germ layers (Xia et al. 2018; Zhu et al. 2018). The number and activity of endogenous MSCs gradually decreases in post-natal development, resulting in a decrease in their natural repair abilities (Xia et al. 2018). Similarly, various chronic pathological conditions, i.e., diabetes mellitus, myocardial infarction, etc., and the process of physiological aging over time cause significant reduction in their functionality and reparability (Jiang et al. 2008; Haider 2018). Likewise, under inflammatory conditions such as pulpitis, periodontitis, osteoporosis, and implantitis, endogenous MSCs largely lose their differentiation ability and immunomodulatory properties (Xue et al. 2016; Di et al. 2018; Yang et al. 2017). Indeed, tumor necrosis factor-alpha (TNF-α) is a vital component of the inflammatory response, and it was reported that excessive levels and prolonged exposure to TNF-α are always associated with inflammatory diseases of the bone or tissue and lead to the death or impairment of endogenous MSCs' function.

Pharmacological approaches are also among the options used for the application of MSCs in bone tissue engineering and dentistry. The addition of pharmacological or biological agents to be incorporated into the structure of tissue scaffolding, membranes, composites, or filling materials for use in bone and dental tissue regeneration may be a good strategy for the recovery of endogenous MSCs' functionality, including survival, proliferation, differentiation potential, and paracrine

activity (Potu et al. 2009; Jeong et al. 2010, 2014; Li et al. 2010; Huang et al. 2012; Gu et al. 2015; Chen et al. 2016; Lee et al. 2016; Mendi et al. 2017a, b, 2019; Bourebaba et al. 2019). Considering these limitations of synthetic drugs, probiotics and/or their metabolites could be a new perspective in cellular therapies in regenerative medicine (Bourebaba et al. 2019; Cai et al. 2019).

The finding of oromaxillofacial tissue-derived mesenchymal stem cells, their biological roles, and comparisons with other tissue-derived MSCs, as well as probiotic bacteria and their relationships, are described in this review.

Identification, Isolation, and Biology of OMT-Derived Stem Cells

OMT cells were classified as epithelial and oral mucosal stem cells (EOM-SCs), cranial bone (CB) MSCs, mandibular bone marrow MSCs, and dental pulp MSCs (dental pulp MSCs, dental follicle (DF) MSCs, periodontal ligament (PDL) MSCs, and apical papilla (AP) MSCs) **(**Fig. 1**)** (Mendi et al. 2019).

Gronthos et al. (2000) were the first to report dental pulp stem cells. They used the same procedure that had previously been used to isolate and characterize iliac bone marrow MSCs (iBM-MSCs). They discovered a population of clonogenic cells within adult human tooth pulp. Cranial bone MSCs, epithelial and oral mucosal stem cells, and dental MSCs were all discovered using the same method **(**Figs. 1b and 2).

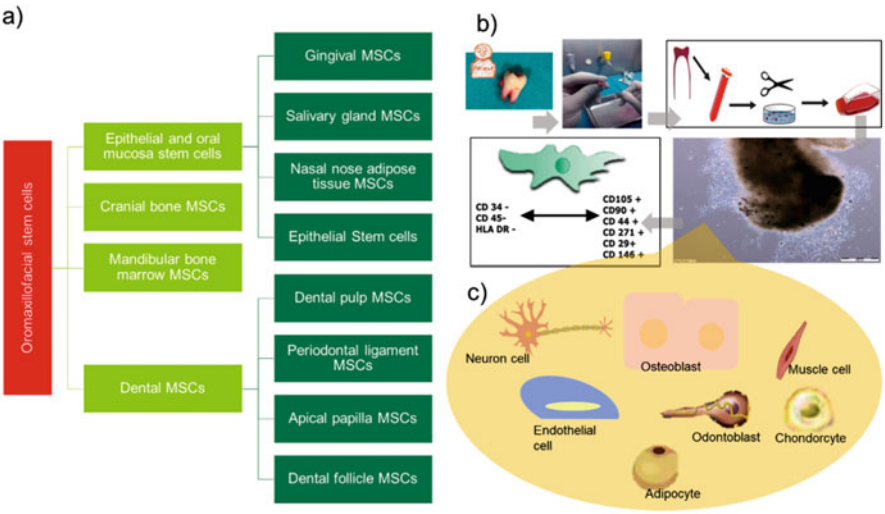

Fig. 1 **(a)** OMT mesenchymal stem cells classification, isolation, and identification. **(b)** Mandibular/maxillar bone marrow tissues or blood samples were removed and cultured using the explant culture method. Flow cytometry was used to sort the generated colonies. **(c)** The ability of OMT-derived MSCs to differentiate (Mendi et al. 2019)

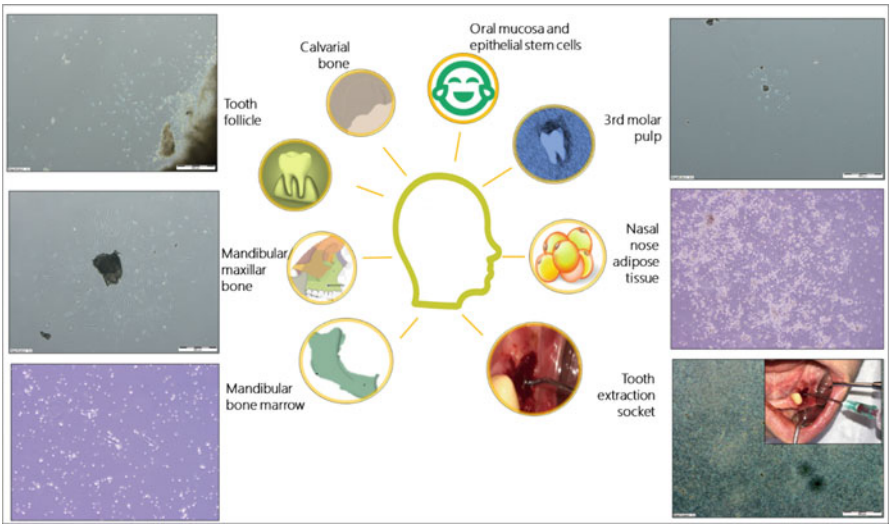

Fig. 2 Isolated OMT-MSCs. Our group had previously isolated MSCs from the third molar pulp, nasal adipose tissue, tooth extraction socket, mandibular bone marrow, cranial bone, and tooth follicle tissue (Mendi et al. 2019) (Olympos CKX 41, Japan)

Dental pulp is a composite tissue consisting of odontoblasts, interstitial fibroblasts, blood vessel networks, and nerve cells on the mineralized dentin surface (Sacchetti et al. 2007; Mendez-Ferrer et al. 2010; Bianco 2011). MSCs originating from DP bear similar surface markings as bone marrow MSCs accepted as reference. CD44, CD73, CD105, STRO-1, and CD146 are positive and also bear neural cell surface markers (Huang et al. 2009). On the other hand, there is a big gap to enrich pure MSCs (Keating 2012; Eleuterio et al. 2013; Liu et al. 2015; Ledesma-Martínez et al. 2016; Aghajani et al. 2016; Niehage et al. 2016; Werle et al. 2016).

OMT-MSCs have been reported to have functional and phenotypic differences from iBM-MSCs. Akintoye et al. (2006) reported that when comparing mandibular BM-MSCs isolated from the same individual and BM-MSCs of iliac origin, mandibular BM-MSCs showed higher proliferation rate and advanced osteogenic differentiation. In a study conducted by our group, it was observed that the adipogenic power of OMT-derived MSCs was lower than that of iliac-derived BM-MSCs (Mendi et al. 2017a, b).

It was also shown by our group that DP-MSCs have a shorter lag phase than iliac BM-MSCs and enter the logarithmic phase at higher cell counts (Mendi et al. 2017a, b). Our findings support the findings of Gronthos et al., who found that DP-MSCs, cranial bone MSCs, and epithelial oral mucosa MSCs colonize at a higher rate than iliac BM-MSCs (2000). The developmental condition of the various tissues can suggest this.

The mechanism in the interaction of OMT-MSCs with each other has not yet been elucidated. It was hypothesized that OMT-MSCs, like osteogenic tissues, have limited differentiation capacity, as they were originally thought to be specialized

tissues. It has been reported that OMT-MSCs have multidifferentiation power in tissue comparative studies published in recent years (Zhang et al. 2009; Wang et al. 2010; Moshaverinia et al. 2012, 2013, 2014).

The oral cavity consists of a flora containing more than 700 pathogenic and nonpathogenic microorganisms with different oxygen needs (Zhou et al. 2020). It's crucial to understand how bacteria in the flora affect MSCs in an inflammatory environment, as well as their effects on tissue repair. It is necessary to know the effects of existing bacteria on the stemness and potency of MSCs. It is known that there is a regression in the viability and differentiation of MSCs in the chronic inflammatory environment (Lee et al. 2009). The MSCs number is relatively sparse (Gao et al. 2018; Roddy et al. 2011). Such a microenvironment will, of course, influence MSCs clinical practice. Therefore, the interaction between OMT-MSCs and oral flora should be well-known.

In vitro and in vivo, MSCs have been shown to have anti-inflammatory and immunomodulatory properties. The effects of inflammation on OMT-MSC proliferation, migration, stemness, differentiation, and cytokine production have been studied in a variety of ways (according to Sensebé et al. 2010). Techniques to boost MSC proliferation, differentiation, and resistance to inflammation and oxidative stress are constantly being researched based on these beneficial features of MSCs. As a result, preconditioning strategies have attracted a lot of attention.

Preconditioning Strategies

MSCs originating from DP bear similar surface markings as bone marrow MSCs accepted as reference. CD44, CD73, CD105, STRO-1, and CD146 are positive and also bear neural cell surface markers. For example, many different osteo-inductive agents stimulate cell migration and proliferation and modulate immune response, including the stimulation of MSCs and/or osteo-progenitors in vitro and in vivo (Giannoudis et al. 2005; Govender et al. 2002). However, because they have a short half-life, bone tissue engineering requires either large concentrations or long-term administration (Itoh et al. 2001). It's also worth noting that their increased concentration could lead to enhanced osteoclastic activity and bone resorption (Kaneko et al. 2000). Therefore, it is important to develop alternative techniques and protocols to avoid these undesired effects.

In recent years, preconditioning strategies have come to the fore in order to increase the engraftment of MSCs in vivo or in clinical applications, to increase their survival in the inflammatory environment, and to differentiate them effectively (Haider and Ashraf 2012). Moreover, preconditioning approach also promotes their emigrational capacity, paracrine activity, and survival rate **(**Fig. 3**)** (Guo et al. 2020). Various stress conditions, including isolation from the issue source and in vitro expansion and harsh microenvironment (ischemia, hypoxia, and inflammation) post engraftment, cause extensive oxidative stress injury to the cells after engraftment at injured sites, which significantly reduces the survival of transplanted MSCs (Guo et al. 2020; Dissanayaka et al. 2020). Thus, different preconditioning strategies have

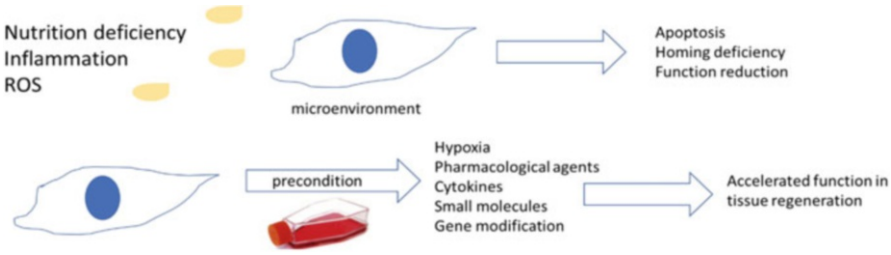

Fig. 3 MSCs face a harsh microenvironment that may induce their apoptosis or functional abrogation, such as poor differentiation potential, low adhesion, or attenuated proliferation

been developed to enhance MSCs functionality and tissue reparability post engraftment.

Among these, there are studies in vitro as well as in the experimental animal models to observe the effect of hypoxia in improving the migrational potential of MSCs. It has been observed that continuous or intermittent exposure to hypoxia or anoxia significantly promotes the differentiation and proliferation potential of MSCs. Similar effects have also been observed after preconditioning with different pharmacological agents, directing immunomodulatory properties by cytokine induction and regulation of differentiation and immune properties by gene modification (Jiang et al. 2006; Haider et al. 2008, 2009; Kim et al. 2009, 2012; Afzal et al. 2010; Lai et al. 2012).

Considering the direct and/or indirect relationship of OMT-derived MSCs with the oral flora, it should be considered that MSCs will also be affected by the effects of the bacterial flora on the immune response.

Among these bacteria, studies show that probiotics, which play a stabilizing role as a part of the intestinal flora, have similar effects on the oral flora and therefore are drawing significant attention by researchers.

Probiotics and their Health Benefits Associated with Gut Microbiota

Probiotics are one of the most remarkable functional foods to emerge in recent decades (Pray et al. 2013). In 2001, a joint committee of the United Nations Food and Agriculture Organization and the World Health Organization (FAO/WHO) defined probiotics as "live bacteria that bestow health advantages on the host when provided in suitable concentrations." The joint committee issued guidelines in 2002 to give a systematic strategy to evaluating probiotics, which included genetic and phenotypic strain identification, safety assessment, and functional analysis (FAO/WHO 2001, 2002).

Probiotics have been linked to a reduction in gastrointestinal pathogens, a reduction in cold and flu incidence, a reduction in colorectal cancer, improved lactose tolerance, and a significant reduction in the symptoms of inflammation-related

disorders (Salminen et al. 2005; Hörmannsperger et al. 2009; Leyer et al. 2009). It's worth noting that, despite a slew of health benefits linked to probiotics, the stated benefits can only be attributed to the strain in question, not the species as a whole or other probiotics. This is significant since some published reviews place a greater emphasis on the practical importance of individual probiotics to their higher taxonomic group than on strain specificity (Hill and Sanders 2013; Sanders et al. 2018).

Probiotic administration activates the immune system of the host, and as a result, some strains of probiotics can help to reduce inflammation in inflammation-related disorders including inflammatory bowel disease (IBD) (Kruis et al. 2004; Mogna et al. 2012). Probiotics can also help to regulate complex allergic inflammatory reactions brought on by allergy illnesses caused by a microbial imbalance (Isolauri et al. 2000; Sanders et al. 2013). A few well-designed trials have provided evidence for the usefulness of certain probiotic strains in treating individuals with atopic illnesses in the treatment of allergic disease. In a double-blind, randomized, placebo-controlled trial, *L. rhamnosus* GG was shown to prevent atopic eczema among children at high risk for atopic eczema. *L. rhamnosus* GG was administered prenatally for 2–4 weeks and postnatally for 6 months. The cumulative risk of eczema development was significantly reduced in patients as long as 7 years after the trial (Kalliomäki et al. 2001; Kalliomaki et al. 2007).

A 3-month trial involving 1,072 senior volunteers who drank probiotic dairy products containing *L. casei* DN-114 001 revealed that the *L. casei* strain is effective against respiratory infections (Boge et al. 2009). In comparison to the control group, the same strain also reduced common infectious illnesses, particularly upper respiratory tract infections (Guillemard et al. 2010).

Probiotics exert their health benefit with the multifactorial mechanism of action, including competing with microorganisms for nutrients and adhesion sites, producing antimicrobial peptides and organic acids, immunomodulation, and enhancing intestinal barrier (Shanahan 2010; Yan and Polk 2020). In a mouse model of acute colitis, *E. coli* Nissle 1917 reduced *Salmonella enterica* Typhimurium intestinal colonization by outcompeting the pathogen for iron, which is a limiting resource in this environment. They also discovered that *E. coli* Nissle mutants lacking in iron absorption can colonize the mouse gut but had no effect on *S. enterica* Typhimurium colonization (Deriu et al. 2013). By improving the gut barrier function, probiotics help to prevent pathogenesis. In IBD patients, the epithelial barrier has been disrupted. In mice with chemically induced colitis, *E. coli* Nissle 1917 inhibits leaky gut (Ukena et al. 2007). In a recent study, the function of the intestinal barrier was restored in an experimental mouse model of autoimmune encephalitis (Secher et al. 2017). The scientists discovered that oral therapy with *E. coli* Nissle 1917, rather than archetypal K12 *E. coli*, reduced the severity of experimental autoimmune encephalitis. The positive benefits were linked to a considerable decrease in pro-inflammatory cytokines along with a rise in the anti-inflammatory cytokine IL-10. Similarly, in mice with intestinal inflammation, VSL#3, a multiprobiotic formulation, enhances intestinal permeability (Corridoni et al. 2012).

Antimicrobial metabolites produced by probiotics can inhibit the growth of other bacteria (O'Shea et al. 2012) or encourage host cells to create antimicrobials (AMPs)

such as defensin, regIII, and lysozyme (Lebeer et al. 2010). AMPs are one of the most important components of the innate immune system, and they help shape the intestinal microbiota by activating the intestinal mucosal defense (Ostaff et al. 2013; Cunliffe 2003; Ganz 2003). Oral dosing of *L. gasseri* SBT2055, for example, stimulated IgA synthesis in the mouse small intestine (Sakai et al. 2014).

Immunomodulation is the most often hypothesized probiotic mode of action, which occurs when probiotic bacteria interact with mucosal immune cells or epithelial cells in the gut (Azad et al. 2018). Substantial evidence has accumulated to support the immunomodulatory effect of probiotic strains (Ishikawa et al. 2005; Ai et al. 2016; Garcia-Castillo et al. 2019). In a double-blind, placebo-controlled trial, lactobacilli strain was found to have an immunomodulatory impact, lowering the levels of IL-5, IL-6, IFN-g, and IgE in patients with seasonal allergic rhinitis and reducing the severity of allergic rhinitis symptoms (Ivory et al. 2008). In another study, daily lactobacilli strain ingestion for 3 weeks decreased natural killer cell activity in male smokers when compared to a placebo control group (Reale et al. 2012). In the gut of patients with ulcerative colitis, rectal administration of *L. casei* DG changes the mucosal microbiota and reduces the production of TLR-4 and inflammatory cytokines while increasing the expression of IL-10, an anti-inflammatory cytokine (D'Incà et al. 2011). Depending on the strain and the situation, probiotics may affect the innate and adaptive immune systems in both directions, acting as anti-inflammatory or pro-inflammatory agents (Rochat et al. 2007; Chiba et al. 2010; Shida et al. 2011). Because MSCs and probiotics have comparable functional characteristics, the investigation of MSCs-probiotic interaction is gaining traction in preconditioning studies.

Mesenchymal Stem Cells-Probiotic Interaction

The human microbiome offers potential treatment approaches including reversing or rebalancing the microbiome toward health, based on an increasing understanding of how the microbiome affects health and disease. There have been several research analyzing the variety of skin and gut microbial communities in health and sickness (Qiao et al. 2018) as well as the function of gut microbiota on intestinal stem cell activity for decades. However, nothing is known about the impact of microbiota on oral wound healing, alveolar bone regeneration, and OMT-derived MSC activity.

With the increase in resistance to antibiotics, the use of probiotics in oral health has come to the fore. In different studies involving dental caries, periodontal diseases, and halitosis, probiotic bacteria therapy was used, and positive results were obtained (Meurman 2005). Recently, studies have been focused on the effect of probiotic bacteria on oral wound healing and bone regeneration and mesenchymal stem cells (Han et al. 2020; Brandi et al. 2020).

Oral disorders are frequently caused by the invasion of pathogenic bacteria into the oral tissues, which disrupts the oral microbial flora balance and alters the oral mucosal immune response (Li et al. 2021). Probiotic bacteria, on the other hand, interact with epithelial cells (ECs), M cells, and dendritic cells in the intestinal milieu

through cell-cell contact or internalization of the bacteria or its components (cell wall, exopolysaccharides) (DCs). It increases IL-6 release from ECs and alters TNF-alpha and IFN-gamma secretion in MCs and DCs as a result of this interaction. At the same time, TGF-beta-induced T cell-independent transition from IgM to A on the surface of B cells is stimulated by IL-4 generated by mast cells (MACs) in combination with IL-6 released by ECs. IgA B cells' clonal growth is accelerated by IL-6, which also boosts the production of IgM, IgG, and IE antibodies. Th1 cells release pro-inflammatory IFN, which inactivates or kills viruses, tumor cells, and pathogenic germs. TNF and IL-2 are cytokines that promote phagocytosis and the formation of macrophages, NK cells, and cytotoxic T lymphocytes (Hoseinifar et al. 2019). It's possible that oral flora bacteria and gingival epithelial cells in the oral mucosa and OMT-derived MSCs in the connective tissue work in a similar way **(**Fig. 4**)** (Hoseinifar et al. 2019).

TLRs expressed by MSCs play an active role in directing the immune response by recognizing bacteria and in the migration, proliferation, and differentiation of MSCs. Long-term inflammation also negatively affects bone regeneration and wound healing through TLRs. In a study by Zhou et al. (2020) in which they compared TLR expression of G-MSCs, DP-MSCs, and BM-MSCs in inflamed and non-inflamed in vitro environments, DP-MSCs expressed TLRs 1–10 at low levels in the non-inflamed environment, while in the inflamed environment, observed increased expression of TLRs 2, 3, 4, 5, and 8. Similar results have been observed in other studies (Ciszek-Lenda et al. 2011; Xu et al. 2012; Tukenmez et al. 2019). Indeed our group demonstrated that *L. rhamnosus* ATCC9595 scaled down the expression of TLR4 and induced TLR2 expression when exposed to *P. gingivalis* stimulation on G-MSCs. ATCC 9595 induced CXCL5 in G-MSCs without

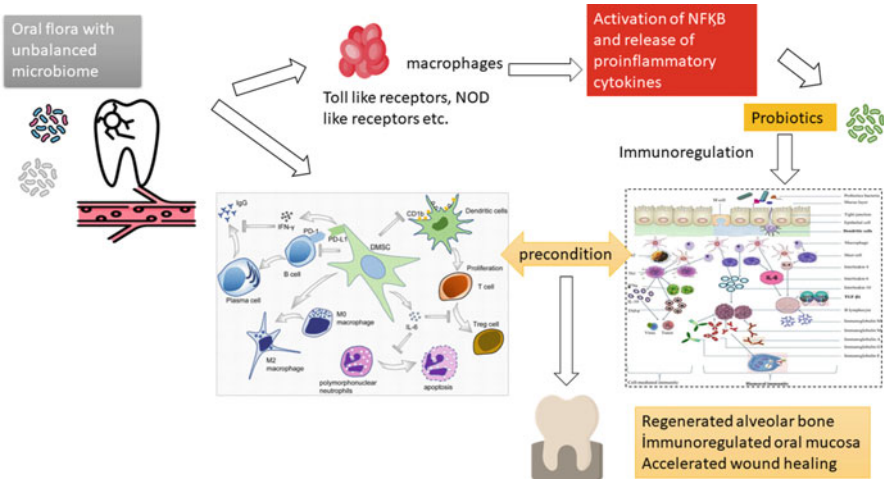

Fig. 4 Probiotic-OMT-MSCs interaction (the figure has been adopted from the Flaticon page) (Mendi et al. 2019)

triggering TLR-4 expression (Mendi et al. 2016). Although the bacteria in the oral flora and the immune signaling pathways they activate have an effect on the wound healing process, it is suggested that pathogenic bacteria delay wound healing (Jones et al. 2004). The common wound bacteria may hasten wound healing by increasing immune cell infiltration, granulation tissue creation, and collagen production, all of which are advantageous to the wound healing process (Su et al. 2018).

Studies reporting that the anti-inflammatory properties of probiotics have a positive effect on bone homeostasis are increasing. *L. rhamnosus* GG has been shown to inhibit bone loss by increasing the osteogenic differentiation of stem cells (Liu et al. 2020). From this point of view, the preconditioning of probiotic bacteria and MSCs for bone homeostasis is a new and up-to-date research topic.

Another study has revealed that LGG has a protective effect against radiation-induced intestinal epithelial damage via lipoteichoic acid. LGG lipoteichoic acid triggers adaptive immune response with macrophages and PGE2 from MSCs and supports epithelial stem cell niche to protect epithelial stem cells. Moreover, *L. rhamnosus* has been shown to improve human MSCs via its antioxidant effect, thus suggesting probiotics to be an alternative cell therapy agent (Ahadi et al. 2020).

By encouraging the migration of MSCs, LGG has been shown to protect intestinal epithelial cells against radiation damage. In an SD rat model, *Lactobacillus* also activates intestinal stem cells. Furthermore, there is emerging evidence that probiotics have a beneficial effect on bone homeostasis as a result of their anti-inflammatory properties. As a result, LGG may be able to prevent bone loss by increasing the osteogenic ability of stem cells (Liu et al. 2020).

Apart from these, there are also studies examining the behavior of mesenchymal stem cells by directing the host flora with probiotic microorganisms. Since, there is a balanced interaction between host immune system and gut microbiota, and this relationship is bidirectional which is necessary for optimal health and requires acknowledging that the disruption of this balance so-called dysbiosis can result in inflammatory and metabolic diseases such as inflammatory bowel disease (IBD), type 2 diabetes, obesity, arthritis, and asthma (Sommer and Bäckhed 2013; Ohno 2015; Hufnagl et al. 2020). Moreover, dysbiosis in oral microbiota leads to modulate epithelial markers such as β-catenin, E-cadherin and mesenchymal markers including fibronectin, and N-cadherin and impacts epithelial-mesenchymal transition (Chakraborti and Das 2020). In a study evaluating gut microbiota during mesenchymal stem cell-based therapy to improve acute liver injury in mice, they showed that change in the gut microbial population due to mesenchymal stem cell infusion to the liver could help liver repair by maintaining the gut mucosal homeostasis (Dong et al. 2019).

