Golden Gate assay (Sindhu et al. 2014). A total of 1536 polymorphic SNP loci were found, and by combining them with previously discovered anchor markers, the first high-density pea SNP map was created, delineating all seven linkage groups. This breakthrough can expedite tagging and mapping the QTLs related with agronomic and HR genes for boosting up seed quality for betterment of human nutrition. Using 12 RIL populations, GenoPea 13.2 K SNP Array has been developed in pea with construction of collinear map of 3918–8503 SNPs and a total of 12,802 transcript-derived SNP markers were available for future genomic study (Tayeh et al. 2015a). The high resolution and high-density consensus map developed with 15,079-marker will further facilitate the identification of ohnologue-rich regions within the pea genome thus strengthen pea genomic resources.

Proteomics and Metabolomics are new emerging arena to study the function of novel proteins associated with various physiological and biological events. Proteomics defined as the high-throughput study of proteins has assumed a leading role in plant biological research and stress responses owing to availability of plant genome sequence information in public database. Moreover, with the advancement of various high throughput approaches like mass spectrometry (MS), Tandem mass spectrometry and other quantitative assay coupled with bioinformatics approaches have offered easy characterization, quantification, and further validation of array of functional proteins from any crop species (Ramalingam et al. 2015). In addition to proteomics, metabolomics is a crucial tool of functional genomics that links cellular metabolic activity with phenotypes through the identification and quantification of metabolomes, a collection of metabolites or small molecules, within a cell, tissue, or organism (Weckwerth 2003). Like transcriptome assembly in pea, most of the proteomics and metabolomics study has been carried out in relation to characterization of proteins and metabolites underlying stress responses (Ranjbar Sistani et al. 2017) with meagre information that can uncover novel HR proteins and metabolites in pea. Improving vicilin concentration in pea is the need of the hour as vicilin having lower concentration of sulphur containing amino acid in comparison to legumin. Proteomic study by Bourgeois et al. (2009) was the first pea mature seed proteome reference map, detected 156 novel proteins including 24 different genes controlling vicilin in pea. This study provided the diversity in relation to seed storage proteins and their plasticity during plant developmental stages. Later on, integrating proteomic and QTL mapping approaches, Bourgeois et al. (2011) developed proteomic atlas from the RIL population developed from three pea genotypes Cameor, VavD265 and Ballet and unveiled the genetic architecture regarding the seed proteome variability. Protein quantity loci (PQL) were hunted for 525 spots noticed on 2-D gels and interestingly, most PQL were mapped in clusters. This demonstrated how a few numbers of loci were responsible for accumulating the major store protein families. Previous study also reported how fast-neutron mutagenesis may be used to disrupt many genes at a single locus, affecting the accumulation of vicilin and other proteins (Domoney et al. 2013). It has been demonstrated that a mutant allele at the Vc-2 gene affects seed nitrogen contents and major vicilin polypeptide synthesis (Chinoy et al. 2011).

9 Genomics-Aided Breeding for HR Traits

Seed quality traits including protein, carbohydrate, and mineral concentration are mostly complex and quantitative in nature. Multiple genes, environment, and genotype × environment interaction create ambiguities towards expression of these HR genes related with seed quality. Besides biparental linkage mapping, genome wide association mapping (GWAS) is nowadays used to understand these complex traits. Association mapping based on the principle of linkage disequilibrium can capture greater number of alleles originated during the course of evolution. The first GWAS was applied to understand the allelic variation regarding starch metabolic pathway that can affect the chain length distribution (CLD) and starch structure in a set of 92 diverse pea accessions (Carpenter et al. 2017). Associations for polymorphisms in seven potential genes and the Mendel's r locus were discovered that govern round versus wrinkled seed phenotype. Amongst seven significant candidate genes, three genes, viz., *r* (rugosus allele), *UGPase* (UDP-glucose pyrophosphorylase), and *AGPS2* (ADP-glucose pyrophosphorylase S2 subunit) portrayed a significant relationship with CLD, and the amylose content was linked with the *r* locus. Another GWAS was performed to track the loci related with agronomic, seed morphology, and seed quality traits (protein, carbohydrate, and fiber content) using 135 diverse accessions of pea from 23 different pea growing countries. GBS approach was also integrated for detection of 16,877 high quality SNP arrays. Five SNPs were recognized that were being linked with ADF concentration (positioned on chromosomes 5, 6, and 7), whereas, eight SNPs were detected with NDF content (chromosomes 2, 3, 5, 6 and 7). Four markers (Chr1LG6_176606388, Chr2LG1_457185, Chr3LG5_234519042, and Chr7LG7_8229439), located on chromosomes1, 2, 3, and 7, were connected with seed starch content, and one marker (Chr3LG5_194530376) identified was linked with seed protein concentration (Gali et al. 2019). Dissanayaka et al. (2020) used a panel of 135 diverse pea accessions for identification of trait associated SNP arrays for an association study concerning seed mineral content. Out of the 16,877 SNP markers deployed for association analysis, five each were recognized for relationship with Fe and Zn content in pea seeds. Markers detected in the present study related with Fe (Chr5LG3_204123886) and Zn (Chr5LG3_1921113554, Chr5LG3_197808492, and Sc4026_15361) would be useful for MAS programme in pea for rapid generation of cultivar with good seed quality traits.

With the expansion of pea genomic resources in recent years, particularly the reference genome sequence, which makes it easier to comprehend the allelic variation underlying the important traits and facilitate towards development of better pea cultivars opting various genomics assisted breeding programme like haplotype-based breeding, genome editing, and genomic selection (GS). Plant breeders are quickly adopting GS, a potent breeding technique, especially for traits that are challenging to detect. In the next 10 years, breeding for increased pea productivity and quality is anticipated to benefit from the use of GS in conjunction with high-throughput SNP genotyping platform. In order to maximize genomic prediction for complex traits, GS models depend on training and testing populations and enumerate the Genomic Estimated Breeding Values (GEBV). Comparatively to conventional

marker-assisted selection, GS enables the simultaneous selection of several attributes. GS programme initiated in pea with the easily observable agronomic traits characterized by high heritability like seed weight, days to flowering, pods per plant, Ascochyta blight resistance, etc., with prediction accuracy of 0.19–0.84% (Tayeh et al. 2015b). These research findings offer "proof of concept" for the idea that selecting pea breeding lines for HR traits in various environments can be made more effective in the future by combining superior training and test population sets and integrating robust and reliable prediction models and high-density marker system.

10 Other Approaches and Future Strategies for Modulating HR Genes in Pea

Like other legume, pea seeds are also fantastic treasury of dietary protein. Although they consist of numerous protein classes that resist proteolysis to varying grades and are adversely correlated with quality and animal health. Protease inhibitors, specifically trypsin/chymotrypsin inhibitors (TI), present in the pea seeds are regarded as antinutritional components that usually require additional heat-treatment or other processing for use as feed for cattle and poultry (Patto et al. 2015). Pea seed TI are mostly of the Bowman-Birk inhibitor (BBI) category, with wide genetic variation exists regarding inhibitory activity (Domoney and Welham 1992). Two closely related genes, *TI1* and *TI2*, have been found to encode the two primary BBI isoforms that are expressed in pea seeds and mostly inhibit both trypsin and chymotrypsin (Domoney et al. 2002). Exploitation of a Targeted Induced Local Lesions IN Genomes (TILLING) population in pea facilitated to detect novel genetic variants regarding various classes of inhibitor proteins, which can provide deeper insight regarding the structure-function and relationships within the protease inhibitors. Moreover, targeted screening within *TI1* gene of pea enabled to detect natural variant devoid of inhibitory activity class of seed protein. A total of 13 nucleotide changes have been detected including seven changes were in noncoding regions and six alterations influencing the coding sequence that generated missense mutations. It was validated from the finding that the substitution of C77Y in the mature mutant inhibitor completely eliminated inhibitor activity. A *P. elatius* accession as a double null mutant for the two closely linked genes *TI1* and *TI2* was detected with extremely low seed protease inhibitory activity, and introgression of the mutant into cultivated germplasm has been achieved (Clemente et al. 2015).

In pea, attempt has been made to introduce antisense construct for genetic manipulation of the inhibitor genes. The promoter from *TI* gene has been isolated, characterized, and reintroduced within pea by *Agrobacterium*-mediated genetic transformation, as a TI promoter-bglucuronidase (GUS) gene fusion. A second gene construct uses the *TI1* gene promoter for direct exhibition of an antisense *TI* gene. Seed *TI* activities in some transformed pea lines with this construct were tested, and it was detected that the activity of inhibitor genes was reduced significantly (Welham and Domoney 2000). Attempt was also being made to understand the structural relationship of multiple genes responsible for governing legumin

biosynthesis in developing pea seeds by Casey et al. (2001). Earlier report confirmed that in pea seeds legumin biosynthesis was usually modified due to the nature of the *r* loci governing the structural gene for starch-branching enzyme isoform I (*SBE I*) or *rb* responsible for synthesis of ADP-glucose pyrophosphorylase. This ultimately led to changes in the ratio of legumin: vicilin within the total seed protein in pea. It was detected that the double mutants (*rrb*) showed a significant drop in the quantity of legumin without altering the concentration of vicilin. Further expression of cloned legumin cDNA construct of pea in transgenic wheat seeds able to synthesize an array of paracrystalline legumins. This evidence validated that, in spite of the presence of multiple genes with structural heterogeneity, the pea legumin comprises of a single type of subunit.

In pea, there is no successful report of genome editing due to the calcitrant nature of this legume. However, the most recent approaches, such as de novo meristem induction by and DNA transfer in mature plants enabled by nanomaterial offered great promise towards the development of genome-edited pea plants with advantageous features.

With the advent of affordable genomic tools, access to pea genomic resources will increase in the near future. This will help to close knowledge gaps regarding allelic variation and the genetic mechanisms governing the metabolism of various HR genes and will hasten the creation of novel pea cultivars through genomic assisted breeding programme with refine HR genes for the benefit of mankind.

11 Future Prospects and Conclusion

Malnutrition has become a serious problem owing to the insufficient supply of nutritionally balanced diets to the resource-poor folks of under developed/developing countries in the prevailing changing climate. Unfortunately, hidden hunger is steadily increasing due to the reliance of the increasing population on cereal based carbohydrate rich diet which is deprived of vitamins and essential micronutrients. Various strategies such as dietary supplementation, fortification of foods, and agrofortification are being used to upsurge the disposal of an essential nutrient in the daily diet, but these are not accessible to the resource-poor population. Thus, genetic biofortification of edible crops through conventional and modern breeding approaches is considered as most effective, economic, and sustainable approach for the entire stakeholders. In the case of peas, very limited systematic efforts have been made to assess the extent of variability for nutritionally important traits such as protein, iron, zinc, folate, vitamins, phenolic compound, and selenium. In addition, the variability so far observed could not be exploited judiciously in the regular breeding programme toward genetic biofortification. Therefore, it is the need of the hour that large-scale high-throughput phenotyping should be done to unveil the genetic variability that exists in peas. Unfortunately, unlike other legume crops, restricted efforts have been made to explore the magnitude of variability that exists

for nutritionally important traits in landraces and crop wild relatives. Thus, proper phenotyping of landraces and CWR needs to be done and subsequently, the identified sources must be embraced in a regular breeding programme to develop nutrient-enriched pea. Indeed, conventional breeding approaches have been well accepted by the public as being cost-effective, free of synthetic inputs, and eco-friendly and sustainable practices, but their laborious and time-consuming nature prompted plant breeders to opt for genomics-assisted breeding. Genomic resources facilitate breeders in the exploitation of existing genetic variability more precisely with minimum duration and expenses. Unlike other legume crops, in pea, the genomic resources have not been developed and exploited to identify genes/QTL for nutritional traits. Therefore, the recently emerged omics-based approaches need to be embraced to facilitate the identification of genes/QTLs and further make available the robust markers platform for a marker-assisted breeding programme in pea. Microarray or RNA sequencing technology and NGS-based transcriptome assembly could be used to generate valuable genomic resources and markers that can be assembled for the construction of highly saturated genome maps, improve genotyping technologies (sequencing and resequencing), and identification of additional markers like SNPs and EST-SSRs. Notably, the pea reference genome assembly offered several contigs, transcripts, markers, and GBS platforms for their further annotation. The transcriptomics, proteomics, and metabolomics analysis have been mostly carried out in pea to unveil the mechanism underlying abiotic and biotic stress resistance, and there is insufficiency regarding analysis of nutrition-related genes, which must be accelerated. However, most recently few valuable transcripts atlas has been generated that will further boost reverse genetic studies, fine mapping, allele mining, and identification of candidate genes. In case genetic variability is inadequate for traits of interest then the desired variability may be created by adopting induced mutagenesis or modern techniques like genome editing (i.e., clustered regularly interspaced short palindromic repeats (CRISPR)- associated system (CRISPR/Cas). However, to date, there is no successful report of genome editing due to the recalcitrant nature of this legume. In addition, exploitation of a Targeted Induced Local Lesions IN Genomes (TILLING) population in peas would facilitate the detection of novel genetic variants regarding various classes of inhibitor proteins which can provide deeper insight into the structure-function and relationships within the protease inhibitors. Another powerful tool is a genetic transformation or transgenic, which possess many advantages including its long-term sustainability. In addition to protein, peas also consist of numerous antinutritional components specifically trypsin/chymotrypsin inhibitors (TI) and phytic acid. Therefore, gene silencing approaches should be used to down-regulate genes encoding antinutritional compounds without affecting other pathways and processes involved in plant growth and development. The advent of affordable genomic tools and access to reference genome will help to reduce the knowledge gaps regarding allelic variation and the genetic mechanisms governing the metabolism of various nutrition-related genes and will hasten the creation of novel pea cultivars with refined HR genes for the benefit of mankind.

health problems are now the major global challenges. Cowpea is a prime pulse legume grown predominantly in the tropical and subtropical regions of Asia, Africa, Latin America, and southern Europe. Compared to other legumes, cowpea is more resilient to climate change and exhibits wider adaptability in different agro-ecologies. Cowpea is a rich source of protein, carbohydrates, minerals, and vitamins with a low lipid content. Besides being nutritious, its health-promoting and health-protective effects are based on resistant starch, dietary fiber, phenolics, and peptides. Major health beneficial features of cowpea include anti-cancer, anti-diabetic, anti-inflammatory activities, and controlling blood lipid content. Germplasm evaluation is paving way for the identification of lines with high protein content and minerals (Cu, Fe, Zn, Mg, Ca, and K) which could be used in breeding for new biofortified cowpea cultivars. Development of databases such as "EDITS-Cowpea" for enabling exploration of cowpea traits, especially those related to grain quality-related traits and "Cowpea Genomics Initiative" for applying modern molecular genetic tools for gene discovery will foster research aimed at cowpea improvement. This chapter examines the nutritive value of cowpea with more emphasis on the remarkable nutraceutical properties of cowpea and suggests taking cowpea forward as a future smart crop for tackling global food and nutritional security.

Keywords

Pulses · Cowpea · Nutritional security · Nutraceuticals · Human health

1 Introduction

Food security for the increasing world population has become a main concern for agricultural scientists and plant breeders, and it is estimated that food production will have to be enhanced by 70% by 2050 (Fróna et al. 2019). The problem is also compounded by the nutritional deficiencies and malnutrition among the world population (FAO 2017). This necessitates that the food will have to be produced in abundance and of good nutritional quality to ensure health of the future generations. Plant breeding over the past several decades has made a significant contribution to the development of high yielding and good quality varieties of cereals, pulses, and oil seeds besides other economically important plants to meet food and nutritional security (Mir et al. 2021).

Cowpea (*Vigna unguiculata*), also known as China bean, black-eyed bean, black-eyed pea, and southern pea, is an annual bean plant and member of the family Fabaceaeor Leguminosae (Oyewale and Bamaiyi 2013). It is widely cultivated in the tropical regions of the world such as Southeast Asia, Africa, Southern United States, and Latin America due to its ability to tolerate climate change. Cowpea is majorly produced and consumed in Sudano–Sahelian zone of sub-Saharan Africa (Boukar

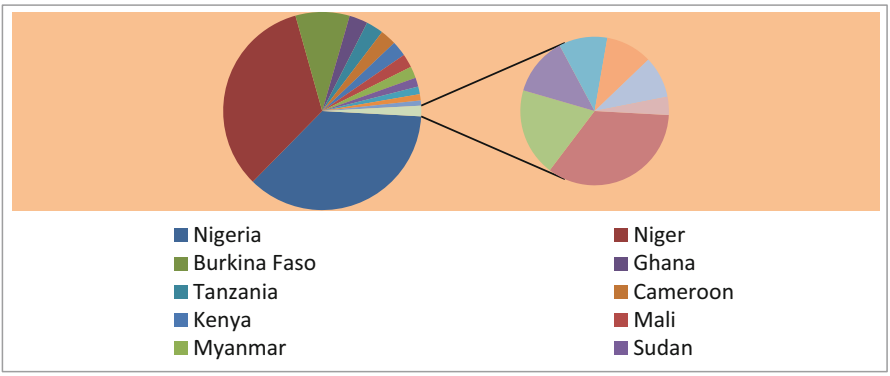

Fig. 1 Global cowpea production (FAOStat 2020)

et al. 2019). According to FAOSTAT report, worldwide production estimates over 8.9 million metric tons of dry cowpeas in 2020, of which 86% is contributed by Western Africa, mainly Nigeria and Niger with 6.3 million tons (FAOSTAT 2020) (Fig. 1). At the global level, cowpea production and yield have been increased by 88% and 35%, respectively (Nedumaran et al. 2015). Most of the cowpea plant parts are edible and consumed such as juvenile leaves, growing points, raw/immature pods, green seeds, and dried/desiccated seeds (Gerrano et al. 2019). It is grown for its high nutritious value, and recently there has been focus on the nutraceutical properties and as fodder for livestock. Moreover, due to its nutritious leaves, cowpea is placed in class of the chief vegetables in Africa and Asia (Mohammed et al. 2021). The American Pulse Association declared "pulses" as the most versatile and multi-faceted food source in the world (American Pulse Association 2020). It is often referred to as a multi-potential crop for the future (Fig. 2).

Cowpea is reported to have originated from Africa (Lazaridi et al. 2016). A recent study in 2020 (Herniter et al. 2020) based on genetic, textual, and archeobotanical data proposed a likely spread of cowpea from the two centres of domestication, West Africa and East Africa. From West Africa cowpea was spread by the Bantu migrations south to the equatorial rainforest and then to the areas of modern Sudan, South Sudan, and Ethiopia followed by diversion into three branches. First branch leads to Southern Africa, which joined the East African domestication. Second branch directed toward north up to the Nile and Egypt and remained there up to 2500 BCE. Later on, by 400 BCE, this branch had entrenched itself as a key food crop in the Mediterranean basin and moved to Spain's colonial holdings in the New World, including the modern south-western United States. The third branch makes its way to the west coast of India by 1500 BCE through the "Sabaean lane" in modern Yemen and then spreads to Southeast Asia. *Vigna unguiculata* ssp. *unguiculata* var. *spontanea* is assumed to be the wild ancestor of cultivated cowpea that is grown in sub-Saharan Africa (Pasquet et al. 2021).

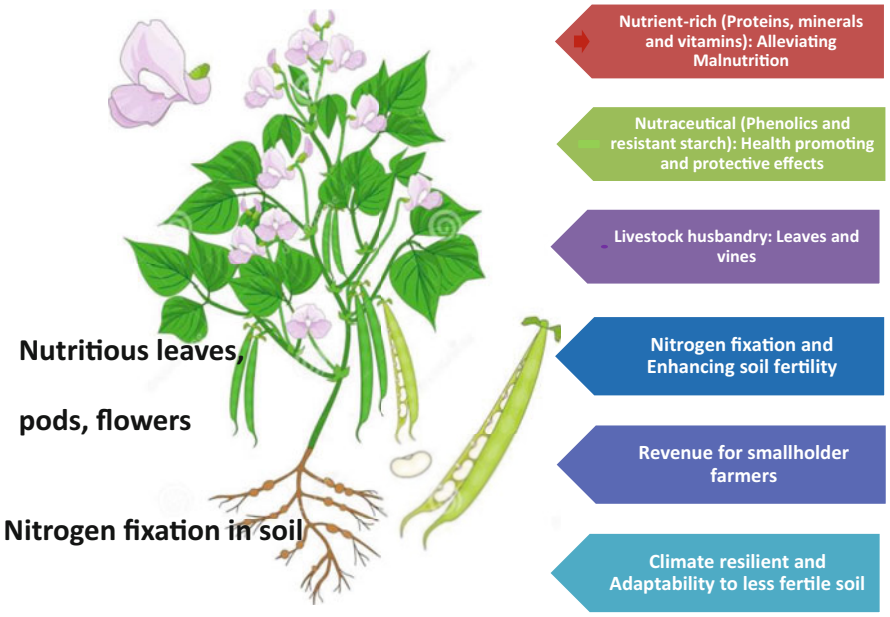

Fig. 2 Multifaceted potentials of cowpea

2 Genetic Resources and Genetic Diversity

Crop genetic resources including germplasm collections are essential for national and global agricultural security. Genetic diversity of crops is important for sustainable development and food security because this gene reservoir will aid in the future in further improvements in the elite cultivars with regard to better performance and well-adaptedness (Pathirana and Carimi 2022). To date several genetic resources have been developed in cowpea to aid in breeding elite varieties. The different forms of these developed genetic resources include physical and genetic linkage maps, genome sequences, databases, microarrays, molecular markers, etc. Few examples of different genetic resources in cowpea are genotyping assays and genetic maps based on single nucleotide polymorphism (SNP), physical maps, mapped quantitative trait loci (QTLs) traits, consensus genetic maps of cowpea (González et al. 2016), reference genome sequence of cowpea (Lonardi et al. 2019), cDNA sequences, unigenes, genic-SSR markers (Mahalakshmi et al. 2007), and linkage maps for cowpea developed using molecular markers and their further refinements through advanced markers (Muchero et al. 2009). Several genetic diversity studies have been conducted to investigate the evolutionary relationships among different genotypes, relationships with wild accessions, origin, taxonomy, domestication, and evolutionary pattern in cowpea. Initially studies were performed using conventional parameters such as allozymes and seed storage proteins that was followed by

different marker systems such as chloroplast DNA polymorphism, restriction fragment length polymorphism (RFLP), amplified fragment length polymorphisms (AFLP), DNA amplification fingerprinting (DAF) simple sequence repeats (SSRs), cross species SSRs from *Medicago*, inter-simple sequence repeats, sequence tagged microsatellite sites (STMS), and single-nucleotide polymorphism (SNP) markers.

The largest collection of cowpea consisting of 16,569 cultivated accessions from 100 countries and around 1500 wild accessions of *vigna* is maintained by the International Institute of Tropical Agricultural (IITA). Based on geographical, agronomical, and botanical descriptors, a central group of 2120 accessions and a minor collection of 376 accessions have been established at IITA (Boukar et al. 2019). Other major collections with overlapped data include the US Department of Agriculture–Agricultural Research Service (USDA-ARS) (Griffin, Georgia, USA) with 8379 accessions, the National Bureau of Plant Genetic Resources (NBPGR, New Delhi, India) holding 4003 accessions, and the University of California, Riverside (UCR, California, USA) harboring 5000 accessions and a mini core of 368 accessions. These cowpea accessions exhibited variations among each other with context to several morphological and agronomical traits such as plant pigmentation, plant kind, plant height, leaf type, growth habit, photosensitivity or insensitivity, maturity, nitrogen fixation, fodder grade, tolerance to high temperature and water deficit, root architecture, pod features, seed traits, grain quality and reaction/response to diseases, root-knot nematodes, insect pests (aphids, bruchid, thrips), and parasitic weeds (Boukar et al. 2020). Large gene bank collections include those of IITA (Nigeria), USDA (Southern Regional Plant Introduction Station, Georgia), World Vegetable Centre (Taiwan), and the N.I. Vavilov Research Institute of Plant Industry (Russia). Padhi et al. (2022) explored 120 diverse cowpea germplasm lines to search for nutri-dense genotypes using biochemical traits and observed broad variability for protein content (19.4 to 27.9%), starch (27.5 to 42.7 g 100 g^{-1}), amylose (9.65 to 21.7 g 100 g^{-1}), TDF (13.7 to 21.1 g 100 g^{-1}), and TSS (1.30 to 8.73 g 100 g^{-1}). The study suggested that the collection showed some nutrient-dense lines having more than a single trait with high nutritional potential.

3 Nutritional and Nutraceutical Profile

The world is facing major critical situations of malnutrition in downtrodden population of developing countries and prevalence of chronic diseases in well-off people in developed countries. Protein energy malnutrition (PEM) is a very serious public health issue in many less developed nations (Bessada et al. 2019). Globally, one-third of all child deaths were estimated to be due to malnutrition, of which 54% occurred in underdeveloped countries (Bain et al. 2013). Thus, there is an urgent need to identify foods that are both nutritious and have nutraceutical properties and to introduce these food types into our regular diet so that their health-protective and health-promoting effects will help in controlling frequent cases of several chronic diseases.

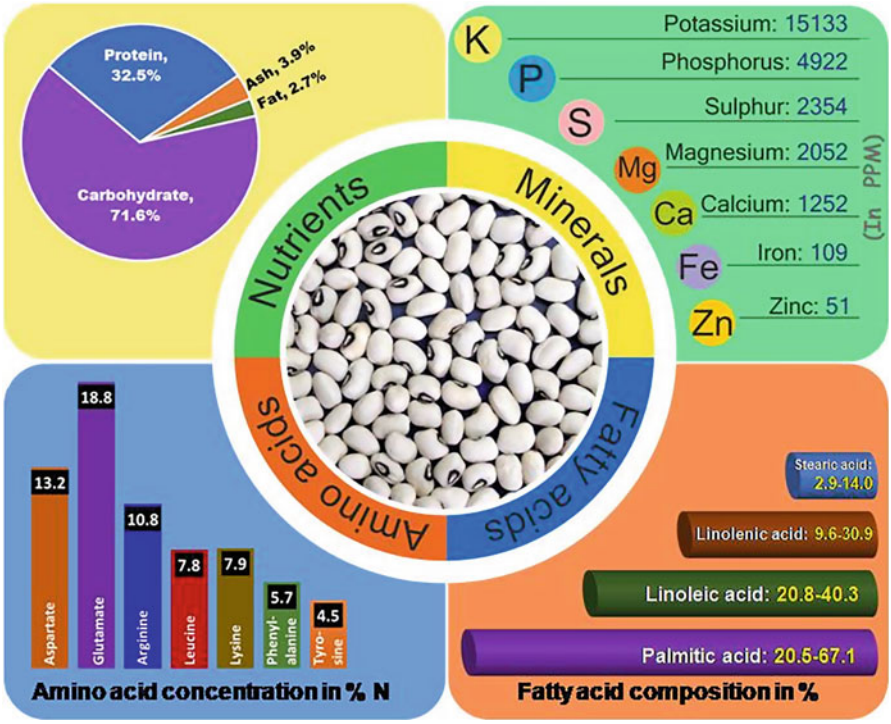

Fig. 3 Major nutritional composition of cowpea seeds (based on the data from Gonçalves et al. 2016)

Legumes are well-known for their protein-richness, of which cowpea has gained more attention due to its remarkable nutritional profile and nutraceutical properties that make it unique among other pulses (Dhanasekar et al. 2021) (Fig. 3). Cowpea is known as "the poor man's meat" because of its protein-rich nature complemented by its less expensive and affordable access to rural poor people (Dugje et al. 2022), and also because the protein content is approximately equal to certain meat types (18–25%). It also has digestible and non-digestible carbohydrates, potassium, and very low lipid and sodium content. The composition of different nutritional components in grains is given in Fig. 4. Cowpea leaves are rich in micronutrients, nutraceuticals, antioxidants (alpha tocopherols, flavonoids, lycopene), and anti-proliferating compounds (Owade et al. 2020). Dakora and Belane (2019) suggested that cowpea leaves could meet the suggested day-to-day dietary intake requirement of the micronutrients Fe and Zn by consuming 4 mg and 76 mg of leaf on a dry matter basis. Cowpea leaves are a nutritious food source, with an abundance of protein and minerals, digestible and non-digestible carbohydrates, and potassium but low lipids and sodium (Kamara et al. 2010). Leaves show higher nutritional content than grains (Fig. 5).

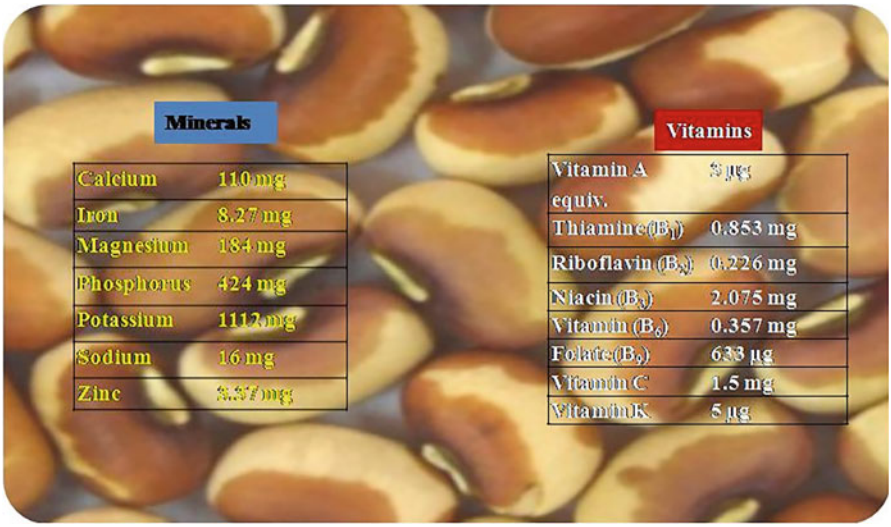

Fig. 4 General nutritional profile per 100 g of raw cowpea seeds. (Source: USDA nutrient database)

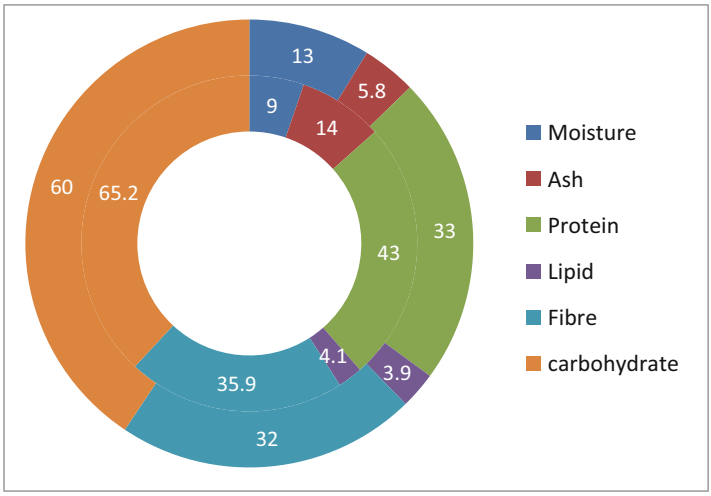

Fig. 5 Proximate and fiber composition (%) of leaves and grain (adopted from Mekonnen et al. 2022)

3.1 Protein Profile

Cowpea is consumed as a high-quality plant-based protein source (Jayathilake et al. 2018) with a protein content of 27 to 43% in leaves and 21 to 33% in dry grains (Gerrano et al. 2019). Cowpea protein fraction includes globulins (legumin and

Table 1 Amino acid composition of cowpea grain and leaves (adopted from Mekonnen et al. 2022)

Amino acid	Leaves (g/100 g protein)	Grain (g/100 g protein)	Amino acid	Leaves (g/100 g protein)	Grain (g/100 g protein)
Arginine	7.4–17.3	5.0–10.8	**Lysine**	3.0–16.3	3.5–8.0
Aspartic acid	10.8–26.7	6.0–13	**Methionine**	1.0–4.5	0.9–3.5
Alanine	4.2–9.8	3.4–5.1	**Phenylalanine**	4.6–14.4	4.4–9.9
Cysteine	0.5–2.9	0.3–2.4	**Proline**	4.0–15.9	3.1–8.9
Glutamic acid	17.2–45.3	8.5–19	**Serine**	3.0–11.6	3.8–5.8
Glycine	3.8–12.6	3.1–4.8	**Threonine**	3.2–10.8	3.0–5.9
Histidine	1.8–8.6	2.0–4.41	**Tryptophan**	1.3–4.1	0.9–1.5
Isoleucine	4.1–11.1	2.8–5.4	**Tyrosine**	3.0–9.3	2.6–4.5
Leucine	7.4–19.6	5.7–11.3	**Valine**	5.0–12.8	3.4–6.2

vicilin/β-vignin), albumins, glutelins, and prolamins (Santos et al. 2012). Because of this, cowpea has been highly promoted in economically backward regions to control protein malnutrition (Iqbal et al. 2006).

Cowpea leaves and grains show a rich profile of different amino acids including essential amino acids like valine, leucine, phenylalanine, lysine, and tryptophan. The amino acid profile of leaves and grains is presented in Table 1.

3.2 Minerals and Vitamins

Cowpea seeds, leaves, and beans are enriched with vital minerals of both macronutrients (Ca, K, Mg, P and S) and micronutrients (Cu, Fe, Mn, Zn, Na, Al, Se, B) that are required for proper functioning of human body (Owade et al. 2020). Cowpea is a source of different vitamins, of which most prevalent are vitamin A, C, and B complex (thiamine, riboflavin, pantothenic acid, pyridoxine, and folic/folate acid) and gamma tocopherol. Cowpea leaves have more vitamin C and minerals compared to grains (Mekonnen et al. 2022). The major and micro-mineral profiles of leaves, immature pods, and grains are presented in Table 2.

3.3 Lipids and Fatty Acids

Cowpea is a low lipid grain crop compared to other legumes (chickpea, lentil, green gram, and lupin) (Belane and Dakora 2011) with 0.5% to 3.9% lipid in grain and 1.3 to 4.3% in leaves. The lipid profile of cowpea is composed of triglycerides (41.2%), phospholipids (25.1%), monoglycerides (10.6%), free fatty acids (7.9%), diglycerides (7.8%), sterols (5.5%), hydrocarbons, and sterol esters (2.6%)

Table 2 Mineral composition of cowpea grains, immature pods, and leaves (adopted from Mekonnen et al. 2022)

Minerals	Grains Mean range	Immature pods Mean range	Leaves Mean range
Macro-minerals (mg/100 g dry matter)			
Phosphorus	2.3–6.10	383.43–537.53	2.1–592.4
Potassium	9.30–35.60	170.74–240.78	9.57–1445.2
Magnesium	4.3–8.4	297.97–426.20	1.3–227.4
Sulfur	153.3–200.0		120.0–147.3
Micro-minerals (mg/100 g dry matter)			
Copper	0.15–2.2	0.48–0.95	0.5–2.2
Iron	26.76–182.33	6.01–9.78	3.4–10.6
Manganese	10.57–204	2.11–4.77	1.38–4.3
Sodium	11.59–43.95	13.70–32.93	8.4–79.81
Zinc	2.78–22.3	1.42–5.63	2.4–5.11
Aluminum		1.84–7.86	
Boron	3.14–5.01	2.13–4.03	1.47–2.14
Selenium		2.5–3.4	

(Kapravelou et al. 2015). Among fatty acids, palmitic and linoleic acids and, within sterols, stigmasterol (42.1 to 43.3%) are predominant (Antova et al. 2014).

3.4 Carbohydrates

Cowpea is also rich in carbohydrates containing 30.39 to 31.11% in leaves and 50 to 60% in grains. Popova and Mihaylova (2019) suggested that the good fraction of carbohydrates consists of sucrose, glucose, fructose, galactose, and maltose, whereas anti-nutrient components of carbohydrates are mostly raffinose, stachyose, and verbascose.

4 Health-Promoting and Health-Protective Properties

Besides above-specified nutritional value, cowpea exerts several health benefits due to presence of soluble and insoluble dietary fibers, phenol-derived compounds, other functional agents, anthocyanins, and carotenoids (de Silva et al. 2021). Epidemiological evidences showed the nutraceutical aspects, i.e., health-promoting and disease-preventing effects of cowpea such as protection against many incurable and immedicable health situations such as cardiovascular diseases, hypercholesterolemia, and obesity (Frota et al. 2015), anti-diabetic (Barnes et al. 2015), anti-cancer (de Silva et al. 2021), anti-inflammatory (Awika and Duodu 2017), antihypertensive and hypocholesterolemia (Tadele 2019), reducing plasma low-density lipoprotein (Talabi et al. 2022), gastrointestinal disorders (Khalid II and Elharadallou 2012),

weight loss (Perera et al. 2016), and improving assimilation and strengthening blood flow (Trehan et al. 2015). The nutraceutical aspects of cowpea were reviewed (Jayathilake et al. 2018) and credited with plant-derived compounds, resistant starch, dietary fiber, less fat, and good unsaturated fatty acids. Interestingly, upon germination, the nutritive profile of cowpea seeds is enhanced as observed by increase in antioxidant capacity, vitamin C (Doblado et al. 2007), β-carotene, phenolics (hydroxycinnamic acid, syringic acid, vanillaldehyde, ferulic acid, sinapic acid, *p*-coumaric acid, benzoic acid, ellagic acid, and cinnamic acid), and flavonoid content.

4.1 Protein Hydrolysates and Peptides

The protein lysates of cowpea vegetate shows a low lysine/arginine proportion like soybean, thus making it a potential functional ingredient for reducing cholesterol (Kanetro 2015). Cowpea bioactive compounds such as peptides that are products of enzymatic hydrolysis or fermentation are reported to create favorable physiological conditions for proper functioning of the human body (Marques et al. 2015). These peptides function by acting as antihypertensive (Boonla et al. 2015), anti-dyslipidemic (Udenigwe and Rouvinen-Watt 2015), antioxidative (Marques et al. 2015), anti-carcinogenic and antimicrobial (Felicio et al. 2017), and anti-diabetic (Barnes et al. 2015). Cowpea peptides are known to prevent the occurrence of diabetes mellitus by imitating the activity of insulin and inhibiting dipeptidyl peptidase IV activity (Barnes et al. 2015). The antioxidative properties of cowpea peptides were attributed to the hydrophobic and aromatic amino acids like leucine, isoleucine, tyrosine, phenylalanine, tryptophan, and the sulfur-bearing amino acid cysteine due to their proton giving property to free radicals (Xiong et al. 2013). Similarly cowpea proteins and peptides showed antihypertensive by inhibiting angiotensin-converting enzyme (ACE) (de Leon et al. 2013) and hypo-cholesterolemic effects occur in several ways such as bile acid-binding, disruption of cholesterol micelles, changing hepatic and adipocytic enzyme actions, and gene expression of lipogenic proteins, as well as by inhibiting HMG-CoA reductase activity (Marques et al. 2018).

4.2 Phenolics

Cowpea predominantly contains phenolics (70% free phenolics and 30% bound phenolics), flavonoids (flavonols and flavan-3-ols), coumaric acid and ferulic acid (seed), gallic acid, protocatechuic acid, and *p*-hydroxybenzoic acid (seed coat) and thus is supposed to exert high antioxidant activity (Gutierrez-Uribe et al. 2011). Anthocyanins found in cowpea are delphinidin-3-*O*-glucoside, cyanidin-3-*O*-glucoside, delphinidin-3-*O*-galactoside, cyanidin-3-*O*-galactoside, petunidin-3-*O*-glucoside, peonidin-3-*O*-glucoside, and malvidin-3-*O*-glucoside (Ha et al. 2010). Many studies have reported the phenolic composition and their functioning mechanisms in different cowpea varieties (Liyanage et al. 2014). Phenolic compounds have

hypocholesterolemic activity because of inhibition of oxidation of lipids, lowering of blood triglycerides, total cholesterol, LDL, and surge of blood HDL (Hachibamba et al. 2013), anti-inflammatory by downregulating pro-inflammatory gene expression (Ojwang et al. 2015), and having an anticancer effect as antioxidants shields DNA from oxidation and suppress cancerous cell division (Hachibamba et al. 2013).

4.3 Resistant Starch and Fiber

Coming to the other health benefits, cowpea contains high amount of resistant starch up to 12.65 gm per 100 gm (Eshwarage et al. 2017; Chen et al. 2010) which makes it a low glycemic index food. As mentioned earlier, resistant starch and dietary fiber have antidiabetic effect due to slow release of glucose (Onyeka 2007) and hypocholesterolemic effect due to diminution of bile acids from the circulation, abatement of converting cholesterol to supplemental bile acids, and augmenting expulsion of fecal fat (Perera et al. 2016). The two major health benefits of resistant starch are that firstly, it slows the rate of digestion, thus slowing release of glucose into the body followed by less uptake of glucose by the intestinal cells and secondly, due to their incomplete digestion by human digestive enzymes, they act as a substrate for colonic microbes (including probiotics) resulting in production of short-chain fatty acids (butyrate) that aid in proper lipid function and cancer prevention. Cowpea also has low calorific value and thus helps with glucose regulation in diabetic patients and better weight control for the obese (Oboh and Agu 2010).

Cowpea has both soluble and insoluble high fiber content and hence has associated health advantages (Eshwarage et al. 2017). Soluble fiber helps in regulating blood cholesterol and glucose levels, while insoluble fiber due to its water/moisture retention property helps in smooth passage of waste materials through intestine and colon, thereby preventing haemorrhoids, constipation, many other digestive difficulties, colon cancer, diabetes, obesity, cardiovascular diseases, and numerous other long-term health complications (Eshwarage et al. 2017). Some additional health benefits of cowpea include eliminating urination problems such as uneasiness or obstructions, managing leucorrhea, or abnormal vaginal discharge (Alfa et al. 2020).

4.4 Anti-nutritional Factors

Although numerous studies claim cowpea is highly nutritious and a good nutraceutical food, its consumption is still limited due to presence of several anti-nutritional factors, poor digestibility, and lack of sulfur-containing amino acids. These anti-nutrients include some phenolic compounds, such as proanthocyanidins (Ojwang et al. 2013), phytic acid, tanins (Lattanzio et al. 2005), hemagglutinins (Aguilera et al. 2013), cyanogenic glucosides, oxalic acid, dihydroxyphenylalanine and saponins, and enzyme inhibitors (protease inhibitors, phytocystatins) (Monteiro et al. 2017). Phenolic compounds bind proteins and chelate divalent metal ions (Ojwang et al. 2013). Phytic acid (PA), an anti-nutritional factor, is known to conjugate phosphorus and

other essential elements like iron and make it unavailable to organisms that feed on seeds rich in PA. Mutations affecting PA content have been identified, and low PA mutants have been isolated in pulses including cowpea (Dhanasekar and Reddy 2017). These mutants are being exploited in varietal development program so as to reduce the PA content to reasonable levels without affecting the physiological balance as they are further involved in responses to biotic and abiotic stresses (Dhole and Reddy 2016; Dhanasekar and Reddy 2017). Another important anti-nutritional factor in cowpea is the raffinose family oligosaccharides (RFOs) known to cause flatulence in organisms ingesting cowpea seeds. The RFOs are highly recalcitrant to various processing methods, and genetic means of reducing the content is the only amenable method. Therefore, it becomes imperative to identify genotypes with low RFOs content. Mutants with low RFOs have been identified in cowpea (Dhanasekar and Reddy 2015) that could be potential donors for developing varieties with low RFOs. Nevertheless, appropriate processing techniques can be used to lower many of the anti-nutritional compounds and enhance their bioavailability levels. Knowledge of nutritional, nutraceutical, and anti-nutritional aspects of cowpea will help in designing appropriate dietary plans/guidelines as per ethnic groups and geographic regions. Besides being in high demand due to its nutritious and nutraceutical values, cowpea cultivation is also supported because of the desirable agronomic attributes such as ease of cultivation, less necessity for fertile soils, their adaptability, and steadiness across all continents, even in drought-afflicted regions (de Silva et al. 2021).

5 Conventional and Molecular Approaches for Enhancing Nutritional Potential

Different processing methods, depending on geographical regions, are widely adopted by respective natives to reduce anti-nutrients present in cowpea and to enhance nutritional profile and also for the ease of intake. These methods include boiling, sprouting, steaming, frying, soaking, de-hulling, and grinding, which result in the alteration of the properties and bioavailability of some nutrients, increase in protein and mineral content (Fabbri and Crosby 2016), increase in phenolics and flavonoids (Laila and Murtaza 2014), and protein quality and digestibility (Deol and Bains 2010). Fermented cowpea flour showed improved antioxidant and hypolipidemic effects on rat (Kapravelou et al. 2015).

Extensive efforts through molecular tools have been made for breeding cowpea varieties resistant to biotic and abiotic stresses, to enhance yield and productivity, but reports on improving nutritional profile through molecular approaches are scarce. However, research on enhancing cowpea nutritional aspects has been conducted for evaluating biochemical properties of cowpea germplasm. Considerable data has been generated on estimation of the protein and minerals content of cowpea germplasm with the objective to identify appropriate parents for breeding nutrient-dense improved varieties (Fig. 3). For example, evaluation of cowpea germplasm lines for protein and minerals (Cu, Fe, Zn, Mg, Ca, and K) content (Gerrano et al. 2019) and analysis of cowpea cultivars for proteins and minerals under rain-fed conditions in

Petrolina, Brazil (Santos and Boiteux 2013), suggested the identification of high protein and mineral content genotypes which could be used in breeding for new biofortified cowpea cultivars.

Reports on cowpea genetics for biofortification with crucial minerals are still lacking, of which one study provided genetic factors for enhancing minerals in cowpea seeds. This study claimed the least number of genes controlling the augmentation of minerals ranging from 2 (K) to 11 (P) with transgressive segregation pattern and either oligogenic or polygenic control for all minerals analyzed (Fernandes et al. 2015). Composite interval mapping detected two QTLs for total soluble solid in pods using the population derived from the cross between yardlong bean (accession JP81610) and a wild cowpea (*V. unguiculata* ssp. *unguiculata* var. *spontanea*) (accession JP89083) (Kongjaimun et al. 2013). Recently in a genotype-by-environment interaction study, the expression of nutritional properties (protein and minerals concentrations) in cowpea leaves was assessed in different agro-ecologies of South Africa and typical agronomical practices of smallholder farmers (Gerrano et al. 2022). This study showed genetic variations among selected genotypes for all four analyzed traits and also influence of climate on expression of these traits. This study suggested that nutritional profile of legume plants is a function of local soil properties and soil health (Gerrano et al. 2022).

Mutation breeding is generally adopted to introduce desired simply inherited trait in elite cultivars. The International Atomic Energy Agency (IAEA) in association with the Food and Agriculture Organization (FAO) encourages the deployment of mutation-inducing technologies in plants for its member states. So far, there have been 22 mutant varieties developed using physical and chemical mutagens in cowpea. Few reports are available in cowpea cultivar development for biotic and abiotic stress tolerance using induced mutations (Horn et al. 2017), of which one study showed increase in the protein content in grains of some mutants by up to 13.3% (mutant from IT84E-124) and 13.64% (mutant from Vita 7) upon treatment with 1.0 mM NaN_3 (Odeigah et al. 1998). Raina et al. (2022) reported that there was a concurrent increase in yield and nutrient density (Protein, Fe, Zn, and Cu) in M_4 mutant lines in cowpea. Seven cowpea cultivars developed through mutation breeding exhibiting high seed productivity, earliness, large grain size, resistance to yellow mosaic virus, or augmented fodder production were released between 1981 and 2007 in India (Punniyamoorthy et al. 2007). One of the mutant varieties, the multifaceted cowpea mutant variety "TC-901," has desirable attributes like high grain yield, fodder yield, high seed protein content (28%), resistance to cowpea mosaic virus, and amenable for summer cultivation. The progress in enhancing nutritional profile of cowpea is underway through evaluation of germplasm lines for identifying appropriate parents for breeding elite, nutri-rich cultivars.

6 Genomics of Nutritional Quality

Information on genomics of the crop nutrition profile has laid a starting point for the implementation of advanced molecular breeding and genetic engineering methods for crop improvement and also helps in switching from time-consuming

labor-intensive conventional breeding. Nutritive value of a crop can be enhanced either by upregulating genes/QTLs associated with nutritive traits or by suppressing genes involved in anti-nutrient biosynthesis for which knowledge of target genes is required. Efforts have been made to explore and understand the genomics behind nutritional features in crops like cereals, pulses, oil seeds, legumes, millets, and vegetables in the form of evaluation of crop germplasm, development of genetic resources through introduction of new genotypes/novel genes, mapping and characterization of genes through quantitative trait locus (QTL) interval mapping and sequencing, association mapping such as genome-wide association study (GWAS), and marker-assisted breeding as discussed as follows. For example, development of sorghum with low cyanogenic potential suitable for cattle feed generated by down-regulating an important enzyme of dhurrin biosynthesis pathway through antisense strategy (Pandey et al. 2019) provides opportunities for fine-tuning nutritional quality in grain crops. Interestingly in mung bean which is close to cowpea, 43 noteworthy marker trait associations (MTAs) for seed calcium, iron, potassium, manganese, phosphorous, sulfur, or zinc concentrations were discovered through genotyping by sequencing (GBS) approach (Wu et al. 2020). Coming to the crop improvement through genome engineering, the technique has been successfully applied to few crops including soybean for reducing linolenic acid (silencing of the ω-3 *fad3* gene) (Flores et al. 2008) and increasing oleic acid (suppressing *fad2-1* gene) (Christou et al. 1990). A database for cowpea, "EDITS-Cowpea," has all the required information on the cowpea traits especially related to grain quality-related traits which can be useful to breeders for crop improvement (EDITS-Cowpea 2022). A search conducted for nutritional quality as trait and zinc content as the specific search item showed that the cowpea varieties (240) in the database have a range of zinc content (34.5–46 mg/g).

A remarkable initiative is taken by the Kirkhouse Trust, a UK-based charitable organization through Cowpea Genomics Initiative (CGI) project (http://cowpeagenomics.med.virginia.edu/CGKB/) to help cowpea research community. CGI project is aimed at leveraging advanced molecular tools for gene study and bettering cowpea. This project attempts omics studies including transcriptome, proteome, and metabolome analyses to get comprehensive knowledge on the fundamental biology of host and important agronomic characteristics and also sequencing and annotation of the gene space (gene-rich region of the cowpea genome) (Chen et al. 2007). Muñoz-Amatriaín et al. (2017) developed genome resources for the analysis of an African cultivar IT97K-499-35 which included whole-genome shotgun assembly, a bacterial artificial chromosome physical map, and assembled sequences for use in linkage mapping, synteny analysis, and germplasm characterization. In a further study, Lonardi et al. (2019) developed a genomic assembly with the help of single-molecule real-time sequencing complemented with optical and genetic mapping tolls to categorize repetitive elements, genes, and gene families. Noteworthy advanced genome editing technology, CRISPR-Cas9 system, has been successfully applied first time in cowpea which involved the inactivation of symbiosis receptor-like kinase gene via *Agrobacterium*-mediated hairy root transformation method (Ji et al. 2019). Such

project initiatives and implementation of genomics techniques may help in promoting cowpea research for improvement in nutritional quality in related crops through genomics-based trait introgression.

7 Future Perspectives and Conclusions

Increased food production and management of malnutrition always remain major challenges for the underdeveloped and developing countries, whereas in the developed world, increase in the occurrence of several chronic diseases and occupation-related hazards are a priority. The situation is getting worrisome due to the continuously increasing population and climate changes that directly affect agriculture sector. Cultivation of important staple crops in all ecological conditions and climate change scenarios is not possible. In this regard, crops with wider adaptability can help in ensuring food and nutritional safety. Cowpea is a drought-tolerant, climate-adaptable crop amenable to diverse cropping systems. Cowpea is an excellent nutrient-rich food source belonging to orphan crop category that remains to be extensively cultivated since, besides being highly nutritious, it also possesses many health-promoting and health-protective effects. Cowpea nutraceutical properties are attributed to bioactive or functional chemicals like peptides, resistant starch, digestible fiber, plant-derived compounds, antioxidants, vitamins, etc. that get better depending on processing methods. Cowpea has been shown to better the lipid profile, blood glucose content, blood pressure, cancer prevention, anti-inflammatory, anti-diabetic, etc. It is a multipurpose legume crop used for both human consumption and livestock fodder. In the current scenario, though cowpea is a nutrient dense food with several health benefits, it is a neglected crop because of huge losses in its production due to biotic and abiotic stresses, cultural beliefs, and limited research priority. Modern breeding technological interventions will have to be accelerated for cowpea breeding. Also, intensive clinical research on the anti-inflammatory and anti-cancer activity of cowpea is required to realize the nutraceutical aspects of cowpea for better acceptability.

Breeding for biofortification in cowpea is in the budding stage, and hence the adoption of molecular tools and advanced genomic strategies is needed to accelerate the progress of development of nutrient-dense and nutraceutical-rich varieties. This could be achieved through mining available genetic resources for target and novel genes/traits in association with chance breeding (targeted mutation, hybridization, backcrossing, pedigree, and recurrent selection), modern breeding methods (space breeding, speed breeding, genomic selection, and gene/genome editing), innovative techniques (mutagenesis breeding), transgenic development, demand-led breeding, and multi-omics analysis studies. Cowpeas can become a super crop for alleviating nutrient deficiency and health problems. With further research on its nutraceutical aspects, its acceptance will also be on the rise. Being the cheapest protein source and climate change-resilient crop, next-generation cowpea could be promoted for achieving future food and nutritional security at the global level.

Abstract

Lentil is a highly consumed pulse crop in India, Bangladesh, Nepal, and many other countries. This crop is rich in nutrients which are easy to digest and palatable. In the form of a whole food source of nutrition, it can minimize the effect of malnutrition which is prevalent worldwide. Biofortification as a tool provides us great opportunity to further enhance nutrient content biologically. A few studies showed considerable genetic variability for nutrients including iron, zinc, calcium, magnesium, selenium, prebiotic carbohydrates, and folate concentration in lentil, which may be further improved. While breeding for nutrients, the role of environmental effects should be taken into consideration to provide a widely adapted plant variety. A number of genomic regions have been mapped using molecular markers; however, the intensity and coverage of the experiments were low, and this area needs more efforts to make marker-assisted breeding a reality in lentil breeding for nutritional traits. Lentil also has anti-nutrients like phytic acid, which influences the bioavailability of nutrients. In addition to traditional breeding approaches, efforts are underway to make use of cis- or transgenic technologies to enhance nutritional quality in many crops; the same may be adopted based on need in the case of lentil. Biofortified lentil varieties recently released which are rich in iron and zinc concentration; however, more varieties are required to cover different agroclimatic regions or niches. In short, more focused efforts are required to identify high-yielding, biotic and abiotic stress-tolerant, and nutrient-rich new-generation lentil varieties that will definitely boost health status among the consumers, especially from today's perspective when plant-based protein or other nutrients are gaining huge popularity.

1 Introduction

Malnutrition is caused by unavailability of sufficient quantity of nutrients like proteins, carbohydrates, micronutrients, and vitamins. Higher quantity of anti-nutrients in our everyday meals is also detrimental to our health. This situation is present in both developed and developing countries. Consumption of carbohydrate-rich diets throughout the world aggravated the situation further since these are deficient in highly essential micronutrients, causing long-lasting disorders or diseases among the people (Stewart et al. 2010; Bouis et al. 2011). Thus, "hidden hunger" shows its effects on the well-being of the micronutrient-starved population, though in many cases have sufficient calorie intake. Implication of such long exposure to low or less than recommended requirement of micronutrients or vitamins causes serious health issues including lower birth weight, anemic condition, impaired learning ability,

high mortality and morbidity, reduced working ability, and increased treatment costs (Batra and Seth 2002; Welch and Graham 1999). Deficiencies of iron (Fe), zinc (Zn), selenium (Se), and iodine (I) are not uncommon in South and South-East Asian countries along with Indian subcontinent. According to an estimate, nearly 60% of the global population is usually facing deficit of Fe (Yang et al. 2007) whereas 33% of Zn (Hotz et al. 2004) and almost 15% of Se (FAOSTAT 2007).

About one-fourth of the people globally complain of anemia (WHO 2008), whereas 17.3% people are devoid of sufficient Zn intake (Wessells and Brown 2012), causing 433,000 deaths annually of children below age 5 (WHO 2009). About 20% children morbidity of age less than 5 years were due to the inadequate intake of vitamins like vitamin A, Zn, Fe, and/or I (Prentice et al. 2008). In preschool children and pregnant and lactating women, deficiencies of essential micronutrients especially Zn and Fe are observed more common (Welch and Graham 1999; White and Broadley 2009; WHO 2012). About one billion people suffered with Keshan (cardiomyopathy) and Kashin–Beck (osteoarthropathy) diseases caused by Se deficiency (Reilly 1996). Countries like Australia, New Zealand, Africa, the UK, Thailand, Finland, Central Siberia, Denmark, Turkey, Northeast to South-Central China, parts of India, Bangladesh, and Nepal have low levels of soil Se which is bioavailable (100–2000 $\mu g\ kg^{-1}$), and due to this, crops grown in these countries have low concentration of Se in them, creating a perfect ground for Se deficiency-related health issues (Fordyce 2005; Lyons et al. 2005; Spallholz et al. 2004, 2008). Besides the role of a typical micronutrient, Se prevents cytotoxic effect of arsenic (Biswas et al. 1999); arsenic toxicity exists in many crop ecologies in South Asia, as Se and As detoxify each other's effect (Holmberg Jr and Ferm 1969; Levander 1977). Similarly, deficiency of folate prevails worldwide over millions and leads to serious health problems, including birth defects and health risks both for the mother and child (Gupta et al. 2013).

To combat the global malnutrition-related issues, several mitigations have been adopted by governments, nongovernmental organizations, and the United Nation. Food fortification through supplements is effective to bolster health in many communities from both developed and developing world. In fact, for many processed or polished food grains or products, food fortification is mandatory in many countries. However, food fortification causes price of the fortified food to move upward beyond the capacity of common consumers in target communities who are poor or have other priorities than to spend higher for fortified food purchase for consumption. Here comes the role of another very unique and successful strategy to develop biofortified crop varieties, which usually requires one-time investment (Bouis et al. 2011).

Food crops can be biofortified in two ways: one of the popular method is to increase the concentration of target micronutrient by the external application of such micronutrient over the plant part for their ready absorption followed by translocation within the plant system and ultimately in the grain or any other plant part which is consumed. Crop rotations and intercropping including soil microbes may also be the components in agronomic biofortification helping in transport of target micronutrient in the soil (White and Broadley 2009). There are many success stories available for agronomic biofortification like Se can be achieved by its spraying in lentil

(Thavarajah et al. 2015) and so in crops like potato tubers, field pea seeds, and tea leaves (Smrkolj et al. 2006; Turakainen 2007). Increase in production cost, particularly in developing countries, agronomic biofortification is not always feasible among the growers particularly for the smaller-land holdings (Graham and Rengel 1993). Complexity in the application of perfect crop growth stages as this method is vulnerable to both external and internal crop growing conditions (Terry et al. 2000). Application concentration of micronutrients and any allied inorganic nutrients should be standardized in many crops, thereby reducing the chances of any induced phytotoxicity. Secondly, genetic biofortification is a plant breeding-based technique wherein nutritionally rich high yielding food crop varieties are achieved by manipulating the genetic buildup of cultivars using either classical plant breeding tools or modern genomic approaches. This approach offers an one-time investment and cost-effective method of delivering essential micronutrients and, thereby, does not require repeated efforts to fortify during food processing; therefore, biofortified seeds can be supplied to the target community who can easily grow, produce, and maintain the seed chain for a long period (Graham et al. 2007; White and Broadley 2009). It is a tool for food crop improvement, and sustenance which have been discussed by Miller and Welch (2013) and Saltzman et al. (2013). Several workers have discussed approaches to enhance zinc, selenium, and iron (Hawkesford and Zhao 2007; Velu et al. 2014) and deployment of genomics for biofortification of Fe and Zn in wheat (Borrill et al. 2014) and in common bean (Blair 2013; Petry et al. 2015). Genetic potential for high Fe and Zn concentrations and low anti-nutrients like PA in various food crops such as maize (*Zea mays* L.), rice (*Oryza sativa* L.), wheat (*Triticum sativum* L.), common bean (*Phaseolus vulgaris* L.), and field pea had been reviewed in recent years (Frossard et al. 2000; Gomez-Galera et al. 2010; Amarakoon et al. 2012). This chapter will provide information on the genetic potential of lentil as a whole food biofortified crop and recent achievements made in this direction.

2 Description on Nutritional Components

Lentil (*Lens culinaris* subsp. *culinaris* Medikus) is a nutritious food legume crop. It is cultivated in more than 50 countries but majorly grown in India (36%), western Canada (18%), south-eastern Turkey (15%), and Australia (4%) (FAOSTAT 2011). Like other pulses, it is rich in proteins, zinc, iron, folate, selenium, vitamins, and carotenoids (Thavarajah et al. 2011a, b; Johnson et al. 2013a, b; Gupta et al. 2013) (Table 1). Serving 100 g of lentil grain can fulfill the recommended daily allowance (RDA) – Fe: 41–113%; Zn: 40–68%; and Se 77–122% (Table 1). The pulse is rich in ß-carotene (2–12 µg/g) but contains less phytic acid phosphorous (0.7–1.2 mg/g). The amount of phytic acid has been found relatively lower than cereal and pulse crops with low PA (rice: 2.23 mg/g; soybean: 4.86 mg/g; wheat: 2.51 mg/g; maize: 3.7 mg/g; and common bean: 1.38 mg/g). As a whole food, lentil can be cooked within 10 min which is a great time and energy saver (Thavarajah et al. 2011a). Therefore, lentil is a natural candidate for biofortification efforts to develop a nutritionally rich, high protein, high iron and zinc containing pulse crop which if

Table 1 Nutritional value of lentil seeds

Protein	20–25%
Carbohydrate	50–60%
Fat	0.7–0.8%
Ca	60–70 mg/100 g
Fe	7–9 mg/100 g
Zn	4–5 mg/100 g

eaten with cereals can fulfill both calorific as well as micronutrient requirements. This will further help to fight global malnutrition problem among poor populations or communities. The various nutritional/antinutritional compounds estimated in lentil grain are given in Table 1.

3 Traits Required for Development of Biofortified Lentil

Modern breeding approaches along with conventional tools were found to be highly suitable for the breeding of nutrient-dense crop cultivars with high bioavailability of phytonutrients (Nestel et al. 2006). To achieve it, first targets should be fixed with respect to the status of nutrients and anti-nutrients present in the grain or seed. After knowing this information, breeder can plan to improve the bioavailability of a nutrient either by increasing its concentration or by reducing the concentration anti-nutrients present. Main objective of major biofortification efforts in cereals and pulses involves high iron and zinc concentration as target for breeding. Beside this, an anti-nutrient (phytic acid), which reduces the bioavailability of iron and zinc, is also targeted for reduction of their concentration by introgressing the genes or quantitative trait loci (QTLs) that produce anti-nutritional phytochemicals in lower concentration in plants. These potential biofortification-related traits are presented in Table 2.

4 Genetic Resources of Health-Related (HR) Genes

A number of genebanks store cultivated and wild lentils in their repository (Table 3). The largest *Lens* collection (31,970) is Genesys followed by ICARDA genebank which conserved 13,958 *Lens* accessions in Morocco (Dikshit et al. 2022). Australia, Iran, the USA, Russian Federation, and India have 1000–6000 accessions in their respective genebanks (Table 3). Canada has 1139 *Lens* accessions in their genebank. Variable numbers of lentils (678–1095) are collected by Turkey Syria, Hungary, Egypt, China, Pakistan, Bangladesh, and Ethiopia for conservation in respective genebanks. Core and mini-core sets from local collection have been developed by many research groups which are valuable genetic resources for their use in breeding

Table 2 Potential areas for biofortification in lentil

Traits	Range
Nutritional traits	
Protein	15.9–32%
Starch	34.7–65.0%

programs (Tripathi et al. 2022). However, there is a need in lentil for evaluation of these core or mini-core sets for nutrition-related traits.

ICARDA *Lens* accessions around 76% have been characterized for morphological and phenological attributes (Kumar et al. 2016c). Apart from this, under the AGILE project that is led by Canadian Scientists, 324 accessions of lentil diversity panel were phenotyped for phenological traits (different nine diverse locations for two seasons) around the world (Wright et al. 2021). This set has also been genotyped using an exome capture array and seeds from 321 lines have been deposited in the ICARDA genebank (Ogutcen et al. 2018).

Lentil is dense with protein contents and an affordable pulse crop that is an ancient crop and has a long domestication history. The lentil or *Lens* species belongs to the family Fabaceae and its crop wild relatives (CWR) are naturally and widely distributed in Mediterranean regions and Southwest Asia (Guerra-García et al. 2021). The genus *Lens* ($2n = 2x = 14$) phylogenetically belongs to the tribe Vicieae.

The tribe contained cool season legume crops which are members of the family Fabaceae (Ladizinsky 1979). Presently, the *Lens* genus contained seven closely related species mainly *Lens culinaris, L. orientalis, L. tomentosus, L. lamottei, L. odemensis, L. ervoides,* and *L. nigricans* (Table 4). The studied taxonomic relationships on the basis of morphology, hybridization behavior, cytogenetics, and molecular markers do not accept classification at the level of species and

Table 4 *Lens* gene pool and species

S. No	Gene pool	Species name	Type	References
1	Primary	*Lens culinaris*	Domesticated	Ladizinsky 1979; Wong et al. 2015; Guerra-García et al. 2021
		Lens orientalis	Wild	
		Lens tomentosus	Wild	
2	Secondary	*Lens odemensis*	Wild	
		Lens lamottei	Wild	
3	Tertiary	*Lens ervoides*	Wild	
4	Quaternary	*Lens nigricans*	Wild	

subspecies. Although, researchers commonly agree that *L. culinaris* ssp. *orientalis* is the wild progenitor of *L. culinaris* ssp. *culinaris* whereas *L. nigricans* is distantly related. Apart from this, *Lens culinaris* subsp. *culinaris* is subdivided into two types: the microsperma cultivars having small-sized seeds and another with reddish cotyledons which is believed to be originated from near East and Central Asia region and the macrosperma cultivars having large seeded red, yellow, and green cotyledon are native to Mediterranean region.

Based on a study (Schreier et al. 2012), genotyping data-based analysis of all the individuals like *L. culinaris/L. orientalis/L. tomentosus* and *L. ervoides/L. nigricans* each belong to one cluster whereas *L. lamottei and L. odemensis* exhibited diversified ancestry with *L. ervoides/L. nigricans cluster in* major proportion. The Chinese group of researchers (Wong et al. 2015) also categorized *Lens* in seven different taxa in four separate gene pool: as primary (*L. culinaris*), secondary (*L. orientalis*), tertiary (*L. tomentosus* and *L. lamottei)*, and quaternary (*L. ervoides* and *L. nigricans*). However, crossing incompatibility for hybridization in the genus *Lens* among the gene pools reported by Cubero et al. (2009). Many studies reported the crossability of *L. odemensis* and *L. orientalis* with *L. culinaris* (Fratini and Ruiz 2006; Muehlbauer et al. 2006). Whereas, some of the studies showed hybrid embryo abortion, albino seedlings, and hybrid sterility are major restrictions in the wide hybridization among *Lens* species. Gupta and Sharma (2006) stated that hybrid embryos abort while crossing the parents from the tertiary gene pool with *L. culinaris.* These hybridization barriers can be overcome through tissue culture-based embryo rescue methods (Tullu et al. 2013). Apart from this, application of GA3 (gibberellic acid) also impacted positively and produced successful crosses of *L. culinaris* with *L. ervoides, L. odemensis,* and *L. nigricans* (Fratini and Ruiz 2006).

In due course of lentil domestication process, uninterrupted selection reduced genetic variation/allelic diversity of members of primary gene pool in comparison to secondary, tertiary gene pool or wild progenitor. In the *Lens* primary gene pool,

reduced allelic variation during domestication is the major hindrance for enhancing productivity and other useful agronomical traits. Because of the impact of climate change and unpredictable weather condition during growing season, effective adaptation strategies to combat with biotic and abiotic stresses are required.

Therefore, crop wild relatives (CWRs) have remarkable potential and reservoir of economically important genes/alleles to enhance crop productivity as well as the tolerance against the biotic and abiotic stresses. Hence, CWRs are required for lentil improvement as potential sources of useful gene(s) for the deployment in cultivars. Thus, wild relatives act as most important donors for added genetic variability in cultivated crops.

5 Genetic Variability for Biofortification Traits in *Lens* Gene Pool

5.1 Primary Gene Pool

Since the inception of the HarvestPlus program, for many crops, identification of natural variants with high concentrations of iron and zinc in the cultivated gene pool has been a principal approach for the development of biofortified crop cultivars. As the natural variants are identified, if they are of less agronomic value, then such nutritional traits are transferred to agronomic bases by either hybridization or other techniques. As discussed by Kumar et al. (2016a), screening for high iron and zinc concentration in lentil was conducted in many countries, including India, Turkey, Syria, Canada, and Pakistan (Table 5). In these studies, folate, iron, and zinc concentrations have been targeted. In a study involving 19 lentil genotypes pertaining to the concentration of Fe and Zn from various markets of Canada, narrow range of genetic variability was observed. Fe concentration was found ranging between 73 and 90 mg of Fe kg^{-1} whereas Zn concentration between 44 and 54 mg of Zn kg^{-1} in these genotypes (Thavarajah et al. 2009a). This was followed by a large-scale experiment conducted by the International Center for Agricultural Research in the Dry Areas (ICARDA) under the HarvestPlus Challenge program in which they have screened iron (42–132 ppm) and zinc (23–78 ppm) concentration in a large collection of more than 1500 lentil accessions from cultivated gene pool (Sarker et al. 2007; HarvestPlus 2014). In a multiyear and multilocation study with respect to concentration of folate, significant genetic variability was observed which ranged between 216 and 290 μg/100 g in 10 lentil cultivars of the USA. Compared to other pulses like chickpea, yellow field pea, and green field pea, lentil was having more folate concentration than other pulses (Gupta et al. 2013). Geographical areas with limited zinc availability in soils, including India, Pakistan, China, Iran, and Turkey, are also countries where human Zn deficiency is most prevalent (Hotz et al. 2004; Khan et al. 2008). Eyüpoğlu et al. found that more than 50% of the land (14 Mha) in Turkey is Zn deficient. The high prevalence of Zn-deficient soils in Turkey has been suggested as a major cause of Zn deficiency and to be indirectly related to deficiencies of other micronutrients. Turkish landraces of lentil also

Table 5 Genetic variability for biofortification traits in lentil

Type of genetic material	No. of accessions	Compound with range of concentration	Country	References
Landraces, wild types, and breeding lines	1600	Fe: 43–132	ICARDA, Syria	Sarker et al. 2007
		Zn: 22–78	do	Baum et al. 2008
Lentil germplasm		Fe: 41–109 Zn: 22–78

		Zn: 44–54		
		Se: 425–673		
Landraces and cultivars	46	Fe: 49–81	Turkey	Karakoy et al. 2012
		Zn: 42–73		
Landraces and breeding material	96	Fe: 37–157		
		Zn: 26–65	India	Kumar et al. 2018a
Exotic lines		Se: 240–630		
Varieties	19	Fe: 73–90	Canada	Thavarajah et al. 2009a
		Zn: 44–54 mg		
Varieties		Folate: 216–290 μg/100 g	The USA	Gupta et al. 2013
Elite breeding lines	41	Fe: 50.85–136.9 mg	India	Kumar et al. 2014a
		Zn: 40.26–81.5		
Varieties	7	Se: 74–965 μg kg^{-1}	Bangladesh	Rahman et al. 2013
Varieties	23	Fe: 43–92 ppm	Canada	DellaValle et al. 2013
		PA: 3.8–15.9 mol/g		
Germplasm line	–	Beta-carotene: 2–12 μg/g	The USA	Thavarajah et al. 2011b
Varieties	9	Prebiotic carbohydrate	The USA	Johnson et al. 2013b
Cultivars and breeding lines	192	Se: 6–254 μg/kg^{-1}	Syria, Nepal, Morocco, the USA, Australia, and Turkey	Thavarajah et al. 2011b

exhibited a range of genetic diversity not only for different micronutrients (Karakoy et al. 2012).

In India, in a study, 41 elite lentil lines were tested for stability of grain Fe and Zn concentration across multiple locations. Pooled analysis of variance over locations detected significant differences between genotypes, locations, and genotype × location interaction. The average grain Fe concentration over the locations was obtained for L 4704 (137 mg/kg grain), while the grain Zn concentration was highest for VL 141 (82 mg/kg grain). Although both micronutrients were affected by the environment, iron concentration exhibited more G × E interaction compared to Zn concentration (Kumar et al. 2014a). Lentil seeds are also a very good source of organic Se (selenomethionine) (Thavarajah et al. 2007, 2008), and it was also reported that cooking had limited modifying effects on selenomethionine concentration (Thavarajah et al. 2008). In case of Se, significant genetic variability was noted in the genotypes from various countries (Thavarajah et al. 2011b; Rahman et al. 2013). In Bangladesh, total Se concentration was estimated in soil and lentil seeds received from both farmers' fields and yield trials. Average of Se concentration in farmers' fields was 163 and 312 μg kg^{-1}, for soil and lentil seed, respectively. It was further calculated that 50 g of lentil consumption contributes 28% of the recommended daily allowance of Se (55 μg per person per day). Relative bioavailability of Fe was estimated through in vitro digestion/Caco-2 cell model in 23 genotypes of cultivated gene pool of lentil, wherein significant genetic variability reported for Fe and relative iron bioavailability and phytic acid (PA) concentration (DellaValle et al. 2013). The pulse is also a great source of beta-carotene where significant genetic variability (2–12 μg/g) was reported in the USA (Thavarajah et al. 2011b). Prebiotic carbohydrates are important to maintain gut microflora, and significant genetic variation exits in lentil for this complex biochemical trait (Tahir et al. 2011; Wang et al. 2009). Johnson et al. (2013b) reported the genetic variability in prebiotic carbohydrates such as raffinose-family oligosaccharides, sugar alcohols, fructooligosaccharides, and resistant starches in 10 commercially grown lentil varieties of the USA from cultivated genepool, which may be further elevated through the approach of breeding by utilizing more number of germplasm or varieties under screening. Significant environmental effect on this type of traits demands site-specific breeding (Johnson et al. 2013b).

5.2 Secondary or Tertiary Gene Pool

Wild gene pool or alien gene pool or secondary and tertiary gene pool always are sources of lost useful genes or alleles, which were lost from the cultivated species in due course of evolution (Doyle 1988; Tanksley and McCouch 1997). The breeding history of a crop species has a bearing on the extent, type, and size of such wild sources of alleles. Being the most abundant curator of genetic resources in lentil,

ICARDA in Lebanon holds more than 500 wild lentil accessions, representing 6 wild *Lens* species from 26 countries. Many species of wild *Lens* genepool have expressed their cross compatibility with cultivated species (Fratini et al. 2004; Fratini and Ruiz 2006; Muehlbauer et al. 2006) after employing modifications in tissue culture-mediated hybridization procedures (embryo rescue) or by using different doses of plant growth regulators. Accessions from wild genepool have been identified as donors for high concentration of micronutrients in many crops (Cakmak et al. 2000; Ortiz-Monasterio et al. 2007).

Seed micronutrient concentration of cultivated and wild lentils is not much known. Sen Gupta et al. (2016) estimated micronutrients in the seeds of 26 lentil genotypes, representing 4 species and 3 subspecies of *Lens*. Concentrations of Fe, Zn, Ca, Cu, and Mg in seeds varied from 26 to 92, 17–51, 97–536, 3–12, and 272–892 mg kg^{-1}, respectively, among the *Lens culinaris* genotypes. Mineral concentrations for *L. lamottei* (Fe = 64–80, Zn = 26–40, Ca = 311–434, Cu = 2–6, and Mg = 754–839 mg kg^{-1}), *L. nigricans* (60–70, 33–39, 508–590, 3–4, and 445–738 mg kg^{-1}), and *L. ervoides* (65, 37, 339, 6, and 638 mg kg^{-1}) were similar to *Lens culinaris* genotypes. More number of germplasm should be tested in future to identify higher genetic variation in lentil for these micronutrients.