As a result, targeted changes in the gut microbiota could be used to prevent or treat diseases in humans. In Sprague-Dawley rats with collagen-induced arthritis, Li et al. studied the mechanism of human umbilical mesenchymal stem cells. They discovered that human umbilical mesenchymal stem cells, by modifying gut microbiota and immune response, had a therapeutic effect on rats with collagen-induced arthritis. Probiotics are one of the most prevalent ways for changing the gut's microbial composition.

In a study conducted by our group, it was observed that *L. rhamnosus*, one of the probiotic bacteria, preserved cell viability in gingival fibroblast culture in which an oxidative stress environment was created by using hydrogen peroxide, and it was suggested that it may have a protective effect against tissue damage. It is suggested that the examination of probiotic bacteria-connective tissue interactions in oral diseases will be an effective solution in periodontitis, mucosal wound healing, and immune oral diseases (Mendi and Aslim 2014). High EPS production of *B. breve* A28 strain was associated with antioxidant activity. In the results, it was observed that the oxidative stress effect of hydrogen peroxide application on gingival fibroblasts decreased by preventing iron chelation, DPPH radical scavenging, and plasma lipid peroxidation. Kim et al. (2020) demonstrated that *L. rhamnosus* promoted osteogenic and chondrogenic differentiation, reduced oxidative stress, and inhibited adipogenesis in MSCs (Kim et al. 2020).

Future Perspective and Conclusion

The oromaxillofacial tissue is a tissue rich in stem cells due to its composite structure, germ source, and neural crest origin cells. Mesenchymal stem cells abound in the oral and maxillofacial region. Primary teeth, third molars, and gingiva are easily accessible intraoral tissues, although they are frequently thrown as medical waste in clinics. Therefore, it is important for dentists to remember that tissues are a valuable source of stem cells during treatment in regenerative dentistry. Studies with probiotic bacteria in the dental clinic give varying results depending on individual oral flora and hygiene differences. Furthermore there is an apparent lack of sufficient in vitro models regarding the probiotic effect. On the other hand, it was highlighted that the activity of probiotic strains in vitro might not parallel similar behavior in vivo.

To further determine the role of probiotics preconditioned with MSCs in dentistry, large, well-designed, multicentered, controlled clinical trials and translational animal models are needed. The fact that not all *Lactobacillus* and *Bifidobacterium* species are equally beneficial should not be overlooked. Individual mechanism of each strain should be characterized, and the researchers should be aware of that the mechanism of action is dependent on the host characteristics, such as oral hygiene and nutrition habit.

Since different bacteria may have dominant effects in diverse genetic backgrounds and diseases involving their pathogenesis, researchers should prefer oral microbiome probiotics in clinical trials. To achieve more scientific evidence, further randomized controlled clinical trials with long follow-ups are necessitated. Determination of donor and patient histories, dietary patterns, and intestinal and oral flora compositions should be investigated in clinical applications combining cellular therapy and probiotic therapy. Probiotic microorganisms, on the other hand, don't just alter the microbiota. They can also influence MSC stemness by regulating immunological indices, epithelial permeability, and bacterial translocation, as well as supplying bioactive or regulatory metabolites. Thus, the interactions between

probiotic bacteria and MSCs could be explored by using comprehensive in vitro models that included mucosal stem cells.

As a result, the immunoregulatory effect of OMT-MSCs in co-culture with probiotic bacteria facilitates optimal tissue regeneration and can control tissue destruction. On the other hand, the functional properties and activities of probiotic strains vary between strains. It should be noted that not every probiotic strain has the same beneficial effect on health. Moreover, the probiotic strain isolated from the intestinal flora may have different effects in the oral flora due to the microhabitat difference. Probiotic strains in the oral microbiome need to be identified. In the selection and definition of oral probiotic strains, unlike intestinal probiotics, prevention of dental plaque formation, inhibition of periodontal pathogens, and regulation of cellular immune responses should be added. Furthermore, probiotic strain-oral mucosal cell interactions should also be investigated.

Abstract

In vivo, all stem cells reside within distinct and defined microenvironments referred to as stem cell niches. Complex interactions between stem cells and their niche tightly regulate cell fate decisions. This affects live/death decisions, cellular senescence, and cell differentiation. Therefore, removing mesenchymal stromal/stem cells (MSCs) from their niche and cultivation within conventional flat, two-dimensional (2D) cell culture systems affects their cell fate and therefore also their regenerative potential. Nevertheless, routine MSC culture for research and therapy is still conducted in 2D. Three-dimensional (3D) cell culture is a state-of-the-art technology allowing expanding and differentiating MSCs under

more physiological conditions. This chapter will summarize current understanding of the impact of 3D cell culture on fundamental properties of MSCs including their proliferation, viability, cellular senescence, and differentiation. Furthermore, effects of 3D cell culture on the immunomodulatory and anti-inflammatory potential of MSCs will be evaluated.

List of Abbreviations

2D	Two-dimensional
3D	Three-dimensional
AD-MSCs	Adipose tissue-derived MSCs
ALP	Alkaline phosphatase
IL-10	Interleukin-10
IL-24	Interleukin-24
IL-1β	Interleukin-1β
IL-6	Interleukin-6
LIF	Leukemia inhibitory factor
MCP-1	Monocyte chemoattractant protein-1
M-CSF	Macrophage colony stimulating factor
MSCs	Mesenchymal stromal cells/mesenchymal stem cells
OCN	Osteocalcin
OPN	Osteopontin
PGE-2	Prostaglandin E2
TNF-α	Tumor necrosis factor-α

Introduction

MSCs are multipotent, fibroblast-like cells that can be readily obtained from various adult tissues, including the bone marrow, adipose tissue, and peripheral blood as well as from prenatal tissues such as amniotic fluid, umbilical cord, and placenta. Being multipotent adult stem cells originating from the embryonic mesoderm, their differentiation spectrum is limited to mesenchymal derivatives such as bone, fat, and cartilage cells (see Andrzejewska et al. (2019) for review). However, after their initial discovery by Alexander Friedenstein (Friedenstein et al. 1968, 1970, 1974), several reports suggested that MSCs might have an even higher differentiation potential and an intrinsic ability to cross the germ layer boundaries. In this context, differentiation of MSCs into neural and neuronal derivatives has been claimed in multiple independent studies (Jiang et al. 2002; D'Ippolito et al. 2004; Takeda and Xu 2015; Tropel et al. 2006; Scuteri et al. 2011). Notably, a vast majority of these reports relied heavily on nonfunctional data, including morphology and marker

expression without providing a direct side-by-side comparison to neural and neuronal cells. Nevertheless, it is noteworthy that MSCs can display neuron-like morphology in response to cellular stress. Moreover, they have been shown to express neuronal markers even after differentiation into osteogenic and adipogenic fate (Foudah et al. 2013) in vitro suggesting that this might be an in vitro *cell* culture artifact and not a result of functional differentiation across a germ layer boundary.

This view is also supported by several studies showing that MSCs do not differentiate and integrate if transplanted into brain tissue in vivo. In addition to reports suggesting that MSCs can undergo an ectodermal fate, it has been postulated that MSCs could differentiate into endodermal pancreatic islet-like cells (D'Ippolito et al. 2004; Zanini et al. 2011). Notably, also these reports provided no functional data supporting this claim. Nevertheless, over 1250 clinical trials involving MSCs have been registered on the ClinicalTrials.gov database with a wide indication profile including diabetes, cardiovascular disorders, in addition to musculoskeletal symptoms. It is noteworthy that MSCs are believed to be immunoprivileged making them ideal candidates for allogenic transplantation in many acute conditions such as heart infarct, where isolation and expansion of autologous cells is too time-consuming and cumbersome (Atoui et al. 2008a). Indeed, transplantation of allogenic and autologous MSCs has been shown to alleviate symptoms of a broad spectrum of diseases and symptoms including liver cirrhosis (affected germ layer: endoderm) (Kharaziha et al. 2009), severe ischemic heart failure (affected germ layer: mesoderm) (Mathiasen et al. 2015; Kalou et al. 2021), and progressive multiple sclerosis (affected germ layer: ectoderm) (Connick et al. 2011). This discrepancy between the promising preclinical and clinical in vivo data and the lack of cross germ layer differentiation in vitro can be explained by the nowadays widely accepted mode of action of MSCs, which is mediating paracrine bystander effects rather than a consequence of engraftment and differentiation (Sharma et al. 2014; Lee et al. 2009; Zanotti et al. 2013; Timmers et al. 2007; Gnecchi et al. 2005, 2006). The paracrine activity of the transplanted cells also promotes mobilization of the intrinsic stem cells from bone marrow for their participation in the repair process (Haider et al. 2008; Haider and Aziz 2017). Given their paracrine activity containing both soluble and insoluble constituents, cell-free therapy using MSCs-derived paracrine factors is fast emerging as an alternative to cell-based therapy (Haider and Aslam 2018; Haider and Aramini 2020).

Thus, this chapter will focus mainly on the influence of 3D cell culture on osteogenic, adipogenic, and chondrogenic differentiation of MSCs, in addition to an assessment of the effects of cultivation in 3D on viability, proliferation, cellular senescence, and anti-inflammatory and immunomodulatory potential of MSCs' secretome.

3D Cell Culture of MSCs

In the developing embryo and in the adulthood, stem cells reside in defined distinct microenvironments referred to as endogenous niches (Brook and Gardner 1997; Frenette et al. 1998; Johansson et al. 1999). The current understanding of these

stem cell niches is that it not only includes stem cells but also involves cell-cell contacts, the extracellular matrix (ECM), as well as diverse biochemical and biophysical signals. These factors dictate the fate of the stem cells within the niche (Schofield 1978; Collins et al. 2005; Colmone et al. 2008; Conboy et al. 2005). Thus, proliferation, viability, differentiation, and the paracrine activity of stem cells highly depend on extrinsic factors within the microenvironment. As a result, the regenerative potential of stem cells is tightly linked to the homeostasis of its given niche. In vivo, MSCs reside in their respective niche (e.g., the perivascular niche for MSCs within the bone marrow). Their fate is regulated by integrating direct, paracrine, and endocrine signals received from various other cell types, other MSCs, extracellular matrix, and extrinsic and autocrine signaling molecules. In light of the complexity of these signaling networks, it is not surprising that removing stem cells from their niche leads to a profound disturbance of the signaling cascades that regulate cell fate.

Nevertheless, most basic and translational stem research is still conducted as conventional two-dimensional (2D) cell culture. Notably, it has been clearly shown that 2D cell culture results in an unnatural and forced apical cell polarity and changes their proliferation, migration, and differentiation capability. To address this, different strategies have been applied to recreate a more physiological microenvironment in vitro.

One of the most prominent and oldest techniques to cultivate stem cells three-dimensionally has been firstly established in 1992 (Reynolds and Weiss 1992). In this pioneering study, Reynolds and Weiss used a serum-free cultivation medium to enrich neural stem cells from enzymatically and mechanically digested adult mouse brain tissue. This resulted in self-aggregation of neural stem cells into spheroids and proliferation as self-adherent clusters referred to as neurospheres. In the following, similar protocols have been applied to other cell types, including various cancer cells (tumorispheres), embryonic stem cells (embryoid bodies), and MSCs. While being cost-effective and easy, this method is limited by the unequal distribution of nutrients and growth factors within the spheres and a lack of physiological tissue geometry.

An alternative to spheroid cultures is the use of scaffolds that can be solid or provided as hydrogels (Fig. 1). This scenario is the most common strategy to cultivate mammalian stem cells within a 3D environment. Here, the endogenous stem cell niche is mimicked even more closely by matrices or matrix-like structures (Lee et al. 2008).

To overcome the limitations of the conventional 2D cell culture, different 3D cultivation methods have been applied to MSCs (reviewed in Bicer et al. (2021)). Among others, MSCs have been successfully expanded as spheroids (Fig. 2a), and cultivated in 3D within various 3D hydrogels, including alginate hydrogels (Ho et al. 2016), collagen-based matrices (Lund et al. 2009), fibrin-poly(ester-urethane) scaffolds (Gardner et al. 2017), bacteria-derived cellulose (Favi et al. 2013), methylcellulose (Yamaguchi et al. 2014), nano-fibrillar cellulose (Azoidis et al. 2017; Sheard et al. 2019), and the chondrosarcoma (Fig. 2b, c) derived Matrigel™ (Yu et al. 2018).

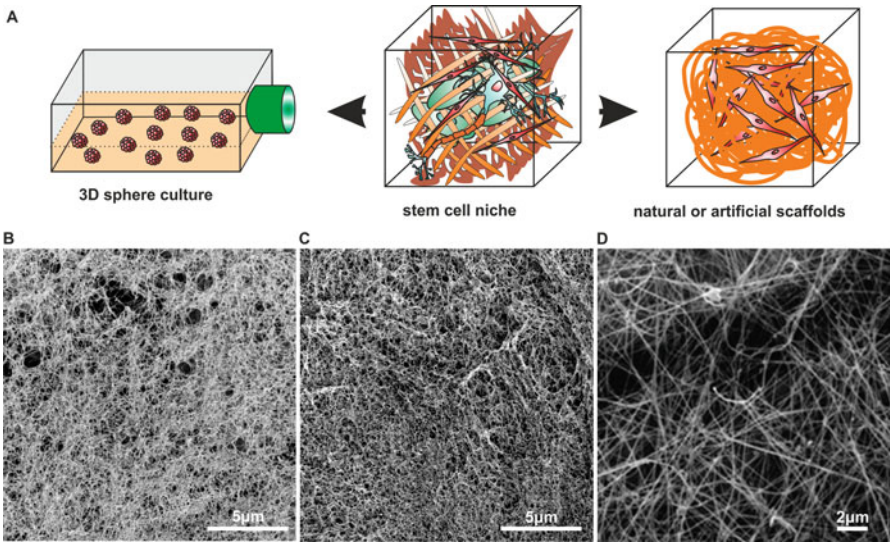

Fig. 1 (**a**) **Schematic view of common 3D methods for stem cell cultivation.** In their niche, stem cells reside in a distinct microenvironment which includes biochemical signals and complex 3D architecture providing physicomechanical cues. Removal from the niche, stem cells can be cultivated as conventional 2D monolayers or be propagated as self-adherent 3D spheres (left). Alternatively, cells can be cultivated on the surface or embedded within 3D scaffolds (right). (**b**–**d**) Microscopic appearance of nanofibrillar cellulose (**b**, unpublished), anionic nanofibrillar cellulose (**c**, (Sheard et al. 2019)), and blood plasma-derived fibrin hydrogels (**d**, (Greiner et al. 2011))

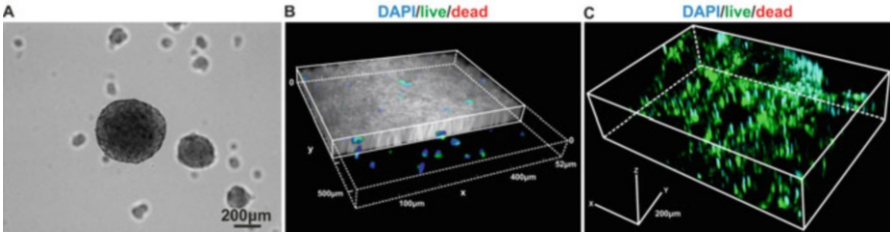

Fig. 2 **Different approaches to 3D cultivation of MSCs.** (**a**) MSCs derived from human dental pulp were cultivated in serum-free medium supplemented with FGF-2 resulting in formation of self-adherent spheroids (unpublished). (**b**) Human AD-MSCs were embedded within a 0.2% nanofibrillar cellulose hydrogel and stained with calcein (living cells), ethidium homodimer-1 (dead cells), and DAPI (nuclei). (Data from Azoidis et al. (2017)). (**c**) AD-MSCs were cultivated in 0.2% anionic nanofibrillar cellular and stained with calcein, ethidium homodimer-1, and DAPI

In addition, MSCs have been cultivated on a variety of stiff scaffolds which are beyond the scope of this chapter. In the following, we will focus on the most common approaches to 3D cultivation of MSCs – the spheroid culture and 3D cell culture within scaffolds.

Impact of 3D Cell Culture on Cell Fate Decisions of MSCs

Two-dimensional (2D) cell culture is still widely used to expand stem cells and to produce other cell-based therapeutics. This usually involves plating cells on flat plastic or glass surfaces. However, it is worth noting that the endogenous stem cell niche is not flat and two-dimensional. Therefore, removing stem cells from their niche not only changes the biochemical signals the cell receives but also mechanophysical aspects of the cell surroundings. This results in unnatural cell polarity and affects the proliferation kinetics, differentiation potential, and the profile of paracrine signals the cell is secreting.

It has been demonstrated that the cultivation of MSCs in traditional 2D cell culture is associated with a loss of multipotency and induction of premature cellular senescence (Turinetto et al. 2016). In addition, conventional cell culture has been suggested to induce chromosomal aberrations within the MSCs' genome (Ben-David et al. 2011; Bara et al. 2014). These artifacts can be avoided by the cultivation of MSCs as modern 3D cell cultures. Indeed, MSCs have been cultivated in a wide range of 3D cell culture systems including spheroids (Redondo-Castro et al. 2018; Bartosh et al. 2010) (reviewed in Cesarz and Tamama (2016)), stiff substrates, including PEDOT: PSS (Shahini et al. 2014), as well as different hydrogels including alginates (Ho et al. 2016), collagen (Lund et al. 2009), Matrigel (Yamaguchi et al. 2014), and different forms and preparations of cellulose (Favi et al. 2013; Cochis et al. 2017; Azoidis et al. 2017; Sheard et al. 2019).

However, the effects of 3D cell culture on the fundamental properties of MSCs seem to be at least partly dependent on the nature of the culture system. In the following, this chapter will discuss how different 3D cell culture systems affect MSC viability, proliferation, differentiation, and paracrine activity in comparison to respective 2D cell culture controls.

Viability and Proliferation

The impact of 3D cell culture on cell viability and proliferation has been extensively studied in cancer cells. Interestingly, the effects of 3D cell culture seem to be cell-type specific and technique-dependent, with some reports suggesting positive effects while others reported negative effects reviewed by Edmondson et al. (2014). A possible explanation is that the applied 3D culture methods varied largely with some reports utilizing scaffold-free tumorisphere cultures and other applying more advanced solid scaffolds or hydrogels. Overall, the cultivation of cancer cells as tumorispheres has frequently been associated with decreased proliferation and viability while 3D hydrogels have been shown to perform equally or be even superior compared to 2D cell culture (reviewed in Mirbagheri et al. (2019)). As proliferation and viability are critical for the expansion of MSCs in a clinical scenario, evaluating the impact of 3D cell culture technology on these parameters is paramount for the successful translation of basic research into the clinics.

While there is some evidence that spheroid culture of other cell types, including cancer cells and neural crest-derived stem cells reduces proliferation and viability (Hauser et al. 2012), the picture is more complex in case of MSCs. Since there is evidence for positive (Lee et al. 2016; Zhao et al. 2015), neutral (Domnina et al. 2018), or even adverse effects on proliferation (Sun et al. 2018; Baraniak and McDevitt 2012; Tsai et al. 2015), the impact of 3D spheroid culture in MSCs is still controversial. Overall, the adverse effects could be results of non-homogeneous nutrient and oxygen supply and impaired waste product diffusion in the core of the spheres (reviewed in Cesarz and Tamama (2016)). In contrast, the positive effects could be explained by more physiological cultivation conditions at the margin of the spheres compared to flat 2D cell culture. The picture gets even more complex when assessing the effects of cultivating MSCs within hydrogels. For several 3D scaffolds, including gelatine, poly lactic-co-glycolic acid, and chitosan, no evident effects on viability and proliferation have been reported (Lo et al. 2016). However, especially collagen hydrogels appear to exert different effects depending on the preparation of the hydrogel and the origin of the cells. While some studies suggest that collagen does not impact proliferation and viability of human MSCs (Lo et al. 2016), other reports indicate that the same scaffold increases proliferation of rat bone marrow MSCs (BM-MSCs) (Han et al. 2012). Similarly, there are contradicting data on the effects of polycaprolactone.

Increased viability and proliferation of minipig MSCs has been described in 2013 (Rampichova et al. 2013), while a recent study did not reveal any changes of proliferation and viability of human adipose tissue-derived MSCs (AD-MSCs) in 3D printed polycaprolactone/tricalcium phosphate compared to 2D controls (Park et al. 2018). Conversely, sprayed micro-fiber polycaprolactone has been suggested to increase the proliferation of human BM-MSCs, while electrospun variants of the same scaffold decreased their proliferation rate (Brennan et al. 2015). Similarly, poly (l-lactic acid) has been suggested to reduce the viability of BM-MSC, while the same scaffold substituted with hydroxyapatite increased it (Persson et al. 2018). In contrast, data from an independent lab indicated that a blend of poly (l-lactic acid) and type I collagen reduces the proliferation of human MSCs (Nguyen et al. 2012).

Similarly, the effects of the cultivation of MSCs in 3D nanofibrillar cellulose seem to differ depending on the concentration of the gel and its charge. While low concentrations (0.2%) did not change the proliferation rate of BM-MSCs, AD-MSCs, and palatal MSCs, higher concentrations (0.5%) resulted in a decrease in viability and proliferation (Azoidis et al. 2017).

However, anionic nanofibrillar cellulose has been shown to increase the viability of human AD-MSCs even at higher concentrations (Sheard et al. 2019) (Fig. 3).

Overall, there is no clear trend regarding the effects of 3D cultivation on the viability and proliferation of MSCs. The outcome is evidently dependent on many parameters, including the method of preparation of the scaffold, its concentration, as well as the species and tissue of origin of the cells used in the 3D cell culture system. Thus, adapting existing cultivation protocols to 3D cell culture requires careful monitoring of both parameters to establish optimized cultivation parameters for each scaffold and each cell type.

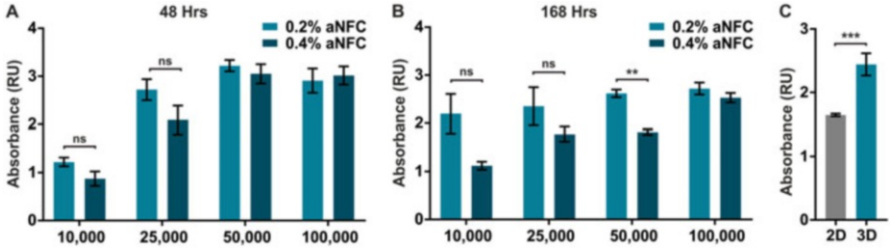

Fig. 3 Viability of MSCs in 3D anionic fibrillar cellulose varies depending on the seeding density and is superior compared to 2D controls. XTT viability analyses of different concentrations of AD-MSCs seeded within different densities of aNFC hydrogels show high viability after 48 h and 1 week (Sheard et al. 2019)

Cellular Senescence

Traditional 2D cell culture of flat, stiff substrates, such as plastic and glass, has been shown to increase cellular senescence of multiple cell types, including but not limited to MSCs. There is growing evidence in the literature suggesting that 3D cell culture might reduce senescence. This could be explained by the fact that the 3D environment closely mimics the endogenous niche of the MSCs while 2D enforces an unnatural apical polarity.

The impact of the most basic 3D cell culture system, the spheroid culture, on MSC senescence is ambiguous. It has been reported that spheroid cultures of AD-MSCs increase their replicative potential whilst reducing their senescence (Cheng et al. 2013; Younis et al. 2018). Similarly, human endometrial MSCs cultivated as 3D spheroids showed reduced levels of cellular senescence in response to heat shock and H_2O_2 compared to 2D controls (Domnina et al. 2020). Interestingly, although the spheroid MSCs did not show signs of senescence, the authors observed a decreased viability compared to 2D cell culture. Conversely, another study indicated that cellular senescence increases in MSC-spheroids, especially at late time points (Whitehead et al. 2020). These contrasting results could be explained by the nature of the spheroid culture system. At early stages, all cells within the clusters have sufficient access to nutrients from the environment and disposal of waste products of metabolism if not yet hampered by surrounding cells. However, once a critical size of the spheres is reached, lack of nutrients and accumulation of toxic waste initiate focal necrosis in the core of the clusters and cellular senescence in adjacent cells.

In contrast, this phenomenon is mainly avoided if 3D cell culture is conducted using hydrogels as scaffolds. A study by Younis and colleagues revealed that TNF-α-induced cellular senescence was largely reduced in MSC-like human periodontal fibroblasts cultivated in 3D methylcellulose hydrogels (Younis et al. 2018) when compared to 2D cultivated control cells. In accordance with these finding, a more recent report has provided clear evidence for a significant reduction in senescence-associated β-galactosidase activity in human adipose-derived MSCs cultivated in commercial polysaccharide hydrogels. Interestingly, the authors also

reported an overall increased telomerase activity when MSCs were subjected to 3D cell culture (Yin et al. 2020).

Overall, both spheroid and scaffold-based 3D cell cultures appears to reduce the cellular senescence of MSCs from different origins. However, sphere-based 3D cell culture seems more suitable for short-term expansion of MSCs since the positive effects on cellular senescence are less obvious at the late stages of the culture.