Kumar et al. (2018b) evaluated a core set of 96 wild accessions extracted from 405 global wild annual collections comprising different wild *Lens* species for micronutrients. Significant genetic variation was observed for different micronutrients including Na (30–318), K (138.29–1578), P (37.50–593.75), Ca (4.74–188.75), Mg (15–159), Fe (2.82–14.12), Zn (1.29–12.62), Cu (0.5–7.12), Mn (1.22–9.99), Mo (1.02–11.89), Ni (0.16–3.49), Pb (0.01–0.58), Cd (0–0.03), Co (0–0.63), and As (0–0.02) (mg/100 g). Significant positive correlations among micronutrients were also observed. It is noteworthy to mention that accessions representation from Turkey and Syria had maximum variability for different micronutrients. Hence, wild gene pool can be used to transfer favorable alleles controlling higher micronutrient concentrations in lentil.

6 Classical Genetics and Traditional Breeding of HR Traits

6.1 Genetics of HR Genes

Traits like iron and zinc concentration and folate concentration are quantitatively inherited. In cereals, it was reported long ago that these kinds of traits are controlled by several genes with individually smaller effects on the trait mean. In wheat, generation mean analysis was conducted to find out the genetics of iron and zinc concentration (Amiri et al. 2020). Due to the role of fixable gene effects and high heritability for grain iron concentration, selection for this trait could be effective in early generations. Grain zinc concentration was having nonadditive gene effects and low heritability; hence selection should be practiced during advanced generations. Both kind of heterosis at both crosses for iron and zinc concentration were significantly negative. Response to selection varied over locations for iron and zinc concentrations.

6.2 Site-Specific Breeding for Biofortification Traits

Environmental conditions during crop growth including soil pH, soil temperature, photoperiod, rainfall, soil organic matter, and texture affect the rate of accumulation of micronutrients into seeds (Cakmak 2008; Joshi et al. 2010). Hence, knowledge of such an optimal environment for growing facilitates the sink deposition of iron and zinc in seed, which is the key to the success of any biofortification research program. Here comes the role of genotype × environment interactions, which is usually very high for traits involving secondary metabolism. It is important to encourage breeders to develop crop cultivars that are site-specific and not look for wider adaptation, as that will be contrary to the overall breeding behavior of these traits.

In lentil, iron, zinc, and phytic acid concentrations vary over locations, soil conditions, and weather parameters (Thavarajah et al. 2009a, b; Kumar et al. 2018a). It was further observed that samples from one geographical region varied from another (Thavarajah et al. 2011a). For example, Fe concentration was higher in samples of Syria (63 mg/kg), Turkey (60 mg/kg), and the USA (56 mg/kg). Likewise, Zn concentration was higher in the seeds from Syria (36 mg/kg), Turkey (32 mg/kg), and the USA (28 mg/kg). Se was high in the seeds from Nepal (180 μg/kg) and Australia (148 μg/kg) to Syria (22 μg/kg), Morocco (28 μg/kg), and Turkey (47 μg/kg) (Thavarajah et al. 2011a). Calcium was high in samples from Turkey (0.48–1.28 g/kg), while lentils grown in India have high Fe (37–156 mg/kg) and Zn (26–65 mg/kg) concentrations (Karakoy et al. 2012; Kumar et al. 2016a).

A significant year × location interaction has been observed for total folate concentration in 10 lentil cultivars from the USA in a study conducted over 2 years (Gupta et al. 2013). It was observed that temperature influences the concentration of iron (Fe), phytic acid (PA), and zinc (Zn) in lentil genotypes on growing under different temperature regimes: Saskatoon, Canada (decreasing temperatures) and Lucknow, India (increasing temperatures).

In lentil seeds, concentrations of Fe, PA, and Zn were significantly higher in the regime with a rising temperature than in the regime with a decreasing temperature. Microclimatic factors control the iron, zinc, and phytic acid concentrations in lentil, which show a quite similar trend as compared to other candidate crops (Gupta et al. 2013). Under changing climatic conditions, fluctuating temperature regimes (particularly warm night temperature) may affect the anti-nutrients like phytic acid biosynthesis in a negative way, further complicating the biofortified varietal improvement in this crop species.

6.3 Breeding for Biofortified Lentil Cultivars

Initially, through the HarvestPlus program, several already released varieties were tested for iron and zinc concentration (i.e., Ethiopia, Bangladesh, Morocco, Turkey, Syria, and Nepal). Many of these varieties which were identified as high yielding as well as having high iron and zinc concentration are listed in Table 3. A few of these lines are promoted by the national partners to reach to lentil growers rapidly. In

Bangladesh, high iron and zinc containing varieties such as Barimasur 4 and Barimasur 5 are promoted to all corners of the country.

HarvestPlus (2014) reported that several released varieties of lentil that possess high iron and zinc concentrations and high yield potential have been identified in Nepal; they are: Sisir (98 ppm Fe and 64 ppm Zn), Khajurah-2 (100.7 ppm Fe and 59 ppm Zn), Khajurah-1 (58 ppm Zn), Sital (59 ppm Zn), Shekhar (83.4 ppm Fe), and Simal (81.6 ppm Fe). In Nepal, another lentil variety, ILL 7723 (Khajura-4), was released for general cultivation in Nepal (Darai et al. 2020) with high iron and zinc concentration. This is a selection in materials from ICARDA, Morocco (Sel89503). In India, two biofortified lentil varieties, Pusa Ageti Masoor (Fe 65 ppm) and IPL 220 with high Fe (73–114 ppm) and Zn (51–65 ppm) concentrations, have been released so far and both of these became very popular among the lentil growers. Pusa Ageti Masoor is covering the central part and IPL 220 covers the northeastern plain zone of the country.

7 Genetic Analysis of Agronomic Traits

The *Lens* gene pool, especially *Lens culinaris* (lentil), and its wild progenitor are successfully cultivated in areas of low rainfall (less than 250 mm/year) on marginal and poor soil. Available germplasm in the primary gene pool demonstrated poor water extraction capacity and a lower growth rate as compared with secondary and tertiary gene pool. It is well known that the most prominent abiotic stress is drought.

The drought tolerance capacity has been identified and reported in *L. ervoides, L. nigricans, and L. odemensis* (Gupta and Sharma 2006). The *L. culinaris.* spp. *orientalis* provides valuable sources of drought tolerance gene for low rainfall environments like Syria, Jordan, Azerbaijan, Turkmenistan, and Tajikistan. Moreover, it is reported that interspecific offsprings are capable of drought tolerance that is associated with relative leaf water content, pubescent leaves, cell membrane stability, higher root-shoot ratio, higher transpiration, decreased wilting, and reduced canopy temperature (Omar et al. 2019). Recombinant inbred lines (RILs) developed from crosses of *L. culinaris* with *L. odemensis* and *L. orientalis* were evaluated by Sanderson et al. (2019). They found that tolerance to stress is associated with delayed flowering, reduced transpiration, and profound root system in the studied *Lens* species. Accessions of *L. orientalis and L. odemensis* with extensive roots showed tolerance to drought, whereas late flowering caused root extension deeper into the soil. The previous study emphasized that *L. tomentosus* showed a reduced transpiration rate, and *L. culinaris ssp. orientalis* and *L. lamottei* accession showed cold tolerance capacities that may be good candidates for lentil improvement breeding programs (Hamdi and Erskine 1996; Gorim and Vandenberg 2017).

Kumar et al. (2011, 2013) and Singh et al. (2013) identified variation of yield attributes and suitable donor for crop duration, biological yield, secondary branches, seed size, pod numbers, and yield in various *Lens* species. The accession ILWL 118 from *L. culinaris* ssp. *orientalis* is an excellent source of earliness that is critical for rice fallows and rainfed condition in Eastern and Central India, respectively. For

improvement in growth habit, biomass production, and seed traits, utilization of *L. ervoidis* as a donor source is reported (Tullu et al. 2013). *L. culinaris* ssp. *orientalis* and *L. lamottei* are the potential sources of genes pertaining to size of seed and seed and pod number (Ferguson et al. 1998; Gupta and Sharma 2006). Singh et al. (2014, 2020) evaluated and found significant variation for agronomical important traits like yield variation and resistance against multiple diseases in *L. ervoidis* and *L. nigricans* of *Lens* wild species. *L. culinaris* accessions JL 1, IPL 98/193, and DPL 53 showed excellent root parameters; therefore, these genotypes survive and sustain in drought conditions (Kumar et al. 2012). Malhotra et al. (2004) has reported that some lentil genotypes have strong mechanism to drought escape, namely ILL7618, ILL7981, ILL9922, ILL9830, ILL9844, ILL9920, ILL6024, ILL7504, ILL8095, ILL8138, and ILL8621 when research was performed in the ICARDA (Mediterranean environment). *Lens* crop wild relatives have developed rich genetic diversities and adapted a broad range of environments for drought tolerances (Hamdi and Erskine 1996). The primary approaches for combating drought stress are avoidance, escape, and tolerance in the evaluated *Lens* species (*L. culinaris* Eston, *L. odemensis* acc. IG 72623, *L. lamottei* acc. IG 110813, and L. *orientalis* acc. PI 572376, PI 572376) that are capable of tolerance to drought stress (Fang and Xiong 2015; Gorim and Vandenberg 2017). Recently studied by Rajendran et al. (2021), they marked the accession ILL 7835 as a considerably good source for stable tolerance against the combined stress of heat and drought under various environmental conditions in Morocco.

Major biotic stress donors for *Lens* species, i.e., Fusarium wilt, Stemphylium blight, Ascochyta blight, anthracnose, rust, powdery mildew, Sitona weevil, bruchids, and Orobanche, have been identified and utilized for improving cultivated lentil spp. (Meena et al. 2017). Moreover, 248 accessions of CWRs germplasm from ICARDA were evaluated for Ascochyta blight resistance by Bayaa et al. (1994). They found suitable donor in 3 accessions (*L. culinaris* ssp. *odemensis),* 12 accessions (*L. culinaris* ssp. *orientalis)*, and 36 accessions (*L. nigricans*) for Ascochyta blight resistance. Fernández-Aparicio et al. (2009) evaluated wild *Lens* accessions and identified resistance to broom rape in *Lens ervoides, Lens odemensis,* and *Lens orientalis*.

8 Brief Account of Molecular Mapping of HR Genes and QTLs

A few molecular mapping studies have been reported in lentil for nutritional traits (Table 6). In this section, we will be discussing them one by one. In a recent study, a set of 96 diverse lentil germplasm lines were evaluated at 3 different locations in India for iron and zinc concentrations, and the entire panel was genotypes with SSR markers (Singh et al. 2017). Association mapping found three simple sequence repeats (SSRs) (PBALC 13, PBALC 206, and GLLC 563) linked with grain Fe concentration (9–11% of phenotypic variation) and four SSRs (PBALC 353, SSR 317–1, PLC 62, and PBALC 217) were associated with grain Zn concentration (14–21% of phenotypic variation). These identified SSRs were found to be

Table 6 Molecular mapping of nutritional traits in lentil

Trait	QTLs	Phenotypic variance (%)	References
Iron concentration	3 MTAs	9–11%	Singh et al. 2017
	3 MTAs	6–13%	Kumar et al. 2019
	2 MTAs	9–21%	Khazaei et al. 2017
Zinc concentration	2 MTAs	6–17%	Kumar et al. 2019
	4 MTAs	14–21%	Singh et al. 2017
Selenium concentration	SeQTL2.1, SeQTL5.2, SeQTL5.1, SeQTL5.3	6–17%	Ates et al. 2016
Manganese concentration	MnQTL1.1, MnQTL1.2, MnQTL3.1, MnQTL3.2, MnQTL3.3, MnQTL7.1	15–24%	Ates et al. 2018

stable across locations. These candidate SSRs can be used in marker-assisted lentil breeding for iron and zinc concentration. In another study utilizing a similar approach using the linkage disequilibrium (LD) analysis with a mixed linear model (MLM), two SSR markers, GLLC 106 and GLLC 108, were associated with grain Fe concentration, explaining 17% and 6% phenotypic variation, respectively, and three SSR markers (PBALC 364, PBALC 92, and GLLC592) were associated with grain Zn concentration, explaining 6%, 8%, and 13% phenotypic variation, respectively (Kumar et al. 2019). Khazaei et al. (2017) used SNP genotyping of a set of 138 cultivated lentil accessions from 34 countries. The entire set was also phenotyped for iron and zinc concentration over four environments. The marker–trait association analysis detected two SNP markers tightly linked to seed Fe and one linked to seed Zn concentration($-\log10\, P \geq 4.36$). A few putative candidate genes were also detected for iron and zinc concentration. Ates et al. (2016) studied a panel of 96 recombinant inbred lines (RILs) developed from the cross "PI 320937" × "Eston" grown in three environments for 2 years. Se concentrations in seed varied between 119 and 883 μg/kg. Genotyping with 4 SSRs and 1780 SNPs and further statistical analysis marked 4 QTL regions and 36 putative QTL markers with seed Se concentration, explaining 6–17% of the total phenotypic variation. In another similar study, Ates et al. (2018) phenotyped a RIL population (120) (CDC Redberry × ILL7502) for manganese concentration. Genotyping with 5385 markers and further linkage analysis found a total of 6 QTL for Mn concentration that were identified using composite interval mapping (CIM). All QTL were statistically significant and explained 15–24% of the total phenotypic variation. Our group at IIPR, India, also identified molecular markers linked with genomic regions in lentil controlling high iron and zinc concentrations; very soon, this information will be in the public domain. It is imperative to mention that in most of the cases, the percent variation explained by linked markers at 0.05 or 0.01 level of significance is lower than their utilization in marker-assisted breeding. Hence, significantly linked SNPs

can be converted to PCR-based KASP (Kompetitive allele specific PCR) markers for routine use in these traits. Khazaei et al. (2017) reported that Fe and Zn concentrations were positively correlated; however, no common molecular marker could be found; hence, implementation of any marker-assisted selection would require independent selections.

9 Genetic Engineering for HR Traits

9.1 Traits of Interest and Foreign Genes

Genetic engineering methods are available today to incorporate alien genes which are usually not possible to be introgressed into cultivars due to hybridization barriers or incompatibility. With the interventions of molecular biology or genetic engineering today, alien gene coding for foreign proteins that improves the nutritional quality of a particular crop cultivar can be introduced, or already existing genes' expression may be enhanced or reduced, as in the case of anti-nutritional factors like phytic acid.

9.1.1 Iron Biofortification

Multiple methods to develop transgenic plants have been studied to enhance the iron concentration in different model species and cereal crops. However, we will be restricting our discussion on food legumes or pulses as far as possible.

Iron-Binding Protein Gene (Ferritin Gene)

Pea ferritin was found to be degraded in the case of exposure to gastric pH treatment, and the released iron was transported into the Caco-2 cells by DMT-1 (divalent metal transporter-1). It was further observed that inhibitors of DMT-1 and nonheme iron absorption reduced iron uptake by 26–40%. On the contrary, in the absence of gastric pH treatment, the iron uptake by pea ferritin was normal and unaffected by the inhibitors. Chlorpromazine (clathrin-mediated endocytosis inhibitor) has a negative impact on pea ferritin content; in the case of exposure to chlorpromazine, iron uptake can be reduced by ~30%, which further indicates that Fe is transported into cells via a clathrin-mediated endocytic pathway. In addition, 60% less ROS production could be found in pea ferritin as compared to $FeSO_4$. Few workers also reported that endosperm-specific expression of wheat and soybean ferritin in wheat led to several fold (1.5-fold for pea and 1.9-fold for soybean) increases in iron content, respectively (Borg et al. 2012; Xiaoyan et al. 2012). A few years back, in lentil, Sen Gupta et al. (2017) developed molecular markers for Ferritin-1, BHLH-1 (basic helix loop helix), or FER-like transcription factor protein and IRT-1 (iron-related transporter) genes utilizing genome synteny with barrel medic (*Medicago truncatula*). Significant expression of Ferritin-1 and IRT-1 was observed under excess iron conditions. More efforts are required for full-length cloning and functional validation of lentil ferritin gene for use in genetic engineering-mediated biofortification experiments in lentil.

Iron-Chelator Gene

Nicotianamine (NA) is involved in chelation of iron and regulate Fe homeostasis within the plant system (Curie et al. 2009). NA is the founding molecule of phytosiderophores, which are produced exclusively by the grass family, helping in the transport of Fe within plant system (Curie et al. 2009).

Iron Reductase Gene

Iron reductase genes reduce ferric ions to ferrous form. This reduction step is required for phytosiderophores-mediated uptake of iron (Schröder et al. 2003). Overexpressing iron reductase gene can help in increased uptake in iron from soil (Douchkov et al. 2005). Pea (brz and dgl) and Arabidopsis (frd3/man1) mutants expressing iron reductase accumulate higher concentration of Fe. In fact, among these mutants, high nicotianamine levels were also observed (Rogers and Guerinot 2002).

Insertion of Transporter Gene

Iron is transported via different plant transporters through root-soil interface and get stored in apoplasm (Morrissey and Guerinot 2009). The metal transporters of lentil may be studied on this aspect based on the clues established in model species and cereals (Kim et al. 2006; Connorton et al. 2017). Sen Gupta et al. (2017) developed molecular marker specific to IRT-1 (iron-related transporter) transporter gene and also observed genotypic variability in gene expression analysis for this gene; full-length cloning and functional analysis are required for this and other heavy metal transporter gene families.

Decreasing Anti-nutrient

Phytic acid is known to be an anti-nutrient which impairs the iron and zinc absorption or bioavailability after consumption. Transgenic wheat plants show an almost fourfold increase in phytase activity (Brinch-Pedersen et al. 2000). In another study, transgenic soybean expressed 2.5-fold higher activity of phytase (Gao et al. 2007). Synthetic phytase gene construct accumulated a higher quantity of proteins than the native ones (Kohli et al. 2006).

Increasing Enhancers for Increased Fe Absorption

Some dietary components have been known to increase iron absorption. These include vitamins such as β-carotene, ascorbic acid, α-tocopherol, and amino acids, which are released from proteins during digestion. Ascorbic acid and citric acid are known to reduce Fe to a ferrous state and improve absorption in the small intestine. Therefore, transgenic approaches can be used to overexpress ascorbic acid in combination with ferritin (Gropper et al. 2006). An increased cysteine content has also been shown to have a good effect on Fe absorption (Layrisse et al. 1984).

9.1.2 Zinc Biofortification

Zinc uptake, transport, and accumulation are similar to iron metabolism; however, more efforts are required to understand the zinc-specific transporter gene families (Zimmermann and Hurrell 2002). It is prevalent worldwide due to widespread soil

deficiency. Hence, there is a strong demand to increase zinc concentration in staple crops. Improving bioavailability is important in this case as this can make use of even lower uptake (Lonnerdal 2003).

Overexpression of NAS Gene Family

Nicotianamine (NA) is a ubiquitous chelator of transition metals which transports iron and zinc within plant system. NA synthase (NAS) enzyme is involved in the synthesis of NA from S-adenosylmethionine (Takahashi et al. 2003). Increasing NA concentration in a plant through transgenics by the overexpression of NAS genes showed optimistic results in many cereals.

Overexpression of NAC Gene Family

NAC transcription factors have a critical role in mobilizing iron and zinc during senescence. By increasing the transcription factors activity, the iron and zinc mobilization may be improved, as was observed in transgenics that showed increased accumulation of zinc (Connorton et al. 2017). In the dicot plant lentil, the importance of these transcription factors has to be studied in detail.

9.2 Achievements of Transgenics in Lentil

Transgenics or genetic engineering technologies are providing opportunity to improve agronomical traits as well as micronutrient concentration in legumes. *Agrobacterium*-mediated genetic transformation has been considered the most common and successful method for trait improvement in grain legumes like pea and soybean (Schroeder et al. 1993). Protoplasts cannot be transformed with *Agrobacterium*, but they can be cloned, whereas single-event transformants takes a long time to regenerate into plants. However, gene gun (particle bombardment) is efficient method to any plant tissue, but has the unpredictability of gene integration and high risks. Also, *Agrobacterium*-mediated transformation in many legumes are difficult due to their susceptibility to *Agrobacterium* infection and very low transformation efficiency (0.03–5.1%) (Yan et al. 2000). The efficiency of explant tissues (cotyledonary, embryo with single cotyledonary disc and node, and decapitated embryo) towards transformation through GUS (β-glucuronidase) found to express the GUS gene following histochemical assay. The explants showed inconsistent nature of GUS expression. In the case of lentil, explants showed much greater areas with GUS expression while some studied samples showed a small portion of the wounded cells competent for transformation (Warkentin and McHughen 1992). However, genetic transformation (*Agrobacterium*-mediated) is also influenced by several factors (Hashem 2007), including bacterial strain, duration of cocultivation time, explant type, etc.

Warkentin and McHughen (1992) reported that inoculation of lentil epicotyl explants for 10–15 min found to be suitable for GUS-positive putative explants. Whereas, many researchers reported that longer coculture period is capable of enhancing the GUS-infected area in lentil explants (Hashem 2007). The virulence

of the bacterial strain on lentil shoot apices explants differs significantly (Warkentin and McHughen 1992).

9.3 Prospects of Cisgenics

Biotechnological approaches based plant improvement is a continuous process that alters heritability of the trait and induces variation. Therefore, cisgenesis and intragenesis are utilized to create genetic variation in cultivated or existing germplasm for improving their quality and quantity. The advancement of sequencing technologies and genome information facilitates the isolation of intact Cis-genes with associated promoter/terminator from wild or cultivated species, which are utilized to insert into the genome of closely related and crossable species. In the case of intragenesis, different coding and regulatory sequences are assembled either in sense or in antisense orientation.

The applications and future prospects of cisgenesis and intragenesis in the improvement of many crops have been studied (Singh et al. 2018b). Disease-resistant cultivar like late blight-resistant potato (gene Rpi-sto1, Rpi-vnt1.1) and scab-resistant apple has been developed. Thus, cisgenesis as a powerful approach to transfer gene of interest without linkage drag. Cisgenic- and intragenic-derived genetically modified plants (GMP) are eco-friendly as classical breeding plants and also exempted from GMP legislation. Dudziak et al. (2019) suggested that application of novel scientific approaches is of major importance for improving the crop plants. However, these most efficient strategies based on genetic modification are still very controversial issues. Opponents of GMO crops do not agree with the use of genetic engineering in crop improvement and the production of new varieties suited for organic agriculture.

Cisgenesis suffers many a times from the random insertion in the genome causing variation in gene expression (Cardi 2016). Also, the random insertion may cause silencing of other genes. Random cisgene integration is similar to transgenic varieties, natural transposons, and induced translocations (Schmidt 2002). Another issue is the copy number and presence of vector sequence while transferred into a recipient genome. Schouten et al. (2006) reported that cisgenic transformation through *Agrobacterium* may also transfer small T-DNA borders. Approximately 80% of plants regenerated from cisgenic transformation experiments with vector backbone sequences. Projects for increasing iron and zinc in crops such as lentil are at varied stages of development (Saltzman et al. 2013). Cisgenesis has a long way to go in lentil improvement since, on the issue of safety, regulators could treat cisgenic plants the same as conventionally bred plants (Schouten et al. 2006).

10 Future Prospects and Conclusion

Lentil is a highly nutritional crop species having a tremendous opportunity as a biofortification crop. Already worldwide biofortified lentil varieties are being grown by the growers. However, there is still scope to better understand metabolism of

biofortification-related traits in lentil. Only two traits, iron and zinc concentration, have been addressed so far; other important traits, such as folate concentration, Se concentration, and other micronutrients, can be investigated. Profiling of wild or related species as new sources of biofortification related traits is required. Moreover, more studies are required to map the biofortification traits in the lentil genome for their use in breeding programs. New tools like haplotype breeding using next-generation sequencing platforms have a great potential for use in this crop species. As far as transgenic or cisgenic research is concerned, functional analysis of genes related to biofortification related traits is a priority area. Lastly, the human nutrition component needs to be included in lentil biofortification research to address the malnutrition in a more holistic way.

Abstract

The green revolution increased crop productivity and significantly reduced starvation and protein malnutrition. However, this caused micronutrient depleted soil, thereby responsible for widespread deficiencies of plant nutrients. Legumes are the important constituents of traditional healthy diets worldwide and second in agricultural importance after cereals. On a worldwide scale, pigeonpea ranks sixth among all legume crops and is India's second most important legume. Biofortification is the process of enhancing the nutrient value of crops using conventional selective breeding and agronomic approaches or via genetically modifying them. In many Indian states, the seeds of pigeonpea serve as a protein-rich pulse and are consumed in many forms including grain, vegetable and fodder. A variety of nutrients are present in the seeds, including carbohydrates, fats, protein, vitamins, minerals, and also some secondary metabolites. Pigeonpea exhibited various ethnomedicinal and pharmacological properties, and it has a long history of ethnobotanical use. Conventional breeding programs are utilized to develop nutritionally improved cultivars, although the success of such a program is very slow due to restricted gene pool and linkage drag. The exploitation of breeding-based approaches along with supportive interdisciplinary research and development have been utilized for biofortified pigeonpea development. Some transgenic approaches were also undertaken for nutritional improvement and antibody production. Further improvement in those approaches and genomic technologies will enhance the nutritional quality of pigeonpea.

1 Introduction

Pulses hold a salient position in Indian Agriculture. India tops the list for being the largest producer and consumer of pulses in the world, contributing about 25% to the global pulse or grain legumes production (Saxena et al. 2019). One such important grain legume, which has originated from the Indian subcontinent, is the pigeonpea (*Cajanus cajan* (L.) Millspaugh). Predominantly grown in rain-fed conditions, pigeonpea is a considerable source of protein to rural and urban households in Asia and Africa. It augments and enhances the soil through symbiotic nitrogen fixation and revitalizes the soil by recycling of soil nutrients, releasing soil-bound phosphorus, and addition of organic matter (Pahwa et al. 2013). Moreover, it is a great source for additional nitrogen supply to the subsequent crops. According to studies, pigeonpea releases roughly 40 kg/ha of residual nitrogen in the crop fields. All these properties cooperatively make pigeonpea a supreme crop for sustainable agriculture, around the equatorial regions of India. About three-fourths of the total

Indian production of pigeonpea is derived from Gujarat, Karnataka, Maharashtra, Madhya Pradesh, Andhra Pradesh, and Uttar Pradesh. In Barbados, pigeons were fed with these pigeonpea seeds grown on barren lands; this justifies the name. Being a short-day plant, it has a longevity of 3–4 years. Plough pan is formed below the normal ploughing zone and is a compact soil layer, which reduces the productivity of the land. The long tap roots of pigeonpea are prominently known as "biological plough" because of their ability to break plough pan.

The pigeonpea seeds consist of three structural features – cotyledons, seed coat, and embryo. The embryo is rich in albumin, globulin, and the cotyledons have high carbohydrate content, along with calcium and iron (Figs. 1 and 2). The albumin has affluent number of amino acids rich in sulphur; which encompasses methionine and cystine. Other amino acids like glycine, lysine, alanine, and aspartic acid are also present. Methionine is a limiting essential amino acid and hence, it is a beneficial factor under nutrition. The pigeonpea seed coat majorly contains amino acids like serine, proline, threonine, and glycine (Saxena et al. 2019).

The pigeonpea seeds are an integral part of Indian diet. The dry seeds are dehusked and split into cotyledons which are commonly cooked as "dal." In many Indian states, the green seeds serve as a protein-rich vegetable. To garner highest seed yield and utmost nutritional quality, the green pods must be harvested at an appropriate stage. An inverse relationship was observed between the starch content and the sugar-protein contents. In the developing seeds, there is a drop in the sugar and protein content and a rapid elevation in the starch content whereas, iron, zinc, calcium, magnesium, and copper contents were found to be more or less unchanged during seed development in pigeonpea.

Pigeonpea also holds certain antinutritional factors. Polyphenols such as tannins and phenols, oligosaccharides, lectins, enzyme inhibitors like chymotrypsin and trypsin are some of the above mentioned factors (Toklu et al. 2021). Trypsin and chymotrypsin inhibitors are expressed only in the seeds. Whole seeds without dehulling are also consumed in many countries. Cooking of pigeonpea also plays a significant role which affects its nutritional features. The seeds are large in size, absorb more water, and have high nitrogen content, which makes it a quick cooking dal. Cooking not only enhances the bioavailability of certain nutrients, it also destroys certain antinutritional components. For instance, starch digestibility is improved by cooking whereas there is a drop in the measure of oligosaccharides. Heat destroys thiamine and riboflavin, but niacin content remains unchanged during roasting and cooking of pigeonpea seeds. Methionine and lysine content decreases upon roasting, whereas there are reports on increased methionine upon boiling.

Pigeonpea possesses many herbal properties which are essentially described in folk medicine and used to treat numerous human illnesses (Salehi et al. 2019). Pneumonia, bronchitis, coughs can be cured using floral extracts of pigeonpea. It can also be employed to treat respiratory infections, menstrual distress, and dysentery. Dried seeds have the ability to ease difficulties like headache and vertigo, whereas fresh seeds help to diminish urinary incontinence, as well as other kidney disorders. The seed extracts aid in curing sickle cell anemia, by impeding the

sickling of erythrocytes. According to some reports, dried pigeonpea roots could be used as anthelmintic, sedative, vulnerary, expectorant, and alexiteric.

2 Limitations in Conventional Breeding and Rationale of Nutritional Genomics

Improving the yield quantity, nutritional quality, and maintenance of genotype stability are the primary approaches to fulfil the demands of the population. Conventional breeding practices coupled with genomics-based selection approaches need to be employed to fight the threats offered by climate change and increasing population (Singh et al. 2020).

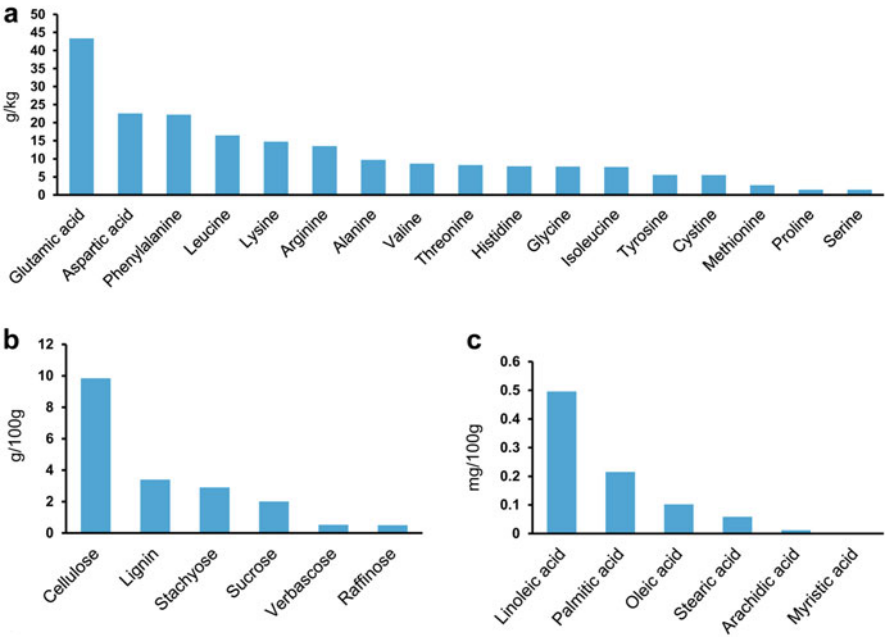

Fig. 2 Detailed nutrient composition of pigeonpea. (**a**) Amino acid composition (Ade-Omowaye et al. 2015). (**b**) Carbohydrate profile (Apata 2008). (**c**) Fatty acid profile (Ade-Omowaye et al. 2015)

Traditional plant breeding methods include the recognition and development of improved parental lines that has quality nutrient content, hybridization with elite genotypes, followed by selection of hybrids over a number of generations to get commercially established cultivars showing required nutritional properties. Additional considerations include quantitative trait complexity and the difficulty of selection of desirable trait because of low heritability. As a result, traditional methods take longer to grow a new and improved variety. Advancement in omics techniques in combination with breeding programs have a lot of potential to contribute for nutritional quality improvement in pigeonpea (Singh et al. 2020). Some of the constraints related to nutritional improvement of pigeonpea are detailed in the next few paragraphs.

Limited diversity within the basic pool of genes was revealed by a polymorphism study of sampled *Cajanus* accessions. Breeders have no choice but to use species and sub-species from secondary, tertiary, and quaternary gene pools through conventional and marker assisted selection techniques. Despite of vast genetic diversity of wild relatives, there is limitation of incorporation of them in breeding program because of lack of accurate information on the availability of desirable features and the necessity for extensive research whenever they are used. Poor agronomic traits in combination with partial characterization of relatively few wild relatives are responsible for lag in genetic improvement of pigeonpea (Saxena et al. 2014).

Pigeonpea is a short-day plant (Vales et al. 2012). A pivotal regulator of flower induction is the interaction of the photoperiod with day and night temperature. Hence, beyond 30° northern and southern latitudes, the cultivation of pigeonpea is restricted. (Saxena 2008). There is an inverse correlation between earliness and photosensitivity which confirms limited success of breeding programs in photo-insensitive and late maturing cultivars. Low-temperature in combination with photoperiod and sensitivity limit the cultivation of this crop in higher altitudes and latitudes (Vales et al. 2012). This is restricting the use of pigeonpea in alternative cropping systems (Vales et al. 2012).

The transfer of the genes of interest into the elite cultivar is highly interfered by the association of unwanted phenotypes with certain nutritional traits. As an example, transferring the genes involved in high protein accumulation was tried from *C. scarabaeoides* and *C. albicans* to the cultivars of pigeonpea. The selection of the desired genotype, high in productivity and protein yield, was obtained only after some 12–14 generations (Saxena and Sawargaonkar 2015).

3 Medicinal Properties of Pigeonpea

Pigeonpea had been used extensively in traditional medicine. In addition, the plant has also exhibited a wide array of pharmacological properties. This section will describe the various ethnomedicinal and pharmacological properties of pigeonpea along with a brief illustration about the selected chemical constituents present in the plant.

3.1 Ethnomedicinal Uses

The *Garo* tribal community of Netrakona district of Bangladesh uses pigeonpea as a remedy for diabetes. The seed paste of this plant is used as a stimulant while the leaf juice is used for the treatment of diabetes (Rahmatullah et al. 2009). In Trinidad and Tobago, the plant is used to treat food poisoning and is considered as colic. It is also used to treat constipation (Lans 2007). In Cote D'Ivoire, extraction from the leaves and stem are utilized for the treating of anemia, skin disease, and wounds (Koné et al. 2011). In Benin, the similar preparation is used for the treatment of candidiasis (Fanou et al. 2020). The local communities of south western Uganda use the juice of the leaves for the treatment of ear disease (Gumisiriza et al. 2019). In south west Nigeria, the leaves of the plants are used for treating malaria (Olorunnisola et al. 2013).

3.2 Active Principles of Pigeonpea

Chemical analysis revealed high quantities of flavonoids and stilbenes in the leaves of pigeonpea. Saponins, a significant quantity of tannins, and modest amounts of reducing sugars, resin, and terpenoids were also reported from the plant (Pal et al. 2011). Pigeonpea flavonoids can be found in a variety of plant organs. There are 27 flavonoids

present. Among them flavones, isoflavones, and flavonols have been noticed in six, eight, and four numbers respectively. Besides them two anthocyanins and several flavanones, isoflavanones are also recorded, along with a solitary chalcone (Nix et al. 2015). Table 1 illustrates the selected flavonoids present in the plant. Apart from these, the plant contains stilbenes in the form of longistylene A (Wu et al. 2020) and longistylene C (Wang et al. 2011). *Cajanus* lactone and cajaninstilbene acid (Wu et al. 2009) along with pinostrobin have also been reported from the leaves of the plant (Patel and Bhutani 2014).

3.3 Pharmacological Uses of Pigeonpea

Since ancient times, different portions of pigeonpea have been used for their biological activity, and some of them have experimental grounds for acceptability. Aside from their use in traditional medicine, there have been various studies on pigeonpea's biological and pharmacological properties (Table 2).

3.3.1 Antibacterial Activity

The antibacterial activity of pigeonpea has been explored in a number of studies. In one experiment it was shown that the ethyl acetate leaf extraction contains naringenin that inhibited growth of *Salmonella typhi* and Staphylococcus *aureus* indicating its potential in the treatment of typhoid (Agus et al. 2017). It was shown that organic solvents extractions and water extracts were inhibiting *Escherichia coli, Staphylococcus aureus* growth, whereas *Klebsiella pneumonae* was inhibited by the extracts of organic solvents only. In addition, the minimum concentration of extract to inhibit *E. coli* was recorded as 0.125–0.25 mg/ml; to inhibit *S. aureus* it was found to be 0.125 mg/ml and that of *Salmonella typhi* was to be 0.0325–0.0625 mg/ml (Okigbo and Omodamiro 2007).

3.3.2 Antifungal Activity

Antifungal activity of the plant was evaluated using ethanolic extract of leaf and root. It was observed that extracts inhibited growth of *Candida albicans* and *Candida tropicalis*. Tannins, flavonoids, and alkaloids in extracts from both organs was discovered to have clinically significant antifungal activity (Brito et al. 2012).

3.3.3 Antiviral Activity

One study looked at the activity of water and ethanolic extracts against the measles virus as well as its toxic effect to embryonated chicken eggs. The in vivo assay using stem extraction in water provided a Log(2) titre of 0.1, and when the assay was done in vitro, a 100% suppression of cytopathic effect was observed in cell lines of Hep-2. Hemagglutination titration revealed a decrease in viral content ($p = 0.05$) at all concentrations of the extracts (Nwodo et al. 2011).

Table 1 Selected flavonoids isolated from pigeonpea

Types	Name	IUPAC name	Source plant organ	References
Flavones	Apigenin	5,7,4′-trihydroxyflavone	Leaves	Fu et al. 2008

19.	Antioxidant activity	Leaf	Aqueous extract Ethanol extract Petroleum ether extract Ethyl acetate fraction *n*-Butanol fraction	Cajaninstilbene acid Pinostrobin Vitexin Orientin	Wu et al. 2009

3.3.4 Antimalarial Activity

Antimalarial activity of the plant was determined in vitro utilizing *Plasmodium falciparum* (K1) which is a multiresistant strain. This variant was used in the parasite lactate dehydrogenase assay employing bioassay-fractionation of the pigeonpea leaf extraction in methanol. Various chromatographic techniques were used to isolate the compound, and spectroscopy was used to determine its structure. The physiologically active ingredient from the ethyl acetate fraction was identified as a cajachalcone also known as 2′,6′-dihydroxy-4-methoxy chalcone. The IC_{50} of cajachalcone was 2.0 μg/ml (7.4 μM). *Plasmodium falciparum* was inhibited by the extracts containing active principle (Ajaiyeoba et al. 2013). In another study, it was observed that in vitro assays performed with the *Plasmodium falciparum* strain 3D7 that shows chloroquine-sensitivity was moderately strong for various compounds like betulinic acid, longistylin A and C, stilbenes (Duker-Eshun et al. 2004).

3.3.5 Antidiabetic Activity

The antidiabetic activity of the methanolic root extract was monitored using alloxan-applied mice with diabetes for 5 days. This indicated that upon oral ingestion of extracts of plant at various doses of body weight (200–400 mg/kg), there was a significant reduction in serum fasting glucose in diabetic mice induced with alloxan (Nahar et al. 2014). Some studies demonstrated that when alloxan applied mice, showing diabetes, were administered with 400–600 mg/kg of methanolic extract, the fasting blood sugar reduced with maximum effect between 4 and 6 h (Ezike et al. 2010).

3.3.6 Hypocholesterolemic Effect

Hypocholesterolemic effect of the leaf extraction of pigeonpea was evaluated on diet-induced hypercholesterolemic mice. Excessive levels of serum and cholesterol from liver were significantly lessened by the 200 mg/kg plant extract after 4 weeks pretreatment, comparing to the model, by nearly 31% and 23% ($p = 0.01$), respectively. The proportions of serum and liver triglycerides were also minimized by 23% and 14%, respectively. During this time, LDL cholesterol from serum reduced by almost 53% ($p = 0.01$), whereas superoxide dismutase activity from serum rose by nearly 21%. The body weight and atherogenic index were both significantly lowered. mRNA transcript accumulation of HMG-CoA reductase, LDL-receptor, and CYP7A1were dramatically increased in mice given 200 mg/kg/day of plant extract, but the hypercholesterolemic diet repressed those expressions (Luo et al. 2008).

3.3.7 Hypolipidemic Effect

Methanolic extraction from leaves of the plant was tested for its hypolipidemic effect. The result showed a significant ($p = 0.05$) reduction in cholesterol, serum triglyceride, HDL, LDL, cholesterol, and blood glucose. The extract also reduced the functionality of aspartate transaminase and alanine transaminase along with reduction in levels of creatinine, urea and malondialdehyde levels in alloxan induced hyperglycemic mice (Akinloye and Solanke 2011).

3.3.8 Neuroactive Activity

Pinostrobin, from pigeonpea, was studied in vitro for its neuroactive characteristics and was found to inhibit voltage-gated sodium channels ($IC_{50} = 23$ μM). This study was based on the previously known background about pinostrobin, which has the capacity to reduce the depolarization effects of a certain selective activator of sodium channels called veratridine, in the brain synaptonemal complex of mice. This compound had nil effect on synaptoneurosomes resting membrane-potential. Pinostrobin's pharmacological profile is similar to that of depressive medications that block sodium channels (Nicholson et al. 2010).

3.3.9 Anthelminthic Activity

Antihelminthic activity was assessed using the ethanolic and aqueous extract of the pigeonpea. The results suggest that, aqueous extraction has anthelmintic action for paralyzing and killing Indian earthworm *Pheritima posthuma* for a long period at 5 mg concentration, whereas the ethanolic extract has paralysis and death in a short time at the same dosage (Khan et al. 2015).

3.3.10 Hepatoprotective Activity

The hepatoprotective activity of the plant was studied with respect to hepatotoxicity in male wistar rats. *N*-Nitrosodiethylamine (NDEA) induced hepatotoxicity which was reversed by the ethanolic extract of the leaf of the plant. The results indicated that pigeonpea-treated groups had considerably ($p = 0.05$) lower alanine and aspartate aminotransferases levels and significantly ($p = 0.05$) higher glutathione *S*-transferase, superoxide dismutase, glutathione, albumin, and catalase levels (Iweala et al. 2019).

3.3.11 Anti-inflammatory Activity

The anti-inflammatory activity of pigeonpea was evaluated in an in vitro experiment using RAW 264.7 cells. The results confirmed that 95% ethanolic extract of the roots dramatically reduced intracellular reactive oxygen species and increased superoxide dismutase and catalase activity. EECR95 induced nuclear factor (NF) erythroid 2-related factor 2/antioxidant protein heme oxygenase-1 and hindered nuclear factor kappa B (NF-B) signaling pathways, resulting in antioxidant and anti-inflammatory properties, according to mechanism studies (Vo et al. 2020). In another experiment, albino rats were used as experimentation models to study the anti-inflammatory and antinociceptive activities of the plant seeds. The results indicated that in hexane extract of seeds, twenty-one unsaponifiable chemicals (including various phytols, stigmasterol, 2,6-di-(t-butyl)-4-hydroxy-4-methyl-2,5-cyclohexadiene-1-one, campesterol, and sitosterol) as well as fatty acids described mostly as palmitic acids and 9,12-octadecadienoic, almost 12 in numbers were found. Quercetin, Orientin, Luteolin, Quercetin-3-*O*-D-Glucopyranoside, Vitexin, Apigenin, and Isorhamnetin are all found in the n-butanolic extraction part. Three hours after carrageenan challenge, the hexane extract (200 and 400 mg/kg) reduced carrageenan induced inflammatory effects by a significant 85% and 95%, respectively. This was associated by a reduction in TNF- and IL-6 levels of 11% and 20%, 8% and 13%, respectively, as well as a significant reduction in IgG serum quantity. In

addition, hexane fraction (200 and 400 mg/kg) reduced writings by 61 and 83%, respectively (Hassan et al. 2016).

3.3.12 Anticancer Activity

The anticancer activity of cajanol, an isoflavanone derived from pigeonpea roots, was noted in a study using breast cancer cell lines from human (MCF-7). Cajanol suppressed MCF-7 cell growth depending upon dose- and time-specificity. After 24 h of treatment, the IC_{50} value was 83.42 μM, reached 58.32 μM after 48 h, and reduced to 54.05 μM after 72 h. Cajanol used a ROS-mediated mitochondria-dependent route to inhibit the cell cycle in the G2 and M stage and cause programmed cell death. Cajanol blocked the expression of Bcl-2 expression and elevated expression of the Bax gene, which led to the rupture of the outer mitochondrial membrane and resulted in cytochrome c liberation, as experimented through Western blot. The induction of the caspase-9 and caspase-3 cascades was linked to mitochondrial cytochrome c release, while active-caspase-3 was engaged in PARP cleavage (Luo et al. 2010). Another research showed cajanin stilbene acid obtained from the plant were investigated for its anticancer properties. Cajanin caused apoptosis and G2/M inhibition in a concentration-specified manner. Matrix Metalloproteinases was degraded, Bax level was increased, Bcl-2 was decreased, and caspase-3 was induced. BRCA-specific DNA impairment responsive pathways as well as cell cycle-controlling chromosome replicative pathways were both impacted by cajanin stilbene acid, according to microarray profiling (Fu et al. 2015). Other study indicated that the fractions of stem and root extracts inhibited melanoma proteases and generated cellular toxicity in SK-MEL-28 cells, cultured in vitro (Teixeira et al. 2021).

3.3.13 Antioxidant Activity

In a study, the antioxidative nature of pigeonpea from aqueous and ethanolic leaf extracts, as well as ethyl acetate, n-butanol, petroleum ether, and water fractions, as well as the four main compounds separated from the ethanol extract, namely pinostrobin, cajaninstilbene acid, orientin, and vitexin were investigated by a DPPH radical-scavenging assay. An IC_{50} value of 194.98 μg/ml, the ethyl acetate fraction had the highest scavenging power among the four fractions. Pinostrobin and vitexin were shown to have less effective radical-scavenging powers than cajaninstilbene acid (302.12 μg/ml) and orientin (316.21 μg/ml). The inhibition ratio (%) of the ethyl acetate fraction (94.13% ± 3.41%) was found to be the greatest in the beta-carotene-linoleic acid test, practically matching the inhibitory capability of the positive control BHT (93.89% ± 1.45%) at 4 mg/ml. When compared, cajaninstilbene (321.53 μg/ml) and orientin (444.61 μg/ml) had moderate antioxidant effects, while pinostrobin and vitexin both exhibited antioxidant activities at greater than 500 μg/ml (Wu et al. 2009).

4 Genetic Resources of Health-Related (HR) Genes

A large number of genetic resource accumulations, including genetic maps, molecular markers, whole-genome resequencing (WGRS) data, transcriptome assemblies, a reference genome sequence (Fig. 3) (Varshney et al. 2012) from multiple cultivars,

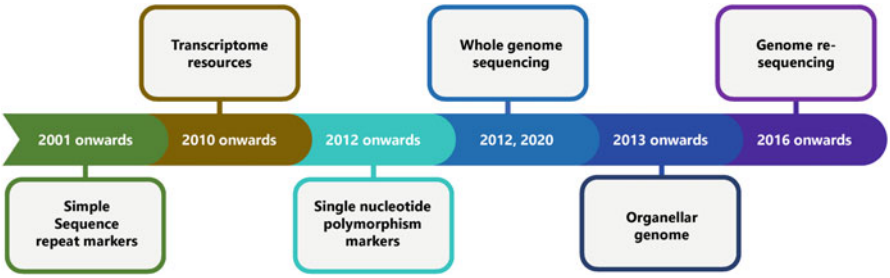

Fig. 3 Timeline of major genomic approaches adopted in pigeonpea

have become available in pigeonpea (Kumar et al. 2016; Varshney et al. 2017). These resources have aided in the creation of high-resolution genetic maps as well as efficient and expeditious genetic analysis of quantitative trait loci (QTLs) and genes regulating important nutritional traits in pigeonpea (Saxena et al. 2012).

Pigeonpea is an essential food source with amino acid rich plant protein for more than a billion people worldwide. However, genetic improvement for seed protein content (SPC) in the crop has acquired little concern in the past. The use of genomics-assisted breeding could aid in the acceleration of SPC genetic gain. Four genotypes of pigeonpea were taken for whole-genome resequencing data to recognize sequence-based markers and associated possible SPC genes (Obala et al. 2019). One hundred and eight sequence variations obtained from 57 genes were recognized by combining a common variant sieving methodology on already procured WGRS data with the gene functioning data concerning SPC. Subsequently, 17 of the 30 sequence variants when transformed into CAPS/dCAPS markers showed significant polymorphic traits between genotypes of low and high SPC. A significant ($p = 0.05$) co-segregation of 4 of the CAPS/dCAPS markers was observed with SPC when 16 polymorphic CAPS/dCAPS markers were tested on F_2 generation which is a cross of ICP 5529 and ICP 11605, former with high SCP and the latter with low SCP. In summary, mutations in four gene sequences gave rise to four markers and were suggested to be helpful in pigeonpea crop improvement programmes for enhancing/regulating SPC (Obala et al. 2019).

5 Classical Genetics and Traditional Breeding for HR Traits

Over the last two decades, many attempts have been made to create high-yielding cultivars by traditional breeding methods and advancements in biotechnology. These investigations have given information and understanding for creating superior pigeonpea varieties with many agronomically important quality characters and show great yield potential even in challenging agro-climatic settings. New cultivars with better nutritional content and boosting production potential have already been created using traditional plant-breeding techniques. To develop genotypes with the required nutritionally rich and agronomically superior features, classical plant breeding requires identifying and developing parental lines showing enhanced nutrition-rich content, crossing the latter with elite germplasm, and selection of the

segregating population for some generations (Pfeiffer and McClafferty 2007). Thus, it pertains to a much-extended time to procure a novel or better variety. The complications at genetic level of quantitative traits and low heritability are some bottlenecks that pose challenges for selecting superiors.

Due to a number of specific features, breeding of pigeonpea has proven to be more difficult than breeding other edible legumes. Pigeonpea is often cross-pollinated crop. Insect-aided natural outcrossing rates of 20–70% in pigeonpea, have restricted the application of effective selection and mating methods are available in self-pollinating species (Saxena and Sharma 1990). This crop's yield potential has gradually increased due to the employment of extensive hybridization, pure line breeding, population breeding along with mutation breeding hence create new pigeonpea varieties. Two genetic male-sterility (GMS) systems were found in pigeonpea to help with this bottleneck (Reddy et al. 1979). The GMS-based hybrids had a yield which was 30% more than that of nonhybrids but did not prove to be commercially viable because of its exorbitant production cost.

The alternative and more effective cytoplasmic-genetic male-sterility (CGMS) approach was created in response to the yield-jump seen in the GMS hybrids (Saxena and Kumar 2003). In 2004, India had its first cytoplasmic male sterility (CMS)-based hybrid GTH-1 available from ICRISAT's hybrid development programme in partnership with its partners. Furthermore, another CMS-based pigeonpea hybrid, ICPH 2671, was created in 2005 at ICRISAT utilizing *C. cajanifolius* (A4 cytoplasm) and has since been commercially available by Pravardhan Seeds under the name "Pushkal" for cultivation in various Indian states, including Maharashtra, Madhya Pradesh, Karnataka, and Andhra Pradesh. The expanded area cultivating pigeonpea hybrids is projected to result in higher crop yield and satisfying returns for farmers and pigeonpea production in a sustainable manner was possible. This will again be made feasible by ongoing attempts to breed resistance to biotic and abiotic challenges.

Besides breeding for yield, breeding for nutrition has always been the focus of pigeonpea breeders. Despite pigeonpea being the household dal, consuming every single day, the average protein requirement of an Indian adult is not met. Hence, a breeding programme was initiated back in 1982 at ICRISAT. ICRISAT's genebank houses 13,632 germplasm which has a protein range from 9% to 30% (Varshney et al. 2012). Protein content in pigeonpea is controlled by additive genetic action. Based on available information from the genebank, wild progenitors *C. scarabaeoids* (28.4%), *C. sericeous* (29.4%), and *C. albicans* (30.5%) were utilized to develop new protein lines. Accordingly, newly bred lines, called high protein lines (HPL) reported protein content up to 32%. These lines are in preliminary yield testing stage and serve as a donor for high protein trait in a breeding program. This twenty-first century has greater innovation in terms of protein. Protein based markets are worth USD 38 billion (2019) and is expected to grow at a rate of 9.1% from 2020 to 2027. Increasing traction towards plant-based protein (either as protein isolate or protein concentrates) is a greater opportunity for paradigm shift in nutritional breeding. Utilization of indigenous crops for protein source has been the current focus in Indian protein market. "Smart Protein" is a budding concept, pulses including pigeonpea is a part of this initiative. Harnessing the protein content of indigenous crops to be used as alternative protein

source without burdening the environment is the aim. With nonmeat, vegan, dairy-free, vegetarian, and ethical food systems in rise "smart protein" will be the future.

Next nutritive trait is Fe and Zn. The recommended daily allowance (R.D.A.) of Fe for a child and an adult in India is 13 and 17 mg per-day, respectively. Whereas the R.D.A. of per-day Zn for a child and an adult is 7 and 12 mg. Nevertheless, a food proportion of 7 g a day per person in India, imparts a daily per capita iron intake of 14.93 mg, which is much lesser than R.D.A. With this backdrop, a baseline study of genetic variability was taken for Fe and Zn content in pigeonpea at ICRISAT. Accordingly, a range of 24.91–44.65 mg/kg seed for Fe content and 26.08–47.80 mg/kg seed for Zn content was noted. Both wet methods, as well as Energy-dispersive X-ray fluorescence technique, were used to calibrate and estimate whole seed Fe and Zn content. A breeding programme is halfway in fortifying for Zn and Fe in pigeonpea. Marker-assisted backcrossing is effectively carried out for forwarding the generation.

Recent development of early and photo-insensitive pigeonpea lines coupled with rapid-generation turnover methods has helped in fast-forwarding the generation. Interestingly, early genotypes are high in nutritional traits and is a win-win situation for introgression and generation advancement. Unlike the 1990s, three cropping seasons with year-round breeding can now be done. Conventional breeding coupled with genomic selections has increased the selection efficiency. Reduction in time taken for completion of a cropping season has increased the genetic gains in pigeonpea.

6 Genetic Diversity with Regard to HR Traits

Molecular markers play a pivotal role in genetic improvement program of any crop. These are used both in the genetic diversity assessments as well as trait-specific molecular mapping. Various kinds of molecular markers have been adopted in pigeonpea also including first generation restriction fragment length polymorphism (RFLP), and subsequently, random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), simple sequence repeat (SSR), and latest single-nucleotide polymorphism (SNP) (Saxena et al. 2014; Pazhamala et al. 2015) markers. Amongst these, SNP markers stand for ideal DNA marker owing to their higher abundance throughout the genome and high throughput estimation procedure, apart from other advantages of a codominant marker.

WGRS was given about 292 accessions to track the genetic diversity of pigeonpea. This included wild species, landraces, and breeding lines, yielding a total count of 17.2 million variations (Varshney et al. 2017). To discover how several candidate genes were related to agronomically significant variables, a GWAS was conducted. Sequence similarities exist between the genes functionally described in other plants for flowering time control, seed development, and pod dehiscence and the candidate genes for these features in pigeonpea. These polymorphic locations will help create high-density SNP arrays, genotyping of various mapping populations to create genetic maps, and identify the genomic areas underlying significant agronomic features. A total of 932 markers were used to create a condensed intraspecific pigeonpea linkage map, covering an overall adjusted map

length of 1411.83 cM to enhance chromosomal anchoring and to map the genes linked to useful agricultural traits. It contains 65 SSR marker loci, 319 RAD-SNPs, and 547 bead-array SNPs (Arora et al. 2017). The genetic advancement of pigeonpea could be sped up with the help of this information. Recently, two high-density Affymetrix Axiom genotyping chips have been created in pigeonpea to accelerate the genetic gain. A 56 K *Cajanus* SNP chip has been created to study the genetic variation across 103 pigeonpea lines (Saxena et al. 2018).

7 Molecular Mapping of HR Genes and QTLs

High-throughput genotyping applications have caused drastic improvements in the density of markers which were used to generate genetic maps of pigeonpea. These have been adopted in pigeonpea, too, for the last two decades. Several genotyping programs targeting the F_2 populations have resulted in high-density genomic maps to date (Arora et al. 2017; Saxena et al. 2017; Yadav et al. 2019). Such genetic resources were crucial to dissect the genomic design of agronomic traits in pigeonpea, including its nutritional appearances. Fine mapping of QTLs responsible for nutritive properties of pigeonpea is essentially required to generate superior cultivars/genotypes with potential well-being properties (Fig. 4).

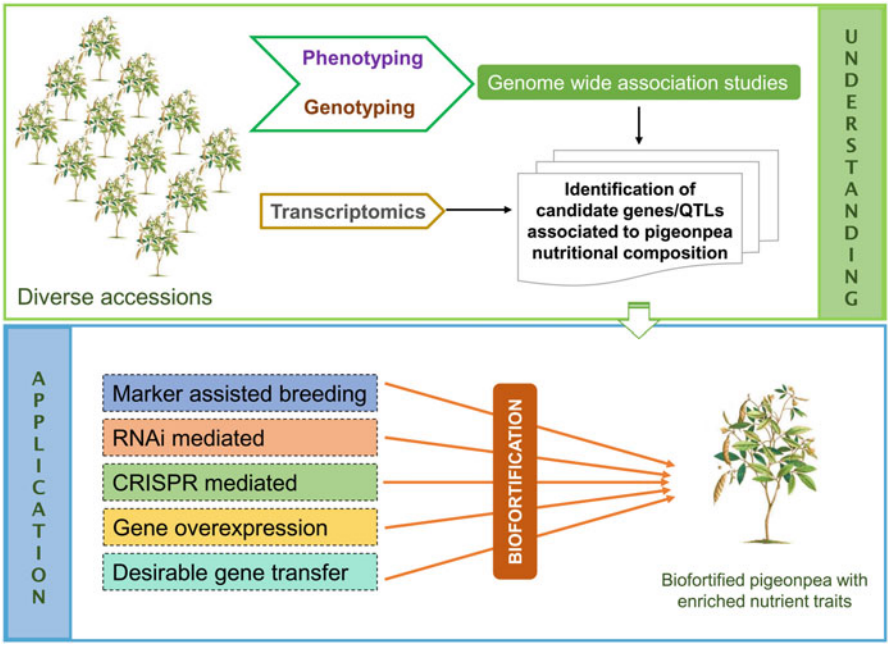

Fig. 4 Overview of concurrent genomic technologies for designing biofortification of pigeonpea

8 Marker-Assisted Breeding for HR Traits

In recent times, the availability of convenient library preparation methods and greater multiplexing capacity has facilitated the genotyping-by-sequencing (GBS) approach as a promising tool for the simultaneous discovery and characterization of numerous SNPs (Saxena et al. 2017). Whole-genome resequencing (WGRS) has become the latest high-throughput option for determining genetic variation and trait-linked marker discovery. Accordingly, an SNP array has been developed by resequencing diverse germplasm of pigeonpea with as many as 56,512 unique informative sequence variations (Saxena et al. 2018). Furthermore, identifying key agronomic traits associated with 1554 SNPs and 385 insertion/deletion (InDel) markers potentially enriched the genomic resource in pigeonpea toward marker-assisted selection. The WGRS-based first-generation HapMap of pigeonpea unveiled 5.5 million genome-wide variants (4.6 million SNPs and 0.7 million InDels) (Kumar et al. 2016). Using a different whole-genome resequencing method, candidate gene sequence-based markers in relation to seed protein content were recognized, using four pigeonpea genotypes (Obala et al. 2019). The first-generation HapMap in *Cajanus* spp. was created using the whole-genome resequencing (WGRS) method to develop genetic resources. In a panel comprising of 20 *Cajanus* spp., including 2 wild and 18 cultivated species, there are 5,465,676 genome-wide variants, comprising 4,686,422 SNPs and 779,254 InDels. These sequence variations make mapping the genomic areas underlying fundamental features possible.

9 Map-Based Cloning of HR Genes/QTLs

Pigeonpeas have a protein level of about 21%. However, because they contain less lysine than other legumes, they have poor nutritional value. Dihydrodipicolinate Synthase, or DHDPS, is a crucial regulator of lysine biosynthesis. The DHDPS genes is inactivated by even trace amounts of lysine via a feedback mechanism, as a result pigeonpea exhibits low levels of lysine. Hence, the pigeonpea was transformed with the mutant DHDPS gene (dhdps-r1 from *Nicotiana sylvestris*), since it is no longer responsive to the feedback inhibition by lysine. DHDPS activity was two to six times higher in transgenic pigeonpea, resulting in an 8.5-fold increase in the amount of free lysine in the seeds (Thu et al. 2007). Additionally, pigeonpea has been utilized in the creation of edible vaccinations. With a transformation efficiency of roughly 67%, the Rinderpest virus's haemagglutinin protein antigen was successfully produced in pigeonpea (Satyavathi et al. 2003). An Indian isolate of the Peste des Petits Ruminants (PPR) virus's hemagglutinin-neuraminidase gene (HN) has also been successfully converted and expressed in transgenic pigeonpea. Neuraminidase activity showed that HN protein was physiologically active in transgenic pigeonpea (Prasad et al. 2004).

10 Genomics-Aided Breeding for HR Traits

Conventionally identified QTLs controlling key agronomic traits in pigeonpea available so far (Bohra et al. 2019; Varshney et al. 2013) are inconvenient due to time challenges, cost, and labor faced by those low-throughput marker systems. The pitfalls of conventional marker systems can be overcome by employing high-density genome-wide marker systems. Genome-wide association study (GWAS) is one of the approaches that address the concern of low precision conventional QTL mapping. Instead, being independent of the biparental mapping population helps better understand the genomic background underlying complex phenotypic traits with higher resolution (Huang and Han 2014; Liu and Yan 2019). Accordingly, association mapping of diverse genotypes came out with the significant number of SSRs and SNPs throughout pigeonpea genome governing multiple traits of interest (Mir et al. 2014; Patil et al. 2017). The breakthrough GWAS of 286 resequenced pigeonpea accessions pinpointed numerous marker trait associations related to domestication and with prospects to breeding (Varshney et al. 2017). Nonetheless, more rigorous genotyping of potential accessions/cultivars and simultaneous high-resolution marker-trait association studies would still be required for the efficient next-generation genomics-assisted breeding programs in pigeonpea.

11 Transgenic Studies

Owing to properties such as rapid growth, lofty protein content, capacity to tolerate drought conditions, and a deep root system, pigeonpea is an economically essential crop. There is a huge breach created between the demand and supply of pigeonpea. This has been caused due to the explosion of population and the interplay of biotic and abiotic stresses affecting the growth of the crop. Biotic factors include certain insect pests, like *Helicoverpa armigera*; and some fungal diseases like Fusarium wilt. Abiotic stresses which lead to a drop in productivity include salinity and water logging. Other factor like extensive use of pesticides and herbicides which decreases soil fertility also effects the production of pigeonpea (Negi et al. 2021). Crop breeding has been the most traditional and well-established method of crop improvement. Plant breeding in pigeonpea is a laborious and time-consuming process. One of its main drawbacks is the restricted genetic diversity that results from gene loss during artificial selection. In order to resolve the issues and increase the pigeonpea production, several biotechnological approaches have been used. One of the most triumphant biotechnological approaches has been transgenic technology which removes the major breeding barriers. The development of transgenic technology has demonstrated remarkable success in pulse crop protection. It has also long-term supported research on the inclusion of agronomically advantageous traits, which improves crops and increases the world's population's access to high nutritious food (Saxena et al. 2016). The effective integration of many foreign genes using recombinant DNA technology has opened up new possibilities for the creation of tolerant pigeonpea cultivars with built-in resilience to survive biotic stress factors (Ghosh et al. 2014a).

The availability of several transformation techniques has facilitated the production of effective transgenic crops in many crop species. Of them, *Agrobacterium tumefaciens*-mediated genetic transformation is the most practical and widely applied method on a variety of plants. Researchers employed genetic transformation technology to improve more than 15 cultivars of the pigeonpea by enhancing nutritional quality or by including resilience against various environmental factors. Transgenic pigeonpea has been developed by incorporating a variety of genes, including cowpea *protease inhibitor* (*CPI*), *Bacillus thuringiensis* endotoxins *cry1A(b), cry1Ab, cry1Aabc, cry1AcF, cry1Ac, cry2Aa, and cry1 E-C,* etc. This has elevated the toxicity against the lepidopteran insects (Nandini et al. 2022).

The antibiotic selection based in vitro tissue culture approaches showed numerous drawbacks despite extensive use, such as after successful transformation, small percentage of totipotent cells were able to survive, the selection pressure lowering the explants' overall capacity for regeneration, and inadequate rooting responses (Ghosh et al. 2014b). In 2008, Ramu et al. first introduced *in planta* transformation method which fully skipped the in vitro co-cultivation and selection process and produce a large number of transgenics. Ghosh et al. (2017) developed a unique shoot grafting technique to develop Cry1Ac and Cry2Aa transgenic pigeonpea lines with steady DNA integration up to the T_2 generation. Furthermore tissue culture independent technique was introduced by Ganguly et al. (2018) as plumular meristem transformation method with increasing transformation frequency and PCR based screening process.

11.1 Transgenic Pigeonpea Development for Biofortification

Various agronomically important genes has been discovered in well-characterized systems like *Arabidopsis*, tobacco, rice, pea, carrot, and other plants, and scientists were working to create transgenic pigeonpea plants that were resistant to biotic, abiotic stresses, and with good agronomic traits. (Banu et al. 2014).

The ability to fix nitrogen in the roots is one of the most significant crop-specific characteristics of pigeonpea. This attribute improves and increases soil fertility. However, due to its high fixation in soil and low mobility, availability of phosphorous is constrained. As an adaptive strategy, plants vary the number of lateral roots, develop excessively root hair, and exude organic acids, particularly citrate to alter the rhizosphere (Shen et al. 2005). In order to refine and upgrade P uptake, Transgenic pigeonpea was created by overexpressing *Daucus carota citrate synthase* (DcCs) gene from carrot (*Daucus carota*), under a constitutive and root specific promoter. In both P deficient and P available situations, transgenic pigeonpea lines overexpressing the DcCs gene demonstrated higher level citrate synthase production and enhanced root growth (Hussain et al. 2016).

Pigeonpea serves as an important source of protein, often high lysine content and complements the protein in cereals. Although during agricultural processing, lysine and tryptophan are lost in large amounts (Singh and Eggum 1984). Additionally, *Dihydrodipicolinate synthase* (*DHDPS*), the main enzyme of lysine biosynthesis pathway is also feedback-inhibited by lysine. Under the control of a phaseolin seed-

specific promoter, a mutant *dhdps-r1* gene from *Nicotiana sylvestris* that expresses a lysine insensitive enzyme was inserted into the pigeonpea genome by Thu et al. (2007) through particle bombardment and *Agrobacterium* mediated transformation. They examined 11 lines which showed two- to sixfold increase in DHDPS activity compared to wild type in immature seeds at a late stage of development. In comparison to control lines, the *dhdps-r1* overexpression increased the free lysine concentration in pigeonpea seeds by 1.6–8.5 times.

Proline is an important amino acid in plants functions as an osmoprotectant and is crucial for maintaining osmotic balance, safeguarding enzymes and subcellular structures, and raising cellular osmolarity, which provides the turgor required for cell expansion under stressful circumstances. The rate-limiting enzyme in the production of proline, *1-pyrroline-5-carboxylate synthetase* (*P5CS*), is also inhibited by proline through feedback inhibition. Surekha et al. (2014) inserted a mutated version of *P5CS* named *P5CSF129A* from *Vigna aconitifolia* into pigeonpea genome. This mutated *P5CSF129A* gene is indifferent of feedback control. T_0 transgenic generation showed higher proline accumulation than control plants. A significant improvement was seen in chlorophyll content and growth performance in T_1 lines alongside decreased levels of lipid peroxidation. The relative water content under high salinity also showed improvement. *Render pest virus* (*RPVH*) and *peste des petits ruminants' virus* (*PPRV-HN*) both are the causal agents of devastating diseases in cattle animals with very high mortality rate such as cattle plague and Peste des Petits Ruminants respectively. New vaccination methods were developed using pigeonpea transformation to strengthen the immune systems of sheep, goats, and bovids against those viruses as the existing live attenuated vaccines are heat labile. Satyavathi et al. (2003) developed pigeonpea line that express *Rinderpest virus's hemagglutinin* protein. T_1 Pigeonpea leaves had the highest expression of the *hemagglutinin* protein at 0.49% of the total soluble protein. The transgene was expressed in the offspring of the fertile transgenic plants. Prasad et al. (2004) successfully generated transgenic pigeonpea lines by inserting two *PPRV* surface glycoproteins, hemagglutinin-neuraminidase, and fusion protein using pBI121 binary vector. T_1 plants showed transgene's inheritance.

Extracellular enzymes, especially those that cause the proteolytic breakdown of proteins in host plants are secreted by many phytopathogenic bacteria and some insects and crucial for pathogenesis. Plants have many inhibitors that work against these proteolytic enzymes as a key line of defense against these diseases. One such inhibitor named *cowpea protease inhibitor* (*CPI*), isolated from cowpea was inserted into pigeonpea genome through *Agrobacterium* mediated transformation. Transgenic pigeonpea lines showed higher level of defense against the lepidopteran insects (Lawrence and Koundal 2001).

11.2 Biofortification Resources of Pigeonpea Used in Other Transgenic Crops

In pigeonpea, under biotic and abiotic stress conditions, complex signaling pathways were found to be activated, causing changes in gene expression, necessary for plants

to adapt and acclimate. One such gene named *Pigeonpea hybrid-proline-rich protein encoding gene* (*CcHyPRP*) was used to develop transgenic tolerance lines in rice by Mellacheruvu et al. (2016). *CcHyPRP* was cloned under an inducible *rd29A* promoter and a constitutive *CaMV35S* promoter. Four independent homozygous T4 lines for each rd29ACcHyPRP and CaMV35SCcHyPRP were developed, which revealed very high accumulation of proline and endochitinase. In comparison to the control lines, the CcHyPRP transgenics showed greater resistance to rice blast disease causing fungus *Magnaporthe grisea*. Transgenic rice was shown to have more bZIP and endochitinase transcripts and endochitinase activity than control plants. These T_4 lines also demonstrated excellent levels of tolerance to the main abiotic stimuli, including heat, salinity, and drought, as demonstrated by enhanced chlorophyll content, survival rate, biomass, root, and shoot growth, in comparison to the untransformed lines. Additionally, under various biotic and abiotic stress situations, transgenic rice lines had larger panicles and more grains in comparison. In comparison to the control, the *CcHyPRP* transgenics showed increased catalase and superoxide dismutase (SOD) enzyme activity as well as decreased malondialdehyde (MDA) levels.

12 Future Prospects

In the post-green revolution period, improving the nutritional value of pigeonpea has become crucial for reducing malnutrition issues in developing nations. Establishing desired genotypes will be aided by in-depth knowledge of the genes and QTLs related to nutritional quality and seed quality (Singh et al. 2020). In order to develop molecular techniques aiming at enhancing seed quality and other nutritionally related qualities in pigeonpea, it will be essential to identify the genes/QTLs controlling the quality traits. To define quality features, attention should be paid to locate genetically varied and nutritionally improved pigeonpea lines (Singh et al. 2020). In order to measure various phenotypic features, it is crucial to design a high-throughput phenotyping platform. Examples of techniques that will be impactful for high throughput phenotyping include picture-based computer vision phenotyping, image processing, and data extraction tools. All integrated approaches will improve the understanding of systems biology by providing information on gene function, genomic architecture, organization, biological pathways, and metabolic and regulatory networks (Fig. 4).

The world's problems with malnutrition can be addressed in a new way by utilizing and combining cutting-edge NGS "omics" technology to sequence vast populations, uncover the genetic basis of agronomically essential traits, and anticipate breeding value. Breeders will be aided to gather information on specific alleles of known genes involved in nutritional grain quality attributes to achieve this goal through the availability of gene-based markers and cutting-edge techniques. Genomic regions/genes can be found that are expected to influence seed quality and nutritional qualities of interest by genotyping and phenotyping for those traits utilizing associations and machine learning models, drawing on the collection and

use of numerous unrelated lines. When omics technologies are used in conjunction with breeding programmes, it is anticipated that the nutritional quality of pigeonpea will improve.

Abstract

Mungbean (*Vigna radiata* (L.) Wilczek), one of the important leguminous crops, contains balanced nutrients protein, dietary fiber, minerals, vitamins, and good amounts of bioactive compounds such as phenolic acids, flavonoids, and tannins. The discipline of nutriomics or nutrigenomics explains the reciprocal interaction of nutrients and genes at the molecular level. Nutrigenomics can be helpful for better perceptiveness of nutrient-gene interactions and the development of "personalized nutrition" for good health and disease prevention. Considering the worldwide importance of mungbean, there is a scope for improving its nutritional value. Crop improvement focuses on enhancing protein and starch content and quality, the content of minerals like iron, zinc, and also in removing the anti-nutritional compounds like phytic acid. The mungbean whole-genome sequence data helps in the advancement of genomics research in Vigna species and speed up the mungbean breeding programs. Genotyping has enabled marker-assisted selection (MAS) and identified SNPs, serve as important resources to facilitate MAS for nutritional improvement. 8Sα globulin or vicilin is the major storage protein of mungbean and was engineered using site-directed mutagenesis. Transcriptomic, metabolomic, and ionomics analyses reveal the molecular mechanisms of nutrient accumulation, nutritional/nutraceutical value and health-promoting properties, and bioavailable minerals.

Keywords

Nutrition · Nutrigenomics · Transcriptomics · Metabolomics · Ionomics · Disease · Health

1 Introduction

Mungbean (*Vigna radiata* (L.) Wilczek) is a low-input, short-season, important grain legume of tropical countries and is also known as greengram and moong. This crop is grown in various climatic conditions, locations, and seasons due to its inherent intrinsic tolerance mechanisms. It is grown over seven million hectares in South and Southeast Asia, Australia, Africa, and South America. It is cultivated as an intercrop or subsistence monocrop predominantly by small and marginal farmers; it is consumed as whole seed or split cooking, flour, or as sprouts; and it is a cheap source of vegetable protein, minerals, vitamins, and dietary fiber for the vegetarian population. The crop has valuable nutritional and health benefits, where malnutrition is a key concern. It has the ability to improve the soil health by fixing atmospheric nitrogen through a symbiotic association with *Rhizobium*, thus enhancing the yield of the subsequent crops. Other major benefits of this crop to farmers are its high nutritional and monetary value, as it fits into intensive wheat, rice, and summer cereal rotation systems, short duration, photo-thermo insensitivity, low input requirement, and heat and drought stress tolerance. Development of extra-early and yellow mosaic-resistant varieties paved the way for extensive cultivation

of the crop in several parts of India into different cropping systems (rice-fallow, rice-rice, rice-wheat, and rice-maize) and for cultivation in different parts of the world including South America and sub-Saharan African regions (Moghadam et al. 2011). The yield potential of mungbean is 2.5–3.0 t/ha; however, the global productivity of mungbean is only 0.5 tons per hectare, impacted due to traditional low input farming system, nonavailability of quality seeds of improved varieties to farmers, and biotic and abiotic stress factors. The major biotic factors include insect pests, diseases, and weeds (Pandey et al. 2018; Nair et al. 2019). Insect pests cause direct damage by feeding the crop and indirect damage by transmitting viral diseases. Abiotic stresses, waterlogging, salinity, heat, and drought stress are key concerns in mungbean production (Hanumantha Rao et al. 2016).