Osteogenic Differentiation

Osteogenic differentiation is the most widely studied cell fate of MSCs (Shima et al. 2015; Matta et al. 2019; Zhang et al. 2021). This is highlighted by the vast amount of research studies focused on MSC-based bone regeneration and numerous clinical trials exploiting the potential of MSCs to undergo this differentiation path. Interestingly, the data regarding the effects of 3D cell culture on osteogenic differentiation of MSCs are much more coherent than data sets focused on its influence on proliferation, viability, and senescence (Fig. 4). Overall, both scaffold-free and scaffold-based 3D cell culture systems appear to increase the osteogenic potential of MSCs. In this context, rat BM-MSCs expanded as spheroids showed a higher Osterix expression, increased ALP activity, and higher mineralization compared to 2D controls (Yamaguchi et al. 2014). In accordance with this report, the cultivation of

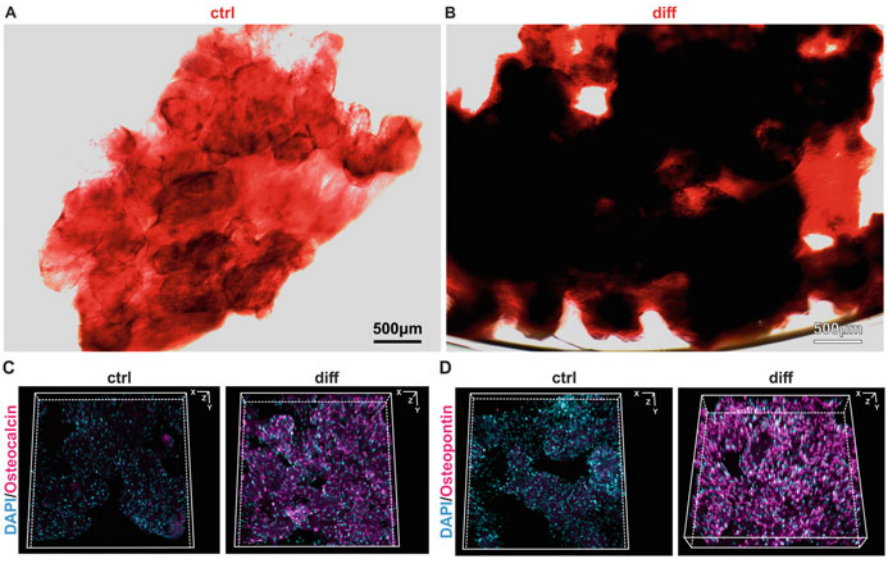

Fig. 4 Osteogenic differentiation can be conducted in 3D. (**a**, **b**) Alizarin Red S staining of human AD-MSCs subjected to osteogenic differentiation in anionic nanofibrillar cellulose hydrogels. Please note a more intense staining in cells cultivated in osteogenic differentiation medium. (**c**, **d**) 3D osteogenic differentiation of AD-MSCs in anionic nanofibrillar cellulose increase expression of osteocalcin and osteopontin. (Data from Sheard et al. (2019))

mouse BM-MSCs as scaffold-free spheroids resulted in fivefold higher levels of calcium deposition compared to 2D cultures exposed to the same osteogenic differentiation medium (Baraniak and McDevitt 2012).

Similarly, scaffold-based 3D cell culture systems have been consistently shown to increase the osteogenic potential of MSCs from different species and tissues. Human AD-MSCs cultivated in 3D rat tail collagen hydrogels revealed increased the expression of osteogenic markers, including type I collagen, osteopontin (OPN), and osteonectin (OCN) (Sefcik et al. 2008). Consistently, rat BM-MSCs expanded in 3D collagen scaffolds expressed higher levels of OCN and OPN as well higher levels of calcification compared to osteogenically differentiated cells in 2D (Han et al. 2012). In accordance with these reports, human MSCs of undefined origin showed higher levels of OCN and OPN and increased mineralization when subjected to osteogenic differentiation in blended scaffolds composed of collagen and electrospun poly(l-lactic acid) (Nguyen et al. 2012). Similarly, a significant increase in calcium deposition was observed in human BM-MSCs cultivated in 3D scaffolds composed of pure poly (l-lactic acid) (Persson et al. 2018). Similarly, differentiation of human BM-MSCs in Engelbreth-Holm-Swarm mouse sarcoma-derived Matrigel increased the ALP activity (a marker of osteogenic differentiation) and led to higher mineralization levels compared to cells differentiated in 2D (Yu et al. 2018).

Consistent with the results discussed above, scaffold-based 3D cell culture in 3D poly (ε-caprolactone) has been also shown to increase osteogenesis of minipig BM-MSCs (Rampichova et al. 2013), and human fetal and adult BM-MSCs (Shekaran et al. 2015; Brennan et al. 2015). Finally, alginate and gelatine blends increased the levels of osteogenic differentiation of AD-MSCs and BM-MSCs (Lo et al. 2016; Wang et al. 2016).

Adipogenic Differentiation

In 2019, Zohora and colleagues analyzed gene expression patterns of human AD-MSCs differentiating toward the adipogenic fate in 2D and embedded within hydrogels composed of self-assembling peptides. Although no comparison of the levels of lipid accumulation between 2D and 3D has been performed, the authors noted that the expression of genes regulating adipocyte-like cell properties was more consistent in 3D-cultivated cells (Zohora et al. 2019). Earlier reports also suggested that mouse BM-MSCs cultivated as 3D spheroids accumulate higher levels of lipids than 2D controls when subjected to adipogenic differentiation (Baraniak and McDevitt 2012; Bae et al. 2017). Interestingly, a recent study by Niibe and colleagues showed that the adipogenic potential of mouse and human MSCs pre-cultivated as adherent 2D monolayers lost as a result of long-term culture can be restored by transferring the cells into shaken 3D sphere culture systems (Niibe et al. 2020). Moreover, it has been shown that human AD-MSCs cultivated within polycaprolactone hydrogels accumulate higher levels of lipids and have a more mature adipocyte phenotype compared to their 2D cultivated counterparts. In contrast, Zou et al. reported in 2017 that the cultivation of human AD-MSCs in gelatine-based hydrogels does not significantly change lipid accumulation and the expression

of the adipogenic marker FABP-4 (Zou et al. 2017). Nevertheless, a vast majority of studies indicate that similar to the osteogenic potential, the adipogenic differentiation potential is increased in 3D as well (Miyamoto et al. 2016).

Chondrogenic Differentiation

As the chondrogenic differentiation of MSCs is mostly conducted as highly compact 3D pellets, a side-by-side 2D vs. 3D comparison of chondrogenic differentiation potential is challenging. Nevertheless, Merceron et al. compared chondrogenic differentiation of human AD-MSCs in 3D hydroxypropylmethyl cellulose hydrogels to differentiation in 2D. The authors provided clear evidence that the levels of chondrogenic differentiation are increased if chondrogenesis is conducted in 3D. Interestingly, thermo-reversible 3D methylcellulose-based hydrogels have also been shown to allow upscaling compatible chondrogenic differentiation of human BM-MSCs in bioreactors (Cochis et al. 2017). A direct comparison of chondrogenic differentiation of AD-MSCs as 3D pellets and within collagen I scaffolds indicated that scaffold-based culture might indeed result in a higher chondrogenic potential as evidenced by higher levels of type II Collagen, Aggrecan, and Sox9 as well as by a more intense Alcian blue staining. However, as mentioned above, the nature of the standard differentiation protocols makes assessing the impact of 3D cell culture on chondrogenic differentiation challenging.

MSC-Secretome, Immunomodulation, and Anti-Inflammatory Potential

Paracrine "bystander" effects are nowadays believed to be the primary regenerative mode of action for MSCs. This is especially important because MSCs exert beneficial effects on the regeneration of non-mesodermal tissues despite their lack of differentiation capacity into these cell types. Paracrine factors within the MSCs secretome mediate their beneficial effects mainly by reducing the levels of inflammation, modulating immune cells, increasing the levels of local angiogenesis, and inducing proliferation of endogenous tissue-resident progenitor and stem cells.

Consequently, evaluating the effects of 3D cell culture on the anti-inflammatory and immunomodulatory potential of MSCs is essential for a holistic analysis of their regenerative potential.

Overall, although very few reports suggest a reduction of the anti-inflammatory and immunomodulatory potential of MSCs as a result of 3D culture as spheroids (Burand et al. 2020), most studies provide strong evidence that secretomes produced by MSCs in 3D have an anti-inflammatory and immunomodulatory potential that is superior to their 2D cultivated counterparts. In this context, it has been demonstrated that AD-MSCs spheroids increase the expression and secretion of the pro-angiogenic vascular endothelial growth factor (VEGF) compared to 2D (Cheng et al. 2013). In addition, Bartosh et al. showed that spheroid cultures of BM-MSCs secrete higher levels of IL-24, which is a widely known anti-inflammatory

cytokine (Bartosh et al. 2010). The authors also revealed that spheroid BM-MSCs could more efficiently suppress LPS-induced inflammation compared to 2D cultivated cells.

Similarly, human MSC spheroids showed increased levels of IL-24 secretion (Frith et al. 2010). In a more recent study, Follin et al. demonstrated that MSC cultivated as spheroids secrete higher levels of VEGF than control 2D cultures (Follin et al. 2016). A similar increase of VEGF secretion has been reported in 3D spheroid cultures of human BM-MSCs (Redondo-Castro et al. 2018). In addition to the secretion of pro-angiogenic factors and reduction of inflammation, a pronounced increase of immunomodulatory activity has been observed in 3D cultivated MSCs. Briefly, MSCs cultivated as spheroids had higher potential to polarize macrophages toward the anti-inflammatory M2 phenotype. This has been attributed to increased secretion of prostaglandin E2 that mediated the macrophage polarization (Bartosh et al. 2013; Ylostalo et al. 2012). In addition to spheroid cultures, MSCs cultivated in hydrogels appear to produce secretomes with a higher regenerative potential than MSCs cultivated in 2D.

It has been reported that AD-MSCs cultivated in 3D bovine collagen/polyethylene glycol and collagen/low-molecular-weight hyaluronic acid hydrogels mediated higher levels of secretome-mediated neuroprotection of SH-SY5Y neuroblastoma cells following 6-hydroxydopamine insult compared to 2D cultivated controls (Chierchia et al. 2017). Similar to the changes in secretome profiles of spheroid cultured MSCs, scaffold-based 3D culture increased the secretion levels of HGF, VEGF, stromal cell-derived factor (SDF), and FGF-2 in AD-MSCs (Lee et al. 2016; Kim et al. 2013; Young et al. 2018). A recent study revealed that 3D cultivation of human BM-MSCs in electrospun gelatine/polycaprolactone scaffolds results in increased secretion of FGF-2, IL-6, VEGF, and HGF. Importantly, the authors also demonstrated that the secretomes from 3D cultivated cells were more efficient in corneal wound healing (Carter et al. 2019). Similarly, 3D cultivated umbilical cord MSCs secreted higher levels of IL-10, LIF, FGF-2, I-309, SCF, and GM-CSF than cells cultivated in 2D. Moreover, the same study showed a superior regenerative and anti-inflammatory potential in a rat in vivo arthritis model (Miranda et al. 2019).

Overall, 3D cell culture has been demonstrated to increase the regenerative potential of MSC secretomes independent of the nature of the cell culture system, suggesting that adapting 3D cell culture for cell expansion might be a promising step in improving the efficacy of MSC-based cell-free therapeutics (Kusuma et al. 2020; Bou-Ghannam et al. 2021).

Conclusions

Within their endogenous niche, the fate of MSCs is dictated by a complex network of signals, including cell-cell communication, geography of the niche, and interactions with the extracellular matrix. 3D cell culture mimics the niche more closely than flat, 2D cell culture. This chapter evaluated how 3D cell culture affects cell viability, senescence, differentiation, and paracrine potential of MSCs. As summarized above, the effects of 3D cell culture on cell viability and proliferation depend on the nature of

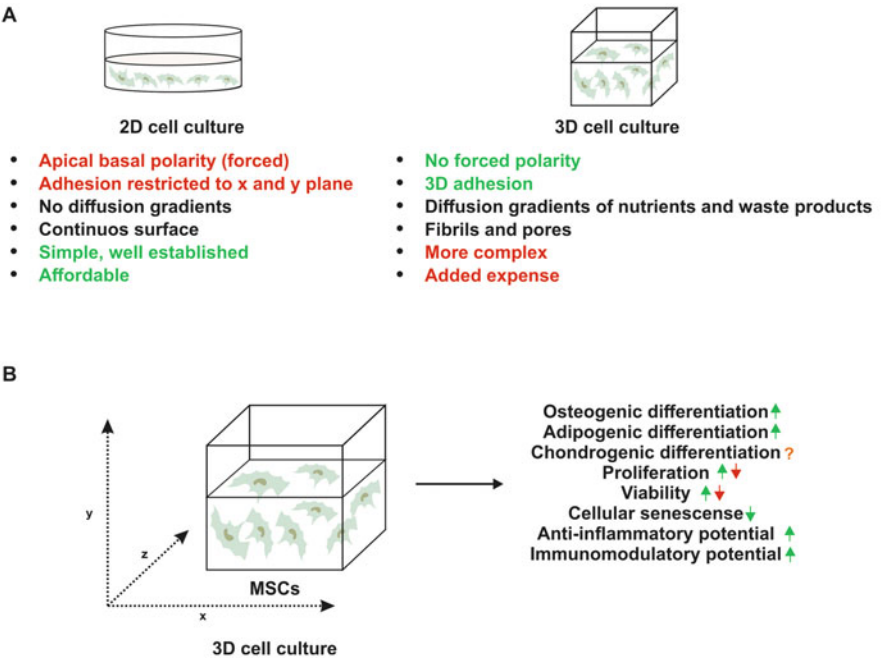

Fig. 5 **Effects of 3D cell culture on the cell fate of MSCs** (**a**). Advantages and drawbacks of 3D cell culture compared to traditional 2D cell cultivation. Advantages are highlighted in green, drawbacks in red, inconclusive aspects in yellow (**b**). 3D cell culture increases osteogenic and adipogenic differentiation potential of MSCs while there is not enough evidence to address the question how it affects chondrogenic differentiation. While there are conflicting reports on the impact of 3D cell culture on proliferation and viability, it decreases cellular senescence of MSCs and increases their anti-inflammatory and immunomodulatory potential

the applied cell culture technique and the origin of the MSCs. In contrast, the effects of 3D cultivation of cellular senescence, differentiation capability, and immunomodulatory and anti-inflammatory capacity are positive independent of the applied technique or scaffold (Fig. 5). Thus, going 3D might ultimately pave the way for better stem cell therapies and cell-free, MSCs-based therapeutics. Additionally, strategies based on physical, chemical (i.e., growth factor treatment), pharmacological, or genetic engineering as well as subcellular preconditioning could further augment the effects of 3D culture on MSCs in terms of survival, proliferation, differentiation, and paracrine potential (Lu et al. 2009, 2010; Kim et al. 2009; Afzal et al. 2010).

Abstract

Stem cells are defined as precursor cells with capabilities of self-renewal and the potential to differentiate into any type of specialized cells in the human body. Stem cells are categorized into two main types: pluripotent stem cells and adult stem cells. The former are derived from an embryo or can be generated by reprogramming and the latter from somatic tissues. The pluripotent stem cells can differentiate into three germ layers and tissue-specific stem cells, whereas the adult stem cells residing in somatic tissues can differentiate into specific cell lineage depending on the tissue environment. Multiple studies have characterized

adult stem cells in many human tissues, including the eye, and in recent years, there have been many reports highlighting the critical role of adult stem cells in maintaining the natural homeostasis of the eye. This chapter reviews the various populations of adult stem cells that exist in multiple compartments of the eye and their critical role in regeneration and repairability during ocular damage and/or disease.

Cornea · Embryonic stem cells · Eye · Homeostasis · Induced pluripotent stem cells · Ocular · Pluripotent · Reprogramming · Retina · Stem cells

Abbreviations

AMD	Age-related macular degeneration
ESCs	Embryonic stem cells
iPSCs	Induced pluripotent stem cells
RP	Retinitis pigmentosa

Introduction

Pluripotency, the capability of differentiating into numerous cell lineages and self-renewal are characteristics of stem cells (Thomson et al. 1998). Stem cells can be classified into totipotent, pluripotent, multipotent, oligopotent, and unipotent depending upon their location and the inherent ability of differentiation into multiple cells (Thomson et al. 1998; Mimeault et al. 2007; Takahashi et al. 2007). The human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs) unlocked diverse practical opportunities for cell-based therapies and served as important ex-vivo models to investigate human hereditary ailments (Thomson et al. 1998; Mimeault et al. 2007; Takahashi et al. 2007).

Unlike other organs, the immunologically privileged status and convenience for treatment make the human eye a paradigm for cellular therapies. The stem cell-mediated treatments include ocular and nonocular adult stem cell therapies and pluripotent stem cell-based treatments. The adult ocular stem cell therapies include the treatments derived from lens epithelial progenitor/stem cells (Lin et al. 2016), ciliary pigment-epithelial stem cells (Ahmad et al. 2000; Tropepe et al. 2000), retinal pigment epithelial stem cells (Salero et al. 2012), and retinal Muller stem cells (Ooto et al. 2004; Reichenbach and Bringmann 2013). Different studies have documented the differentiation of iPSCs and hESCs into specified ocular cells, corneal epithelial cells (Hayashi et al. 2012), retinal pigment epithelial cells (Buchholz et al. 2009; Hirami et al. 2009), photoreceptors, and retinal ganglion cells (Osakada et al. 2008; Lamba et al. 2009; Eiraku et al. 2011; Homma et al. 2013; Zhong et al. 2014; Maekawa et al. 2016).

Corneal stromal stem cells, corneal epithelial stem cells, and corneal endothelial progenitor cells have been documented to exhibit self-renewal potential (Cotsarelis

et al. 1989; Hall and Watt 1989; Pinnamaneni and Funderburgh 2012). So far, a small number of studies have shown the isolation of presumptive progenitor cells from eye lens (Hanna and O'Brien 1961; Persons and Modak 1970; Rafferty and Rafferty 1981; Zhou et al. 2006; Yamamoto et al. 2008). Recently, Lin et al. isolated lens epithelial stem cells in mammals and have shown that endogenous lens epithelial stem cells can achieve lens regeneration in macaques, rabbits, and human infants having cataracts (Lin et al. 2016).

Adult ocular stem cells, including multipotent retinal progenitor cells present in ciliary pigment epithelium, have been documented to generate photoreceptors (Xu et al. 2007; Ballios et al. 2012; Clarke et al. 2012; Del Debbio et al. 2013). The partial regeneration ability of retinal pigment epithelial cells has been reported (Fischer 2005). Recently, a small population of retinal pigment epithelial cells has shown stem cell-like differentiation potential into several retinal cell types (Osakada et al. 2007; Lu et al. 2013).

In this chapter, we discuss the stem cell populations residing in different compartments of the eye with an overall focus on their potential in cell-based therapies. This is an update to the chapter titled stem cell for ocular therapies in DE Gruyter 2018 publication, Stem cells: from hype to real hope.

Cornea

The cornea, an avascular transparent tissue, is an outermost layer that covers the iris, pupil, and anterior chamber of the eye (Delmonte and Kim 2011). The cornea comprises three cellular layers, including endothelium, stroma, and epithelium, and two noncellular layers, i.e., Descemet's membrane and Bowman's layer (Delmonte and Kim 2011). As the outermost layer of the eye, the cornea serves as a barrier and provides an optical function and accounts for about two-third of the entire refractive potential of the human eye (Delmonte and Kim 2011).

Corneal Epithelium

The corneal epithelium is a stratiform, nonkeratinizing, and the outermost layer of the cornea (Cotsarelis et al. 1989; Dua et al. 2003). The stem cells present in the limbal lower region, also called limbal stem cells, exhibit self-repairing capability of the corneal epithelium (Cotsarelis et al. 1989; Hall and Watt 1989). The limbal stem cells give rise to two daughter cells, an oligopotent-limbal stem cell and the other cell form transient fast-dividing cells which eventually make terminally differentiated cells (Schermer et al. 1986; Tseng 1989b; Kruse and Tseng 1993; Kruse 1994; Zieske 1994; Pellegrini et al. 2009).

The limbal stem cell deficiency due to the loss of limbal stem cells leads to the malfunction of limbus barrier function, new vessel formation, and the loss of corneal transparency (Dua et al. 2000). The limbal stem cell deficiency could be caused by inherited stem cell-aplasia, ocular surface injury, idiopathic diseases, and stem cell

exhaustion (Hughes 1946; Tseng 1989a; Nishida et al. 1995; Dua et al. 2000; Ramaesh et al. 2005).

Corneal Stroma

The corneal stroma is a collagenous-connective tissue and accounts for 80–90% of the total thickness of the cornea (Patel et al. 2001, 2002). The keratocytes, proteoglycans, collagens, and glycoproteins are accountable for collagen formation in the stroma (Maurice 1957; Freegard 1997; Knupp et al. 2009).

Corneal stromal fibrosis (also known as stromal scarring) can occur as a consequence of surgery and/or infection that contributes to a major portion of corneal blindness worldwide (Shortt et al. 2010; Oliva et al. 2012). During stromal fibrosis, the keratocytes differentiate into fibroblasts that result in a disorganized extracellular matrix in the stroma (Cintron et al. 1973; Fini 1999; Funderburgh et al. 2001; Funderburgh et al. 2003). Corneal transplantation is the only available remedy for corneal blindness (Tan et al. 2012). However, the limited availability of cadaveric human stromal tissue compelled the requirement of alternative sources, i.e., the biosynthetic cornea (Lagali et al. 2011), human corneal stromal stem cells (hCSSCs), and the generation of stromal tissue using different cell types (Ren et al. 2008; Du et al. 2009; Du and Wu 2011; Arjamaa 2012; Espandar et al. 2012; Wu et al. 2012; Yoeruek et al. 2012; Wu et al. 2013; Basu et al. 2014; Boulze Pankert et al. 2014; Giasson et al. 2014; Katikireddy et al. 2014; Nakatsu et al. 2014). In a study, Funderburgh et al. showed specialized cells exhibiting mesenchymal stem cell characteristics from bovine corneal stroma (Funderburgh et al. 2005).

In a subsequent study, Du and coworkers isolated the keratocyte progenitor cells from the human corneal stroma and identified the expression of ABCG2, an adult stem cell marker in keratocyte progenitor stromal cells (Du et al. 2005). Several studies have reported the stromal cells demonstrating properties similar to mesenchymal stem cells (Amano et al. 2006; Yoshida et al. 2006; Polisetty et al. 2008; Branch et al. 2012; Garfias et al. 2012; Li et al. 2012). Du et al. injected hESCs in the Lumincan-null mice stroma which resulted in stromal-transparency (Du et al. 2009). Pinnamaneni and Funderburgh documented the potential of hESCs for the treatment of stromal-scarring (Pinnamaneni and Funderburgh 2012).

Corneal Endothelium

The corneal endothelium is a monolayer of hexagonal cells located on the posterior surface of the cornea and serves as a barrier against the uncontrolled flow of the aqueous humor into the cornea (Bonanno 2012). The corneal endothelium is essential for corneal transparency by mediating hydration through barrier and pump functions (Bonanno 2012). The corneal endothelial cell density is ~2500 cells/mm^2 in normal adult corneal endothelium (Tan et al. 2012). Surgical fumble and inherited corneal endothelial dystrophies are the leading causes responsible for

corneal endothelial cell loss and reduction in corneal endothelial cell density (Lorenzetti et al. 1967). The corneal endothelium function is strikingly affected below 500 cells/mm^2 corneal endothelial cell density resulting in corneal edema and loss of vision (Tan et al. 2012).

To date, several studies have been performed to recognize corneal endothelial-stem cells. In two independent studies, the researchers conducted a sphere-forming assay to identify human corneal endothelial stem cell-precursors (Yokoo et al. 2005; Amano et al. 2006). The analysis demonstrated no expression of stem cell-associated markers in precursor cells; however, the clonogenic potential, proliferative capacity, and the ability to form a hexagonal monolayer of cells may indicate that they are corneal endothelial progenitor cells (Yokoo et al. 2005; Amano et al. 2006). In addition, the sphere-forming assay revealed a higher propensity of sphere-forming in peripheral cells compared to centrally residing cells of the endothelium (Mimura et al. 2005; Yamagami et al. 2007). In another study, likely progenitor cells were recognized in the region among Schwalbe's line and peripheral endothelium (Bednarz et al. 1998; Whikehart et al. 2005; Mimura and Joyce 2006; He et al. 2012). Increased density and proliferative potential of corneal endothelial cells situated at the peripheral portion of the cornea in comparison to the middle portion further supported the identification of progenitor-like cells (Bednarz et al. 1998; Whikehart et al. 2005; Mimura and Joyce 2006; He et al. 2012).

In addition, multiple studies were executed to document the expression of stem cell-associated markers in stem/progenitor-like cells in human corneal endothelium (Hirata-Tominaga et al. 2013; Hara et al. 2014). Hirata-Tominaga et al. discovered the expression of a stem cell marker i.e., LGR5, in the peripheral cells of corneal endothelium (Hirata-Tominaga et al. 2013). The authors stated that LGR5 (+) corneal endothelial cells exhibit elevated proliferative potential compared to LGR5(−) cells. They further demonstrated that LGR5 expression is responsible for endothelial phenotype and also impedes endothelial-mesenchymal-transformation (Hirata-Tominaga et al. 2013). Based on the neural crest origin of human corneal endothelial cells, several studies employed neural crest-associated markers to separate and typify the likely progenitor-cells from human corneal endothelium (Hara et al. 2014; Katikireddy et al. 2016). However, the progenitor cells from the young cornea exhibited higher proliferative potency compared with the older cornea (Katikireddy et al. 2016).