During the eighteenth century, the "analytical chemistry era" Lavoisier discovered how carbon dioxide, water, and energy were generated after food digestion in the body (Vasconcelo 2010). In the "biological era" around the nineteenth century, where important discoveries in metabolism and chemistry were done, helping the science of nutrition to prevent metabolic disorders (Cruz et al. 2003). Dietary components/nutritional attributes are environmental factors that can interact with the genome which determines the health condition of individuals (Ronteltap et al. 2008). With the advancement of science, the discipline of nutriomics or nutrigenomics was introduced to get insights regarding how could food bioactive molecules and genes influence the health of an individual positively and negatively (C. Kole and AG Abbott 2011 for ICPN at PAG 2011; Dauncey 2014; Cozzolino and Cominetti 2013). Nutrigenomics is an area of nutrition that corresponds to the use of physiology, biochemistry, genomics, metabolomics, proteomics, transcriptomics, nutrition, and epigenomics to explain the reciprocal interaction of nutrients and genes at the molecular level (Dauncey 2014; Cozzolino and Cominetti 2013). The study of nutrigenomics has progressed considerably in recent times, nutrigenomics aims at understanding the impact of nutritional factors in protecting the genome. Studies on folate metabolism proved that folic acid is a nutrient, ensures the genetic integrity of an individual, and acts as a cofactor for the biosynthesis of nucleotides and thymidylate (Liu and Qian 2011; Cozzolino and Cominetti 2013). Bioactive molecules contained in the diet act as cofactors/substrates in DNA metabolism and repair. Studies showed that vitamins A, D, and fatty acids activate nuclear receptors by direct action and induce gene transcription, and some of the bioactive compounds influence molecular signaling pathways (Fialho et al. 2008; Cozzolino and Cominetti 2013).

2 Nutritional Profile of Mungbean

Mungbean (*Vigna radiata* L.), an important pulse crop consumed across the world, especially in Asian continents, has a long history of usage in traditional medicine. Mungbean is consumed as a food for centuries. Mungbean contains balanced nutrients, importantly protein, minerals, dietary fiber, vitamins, and enough amounts of bioactive compounds (Gan et al. 2017). For those individuals who are vegan or cannot

afford animal proteins, the mungbean is a relatively low-cost and has a good amount of protein. Furthermore, this protein is easily digestible in comparison protein of other legumes (Mubarak 2005; Yi-Shen et al. 2018), that is the how, it is becoming as a popular functional food in promoting good health (Tables 1, 2, and 3).

The mungbean is a rich source of polyphenolics. The important phenolic contents in the mungbean are phenolic acids, tannins, and flavonoids (Lee et al. 2011; Shi et al. 2016; Singh et al. 2017a). The seed coats and cotyledons of mungbeans contain phenolics; however, most are present in the coats of seed. The most abundant secondary metabolite in the mungbean is flavonoids. The five subclasses of

Table 1 Macronutrient composition of mungbean (Dahiya et al. 2015a)

Macronutrient	Average[a]	Minimum	Maximum
Moisture (g/100 g)	9.80	4.10	15.20
Crude protein content (g/100 g dm)	23.8	14.6	32.6

Table 3 Mungbean mineral nutrients content (Habibullah et al. 2007)

Mineral	Content (mg/100 g)
Na	22 mg/100 g
K	1443 mg/100 g
Ca	216 mg/100 g
Mg	204 mg/100 g
P	374 mg/100 g
Fe	11.34 mg/100 g
Zn	1.88 mg/100 g
Cu	1.92 mg/100 g
Mn	1.49 mg/100 g
Pb	2.64 mg/100 g

flavonoids in the mungbean are, i.e., flavonols, flavones, isoflavonoids, flavanols, and anthocyanins. Flavones (isovitexin, vitexin, isovitexin-6″-*O*-α-l-glucoside, and luteolin) and flavonols (myricetin, quercetin, and kaempferol) are the most occurring flavonoids found in the mungbean. Isovitexin and vitexin were considered to be the two major flavonoids in the seed of mungbean; their contents in the seed coat are attributed to 95.6% and 96.8% of the total vitexin and isovitexin, correspondingly (Cao et al. 2011; Peng et al. 2008). Quantification by chemical analysis indicated that the contents of isovitexin and vitexin in the seed coat were high, 37.43 mg/g and 47.18 mg/g, correspondingly.

Legumes constitute the most abundant and least expensive protein source for human and animal diets; however, their utilization is limited largely because of the anti-nutritional/anti-physiological compounds (Liener 1994) present in these. Those are protease inhibitors (trypsin), amylase inhibitors, lectins, polyphenols, tannins (TN), phytic acid (PA), flatulence factors, and allergens (Liener and Kakade 1980; Liener 1995). These factors downgrade the nutritive value of beans through direct and indirect reactions, inhibit protein and carbohydrate digestibility, induce pathological conditions in the intestine and liver tissue, and finally affect metabolism, inhibit enzymes, and bind to nutrients, making them unavailable (Bressani et al. 1989; Bressani 1993). Anti-nutritional factors: trypsin inhibitor (TIUA; trypsin inhibitor units /mg protein) is 15.8, hemagglutinin activity (HUB; hemagglutinin units/g) is 2670, tannins (mg/g) 3.30, and phytic acid (mg/gm) is 5.80.

3 Approaches of Biofortification Through Omics Methods

3.1 Nutritional Genomics and Epigenomics

Nutrigenomics is the study of the gene-nutrient interaction, and it shows that some nutrients, called bioactive compounds, can shape the genetic expression or change the nucleotide sequence. To analyze the interaction between genes and nutrients, the term "nutrigenomics" was proposed. Hence, nutrigenomics makes use of biochemistry, physiology, nutrition, genomics, proteomics, metabolomics, transcriptomics,

and epigenomics to get and explain the interactions between genes and nutrients at a chemical level. Nutrigenomics can be helpful for better perceptiveness of nutrient-gene connections and the development of "personalized nutrition" for good health and disease prevention (Di Renzo et al. 2019).

3.2 Important Traits and Breeding Goals

Mungbean is having a considerably good amount of protein, carbohydrates, and minerals such as zinc and Iron. Considering its worldwide importance, the crop is having a scope for improving its nutritional value with the available germplasm (Singh 2013). Studies must be conducted to understand the diversity at the level of nutrients in the mungbean germplasms. The increasing need for plant-based protein foods is a scope to study the functional properties of mungbean protein and starch (Shrestha et al. 2022). The mungbean breeding program should expand research to nutritional and food processing properties. Studies have to be conducted on several factors including the variety used, the region where the crop is grown, agronomic practices that have been adopted, and the storage environment. Further, studies have to be undertaken on the postharvest processes such as sprouting, dehulling, soaking, boiling, autoclaving, and microwave cooking to analyze their effect on the composition of nutritional and anti-nutritional contents of mungbean. Crop improvement in mungbean should further focus on enhancing protein and starch content and quality, the content of minerals like iron and zinc, and also in removing the anti-nutritional compounds like phytic acid (Samtiya et al. 2020). Micronutrients such as iron and zinc should be biofortified, for which identification of suitable parents, improvement of populations, and identification of quantitative trait loci (QTLs) for marker-assisted selection (MAS) are essential.

3.3 Genome Size and Genomic Resources

Mungbean is a member of the subgenus Ceratotropis of the genus Vigna, which also includes several agriculturally significant legumes, including rice bean, black gram, adzuki bean, and moth bean. While the majority of Vigna species are diploid (Egawa and Tomooka 1994), *Vigna reflexo-pilosa* ($2n = 4x = 44$) is a tetraploid species. The genomic sizes of the Vigna species range from 416 to 1394 Mb (Parida et al. 1990; Lakhanpaul and Babu 1991).

A consortium of 12 universities, led by Suk-Ha-Lee of Seoul National University in Korea, completed the draft genome sequencing of the cultivated mungbean (*V. radiata var. radiata* VC1973A), using two next-generation sequencing platforms HiSeq2000 and GS FLX+ were employed to sequence and assemble the information into 11 pseudo chromosomes. For a thorough understanding of genus Vigna's polyploidization, speciation, and domestication processes, whole-genome sequences of a wild relative mungbean (*V. radiata var. sublobata*) and a tetraploid relative of mungbean (*V. reflexo-pilosa* var. *glabra*), similarly transcriptome sequences of 22 Vigna accessions of 18 species were deciphered. The scientists also constructed a genetic map based on F6 population of 190 recombinant inbred lines (RIL) using genotyping by sequencing

(GBS) strategy. The work of Kang et al. (2014) provided a deeper understanding of the evolutionary history of Vigna spp. (particularly subgenus Ceratotropis) based on comparative genomics strategy, with the 421 Mb (80%) assembled genome coupled with sequence information of related Vigna species. Vigna species may be utilized as model legume plants in genetic studies to shed light on crop domestication and species divergence due to their short life cycle and small genome size. The mungbean whole-genome sequence data will help in the advancement of genomics research in Vigna species and speed up mungbean breeding programs, which could serve as a model for future efforts to resequence the Vigna germplasm. Scientists have also developed webserver/repositories (Table 4) containing the genomics and related information of selected Vigna species, like Vigna Genome Server (Vig GS) which incorporates annotated exon-intron structures, along with evidence for transcripts and proteins, visualized in GBrowse (Sakai et al. 2016).

3.4 Molecular Mapping and Breeding

DNA-based marker systems have become available over the past three decades. These include restriction fragment length polymorphisms (RFLPs), SSRs or microsatellites,

random amplified polymorphic DNA (RAPD), amplified fragment length polymorphisms (AFLPs), single nucleotide polymorphisms (SNPs), and diversity array technology (DArT). Among these markers, RAPD, AFLP, and RFLP are frequently utilized for marker-trait association and analysis of pulse diversity. However, plant breeders do not prefer their use for MAS because of the difficulty in handling, low reproducibility, and use of radioactive elements for generating these markers (Gupta et al. 2010). Only PCR (polymerase chain reaction)-based SSR and SNP are preferred by breeders, as these markers can easily be employed in genotyping of large populations. Also, more reproducibility and ease in usage make them preferential to conventional plant breeders for MAS (Gupta et al. 2010). These have been extensively utilized (Kumar et al. 2011) in many crops; however, their use is still inadequate in pulses (Varshney et al. 2009; Saxena et al. 2010). Therefore, greater focus is being put to develop more markers for pulses, which are considered orphan legumes (Hamwieh et al. 2009; Varshney et al. 2009). Close phylogenetic similarity has spurred researchers to transfer SSR markers from one pulse crop to another to lower the cost of developing these markers (Datta et al. 2010; Reddy et al. 2010.) Different types of markers such as RFLPs, RAPDs, AFLPs, SSRs, and ISSRs have been used in discerning genetic diversity and developing linkage maps in these crops. In mungbean, eight genetic linkage maps have been developed so far but no map contained enough markers to resolve all the 11 linkage groups.

Scientists are also working on genome-wide identification of SNP and association mapping of seed mineral concentration in mungbean (*Vigna radiata* L.). To assess the diversity of mungbeans available to breeders in the United States and to execute a genome-wide association study (GWAS), Wu et al. (2020) used genotyping by sequencing (GBS) tool. This study identified high-quality single nucleotide polymorphisms (SNPs) a total of 6486 from the GBS dataset and found marker x trait associations (MTAs) with calcium, iron, manganese, potassium phosphorous, zinc, or sulfur contents in mungbean grain. The 43 MTAs spread across 35 genomic regions elucidating an average of 22% of the variation for each seed nutrient. SNPs identified will serve as important resources of marker-assisted selection (MAS) for nutritional value in the mungbean.

4 Metabolomics

Plants produce wide numbers of nutrients that impart synergistic relations among the different combinations of nutrients. Therefore, inclusive nutrient profiling is required to evaluate the nutritional/nutraceutical value and health-promoting properties of crops. To acquire such datasets of mungbean, which is well known as a medicinal crop with heat-alleviating character, metabolites profiling is essential. Metabolomic and proteomic analysis of four genotypes from China, Thailand, and Myanmar has indicated a total of 449 proteins and 210 metabolic compounds in the seed coat. The first complete dataset of mungbean for nutraceutical values has indicated 480 proteins, and 217 metabolic factors in seed flesh. Whereas, gel-free/label-free proteomic analysis and metabolomic analysis in combination and pathway reconstruction

detected that amino acid metabolism is more predominant in flesh. Compared to flesh coat contains a wider variety of lipids and phenolic acids/flavonoids. Among the compounds detected in the coat, sphingolipids, arachidonic acid, and prostaglandin E2 are related to defense response induction. Furthermore, the identification of prostaglandin F2α added support to the empirical validity of the usage of mungbean. The abundance of bioactive compounds such as naringenin, which can be metabolized into vitexin, varied among genotypes. Lipids together with flavonoids may be possibly responsible compounds for the biological activity of mungbean coat and flesh (Hashiguchi et al. 2017).

5 Nutritional Transcriptomics

The recent availability of genome sequence information of several legume crops has led to boosting genomics research. Study of the transcriptome at a global level can provide insights into the gene space, gene function, transcriptional programs, and molecular basis of various cellular events, even in the absence of genome sequence (Garg and Jain 2013). Transcriptome analysis has been shown as an indispensable step for basic and applied research in any living system. High-quality sequence reads of cDNA obtained using sequencing technology, Illumina paired-end sequences, were assembled into unigenes (48,693) with a length of 874 bp, on an average. Among these unigenes, 25,820 (53.0%) and 23,235 (47.7%) indicated significant similarity to nonredundant protein and nucleotide sequence databases in the NCBI, respectively. A set of unigenes, 19,242 (39.5%), were classified into gene ontology categories, whereas 18,316 (37.6%) were classified into Swiss-Prot categories and 10,918 (22.4%) into KOG database categories (E-value $<$1.0E-5). By using the Kyoto Encyclopedia of Genes and Genome (KEGG) pathway database, a total of 6585 (8.3%) were mapped onto 244 pathways (Jain et al. 2020). During legume development, gene expression profiles were closely related to the ascorbic acid and phenolics accumulation regularity. The gene expression profiles of 25 key-coding genes in ascorbic acid and phenolics metabolic pathways, as well as the dynamitic changes of ascorbic acid, phenolic profiles, and antioxidant activities with the legume. From 8 to 17 days after flowering (DAF), *VrVTC2* and *VrGME* played important role in ascorbic acid accumulation. *VrPAL* and *VrCHS* were shown positive correlations with daidzein and glycitin accumulation, and *VrIFS* had a strong positive correlation in glycitin synthesis. Ascorbic acid and phenolics compounds dramatically increased the antioxidant properties during the mungbean maturation stage (Lu et al. 2019).

Molecular mechanisms, involved in the primary metabolic pathways and regulation of post-germination seedling growth, are understood in mungbean. In mungbean, during post-germination seedling growth, various metabolic and physiological changes occur, leading to the improvement of its nutritional values. Transcriptomic and metabolomic analyses of mungbean samples from 6-hour, 3-day, and 6-day after imbibition (6-HAI, 3-DAI, and 6-DAI) revealed the primary metabolites regulatory mechanism during the post-germination seedling growth.

Rapid changes in the transcript level of starch and sucrose metabolism were observed from 6-HAI to 3-DAI, glycolysis, citrate cycle, amino acids synthesis, and plant hormones regulation (Wang et al. 2020). An increase in transcript levels has led to later changes in the metabolites, including carbohydrates and amino acids. During this process, most amino acids and monosaccharides went on increasing and accumulated in germinated sprouts for 6 days. Changes in hormones including abscisic acid, gibberellin, jasmonic acid, indole-3-acetic acid, etc., were observed during this process (Fig. 1).

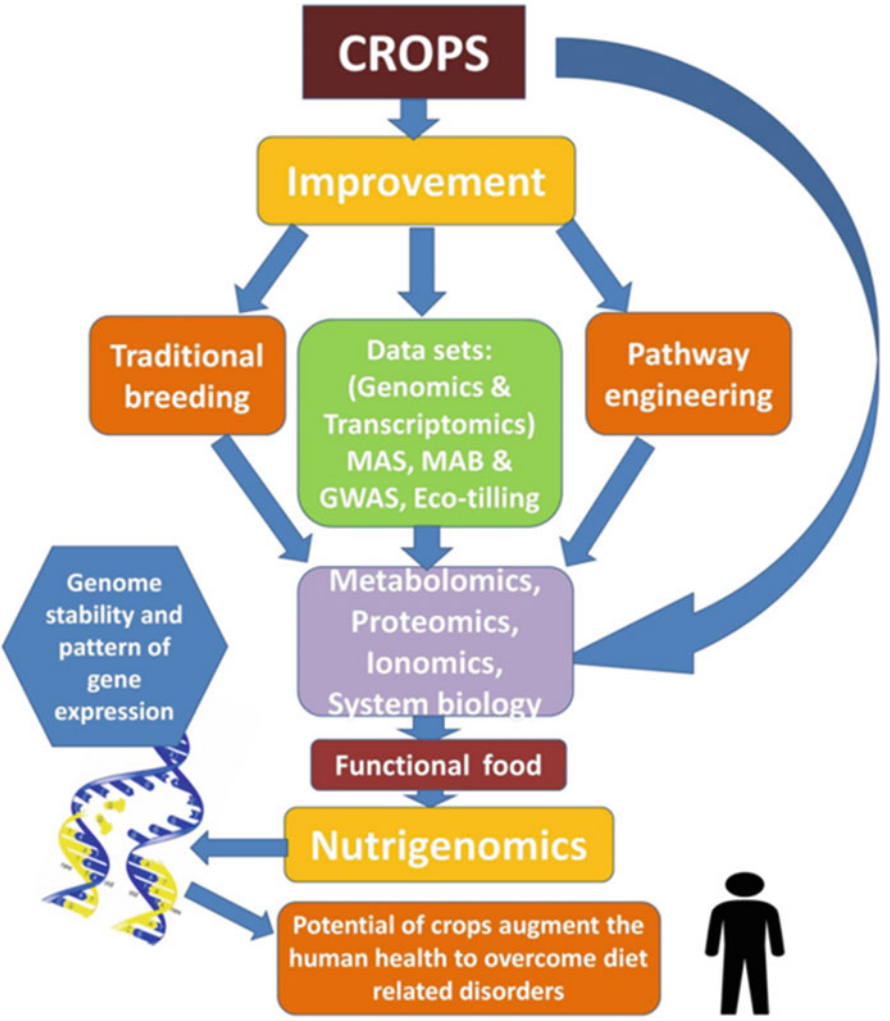

Fig. 1 Nutrigenomics: exploration of crops as functional food for human health and nutrition

6 EcoTILLING

Ecotype targeting induced local lesions in genomes (EcoTILLING) is a variant of TILLING, which examines natural genetic variation in populations and is been successfully utilized in animals and plants to identify the SNPs including rare ones (Barkley and Wnag 2008). A genome-wide association study (GWAS) was employed for elucidating the nutrient concentrations based on seven mineral analyses employing inductively coupled plasma (ICP) spectroscopy (Pratap et al. 2022). A core collection representing accessions collected from 13 different countries identified a total of 6486 high-quality SNPs from the GBS dataset and found 43 marker × trait associations (MTAs) with calcium, iron, potassium, manganese, phosphorous, sulfur, or zinc concentrations by considering 95 cultivated mungbean genotypes collected from the United States Department of Agriculture (USDA) produced in field experiments from 2 consecutive years. The MTAs were distributed in 35 genomic regions, explained on an average of 22% of the variation for each seed nutrient for every year. Most of the genic regions have given important candidate loci for employing in the breeding of new genotypes of mungbean and further in perceptive of genetic control of nutritional traits in the crop. Other identified SNPs in the study will provide an important resource to facilitate MAS for the improvement of nutritional value in mungbean and to assess the cultivars of mungbean (Wu et al. 2020).

7 System Biology

Mungbean is intensively studied; enough data are available on various characters. Data on physical, chemical, food processing, and nutritional properties were obtained from whole mungbean grains and analyzed to reveal the mungbean's potentiality as a food and to understand the research (Dahiya et al., 201). Data revealed that mungbean is a good source of protein (14.6–33.0%) and iron (5.9–7.6 mg/100 g). Grain hardness is linked with fiber content and color is associated with compounds like polyphenols and carotenoids. Physical properties like grain dimensions, sphericity, bulk, porosity, and true density are linked to the moisture percentage of the seed. Antinutrients are phytic acid, tannins, hemagglutinins, and polyphenols. Indicated nutrient contents differ greatly, the reasons for which are not well understood. Grain size and color are associated with different regions and can be used by plant breeders for selection purposes (Saa et al. 2022).

8 Genetic Engineering

Genetic engineering of metabolites is an efficient technology for the development of nutritionally fortified crops (Garg et al. 2018). Protein engineering is considered a potentially important tool in the improvement of proteins in important crops such as mungbean in terms of nutritional and functional attributes (Altenbach et al. 1989; Hoffman et al. 1988; Kim et al. 1990; Utsumi 1992).

8.1 Genetic Engineering of Relevant Biosynthetic Pathways

Mungbean is a well-known source of protein. To increase its bioactivity and nutritional content as a functional food and food additive, lactostatin (IIAEK), a cholesterol-lowering peptide was engineered into mungbean 8Sα globulin, a major storage protein (Gamis et al. 2020). The results indicated that the mutated peptide 8S α globulin has a significant bile acid binding capacity (lowers the cholesterol activity) up to 47.25%. Moreover, superimposed mutant, Mut2, and wild-type, Wt, 3D protein structures showed a 93–97% identity, indicating that the mutant protein's integrity is stable. A similar retention time for wild-type and mutant protein samples was found in ultra-performance liquid chromatography (UPLC)-based assay. Both IIAEK peptide standard and Mut2 digest had comparable baseline peaks, which correspond to the same molecular size based on the data of liquid chromatography-mass spectrometry (LC-MS). A 573.36-Da mass spectrum was seen in Mut2, which indicates that Mut2 8Sα globulin has been successfully mutated and digested to release the bioactive peptide, IIAEK. In vitro bile acid binding capacity showed that the 6-h Wt and 12-h engineered protein (Mut2) digests had the highest cholesterol-lowering activity. Lastly, potential allergenicity was checked in the Allergen Database for Food Safety (ADFS) and the AllerBase database, and the IIAEK peptide matched the Bos d 5 epitopes. This study provides a strong foundation and basis for mungbean nutrition improvement and the development of nutritionally potential cultivars.

The introduction of sulfhydryl groups and disulfide linkage to mungbean 8Sα globulins is attempted by Torio et al. (2011) for the improvement of functional and nutritional qualities. 8Sα globulin or vicilin, the major storage protein of mungbean, was engineered using site-directed mutagenesis to increase the methionine (Met) residues in the protein. Eight Met-rich proteins were engineered and organized to have 2–10 Met residues incorporated in disordered regions, II and IV. The engineered proteins were highly expressed in soluble form in *Escherichia coli*. Their production level of the modified proteins was quantified to be about 30% and was almost the same as that of 8Sα globulin wild type (WT). The modified proteins were in a stable native conformation similar to WT as shown by gel filtration chromatography and also confirmed the greater stability for thermal denaturation, greater emulsifying ability, and emulsion stability, especially the 10-Met protein in comparison to the wild type. Met-rich proteins with 3, 5, and 10 Met residues had 74%, 96%, and 145%, respectively, of the nutritional requirement for Met compared with that of WT, which is 41%. Based on allergenicity prediction programs, WT and all the modified proteins had no allergenic properties.

9 Ionomics

Ionomics is a new platform for understanding the function of the plant ionome during stress and also identifying the genes and regulatory pathways related to mineral accumulation, transportation, and involvement in different molecular mechanisms under normal as well as in stress conditions (Ali et al. 2021). In conjunction with the many expansions in genomics, advances in other "omics" technologies particularly

plant ionomics or ionome profiling have opened up unique opportunities to comprehensively examine the elemental composition and mineral networks of an organism quickly and cost-effectively. These emerging technologies would effectively guide the researchers to enrich the edible parts of grain legumes with bioavailable minerals and enhancers/promoters (Bohra et al. 2015).

Phytic acid (PA) is the storage organic form of phosphorus (P) in the seeds of legumes and cereals. PA is a strong inhibitor against the absorption of nutrients in monogastric animals. The variation of total P (TP) in the seeds of mungbean germplasm and the inheritance property of the seed P compound and phytate contents were studied by Sompong et al. (2010). TP content in seeds of 250 accessions ranged from 2.34 to 5.75 mg/g. The inheritance was studied in the F2 population derived from a cross between two accessions with the lowest (V1658BBR) and highest PA contents (V1141BG). Broad-sense heritability estimates of TP, inorganic P (IP), and phytate P (PhyP) contents were 80.8%, 78.6%, and 80.7%, respectively. The segregation ratio of 9:7 of the F2 population showed that high TP and PhyP were controlled by dominant alleles by two independent loci of major genes indicating duplicated recessive epistasis.

10 Conclusion and Future Perspectives

Pulses are a rich and economical source of proteins and are mainly important in Asian and African vegetarian diets. Among the various pulses, mungbean is an important short-duration pulse crop used in diets across the world, and it has been known to be an excellent source of protein, dietary fiber, minerals, and vitamins. Among the pulses, mungbeans are known for their good digestibility and low flatulence. They are a rich source of phosphorus and pro-vitamin A and are relatively free from anti-nutritional factors. The high protein levels and high lysine/low methionine amino acid profile of mungbean complement the high carbohydrate and low lysine/high methionine content of cereals to form a much balanced amino acid diet. It is the best source of folate as well as iron compared to other pulses. Regular consumption of mungbean seed sprouts in the diet helps in maintaining the beneficial microbial flora in the gut and reduces the absorption of toxic compounds and therefore prevents various metabolic disorders. Recent studies suggest that various bioactive compounds present in mungbean have health-promoting effects on humans. This includes organic acids, flavonoids, and phenolic antioxidants compounds that are known for their effects on detoxification, antihypertension, antipyretic, and anticancer properties. It has great nutritional, agronomic, and pharmacological significance. But the production crop is adversely affected by the cumulative effects of various biotic and abiotic stress factors existing in the environment. Narrow genetic base and poor exploration of available germplasm for valuable traits further restrict the genetic improvement of this crop. The identification and transfer of useful genes from wild species and exotic gene pools into the cultivated environment through various biotechnological and conventional breeding approaches are more promising to develop climate-resilient and nutritionally superior mungbean. It plays important role in agricultural systems and the food sector.

The seeds of mungbean are commonly consumed in processed forms or directly in the form of germinated sprouts in most developing countries. Thus, research on mungbean plays a significant role in nutritional security and soil health on a long-term basis. Identification and development of climate-resilient cultivars should be on priority for the plant breeders involved in the crop improvement of mungbean. The presence of various metabolic compounds in mungbean providing various health benefits has increased the scientific interest in this crop. In the future, mungbean can be explored as a potential source of nutraceuticals and functional foods.

Abstract

Rice bean (*Vigna umbellata* syn. *Phaseolus calcarata* (Roxb.); *Azuki umbellata* (Thunb.) Owhi and Ohashi) is an obscure crop that is underexposed to the scientific investigation as yet. However, the crop has the essence of a potential crop, and it is considered a food and nutrition security grain for farmers of Southeast Asia, where rice bean is grown by small farm holders on marginal land with minimum agricultural inputs. Due to its potent nutrient profile, it is grown and diversified since its origin from Indo-China region; however, the crop till now has not received the requisite attention. The agronomic disadvantage like low palatability and indeterminate growth pattern with delayed flowering hampers the productivity and quality of the crop product and limits its spread, utilization, and commercialization. However, there has been a renewed interest in this underutilized crop, because it is a great genetic source of biotic and abiotic stress tolerance. Recent omics investigations and the literature available have highlighted the genes involved in the agronomically negative transactional traits.

The identification of vital target genes is a prerequisite for trait improvement. Crop improvement and the identification of new target crops at the verge of population explosion, climatic, and environmental changes are crucial. The present endeavor has tried to highlight the importance of rice bean and recognize it as a crop for the future since staple crops are facing challenges for further improvement. We have discussed the work done in this direction along with the recent revelations and the need for genetic improvement for developing the rice bean as robust, high quality, and yielding crop.

Rice bean · Underutilized crop · Nutrition · Genomic resource · Omics · Crop improvement

1 Introduction

A versatile, underutilized, less well-known legume known as the rice bean (*Vigna umbellata* syn. *Phaseolus calcarata* (Roxb.); *Azuki umbellata* (Thunb.) Owhi and Ohashi) has the potential to provide the rising human population with nutritious feed in the near future (Bhat and Karim 2009). It is a member of the Fabaceae (Leguminosae) family (Bhardwaj et al. 2021; Dahipahle et al. 2017) (Fig. 1). Therefore, it has the innate ability to assimilate biological nitrogen to restore soil fertility and serve as a substitute for intercropping. It is regarded as a resource for nutritious flour, dietary needs, and livestock feeding and fodder (Dahipahle et al. 2017; Khanal et al. 2009). (Tripathi et al. 2021). Although it holds such worthwhile agricultural capabilities and nutritional brilliancy, rice bean still has been abandoned by breeders. Attributions such as delay in flowering (Kaul et al. 2019a; Joshi et al. 2007; Takahashi et al. 2015) and unpalatableness (Basu and Scholten 2012) are two major constraints associated with cultivated varieties. More is concerned with the inadequate information on its nutritious advantage and the presence of anti-nutrients (Katoch 2020). Minimal advancement has been accomplished in achieving potentiality of rice bean due to the main matters associated to late induction of flowering (Joshi et al. 2007), unpalatableness (Kaul et al. 2019a), hard and coarse type of grain (Andersen 2012), shattering sensitivity (Parker et al. 2021), disease resilience (Pandiyan et al. 2008), and the presence of anti-nutrients (Bajaj 2014). Several kinds of literature evince rice beans' resiliency towards adverse environments consisting of some familiar biotic and abiotic stresses along with abilities to tolerate metal toxicity in the soil. *Vigna umbellata* has been identified by the Food Security, Rice Bean Research in India and Nepal (FOSRIN) network as one of the impending crops for the nutrified future (Andersen 2007; Basavaprabhu et al. 2013). Originated from Southern and Southwestern Asia (Bisht and Singh 2013), it had been adapted in Indo-China area (Doi et al. 2002) and became a conventional crop in East, Southeast, and South Asia (Tomooka et al. 2002; Seehalak et al. 2006). It is mostly cultivated in the belt of Indonesia, Vietnam, Myanmar, Bhutan, Southern China, Laos, Northern Thailand, East Timor, and India

Fig. 1 Life cycle of rice bean: (**a**) seedling stage; (**b**) reproductive stage: vine legume plants with yellow flowers and small edible beans; (**c**) inflorescence having flowers in different stages; and (**d**) variability of seed coat color and seed size (diameter of each unit is 4 cm) in rice bean. The vegetative parts can be fed to livestock as fresh or made into hay. Grain is generally used as dal/boiled soup for human consumption. Grain foliage is used as livestock fodder and manure

(Tian et al. 2013; Iangrai et al. 2017; Pattanayak et al. 2018). The wild type of rice bean, *V. umbellata* varieties *gracilis*, inhabiting the zone from Himalayan and Central Land of China to Malaysia (Seehalak et al. 2006; Rejaul et al. 2016), is presumed as the pioneer of today's cultivated crop. Although wild types exhibit intermediacy in qualities such as small seeds, free branching, and sensitivity towards photoperiod as compared to the cultivated varieties, till now, only the northern east area of India grow such wild-type intermediate varieties (Iangrai et al. 2017). Research on related members like *V. mungo* revealed the coevolution of this species during an individual domestication event in Thailand or Myanmar. Conspecific to the cultivated *V. umbellata* grown in South and Southeast Asia, this species is thought to have arisen from *V. umbellata* var. gracilis (Tomooka et al. 1991, 2002; Bisht et al. 2005; Seehalak et al. 2006). Rice bean has been embraced as a cover crop in places like Ghana, Sri Lanka, Indonesia, Jamaica, Haiti, Fiji, and Mexico, but it is only in limited cultivation

in West Indies, Australia, Africa, Brazil, the United States, and Honduras (Wang et al. 2015; Khadka and Acharya 2009; Rajerison 2006; Burkill 1953) (Fig. 2). The location of the crop is mostly determined by the necessary growth factors; the rice bean thrives in regions with an annual rainfall of between 1000 and 1500 mm, although it also tolerates dry seasons to a reasonable extent. This crop can grow in the temperatures ranging between 18 °C and 30 °C, but it also can withstand cold temperatures as low as 10 °C with a vulnerability to more lower temperatures like frost, as well as temperatures as warmer as 40 °C. (Pattanayak et al. 2019). The screening of rice bean's germplasm for unexplored genomes may surface new approaches for unearthing neoteric traits and linked genes (Sarma et al. 1995). These agricultural endeavors favor generating robust and climate-resilient crops against the backdrop of adverse environments. The current circumstances of world hunger and the tendency of developing lifestyle-related severe disorders demand improvement and domestication of unexplored crops like rice bean to create unique sustainable landraces with increased productivity and lower levels of anti-nutrients. Rice bean may be enlisted as one of the crucial futuristic crops. In order to accelerate its domestication process, the crop necessitates more focused research. In comparison to other economically significant legumes including soybean, common bean, azuki bean, and mung bean, the absence of polymorphic molecular markers in rice bean has lagged in genomic investigations. So far, only a few papers have indicated intra- and inter-species molecular diversification of *V. umbellata* via application of simple sequence repeat (SSR), amplified fragment length polymorphism (AFLP), and random

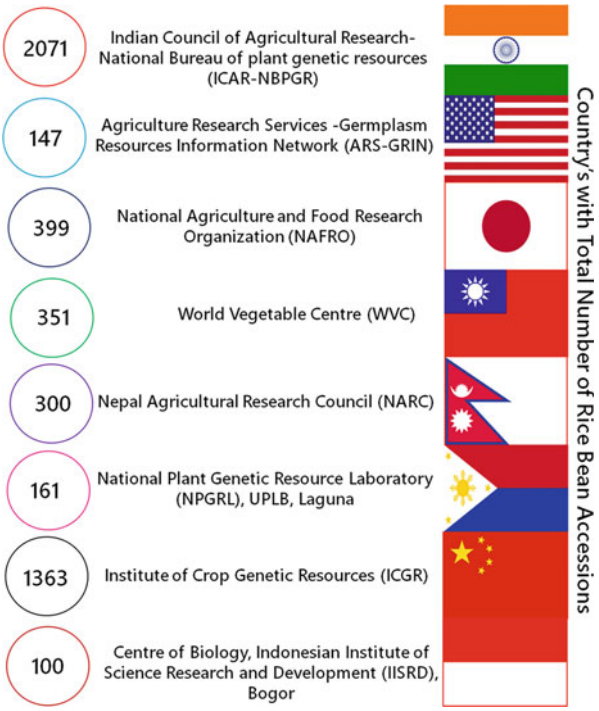

Fig. 2 Diagrammatic representation depicting the worldwide distribution of rice bean accessions in diverse agroecological microhabitats

amplified polymorphic DNA (RAPD) markers (Iangrai et al. 2017; Thakur et al. 2017; Tian et al. 2013; Bajracharya et al. 2008; Muthusamy et al. 2008). An in-depth draft genome assembly of rice bean will provide information on nucleotide polymorphism existing in the population, which will be turned into the resource of polymorphic SSRs applicable in determining how the marker linked to particular trait. The molecular breeding strategy for crop advancement can be efficiently regulated by the identification of genome-wide relevant trait-related markers, particularly markers linked to quantitative traits (Muthusamy et al. 2008). Landraces from various geographical areas must be included in order to fully represent the genetic variety. SSR markers addressed the greatest variation in an examination of 112 regionally collected different rice bean varieties from India and Nepal using 35 azuki bean's polymorphism markers (Bajracharya et al. 2008). To analyze the diversity indices for the target crop's genotype, polymorphic markers created for the orthologous crop can be used for the less-known sister crops. It is important to note that the first comprehensive SSR analysis, which included 84 wild and 388 cultivated accessions from 16 different geographic zones in Asia, revealed that the genetic diversity is highest in accessions from Nepal, Myanmar, Vietnam, and India (Tian et al. 2013). Among 65 accessions investigated using a cluster of 28 SSR markers, accessions were collected from Japan, Thailand, Korea, and China with significant diversified genetic characteristics. It is crucial to carefully examine the rice bean germplasm in order to benefit from the diversity that is intrinsically present there and to minimize the risks associated with farmers giving up the crop. Therefore, more emphasis on genetically governed key characteristics of rice beans is highly required for its adaptation, like taste, latency, and early floral induction to make this crop more feasible. This kind of approach permits the study of evolutionary components and the effects of domestication and breeding on rice bean molecular function (Fig. 1).

What necessitate the exploration of the underutilized crops? Will the endeavors be advantageous to resolve the problem of yield loss, biotic/abiotic stress vulnerability, and malnourishment? Invariably, these grave questions are relevant during a time when staple food crops are facing numerous challenges (Mayes et al. 2012; Andersen et al. 2009); moreover, the situation will escalate with the discrepancy in the current high population growth rate and low food productivity. Thus, with the upsurge to provide safe and healthy nutrition for underprivileged and deprived populations, food grain productivity must be increased urgently in order to feed the rapidly growing population. Considerably, the underutilized crops are more resilient to the changing environment or biotic/abiotic stress and well equipped to dwell on marginal lands with minimal investments of capital and agricultural products. Thus, the underutilized, neglected, or non-staple food crops are generally accepted alternatives to meet the Sustainable Development Goal (SDG).