In a recent study, the authors explored the neural crest origin of likely proenitor-cells separated from Fuchs endothelial corneal dystrophy and normal corneas (Katikireddy et al. 2016). These neural crest-originated progenitor cells revealed the nonexistence of senescence with an increase in passage number, sphere-forming potential, and elevated colony-making capability in contrast to the primary cells (Katikireddy et al. 2016).

Ali et al. reported differentiation of peripheral blood mononuclear cells originated, iPSCs to corneal endothelial cells which share a similar proteome profile with human corneal endothelium, and further demonstrated that cryopreservation does not affect the cardinal features of corneal endothelial cells (Ali et al. 2018b). The authors subsequently confirmed that iPSCs- and hESCs-derived corneal endothelial cells have comparable transcriptome profiles (Ali et al. 2018a). In a recent study, Ali

et al. demonstrated the efficacy of cryopreserved hESC-derived corneal endothelial cells to form a functional corneal endothelium on the denuded Descemet's membrane (Ali et al. 2021). The authors generated pluripotent stem cell-derived corneal endothelial cells under xeno-free conditions, characterized cryopreserved pluripotent stem cell-derived corneal endothelial cells using next-generation RNA sequencing, and successfully evaluated intracameral injection of cryopreserved corneal endothelial cells to form a functional corneal endothelium in rabbits and monkeys (Ali et al. 2021).

Conjunctiva

Conjunctiva is a mucous membrane lining the eyelids and provides protection and lubrication to the eye (Inatomi et al. 1996; Di Girolamo 2011). The conjunctiva can be distinguished into three portions: the bulbar that covers the eye surface, the forniceal that forms the junction between the bulbar and the palpebral conjunctivas, and the palpebral that makes the lining of the undersurface of eyelids (Inatomi et al. 1996; Di Girolamo 2011).

Several studies have identified putative conjunctival stem cells in the conjunctiva (Wei et al. 1995; Pellegrini et al. 1999; Wirtschafter et al. 1999; Chen et al. 2003); however, the precise location of conjunctival stem cells is yet not well defined. Nagasaki et al. reported the even dissemination of conjunctival stem cells in the conjunctiva in GFP-labeled mice (Nagasaki and Zhao 2005; Stewart et al. 2015). In another study, Pellegrini et al. reported uniform distribution of conjunctival stem cells in the fornices and bulbar conjunctiva (Pellegrini et al. 1999). In a recent study, Stewart et al. inferred the conjunctival stem cell location in medial canthal and the inferior forniceal conjunctiva based on colony-forming potential and expression-pattern of stem cell-associated markers (Stewart et al. 2015). Further, stem cell features, i.e., reduced cell cycling, and the elevated proliferation rate were used to characterize the putative stem cell niche in the conjunctiva of rabbits (Wei et al. 1993; Wei et al. 1995). These studies revealed forniceal conjunctiva exhibiting a higher number of cells displaying stem cell characteristics compared to bulbar and palpebral conjunctiva (Wei et al. 1993, 1995).

To date, conjunctival stem cell specific markers have not been identified; nevertheless, *ABCG2* and *p63* are considered to be the most reliable markers (Watanabe et al. 2004; de Paiva et al. 2005; Kawasaki et al. 2006). Budak et al. reported that the human bulbar region of the conjunctiva possesses *ABCG2* positive cells which exhibit features similar to epithelial stem cells (Budak et al. 2005). Likewise, Vascotto and Griffith documented the existence of *ABCG2* and *p63* positive cells in the bulbar portion of the conjunctival-epithelium (Vascotto and Griffith 2006).

Iris

The iris is a thin, annular structure that splits the space among the lens and cornea (Grierson et al. 2002). The iris is composed of four layers: the anterior border layer, the stroma, the dilator muscle layer, and the posterior epithelium double monolayers

of iris pigment epithelial cells on the posterior part of the iris (Freddo 1984; Grierson et al. 2002).

Different authors documented the potential of iris pigment epithelial cells as progenitor cells based on their growth in spheres and the expression of neural stem/progenitor cells (Arnhold et al. 2004; Seko et al. 2012). In two sovereign studies, the analysis showed that iris pigment epithelial cells can also be differentiated into glial and neuronal cell types (Arnhold et al. 2004; Seko et al. 2012). Based on their origin, the iris pigment epithelial cells can form a complete lens in adult newt (Eguchi 1988; Tsonis and Del Rio-Tsonis 2004). Similarly, Kosaka et al. showed that one day old chicken iris pigment epithelial cells can sustain a differentiated form and may give rise to retinal pigment epithelium and lentoid bodies (Kosaka et al. 1998). In another study, Sun et al. isolated chicken iris pigment epithelial cells exhibiting sphere-forming potential and expression of retinal progenitor markers in non-adherent culture (Sun et al. 2006). In addition, they showed that iris pigment epithelial cells derived from postnatal chicken can proliferate similar to neural progenitor/stem cells with the ability to regenerate several cell types, such as retina-associated glia, neurons, and the lens (Sun et al. 2006).

Ciliary Body

The ciliary body is comprised of epithelium and muscle that is mainly involved in the production of aqueous humor (Napier and Kidson 2007). The ciliary body also regulates intraocular pressure, aqueous flow, and the maintenance of the immune-privileged status of the anterior chamber of the eye.

Multiple studies have demonstrated the presence of multipotent stem cells in the ciliary pigment epithelium isolated from adult mice, rats, rabbits, porcine, and humans (Ahmad et al. 2000; Tropepe et al. 2000; Inoue et al. 2005; Abdouh and Bernier 2006; MacNeil et al. 2007; Moe et al. 2009). In three independent studies, the analyses revealed about 1 in 100 and 1 in 500 ciliary body cells have proliferative capability isolated from adult mice and rats, respectively (Tropepe et al. 2000; Das et al. 2004; Kohno et al. 2006). Further, it has been reported that ciliary pigment epithelium-derived progenitor cells can be identified and isolated using neural retinal and/or progenitor associated markers (Xu et al. 2007; Moe et al. 2009). Xu et al. documented isolation of progenitors-like cells from the ciliary body of adult rats, mice, and human cadaver eyes (Xu et al. 2007) and have shown the expression of retinal/neuronal markers and neurospheres formation by ex vivo culturing of ciliary pigment epithelium-derived progenitor cells (Xu et al. 2007).

Trabecular Meshwork

The trabecular meshwork is a triangular-shaped tissue that lies in between the iris and cornea and regulates the outflow of aqueous humor fluid in the eye (Buller et al. 1990). The features of trabecular meshwork cells include the secretion of specific

enzymes, extracellular matrix, and phagocytosis in the aqueous humor (Buller et al. 1990; Stamer et al. 1995).

The attenuation in trabecular meshwork-cellularity was observed with the progression of age and glaucoma and linked with elevated outflow resistance and increased intraocular pressure (Alvarado et al. 1981, 1984; He et al. 2008). Multiple studies have documented a subpopulation of cells that express mesenchymal cell-specific markers, escape replicative senescence in human primary trabecular meshwork cells, and the potential to differentiate into various lineages by characterizing trabecular meshwork cells (Du et al. 2012; Tay et al. 2012). Recently, Du et al. reported phagocytic activity of multipotent stem cells from human trabecular meshwork tissue (Du et al. 2012). Further, multipotent stem cells isolated from trabecular meshwork revealed the expression of pluripotent stem cell- and mesenchymal stem cell-markers examined by gene expression analysis (Du et al. 2012, 2013). These cells also demonstrated the expression of trabecular meshwork-associated markers including *MGP, AQP1, CHI3L1,* and *TIMP3* (Du et al. 2012, 2013). Similarly, multiple studies reported stem cell-like cells in primary trabecular meshwork cultures which can form free-floating neurospheres (Vittitow and Borris 2004; Gonzalez et al. 2006; McGowan et al. 2007; Xu et al. 2007; Kelley et al. 2009).

Lens

The lens is structurally transparent tissue without vessels which is mainly responsible to focus light on the retina (McAvoy et al. 1999; Cvekl and Ashery-Padan 2014). The lens originates from the head-ectoderm which forms the lens placode. The lens placode further turns inward along with the optic vesicle to constitute the lens pit, and the optic cup, respectively (McAvoy et al. 1999; Cvekl and Ashery-Padan 2014). Next, the lens pit detaches from the ectoderm to create the lens vesicle which generates anterior and posterior single layers of cells (McAvoy et al. 1999; Cvekl and Ashery-Padan 2014). The lens develops quickly during late-embryonic and early post birth stages as the epithelial cells differentiate into secondary fiber cells (McAvoy et al. 1999; Cvekl and Ashery-Padan 2014). The closely packed lens fiber-cells, the maximum quantity of crystallin proteins, and the organelle loss during the differentiation process lessen light scattering and offer the refractive index essential for transparency and focusing (Michael et al. 2003; Bloemendal et al. 2004).

The quest of presumptive progenitor cells identification in the eye lens has been investigated in multiple studies (Hanna and O'Brien 1961; Persons and Modak 1970; Rafferty and Rafferty 1981; Zhou et al. 2006; Yamamoto et al. 2008). Overall, these investigations focused on the identification of slow and fast cycling-cells employing DNA-tagging methods in chick, rat, and mouse lenses (Hanna and O'Brien 1961; Persons and Modak 1970; Rafferty and Rafferty 1981; Zhou et al. 2006; Yamamoto et al. 2008). The epithelial cells situated at the peripheral zone of lens epithelium in the transition region exhibit increased proliferative potential. In contrast, the central portion of the lens demonstrates mitotically inactive epithelial

cells (Hanna and O'Brien 1961; Persons and Modak 1970; Rafferty and Rafferty 1981; Zhou et al. 2006; Yamamoto et al. 2008). It is well documented that lentoid bodies and lens progenitor cells can be generated from iPSCs and hESCs (O'Connor and McAvoy 2007; Yang et al. 2010; Qiu et al. 2012; Li et al. 2016; Fu et al. 2017; Ali et al. 2019, 2020). We previously showed that lentoid bodies can be generated from hESCs and peripheral blood mononuclear cells.

Originally, both hESCs and iPSCs shared similar morphological characteristics and expression pattern. We generated lentoid bodies using the "fried egg" method (Ali et al. 2019). Both hESCs and iPSCs were cultured on Matrigel-coated plates in mTeSR1 medium. The fried-egg like structures were observed on day 8 during the differentiation procedure. The phase-contrast microscopy of hESC- and iPSC-derived lentoid bodies revealed lens-like morphological appearance on differentiation day 25 (Fig. 1).

The lentoid bodies were harvested at differentiation day 25 and subjected to next-generation RNA sequencing (RNA-Seq) analysis. The mapped reads represented 263.42x and 238.01x sequence coverage for hESC- and iPSC-derived lentoid bodies, respectively, for ~70 Mb human transcriptome (Ali et al. 2019). The datasets revealed the expression ($\geq$ 0.659 RPKM) of 13,975 and 14,003 genes in hESC- and iPSC-derived lentoid bodies, respectively (Ali et al. 2019). A comparative analysis of these data suggested similar transcriptomes of hESC- and iPSC-derived lentoid bodies (Ali et al. 2019).

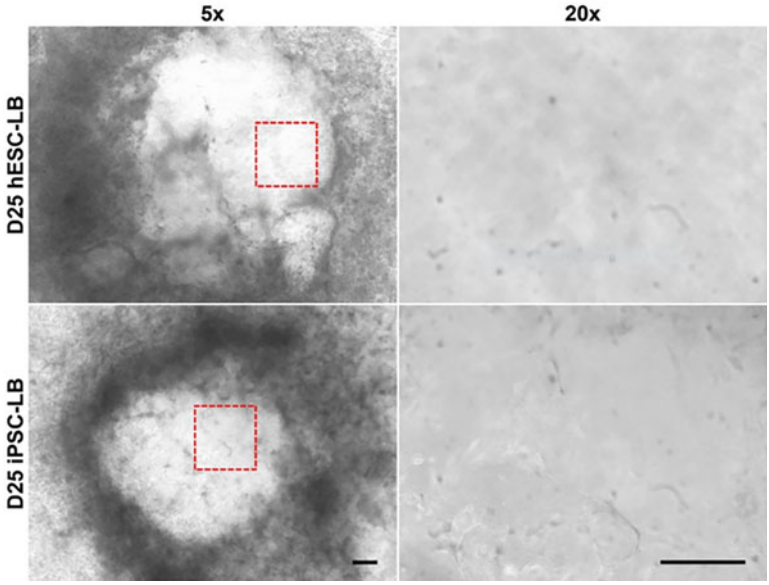

Fig. 1 Generation of lentoid bodies from H9 human embryonic stem cells (hESCs) and peripheral blood mononuclear cell (PBMC)-originated, induced pluripotent stem cells (iPSCs). The red dotted square indicates a lens-like transparent structure on differentiation day 25. The images are of 5x and 20x magnifications, and the scale bars represent 100 μm

Retina

The retina is a complicated structure, comprised of neural cell layers (ganglion cells, bipolar cells, and photoreceptor cells) and retinal pigment epithelium (Raymond and Hitchcock 1997). The human retina has reduced repair potential. Multiple retinal disorders including age-related macular degeneration (AMD), retinitis pigmentosa (RP), diabetic retinopathy, glaucoma, and Leber congenital amaurosis (LCA) have been reported to cause retinal damage and eventually resulting in vision loss (Alonso-Alonso and Srivastava 2015).

The human retina has shown restricted renewal potential; however, the neural retina can be regenerated in lower vertebrates (Raymond and Hitchcock 1997; Reh and Levine 1998). In amphibians and fish, retinal injury can prompt the proliferation of retinal pigment epithelial cells (Mitashov 1997). Fischer and Reh documented that the postnatal chicken retina exhibits the regeneration potential to generate neurons (Fischer and Reh 2001). Following injury, Muller glial cells enter the cell cycle, dedifferentiate, attain progenitor-like properties, and generate new neurons and glia (Fischer and Reh 2001). The retina of adult birds (Goldman and Nottebohm 1983) and mammals (Tropepe et al. 2000; Fischer and Reh 2001) have demonstrated the presence of multipotent stem cells.

Retinal Pigment Epithelium

The retinal pigment epithelium originates from the outer layer of the optic cup (Rapaport et al. 1995). Multiple reports have shown the proliferation proficiency of retinal pigment epithelium harvested from the adult and fetal human retina (Hu and Bok 2001; Maminishkis et al. 2006; Blenkinsop et al. 2012). Salero et al. explored a retinal pigment epithelial cell subpopulation that can be prompted to a stem cell-state presenting self-renewing and multipotent competencies (Salero et al. 2012). Blenkinsop et al. reported that retinal pigment epithelial stem cells can divide efficiently and retain the capability to differentiate into an exceedingly polarized retinal pigment epithelium monolayer (Blenkinsop et al. 2012).

Biswas et al. recently reported detection and validation of the underlying cause of progressive retinal degeneration (Biswas et al. 2021). Whole-genome sequencing identified a novel intron 8 donor splice site variant (c.1296 + 1G > A) and a novel exonic deletion encompassing the Mer tyrosine kinase proto-oncogene (*MERTK*), which is highly expressed in the retinal pigment epithelium (Biswas et al. 2021). To evaluate the impact of these novel variants, the authors reprogrammed peripheral blood mononuclear cells of the patient and parents of the patient to human iPSC lines, which were differentiated to retinal pigment epithelium (Biswas et al. 2021). The analysis of human iPSC–derived retinal pigment epithelium revealed the absence of both *MERTK* transcript and its respective protein as well as abnormal phagocytosis when compared with the parental human iPSC–retinal pigment epithelium (Biswas et al. 2021). Importantly, this approach using a human iPSC-derived retinal pigment epithelium model to establish the functional impact of disease-causing mutations to establish the potential mechanism underlying retinal pathology advocates for the use of patient-specific iPSCs. Characterization of iPSC-derived

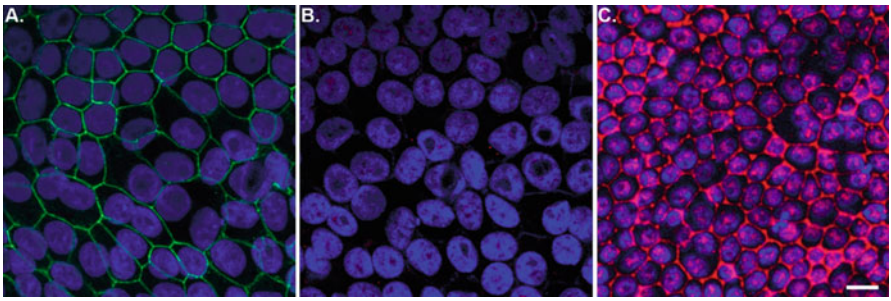

Fig. 2 Characterization of human induced pluripotent stem cell (iPSC)-derived retinal pigment-epithelial cells. Human iPSC-derived, retinal pigment epithelium is examined for the expression of multiple retinal pigment-epithelium markers including (**a**) Zona occludens-1 (ZO1), (**b**) the helix-loop-helix leucine zipper transcription factor MiTF, stained red, and (**c**) BEST1 localized to the basal side of human iPSC–retinal pigment epithelium which are shown. Scale bar: 10 μm

retinal pigment epithelial cells was confirmed by examining the expression of retinal pigment epithelium-associated markers including zona occludens-1 (ZO1), the helix-loop-helix leucine zipper transcription factor MiTF, and BEST1 (Fig. 2).

Retinal Muller Cells

Multipotent retinal progenitor cells give rise to Muller glial cells (Martin and Grünert 1992; Strettoi and Masland 1995), which constitute ~4–5% of total cells of the mouse retina (Young 1985; Jeon et al. 1998). It is well documented that retinal Muller cells can differentiate into various retinal cell types (Bernardos et al. 2007; Jadhav et al. 2009). Multiple studies reported the limited regeneration ability of Muller cells in chicken (Fischer and Reh 2001), rats (Reyes-Aguirre et al. 2013; Ferraro et al. 2015), mice (Ooto et al. 2004; Karl et al. 2008), and humans (Lawrence et al. 2007). It has been reported that Muller cells can reenter the cell cycle and redevelop the ganglion cells and inner nuclear layer in the injured retina of zebrafish (Raymond et al. 2006; Fimbel et al. 2007). Muller glia cells have also shown the regeneration potential into different types of neurons following N-methyl-d-aspartate (NMDA) injury to the retina in rodents (Ooto et al. 2004). Wan et al. documented photoreceptor repair in NMDA-induced retinal photoceptor-degenerated adult rats using Muller glial cells (Wan et al. 2008). Further studies have demonstrated the differentiation capability of Muller glia into ganglion cells under defined conditions (Zhao et al. 2014; Song et al. 2015, 2016).

Summary

In summary, we have provided a comprehensive view of adult stem cell populations residing in various compartments of the eye with an overall focus on their functional applications in cell-based therapies. Multiple studies have characterized adult stem

cells in different human body tissues including the eye and highlighted the crucial role of adult stem cells in maintaining natural homeostasis. Stem cells have distinct properties which permit them to regulate cell replacement during homeostasis and tissue repair. During homeostasis and after injury, the stem cells divide to generate daughter-transient amplifying cells which proliferate, migrate, and differentiate to replace the missing cells. However, this cannot happen when the stem cell population is depleted as a result of some diseased condition or trauma. The stem cell activity in any system requires to be strictly regulated for keeping the tissue in equilibrium. In this regard, the niche or tissue microenvironment, where stem cells exist, plays a crucial role in regulating stem cell fate decisions. Within these specified microenvironments, multiple signals are delivered, which guarantee correct stem cell activity. However, the exact cellular and molecular mechanisms by which the niche controls stem cell behavior remain elusive. It is important to note that stem cells are profound to the microenvironment they are exposed to, and irrelevant microenvironmental signals may lead to their depletion or impaired function. Therefore, further studies are required to conclude how stem cells are regulated by the niche and how niche components alter during infection or injury which ultimately will improve therapeutic strategies for the treatment of multiple ocular dysfunctions.

Abstract

Although conventional treatment strategies of drug administration and surgical intervention have been successful in protecting vision loss, however these efforts have been unable to discover a comprehensive approach to prevent the progression of disease in many ocular disorders. In this context, stem cell-based therapies provide an alternative approach to prevent vision loss in instances where conventional treatments have failed. The immune-privileged status and easy accessibility of different tissue of the eye offers several advantages for stem-cell-based therapeutic intervention. The pluripotent stem cells have been used to generate multiple eye cell types including corneal epithelial- and endothelial-cells, retinal pigment-epithelial cells, photoreceptors, retinal ganglion cells, and lens, conjunctival, limbal, and trabecular meshwork cells. Multiple pluripotent stem cell-based clinical trials for the treatment of a wide range of eye diseases are in progress.

iPSCs	Induced pluripotent stem cells
RGCs	Retinal ganglion cells
RP	Retinitis pigmentosa
SEAM	Self-formed ectodermal autonomous multizone

Introduction

Stem cell-based regenerative medicine is an emerging field where stem cells or their derivatives have been used to regenerate and restore the physiological functioning of several ocular tissues in preclinical models and human patients (Streilein et al. 2002; Jones et al. 2017). The mammalian eye has an intricate structure and harbors various advantages for stem cell-based therapies. Retinal degenerative diseases, such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD), are characterized by the early loss of photoreceptors or retinal pigment-epithelial cells (de Jong 2006; Ferrari et al. 2011), while glaucoma is characterized by retinal ganglion cell (RGC) degeneration (Davis et al. 2016a). These clinical conditions lead to the loss of photoreceptors over time, resulting in permanent blindness (Berson 1993; Quigley 1993; de Jong 2006).

Over the past two decades, many ocular cell types have been generated through differentiation of embryonic stem cells (ESCs) and, more recently, using induced pluripotent stem cells (iPSCs) including corneal epithelial cells (Zhu et al. 2018), retinal pigment-epithelial cells (Buchholz et al. 2009; Hirami et al. 2009), photoreceptors, and retinal ganglion cells (Osakada et al. 2008; Lamba et al. 2009; Eiraku et al. 2011; Homma et al. 2013; Zhong et al. 2014; Maekawa et al. 2016). Importantly, the generation of these cells has propelled their use in therapeutic applications to cure degenerative ocular diseases. Among these, limbal stem cells and corneal endothelial cells have been examined for their use in treating clinical conditions that involve degeneration of the corneal epithelium (Daniels et al. 2007; O'Sullivan and Clynes 2007) and corneal endothelium, respectively (Ali et al. 2021). Human pluripotent stem cell-derived trabecular meshwork cells (Du et al. 2012; Zhu et al.

2016, 2017) and RGCs (Kador et al. 2013; Sluch et al. 2015; Venugopalan et al. 2016) have been investigated for treating glaucoma.

Moreover, amacrine, retinal Muller cells, and retinal pigment epithelium derived from stem cells have been examined for the treatment of retinal diseases including RP and AMD (Dyer and Cepko 2000; Fischer and Reh 2001; Fausett and Goldman 2006; Bernardos et al. 2007; Lenkowski and Raymond 2014; Chen et al. 2015).

In this chapter, we discuss advances in stem cell-based therapeutic routes for the restoration of the physiological functioning of ocular tissues. This is an update to the chapter titled "Stem cells in ophthalmology" in DE Gruyter 2018 publication, Stem cells: from hype to real hope.

Cornea

Cornea is the outermost tissue of the eye consisting of three cellular layers (epithelium, stroma, and endothelium) and two acellular layers including Descemet's membrane and Bowman's layer (also known as Bowman's membrane) (Fig. 1). The cornea is responsible for two-thirds of the refractive power of the eye, and it provides a protective barrier against infection and debris entering the eye (Delmonte and Kim 2011).

Corneal Epithelium

The corneal epithelium is comprised of polygonal superficial cells, middle wing cells, and small basal cells (Delmonte and Kim 2011). The epithelium stem cells, also called limbal stem cells, are located in a limbal basal layer, the region between the conjunctiva and cornea (Delmonte and Kim 2011). The physiological damage

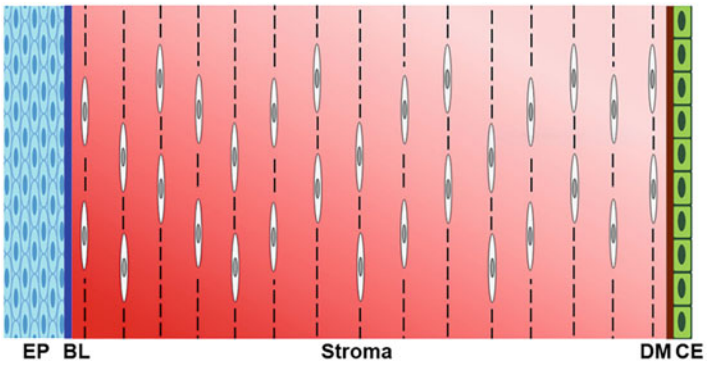

Fig. 1 A schematic of the three cellular layers, the epithelium (EP), stroma, and corneal endothelium (CE), and two acellular layers, Bowman's layer (BL) and Descemet's membrane (DM) of the cornea

and/or deterioration of the limbal epithelial cells leads to the limbal-stem-cell-deficiency (Dua et al. 2003).

Different studies have documented the capability of limbal stem cells to treat limbal-stem-cell-defeciency by substituting the disintegrated corneal epithelium (Kenyon and Tseng 1989; Ilari and Daya 2002; Gomes et al. 2003; Utheim 2013). It is well documented that transplantation of autologous cultured limbal stem cells can repair human limbal-stem-cell-deficiency (Pellegrini et al. 1997). Both allogeneic and autologous transplantation of limbal stem cells have been reported (Kenyon and Tseng 1989); nevertheless, these are hindered by posttransplantation complications and donor shortage (Shimazaki et al. 2000; Ilari and Daya 2002; Samson et al. 2002; Gomes et al. 2003).

The treatment of unilateral limbal-stem-cell-deficiency patients using autologous limbal stem cells transplantation has shown promising results. However, it is worth noting that other source(s) of limbal stem cells will be needed for the treatment of patients with bilateral limbal-stem-cell-deficiency. To circumvent these hurdles, human autologous buccal-epithelial stem cells originated from epithelial cell sheets were employed to treat bilateral limbal-stem-cell-deficiency patients (Priya et al. 2011). Further, Homma et al. examined the potential of ESC-derived epithelial progenitors to treat impaired cornea (Homma et al. 2004). Hayashi et al. differentiated human iPSCs into corneal epithelial-like cells (Hayashi et al. 2012). Next, Hayashi et al. generated self-formed ectodermal autonomous multizone (SEAM) ocular cells from iPSCs and demonstrated that cells from the SEAM can be separated and expanded to construct a corneal epithelium. The reconstructed corneal epithelium successfully mended the corneal blindness in an animal model (Hayashi et al. 2016).

Corneal Stroma

The stroma is comprised of collagens, glycoproteins, keratocytes, and proteoglycans, which play a crucial role in collagen formation (Maurice 1957; Freegard 1997; Knupp et al. 2009). Stromal fibrosis, as a result of infection, surgery, or ocular trauma, can lead to opacification, which is a substantial contributing factor to corneal blindness globally (Shortt et al. 2010; Oliva et al. 2012). To date, the only therapeutic option for the treatment of corneal stromal disease is deep anterior lamellar keratoplasty (Tan et al. 2012). However, this approach has restrictions such as lack of donor corneas and immune rejection (Tan et al. 2012).

Further, immortalized human corneal cells have been employed to generate functional human corneal equivalent. Buznyk et al. reported successful rehabilitation of visual acuity in two out of three patients by transplanting bioengineered corneal grafts (Buznyk et al. 2015), while Basu et al. documented the repair of injured stroma in mice by implanting human limbal biopsy-originated stromal cells (Basu et al. 2014). Furthermore, many studies have generated stromal keratocytes by differentiation of pluripotent stem cells, adult dental pulp stem cells, and mesenchymal stem cells (Syed-Picard et al. 2015; Zhang et al. 2015; Hertsenberg and Funderburgh 2016).

Stem Cell-Based Treatment for Corneal Edema

The corneal endothelium, the innermost layer of the cornea comprising of hexagonal/polygonal cells, is essential to retain corneal transparency by maintaining hydration through the pump and the barrier functions (Bonanno 2012). Corneal hydration is maintained primarily by the balance between the aqueous humor flow into stroma through the corneal endothelium and pumping out the fluid from the stroma (Nishida et al. 2010; Dawson et al. 2011). The accumulation of fluid in the stroma as a result of disruption of this balance may cause corneal opacity with reduced transparency. Tight junctions regulate the flow of aqueous humor through the corneal endothelium into the stroma, and sodium- and potassium (Na^+- and K^+)-dependent ATPase in the basolateral membrane is accountable for the pump function of the corneal endothelium (Dawson et al. 2011). The corneal endothelial cell density is approximately 2500 cells per square millimeter (cells/mm^2) in adult corneal endothelium, and the functioning of the corneal endothelium is significantly affected below a density of 500 cells/mm^2 resulting in corneal edema that eventually leads to vision loss (Tan et al. 2012).

Surgical trauma and corneal endothelial dystrophies are mainly responsible for corneal endothelial cell loss and a reduction in corneal endothelial cell density (Lorenzetti et al. 1967). Keratoplasty has been successful in visual restoration; however, the complexity of the procedure, the shortage of donor tissue, and graft rejection continue to impede the efforts to reduce corneal-blindness globally (Tan et al. 2012). The eye banking and worldwide estimation of corneal transplantation report the considerable shortage of corneal graft tissue, with only 1 cornea available for 70 needed (Gain et al. 2016), which compels for the development of alternative therapies.

Multiple alternate sources including ESCs, neural crest cells, adipose-derived stem cells, skin-derived precursors, and corneal stromal stem cells have been explored for corneal endothelial cell generation. Many research groups have shown that corneal endothelial cells can be generated by the differentiation of pluripotent stem cells (Fukuta et al. 2014; Zhang et al. 2014; McCabe et al. 2015; Song et al. 2016; Zhao and Afshari 2016). Fukuta et al. generated corneal endothelial cells from pluripotent stem cells using chemically defined conditions (Fukuta et al. 2014). Further, Zhang et al. reported restoration of corneal clarity in rabbits by transplanting corneal endothelium-like sheets (Zhang et al. 2014).

Intracameral injection of cultured corneal endothelial cells has been shown to restore corneal endothelium function in corneal endothelial dysfunction rabbit and monkey models (Okumura et al. 2016). A preclinical study in a primate model revealed corneal endothelium regeneration after the injection of human corneal endothelial cells or cultured monkey corneal endothelial cells, along with a Rho kinase inhibitor, into the anterior chamber of the primates' eye (Okumura et al. 2016). Many groups have reported the use of Rho kinase inhibitor to augment the adhesion of cultured corneal endothelial cells (Okumura et al. 2009; Peh et al. 2015).

Recently, Kinoshita et al. reported a revolutionary study in corneal transplantation and successfully treated the human subjects suffering from bullous

keratopathy (BK) by injecting cultured human corneal endothelial cells along with a Rho kinase inhibitor (Y-27632) into the anterior chamber of the eye (Kinoshita et al. 2018). Pan et al. reported a stepwise strategy to generate corneal endothelial cells from mice fibroblasts under chemically defined conditions using small molecules and successfully reversed the corneal opacity by the transplantation of corneal endothelial cells into a rabbit model with BK (Pan et al. 2021). Shen and the co-authors reported the generation of corneal endothelial cell-like cells derived from human skin-derived precursors, and subsequent injection of corneal endothelial cell-like cells revealed excellent therapeutic outcomes in rabbit and monkey corneal endothelial dysfunction models (Shen et al. 2021). In a recent study, Ali et al. demonstrated the efficacy of cryopreserved human embryonic stem cell (hESC)-derived corneal endothelial cells to form a functional corneal endothelium on the denuded Descemet's membrane (Ali et al. 2021). The authors first demonstrated through comparative gene expression analysis that cryopreservation of hESC-derived corneal endothelial cells for more than 5 weeks in liquid nitrogen does not affect their cardinal features.

In parallel, the authors developed animal models mimicking corneal endothelium edema by removing the central corneal endothelium. The cryopreserved hESC-derived corneal endothelial cells were injected into the anterior chamber of the corneal endothelium dysfunction animal (i.e., rabbit and monkey) models. As reported by Ali and colleagues, the transparency of the cornea reduced in the initial days after removal of central corneal endothelium; however, the transparency improved after the intracameral injection of hESC-derived corneal endothelial cells, and the transparency of the injected corneas became comparable to the uninjected control eyes in all animal models within 3 weeks postinjection (Fig. 2). Importantly, necropsy examination of these preclinical animal models confirmed no remarkable change in multiple tissues examined for tumorigenesis, alleviating the concerns of teratoma formation associated with the use of pluripotent stem cells and/or pluripotent stem cell-derivatives.

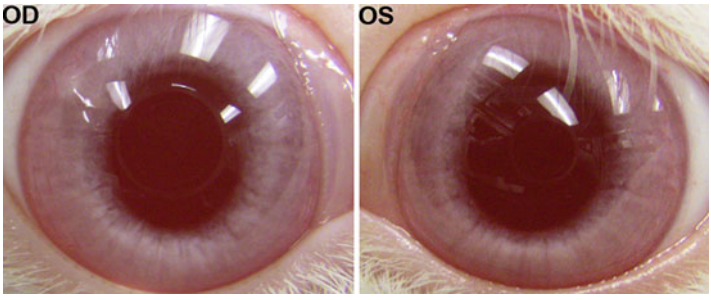

Fig. 2 Injection of human pluripotent stem cell-derived corneal endothelial cells into anterior chamber results in the generation of a functional monolayer of the corneal endothelium within 3 weeks. Importantly, the transparency of the injected right eye (OD) is comparable to the untreated left eye (OS). OD: oculus dextrus (right eye); OS: oculus sinister (left eye)

Trabecular Meshwork

The trabecular meshwork is critical for the drainage of the aqueous humor in the eye (Buller et al. 1990), and a reduction in trabecular meshwork cellularity (observed in case of glaucoma, and normal aging) links with high intraocular pressure (Alvarado et al. 1981, 1984). The general approach of treatments for glaucoma includes a drug-dependent decrease of aqueous humor formation and the surgical improvement of outflow to maintain normal intraocular pressure (Serle 1994; Kaufman and Rasmussen 2012). Stem cell-based therapy has remarkable potential for the repair of trabecular meshwork cellularity in aging and glaucoma patients (Pearson and Martin 2015). Alexander and Grierson were the first to report successful rehabilitation of trabecular meshwork function employing laser trabeculoplasty technique (Alexander and Grierson 1989). Laser trabeculoplasty treatment caused elevated trabecular meshwork cell division which is suggestive of the existence of "likely stem cells" in the anterior nonfiltering portion of the trabecular meshwork (Acott et al. 1989; Dueker et al. 1990). Du et al. examined the therapeutic efficacy of stem cell-like cells from human trabecular meshwork by transplanting them into mouse-trabecular meshwork tissue (Du et al. 2013). Differentiation of human embryoid bodies-derived iPSCs into trabecular meshwork cells has been reported by Abu-Hassan et al. (2015). In another study, mesenchymal stem cells were employed to regenerate the trabecular meshwork in laser-mediated glaucoma animal models (Manuguerra-Gagné et al. 2013). Next, Ding and coworkers employed primary human trabecular meshwork cell preconditioned media for the generation of trabecular meshwork cells from mouse iPSCs (Ding et al. 2014). Moreover, Zhu et al. evaluated the potential of iPSC-derived trabecular meshwork cells in a glaucoma mouse model (Zhu et al. 2016, 2017). It is well documented that iPSC-derived trabecular meshwork cells helped in decreasing intraocular pressure, repairing aqueous humor drainage, preventing retinal ganglion cell loss, and improving the proliferation of endogenous trabecular meshwork cells (Zhu et al. 2016, 2017).

Ocular Lens

Lens cloudiness or cataracts including age-linked and congenital cataracts are the primary cause of vision loss globally (Stevens et al. 2013). The most effective strategy for cataract treatment is the replacement of the cloudy lens with an artificial intraocular lens (Visser et al. 2013). Cataract surgical procedure is very successful in visual rehabilitation, however, linked with postsurgical hitches including posterior-capsule-opacification (Wormstone 2002; Lois et al. 2005). Further, the role of stem cells has been studied in lens regeneration (Tsonis and Del Rio-Tsonis 2004; Barbosa-Sabanero et al. 2012). It is well documented that in rabbits, the residual lens progenitor/epithelial stem cells give rise to a partial generation of lens fiber cells following removal of the eye lens (Gwon et al. 1990; Gwon 2006). Recently, Lin et al. documented an innovative approach for the elimination of cataractous lens by retaining resident lens-epithelial-cells and attained a functional restoration of the lens

in macaques, rabbits, and in human infants (Lin et al. 2016). O'Connor and McAvoy demonstrated that rat limbal epithelial cell monolayers can form functional lens-like structures ex vivo (O'Connor and McAvoy 2007). They noticed that regenerated rat lenses were meticulously similar to those of neonatal rat lenses and extended culturing of these regenerated rat lenses exhibited cataractogenesis (O'Connor and McAvoy 2007). Several groups have described that iPSCs and hESCs can form lens progenitor cells as well as lentoid bodies (Yang et al. 2010a; Qiu et al. 2012; Li et al. 2016; Fu et al. 2017b). Yang et al. generated lentoid bodies employing hESCs under chemically defined conditions (Yang et al. 2010b). The lentoid bodies produced by Yang et al. showed lens-associated makers; however, they do not exhibit optical properties (Yang et al. 2010b). Recently, Fu et al. developed human urinary cell, originated iPSC-derived lentoid bodies adopting the fried-egg approach (Fu et al. 2017a). These lentoid bodies demonstrated lens-associated markers as well as transparency similar to the human lens (Fu et al. 2017a). Moreover, Murphy et al. documented the human pluripotent stem cell-derived microlenses (Murphy et al. 2018). More recently, Ali et al. produced lentoid bodies from human iPSCs and hESCs and performed characterization using next-generation RNA sequencing (RNA-Seq) and TMT-based proteome profiling (Ali et al. 2019, 2020).

The Retina

Pluripotent stem cells have unlimited self-renewal capability, and pluripotent stem cell-derived retinal cells can be an ideal source to repair the degenerating retina. Human iPSCs and hESCs have been used for the generation of retinal photoreceptor cells and retinal pigment epithelium. To this end, several investigations have examined the therapeutic efficacy of adult progenitor/stem cells to treat retinal deteriorating diseases.

Salero et al. showed that the retinal pigment-epithelial stem cells (lacking the retinal pigment epithelial-associated markers) can proliferate and generate cobblestone-like monolayers (Salero et al. 2012). Blenkinsop et al. published a novel culture approach and proved that adult human eye-originated, retinal pigment epithelial cells can generate highly purified retinal pigment-epithelial cultures that demonstrate native retinal pigment epithelial-like properties (Blenkinsop et al. 2015). Moreover, Davis et al. documented that subretinal transplantation of retinal pigment-epithelial stem cell-derived retinal pigment-epithelial cells in rats inhibits loss of photoreceptors (Davis et al. 2016b, 2017). Further, Davis et al. reported that subretinal transplantation of retinal pigment-epithelial stem cell-derived retinal pigment-epithelial cells prevents vision loss in the retinal pigment-epithelial cell dysfunction rat model (Davis et al. 2017).

Mitashov et al. reported that Muller glial cells reveal characteristics similar to stem cells and contribute to the restoration of the damaged retinas in amphibians (Mitashov 1996). Additionally, Jayaram et al. showed photoreceptor cells, derived from Muller cells, when injected in the retinas of 3-week-old P23H-rats can

incorporate into the outer nuclear layer of deteriorated retinas, which results in improvement of rod photoreceptor function (Jayaram et al. 2014).

Several studies have documented the use of hESCs for the generation of neural retinal progenitor cells and functional retinal pigment-epithelial cells (Klimanskaya et al. 2004; Lamba et al. 2006; Lund et al. 2006; Osakada et al. 2008; Hirami et al. 2009; Idelson et al. 2009). It is well documented that three-dimensional organoid similar to the optic cup and the neural retina can be generated from mouse-pluripotent stem cells (Eiraku et al. 2011; Nakano et al. 2012; Zhong et al. 2014). Recently, DiStefano et al. generated retinal organoids employing rotating wall vessel-bioreactors from pluripotent stem cells (DiStefano et al. 2018). Gonzalez-Cordero et al. examined the integration-efficacy of rod precursor cells into the deteriorated retinas of adult mice (Gonzalez-Cordero et al. 2013). In another study, the authors transplanted three-dimensional retinal sheets derived from mouse iPSCs or ESCs in a retinal deterioration model in which the outer nuclear layer was absent (Assawachananont et al. 2014). In two different studies, the intraocular transplantation of neural precursor cells derived from hESCs and donor cells from developing retinas in the subretinal microenvironment presented integration and differentiation into various cell types (Banin et al. 2006; MacLaren et al. 2006).

It is worth noting that iPSC-based treatments showed a promising method for the repair of degenerative retinal diseases. iPSCs reveal a better option in contrast to hESCs because of the patient-specific method: utilizing the identical genetic background, decreasing the chances of immune rejection while also eliminating the numerous ethical concerns linked with ESCs. Moreover, genome-editing techniques such as transcription activator-like effector nucleases (TALENs), zinc finger nucleases (ZFNs), and clustered regularly interspaced short palindromic repeats (CRISPR/Cas9) have been employed to correct patient-specific iPSCs which can be used for the repair of retinal deteriorating diseases (Hung et al. 2016; Chuang et al. 2017; Peng et al. 2017). Bassuk et al. reported editing of patient-specific iPSCs to correct a mutation present in an RP-GTPase regulator gene using CRISPR/Cas9 (Bassuk et al. 2016).

Several groups have reported that hESC- and iPSC-derived retinal pigment-epithelial cells exhibit comparable gene expression profiles and phenotypic characteristics (Buchholz et al. 2009; Meyer et al. 2009; Osakada et al. 2009). Additionally, many research groups have successfully generated neural retinal progenitor cells, such as photoreceptor cells from human iPSCs (Meyer et al. 2009; Osakada et al. 2009; Lamba et al. 2010; Mellough et al. 2012; Zhong et al. 2014). Multiple studies documented enhanced optical function following transplantation of iPSC-derived retinal pigment-epithelial cells in various RP-mouse models (Lopez et al. 1989; Yamamoto et al. 1993; Carr et al. 2009; Tucker et al. 2011; Li et al. 2012; Sun et al. 2015). Recently, Tucker et al. reported successful rehabilitation of retinal structure and function by transplanting iPSC-derived retinal precursor cells in rhodopsin-null mice (Tucker et al. 2011, 2013). Two different studies demonstrated the potential of native retinal pigment epithelial-transplantation to enhance electroretinogram activity in Royal College of Surgeons (RCS) rats (Lopez et al. 1989; Yamamoto et al. 1993).

In addition, Carr et al. generated functional retinal pigment-epithelial layers from human iPSCs and transplanted them in RCS rats to facilitate short-term maintenance of the photoreceptor-mediated phagocytosis of photoreceptor outer segments (Carr et al. 2009). Sun et al. investigated the therapeutic potential of human iPSC-derived retinal pigment-epithelial cells, neural stem cells, and human mesenchymal stromal cells using *rd1* mice, and the results suggested that iPSC-derived retinal pigment-epithelial cells can slow the deterioration of photoreceptors (Sun et al. 2015). Further, Li et al. showed the integration of administered iPSC-derived retinal pigment-epithelial cells with the resident retinal pigment epithelium of retinal pigment epithelial-65 mouse model resulting in enhanced visual activity (Li et al. 2012).

Given the identical developmental origin of retinal pigment-epithelial and iris pigment-epithelial (IPE) cells, several studies were conducted to administer cultured autologous or freshly isolated IPE cells in rats, rabbits, and nonhuman primates, i.e., monkeys and humans, for the treatment of retinal deteriorating diseases (Sheedlo et al. 1991; Rezai et al. 1997; Abe et al. 1999; Schraermeyer et al. 1999; Thumann et al. 1999; Abe et al. 2000a, b; Lappas et al. 2000; Thumann et al. 2000; Crafoord et al. 2002; Lappas et al. 2004; Aisenbrey et al. 2006). The administration of fresh autologous-IPE cells into the rabbit subretinal region caused no immunological rejection and injected IPE cells exhibited specific-phagocytic activity (Thumann et al. 1999). Importantly, similar results were examined following the administration of autologous cultured IPE-cells in monkeys (Abe et al. 2000a). Moreover, multiple studies employed the autologous IPE-cells to treat subretinal-neovascularization and AMD in humans (Abe et al. 1999, 2000b; Lappas et al. 2000; Thumann et al. 2000). Recently, Thumann et al. administered autologous IPE-cells into the subretinal region of 20 patients exhibiting neovascularization and advanced AMD, which showed improvement of visual acuity without any side effect (Thumann et al. 2000). Likewise, Abe et al. demonstrated similar findings by administering autologous cultured IPE cells into the subretinal region of eight patients with AMD (Abe et al. 1999, 2000b). In contrast, Lappas et al. completed IPE-cell administration in 12 patients with wet-AMD and documented preserved preoperative visual acuity but no improvement after a follow-up period of 6 months (Lappas et al. 2004).

Retinal pigment-epithelial cells derived from hESCs have been employed in multiple human clinical trials (Reardon and Cyranoski 2014; Kimbrel and Lanza 2015; Schwartz et al. 2015, 2016; Song et al. 2015), while only one human clinical study was conducted utilizing iPSC-derived retinal pigment-epithelial cells (Mandai et al. 2017). The iPSC-based autologous cell administration in one patient revealed no harmful effects including immunological rejection and tumor formation, whereas the transplanted retinal pigment epithelial-sheet remained intact with no improvement in best-corrected visual acuity (Mandai et al. 2017). However, retinal pigment-epithelial cells derived from iPSCs were not further administered to other patients since the patient-specific iPSCs harbor multiple genetic lesions that were absent in patient fibroblast cells (Mandai et al. 2017).

Conclusion

In conclusion, we provide the potential of stem cells including nonocular, ocular, and pluripotent stem cells for the treatment of ocular dysfunctions. Ocular diseases such as RP, AMD, diabetic retinopathy, cataractogenesis, uncorrected refractive errors, glaucoma, and corneal dystrophies are responsible for severe visual impairment worldwide. In the near future, the count of individuals with compromised vision is projected to escalate dramatically because of aging and population growth. Stem cells owing to their repair and regeneration ability have immense potential to treat multiple ocular conditions. The eye is an ideal site to examine the therapeutic efficacy of stem cell-based transplantation. The ocular function can be evaluated using standardized outcome measures and in vivo imaging of the retina, lens, and cornea. To this end, multiple stem cell therapies employing cultured and pluripotent stem cell-derived differentiated cells have been investigated as potential treatment options for limbal-stem-cell-deficiency, corneal endothelial dysfunctions, glaucoma, AMD, and other retinal dystrophies in preclinical and clinical settings. A better understanding of the location and function of ocular stem cells has led to the exploration of possible therapeutic options for ocular diseases. However, the evaluation of stem cell treatments in clinical settings regarding long-term complications and technical challenges needs further attention. In conclusion, working on stem cells is one of the sizzling research sectors in biology. Both tissue-resident as well as pluripotent stem cell-derived differentiated cells can prevent vision loss by repairing/replacing the degenerative cells in ocular diseased tissues.

Abstract

Intramuscular implantation of cultured allogeneic myoblasts derived from pathogen-free muscle biopsies of genetically normal human volunteers demonstrated safety and efficacy in clinical studies of Duchenne muscular dystrophy (DMD), heart failure, ischemic cardiomyopathy, Type-II diabetes, cancer, and aging disfigurement. Through natural cell fusion, donor myoblasts inserted their normal nuclei that supplied the complete human genome to replenish the aberrant gene(s). The replacement gene(s) produced single or multiple gene transcripts, factors, and protein(s) in multiple pathways to effect complementary genetic repair. Donor myoblasts also fused among themselves to form normal myofibers. Applications included diagnostic screening, disease prevention, disease treatment, drug discovery, and selection of superior cell clones for therapies. Only 3-week cyclosporine immunosuppression was necessary to support engraftment, development, and functioning. Improvement in the host included production of repairing structural and regulatory proteins, increases in muscle cell number and function, increases in locomotive capacity, breathing capacity and life span in DMD boys, increases in blood ejection and vascularization in heart failure and ischemic patients, and transfer of biochemicals and ions across the muscle cell membrane in diabetic patients. Intra-tumor implantation of allogeneic human myoblasts induced cancer apoptosis, inhibiting metastasis and tumor growth with cancer patients. FDA currently listed 23 myoblast implantation projects, and EMA listed 6, mostly in Phase II with some in Phase III clinical trials. This unique platform technology, patented for its compositions, methods, and related medical devices of cell/gene

therapies, promised to be of great social and economic values in world health and human services.

TNF-α	Tumor necrosis factor-α
UBT	Upper body treatment
$VEGF_{165}$	Vascular endothelial growth factor 165
WBT	Whole body treatment

Introduction

Gene Defect: The Original Sin

The Book of Genesis has it that when Eve and Adam ate the fruits of the forbidden tree in Eden, they committed the Original Sin and lost eternal life and happiness. Without tasting the forbidden fruit, their children inherited the Original Sin and needed rebirth to regain what was lost. Gene defects are inherited like the Original Sin. By inheriting these defects, human beings lose even normal life and happiness. Myoblast therapies were pioneered, tested, and established by Professor Peter K. Law's teams and colleagues for most human beings to regain what was or may be lost in health because of gene defects.

Genetic Diseases Account for >80% of Human Death

Genetic diseases are those that have demonstrated gene defects with heritability. In additional to single gene defects causing, for example, Duchenne muscular dystrophies (DMD), many incurable diseases are the result of multiple gene defects and haphazard interactions between them. The latter include top killers of mankind such as cancer, cardiovascular diseases, Type II diabetes, and aging. Together, these fatal and debilitating diseases account for more than 80% of human death, for which the human and health services have provided neither prevention nor effective treatment.

Approaches Towards Treatment

Regenerative medicine using biologics is the medicine of the twenty-first century. Cell therapies regenerate degenerative tissues and enhance organ appearance and functions with little side effects. From the fertilized ovum unto death, the cell is the

basic unit of life in the human body. Whereas numerous molecular genetic pathways have yet to be discovered, advent in cell culture and transplantation techniques has culminated into many somatic cell therapies being practiced. They achieve where drugs, devices, organ transplants, and single gene therapies have failed.