2 Nutritional Composition of Rice Bean

Compared to other commercially grown crops, rice beans have a considerable amount of nutritional content and various health advantages. Furthermore, it holds tremendous potential to mitigate global micronutrient deficiency among the population. In South

Asian nations, rice bean is often eaten as a boiled soup or dal, as well as whole grain cooked by using dry heat and hot air, combined with wheat flour or chickpea. They provide a substantial quantity of nutritional fiber, tannin, slowly absorbed carbohydrates, significant minerals, and important amino acids. Rice bean has more iron (Fe), calcium (Ca), zinc (Zn), potassium (K), thiamine, riboflavin, and niacin compared to other leguminous crops. Moreover, it has a lower glycemic index (Katoch et al. 2014; Saharan et al. 2002). A large variety of bioactive compounds contain those that protect the liver, fight inflammation, lower blood pressure, improve immunity, fight cancer, fight infections and fungal growth, fight diabetes, inhibit HIV-1, and fight health hazards (Wei et al. 2015). In particular, ischemic heart disease, diabetes mellitus-type 2, colorectal cancer, and other metabolic ailments can be curbed and/or prevented by the bioactive phytochemical profile of rice beans (Tharanathan and Mahadevamma 2003). Rice bean is becoming an excellent choice for underdeveloped and developing countries because the nutritive profile holds huge health and nutritive benefits (Dhillon and Tanwar 2018; Katoch 2013; Parvathi and Kumar 2006). Digestible and non-digestible carbohydrates are the primary component of any legume (Priyadarshini et al. 2021). Rice bean contains more than 58% carbohydrate and up to 72% carbohydrate (Katoch 2013; Buergelt et al. 2009; Sadana et al. 2006), from 3.60% to ~5.56% of crude fiber (Bajaj 2014; Buergelt et al. 2009), while ~9 g per 100 g of acid detergent fiber (ADF) and ~13.0 g per 100 g of neutral detergent fiber (NDF) are present (Katoch 2013). Rice bean has 5–6 g/100 g of soluble sugars, 4.7–5.3 g/100 g of nonreducing sugars, and comparatively low starch (50–55 g/100 g) compared to other beans (Saharan et al. 2002). Rice bean has fewer oligosaccharides like raffinose, which ranges from 1.56% to 2.58%, while verbascose and stachyose are present in a percentage of 0.85–1.23 and 0.94–1.88, respectively. Food rich in raffinose and stachyose such as soybean, sword bean, and lima bean causes flatulence in the human body (Katoch 2013).

Rice bean has a total protein level ranging from 14% to 26% with better protein digestibility (86.1–89%) in vitro as compared to other legume crops (Bajaj 2014; Buergelt et al. 2009). Katoch (2013) reported rice beans have a greater amino acid profile, specifically tryptophan and methionine, whereas black and green gram have equivalent tyrosine, lysine, and valine levels. The reported fat content of 1.92–3.42% is also significantly lower than that of legumes (Bepary et al. 2017; Buergelt et al. 2009; Sadana et al. 2006). Rice bean can provide a resource for unsaturated fatty acids such as oleic acid and linoleic acid with a percentage of 15.6–17.91 and 17.24–18.98, respectively, while linolenic acid, stearic acid, and palmitic acid with a percentage of 39.89–44.36, 4.36–5.87, and 14.23–16.88, respectively (Katoch 2013; Pugalenthi et al. 2004). In rice bean, Katoch (2013) discovered 3.48–4.26 mg/100 g niacin and 15.33–29.00 mg/100 g ascorbic acid. Interestingly, phytic acid, a key anti-nutrient feature in legume grains, is present in trace amounts of 0.20–2.27% and is comparatively less than in other crops (Bepary et al. 2017; Bajaj et al. 2014). However, the anti-nutrient qualities, such as activities of phytic acid, polyphenols, trypsin inhibitors, and saponins, can be reduced by soaking and pressure cooking. As a result, its nutritional content may offer a hopeful addition of healthy and inexpensive value to impoverished and advanced nations in order to counter the food crisis (Dhillon and Tanwar 2018).

3 Problems with the Commercial Use of Rice Beans

Despite having health benefits, rice beans are considered an underdeveloped crop; however, it is difficult to pinpoint what characteristics make a crop underutilized: they are frequently linked to the cultural heritage of their region of origin; there is inadequate evidence of their farming and use; they are customized to specific marginal land and agroecological microhabitats; and there is no formal document for seed distribution mechanisms. Its anti-nutritional components, including phenolic compounds, alkaloids, phytate, enzyme inhibitors, late flowering, prolonged cooking time, inferior processing, and tough seed coatings, all contribute to its poorer usage. Additionally, its anti-nutritional contents, notably phenolic compounds, tannins, phytate, enzyme inhibitors, late flowering, extended cooking time, poor processing methods, and hard seed coats, contributes to its less utilization. Thereby, farmers are less eager to spend their time and resources on the expansion and production of underutilized crops (Nnamani et al. 2017; Popoola et al. 2020). In addition, rice bean is mostly grown by rural farmers who lack the resources, i.e., high-input farming practices required to raise essential crops (Conti et al. 2019). Additionally, their production has been limited by low market prices, low demand, a lack of purchasers, an inadequacy of improved varieties, and insufficient funding (Khan et al. 2021). In addition, light sensitivity and indeterminate vegetative developments due to delayed flowering have lost market attraction compared to crops like chickpeas, pigeon peas, lentils, peas, and black and green grams. Rice bean verities with prolonged vegetative development periods seem unpleasant, and the subsequent cropping is hampered by this prolonged period. Also, the tough and coarse grains limit daily consumption even after boiling (Andersen 2012). Early flowering may be accelerated by manipulating genes involved with the flowering pathway (González et al. 2016; Dhanasekar and Reddy 2014; Joshi et al. 2007). Furthermore, it is reported that rice beans may grow in a variety of climates. However, their cultivation is restricted by their need for moderate temperatures and rainfall and their sensitivity to prolonged exposure to harsh settings (Noda 1951). Rice bean cultivation is reduced in the cropping system due to the crop's rigid reaction to the mechanized cultivation system and lower harvest index, which contrast with other economically relevant pulses like lentils, peas, and soybean (Jayasundara 2015). Due to these serious issues, there are no legal channels for trade; still, it is locally marketed in Thailand, Nepal, India, and Myanmar through an unorganized trade.

4 Omics Approach: Identifying Novel Genes Associated with Stress Resistance and Nutritional Improvement

Due to the limited geographical distribution in congruence with restricted marketing channels and inadequate commercialization, rice bean has been unexplored for their underlying genetic richness. Thus, unraveling the rice bean' genome is critical, but it could provide ideal candidate genes for stress resilience and an extraordinary range of nutrients within the genus *Vigna* (*V. umbellata*) (Rana et al. 2014). Thereby, a major

contribution has been made by Kaul et al. (2019a) with a 414 MBP genome draft assembly, i.e., NCBI.SRA.SRP132447 consisting of high confidence, identified 31,276 genes via analysis of 15,521 scaffolds. Primarily, it is critical to cover the whole genome. Functional coverage of almost 96.08% was attained via coverage of around 30X reads developed through Illumina along with the PacBio approach (Kaul et al. 2019a, 2022). The assembled genome indicated the closest relation of *Vigna umbellata* genome with *V. angularis*, followed by another closely related associate present in same genus, i.e., *Vigna radiata* and *Vigna unguiculata*. Collinearity block mapping, an alignment technique to compare crop genome assembly to other related plants' genomes, is employed and aligns the rice bean draft assembly with 13 complete genomes and 18 partial genomes available for legume crops. It revealed peculiar information about rice beans. The whole coding sequence (CDS) alignment also provided critically relevant findings. Moreover, with the application of LCB, i.e., locally collinear alignment block clusters, aligning with 17 medicinally relevant plant genomes incorporated in the National Institute of General Medical Sciences-NIH database, are able to decipher the 18,000 potential medicinally pertinent genes. In conclusion, the endeavors encompassing comparative genomics studies have highlighted the fundamental symplesiomorphic traits that have assisted in establishing the origin and relation of rice beans related to their genetic and functional lineage. Considerably, the major contribution of this study is the identification of neoteric palatability and late-flowering related genes and deciphering the position of a few of them in the mitochondria and chloroplast genomes. These genes are involved in functionally diverse metabolic pathways for the regulation of flavor, abiotic/biotic stress, disease resistance, photoperiod responsiveness, and more. The material and data have been made available at http://www.nicg.in to advance molecular breeding studies to produce rice beans as a potential resource. Kaul et al. (2022) reported the existence of genes that responded to stress from a variety of families, including stress-enhanced protein 1 (SEP-1), universal stress protein PHOS32 precursor (PHOS32), heat shock transcription factor HSF-02 (GMHSF-02), stress-responsive alpha-beta barrel domain-containing protein (GSU2970), and stress-enhanced protein 2 (SEP-2) in rice bean (Kaul et al. 2022). Targeting photoperiod-independent early flowering genes like the early flowering 3 (Elf3) gene, FLC-transcription factors, flowering locus T1 (Rft1), determinant stem 1 (DT1), ethylene-responsive transcription factor tiny (TINY), and Dead/dead box helicase domain-containing protein (PIE1) can increase yield by lowering vegetative and indeterminate growth. In India, the Nutritional Improvement of Crops (NIC) Group at ICGEB, New Delhi, has pioneered molecular studies in rice beans to add features including determinate habit, early flowering, and palatability using a clustered regularly interspaced short palindromic (CRIPSR)-based genome editing system (Fig. 3).

The advances in sequencing technology have made genomic exploration less challenging, which contributes primarily toward the visible paradigm shift in agriculture. Conventionally, till now, quantitative trait locus (QTL) mapping has harnessed the uncloaked capabilities of these underutilized crops and characters related to domestication via inter- and intraspecific mapping (Isemura et al. 2010). Rice bean projects resistance capability against mung bean yellow mosaic virus

Fig. 3 Schematic representation depicting the genome editing approach to target the palatability and late flowering genes to resolve the issues with the rice bean. Recent innovations like CRISPR/Cas9 could accelerate the breeding process

(Pandiyan et al. 2008, 2010; Sudha et al. 2013), pests actively affect storage conditions such as bruchid beetles (*Callosobruchus* spp.) (Tomooka et al. 2000; Kashiwaba et al. 2003; Somta et al. 2006) and bacterial disease like leaf spot (Arora et al. 1980). Generally, the underused crops are efficiently habituated to a variety of soil types. Specifically, the inherent capability of rice beans to secrete organic acids like citric acid and others curb the acidity of the soil and aluminum accumulation (Fan et al. 2014). MATE has identified resistance power to aluminum toxicity in rice beans, i.e., multidrug and toxic compound extrusion family organic acid efflux transporters such as VuMATE1 and VuMATE2 (Yang et al. 2006; Liu et al. 2018). Furthermore, the absorption of micronutrients like iron and zinc is reduced due to the prevalence of anti-nutrients such as polyphenols, saponins, tannin, phytic acid (PA), hemagglutination, and trypsin inhibitors. Thereby, the identified followed by functionally characterized micronutrient transporters can be targeted for the improvement of nutrition in rice beans such as iron-phytosiderophore transporter yellow stripe 1 (YS1), iron-regulated transporter-1(IRT1), constitutive photomorphogenic 1 (COP1), ferric reduction oxidase 2 (FRO2), nicotinamide synthase 1 (NAS1), and natural resistance-associated macrophage protein (NRAMP). In general, the PA residues form a complex with the micronutrient and thus make it inaccessible for absorption in the animal body too. Therefore, targeting genes such as phospholipase D (PLD) and inositol triphosphate kinase (ITPK6) can lead to a lower phytic acid concentration in rice bean grain. Likewise, the main reason for the low palatability index of rice beans is the presence of taste deterrents or pungent taste developers, for instance, polyphenols and tannins. Thereby, genes like N-(5-phosphoribosyl) anthranilate isomerase – a chloroplastic isoform, liquiritigenin 2-*O*-methyltransferase-like (ILMT), chalcone synthase 17-like (CHS-17), leucoanthocyanidin dioxygenase (LDOX), and spermidine hydroxycinnamoyl transferase-like (SHT) can be targeted due to their involvement in biosynthesis pathways of polyphenol and tannin. In accordance with this, the application of genome editing may lead the way to

understanding the functional characterization of genes connected to critical agricultural factors determining crop habituation (Schenke and Cai 2020; Zafar et al. 2020).

5 Crop Improvement

If the underutilized crops are as superior as they are represented and promoted as having agro-economic, stress tolerance, and nutritious advantages, why then don't they reproduce on their own? Will they suffer if agriculture is increasingly commercialized and the food trade is more international? These barriers can be overcome using the traditional and molecular methods outlined below. These crops are frequently discussed in cross-disciplinary stakeholder/partnership efforts in agricultural progress (Padulosi and Hoeschle-Zeledon 2004, 2008), and as a result, they are covered under post-green revolution development policies. Both producers and consumers are unenlightened of rice beans' tremendous potential to enhance food and nutritional advantages, so, emphasizing its marketing and utility are highly significant. For novel varieties and flexibility in seed selection, old variety material should be exploited. For crop improvement and propagation, it demands a focus on breeding and on-farm trials. Seed providers should promote seed distribution and accessibility easily. By educating larger audiences about rice bean seed production in native places and handing out grains at trade fairs, access can be increased. In addition, quality assessment is vital (regarding germination and resilience to disease). Furthermore, timely circularization of information regarding the adaptability and technologies related to better production of rice beans is necessary. Alliance with the nongovernmental organization could be the marketing strategy to popularize the rice bean at chains of food hubs (Sthapit et al. 2010). Nutritional, chemical, and sensory analyses must be carried out at several intervals to gain data from various marketing surveys. These methods may create a unique hub for global consumption, achieving security in nutritious food and reducing malnutrition. Moreover, recent advances and implementation of high-throughput next-generation DNA sequencing approaches, like Illumina and Pac bio, have massively furnished the underlying potential of rice bean genomes with high confidence and accurately aligned data. Kang et al. (2014) released the draft genome of *V. radiata* (~genome size of almost 459 MB) with three genome assemblies and one sequencing read. They showed the draft genome of *V. angularis* with a genome size of ~455 MB with five assembled genomes and two sequencing reads by Kang et al. (2015). Similar findings involving *V. unguiculata* with an approximate genome size of 607 MB were reported by Muoz-Amatria et al. in 2017. The researchers developed the draft genome using two assembled genomes. Using next-generation sequencing (NGS) on the rice bean genome, Chen et al. (2016) were able to locate 3011 possible genetic/molecular SSR markers. But before drafting a genome to build confidence and partially annotate it, it is essential to perform an analysis of comparative genomes with the target genome. Kaul et al. (2019a, 2022) mapped the whole genome of rice beans using the anchoring elements of the functional and genetic orthologous sequences of *V. radiata*, *V. angularis*, and *V. unguiculata* as a basis for comparable functional properties. The blueprint of the draft genome, identification of genes, and translational annotation for the target *Vigna*

umbellata can all be designed using the orthologous sequences as a reference. The probable protein-coding genes can also be found from the assembled sequence data utilizing the process, namely MAKER v2.31.9. (Campbell et al. 2014). It results in annotating genes via quality-dependent evidence. These eventually lead to the identification of the target gene or genes for trait modification and raise the market value of the neglected target crop (Kaul et al. 2019a). Genetic engineering techniques must be used to improve traits (Tabassum et al. 2021). Among the several genome editing techniques, CRISPR-dependent toolkits are the most effective, highly specific, and simple to generate editing techniques, which have recently gained attention in the researchers' community. The aforementioned method updates the targeted genome modification appropriately and suitably (Zhang et al. 2018; Ku and Ha 2020; Kaul et al. 2019b, 2020). These have been used extensively to discover traits and develop high-yield crops (Wang et al. 2018, 2019). Similar to this, rice bean characteristics such as less palatability, late regulation of flowering, and presence of anti-nutrients, alongside photoperiod sensitiveness, can be altered using CRISPR/Cas-dependent methods. As a result, it might be a ground plan to fix and eliminate the problems linked to the domestication of rice beans.

6 Conclusion

A long-term, affordable solution to the problem of malnutrition is to incorporate dietary heterogeneity into the food system in order to attain zero hunger. The rice bean is a rich source of high-quality protein, soluble fiber, minerals, and antioxidants, as well as a broad range of health supplements and pharmaceuticals that can cure or prevent diseases influenced by food. Due to its several uses as manure, fodder, and food for people, it is advantageous and economically viable for farms in underdeveloped areas. As a result, there are large gaps in current research on rice beans and marketing, necessitating increased effort. Farmers should be encouraged to participate in research projects on underutilized local plant varieties like rice beans, and policies should be developed to support this. Scientists should investigate the cultivars that both farmers and consumers favor and undertake awareness campaigns to emphasize the advantages of the crop for malnourished people in underdeveloped countries in order to encourage its planting. The aim is to increase crop yield, remove toxic anti-nutritional components, shorten the time needed to cook, gain consumer acceptance, acquire market approval, and address the protein- and food-insecurity problem. It requires a lot of effort to bring these nutrient-rich crops at the top of any country's food chain. However, recent innovations like CRISPR/Cas9, speed breeding, genomic selection, and other high-throughput approaches could expedite the breeding process (Fig. 3).

Acknowledgements The authors thank the ICAR scheme – National Agricultural Science Fund (NASF/GTR – 7025/2018-19) for financially supporting this research. We also thank the Department of Biotechnology (DBT) Funds (BT/PR38339/GET/119/334/2020) for additional support towards completing this work.

Abstract

Banana (*Musa* spp.) is an herbaceous, everlasting green monocotyledonous plant belonging to the family *Musaceae*. It is a major staple crop after rice, maize, wheat, potato and cassava, and it has a high potential to contribute to food and nutrition security. It is an excellent fruit full of micronutrients, especially vitamin A, iron, potassium, and magnesium, and is a source of energy for millions of inhabitants of tropical and subtropical regions. Despite these qualities, banana is still lacking in various essential nutrients. The conventional breeding program aims to increase the nutritional quality of banana. Still, the program is facing severe challenges due to the sterile seedless nature of banana and the narrow genetic diversity of several banana cultivars. Accessibility of well-annotated *Musa* genome sequences and established transformation and gene-editing platforms can contribute to developing banana with high dietary value. Furthermore, banana can produce edible vaccines, paving the way for future syringe-less vaccine development. This book chapter describes the various aspects of nutrition and the health-related importance of banana.

Keywords

1 Introduction

Banana (*Musa* spp.) is one of humankind's first-ever cultivated crops. It is still a significant fruit of the tropics and subtropics and is reachable globally for sale and consumption. Portuguese explorers introduced it to the African mainland from the Guinea Coast of West Africa. The term "plantain" (for cooking banana) was derived from the word "plantano" of the Spaniards. The term "banana" includes all edible varieties consumed as ripe fruits or cooked food. Banana was first known to the Arabs from very early times, as it appears in "The Holy Koran" as the "tree of paradise" – which is akin to the "tree of knowledge" in Christianity. Banana is an

evergreen, long-lasting, monocotyledonous herb of the *Musaceae* family. It is an essential food security crop in the tropic and subtropic regions and popular fruit globally. It is grown on over 11 million hectares of fertile land in more than 150 countries and islands, with an annual production of approximately 156 million tons (Tripathi et al. 2022). More than 1000 cultivars and landraces of bananas have been recorded (Heslop-Harrison and Schwarzacher 2007). The crop is grown mostly by smallholder farmers as food security and cash crops due to the crop being available the whole year. Most of the banana are cultivated for local consumption, and only about 15–20% enter the world markets for income generation. Banana is also crucial for animal feed, and the leaves can be used as roof covers for mud houses in some villages. The center of origin of the banana is believed to be Southeast Asia, particularly in the forest of Indonesia, Malaysia, and the Philippines, and its domestic cultivation is considered to have been initiated primarily in these countries. It has since spread across south Asia, Africa, and central and southern America. It is also argued that there are two domestication centers, one in Southeast Asia and the other in New Guinea. There are very diverse varieties of banana still found in these regions. Originally, all the cultivated edible seedless and tasty banana originated from two diploid wild species of *Musa acuminata* (genome AA) and *Musa balbisiana* (genome BB) of the genus *Musa* (Tripathi et al. 2022). Most familiar parthenocarpic banana cultivars are triploid (AAA, AAB, and ABB genome). Diploid groups (AA, AB, and BB genome) and tetraploids (AAAA, AAAB, AABB, and ABBB genome) are rarely cultivated. Cooking banana is the main portion of food intake for the local populations in the tropics. The dessert banana has a global distribution and marketing. The nutritional value of banana makes them one of the most important fruit crops. In terms of economic worth, they are the fifth most important agricultural produce traded globally. Throughout history, *Musa* has provided humans with food, medicine, clothing, tools, shelter, paper, and handicrafts. It might be referred to as the "first fruit crop" because it was initially cultivated when hunting and gathering were still the main methods of obtaining food.

The major objective of the banana breeding program is to develop high-yielding banana cultivars with resistance to pests and diseases and focus on the plant architecture to reduce the size of the false stem known as pseudostem, early flowering and maturity, and good quality of the fruit. The greatest challenge for banana breeders is to find suitable mating partners as seed-producing, diploid banana with disease resistance and other beneficial traits and tetraploids with seed fertility for use in banana breeding. Most of the edible banana cultivars are sterile and seedless due to parthenocarpy. These sterile banana cultivars are not suitable for breeding programs. The essential agronomic features are more prevalent in diploid parents. Consequently, the primary banana breeding projects concentrated on creating enhanced diploid parents with fertile seeds that could be crossed. To complement the conventional breeding efforts, it is essential to combine molecular breeding technology, especially transgenic and gene editing, to bypass the reproductive barrier for improving banana cultivars enrich with high nutritional qualities and high yielding. To cultivate sufficient food to fulfill the growing population's increasing demand for food security, more resilient food production technology is required. To

achieve the full potential, advanced breeding techniques like plant genetic transformation and genome editing need to be explored to complement conventional breeding programs. This book chapter aims to provide information on the valuable phytochemicals available in bananas and offer insightful evidence regarding the fruits' possible health advantages and use as a natural food antioxidant.

2 Description of Nutritional Constituents

Banana is a fruit with high nutritional importance and has proven to provide cures for some health challenges, such as constipation and depression. Both unripe green and ripe yellow banana contain 2.6 g dietary fiber, 75 g water, 23 g carbohydrates, 12 g sugars, 1 g proteins, a minimal amount of fat, and vitamins and minerals, especially Vitamin A, choline, B6, vitamin C, and potassium, phosphorus and magnesium, sodium, zinc, and several antioxidants mainly dopamine and catechin (fdc.nal.usda.gov). Yellow- and orange-pulped banana are rich in trans-β-carotene (Fungo and Pillay 2013). Consumption of carotenoid-rich fruits reduces various diseases, such as cardiovascular problems, type II diabetes, and cancer, and boosts immunity (Fungo and Pillay 2013). Specific banana cultivars are rich in provitamin A, an essential alternative for the poor population of the world who have been affected by severe vitamin A deficiency (Fungo and Pillay 2013). The tender core of banana pseudo-stem flour has higher flavonoids, polyphenols, insoluble dietary fiber, total dietary fiber, lignin, hemicellulose, cellulose, antioxidant capacity, and free-radical scavenging (Fungo and Pillay 2013). The male flower buds treat bronchitis, ulcers, and dysentery.

Cooked flowers are regarded as a healthy diabetic diet. Additionally, banana do not contain trace amounts of fat, sodium, or cholesterol, making them a healthy food option even for restrictive diet plans. Banana is considered a functional food due to their immunity-boosting properties. Fully Ripe banana peels comprise a very high number of phytochemicals known as antioxidants. They have been applied in traditional medicine in rural areas as an antiseptic to promote wound healing from insect bites and burns and tans human history (Pereira and Maraschin 2015). Eating a ripe banana helps to relieve constipation; similarly, eating an unripe banana provides a cure for loose motion. Banana is also a source of vitamin C, essential for preventing skin diseases in small children. The antioxidants in banana fruits, like superoxide ions, hydrogen peroxide, hydroxyl radicals, nitric oxide radicals, and singlet oxygen, have been linked to the treatment of a variety of diseases, including diabetes, age-related muscular degeneration, arthritis, some cancers, genotoxicity, inflammation, and Alzheimer's disease (Septembre-Malaterre et al. 2016). The tender core of banana pseudo-stem is used for food and medicinal properties in South India and Northeastern states due to its high phenolic content (Kandasamy and Aradhya 2014). The extract from the core of the stem is thought to be effective in reducing the size and weight of kidney and bladder stones. Banana peels are a rich source of antioxidant phytochemicals, such as delphinidin, anthocyanins, and cyanidins.

Banana is an excellent source of potassium. A single banana has around 23% of the daily recommended potassium intake. Additionally, current research indicates that potassium helps lower blood pressure in people who are deficient in it. Potassium also lowers the chance of having a stroke. Bananas have long been known for their antacid properties, which help to prevent stomach ulcers. Leucocyanidin, a banana flavonoid, significantly thickens the stomach's mucous membrane layer. Banana consumption is an excellent method to treat heartburn since they assist in neutralizing acidity.

Banana is a good source of natural antioxidants for foods. Mainly gallocatechin gallate is more copious in peel (158 mg/100 g wt.) than in pulp (29.6 mg/100 g (Someya et al. 2002). Similarly, banana contains another antioxidant called dopamine, chemically known as catecholamine, both in pulp and peels. Peels contain more dopamine (80–550 mg/100 g) than pulp (2.5–10 mg/100) (Kanazawa and Sakakibara 2000). The bioactive compounds, a product of secondary metabolism, have a beneficial potential by contributing to antioxidant activities. Carotenoids, flavonoids, and biogenic amines are the primary phytochemicals in banana fruits and are well-known to enhance human health.

Banana fruit ripening is a complex biochemical pathway with various activities to improve the fruits' aroma, nutritional quality, color, and texture. Green unripe mature fruits contain many carbon sources in the form of starch (12–35%), which gradually converts into sucrose (80%), glucose (10%), and fructose (10%) as a soluble sugar at the time of late ripening. Understanding the mechanisms that regulate starch conversion into soluble sugars during ripening is essential to minimizing postharvest losses by preventing fast ripening. Ethylene and other hormones are responsible for fruit ripening in banana which converts starch to soluble sugars (Cordenunsi-Lysenko et al. 2019). At the molecular level, it was understood that MaMADS24 and MaMADS49 proteins interact with several *MaMADS* genes for banana ripening, ethylene-signaling genes, and starch solubilization genes (Liu et al. 2017). The promoter regions of several genes also subsidize the mechanism by which ethylene regulates starch accumulation in ripened banana. About 200 AP2/to devise the strategy to prevent postharvest losses due to ripening in the natural conditions hindering the transportation for export purposes.

3 Genetic Resources of Health-Related (HR) Genes

Thousands of banana cultivars have evolved from natural crosses of the diploid A genome of *M. acuminata* Colla and B genome of *M. balbisiana* Colla. At Ethylene Responsive Factor Binding Protein (EREBP), transcription factors (TF) were known in the *Musa* genome (D'Hont et al. 2012). The effects of ethylene hormones and TF on the conversion of the starch-to-sugar pathway in banana remain a challenging trait to understand, and it needs further biotechnological interventions. The banana cultivars include diploids, triploids, and tetraploid genomic constitutions that are primarily sterile and vegetatively propagated. Based on consumption, they are generally classified as

"banana," which are sweet and eaten uncooked as fruit; "cooking banana," such as the East African Highland Banana (EAHB) that is cooked while unripe, "plantains" that are starchy and roasted while unripe, and "beer banana" are used for fermentation and deep frying (Heslop-Harrison and Schwarzacher 2007). The plantain subgroup of the banana belongs to AAB genomic group, while the dessert banana belongs to the AA, AB, AAA, and AAB genomic groups, and the cooking banana falls under AAA genomic group. The hybridization between the diploid species (A and B) resulted in common edible triploid cultivars and tetraploids. The commercially critical cultivated banana belongs to the group AAA. It includes 'Gros Michael', 'Cavendish', 'Grand Naine', 'Robusta', etc. The banana cultivars are classified according to their genome composition (Table 1).

The Cavendish banana is the preferred dessert banana due to its high TSS and vitamin C levels, particularly in 'High gate', 'Gros Michael', 'Jari buaya', and

Table 1 Banana cultivars based on genome constitution. (Adapted from Nayar (2010)

Genomic composition	Banana cultivars
AA	'Inarnibal', 'Paka', 'Matti', 'Anakomban', 'Pisang Jari Buaya', 'Pisang Lilin', 'Senorita', 'Kadali', 'Sucrier', 'Kluai Khai', 'Lady's Finger', 'Orito', 'Pisang Mas'
AAA	'Ambon', 'Cavendish' ('Dwarf Cavendish', 'Giant Cavendish', 'Grand Nain', 'Williams'), 'Gros Michel' ('Cocos', 'Highgate', 'Lowgate'), 'Ibola', 'Basrai', 'Lujugira-Mutika', 'Pisang Masak Hijau' (Lacatan), 'Red' ('Green Red'), 'Robusta' ('Harichal', 'Malbhog'), East African Highland Banana ('Musakala', 'Nakabulu', 'Nakitembe', 'Nfunka', 'Mbidde')
AAAA	'Pisang Ustrali'
BB	'Bhimkol', 'Biguihan', 'Gubao', 'Pa-a Dalaga', 'Tani'
BBB	'Abuhon', 'Inabaniko', 'Lap Chang Kut', 'Mundo', 'Saba Sa Hapon', 'Saba', 'Sabang Poti', 'Turrangkog'
AB	'Kunnan' ('Adukkan', 'Poonkalli', 'Poovilla Chundan'), 'Ney Poovan' ('Kisubi', 'Safed Velchi'), 'Sukali Ndizi' ('Kumarangasenge')
AAB	'False horn' ('French', 'French horn'), 'Laknau', 'Maia Maoli', 'Moongil', 'Mysore' ('Sugandhi'), 'Nendran', 'Pisang Raja', 'Plantain Horn', 'Pome' ('Pachanadan', 'Pacovan', 'Prata Ana', 'Virupakshi'), 'Popoulu', 'Ilohena', 'Rasthali', 'Silk'
ABB	'Bluggoe' ('Nalla Bontha', 'Pisang Batu', 'Punda'), 'Pisang Awak' ('Klue Namwa', 'Karpuravalli', 'Pey Kunnan', 'Yawa'), 'Monthan', 'Peyan', 'Klue Teparot', 'Pelipita', 'Kalapua', 'Cardaba'
AAAB	'Atan'
AABB	'Kalamagol', 'Laknau Der'
ABBB	'Bhat Manohar'
AS	'Aso', 'Kokor', 'Ungota', 'Vunamami'
AT	'Umbubu'
AAT	'Kabulupusa', 'Karoina', 'Mayalopa', 'Sar'
ABBT	'Giant Kalapur', 'Yawa 2'
Unknown	'Fei'

A Musa acuminata, *B Musa balbisiana*, *S Musa schizocarpa*, *T Musa textiles*

'Bucaneiro' have high total phenols and total carotenoid content among cultivars with AAA and AAAA genome (Borges et al. 2014). Studies have shown that cultivars from Papua New Guinea (Englberger et al. 2010) and Malaysia (Borges et al. 2014) possess high amounts of provitamin A. The orange and yellow-fleshed cultivars contained high β-carotene than the cream or white-fleshed cultivars, indicating a correlation between orange/yellow pulp color and carotenoid content. Further, Red Dacca, Latundan, and Cavendish banana varieties were reported to have inhibitory activities against α-amylase and α-glucosidase enzymes and high free radical scavenging abilities, which make them suitable for consumption by type 2 diabetes patients (Adedayo et al. 2016). In general, sugars, minerals, proteins, polyphenols, and carotenoid contents increased during ripening, whereas fiber, lipids, and starch contents were higher in unripe fruits (Kookal and Thimmaiah 2018). Interestingly, banana pseudostem and peel are excellent sources of antioxidants and polyphenols. The pseudostem of a few banana cultivars have high antioxidant properties due to its high phenol and flavonoid content. Besides, various banana and plantain varieties belonging to *M. acuminata*, *M. balbisiana*, and *M. paradisiaca* have shown antimicrobial activity against bacterial and fungal pathogens (Mostafa 2021).

Some banana cultivars that are rich in nutrients and metabolites and valuable for human health are listed (Table 2). Many cultivars were reported to be rich in multiple nutrients like phenolic compounds, minerals, vitamins, TSS, and starch. For example, the cultivar 'Nendran' is high in carotenoids, phenolics, minerals, vitamins, and total soluble sugars. Similarly, cultivar 'Saba', 'Highgate', 'Njali Poovan', 'Karpooravalli', and 'Grand Naine' contains multiple health-related nutrients. Such cultivars can serve as valuable genetic resources for molecular mapping and breeding.

4 Classical Genetics and Traditional Breeding

Conventional breeding is difficult in *Musa* species due to the sterility and high heterozygosity. Hence, developing large segregating mapping populations of triploid, cultivated banana cultivars that are female and male-sterile is cumbersome. Moreover, basic genetic and inheritance studies in banana were hindered in the past due to constant pressure on breeders' need to develop disease and pest-resistant varieties as the banana-growing areas were continuously threatened by conditions such as fusarium wilt and Sigatoka. A few studies had previously examined the inheritance pattern of genes for vegetative and fruit traits using mapping populations or accessions derived from diploid fertile cultivars. Over the years, researchers have attempted to determine the ancestry of the A and B genomes in banana which contributed to the formation of cultivars with different genetic backgrounds worldwide. It was established that the maternal transmission of chloroplast genome and paternal information of mitochondrial genome in banana using Restriction Fragment Length Polymorphism (RFLP) markers. Haplotyping of mitochondrial and chloroplast genomes has supported the theory of the A and B genomes have a common ancestor. In addition, the study established the presence of six chloroplasts and seven

Table 2 Some banana cultivars with high health related traits

Properties	Cultivar name	Reference
Antimicrobial activity	'Dole', 'Fougamou', 'Kluai Tiparot', 'Mbwazirume', 'Namwah Khom', 'Petit Naine', 'Pelipita', and 'Saba'	Jouneghani et al. (2020)
High carotenoid content	'Aibwo/Suria', 'Asupina', 'Berlin', 'Gatagata/Vudito', 'Fagufagu', 'Horn Plantain', 'Hongjiaowang', 'Jari Buaya', 'Jaran', 'Karpooravalli', 'Kirkirnan', 'Kluai Khai Bonng', 'Ropa', 'Wasolay', 'Highgate', 'Thap Maeo', 'Malbut, 'Lahi', 'Apantu', 'Bira', 'To'o', 'Sepi', 'HungTu', 'Parao', 'Pisang Raja', 'Pacific Plantain', 'Wain', 'Red Dacca', 'Lakatan', 'Sucrier', 'Utin Iap', 'Karat', 'Utimwas', 'Iemwahn', 'Utiak', 'Dukerehda', 'Red Banana', 'Nendran', 'Goldfinger' and 'Hua Moa', 'Toraka', 'Warowaro'	Englberger et al. (2010), Ekesa et al. (2015), and Kargar (2019)
High vitamin content	'Karat', 'Aibwo/Suria', 'Gatagata/Vudito', 'Fagufagu', and 'Akeakesusu'	Englberger et al. (2010)
High phenolic content	'Jaran', 'Wasolay', 'Nam', 'Highgate', 'Gros Michel', 'Thap Maeo', 'Saba', 'Champa Madras', 'Bucaneiro', 'Ney Poovan', 'Tiparot', 'Njali poovan', 'Nendran', 'Ducasse', 'Ladyfinger', 'Terrinha', 'Marmelo', 'Ouro', 'Red Banana', 'Poovan', 'Muomva-red', 'Grande Naine', 'Rasbale', 'Pisang Raja', 'Goldfinger', and 'Kandarian'	Bashmil et al. (2021) and Khoza et al. (2021)
High mineral content	'Khai', 'Ouro da Mata', and 'Pacha Nadam', 'Akondro mainty', 'Makyughu 1', 'Ijihu inkundu', 'NIGAB-1', 'NIGAB-2', 'Rasakadali', 'Nendran', 'Saba', 'FHIA-01', 'Basrai', 'Jawari', 'South Tenerife', 'North Tenerife'	Khoza et al. (2021)
High protein content	'Makyughu 2', 'Muraru', 'Akondro mainty', 'Finger Rose', 'Pisang Awak'	Khoza et al. (2021)
High folic acid content	'Lampung'	Ningsih and Megia (2019)
High TSS content	'Kadali', 'Rasakadali', and 'Nendran', 'Njali poovan', 'Robusta', 'Ouro', 'Nanica', 'Nanicão', 'Caru-Roxa', 'Prata', 'Prata-Anã', 'Mysore', 'Williams', and 'Pacovan'	Kookal and Thimmaiah (2018)
High vitamin C/antioxidant content	'Nendran', 'Njali poovan', 'Ducasse', 'Ouro', 'Terrinha', 'Muomva-red', 'Luvhele', and 'Grande Naine'	Bashmil et al. (2021)
High starch content	'Marmelo', 'Terrinha', 'Karpooravalli', 'FHIA-01', 'Macho', 'Enano', and 'Valery'	Khoza et al. (2021)

mitochondrial cytoplasmic-gene pools among the *M. acuminata* and *M. balbisiana* accessions (Boonruangrod et al. 2008). Cytogenetic studies through karyotyping have led to an understanding of chromosomal structural arrangements of genotypes with different genomes in banana. These results indicate that the banana genome is

constituted by common ancestors who were evolved by *M. balbisiana* (BB genome) and *M. acuminata* (AA genome) (Dehery et al. 2021).