Autografts Cannot Treat Genetic Diseases

The same gene defect(s) reside in every living cell of the genetically defective individual throughout life, since all cells of the body are derived from mitosis of the fertilized eggs. Therefore, hereditary degenerative organs cannot depend on any cell derived from the host body to provide regeneration or rebirth. Allograft is a must for the treatment of hereditary degenerative diseases, and the implanted cells must be derived from genetically normal donors to provide the missing gene(s), and not from abnormal donors. By law, cell therapy forbids transplanting genetically abnormal cells into any human being, including oneself.

Treatment Design and Mechanisms

One unique platform biotechnology distinguishes itself from the rest in terms of demonstrated safety, efficacy, applications, maturity, and intellectual property protection. That is human myoblast genome therapy (HMGT) (Law 2009), also known as myoblast transfer therapy (MTT) (Law 1994). Published reports indicated that the MTT platform technology has applications to treating most if not all the genetic diseases mentioned above, and it is the goal of this chapter to provide the essence.

Why Cell Therapy

The cell is the basic unit of all lives. It is that infinitely small entity which life is made of. In hereditary degenerative diseases such as those mentioned, gene defects cause cells to degenerate and die throughout life. When a DMD boy cannot stand by himself, he has already lost 40% of his skeletal muscle cells in his legs, with the remaining cells in his body continue undergoing hereditary degeneration.

An effective treatment must not only repair degenerating cells but replenish dead cells as well (Law 1994). This has been achieved by the transplantation of genetically normal cells called myoblasts because of their unique ability of natural cell fusion and their unidirectional development to become myofibers. Neither pharmaceutics nor molecular medicine can replenish dead cells. There is very limited evidence that they can repair degenerating cells. Myoblasts are efficient, safe, and universal gene transfer vehicles, being endogenous to the body. Since a foreign gene always exerts its effect on a cell, cell therapy will always be the common pathway to health. After all, cells are what life is made of.

Myoblasts: Nature's Chest of Gene Medicine

Evolution of vertebrate muscular system over the past 500 million years witnesses some unique characteristics developed. In human beings, myoblasts are the only cell type which divide extensively without tumorigenicity, migrate, fuse naturally to form syncytia, lose their major histocompatibility class I (MHC-1) antigens soon after fusion, and develop to occupy 55% of the body weight. These combined properties render myoblasts ideal for gene transfer and somatic cell therapy (SCT).

Myoblasts is a living biologic native to the human body, a bioactive product of 500 million years of vertebrate evolution. Each of their nuclei contains the software and hardware of the complete human genome, readily to be switched on and off towards normal muscle development. Because of the vast biodistribution of striated, cardiac, and smooth muscles, any gene defect affecting the myo-genome will have serious consequences, such as found in aging, muscular dystrophy, Type II diabetes, and their related cardiomyopathies.

From human standpoint with 3000 years of recorded medical knowledge, understanding the etiology and pathogenesis will have great bearing in devising preventions and treatments for various muscle diseases. From other mammals' standpoint without any medical capability, myoblasts and other biologics are all they have. The skeletal muscle, being externally located in the body, has developed specific regenerative capabilities and characteristics for frontline defense against predation and diseases, traversing much longer time than human knowledge of medicine.

All the unique properties or specializations, especially the natural cell fusion of myoblasts during muscle development and regeneration, were fully exploited by Law in his pioneer engineering of the MTT platform technology. It should be mentioned that satellite cells, muscle stem cells, and muscle progenitors are essentially myoblasts and have very similar if not exactly the same cell properties.

MTT Platform Technology

MTT is a combined SCT and gene therapy: replenish dead myofibers with live ones, and genetically repairing degenerative myofibers. Intramuscular implantation of cultured allogeneic myoblasts derived from pathogen-free muscle biopsies of genetically normal male volunteers demonstrated safety and efficacy in clinical studies of DMD, heart failure, ischemic cardiomyopathy, Type-II diabetes, cancer, and aging disfigurement.

The MTT invention relates to compositions and methods for preventing and treating mammalian disease conditions that are debilitating, fatal, hereditary, degenerative, and/or undesirable. More specifically, the MTT invention relates to the transplantation of normal, or genetically transduced, or cytokine-converted myogenic cells into malfunctioning, and/or degenerative tissues or organs.

Replenishing Dead Cells

With the immense wisdom and knowledge of human race, scientists have not been able to produce a living cell from nonliving ingredients such as DNA, RNA, ions, carbohydrate, fat, protein, and/or biomaterials. The testing and establishment of MTT concept involved development of two methods between 1975 and 1990: Cell Culture is the only method known to man for the replication of cells in vitro. With proper techniques and precautions, normal myoblasts can be cultured in significant quality and quantity to repair, and to replenish degenerated and damaged myofibers.

Cell transplantation bridges the gap between in vitro and in vivo systems, and allows propagation of "new life" in degenerative tissues or organs of the genetically defective or injured body. Cell transplantation techniques have been developed to ensure donor myoblast survival, development, and functioning. After transplantation, donor myoblasts fused among themselves to form multinucleated myotubes that developed into normal myofibers to replenish degenerated myofibers and lost function (Law 1994).

Repairing Hereditary Degenerative Cells

Cell fusion transfers the nucleus, thus all the normal genes within, like delivering a gene medicine chest to the abnormal myofiber. It is important to recognize that, for proper gene regulation and expression, the DNA software packaged in the chromosomes needs other cell organelles as hardware to operate, with spatial and temporal controls.

Correction of a gene defect occurs spontaneously at the cellular level after cell fusion. The natural integration, regulation, and expression of the full complement of over 30,000 normal genes impart the normal phenotypes onto the heterokaryon. Protein(s) or factor(s) that were not produced by the host genome because of the genetic defect are now produced by the normal genome. Cytokines and cofactors derived from expression of other genes at different time and space all corroborate to restore spontaneously the normal phenotype of the degenerating cell. The latter information is often unknown to the molecular geneticists, thus accounting for the limited success of molecular medicine. In MTT, genome of the donor myoblast operates naturally as usual, but in a multinucleated, heterokaryotic myotube mosaic with the normal and the abnormal nuclei. It is in such manipulated, genetically engineered environment that phenotype correction of gene defect occurs.

Engineering Genetic Mosaicism with MTT: Supply of Normal Genome via Injection of Myoblasts

Myofibers of DMD patients contain genetically dystrophic nuclei each of which lacks the normal dystrophin gene. In MTT, the injection trauma activates the muscle regenerative processes. Through natural cell fusion, donor myoblasts convey their normal nuclei that supply the complete human genome, carrying normal copies of the dystrophin gene into the regenerative myofibers or myotubes. The foreign

dystrophin gene corroborate with various cofactors to produce gene transcripts and the missing protein dystrophin, resulting in complementary genetic repair of the DMD myofiber phenotype (Law et al. 1990a, 1998).

"Gene therapy encompasses interventions that involve deliberate alteration of the genetic material of living cells to prevent or to treat diseases" (Kessler et al. 1993). This FDA definition placed MTT into the field of gene therapy. Genetic mosaicism describes the mixture of genetically normal and dystrophic nuclei coexisting in a myofiber or a myotube in the MTT treated host muscle. This type of myofibers is termed mosaic myofiber, being mosaic with normal and dystrophic nuclei. There is no gene editing. There is no hybridization at the chromosomal level. Every cell is a diploid and not tetraploid.

Genetic mosaicism also describes the mixture of genetically normal, dystrophic, and mosaic myofibers coexisting in the host muscle after MTT. The normal myofibers are newly formed from natural fusion of the donor myoblasts with each other.

Original Testing of Idea

Although the role of myoblasts/satellite cells in myogenesis and muscle regeneration dated back to the early 1960s (Konigsberg 1963; Mauro 1961), the use in animal therapy was not reported until 1978 (Law 1978). The original idea of MTT dated back to 1975, and experiments testing MTT were first published by Law in 1978 (Law 1978). A deliberate attempt was made in adult dystrophic mice to produce mosaic muscles containing normal, dystrophic, and mosaic myofibers from the regenerates of normal and dystrophic minced muscle mixes. The mince and mix procedures were designed to provide an environment for the intermingling and fusion of normal and dystrophic satellite cells. These muscle regenerates produced greater twitch and tetanus tensions and more normal appearing cell structure than control regenerates of minced dystrophic muscles. It was concluded that the introduction of cell contents of normal genotype into dystrophic muscles could improve the function of the latter (Law 1978). Additional proof-of-concept animal studies are described in the section "Pathogenesis: Cell Membrane Defect."

Pertinent Muscle Developmental Biology

Mammalian skeletal muscles are derived from the mesodermal germ layer in the embryo. In human, mesoderm first appears at 20 days after fertilization. Concomitant is the appearance of somite that increase in number with time. Within the somite are uncommitted mitotic precursor cells capable of giving rise to muscle, bone, cartilage, blood, lymphatics, and connective tissues. The commitment to being myogenic occurs early on since myoblasts, as these cells are called, are found in the limb buds at 26 days of gestation. Satellite cells which are myoblast reserves in adult

muscles contain actin-like filaments in their cytoplasm. Such lineage determination is influenced by embryonic induction and irreversible gene expression (Jacobson 1970).

Myogenesis

The developmental processes of myoblasts, myotubes, myofibers, and satellite cells, especially the genetically programming of cell fusion are products of 500 million years of vertebrate evolution. Lack of human fetal tissues for research had deemed myogenesis be studied in vitro. Beginning as small spheres of about 10–12 μm in diameter, myoblasts grow best on collagen attachment which resembles the extracellular matrix in vivo. Under proper cell culture condition, the transformation into spindle-shaped cells occurs within 3 days.

Myoblasts are characterized by their abilities to divide, migrate, align, and fuse to form multinucleated myotubes. Cell division is an intrinsic property of myoblasts as evident by myoblast proliferation in serum-free culture media. However, proliferation over one billion myoblasts from primary culture of 2 g of muscle biopsy requires growth factors. Myoblasts will continue to proliferate for as long as nutrients, adherent space, temperature, and pH are optimal. It is known that myoblasts do not fuse when they are in the S, G2, M, or even the early G1 phases of the cell cycle. Although it is not possible to study division synchronization in the human fetus, the myoblast doubling time in culture is 24–40 h, depending on the regenerative vigor of the satellite cells of the donor. Myoblasts reportedly could undergo 80 mitotic divisions. In our laboratory, myoblasts lost their ability to fuse after 50 generations of proliferation.

A built-in regenerative measure resides with the satellite cells that are basically myoblast reserves found in adult skeletal muscle fibers. These are mononucleated cells located between the basal lamina and the plasma membrane of myofibers. Satellite cells exhibit the same characteristics as myoblasts. Myotubes are formed from natural fusion of myoblasts. Each of them contains 200–500 nuclei, a uniquely large genomic store and manufacture plant for producing and depositing contractile filaments such as actin, myosin, myoglobin, and tropomyosin, and related molecules in an organized manner to form sarcomeres of myofibers. Myotubes can easily be identified by immunologically stained positively for heavy meromyosin. Equipped with these structural and biochemical bases of contraction, some myotubes can contract spontaneously in culture, and eventually pull from the collagen surface. Without neural induction or nerve innervation, the advance myotubes will undergo degeneration and die within 10 days. The myotubes will not develop into a myofiber unless innervated by a motor axon.

Myofibers are formed from developing myotubes when the contractile proteins are structured into filaments and packaged into basic contracting units called the sarcomeres. Hundreds of sarcomeres are aligned to form a myofibril many of which comprise a myofiber. Each sarcomere is made up of myosin and actin filaments linked together by cross-bridges.

Neuromuscular Transmission

With the arrival of the axonal terminal, an area of the myotube membrane which is adjacent to the axonal terminal becomes thickened and convoluted due to the formation of large amounts of acetylcholine receptors and ionic channels. The mature neuromuscular junction is a highly specialized relay station, transmitting the central command to generate contraction of the myofiber. Neuromuscular transmission is through the release of the neuromuscular transmitter acetylcholine which, upon combining with their postjunctional receptors, is metabolized by cholinesterase and produces significant membrane depolarization to generate excitation-contraction. These junctions stain positively for acetylcholinesterase.

Excitation Contraction Coupling

Postjunctional membrane depolarization of more than 40 mv will trigger an action potential to propagate the transverse tubular system, releasing Ca^{2+} from the sarcoplasmic reticulum, triggering millions of cross-bridges to be formed, sliding the actin filaments toward the center of each myosin filament, and results in force generation. Contraction and relaxation require Ca^{2+} and ATP.

Number of Myofibers and Strength

As the bones elongate during puberty, the passive stretch induces additional sarcomere production with subsequent increase in strength. Although the number of myofibers remains constant for individual muscles, the number of myofibrils within the myofiber can vary according to genetic and environmental differences. As more contractile proteins are deposited and the sarcoplasmic reticulum better developed, the centrally located nuclei migrate peripherally.

Numerous structural proteins and glycoproteins are synthesized and deposited during the transition from myotube to myofiber. Among these is dystrophin, a surface membrane protein which is not present in the myofibers of DMD (Hoffman et al. 1987) as a result of the gene defect (Monaco et al. 1986; Koenig et al. 1987).

Parameters Governing Cell Fusion

A condition called serum deprivation or a sudden reduction in serum concentration will precipitate cell fusion in culture. Cell fusion occurs only after the myoblasts have undergone considerable cycles of division and are withdrawn from the mitotic cycle (Banker et al. 1971). In the human fetus, myoblasts within a somite are

essentially replicating clones. Close confinement within the somite ensures that the myoblasts are always at a state of confluence. The latter is a prerequisite for cell fusion. The decision to fuse in vivo is genetically programmed, and fusion occurs without any neural contact or influence. It involves structural gene transcription and RNA synthesis, especially in the formation of the receptors on the myoblast surface that are responsible for cell recognition, cell adhesion, and membrane restructuring (Pearson and Epstein 1982; Davidson 1976). The end products are multinucleated myotubes each of which is formed from fusion of 200 or more myoblasts.

Controlled Cell Fusion

Through unknown mechanisms, the MHC class 1 surface antigens of myoblasts are very mildly expressed after cell fusion and the myotubes so formed exhibit minimal, if any, antigenicity. To foster donor cell survival and development, it would be useful to be able to control, initiate, or facilitate cell fusion once myoblasts are injected. This strategy was engineered to reduce the time of immunosuppression necessary for engraftment of allogeneic myoblasts.

As the myoblasts are injected intramuscularly, injection trauma causes the release of basic fibroblast growth factor (bFGF) and large chondroitin-6-sulfate proteoglycan (LC6SP). These latter growth factors stimulate myoblast proliferation. Unfortunately, they also stimulate the proliferation of fibroblasts that are already present in increased amount in the dystrophic muscle. That is why it is necessary to inject as pure as possible fractions of myoblasts in MTT without contaminating fibroblasts.

Controlled cell fusion can be achieved by artificially increasing the concentration of LC6SP over the endogenous level. LC6SP stimulates cell proliferation towards confluency, thus facilitates cell fusion. In addition, insulin or insulin-like growth factor I (IGF-1) facilitates the developmental process, resulting in the formation of myotubes soon after myoblast injection. Although the use of bFGF, LC6SP, and IGF-1 at optimal concentrations in the injection medium may lead to greater MTT success, inclusion of one or more of these factors would introduce immunologic complications.

Myoblasts fuse readily at low serum concentration in culture. At the end, it was an inventive step introduced exploiting serum deprivation that was found most effective. This involved exposing the myoblasts to 100% host serum as the last step in cell production, a step that provided enough nutrients to sustain cell survival and vigor before implantation. The carrier solution could consist of 100% host serum, or it could be supplemented with human albumin and injection saline when enough host serum was not available. Intramuscular injection of myoblasts dramatically reduced the serum concentration and exposed the myoblasts to intercellular fluid within the perimysium, a condition constituting serum deprivation. This controlled cell fusion procedure supported myoblast survival and development into myotubes in 7–10 days after MTT.

Mitotic Cardiomyocytes via In Vitro Controlled Cell Fusion

Whereas MTT results in the formation of genetic mosaicism with gene transfer occurring in vivo, the production of heterokaryons in vitro has immense medical application. This can be achieved by controlled cell fusion with myoblasts.

The original program of research relates to the in culture transfer of the normal nuclei carrying the regenerative genome from donor myoblasts into the genetically normal and/or abnormal cardiomyocytes. This development is especially important considering that cardiomyopathic symptoms develop in mid adolescence in about 10% of the DMD population. By age 18, all DMD individuals develop cardiomyopathy. Undoubtedly, the ability to replenish degenerated and degenerating cardiomyocytes will have immense impact on heart diseases even in the normal population where there is a great shortage of hearts for transplantation.

Normal cardiomyocytes exhibit very limited ability to proliferate in vivo or in vitro. The heart muscles damaged in heart attacks or in hereditary cardiomyopathy cannot repair themselves through regeneration. It is envisioned that the integration of mitosis, an extremely efficient characteristic of myoblasts, will enable the heterokaryotic cardiomyocytes to proliferate in vitro. Controlled cell fusion between normal myoblasts and normal cardiomyocytes may result in heterokaryons exhibiting the characteristics of both parental myogenic cell types. Clones can be selected based on their abilities to undergo mitosis in vitro, to develop desmosomes, gap junctions, and to contract strongly in synchrony after cell transplantation. These genetically superior cells can then be delivered through catheter pathways after mapping of the injured sites. With the ability to grow large quantity of these cardiomyocytes, the correction of structural, electrical, and contractile abnormalities in cardiomyopathy can be tested first in cardiomyopathic hamsters, ischemic porcine model, and if safe and effective, in humans.

Injection Methods Regulate Cell Distribution and Fusion

The biodistribution of donor myoblasts and the integration of donor nuclei through cell fusion are of supreme importance towards MTT success. Aside from donor cell survival in an immunologically hostile host, cell fusion is the key to strengthening dystrophic muscles with MTT. To improve the fusion rate between host and donor cells, various injection methods aimed at wide dissemination of donor myoblasts were tested and compared. The goal was to achieve maximum cell fusion with the least number of injections.

Methods of myoblast delivery included injecting perpendicular to the muscle fiber surface, parallel to myofibers, and diagonally traversing the myofibers. Myoblasts were infused slowly as the needle was withdrawn. Results indicated that myoblasts injected oblique to myofiber orientation were widely and evenly distributed. Myoblasts injected perpendicular to myofiber orientation were partially distributed. Myoblasts injected longitudinally through the core of the muscles and parallel to the myofibers were poorly distributed (Law et al. 1994a).

Cyclosporine Immunosuppression

When human myoblasts were transplanted into ischemic porcine ventricle, there was a transient elevation of porcine antihuman-myoblast antibodies at 1 week after the xenograft (Haider et al. 2004a, b). The antibody level subsided at the second week after MTT, indicating that no more than 2 weeks of cyclosporine immunosuppression would be necessary for human/pig xenografts or for human allografts. Because of the low antigenicity of allogeneic myoblasts, the only immunosuppressive agent used was cyclosporine, at a dose of 5–7 mg/kg body weight divided into two daily doses. The dosage was varied to maintain serum trough concentrations in the range 100–150 ng/ml. With the newly developed controlled cell fusion procedure, cyclosporine immunosuppression has been reduced from 3 months to 3 weeks, beginning at 3 days before MTT and weaning at half dosage at the beginning of the third week.

Muscular Dystrophy

Muscular dystrophy is a group of inherited diseases characterized by progressive degeneration of skeletal muscles. The word "dystrophy," implicating malnutrition, has been in use since the eighteenth century. At the dawn of Neurosciences in the early 1970s, McComas postulated the neural hypothesis of muscular dystrophy (McComas et al. 1971). Its basic concept was that motoneurons did not supply normal "trophic" substance(s) to maintain muscle fibers in a healthy state.

Etiology

Law and Atwood (1972a) had previously reported, within single mice, the slow contracting soleus muscle being cross-reinnervated by the nerve of the fast contracting flexor digitorum longus. Whereas physiological conversion of the slow muscle by the "fast" nerve was noted in all normal preparations, a similar conversion was noted in the soleus of only one of 10 dystrophic animals. The results were interpreted to mean that either some "neurotrophic" factors were absent in the nerves of dystrophic mice or that the dystrophic muscle was not capable of responding to existing "neurotrophic" factors.

In a continuation study, Law et al. reported parabiosis being established between pairs of dystrophic mice and normal littermates with a cross of the "fast" tibial nerve of one partner onto the slow soleus muscle of the other. This was a "double cross" preparation, such that each parabiont had a soleus muscle cross reinnervated by a tibial nerve of its partner. This unique preparation allowed the investigators (a) to monitor the "neurotrophic" influence of a "fast" nerve on a slow muscle, (b) to assess specifically the influence of the nerve on the expression of dystrophy (Law et al. 1976a), and (c) "myotrophic" influence on motoneurons (Law 1977).

Electrophysiological, cytochemical, and structural analyses indicated that the crossed "fast" nerves of normal or of dystrophic genotype were effective in altering

the cytochemical pattern of the slow muscles to fiber types' characteristic of fast muscles. However, normal nerves innervating solei of the dystrophic parabiont did not arrest the progress of the disease, and nerves of dystrophic genotype innervating muscles of the normal parabiont did not induce a pathological state. The results indicated that the peripheral motor nerves of dystrophic mice were normal in exerting "neurotrophic" influences and that muscular dystrophy progresses despite the presence of normal "neurotrophic" influences. This unique approach of a double nerve cross achieved through parabiosis provided strong evidence that the etiology of hereditary muscular dystrophy in this species was not nerve mediated. The results nullified the hypothesis that a "neurotrophic" deficiency was the primary manifestation of the defective gene in hereditary muscular dystrophy of mice. The findings that the dystrophic nervous system was normal in its ability to form synapses, to induce fiber type differentiation, to bring myofibers to maturity, and to maintain the structure and function of a normal muscle are significant, not only in terms of understanding of the etiology of muscular dystrophy, but also of developing transplant treatments (Law et al. 1976a). Without such knowledge, it would be imprudent to attempt strengthening dystrophic muscles with normal myogenic cell transfer.

Furthermore, a detrimental "myotrophic" influence was found to be exerted on motoneurons in dystrophic mice. Dystrophic solei reinnervated by nerves of normal genotype showed a 23% reduction in number (17 ± 2, mean ± SD) and a 50% reduction in size (78 ± 17 mg, mean ± SD) of motor units as compared to the normal solei reinnervated by nerves of dystrophic genotype (22 ± 1, 154 ± 38 mg, mean ± SD). The former preparations also showed abnormal endplates compared to the latter. These endplates were irregular in size and shape and often exhibited decreased acetylcholinesterase activity (Law 1977; Saito et al. 1983).

Pathogenesis: Cell Membrane Defect

The first direct evidence of membrane abnormality in mammalian dystrophy was reported in 1972 (Law and Atwood 1972b). Subthreshold direct stimulation elicited a smaller response from the dystrophic fiber than from the normal one, indicating that the dystrophic fiber was "leaky" to ionic currents. In a later study, about 55% of dystrophic myofibers examined were abnormal in their ability to generate action potentials. Some of these fibers showed no detectable response to supramaximal stimulation of the motor nerve, whereas in others, abortive spikes or localized end-plate potentials were recorded. The proportion of fibers showing very small or no electrical response increased when recordings were made away from the end-plate zone. The abortive spikes indicated a structural defect in the sarcolemma such that sodium conductance was diminished (Law et al. 1976b).

The abortive spikes did not propagate the whole length of the myofibers such that sarcomeres further away from the motor endplates would not receive depolarization to contract and would be "wasted." Dystrophic myofibers with abortive spikes generated localized contraction close to the endplates but the tensions developed were lower than normal. When given a normal resting potential, hyperpolarization to

−80 mV of fibers with abortive spikes could not cause the indirectly elicited abortive spikes to increase in amplitude. This indicated that the abortive spikes were the result of membrane "leakiness" rather than reduced membrane hyperpolarization. Furthermore, when these fibers were subjected to the passive stretch of the antagonistic muscle and the active pull of the localized contraction, breach in the plasma membrane (Law et al. 1983) occurred at the region of nonactivated sarcomeres.

With leakage of Ca^{2+} into the myofibers, there are mitochondrial Ca^{2+} overload and localized hypercontraction. Also, Ca^{2+}-activated neutral proteases and lysosomal activities are activated resulting in muscle necrosis. Some fibers showed positive acid phosphatase reaction in muscle nuclei, mitochondria, sarcoplasmic reticulum, and contractile myofilaments. Membrane defect was found not only in the sarcolemma but also in the sarcoplasmic reticulum and the nucleus. Eventually, the contractile elements are replaced with connective tissue (Law et al. 1983, 1990b).

To conclude, the dystrophic gene is transcribed into a structural protein abnormality which directly or indirectly results in membrane "leakiness." The establishment of an abnormal ionic equilibrium across the membrane especially that of Na^{+}, constitutes the earliest detectable pathophysiology in mediating weakness and necrosis of dystrophic myofibers (Law 1980). It was not until 1987 that dystrophin was identified as the structural protein defect in the sarcolemma of DMD myofibers.

Duchenne Muscular Dystrophy

Natural History

DMD manifests as a continuous muscle degeneration and loss of strength beginning at 1.5 years of age and lasting throughout life (Ziter et al. 1977; Brooke et al. 1983; Mendell et al. 1989; Fenichel et al. 1991). Growth outstrips the disease progress between ages 3 and 5, giving a false impression of remission; otherwise deterioration is continuous (Roelofs et al. 1979; Walton and Gardner-Medwin 1981). Degeneration is more severe in the proximal and anti-gravitational muscles than distal ones (Roelofs et al. 1979; Walton and Gardner-Medwin 1981) and proximal muscle weakness in the lower body is responsible for the Gowers' sign used in physical diagnosis.

Debilitating and fatal, DMD affects 1 in 3300 live male births (Emery 1991). DMD boys usually lose 50% of the strength in their leg muscles by age 9, and are wheelchair-bound by age 12. Three-quarters die before age 20. Pneumonia usually is the immediate cause of death, with underlying respiratory muscle degeneration, failure to inhale enough oxygen and to expel lung infection. Cardiomyopathic symptoms develop in mid-adolescence (Engel 1986) in about 10% of the DMD population. By age 18, all DMD individuals develop cardiomyopathy (Nigro et al. 1990), but cardiac failure is seldom the primary cause of death (Walton and Gardner-Medwin 1981).

Strategizing DMD Treatment

Human race is far from curing any genetic disease, not only from the practical standpoint but also conceptually how to convert the abnormal genome back to normal again. Perhaps the best alternative to sustain normal function was to engineer genetic mosaicism into muscles of the DMD boy as found in the X-linked carrier, the boy's mother. According to the Lyon hypothesis (Lyon 1961), random inactivation of one or the other X-chromosome can occur in any nucleus throughout the body of a Duchenne female carrier; individual myofibers would therefore contain mixtures of normal and dystrophic nuclei similar to the mosaic fibers produced by injecting normal myoblasts into dystrophic muscles (Law et al. 1990c). The mosaic myofibers exhibit normal phenotype, presumably due to metabolic or developmental complementation as a result of sharing the normal nuclei and therefore the normal genes. In addition, muscles of chimeric mice containing fibers of normal, dystrophic, and mosaic genotypes exhibit normal function (Law and Yap 1980; Peterson 1974).

It thus appeared that the logical and practical approach to reverse the expression of dystrophy in DMD muscles was to induce genetic mosaicism with the incorporation of the normal nuclei through MTT. Natural transduction with the normal nuclei ensured orderly replacement of dystrophin and related proteins at the cellular level in DMD. This ideal gene transfer procedure is unique to muscle. After all, only myoblasts could fuse and only myofibers were multinucleated in the human body. By harnessing these intrinsic properties, MTT transferred all normal genes to effect genetic repair, without the need to identify which gene was abnormal and which protein was missing (Law et al. 1990a).

Induction of Genetic Mosaicism

Normal and Dystrophic Minced Muscle Mixes

The foremost study in adult dystrophic mice was aimed at producing mosaic muscles containing normal, dystrophic, and mosaic myofibers from the normal and dystrophic minced muscle mixes (Law 1978). It focused on incorporating the "missing" gene and its product(s) into genetically defective cells through cell transplantation and natural cell fusion, the result of which is strengthened dystrophic muscles.

Newborn Muscle Transplant

In a later study, muscles of newborn normal mice were grafted into recipient soleus muscles of dystrophic mice. Results obtained 6 months after the grafting indicated that the grafts survived, developed, and functioned in the dystrophic environment. The regenerates had larger cross-sectional areas and more muscle fibers than the contralateral dystrophic solei. MTT increased the mean twitch tension of adult dystrophic muscles to that of the normal (Law and Yap 1979). The concept of replenishing lost cells and repairing degenerative cells through the production of genetic mosaicism using MTT was firmly established (Law and Yap 1979).

Mesenchymal Cell Transplant

MTT with myoblasts became the logical development since myoblasts do not require neuronal and capillary connections to survive and develop, and since myoblasts can fuse to effect genetic repair. A convenient way to obtain normal myoblasts in mice is through dissection of limb-bud mesenchyme of day-12 embryos. Dissected mesenchyme was surgically implanted into the solei of dy2Jdy2J mice. Host and donors were histocompatible. Contralateral solei served as controls. Six to seven months postoperatively, the myoblast-implanted solei exhibited greater cross-sectional area, total fiber number, better cell structure, and twitch and tetanus tensions than their contralateral controls (Law 1982).

MTT with Primary Myoblast Culture

In 1988, primary myoblast cultures from limb-bud explants of normal mouse embryos were injected into the soleus muscles of histocompatible dystrophic hosts (Law et al. 1988a). In addition, clones of normal myoblasts were injected into the leg and intercostal muscles of histoincompatible hosts, using cyclosporine-A (CsA) as a host immunosuppressant (Law et al. 1988b). Using glucose phosphate isomerases (GPI) as genotype markers, donor myoblasts were shown to have fused among themselves and developed into normal myofibers. They also fused with dystrophic host myogenic cells to form mosaic myofibers of normal phenotype (Law et al. 1988a, b, 1990b, c). These two mechanisms of genetic complementation were shown to be responsible for improvement in muscle genetics, structure, function, and animal behavior of the test dystrophic mice. Prolongation of the life spans of the myoblast-injected dystrophic mice was demonstrated (Law et al. 1988a, b, 1990b, c). The improvement persisted despite cyclosporine-A withdrawal.

With the discovery of the mdx mouse dystrophy model, and of the absence of the gene product dystrophin being the membrane defect of DMD (Hoffman et al. 1987), a new biochemical marker became available to demonstrate MTT efficacy (Partridge et al. 1989; Karpati et al. 1989; Chen et al. 1992). With implantation of cultured normal myoblasts into muscles of immunosuppressed mdx mice, MTT was shown to convert mdx myofibers from dystrophin-negative to dystrophin-positive (Partridge et al. 1989; Karpati et al. 1989; Chen et al. 1992). The study demonstrated biochemical improvements in the mdx mouse model, an additional evidence to confirm the efficacy of MTT.

MTT in DMD Subjects

All critical animal experimentation had been completed (Law et al. 1990b; Law 1990) when we began the MTT clinical trial. Phase I MTT began on February 15, 1990 (Law et al. 1990a) after approval from four institutional review boards. It was the first human gene therapy and the first somatic cell therapy clinical trial as reported by Hooper (1990). Cultured human myoblasts were used as vehicles to deliver the normal genome into DMD myofibers to repair genetic defects. As a cell therapy,

MTT was to replenish the degenerated myofibers also. The clinical trials were based on the safety and efficacy of MTT previously demonstrated in the dydy, $dy^{2J}dy^{2J}$, and mdx mice (Law 1978, 1982; Law et al. 1988a, b, 1990b, c; Law and Yap 1979; Partridge et al. 1989; Karpati et al. 1989; Chen et al. 1992).

A pioneering work (Anderson 1990, 1992, 1995; Beardsley 1990) has often been considered as the "first human gene therapy." Correction of the ADA deficiency study began on September 14, 1990 (Anderson 1990, 1992), 2 months after the MTT correction of the DMD gene defect was published (Law et al. 1990a).

Single Muscle Treatment (SMT): Phase I Trial

The randomized, double-blind study aimed to determine the survival, development, and functioning of donor myoblasts in dystrophic muscles of 11 DMD boys. We hypothesized that intramuscular injection of normal myoblasts could significantly improve the biochemistry, structure, and function of dystrophic muscles. Subjects and parents gave informed consents.

The safety and efficacy of MTT was assessed by injecting the left extensor digitorum brevis (EDB) muscle of a 9-year-old DMD boy with about 8×10^6 myoblasts. Donor myoblasts were cloned from satellite cells derived from a 1 g rectus femoris biopsy of the normal, adoptive father. Cyclosporine was administered for 3 months at a dose of 5–7 mg/kg body weight divided into two daily oral doses. Donor myoblasts survived, developed, and produced dystrophin in myofibers biopsied from the myoblast-injected EDB 92 days later. Dystrophin was not found in the contralateral sham-injected muscle. This first case, published in Lancet on July 14, 1990, suggested that MTT offered a safe and effective means for alleviating biochemical deficit(s) inherent in muscles of DMD (Law et al. 1990a).

Six years after the foremost MTT, dystrophin was found in the myoblast-injected muscle but not in the sham-injected muscle (Law et al. 1997a). Six years was the longest period through which any gene therapy had sustained positive results. Despite cyclosporine withdrawal at 3 months after MTT, myofibers expressing foreign dystrophin were not rejected. This was because dystrophin was present in the inner surface of the plasma membrane, and because mature myofibers did not exhibit MHC class 1 surface antigens. Not only had the result demonstrated MTT overall safety and efficacy in this single case, it also showed stability in the integration, regulation, and expression of the inserted dystrophin gene. The presence of dystrophin in the myoblast-injected but not in the sham-injected muscle provided unequivocal evidence of the survival and development of donor myoblasts in the myoblast-injected muscle.

SMT Safety

At no time during the 92 days after myoblast injection of the 11 subjects were there any sign of erythema, swelling, or tenderness at the injection sites. Serial laboratory evaluation, including electrolytes, creatinine, and urea, did not reveal any significant changes before or after MTT. There was no clinical evidence of an adverse reaction to MTT or to Cy (Law et al. 1990a).

SMT Efficacy

Myoblast-injected EDBs showed increases in maximal contractile force whereas sham-injected EDBs showed reductions (Law et al. 1991a, b, c). Both immunocytochemical staining and immunoblot revealed dystrophin in the myoblast-injected EDBs. Dystrophic characteristics such as fiber splitting, central nucleation, phagocytic necrosis, variation in fiber shape and size, and infiltration of fat and connective tissues were less frequently observed in these muscles (Law et al. 1991a, b, c).

SMT Significance

The first MTT on a DMD boy on Feb. 15, 1990 (Law et al. 1990a) marked the first clinical trial on human gene therapy (Hooper 1990). Its success was reported (Law et al. 1990a; Kolata 1990). MTT inserted, through natural cell fusion, all the normal genes within the nuclei of the donor myoblasts into the dystrophic myofibers to repair them. In addition, donor myoblasts also fused among themselves, forming genetically normal myofibers to replenish degenerated ones. Thus, full complements of normal genes were integrated, through a natural developmental process of regeneration, into the abnormal cells and into the abnormal organ to effect genetic cell therapy.

The US Patent Office issued to Law a pioneering patent (U.S. Pat. No. 5,130,141) entitled "Composition for and methods of treating muscle degeneration and weakness" on July 14, 1992.

In October 1993, the FDA officially began regulating SCT with a definition of "autologous, allogenic, or xenogeneic cells that have been propagated, expanded, selected, pharmacologically treated, or otherwise altered in biological characteristics ex vivo to be administered to humans and applicable to the prevention, treatment, cure, diagnosis, or mitigation of disease or injuries" (Federal Registrar 1993). MTT fell under the umbrella of SCT and myoblasts and its physical, genetic, or chemical derivatives became potential biologics in the treatment of mammalian diseases.

On May 25, 1994, FDA granted permission for Cell Therapy Research Foundation (CTRF) to charge $63,806 per subject. CTRF was a nonprofit 501 (c) (3) research foundation founded in 1991 by Peter K. Law, the MTT inventor. Authorization by the FDA for CTRF to recover costs from subjects of these clinical trials was extremely important to establish the scientific credibility MTT and CTRF deserved, quoting FDA spokesman Monica Revelle, "Permission to bill for an Investigational product is granted rarely," "Applicants must endure numerous procedures, and must have what looks like a viable product at the end of the rainbow. It's used mainly to support testing of promising technology by small companies." (Shepard 1994).

At the time CTRF held the first and only FDAapproved human clinical trial under an Investigational New Drug (IND) application on MTT. It is extremely important to realize that CTRF had been working closely with the FDA to establish criteria and policies in the approval process of this IND for genetic cell therapy. The use of viral vector mediated gene therapy on human neuromuscular diseases had not met FDA approval.

Lower Body Treatment (LBT): Phase II Trial

This was the first attempt to improve the locomotive ability and thus the quality of life of DMD patients using MTT. The LBT protocol received approval from the Essex Institutional Review Board Inc. in Lebanon, NJ, and from the Patient Participation Committee of the Baptist Memorial Hospital Medical Center in Memphis, TN. Both were in compliant with the regulations of the FDA. The SMT and the LBT studies had long begun before the FDA established policies and regulations for cell/gene therapies in October 1993. Whereas the patient families were in great support of CTRF and MTT according to Dr. Thomas E. Furlong's letter in Science (Law 1992), the Muscular Dystrophy Association Inc. (MDA) was attempting to derail CTRF's MTT program through its association with the Appropriation Committee Chairman of the US Congress acting on NIH and FDA (Law 1992, 1993).

The feasibility, safety, and efficacy MTT were assessed in an experimental lower body treatment (LBT) involving 32 DMD boys aged 6–14 years, half of whom were nonambulatory. Through 48 injections, five billion (at concentration of 55.6×10^6/mL) normal myoblasts were transferred into 22 major muscles in both lower limbs, in 10 min with the subject under general anesthesia (Law et al. 1992). Ten subjects received myoblasts cultured from satellite cells derived from 1-g fresh muscle biopsies of normal males aged 9–21 years. Donor myoblasts for the remaining 22 boys were subcultured from reserves frozen 1 month to 1.5 years ago. Only four donors were known to have identical histocompatibility with their recipients. All subjects took oral doses of the immunosuppressant cyclosporine, beginning at 2 days before MTT and lasting for 6 months after MTT to facilitate donor cell survival.

There was no evidence of an adverse reaction to MTT or cyclosporine as determined by serial laboratory evaluations including electrolytes, creatinine, and urea. This was the first study, using conservative and objective quantitative analyses, to have produced a statistically significant 50% increase in strength in 36% of 180 muscle groups in 31 DMD boys, despite a 9-month period of dystrophy progression. In addition, 25% of the muscle groups were as strong as they were 9 months ago.

Objective functional tests using the KinCom Robotic Dynamometer measured the maximum isometric contractile forces of the ankle plantar flexors (AF), knee flexors (KF), and knee extensors (KE) before MTT and at 3, 6, and 9 months after MTT. The AF, being distal muscles and less degenerative than the KE and the KF, showed no decrease in mean contractile force 3 months after MTT, and progressive increases in force at 6 and 9 months after MTT. At 9 months after MTT, 60% of the 60 AF examined showed a mean increase of 50% in force; 28% showed no change; and only 12% showed a mean decrease in force of 29% when compared to the function of the same muscles before MTT. The KF, being proximal muscles and more degenerative, showed no change in function at 9 months after MTT. The KE, being proximal and anti-gravitational, were most degenerative before MTT. They showed no statistically significant change in force at three months after MTT but showed decreases at 6 and 9 months after MTT. At 9 months after MTT, 23% of the 60 KE

examined showed a mean increase of 65% in force; 22% showed no change; and 55% showed a mean decrease of 24% in force. When results of all muscle groups (AF, KF, KE) were pooled, there was no change in force at 3, 6, or 9 months after MTT versus before MTT according to the Wilcoxon signed rank test. The ambulatory subjects showed more muscle improvement than the nonambulatory ones at various times after MTT. Statistically significant progressive increase in force in the AF and arrest of weakening in the KF and KE were observed in the ambulatory subjects as early as 3 months and continued up to 9 months after MTT.

The results indicated that (1) MTT was safe; (2) MTT improved muscle function in DMD: 88% of the AF, 49% of the KF, and 45% of the KE showed either increase in strength or did not show continuous loss of strength 9 months after MTT; (3) LBT significantly strengthened the lower bodies in one-third of the 32 DMD boys, improving their locomotive ability and quality of life. The behavioral improvement subsided for insufficient dosage of myoblasts and continual upper body weakening; (4) the dosage used was more effective in the AF than in the KF, and was least effective in the KE; (5) more than five billion myoblasts were necessary to strengthen both lower limbs of a DMD boy between 6 and 14 years of age; (6) the more degenerated proximal muscles would need more myoblasts per unit muscle volume than the distal muscles for MTT to be effective; (7) MTT was more effective in the younger, ambulatory subjects than in the older, nonambulatory subjects; (8) cyclosporine was not responsible for the functional improvement, since muscle function continued to improve 9 months after MTT despite cyclosporine withdrawal at 6 months after MTT; (9) cyclosporine immunosuppression permits donor cell survival and development, without overt rejection symptoms, when properly managed; (10) myoblasts from frozen reserves were as effective as those from fresh muscle biopsies; (11) fifteen billion myoblasts could be cultured from a 1-g muscle biopsy; and (12) billions of cultured myoblasts could be injected into subjects without tumor formation (Law et al. 1992).

Whole Body Treatment (WBT): Phase II and III Trials

Rationale

One of the conclusions of the LBT study was that the dosage used was more effective in the distal muscles than in the proximal muscles. MTT might be more effective in the more degenerative proximal muscles if the number of myoblasts per unit muscle volume was increased. Furthermore, the LBT study indicated that more than five billion myoblasts were necessary to strengthen both lower limbs of a DMD boy between 6 and 14 years of age (Law et al. 1992).

Whereas some of the subjects showed muscle strengthening in both distal and proximal muscles of their lower limbs, their upper body muscles continued to degenerate, with drastic loss of function and balance. The latter prompted us to initiate the administration of myoblasts to muscles in the upper bodies of DMD subjects, and, if safe, to further readminister myoblasts to muscles in their lower bodies.

Dose Escalation

The first administration of eight million myoblasts, starting in February 1990, into a small foot muscle of 11 subjects did not generate any graft-versus-host reaction. The second administration of five billion myoblasts into the lower body of 32 subjects, which represented a dose increase of 625 folds, again did not produce any adverse effect. The last dose was increased 2.5 times, to 12.5 billion myoblasts injected into the upper body. If this dose was found to be safe within 2–3 months after this upper body treatment (UBT), it would be further assessed for accumulative safety by readministering an additional 12.5 billion myoblasts to muscles of the lower body. Thus, this WBT protocol examined a maximum dose of 25 billion myoblasts to be widely distributed in the whole body of each DMD subject (Law et al. 1993).

Objective

The objective of this project was to determine the safety and efficacy of injecting 25 billion cultured myoblasts into 64 large dystrophic muscles of DMD boys over a 9-month period. The study tested (1) whether widely distributed multiple intramuscular injections with large numbers of cells delivered on two separate occasions all over the body were safe; (2) whether MTT was effective in improving, or halting the deterioration of, muscle function in biceps brachii, triceps, knee extensors, and ankle plantar flexors; (3) whether MTT was effective in improving, or halting the deterioration of, muscle structure in the biceps brachii and quadriceps; (4) whether MTT would induce production of dystrophin in the myoblast-injected biceps brachii and quadriceps; and (5) whether MTT in the upper body would improve pulmonary function.

The goal of this WBT clinical trial was to determine whether MTT could be a safe and effective treatment program against muscular weakness in DMD. If MTT was effective, strengthening the arm muscles would improve motor control; strengthening the back musculature would improve balance; strengthening the lower limb muscles would improve locomotor ability; and strengthening the accessory respiratory muscles would improve pulmonary function and prevent premature death.

Study Design

Thirty-two DMD boys, aged 6–16 each underwent two procedures of MTT: an UBT in which 28 muscles were injected with 12.5 billion myoblasts, and a LBT in which an additional 12.5 billion myoblasts were injected in another 36 muscles (Law et al. 1993). Subjects were selected into two equal groups, ambulatory and non-ambulatory. Half of each group was randomized to receive early UBT or LBT treatment. The late treatment group served as control for the early treatment group. Subjects receiving early UBT received sham injections in one randomly selected biceps brachii; subjects receiving early LBT received sham injections in one randomly selected quadriceps. The contralateral biceps or quadriceps's were myoblast injected. In addition, each boy received injections in major muscle groups of the neck, back, upper limbs, shoulders, abdomen, and lower limbs bilaterally. The immunosuppressant cyclosporine was administered from 5 days before until 3 months after each MTT.

At 3 months and at 3 days before each MTT, and at 3, 6, and 9 months after each MTT, the maximum voluntary contractions of the biceps brachii, triceps, quadriceps, and ankle plantar flexors were measured with Kin-Com dynamometry. Muscles of MTT-2 were examined at 12, 9, and 6 months before MTT to determine the progression of the disease. Pre-MTT data yielded natural history controls. Comparison of the myoblast-injected versus the placebo muscles would determine if MTT was beneficial.

At 9 months after MTT-1, biopsies were obtained from the biceps or quadriceps. The presence of dystrophin in immunocytochemical and Western immunoblot assays substantiated graft survival and biochemical improvement. Reduction of dystrophic characteristics such as central nucleation, fiber splitting, phagocytic necrosis, and infiltration of fat and connective tissues were indicative of structural improvement. Correlation of biochemical, structural, and functional data would determine the efficacy of MTT, if any. Absence of adverse reactions would substantiate MTT safety.

UBT/LBT Randomization

Sixteen ambulatory subjects were randomly assigned to receive either early UBT treatment or early LBT treatment, with the constraint that an equal number of subjects (8) be assigned to each group. Similar randomization for the 16 non-ambulatory subjects was also be instituted.

Myoblast/Placebo Randomization

The randomization design (Law et al. 1995) also included a randomized, double-blind study of one muscle in MTT-1. Subjects assigned to early UBT had one biceps brachii selected for myoblast injections with the contralateral biceps brachii receiving sham injections. Subjects receiving early LBT had one quadriceps selected for myoblast injections with the contralateral quadriceps receiving sham injections. Within each of these two treatment groups, equal numbers of subjects received myoblast injections on the right side and sham injections on the left side, and vice versa.

The biceps brachii were solely responsible for flexion of the forearm; the quadriceps were solely responsible for extension of the leg. As proximal muscles, they were more involved in the degenerative process of dystrophy than distal muscles. The randomization code was applied by an in-house person as subjects were entered into the study. He advised the administering surgeon of the designation of the MTT and placebo arms/legs. These two individuals were the only ones who knew which side was injected with myoblasts and which side was injected with saline. Neither the patient, nor his family and personnel evaluating MTT efficacy were made aware of which arm/leg received myoblasts and/or which arm/leg served as control. The surgical suite was configured so that those outside the suite could not see the injections.

Donors

The donors were male volunteers, in good general health, and between the ages of 8 and 22 (Law et al. 1995). They were certified by physicians as being in good health, not having a CK level of more than twice the upper limit of normal, and testing

negative for human immunodeficiency virus (HIV), hepatitis B surface antigen (HBSAg), hepatitis C (HCV), syphilis (RPR), and cytomegalovirus (CMV). Donors would be excluded if they had any chronic, infectious diseases or were allergic to the local anesthetic. Conformity to the selection criteria were documented by the clinical monitor. Informed consents were obtained from the donors or from the parents of minors after thorough discussion of the procedures and risks.

Myoblast Preparation

Two months before MTT, the donor came to the hospital outpatient clinic to donate muscle biopsy. Three days before each biopsy, a 22 gauge spinal needle (2 inches long) were inserted momentarily without injection several times into the future biopsy site (about 1 inch diameter) of the rectus femoris muscle of the donor to induce satellite cell proliferation. These needle insertions, done under local anesthetic using lidocaine, were completed in about 30 s and would cause short-term (< 5 min) pain. The area would bruise for a few hours. Three days later, under local anesthesia and in a sterile field, about 2 g of muscle were surgically removed from the site of injury using an open biopsy technique (Law et al. 1995). The biopsied muscle was immediately dissociated. Complete dissociation of 2 g of fresh skeletal muscle occurred after 45 min of stirring with three changes of collagenase solution, alternated with three changes of neutralizing medium. Cells were then placed in fresh growth medium. Myoblasts were fed with fresh growth medium every 2 days and incubated in 7% CO_2 at 37 °C as previously described.

Myoblasts were harvested for injection when they filled 250 roller bottles, each containing about 50 million myoblasts on a 900 cm^2 surface as determined with a hemocytometer. Representative samples of myoblasts were tested for their ability to divide, fuse, and form myotubes and immature myofibers that could contract spontaneously in vitro. Donor myoblasts were detached from each bottle with trypsin solution. An equal volume of neutralizing medium was then added to stop the action of trypsin after 5 min of incubation. Cell suspension from 250 roller bottles was pooled for each harvest. Myoblasts were centrifuged, rinsed three times, and resuspended in 312.5 ml of a solution containing 5% host serum in injection saline (Sigma). The procedure of harvesting was timed in each case to relay immediately to the procedure of myoblast transfer itself. The culture procedure took about 6 weeks to obtain the 25 billion myoblasts from a 2 g muscle biopsy. It took ten workers 4 h to complete harvesting 250 roller bottles of myoblasts under five laminar flow sterile hoods (Law et al. 1995).

The 25 Billion Myoblast WBT Protocol

Under FDA purview, 1 infantile facioscapulohumeral dystrophy and 40 DMD boys aged 6–16 received WBT in 36 months with no adverse reaction. Subjects took oral cyclosporine for 3 months after each MTT. Nine months after MTT immunocytochemical evidence of dystrophin were demonstrated in 18 of the 20 DMD subjects biopsied. Dystrophin positive sections showed less dystrophic characteristics than dystrophin-negative ones. Forced vital capacity increased by 33.3% and maximum voluntary ventilation increased by 28% at 12 months after UBT (Law et al. 1994b, 1995, 1996, 1997b, c, d, 1998, 65).

Plantar flexion showed an increase of 45% in maximum isometric contraction force in 12 months in the DMD subjects when compared to the natural deterioration. Behavioral improvements in running, balancing, climbing stairs, and playing ball were noted (Law et al. 1994b, 1995, 1996, 1997b, c, d). Notable was a 16-year-old DMD subject who continued to walk without assistance and capable of driving an automobile by himself.