Interestingly, the invention of next-generation sequencing technology validated the cytogenetic finding by identifying two structural variations in A and B genomes, thereby influencing local recombination and causing a segregation distortion and aneuploidy in edible interspecific triploid hybrids (Baurens et al. 2019). About inheritance of fruit quality traits in cultivar 'Sukali Ndizi', TSS exhibited nonadditive and dominant gene action. In contrast, pulp texture and flavor traits were found to be influenced by additive and complementary gene action. Fruit acidity showed an incomplete dominance effect, with a single major gene and multiple genes controlling the trait (Buregyeya et al. 2021). Furthermore, phenotypic characteristics like finger weight and bunch weight were shown to strongly correlate positively with yield-related attributes in banana. Albinism in banana is a harmful trait caused by a lack of chlorophyll in the plant tissues. Using full-sib plantain-banana hybrids, researchers determined that the segregating ratio of albinism was 15:1, which might be due to the complementary gene action of one or two recessive alleles. Dwarfism is a desirable commercial trait in banana due to the toppling of large-size pseudostem after bearing the big bunches of the fruits. Dwarfism in segregating population generated by crossing triploid cultivar 'Bobby Tannap' (AAB) and diploid 'Calcutta 4' manifested a trisomic test-cross segregation ratio of 2:1, indicating that the trait was regulated by a single recessive gene, known as a dwarf gene. Ortiz (1997) reported the presence and inheritance of 2n pollen in *Musa* diploid and polyploidy cultivars. A single dominant gene that controls 2n pollen facilitates the introgression of beneficial alleles from diploid species to polyploidy cultivars through sexual polyploidization. However, banana lacks extensive studies on the inheritance patterns of fruit traits. An increased focus on improving cultivars with favorable fruit characters and disease and pest resistance can be achieved only when genetic mechanisms underlying these traits are thoroughly known. Therefore, adapting molecular breeding approaches will ease the burden of conventional breeding methods in developing seedless, vegetatively propagated banana progenies.

5 Genetic Diversity Analysis of Banana

Knowledge of the genetic diversity of banana germplasm, cultivars, and wild types is crucial for understanding the genetic makeup and their suitability in breeding programs. Lots of genetic diversity is observed in the plantain and the desert banana. Different morphometric indicators and molecular marker-based diversity studies have been reported in banana over the years. The phenotypic polymorphisms among plantain cultivars based on yield-related traits can serve as indicators for the field performance of cultivars (Brisibe et al. 2021). The important phenotypic traits like size and weight of bunch per plant, the total number of fruits per bunch, the girth of the pseudostem, height of the plant, time period from flowering to harvest, the color of the leaf, rachis type, peduncle hairiness, fruit shape, fruit apex, etc., were used to study the diversity among banana cultivars and hybrids (Brisibe et al. 2021). Similarly, descriptors like petiole canal, bract curling, and color have helped in differentiating cultivars with different ploidy levels as well as between cooking and dessert banana. In

addition, mineral profiling of fresh fruit pulp has been used as an indicator to study variability among Indian *Musa* accessions (Devarajan et al. 2021).

Molecular marker-based diversity analysis aid in minimizing discrepancies in phenotyping and distinguishing cultivars with high phenotypic similarities. Molecular markers have facilitated studies on interspecific and intraspecific diversity, relatedness, and population structure among banana cultivars. It includes random amplified polymorphic DNA (RAPD; Wahyudi et al. 2020), Inter Simple Sequence Repeat (ISSR; Wahyudi et al. 2020), Simple-sequence repeats (SSR; Brisibe and Ubi 2020), Internal transcribed spacer (ITS), Sequence-related amplified polymorphism (SRAP), *MAT*K marker (Hariyanto et al. 2021), Conserved DNA-Derived Polymorphism, Start Codon Targeted (SCoT; Igwe et al. 2022), Directed Amplification of Minisatellite-region DNA (DAMD; Pinar et al. 2019), and Inter-Retrotransposon Amplified Polymorphism (IRAP) markers (Saraswathi et al. 2020). Microsatellite markers are employed to analyze the population structure and genetic diversity of banana (Mertens et al. 2021). Besides, rbcL plastid gene sequences were utilized to understand the genetic relatedness and diversity among the cultivars and wild species of *M. acuminata* (AA genome), *M. balbisiana* (BB genome), and *M. paradisiaca* (AAB, ABB genome). This rbcL sequence-based barcoding can be useful in species identification and discrimination in banana (Ainiyah et al. 2020). Biswas et al. (2020) recently reported the development and validation of functionally relevant genic SSR markers in *Musa* species which were mapped to *M. acuminata*, *M. balbisiana*, and *M. Schizocarpa* genomes. Similarly, genic SSR markers were developed from the transcriptome of cultivars 'Bee Hee Kela' and 'Calcutta-4' (Venkataramana et al. 2015). These SSR markers can be used in genetic diversity studies, germplasm characterization, population structure analysis, and comparative mapping not only in banana but also in related monocot species. In addition, methylation-sensitive Amplified Fragment Length Polymorphism (AFLP) markers were used to determine the epigenetic variations among the genetically identical East African Highland banana. These heritable epigenetic changes in the offspring can lead to different functional traits. Consequently, using epigenetic markers in diversity analysis can aid in the conservation of epigenetic resources and their integration in breeding programs Further, genotyping of the external transcribed spacer region of the ribosomal DNA locus of *M. acuminata* and *M. balbisiana* subspecies led to the development of a SCAR marker that can differentiate the gene pools and identify the wild ancestors (Jeensae et al. 2021). Phenotyping and genotyping employing morphological descriptors and molecular markers, respectively, will be an efficient method for comprehending the variability and relatedness of *Musa* species.

6 Molecular Analysis of Hypersensitive Response Genes and Quantitative Trait Loci on Banana Genome

Mapping population studies for the banana genome are faced with various constraints like parthenocarpy, low fertility, polyploidy, heterozygosity, and small population size. In a molecular mapping study, the first requirement is generating

mapping populations. Diploids, fertile cultivars, wild types, and triploids have been used to create mapping populations to examine the segregation pattern of genes involved in different quantitative traits and disease resistance (Ahmad et al. 2020). Very few efforts were made to generate a mapping population and identify QTLs concerning biotic and abiotic resistance in *Musa* species. Thus, there are very few studies regarding QTLs or genes related to fruit or other morphological traits in banana. Recently, Biobiany et al. (2022) have used genotyping by sequencing to identify QTLs linked to fruit traits like pulp acidity, firmness, and dry matter content. Twelve prominent QTLs were identified, among which a QTL for pulp acidity was located in the LG1_7 of the genetic map of 'Pisang Madhu'.

Further, a di-haploid mitochondrial genome of *M. acuminate subsp. malaccensis* DH-Pahang was sequenced and assembled. Similar efforts will help improve our understanding of cytoplasmic male sterility and flower and seed development in banana, as these traits are controlled by the genes present in the mitochondrial DNA (Prakash et al. 2022). Despite the lack of mapping studies related to fruit traits, the availability of complete genome sequences of *M. acuminata* and *M. balbisiana* has enabled genome-wide identification of several transcription factors (Wang et al. 2022) and flavonoid gene families (Pandey et al. 2016) that are involved in plant development, fruit ripening, various metabolism and plant stress responses from biotic and abiotic stresses. The genes identified in these studies could help assist banana breeding program initiatives in improving the fruit quality of the existing cultivars.

7 Genomics-Aided Breeding for HR Traits

The seedless trait (parthenocarpy combined with female sterility) was studied utilizing Genome-wide association studies using DArt markers in 105 diploid accessions with *M. acuminata* genetic background. This helped identify six candidate genomic regions with two genes related to female sterility (Sardos et al. 2016). Interestingly, Genome-wide association studies (GWAS) on 33 accessions from Papua New Guinea confirmed the six-candidate regions and discovered an orthologous gene to Histidine Kinase CKI1 that may control the female sterility trait (Sardos et al. 2016). Similarly, GWAS and genomic selection (GS) using prediction-based models were reported in a multiploidy training population of 307 banana genotypes. Out of the six prediction models employed, the BayesB model had the highest prediction capability for fruit-filling and fruit bunch traits.

Further, more models considering additive gene effects performed better in prediction Also, multiple QTLs with significant results are located on chromosome 3, responsible for controlling the fruit-filling trait in banana (Nyine et al. 2019). Further, transcriptome analysis has shed light on the expression pattern of genes involved in carotenoid metabolism in the 'Xiangfen1' banana (Dong et al. 2022). In the future, "Omics" based studies can help identify genes controlling critical health-related traits, supporting genomics-assisted breeding efforts. Henceforth, the use of

GWAS and genomic selection in banana breeding provides new possibilities for improving selection efficiency, particularly for fruit quality attributes.

8 Recent Concepts and Strategies for Banana Improvement

The global population is increasing day by day at an alarming rate. By 2050, the population of the world is expected to surpass 9 billion. This increasing population burden on the planet and the serious impact of climate change on agriculture production will fuel a massive demand for food, and it is estimated that nearly 1 billion people suffer from nutritional and food insecurity. Increased production of food crops with high nutritional quality using advanced technologies such as genome editing promises to address these insecurities. Plant genome editing tools are a group of advanced genetic engineering and molecular biology techniques that allow the plant biotechnologist to knock out faulty genes with high precision. Currently, several gene editing technologies are available in the hand of plant biotechnologists for crop improvement especially site-directed nucleases (SDNs), zinc-finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and the clustered regularly interspaced short palindromic repeats/CRISPR-associated protein (CRISPR/Cas). These techniques have been applied to manipulate plant genes in several crop species for increased nutritional quality. These gene editing tools cause specific double-strand breaks (DSBs) in DNA at targeted sites to modify genes in a highly precise method with minimal or no off-type effects. The double-stranded break in the DNA is repaired by the self-healing mechanism in the plant cells, either of nonhomologous end joining (NHEJ) or homology-directed repair (HDR) if there is a donor template available, leading to small insertions, deletions, substitutions of nucleotides, or gene replacement depending on the cell cycle phase and the presence or absence of a repair template containing homologous terminal sequences (Fig. 1). There are three types of editing techniques especially site-directed nucleases 1, 2 and 3 (SDN1, SDN2, and SDN3), have been used with respect to the DNA repair mechanism (Tripathi et al. 2020). SDN1 is effective and is based on NHEJ error-prone repair of DBS in the host genome, resulting in gene silencing, gene knockout, or alteration in the gene function. SDN2 is less efficient and has high reliability and is achieved when a repair template that is like the DSB is added to the CRISPR machinery. The DSB is then repaired via HDR, producing nucleotide substitution or targeted indels. In SDN3, a donor template that is longer than the homologous sequences in which the DSB was formed is used to repair the DSB via HDR. Based on the donor sequence, SDN3-type repair in DNA results in the insertion of the full gene or part of genetic material being used at the target location. The repair is less efficient and reliable.

8.1 Zinc Finger Nucleases (ZFN)

Zinc finger nucleases (ZFN) are synthetic endonucleases that include zinc finger DNA-binding region and a nuclease subunit, similar to the type of II restriction enzyme FokI endonuclease (Fig. 1). ZFN contains C2H2 zinc-finger domains, with each finger recognizing three nucleotides on the specific gene target. ZFNs have

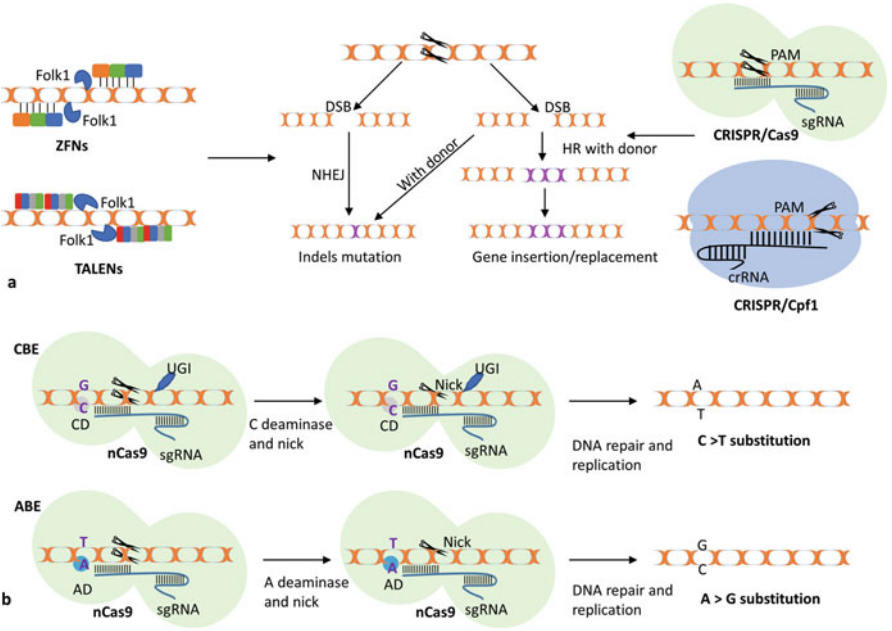

Fig. 1 Commonly used genome editing tools used for genetic manipulation of plants. (**a**) Genome editing tools which create double-stranded break (DSB). The break, shown in the middle, is restored either by homology recombination (HR) or nonhomologous end-joining (NHEJ). NHEJ inserts small indels (insertion, deletion, or substitution) into the DSB site of the genome and results in frame-shift mutations or premature stop codons. HR can cause small indels, gene substitution, and insertions depending on the presence or absence of a homologous donor DNA. (**a**) Zinc finger nucleases (ZFNs) and Transcription activator-like effector nucleases (TALEN) on the left panel use FokI endonuclease to cut DNA double strands. Clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated protein 9 system on the right panel employs single-guide RNA (sgRNA) for DNA binding and Cas9 protein for DNA cleavage. While CRISPR/Cpf1 system uses mature clustered, regularly interspaced, short palindromic repeats RNA (crRNA) for DNA binding and Cpf1 protein for DNA cleavage. CRISPR/Cas9 recognizes a G-rich protospacer adjacent motif (PAM) while CRISPR/Cpf1 recognizes a T-rich PAM. (**b**) Diagrammatic presentation of CRISPR/Cas9-mediated base editing technique. In the cytosine base editor (CBE) system, cytosine (C) in the targeting region replaces with uracil (U), then U is replaced with thymine (T) in DNA repair or replication processes, creating a C-G to T-A substitution. In the Adenine base editor (ABE) technique, adenine (A) in the genome targeting region is converted to inosine (I), which is used as guanine (G) by polymerases, creating A-T to G-C substitutions. Abbreviations used in the diagram: *ZFN* - zinc-finger nuclease, *TALEN* - transcription activator-like effector nuclease, *DSB* - double-strand break, *NHEJ* - nonhomologous end joining, *HR* - homologous recombination, *PAM* - protospacer adjacent motif, *CRISPR* - clustered regularly interspaced short palindromic repeats, *Cas9* - CRISPR associated protein 9, *sgRNA* - single-guide RNA, *crRNA* - CRISPR RNA, *ABE* - adenine deaminases-mediated base editing, *CD* - cytidine deaminases, *AD* - adenine deaminases, *CBE* - cytidine deaminase-mediated base editing, *nCas9* - Cas9 nickase, *UGI* - uracil glycosylase inhibitor

successfully been used to target endogenous genes in Arabidopsis, tobacco, and soybean, creating desired mutations, gene replacements, deletions, or inversions. The main issues with ZFNs, however, are their limited specificity, which causes severe off-type effects in the plant genome, and their excessive complexity in the

designing of the construct, which causes a lower rate of the success of the endonuclease enzymes (Tripathi et al. 2020). These limitations of ZFN led to the discovery of the upgraded version of the endonucleases known as *transcription activator-like effector nucleases* (TALEN).

8.2 Transcription Activator-Like Effector Proteins (TALEN)

TALENs are synthetic restriction enzymes that contain FokI endonuclease subunit with a DNA-binding site and repeats of the DNA restriction domain to cut any desired site of the genome. TALEN proteins are secreted by Xanthomonas bacteria linked with the Fok1 nuclease domain. It is similar to ZFN proteins rely on the FokI nuclease subunit functioning as a dimer, with two monomers designed for each genomic target (Fig. 1). However, unlike ZFNs, TALENs possess a broader targeting range and are less challenging to engineer, appear to be more mutagenic than ZFNs, and are highly specific. TALEN-directed mutagenesis has been used in rice to target resistance against bacterial blight disease (Tripathi et al. 2020), and many plant species have been successfully edited utilizing this technology.

With the availability of banana genomic sequences, both ZFN and TALEN can be used for genome editing in a banana to increase nutritional quality. Unfortunately, these technologies require expertise in molecular cloning as well as knowledge of DNA binding sites for individually targeting applications. Recently, CRISPR/Cas9 has empowered researchers to perform genome editing in plants more conveniently, precisely, and safely with minimal off-type effects.

8.3 Clustered Regularly Interspaced Palindromic Repeats (CRISPR)/Cas9

The CRISPR/Cas9 system is based on small RNA-guided which bind on the targeted site of the genome and Cas proteins that cut the specific site of DNA to provide a double-stranded break, in comparison to TALENs and ZFNs, which are based on protein-DNA binding endonuclease. Theoretically, CRISPR/Cas9 technology originated from bacterial type II CRISPR/Cas immune system, which protects them against an invasion of bacteriophages and viruses. Because of its simplicity, design flexibility, high efficacy, and ability to simultaneously edit several genes, CRISPR/Cas9 technology has become the most popular and widely used technique (Ntui et al. 2020).

CRISPR/Cas9 system has two main components, the small guide RNA (gRNA) and the Cas proteins (Fig. 1). The Cas proteins are endonuclease that recognizes target DNA by matching the 5′ leading sequences of gRNA with the 5′ leading sequences of DNA. It also recognizes the adjacent protospacer motif (PAM) sequence and starts editing the DNA upstream. The gRNA consists of a framework of a 20-nucleotide user-defined spacer sequence that directs the Cas endonuclease to a target sequence in the specific genome that is complementary to the 20 nucleotides before the adjacent protospacer motif (PAM). The PAM is a three-nucleotide

sequence, typically NGG or NAG, found near the cleavage site of the target DNA. The main function of the Cas proteins is to start DSB in the DNA upstream in the targeted region of the genome (Ntui et al. 2020).

8.4 CRISPR12a and Cas13a Systems

There are several other Cas proteins have been discovered and applied for plant genome editing, for example, Cas12a (Cpfl) and Cas13a. Cas12a (Cpf1) is a class 2 type V-CRISPR that consists of RuvC sites that belong to the retroviral family. It comprises crRNA biogenesis RNase and single-stranded DNase activity and functions by first chopping up target DNA and processing its crRNA. It was developed from Prevotella and Francisella 1 bacteria (Roy and Soni 2021). It recognizes T-rich PAM, TTN/TTTN/TTTV (N = A/T/C/G; V = A/C/G) which is situated upstream of the target site, hence cutting DNA at the distal location of the PAM. It uses RuvC endonuclease, which is regulated by a single RNA. The endonuclease then recognizes PAM, which is rich thymidine-rich and produces staggering cuts (Roy and Soni 2021. Cas12a has shown more efficient multiplex gene manipulation by a single sequence array on the selected gRNA (Roy and Soni 2021). Cas13a is a class 2 type VI-A ribonuclease capable of targeting and cleaving the phage genome, which consists of single-stranded RNA molecules. It has shown potential for use in detecting RNA viruses, with more accuracy and specificity than PCR detection. A PAM region is not required for Cas13a ribonuclease to detect the RNA viruses in plants (Aman et al. 2018).

8.5 Base Editing and Prime Editing System

The Cas proteins use NHEJ and HDR processes to repair DSB in the target genome. These approaches have disadvantages, including decreased delivery, efficiency, and unwanted rearrangements caused by DSB at the targeted locus. To refine the gene editing with minimal damage to the parent genome, an upgraded version of CRISPR/Cas9 editing known as base editing technique (BE) was invented. BE is used for target manipulation of a single base pair without involving DSB in the genome. The base-editing tools use Cas9 nickase (nCas9) or inactive Cas9 fused to an endonuclease enzyme with single base pair conversion activity. In the base editing technique, a guide RNA binds to the target DNA, and when the bases pair, a DNA bubble having a short segment of ssDNA is produced (Roy and Soni 2021). A DNA deaminase fused to an inactive Cas9 or (dCas9) enables the base substitution at single-nucleotide resolution. Base-editor tools having cytosine deaminases convert cytosine (C) to thymine (T), creating a C-G to T-A or A-T to G-C substitution.

Similarly, the adenine deaminase base editor converts adenine (A) to guanine (G), making A-T to G-C substitutions (Fig. 1). The DNA deaminases function as effectors allowing C-G to T-A or substitution. At the same time, the RNA-guided CRISPR system acts as a genomic locator of the targeted locus. Cytidine-deaminase

base editing (CBE) has been used in several economically important crops. Zong et al. 2018). Adenine-deaminase base editor (ABE) is more difficult to use than CBE. However, researchers developed Adenine-deaminase effectors, which they can use to generate point mutations in some crops (Kang et al. 2018).

Prime editing is another tool developed to achieve gene editing in various organisms. It works the same way as traditional CRISPR/Cas systems, allowing DNA base pair replacements, minor insertions, and deletions (indels) (Chen et al. 2021). Primer editing, on the other hand, does not cause DSB and does not necessitate the use of a foreign DNA segment; it addresses frameshifts caused by indels and reduces off-target effects. To edit the genome, a fusion protein composed of Cas9 H840A nickase connected to a designed RT enzyme and long gRNA, known as pegRNA, is required. Although prime editing has the potential to supplement current CRISPR editing methods and enables precise and targeted DNA alterations, the biological process has yet to be well known, even though prime editing can be a fascinating tool to modify the genome of a banana.

8.6 CRISPR Activation

CRISPR/Cas9 gene editing tools have supported the creation of new technologies that rectify some of the limitations of traditional genetic editing systems and revolutionize many fields of plant science. The CRISPR/Cas9 transcriptional activator technique (CRISPRa) embraces a lot of potential to generate improved crops with desirable agronomic traits. CRISPRa is a form of CRISPR tool that induces gene expression by combining transcriptional activators with a modified version of Cas9 devoid of endonuclease activity (dead Cas proteins, also known as dCas). When the nuclease activity of the Cas9 protein is converted into a deactivated form (dCas9), CRISPR/dCas9 retains the ability to bind the targeted DNA sequence but does not cause DSB on the targeted site of the genome. This combination of dCas9 and transcriptional activation sites enables the precise and effective transcriptional activation of any genes without causing DSB at the DNA of targeted sequences of endogenous genes.

The most common type of CRISPR activator is VP64, a tetramer of VP16, a well-characterized transcription activator from the herpes simplex virus. VP64 has been shown to increase endogenous gene expression. It was one of the first CRISPRa systems developed, and it has demonstrated a significant induction gene over-expression in many crops (Shakirova et al. 2020). CRISPRa systems of the first generation have two components: dCas9 coupled with transcription factors and sgRNA. P65 and p300, two more first-generation dCas trans-activators, were also synthesized and employed for gene activation (as activators, various oligomers of VP16 have been developed).

According to Lowder et al. (2018), a dCas9 containingVP64 system including the deactivated CRISPR-associated protein 9 (dCas9) coupled with four tandem repetitions of the transcriptional activator VP16 (VP64) was shown to activate endogenous genes in plants. Arabidopsis and tobacco observed effective transcriptional

activation of protein-coding and noncoding genes. However, the gene activation rate of the first-generation of CRISPRa system with single-domain Cas9 fusions showed only low/moderate overexpression of the targeted endogenous gene in plants. The Second-generation CRISPRa system has also been explored.

The second-generation system consists of dCas9, sgRNA, and effectors recruited in multiple copies by specific dCas9 or sgRNA domains. This type of arrangement can cause changes in gene expression, be it activation, repression, epigenetic alterations, or something else (Shakirova et al. 2020). These systems include the following: (1) the scaffold and casilo, both of which are based on the scaffold RNA (sRNA). (2) The Synergistic Activation Mediator, based on a chimeric MS2-p65-HSF1 activation helper protein and chimeric dCas9-VP64, sgRNA with synthetic aptamers for MS2 recruitment, and a chimeric MS2-p65-HSF1 activation helper protein. The Supernova Tagging System is effective because antibodies have a high affinity and specificity for short peptide sequences. Lowder et al. (2018) used the second generation to create a CRISPRa system that targeted protein-coding and noncoding genes previously manipulated in Arabidopsis by the dCas9-VP64 system. They used a modified guide RNA scaffold gRNA2.0 (designated CRISPR-Act2.0) with VP64 fused to dCas9 and discovered that the CRISPR-Act2.0 system activated transcription more efficiently than the dCas9-VP64 system alone.

Selma et al. (2019) have developed a CRISPRa system in *Nicotiana benthamiana* using dCasEV2.1 loaded with a six-gRNA combination targeting the promoters of the NbDRF and NbAN2 genes. Compared to the first-generation CRISPRa system, transgenic lines harboring the second-generation CRISPRa system demonstrated significant gene activation (Selma et al. 2019). Pan et al. (2021) recently established a highly robust CRISPR-Acct3.0 system for inducing several genes in rice, tomato, and Arabidopsis. The CRISPR–Act3.0 system was developed by experimenting with several transcription activators based on deactivated Streptococcus pyogenes Cas9 (dSpCas9). Compared to the CRISPR-Act2.0 and the first-generation systems, the CRISPR–Act3.0 system activated genes four to six times more (Pan et al. 2021).

In our laboratory at IITA-Kenya, we are using CRISPRa to induce the overexpression of endogenous banana genes, including antibacterial Vicilin, Leucine-Rich Repeat, Wall Associated Kinases, Pathogenesis-Related gene, and disease resistance R gene by transcriptional factor inducers to confer resistance to banana Xanthomonas wilt. The endogenous *Musa* genes were annotated based on transcriptome analysis of bacterial disease-resistant progenitor *Musa balbisiana* and disease-susceptible Pisang Awak (Tripathi et al. 2020). Six constructs were designed and delivered to embryogenic cells, each targeting the promoters of three endogenous genes. Initial screening of the regenerated plants revealed targeted gene overexpression ranging from two- to eightfold by relative real-time qPCR, and further, these events evaluated in the screen house showed enhanced resistance against *Xanthomonas campestris* pv. *musacearum*. Apart from overexpressing disease resistance genes, the CRISPRa system can also activate genes to increase the nutritional composition of banana cultivars.

8.7 Gene Editing of Banana

A couple of studies have been documented on gene editing in banana. Currently, the genome editing strategy focuses on the CRISPR/Cas9 knockdown of endogenous genes. It is now possible to precisely target and alter banana genes thanks to the availability of reference genome sequences. The first gene editing was reported in the banana cultivar 'Rasthali' containing the AAB genome using phytoene desaturase (PDS) as a visual marker gene (Kaur et al. 2020). The researchers utilized a single gRNA to knockout in the PDS gene, producing albino phenotypes in the generated plants. However, the mutation efficiency was detected at about 59%. In the same year, Naim et al. (2018) reported employing polycistronic gRNAs to edit the PDS gene in 'Cavendish Williams' with the AAA genome, and mutation efficiency was detected at about 100%.

Ntui et al. (2020) also reported the generation of edited events with two gRNAs targeting the PDS gene to achieve 100% mutation efficiency in sweet banana 'Sukali Ndiizi' (AAB genome) and plantain 'Gonja Manjaya' (AAB genome). The PDS is a visual marker frequently used to optimize gene editing protocol in plants. Phytoene desaturase is an enzyme in the primary carotenoid pathway that alters phytoene into carotenoid precursor's phytofluene and ζ-carotene. When its function is knocked out, plants with albino, variegated, or pale green phenotypes are generated, and they can be seen with the naked eye, depending on the mutation pattern.

Generating disease-resistant plants with increased economic value, food, and nutritional enhancement are the main objectives of the genome editing of the banana. The major banana diseases that affect yield are the banana streak virus (BSV) and banana Xanthomonas wilt (BXW). BSV is a dsDNA badnavirus that integrates into the B genome of plantain (AAB genome). CRISPR/Cas9-based editing was performed to inactivate the endogenous banana streak virus (eBSV) in the plantain cultivar 'Gonja Manjaya', rendering functional viral proteins which were unable to develop new coat proteins (Tripathi et al. 2020). Further, it has been investigated that CRISPR/Cas9-mediated genome editing of Musa Downy mildew resistance 6 (Musa DMR6) in desert banana 'Sukali Ndiizi' led to enhanced resistance to bacterial disease (Tripathi et al. 2022).

Apart from disease resistance, genome editing has also been investigated to increase the shelf life of banana fruits and change plant architecture. In the banana cultivar 'Gros Michel,' CRISPR/Cas9 technology was applied to generate disruption in the gibberellin 20ox2 (MaGA20ox2) gene of M. acuminata. The gibberellin pathway was disrupted, resulting in shorter plants (Shao et al. 2020). CRISPR/Cas9 was exploited by Hu et al. (2021) to alter aminocyclopropane-1-carboxylase oxidase (MaACO1) in M. acuminata (AAA group, cv. Brazilian). ACO is a significant enzyme of the ethylene biosynthetic pathway, which uses a reduction process to convert ACC to ethylene. The MaACO1 gene was disrupted, resulting in plants that grew and developed similarly to control plants but were significantly shorter. Furthermore, the fruits of the MaACO1 mutants were somewhat shorter, lighter, and had a 60-day delay in ripening compared to the control (Hu et al. 2021).

8.8 Genome Editing of Banana for Nutritional Quality

Increasing specific vitamins and essential components in food crops to increase their nutritional content is gaining considerable attention. This practice is known as biofortification. It is a cost-effective method of increasing vitamin and mineral content in food crops, hence alleviating malnutrition (hidden hunger). Cereals, roots, tubers, and banana are vital staple crops in various parts of the world. These crops may be high in carbs, but they may be lacking in quality proteins and micronutrients. Malnutrition and its related disorders will be reduced by increasing protein and micronutrient content in these crops.

The application of gene editing technology has been used in several crops, especially camelina, grape, potato, rapeseed, rice, sweet potato, tomato, and wheat, to enhance nutritional qualities (Liu et al. 2021). Only one study has been published using a CRISPR/Cas9-based strategy to biofortify banana. By targeting to edit lycopene epsilon-cyclase (LEC) gene with CRISPR/Cas9 technology, Kaur et al. (2020) increased β-carotene concentration in the 'Grand Naine'. They reported that the edited events exhibited a sixfold higher concentration of β-carotene in the fruit pulp than the nonedited plants. These strategies can increase bananas' nutritional contents, especially amino acids, iron, zinc, and other nutrients.

8.9 External DNA Free Gene-Editing

Banana genome editing for nutritional quality using CRISPR/Cas9 and plasmid delivery might be accomplished with high efficiency. On the other hand, the genome-edited banana obtained through plasmid delivery contains selection marker genes and the Cas9 protein, which are introduced into plant cells by *Agrobacterium*. Because breeding to remove these selection marker genes and Cas protein sequences is impossible in asexually propagated bananas, the mutated plants may be classified as GMOs by regulatory authorities in some countries, decreasing public acceptance. It is necessary to develop gene-edited banana without any external DNA that will evade strict scrutiny and be acceptable to the regulators and consumers without any unwanted fear and assumptions. To create DNA-free genome-modified banana plants, various protocols could be used. A protocol was developed to insert Cas9 protein-gRNA ribonucleoproteins (RNPs) complexes into plant cells (Liang et al. 2017). After mutation, these RGENs-RNPs complexes dissolve themselves and are removed by the cellular mechanism in the plant cells, minimizing off-target effects and leaving no evidence of external DNA sequences in the plant genome (Liang et al. 2017). There are various methods to deliver RGENs-RNPs into plant cells by application of electroporation, particle delivery system, protoplast transfection, coated silica nanoparticle, and polyethylene glycol method, using cell-penetrating proteins. The generation of plants from banana protoplasts remains difficult and time-consuming work, even though protoplasts are excellent starting material to produce external DNA sequences free plants. Even though plant regeneration from protoplasts, isolated from embryogenic cells from banana, has been reported by

several researchers in the past. Still, most of the protocols need to be reproducible for plant regeneration. However, the protoplasts' high fragility, meager plant regeneration efficiency, nonreproducibility of protocols, complex regeneration, and a high percentage of somaclonal changes make this technique more challenging. Researchers are devoting more time and effort to solving the bottleneck of the protoplast regeneration system to speed the development of external DNA-free gene-edited plants in banana and several other crops.

Another strategy is to express the editing compounds into the plant cell transiently. *Agrobacterium* infection can be applied to deliver the editing complexes transiently and produce external sequences-free plants without the plasmid DNA being integrated into the plant genome. This technology has been proven in tobacco, and 8.2% of nontransgenic plants were generated by momentary expression of CRISPR/Cas9-encoded gRNAs, knocking out the *PDS* gene (Chen et al. 2018). Veillet et al. (2019) used a similar technique, and they developed a cytidine-based editor to mutate the acetolactate synthase (ALS) gene in potatoes and tomatoes via *Agrobacterium* transient infection (CBE). They successfully generated potato and tomato plants with high mutation efficiency. However, several undesired effects were seen in the generated plants, indicating that the approach needs to be tweaked further. The critical bottleneck of both RNP complexes and momentary expression is that, without a visible marker, identifying possible mutants is difficult due to the thousands of generated plants that must be evaluated to select the mutants. The most effective way to insert CRISPR/Cas9 components into plant cells is by *an Agrobacterium*-mediated system with appropriate antibiotic selection. However, plasmids with T-DNA excision and removal features after editing are required. Costa et al. (2020) proposed two strategies for removing T-DNA from mutants. The primary method is based on the Flippase (Flp) site-specific recombinase, which distinguishes the 34 bp long FRT sequences (Flp/FRT) system, and another technique is based on Cas9 and synthetic cleavage target sites (CTS) near T-DNA boundaries, which are recognized by the sgRNA. Unluckily, adornment at T-DNA boundaries was discovered, damaging the t-DNA removal mechanisms. Despite this, the research represents a significant step forward in synthesizing DNA-free CRISPR plants using *Agrobacterium* harboring plasmid and antibiotic selection.

We are vigorously developing a methodology for producing external DNA-free banana using the momentary *Agrobacterium* system of the Cas9-gRNA reagent targeting the *PDS* gene in our laboratory. Additionally, we are optimizing various protocols for protoplast isolation, PEG transfection, and plant regeneration. If this happened, it would open up the robust technique to produce external DNA-free plants with increased nutritional contents that will be unfettered, pass through present GMO legislation, and be acceptable to consumers and producers globally.

8.10 Nanotechnology

Nanotechnology deals with nanoparticles to prevent postharvest losses of fruits and vegetables. The mostly edible nanoparticles of 1–100 nm coat fruits sold at distant

locations. Edible coating of nanoparticles like chitosan, zinc, and silver is a potential technology for delaying the ripening and increasing the self-life of banana fruits because nanoparticle coatings are simple and affordable. Cold chains are not required for storage. Nanoparticles also have biopolymer properties, which protect fruits from bacterial, fungal, and other pathogens (Odetayo et al. 2022).

9 Genetic Modification of Banana

Biofortification of banana with provitamin A and iron are the primary health-related trait for genetic modification. The production of plant-based edible vaccines is a primary focus for researchers in future programs for human diseases. The low-income families are highly suffering from micronutrient deficiencies due to insufficient fulfillment of daily dietary requirements. Vitamin A deficiency is one of the critical health complications in children and lactating mothers globally, especially in developing countries, even though massive food fortification and supplement programs have been implemented. Using genetic engineering, biofortification of banana is a potential strategy to develop provitamin A (PVA) enriched banana. Paul et al. (2017) reported overexpression of the carotenoid biosynthetic pathway enzyme phytoene synthase as a strategy to increase PVA and prolong fruit maturation time in banana fruit. Iron is another micronutrient essential for human health, mostly in growing children and pregnant and lactating mothers. Yadav et al. (2017) reported enhancing the iron in the 'Rasthali' cultivar of banana (AAB) using *MusaFer*1. Similarly, Kumar et al. (2011) enhanced iron and zinc contents in 'Rasthali' with soybean ferritin cDNA using two different plasmid constructs, pSF, and pEFE-SF.

Banana as a fruit can be an excellent choice for developing edible vaccines due to the availability of an optimized transformation and regeneration system and the fact that the fruits are eaten raw. Edible plant-based vaccines do not require cold chains and high-end manufacturing facilities that reduce the cost of vaccination. Edible vaccines can be a realistic approach if researchers from medicine, biotechnology, and agronomy work together; this will eliminate the pains caused by the syringe in infants.

Genetic improvement of banana commenced during the 1990s to develop a protocol of clonally propagated plants by protoplast electroporation, microprojectile bombardment, and *Agrobacterium*-mediated gene insertion. Embryogenic cells (EC) are favored for genetic transformation in banana due to high regeneration and transformation efficacy and reduced chimerism. EC regeneration systems and transformation protocols have been optimized for several banana and plantain cultivars. However, the production of embryogenic cells is a laborious, lengthy, and extremely cultivar-dependent process (Tripathi et al. 2022). These protocols have been established to develop high-yielding disease and pest resistance climate-smart banana cultivars (Tripathi et al. 2022). An efficient *Agrobacterium*-mediated genetic transformation platform for banana and plantain is fully operational at IITA-Kenya (Tripathi et al. 2022). Our laboratory can generate hundreds of transgenic and gene-edited events annually for several cultivars of plantain and banana.

In the absence of natural resistance in the cultivated edible banana to *Xanthomonas campestris* pv. *musacearum* and the various bottleneck of conventional breeding favor biotechnological applications like genetic engineering and gene editing. Transgenic bananas overexpressing the *Capsicum annuum* hypersensitive response-assisting protein or plant ferredoxin-like protein genes were generated and evaluated in the greenhouse and as well as in a confined field in Uganda (Tripathi et al. 2020). These transgenic bananas showed resistance to *Xanthomonas campestris pv. musacearum* (Xcm) and good agronomic performance comparable to control uninfected plants (Tripathi et al. 2020). Two or more genes can be stacked in a construct and delivered into banana cells. In the cells, these genes will act independently to produce the desired trait. Gene stacking has been achieved in banana for disease resistance. For example, transgenic banana developed using stacked gene constructs *Hrap* and *Pflp* showed enhanced resistance against bacterial pathogen Xcm (Tripathi et al. 2022). Besides, reduced disease symptoms of *Fusarium oxysporum* f.sp. *cubense* was seen in the two events of banana cultivar Rasthali (AAB) transformed by stacked antimicrobial plasmid construct (*Ace-AMP1* and *Pflp*) (Sunisha et al. 2020). Plant-parasitic nematodes incur huge losses on plantains and cooking bananas. Transgenic plantain transformed with antifeedant cysteine proteinase inhibitor and synthetic peptide-related genes showed enhanced resistance against *Radopholus similis* and *Helicotylenchus multicinctus* in the confined field trial in Uganda (Tripathi et al. 2022).