The 50 Billion Myoblast WBT Protocol

The most effective design involved a one-time injection of fifty billion myoblasts into 80–82 muscles with 179 skin punctures, approved by the FDA for subjects with DMD, Becker MD, and limb-girdle MD (Law et al. 1997a, b, c, 1998). Over 200 subjects who underwent this protocol had experienced no serious or permanent adverse reaction. None of the subjects died within 2 years after MTT. The demonstrated efficacy included:

- Correction of gene defect with dystrophin production induced by MTT.
- 70% more myofibers and histological improvement at 9 months after MTT.
- 123% increase in maximal contractile force at 18 months after MTT.
- 39% decrease in serum CPK at 12 months after MTT.
- 19% increase in forced vital capacity at 9 months after MTT.
- Clinical improvement in 75% of all subjects participated.
- Life prolongation up to 45 years of age with many subjects in their 30s.

WBT Significance

During Phase II and Phase III clinical trials from 1994 to 1999, FDA allowed CTRF charging up to USD150,000 per MTT procedure after annual review of progress. On October 16, 1998, FDA designated CTRF's MTT program on Fast Track, once again confirming its safety and efficacy. The charge allowed by the FDA was often paid by governments or health agencies of the USA, Russia, West Germany, Hungary, Brazil, Mexico, and Korea for their citizens.

According to the late Leon Charash, former Director of the Medical Committee of MDA, it was jealousy, greed, and insecurity that drove the MDA to eventually derail the CTRF's MTT programs (Law 2017).

Heart Muscle Degeneration

Heart muscle degeneration is the leading cause of debilitation and death in humans. Atherosclerosis, ischemic cardiomyopathy, and heart failure are genetic predisposed (Beutner et al. 2011). These are multifactorial and polygenic diseases with significant polymorphism. It will be an insurmountable task to identify the various gene defects and to design molecular gene therapies toward treatment, not to mention that such designs do not replenish myocardial cells that had degenerated previously, without which the damaged myocardium cannot regain its function.

The primary cause of ischemic cardiomyopathy is partial or complete obliteration of the coronary artery, often precipitating in acute myocardial infarction (MI). Long-term ischemia leads to ventricular cell death and myocardial necrosis. Although medication, trans-myocardial revascularization (TMR), and coronary artery bypass grafting (CABG) can increase local blood supply and reduce short-term mortality and morbidity, most patients continue suffering decreased ventricular function and chronic heart failure.

Severe Myocardial Infarction

Severe myocardial infarction conveys serious complications such as ventricular aneurysm, wall thinning, and rupture with fatal consequences. Prognosis for these severe heart failure patients is 3–6 months of life despite CABG. Heart transplantation has been the gold standard for patients with end-stage heart failure, but donor heart nonavailability and lifelong immunosuppression dictate its limited usage. It is urgent to explore new therapeutic measures to increase the quality of life and life span of these patients.

Chronic ischemia after AMI causes loss of cardiomyocytes, contractile filaments, and ventricular contractility. Regeneration attempt by surviving cardiomyocytes consists of undergoing at most four mitotic divisions because the telomeric DNA repeats (Ishikawa et al. 1993) in these terminally differentiated cells are minimal. Such attempt cannot regenerate enough cardiomyocytes to produce the necessary quantity of contractile filaments such as myosin, actin, troponin, and tropomyosin to sustain normal heart contractility. The degenerative heart also transmits biochemical signals to recruit stem cells from the stroma and from the bone marrow to repair the muscle damage. Due to the significant increase in fibroblast growth factor release after infarction, much of the recruited stem cells differentiate to become fibroblasts instead of cardiomyocytes, forming scars and not contractile filaments.

The damaged myocardium needs replenishment of live, genetically normal, myogenic cells to deposit contractile filaments to regain heart function, preferably before fibroblast infiltration. This is when allogeneic myoblast transplantation (AMT), formerly known also as MTT or heart cell therapy, has an advantage over all other cell types (Law et al. 2004a, b). Considering dystrophic and diabetic cardiomyopathies as hereditary, and ischemic cardiomyopathy as genetically predisposed, AMT was designed to genetically repair hereditary degenerative cells and to replenish degenerated cells with live ones.

Proof-of-Concept for AMT

Myoblasts are differentiated cells destined to become muscles. Unlike cardiomyocytes, myoblasts possess long telomere DNA subunits and can undergo 50 mitotic divisions without loss of myogenic capacity (Law et al. 2004a, b) or developing into tumor (Di Donna et al. 2003). The transition from animal

experimentation (Koh et al. 1993; Taylor et al. 1998) into cardiac clinical trials was largely based on previous demonstration of significant safety and efficacy in the treatment of Duchenne muscular dystrophy in FDA approved Phase II and Phase III clinical trials using allogeneic myoblast allografts (Law 2004; Law et al. 1998, 2019).

Law et al. reported the pioneering study of implanting human myoblasts into the porcine hearts with endovascular catheter of the NOGA system (Law et al. 2000). The mechanisms by which allogeneic human myoblasts survived, developed, and functioned with the use of cyclosporine immunosuppression were examined through open chest endomyocardial injections of cultured skeletal myoblasts into infarcted porcine myocardium. Three mechanisms were elucidated as proof-of-concept using genetic markers to label the nuclei of the donor myoblasts (Law et al. 1992, 2004a, b). Under the influence of hormones and slow contractile activity of the heart, donor myoblasts fused among themselves to form new cardiomyocytes, depositing contractile filaments to improve heart contractility. Others fused with the host cardiomyocytes through natural cell fusion, spontaneously transferring their nuclei into host cardiomyocytes to impart myogenic regeneration. Still others fused to form myotubes that eventually developed into immature skeletal myofibers containing satellite cells. New production of contractile filaments augmented heart contractility (Law et al. 1992, 2004a, b).

AMT Is Safe and Efficacious with MI Patients

In 2004, Law et al. reported the world's first two cases of using allogeneic myoblast transplantation (AMT), cyclosporine immunosuppression, and CABG for MI (Law et al. 2004b, 2006). Results demonstrated that the left ventricular ejection fraction (LVEF), viability, motility, myocardial perfusion, and ventricular wall thickness were significantly improved. The end-diastolic and end-systolic blood volumes were increased without significant arrhythmia. At 12 months after implantation, LVEF was increased by about 40%, and perfusion capacity increased by 38% (Law et al. 2004b, 2006).

More than 300 cases of autologous myoblast transplantation internationally have showed that it was safe and efficacious in treating ischemic cardiomyopathies and heart failure. Approximately 200 cases were injected after thoracotomy and 100 cases were injected with endovascular catheters (Law et al. 2006, 2019). Further advance with myoblast clinical trials had been distracted for 17 years by Piero Anversa's misconduct in cardiac stem cell research in Harvard University until 10/14/2018.

AMT Is Safe and Efficacious with End-Stage HF Subjects

Recently, AMT, cyclosporine immunosuppression, and CABG were used to treat end-stage HF subjects without hope of obtaining a heart transplant (Li et al. 2021). It was demonstrated to have sustained the life spans to 2 years postoperatively on ten

end-stage HF patients having 2.21-mm mean thinnest wall thickness and ventricular aneurysms, with significant improvement in LVEF, NYHA cardiac function, viability, and quality of life.

Regulatory

This study was approved by the Ethics Committee of the Third Affiliated Hospital of Xinxiang Medical College to obtain preliminary safety and efficacy information to justify future clinical trials of AMT. This study was registered in the Chinese Clinical Trial Registry numbered **ChiCTR2000039590**.

Case Selection

A total of ten heart failure subjects suffering severe MI with ventricular aneurysm in the Cardiothoracic Surgery Department of the Third Affiliated Hospital of Xinxiang Medical College from February 2016 to March 2018 were selected. Subject profiles are shown in Table 1.

Table 1 General information of subjects. (Reproduced with permission from Li et al. *Open Journal of Regenerative Medicine* 2021; 10: 1–18. © Scientific Research Publishing)

	Gender	Age	Combined disease	Infarct area	Abnormal movement (Y/N)	Bypass vessels

Zhang	M	64	Hypertension, history of cerebral, hemorrhage, and diabetes	Anterior wall near apex	Y	LAD, LCX

Patient Selection

After meeting Inclusion/Exclusion criteria and signing Patient Informed Consents, ten HF subjects having mean thinnest wall thickness of 2.21 ± 0.55 mm and ventricular aneurysms were admitted under intensive care. Each subject took daily cyclosporine for 3 weeks. On the third day of cyclosporine administration, approximately one billion myoblasts were implanted through 20 injections into the infarcted myocardium following CABG.

Manufacture of Allogeneic Human Myoblasts

Donors. Upon approval of the Institutional Review Board (IRB) of the Cell Therapy Institute and the signing of the Donor Informed Consents, muscle donors were admitted after meeting the Inclusion and Exclusion criteria. They were male volunteers between the ages of 16 and 36. They were certified by a physician as being in good health, having normal levels of aspartate aminotransferase (AST), alanine transaminase (ALT), lactate dehydrogenase (LD), and tested negative for human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), syphilis (RPR), and cytomegalovirus (CMV). They also received the following tests: Chem 24, CBC, and physical examination with normal results. Donors were excluded if they had any chronic or infectious diseases, and if were allergic to the local anesthetic lidocaine.

Muscle Biopsy. About 2 g of muscle were removed from the quadriceps muscle using an open biopsy technique under local anesthetic (lidocaine patch) in a sterile field of a surgical suite of a hospital. The donor site was sutured and bandaged. No prophylactic antibiotic was used. The donor was discharged after recovery from the surgical procedure to be followed by his physician if infection occurred.

Preparation of Myoblasts. Biopsy specimen obtained was processed immediately using sterile techniques meeting CFDA approved GMP standards. Myoblasts were cultured in growth medium and incubated at 37 °C and in 7% CO_2 as previously described (Law et al. 1992; Law 1995). Myoblasts were frozen at different stages so the time allotted for culturing could be coordinated with a scheduled transplant. The number of frozen cells and the number of samples were documented. One test vial was reserved in liquid nitrogen for each biopsy. Random samples of the myoblasts were tested for their ability to divide, fuse, and form myotubes (Law et al. 1992). Lot release testing consisted of sterility, endotoxin, mycoplasma, and testing for myoblast identity, purity, potency, viability, and cell count on a pooled sample prior to transplant meeting quality control standards (Law et al. 1992, 2008; Law 1995). A retain sample of myoblasts was reserved from each transplant.

Cyclosporine Immunosuppression

Each subject took daily oral doses of 5 mg/kg body weight of cyclosporine for 3 weeks with weaning using half doses after the second week to suppress rejection of the allografts. Since myoblast fusion completed within 1 week after transplantation (Law et al. 1994a; Haider et al. 2004c), and since myotubes and mature myofibers did not express MHC class 1 surface antigens (Law 1994; Law et al. 1994a), it was not necessary to administer lifelong immunosuppression as in heart transplants (Law et al. 2019). Clinical evaluation was performed using a self-contrast method.

Clinical Research Procedures

All patients were given CABG and conventional medication for symptomatic control of blood pressure, blood lipid, blood glucose, anticoagulation, coronary expansion, cardiac strengthening, and diuretics. Traditional aneurysm resection was not used in this study.

AMT

AMT was performed following distal anastomosis of the coronary artery bypass surgery on the third day of cyclosporine administration. Approximately 1 billion myoblasts (at 10^8 cells /mL) were injected with 20 injections placed 1 cm apart along the inside border of the infarction. For each injection, about 50 million myoblasts were carefully deposited in a centripetal diagonal track (< 5 mm) as the needle was slowly withdrawn out of the inner border of the infarcted myocardium.

Data Analysis and Interpretation

Statistical Analyses

Data were analyzed with one-way analysis of variance (ANOVA) using SPSS19.0 software. $P < 0.05$ indicated significant statistical differences.

Safety Assessment

Adverse Reaction Assessment

All ten subjects successfully underwent treatment without malignant arrhythmia, chills, fever, allergic reactions, vomiting, viral infection, or other adverse reactions. Throughout the course of the entire study, two subjects exhibited early postoperative occasional ventricular premature beats. Another two subjects demonstrated atrial premature beats. Considered related to electrolyte disorders and myocardial damage of the primary disease, they were converted to sinus after symptomatic treatment. No malignant arrhythmia and no deaths occurred, and there was no virus infection after treatment. There were no statistically significant differences between the means (±SD) in the leukocyte count, neutrophil count, hemoglobin, red blood cell count, and platelet count before versus at 6 months, and at 2 years after treatment ($P > 0.05$) (Table 2).

Ca^{2+}	2.17 ± 0.09	2.29 ± 0.10	2.26 ± 0.13	0.075

There was no statistically significant difference between the mean levels (± SD) of total bilirubin, albumin, alanine aminotransferase, and aspartate aminotransferase before versus at 6 months, and at 2 years after treatment ($P > 0.05$) (Table 3). There was no statistically significant difference between the mean levels (± SD) of serum creatinine or urea nitrogen before versus at 6 months, and at 2 years after treatment ($P > 0.05$) (Table 4). There was no statistically significant difference in the mean levels (±SD) of serum K^+, Na^+, Cl^-, and Ca^{2+} before treatment versus at 6 months and at 2 years after treatment ($P > 0.05$) (Table 5). There was no statistically significant difference in the mean levels (± SD) of prothrombin time, fibrinogen, and partial prothrombin time before versus after treatment ($P > 0.05$) (Table 6).

Efficacy Assessment

Objective Evaluation

Cardiac ECT demonstrated significant improvement in myocardial perfusion and in viability of ventricular myocardium at 6 months and at 2 years after surgery (Fig. 1). The mean LVEFs were increased by 20.1% at 6 months after treatment, and by 19.3% at 2 years after treatment as compared to the control mean before treatment.

	Preoperative	6 months postoperative	2 years postoperative	P
Prothrombin time(s)	13.18 ± 0.50	13.30 ± 0.54	4.01 ± 0.35	0.951
Fibrinogen (g/L)	3.13 ± 0.17	3.26 ± 0.17	2.88 ± 0.20	0.341
Activated partial Thromboplastin time(s)	29.55 ± 1.13	30.94 ± 0.98	32.63 ± 1.22	0.169

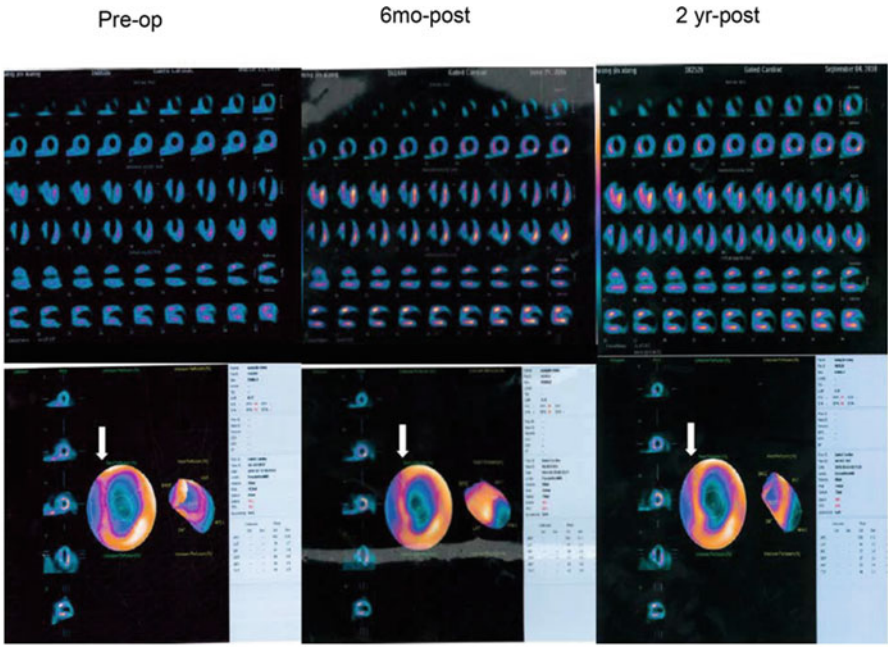

Fig. 1 Representative ECT indicated significant increase in viability (Arrow) of ventricular myocardium at 6 months and at 2 years after surgery. (Reproduced with permission from Li et al. *Open Journal of Regenerative Medicine* 2021; 10: 1–18. © Scientific Research Publishing)

These mean increases were of statistical significance at $P < 0.05$ (Figs. 1 and 2a; Table 7). There was no significant difference (Table 7) in the mean levels (±SD) of LVDd (Fig. 2b) and CO (Fig. 2c) before versus after treatment ($P > 0.05$). Although the mean difference in CO before versus after treatment was of statistical insignificance, the postoperative means were all higher than before treatment. Consistently, the mean postoperative lengths of LVDd were lower than that before treatment. MR imaging showed no significant difference in the mean levels (±SD) of ventricular aneurysm area and wall thickness before versus after treatment ($P > 0.05$) (Table 8) though individual variations did demonstrate significant increases in wall thickness (Fig. 3).

Subjective Evaluation

Postoperative clinical improvement included significantly fewer episodes of angina pectoris, chest tightness and shortness of breath after activity, nighttime sit-up breathing, and increase in appetite and urine output. The 6MWT distance increased steadily. The results depicted essentially derived from allogeneic myoblast culture and transplantation (Fig. 4), in addition to CABG and cyclosporine immunosuppression.

Understanding and Debating the Study Outcomes

For the first time, AMT in adjunct use with CABG and cyclosporine was demonstrated to be safe and efficacious in sustaining the life span of ten end-stage heart failure patients, who suffered myocardial infarction with ventricular aneurysm, for up to 2 years, with significant improvement in LVEF (Table 7), NYHA cardiac function (**Central Illustration**; Fig. 5) and quality of life.

It was the original design to define a treatment modality that could 100% sustain the survival of the severe heart failure patients having no more than 6 months of life expectance, and such design was demonstrated to be successful. The statistically significant increases in the mean LVEF by 20.1% at 6 months after treatment, and by 19.3% at 2 years after treatment compared favorably to those reported by all other studies using autologous myoblasts (Menasché et al. 2001a, b, 2003, 2008; Ghostine et al. 2002; Herreros et al. 2003; Siminiak et al. 2004, 2005; Dib et al. 2005; Fernandes et al. 2006; Gavira et al. 2006; Steendijk et al. 2006; Menasché 2007; Duckers et al. 2011; Povsic et al. 2011; Sawa et al. 2015). As the trend of improvement indicated, statistically significant difference in LVDd and CO before versus after treatment would have become apparent if more subjects were enrolled.

The ultimate demonstration of AMT efficacy by itself should be from randomized, double-blinded studies involving more subjects of dystrophic cardiomyopathies, diabetic cardiomyopathy, or dilated cardiomyopathies that would not necessitate CABG. This study showed that white blood cell count, neutrophil

count, total bilirubin, alanine aminotransferase, aspartate aminotransferase, total red blood cells, hemoglobin, platelets, total protein, renal function, fibrinogen, prothrombin time, and partial prothrombin time before versus after treatment of

myoblasts were not different ($P > 0.05$). On repeated follow-ups after the operation, there were no deaths, malignant arrhythmias, or viral infections. The results demonstrated that allogeneic myoblast transplantation had no significant impact on various important indicators of the human body, and there was no serious adverse reaction. Although occasional ventricular premature beats occurred in four subjects after CABG, all symptomatic treatments were traced to the sinus and were related to electrolyte disturbance, myocardial damage, and the primary disease. None of the subjects experienced malignant arrhythmia or ventricular tachycardia.

AMT represented the earliest human cell therapy for heart disease (Law et al. 2000). Without significant knowledge of myoblast manufacture, quality control, and cell transplant techniques, many clinicians rushed into clinical studies. Menasche et al. first reported feasibility and safety data on ischemic heart failure patients, implanting 650 million to one billion autologous impure myoblast cells with overly large number of injections into the infarctions during CABG (Menasché et al. 2001a, b). Follow-up studies showed that patients had significantly improved left ventricular function and NYHA function level, decreased ventricular remodeling, and increased myocardial tolerance confirmed by histology. However, four patients had delayed episodes of sustained left ventricular tachycardia (Menasché et al. 2001b). During this period, similar reports continued to appear around the world with mixed results.

In most of the reports, myoblast purity was determined using $CD56^{+}$, an antibody that reacts with fibroblasts, neurons, and myoblasts indiscriminately. A common pitfall of myoblast culture is fibroblast contamination. Since myoblast doubling time is about 21 h and fibroblast doubling time is about 15 h, fibroblast growth often overtakes the myoblast culture (Law et al. 1992; Law 1995). Without published documentation of quality controls, authors of these studies were implanting very impure myoblasts. Fibroblasts produce scars but not contractile filaments. These scars created numerous barriers to electric coupling and rhythmic synchronization of ventricular contraction. This pitfall, together with the physical trauma induced by overly large number of injections, were largely responsible for the malignant arrhythmia and tachycardia reported in some early patients, not to mention the gross GMP noncompliance in quality control of myoblast identity, viability, purity, quantity, potency, no mycoplasma, no endotoxins, and no bacteria (Ghostine et al. 2002; Menasché et al. 2003, 2008; Herreros et al. 2003; Siminiak et al. 2004, 2005; Dib et al. 2005; Fernandes et al. 2006; Gavira et al. 2006; Steendijk et al. 2006; Menasché 2007; Duckers et al. 2011; Povsic et al. 2011; Sawa et al. 2015). The latter explained cell death of up to 90% that affected the safety and efficacy of myoblast transplantation (Suzuki et al. 2004). Clinical studies confirmed that CABG with transplantation of impure and nonviable myoblasts produced ventricular tachycardia (Fernandes et al. 2006). The intercalated disc, the basic unit for the transmission and synchronization of electrical activity and mechanical function between adjacent cardiac fibers were not found, and its absence constituted a risk of malignant arrhythmia after transplantation with substandard myoblasts (Ferreira-Cornwell et al. 2002). Therefore, the safety and efficacy of myoblast transplantation depend largely on high quality control of myoblast production and the technique of implantation.

Heartbeat is myogenic in origin and is initiated by pacemaker activity in the sinoatrial node. As depolarization sweeps through the atrioventricular node, the depolarization excites the Purkinje fibers of the bundle of His, which, in turn, signals the ventricles to contract rhythmically. Heart function would be impaired if the rhythmic action potentials do not synchronize the fiber contractions. In the regenerative heart with AMT, excitation of the newly formed and heterokaryotic cardiomyocytes remained unchanged because there was little change in gap junctions for current flow. However, where new skeletal myofibers (Law et al. 2004a, b, 2006; Pagani et al. 2003) were formed, presumably at the inner border of the infarction, such heterogeneity might create aberrant electric activities such as arrhythmia, especially when earlier studies reported absence of gap junction protein connexin 43, a marker protein responsible for electrical coupling between cardiomyocytes (Tolmachov et al. 2006).

Conceptually, myoblast transplantation should not cause arrhythmia if the well-researched standard operation procedures were followed. The thresholds of excitation for cardiac and skeletal myofibers are similar, i.e., between +40 mV and +50 mV depolarization. Whereas the cardiomyocyte action potential is triggered with an increase in Ca^{2+} conductance into the cell, the skeletal myofiber action potential is triggered with an increase of Na^{+} conductance. As Ca^{2+} has a greater ionic size than Na^{+} and thus lower ionic mobility, the action potential of cardiomyocytes has a longer duration (~250 ms) than that of skeletal myofiber (~1.5 ms). This duration difference is advantageous because the same myocardial depolarization can simultaneously and synchronously stimulate the cardiac and skeletal myofibers through direct excitation contraction coupling. Since the action potentials of skeletal myofibers are of short duration, they will merge into the longer compound action potential of the heart. The skeletal myofibers will cease to fire and stop contracting once Cl^{-} efflux hyperpolarization of the myocardium reaches approximately +40 mV. Since 90% of the transplanted myoblasts developed to become cardiomyocytes or heterokaryotic cardiomyocytes and only a small amount of skeletal myofibers were formed, the electrophysiological treatise explains why none of the subjects in the current study experienced malignant arrhythmia from the myoblast transplantation (Law et al. 2004a, b, 2006).

Abraham et al. demonstrated in vitro that connexin 43 was expressed when exogenous connexin 43 gene was transferred into myoblasts (Abraham et al. 2005). Electrophysiological studies had also found that there was synchronized instantaneous calcium current between skeletal muscle myotubes and adjacent cardiomyocytes, further confirming that after transplantation, cardiomyocytes, heterokaryotic cardiomyocytes, and skeletal myotubes were simultaneously activated through the same excitation-contraction coupling. Simultaneous contraction could not only promote the formation of gap junctions, but also effectively reduced the incidence of arrhythmia. In addition, a sodium ionic current was detected (Zebedin et al. 2007) confirming that some myoblasts developed to become myotubes and immature myofiber (Law et al. 2004a, b, 2006). Skeletal myofibers are known to adapt to the frequency of electric excitation to which they are subjected. Under the influence of hormones and slow contractile activity of

the heart, these immature skeletal myofibers developed characteristics of cardiomyocytes.

The regenerative heart with myoblasts was endowed with a greater number of myogenic cells capable of mitosis and was prepared to regenerate upon injury. These cells produced more contractile filaments to augment heart contractility. The latter is fundamental to the quality of life and the life span of patients suffering various forms of cardiovascular diseases. Being pluripotent, embryonic or adult stem cells exhibit uncontrolled differentiation into various lineages to produce bone, cartilage, fat, connective tissue, skeletal and heart muscles. Until scientists can accurately define the specific transcriptional factors and pathways to guide stem cell differentiation into adequate quantity of cardiomyocytes, the use of stem cell injection into the human heart would have a risk-benefit ratio much higher than the use of myoblasts.