RNA interference (RNAi) induced gene silencing approach is a posttranscriptional gene silencing mechanism applied to study functional genomics of a particular gene and related products with high efficiency, specificity, and easiness in several crops. RNAi-induced technology has been proven in several other crops, especially maize, rice, wheat, and Arabidopsis. RNAi-induced gene silencing of the *gusA* gene was reported in banana, where the regenerated plants showed a reduction in gene expression and enzyme activity (Dang et al. 2014). RNAi was used to control the banana bunchy top virus (Elayabalan et al. 2013). Further, RNAi technology was applied to control banana aphids (*Pentalonia nigronervosa)* in transgenic banana (Cavendish Williams) and plantain (Gonja Manjaya and Orishele), targeting the silencing of the *AChE* gene (Jekayinoluwa et al. 2021).

Plant biotechnologists are exploring ways to bypass tight biosafety regulatory guidelines and public perceptions against genetically modified crops and their products by inserting plant genes from sexually compatible wild plants of the same species to develop new plant varieties with beneficial traits. All the genes, including the selection marker gene, promoter, and terminator, are derived from the same species. The cisgenesis technique is a potential tool for developing plant varieties that propagate vegetatively, such as potatoes, apples, and banana (Telem et al. 2013). It can directly improve an existing variety without disturbing the plant's genetic makeup by transferring beneficial trait-specific genes. The production of selection marker-free plants usually requires optimization of protocols to generate cisgenic plants. Kleidon et al. (2020) devised a technology for developing cisgenic banana plants through steroid-induced recombination that produced marker-free transgene events with minimal copy number.

10 Bioinformatics as a Tool

The first banana draft genome was obtained by genotype *Musa acuminata* subspecies *malaccensis* doubled-haploid genotype Pahang (DH-Pahang), yielding a 523 megabase genome. Shortly after this first sequencing, *M. balbisiana* variety 'Pisang Klutuk Wulung' (PKW) a diploid, was sequenced (Davey et al. 2013). Currently, the full-genome sequence of banana is accessible through the Banana genome hub platform (http://banana-genome.cirad.fr/) for the application of comparative genomics. In addition, bioinformaticians have created the 472 Mb sequence assembly of DH-Pahang and *Musa balbisiana* (Droc et al. 2013). Such comparative genomic approaches are essential for predicting functional gene annotations within *Musa* genomes.

Additional genomes of cultivated banana, their wild relatives, and those of closely related species have been sequenced to improve the database (Wang et al. 2019). The exponential increase in sequenced genomes has proportionately occurred in other plant species. The large sequencing projects have increased the demand for databases and tools to manage, process, and derive meaning from the vast amounts of data. This section will discuss the different databases and platforms currently available to handle various aspects of the processing of genome sequences. Characterization of an organism's genome involves functionally comparing the species to characterize the content and structure of its genes. This ultimately results in a deeper understanding of gene arrangements within the chromosomes, observations of any similarities or differences in the evolution, and identification of the functional significance of distinct genetic representations.

10.1 International Nucleotide Sequence Database Collaboration (INSDC)

Genomic information databases started in 1979 as the Los Alamos Sequence Database initiative to store biological sequences. This database was renamed GenBank 3 years later and relocated to the National Center for Biotechnology Information (NCBI), where it currently resides (Sayers et al. 2022). The creation of the International Nucleotide Sequence Database Collaboration (INSDC; http://www.insdc.org/), a joint initiative of the NCBI, the European Molecular Biology Laboratory (EMBL) and the DNA Databank of Japan (DDBJ) ushered in core infrastructure for sharing nucleotide sequence data and metadata to the public (Arita et al. 2021). The three INSDC nodes synchronize data daily to ensure its similarity. The collaboration is not limited to nucleotide data but also a collection of information on research projects deposited into the database of Bio Project.

10.2 Gene and Genome Databases of the NCBI

There are 13 NCBI databases with information about genes and genomes. Eight out of these 13 store genome and genome-associated data, while five are for gene storage (Sayers et al. 2022).

10.3 NCBI Genome Data Storage Databases

10.3.1 Nucleotide Database

This database collects nucleotide sequences from the GenBank, RefSeq, Third Party Annotation, and protein databases. The Nucleotide database is, in fact, a collection of different databases. The GenBank, for example, the National Institutes of Health (NIH) in the USA, genetic sequence databases, is an assortment of well-annotated gene sequences. The RefSeq is another component of the Nucleotide database and contains sequences of curated genomic DNAs, RNAs, and proteins (Sayers et al. 2022). RefSeqs stably reference genome annotation, gene identities and characteristics, analysis of mutations and polymorphisms, and expression and comparatives studies.

10.3.2 BioSample Database

The BioSample database stores descriptive information, aka metadata supplied by the submitter, and relating to biological materials from which the primary data archives are derived (Sayers et al. 2022). The NCBI's libraries have data from a wide range of samples from any species making the BioSample database equally diverse.

10.3.3 Sequence Read Archive (SRA) Database

The SRA comprises all sequencing data generated on the sequencing platforms, including Roche 454 GS System®, Illumina, Life Technologies AB SOLID System®, Helicos Biosciences Heliscope®, Complete Genomics®, Pacific Biosciences SMRT® and, Oxford nanopore® (Sayers et al. 2022).

10.3.4 Taxonomy Database

This database contains the names and phylogenies of more than 160,000 organisms containing molecular data within the NCBI. Continuous additions to the taxonomy database aimed at synchronizing it to other databases are an ongoing effort (Sayers et al. 2022).

10.3.5 The Assembly Database

This database contains information on the structural organization of genomes of various organisms, assembly names and related meta-data, reports on statistics, and links of genomic sequences (Sayers et al. 2022).

10.3.6 Bio Project Database

This database was also known as ASD Genome Project. It comprises data on genomics, including functional genomics, genetics, and the resulting dataset links. This database describes the project scope, material, and objectives. A provision for retrieval of datasets is challenging to find due to inconsistent annotation (Sayers et al. 2022).

10.3.7 Genome Database

This database is a collection of the complete and fully drafted genomes of the various organisms and related data, such as well annotated sequences, maps, chromosomes, assemblies (Sayers et al. 2022).

10.3.8 Bio Collections Database

This database stores curated culture collection metadata, museums, herbaria, and other collections of natural history. On display in the records group are codes, collections' institution information, and links to corresponding NCBI data (Sayers et al. 2022).

10.4 NCBI Gene Expression and Storage Databases

10.4.1 Gene Expression Omnibus (GEO) Profiles

This database stores individual gene expression and molecular abundance profiles assembled from the Gene Expression Omnibus (GEO) repository (Sayers et al. 2022).

10.4.2 Gene Database

The Gene database integrates information from many species, including nomenclature, Reference Sequences (RefSeqs), maps, pathways, variations, phenotypes, and their corresponding genome-, phenotype-, and locus-links (Sayers et al. 2022).

10.4.3 GEO Data Sets Database

This database stores a curation of assembled gene expression and molecular abundance datasets from the GEO repository. The database can be queried to locate experiments of interest by entering search terms. Additional DataSet records include cluster tools and differential expression queries (Sayers et al. 2022).

10.4.4 PopSet Database

This database is a compilation of related DNA sequences from the population, phylogenetic, mutation, and ecosystem deposited with the GenBank. A population set contains information on genetic variation within an organism, whereas a phylogenetic group has sequences and their respective alignments for a single gene from several closely related organisms (Sayers et al. 2022).

10.4.5 HomoloGene Database

This database is a system for constructing putative homology groups from the complete gene sets of eukaryotic species and is automated (Sayers et al. 2022).

10.5 Comparative Plant Genome Databases

Comparative genomics involves analyzing genomes emphasizing similarities and differences at the sequence or the annotation level. The major types of comparison are pairwise involving two genomes or multiple whole-genome alignments involving more than two sequences. A wide array of comparative genomics databases has been established, primarily plant specific. The central banana-specific database is the Banana Genome Hub (Droc et al. 2013) (https://banana-genome-hub.southgreen.fr/).

The Banana Genome Hub is a public banana-specific hub providing genomic information in *Musa*. The strategy used in implementing Banana Genome Hub was exploiting interconnected generic software and establishing a reliable framework for those interested in banana research (Droc et al. 2013). The Banana Genome Hub depends on a robust comparative genomics database called GreenPhylDB, which contains the *Musa* protein-coding genes. GreenPhylDB includes protein gene families based on the automatic clustering of 22 whole plant genome sequences.

Various other plants comparative genomics databases that can serve the banana research community exist. One such is EnsemblPlants a (Bolser et al. 2016) **(**https://plants.ensembl.org/) EnsemblPlants is an integrative database carrying genome-wide information for sequenced plant species. This database provides data on the genome sequence, gene models, functional annotation and polymorphisms, the structure of populations, linkage, and phenotypic data (Bolser et al. 2016). Another nonbanana plant comparative genomic database important for the banana community is Phytozome (https://phytozome-next.jgi.doe.gov/). Phytozome was first released in 2008 to provide a centralized hub for use by people with varying degrees of computational sophistication. The data to be accessed in phytochrome include annotated plant gene families, the evolutionary history of gene families and individual genes, plant genes in their genomic context, and the assignment of putative function to uncharacterized user sequences, among others. The numbers and sophistication of existing comparative genomics platforms will continue growing owing to the elaborate sequencing efforts facilitated by advancements in high-throughput genome sequencing approaches.

10.6 Protein or Metabolome Databases

The major protein-related databases include (1) the NCBI Protein database, which comprises a collection of sequences from several sources (https://www.ncbi.nlm.nih.gov/). Uniprot is a protein database geared toward providing the scientific community with comprehensive, high-quality protein sequences, and functional information (UniProt Consortium 2021). The Uniprot provides well-annotated protein sequence data linked to summaries of experimentally verified or computationally predicted functional information about proteins (UniProt Consortium 2021).

10.7 Metabolome Databases

The most comprehensive metabolite and pathway database are the KEGG which comprises PATHWAY, BRITE, and MODULE databases aimed at understanding cellular and organismal processes (Kanehisa et al. 2017). The other metabolic pathway-specific database that features banana is the MetaCyc, where a total of 3006 pathways are described. The number of enzymes and transporters deposited in the MetaCyc is 17.1%, comprising 6128 enzymes, 112 transporters, and 36,528 proteins.

11 Political and Regulatory Issues

Significant concerns about genetically modified or gene-edited crops are common, especially public acceptance, loss of biodiversity, food allergy, the risk to natural environments, antibiotic resistance, creation of super weeds, ownership by big companies, and several mythical issues. Researchers have only been concerned about potential governmental support by funding and scientific evidence-based decision-making policies to avoid unnecessary implementation delays and reap the benefits of advanced scientific tools for food production to feed the growing population globally. According to the International Treaty on Plant Genetic Resources (Article 9), the farmers and farming communities are the primary custodians of plant genetic possessions and germplasm for food and agriculture (https://www.fao.org/plant-treaty/areas-of-work/farmers-rights/en/).

The use of banana plants and their leaves has been every day in religious ceremonies for ages in India. Traditional foods are prepared by wrapping them in green banana leaves to provide an enriched aroma. Banana leaves are believed to be antibacterial due to their high phenolic compounds. This is traditional knowledge to prepare food in banana leaves by baking or boiling. It needs to be further confirmed by scientific evidence.

The participatory breeding program of roots, tubers, and banana involve farmers and other food processors for variety selection and success of the breeding program through collaborative, multifaceted approaches based on demand in the community and other participants in the food chain. The breeding program of banana is mainly focused on the quality and taste of the final product instead of a high-yield disease-resistance crop. This revolutionary technique is currently being applied in sub-Saharan Africa, and it has profuse potential globally for the success of the breeding program of other major crops.

The application of gene editing tools in agriculture is rapidly expanding worldwide. Since CRISPR/Cas-mediated editing improves crop varieties by modifying their endogenous genome through deletions, insertions, or substitution, or even inserting or replacing a full-length gene at the targeted site precisely, these edited varieties do not contain any external genes from other sources. They do not have to undergo complex and time-consuming biosafety regulations like GMOs for commercialization. The gene-edited crop varieties will be similar to those developed through conventional breeding tools. Gene-edited products of the crops with no external gene integration, especially SDN1 products, are not certified as GMO products in several countries, including Argentina, Chile, Brazil, Colombia, Paraguay, Ecuador, Honduras, Guatemala, Australia, Canada, USA, India, China, Japan, Kenya, and Nigeria (Tripathi et al. 2020).

12 Conclusions

Banana is an excellent fruit full of nutritional value but simultaneously affected by various biotic and abiotic production constraints, especially bacterial, fungal, and viral diseases. The focus of banana researchers is on increasing banana production

by developing disease and pest-resistant varieties by applying transgenic and gene-editing technologies. Few published reports are available on enhancing the nutritional value of the crop, mainly on the golden banana with increased provitamin A. Currently, several bioinformatic tools are available to identify and validate the gene of interest in the banana genome hub, which can be targeted to increase the nutritional value of the crop. Genetic engineering and CRISPR/Cas targeted gene editing are revolutionary technologies that can be adapted to produce banana with the desired nutritional traits.

However, classical genetic engineering, if used, would produce GMOs, which will be regulated and have limited acceptance. In this regard, CRISPR/Cas editing technique becomes an option, especially one which results in producing foreign DNA-free banana. Several countries have formulated and published biosafety guidelines on gene-editing products, especially SDN1 products, which are not regulated as genetically modified products in the absence of a foreign gene or selection marker gene in the final product. As banana is loved and eaten all over, especially by children, plant biotechnologists should explore the possibility of using banana to produce an edible vaccine for future generations.

Abstract

Apples have long been deemed critical for maintaining a balanced human diet. This is attributed to the apple fruit's contents of fiber, vitamin C, potassium, and various phytochemical secondary metabolites. In fact, apples are known to be excellent sources of various phytochemicals, including secondary metabolites such as polyphenols that have antioxidant properties that protect against oxidative damage. Therefore, these compounds in apple fruit provide additional health benefits to protect against disease in addition to their nutritional value. These antioxidant phytochemical compounds are termed as nutraceuticals. Efforts to investigate, assess, and enhance the nutraceutical content of apple fruits by capitalizing on the collective tools of genetics, genomic selection, genomics, transcriptomics, metabolomics, and other "omics" are contributing to our expanded knowledge of the relatively new field of apple nutraceutomics. However, it is important to keep in mind that there is a complex relationship between nutraceutical content, gene expression, and environmental factors in apple nutraceutomics. This chapter will provide an overview of various nutraceutical compounds present in apple fruits, their roles in benefiting human health and alleviating human health disease, structural and regulatory genes involved in key pathways of secondary metabolites, as well as ongoing efforts and future perspectives in the field of apple nutraceutomics.

Keywords

Antioxidants · Human health · Nutraceutomics · Phenolic compounds · Phytochemical secondary metabolites

1 Introduction

The apple (*Malus* × *domestica* Borkh.), belonging to the family Rosaceae and the tribe Pyreae, is one of the most important temperate fruit crops that is widely grown across the world, and it is widely consumed in multiple forms, including fresh, processed, canned, juiced, and dried. In 2020, the total worldwide production of apples is recorded to be more than 126 million metric tons (Food and Agricultural Organization – FAOSTAT 2022). The top ten apple-producing countries, as of 2020, are China, the USA, Turkey, Poland, India, Italy, Iran, France, Chile, and Russia (FAOSTAT 2022). Although there are thousands of known apple cultivars that are grown worldwide, the commercial apple market is dominated by about dozen cultivars, some that are quite old, such as 'Golden Delicious', 'Delicious', 'Gala', 'Granny Smith', 'Jonathan', 'Braeburn', and 'Fuji', while others that have come along in recent decades such as 'Pink Lady', 'Honeycrisp', 'Envy', and 'Jazz', among others, that have gained commercial importance (O'Rourke 2021; Teh et al. 2021).

The apple, originated in the Tian Shan Mountain region in China, has undergone interspecific hybridization early on, with most of the genome derived from the wild species *M. sieversii* and with some contribution from the crabapple *M. sylvestris* (Khan et al. 2021). The apple is a paleopolyploid but acts as a functional diploid ($2n = 2x = 34$) with a base chromosome number of $x = 17$ that is derived from two successive whole genome duplication (WGD) events of an ancestral genome ($x = 9$) that must have undergone an early WGD event followed by loss of a single chromosome (Khan and Korban 2022; Podwyszyńska and Marasek-Ciołakowska 2021; Celton et al. 2021). This allows for the apple genome to carry most of the genes in duplicate (Li et al. 2019; Podwyszyńska and Marasek-Ciołakowska 2021). The majority of apple cultivars are diploid, but there are some triploid and tetraploid cultivars (Dickson et al. 1992; Podwyszyńska and Marasek-Ciołakowska 2021). The apple is highly heterozygous and self-incompatible and requires cross-pollination to set a good crop (Teh et al. 2021).

It is well known that apple production requires intensive management practices, including training, pruning, cover crop management, irrigation systems, and annual applications of sprays for control of fungal and bacterial diseases, insects, mites, and weeds, thereby contributing to increased costs, particularly in modern high-density orchards (O'Rourke 2021). Thus, it is imperative that decisions are made early in selection of apple cultivars and of rootstocks that are optimal for maintenance in a productive orchard with minimal labor and production costs. Moreover, it is critical that modern apple orchards are tailored for a growing apple industry that is mindful of discerning consumers who are highly aware of the nutritional and health benefits of fresh and processed fruits (Korban 2021).

Apples have long been known to be critical in a balanced human diet as this is due to the fiber, vitamin C, potassium, and antioxidant contents, including various phytochemicals (Brazier 2019). However, these phytochemical compounds in apple fruits that provide extra health benefits such as promoting overall well-being, controlling symptoms, and preventing malignant processes in addition to their basic nutritional values are referred to as nutraceuticals. A medium-sized apple provides the following: 13–20% of a person's daily fiber needs; 9–11% of a person's daily vitamin C needs; and 4% of a person's daily potassium needs (Brazier 2019). Moreover, antioxidant contents contribute to sensory qualities of fresh and processed apple (Mignard et al. 2021) as well as provide benefits to human health (Boeing et al. 2012; Ho et al. 2020; Mignard et al. 2021).

There is increasing evidence that there is a relationship between consumption of fruits and vegetables and reduced risk of various human diseases. In particular, there are many epidemiological studies that have noted that apples are associated with various health benefits. These range from decreased risk of cancer in both women and men, decreased risk of asthma and bronchial hypersensitivity, lower risk for type II diabetes, lower risk of cardiovascular disease (CVD) in women and thrombotic stroke, as well as reduced levels of total cholesterol, particularly LDL ("bad") cholesterol and triglyceride levels, among others (Boyer and Liu 2004; Brazier 2019; Hodgson et al. 2016; Koutsos et al. 2020; Koh et al. 2019). These and other health benefits of apple nutraceuticals will be discussed in more detail in this chapter.

Apples are known to be excellent sources of various phytochemicals, including secondary metabolites such as polyphenols (~110 mg/100 g), as well as fiber (~2–3 g/100 g), and it is these bioactive components that have been investigated for their roles in eliciting potential health benefits (Koutsos et al. 2015, 2020; Koh et al. 2019). Among the group of polyphenols present in apple fruit, flavanols (catechin and procyanidins) account for the largest class (71–90%), followed by hydroxycinnamates (4–18%), flavonols (1–11%), dihydrochalcones (2–6%), and anthocyanins (1–3%), present only in red apples (Koutsos et al. 2015). Based on their chemical structure, phenolic compounds can be subdivided into phenolic acids and flavonoids (Cuthbertson et al. 2012). Within phenolic acids, one of the most relevant in apple is chlorogenic acid, while for flavonoids, these include various compounds including flavonols (quercetin), flavan-3-ols or flavanols (catechin and epicatechin), dihydrochalcone (phloridzin), hydroxycinnamates (coumaric acids, 5′-caffeoyl quinic acid), and anthocyanins (Volz and McGhie 2011). The health protective role of these phenolic compounds is primarily attributed to their redox capacities by allowing for quenching of singlet oxygen molecules and scavenging of free radicals and reactive oxygen species (ROS) (Busatto et al. 2019; Kschonsek et al. 2018). Following ingestion of these polyphenolic compounds, this results in modification of these molecules into other bioactive compounds or this directly allows for interactions with gut microbiota to confer this health benefit (Busatto et al. 2019). Recently, Ichwan et al. (2021) have reported that both flavonoids, in particular quercetin, predominant flavanol in apple peel, and 3,5-dihydroxybenzoic acid, unrelated to flavonoids, but present in apple flesh, are pro-neurogenic. It is reported that quercetin and 3,5-dihydroxybenzoic acid activate precursor cell proliferation, as well as promote cell cycle exit, cellular survival, and neuronal differentiation in brains of test animals, thus promoting adult hippocampal neurogenesis, i.e., brain plasticity (Ichwan et al. 2021). On the other hand, pectin, the main soluble fiber in apples, is reported to influence nutrient transport time, nutrient absorption, and gastric emptying, thus influencing glucose and lipid metabolism (Koutsos et al. 2015; Efimtseva and Chelpanova 2020). Moreover, pectin plays a role in modulating gut microbiota, a key determinant of the bile acid chemical structure, and thus has a signaling potential (Koutsos et al. 2017). Furthermore, fiber appears to help manage blood pressure, which may reduce the risk of cardiovascular disease. Moreover, **vitamin C** is an antioxidant that, alongside other antioxidants, may play a role in protecting some aspects of heart health. Vitamin C may also boost the immune system and help defend the body from infections and diseases. Moreover, potassium helps relax the blood vessels, reducing the risk of high blood pressure and cardiovascular complications. Overall, these critical "health-associated" qualities of apples provide them with advantages that are becoming more readily promoted to expand their marketability.

It is important to point out that levels of polyphenols along with other compounds in apple fruit vary during ripening, as contents of phenolic acids and flavonoids in epicarp and endocarp tissues change during ripening, and these are likely influenced by growing conditions (Stracke et al. 2009; Alberti et al. 2017). However, it is the genetic variability that likely plays a primary role in determining polyphenol levels,

as most of these observed variations are attributed to differences among apple cultivars (Alberti et al. 2017; Kschonsek et al. 2018; McClure et al. 2019).

Assessing and maintaining genetic variability are critical in current concerns over climate change (Boudichevskaia et al. 2020; Mignard et al. 2021). Apple fruit quality and their bioactive compounds are quantitatively controlled traits that are influenced by environmental conditions, such as temperature, solar radiation, and precipitation, as well as management practices, as these contribute to wide variations in accumulation of bioactive compounds (Mignard et al. 2021). In response to increasing concerns over climate change and increasing temperatures, there is an increased interest in developing and selecting for apple cultivars that are resilient to climate change (Boudichevskaia et al. 2020; Mignard et al. 2021).

2 Nutraceutical Content of Apple Fruit

Apple fruits are rich with various groups of secondary metabolites that are known to elicit positive effects on human health (Boyer and Liu 2003–2004). These secondary metabolites consist of a wide set of bioactive phytochemicals including phenylpropanoids, triterpenoids, organic acids, fatty acids, and phenolic compounds (Fig. 1) (Kidoń and Grabowska 2021). Phenylpropanoids contain the flavonoid subclass that includes anthocyanins, pigments responsible for the red color of apple. Triterpenoids are primary components of apple wax (Dashbaldan et al. 2020). The major triterpenoids in apple include oleanolic, betulinic, and ursolic acids along with their derivatives including maslinic, corosolic, euscaphic, pomaceic, and pomolic acids (Sut et al. 2019). Among the most investigated of these phytochemicals are phenolic compounds, as they have been deemed to confer various health benefits (Nezbedova et al. 2021). Some of

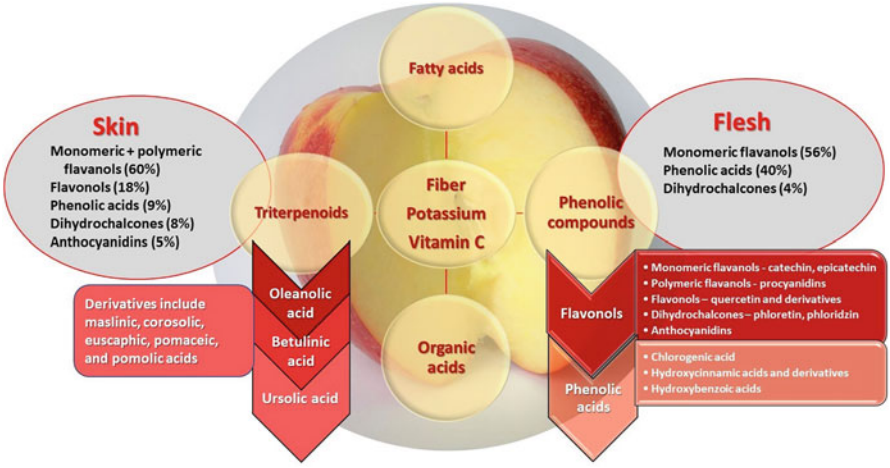

Fig. 1 Groups of phytochemicals present in apple along with average distribution of phenolic compounds in skin and flesh tissues of an apple fruit. (Modified from Nezbedova et al. (2021))

these potential health benefits include anticarcinogenic, anti-inflammatory, and antioxidant properties, among others (Nezbedova et al. 2021; Cosme et al. 2020; Bars-Cortina et al. 2020).

Apples rank second for total content of phenolic compounds. Interestingly, when compared to other fruits, apples have the highest proportion of free phenolics (Boyer and Liu 2004). This renders these free phenolic compounds more available for absorption into the bloodstream. As apples are high in antioxidants, consumption of apples is associated with decreased risk of chronic disease (Boyer and Liu 2004). Apples contain large amounts of various phytochemicals, including phenolic compounds and flavonoids. Levels of these phytochemicals may depend on various factors, including cultivar, harvest, storage conditions, and processing. Moreover, levels of these phytochemicals also vary widely between apple peel and apple flesh. Some of the most well-investigated antioxidant compounds in apples include quercetin-3-galactoside, quercetin-3-glucoside, quercetin-3-rhamnoside, catechin, epicatechin, procyanidin, cyanidin-3-galactoside, coumaric acid, chlorogenic acid, gallic acid, and phloridzin (Boyer and Liu 2004).

Various studies have demonstrated that phenolic compounds in apple contribute up to 22% of phenolic intake in the human diet, and these phenolics in apple fruit are available in conjugated forms as glycosides or esterified carboxylic acids (Nezbedova et al. 2021). However, apple fruits contain more of readily bioavailable free form of phenolic compounds compared to those present in other fruits such as pear, peach, and plum, among others. For example, apple cv. Delicious has the highest level of free forms of phenolics compared to those found in peach, plum, and pear (Imeh and Khokhar 2002).

These antioxidants aid in neutralizing free radicals. Although the terms "reactive oxygen species" (ROS) and "free radicals" are often used interchangeably, they are not synonymous. While ROS is used for those reactive oxygen species whether or not they are free radicals, some ROS are not free radicals, but they are reactive (Stone and Pham 2022). In general, free radicals are reactive molecules that can accumulate due to natural processes and environmental pressures. Thus, when high levels of free radicals accumulate in the human body, they can induce oxidative stress which, in turn, may lead to cell damage. Such damage can contribute to various diseases, including diabetes and cancer. Apples contain a wide range of antioxidants, including quercetin, catechin, phloridzin, and chlorogenic acids (Brazier 2019). Much of the protective qualities of fruits and vegetables have been attributed to various phytochemicals, which are the non-nutrient plant compounds such as carotenoids, flavonoids, isoflavonoids, and phenolic acids. Various phytochemicals are involved in different activities that may help protect against chronic disease. For instance, phytochemicals have been found to inhibit cell proliferation, regulate inflammatory and immune response, and protect against lipid oxidation (Boeing et al. 2012; Ho et al. 2020). In fact, the primary role of phytochemicals is to protect against oxidation. As our living environment is highly oxidative, various processes involved in metabolism may contribute to the production and release of additional oxidants. It is this oxidative damage that plays a role in cardiovascular disease and cancer. Furthermore, with accumulation of such oxidative damage, this will generally

contribute to the aging process. Therefore, it is critical to protect against such oxidative damage to avoid these adverse conditions. It is estimated that there are 10,000 oxidative hits to DNA per cell, per day, in humans (Nezbedova et al. 2021).

The antioxidant compounds commonly found in the apple peel are procyanidins, catechin, epicatechin, chlorogenic acid, ploridizin, and quercetin conjugates. While catechin, procyanidin, epicatechin, and phloridzin are present in the flesh, these are present at lower levels in the flesh than in the peel. Of note, quercetin conjugates are found exclusively in the apple peel, while the only compound that is present at higher levels in the flesh is chlorogenic acid (Nezbedova et al. 2021). In general, it can be concluded that the apple peel contains higher levels of antioxidant compounds. Thus, as the apple peel contains more antioxidant compounds, it can be inferred that the apple peel may have higher antioxidant activity and higher bioactivity than that of the apple flesh, and several studies have confirmed this assumption. Various studies have demonstrated that peeled apples had lower antioxidant activity than apples with peels, as these latter apples are more actively involved in inhibition of cell proliferation, a measure of a compound or fruit extract to inhibit growth of tumor cells. Boyer and Liu (2004) have reported that depending on the cultivar, apple peels contain anywhere from two- to six-fold more phenolic compounds in the peel than in the flesh and two- to three-fold more flavonoids. Furthermore, the antioxidant activity of the peel is also higher than that of the flesh, ranging from two- to six-fold higher, depending on the apple cultivar (Boyer and Liu 2004).

It is known that phenolic compounds in apple fruit belong to one of two major classes, flavonoids and phenolic acids (Fig. 1). Furthermore, flavonoids belong to one of four structural subclasses, namely, flavonols, anthocyanidins, monomeric and polymeric flavan-3-ols (flavanols), and dihydrochalcones (Almeida et al. 2017; Rana and Bhushan 2016). On the other hand, phenolic acids include hydroxycinnamic, hydroxybenzoic, and chlorogenic acids. Overall, among the major phenolic compounds present in apple fruit are monomeric and polymeric flavanols along with chlorogenic acid, while those minor phenolic compounds consist of anthocyanins and dihydrochalcones. It is anthocyanidins that confer the red color of apple fruit, and therefore these compounds are highly abundant in apple cultivars that are red pigmentated, while these levels are either present at low levels or are absent in yellow and green-pigmented apple cultivars (De Paepe et al. 2015; Honda and Moriya 2018; Nezbedova et al. 2021).

As phenolic compound contents in apple are highly variable among different cultivars (Francini and Sebastiani 2013; Brizzolara et al. 2021; Kaeswurm et al. 2022), these contents are also highly variable within tissues of a single fruit, e.g., peel versus flesh (Kim et al. 2019, 2020a; Busatto et al. 2019). For instance, total phenolic contents range between 1157 and 5119 μg/g in peel and 423 and 1534 μg/g in flesh in a group of 12 apple cultivars (Kim et al. 2019). In a recent study, the content of phenolic compounds in seven apple cultivars varied between 112 and 604 mg in 100 g dry weight (or 17–127 mg/100 g fresh weight), while this was significantly higher in peel, ranging between 378 and 1224 mg/100 g dry weight (or 68–285 mg/100 g fresh weight); i.e., the content of phenolic compounds in the dried peel was 2.64- to 4.45-fold higher than that in the dried flesh (Kaeswurm et al. 2022).

These differences in phenolic compound contents between peel and flesh tissues are accompanied by differences in the form of phenolic compounds as well (Brizzolara et al. 2021). For instance, quercetin-3-*O*-galactoside, quercetin-3-*O*-glucoside, catechin, phloridzin, and cyanidin-3-*O*-galactoside are the predominant phenolics in peel (Tsao et al. 2003), while chlorogenic acid, epicatechin, phloridzin, and protocatechuic acids are the predominant phenolics in flesh tissues of apple (Figs. 1 and 2)

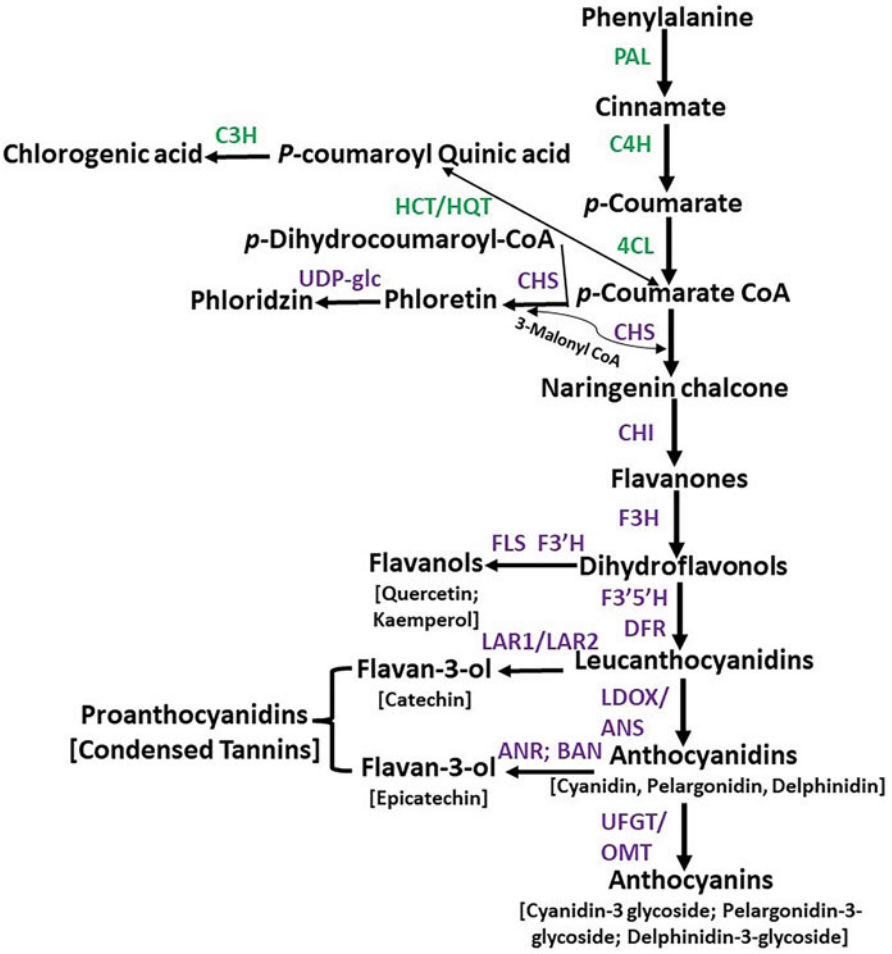

Fig. 2 Schematic diagram of the phenylpropanoid pathway including the flavonoid synthesis and anthocyanin pathways. *PAL* phenylalanine ammonia lyase, *C4H* cinnamate-4-hydroxamate, *4CL* 4-coumarate-coenzyme A ligase, *HQT/HCT* quinate hydroxycinnamoyl/hydroxycinnamoyl CoA shikimate, *C3H p*-coumarate 3-hydroxylase, *UPD-glc* uridine diphosphate glucose, *CHS* chalcone synthase, *CHI* chalcone isomerase, *F3H* flavanone 3-hydroxylase, *F3′H* flavanone 3′-hydroxylase, *FLS* flavonol synthase, *F3′5′H* flavonoid 3′5′-hydroxylase, *DFR* dihydroflavonol-4-reductase, *BAN* BANYULS, *ANR* anthocyanidin reductase, *LAR1/2* leucoanthocyanidin reductase, *LDOX* leucoanthocyanidin dioxygenase, *ANS* anthocyanidin synthase, *UFGT* UDP-glucose flavonoid 3-*O*-glucosyl transferase, *OMT O*-methyl transferase

(Veberic et al. 2005). These observed differences are attributed to genetic diversity, maturity stage, growing conditions, harvest, and storage conditions (Nezbedova et al. 2021; Brizzolara et al. 2021; Alberti et al. 2017; Busatto et al. 2019).

Several studies have confirmed that in general the peel contains about two- to five-fold higher contents of phenolic compounds and of all groups of these compounds, as well as higher contents of total procyanidins and total flavonoids, than those present in the flesh of apple fruit (Łata et al. 2009; Kalinowska et al. 2020; Nezbedova et al. 2021). However, there are some exceptions, e.g., the content of procyanidin B1 in the flesh of 'Gloster', 'Elstar', and 'Gala' is higher compared to that found in the peel (Kalinowska et al. 2014). Similarly, the phloridzin content in the flesh of 'Lodel' is higher than that in the peel (Raudone et al. 2017), as well as the chlorogenic acid content in the flesh of 'Golden Delicious', 'Granny Smith', and 'Idared' is higher in the flesh than that in the peel (Alberti et al. 2017). For some other phenolic compounds, such as quercetin glycosides, these are often found only in the peel (Kschonsek et al. 2018). Furthermore, Kschonsek et al. (2018) have reported that the predominant phenolic compounds found in the flesh are phenolic acids (43%), while flavonols, in particular quercetin and its glycosides, are predominantly present in the peel (72%), and these are not detected in the flesh.

As the apple peel accounts for up to 10% of the weight of a whole fruit, the intake of phenolic compounds following consumption of an apple is not as significant from the peel as that of the flesh (Nezbedova et al. 2021). Earlier, Łata (2007) has reported that the peel of several apple cultivars including 'Braeburn', 'Royal Gala', 'Red Delicious', 'Granny Smith', 'Idared', 'Jonamac', and 'Starking Delicious', among others, accounted for 50% or more of the total content of phenolic compounds in the whole fruit, while the peel of other cultivars, including 'Pilot', 'McIntosh', and 'Prima' contributed less to the total phenolic compounds of the whole apple fruit. Subsequently, Łata et al. (2009) have found that on average, 8%, 24%, 32%, 50%, and 66% of chlorogenic acid, (+)-catechin,(−)-epicatechin, phloridzin, and rutin, respectively, are present in the peel, accounting for 6–8% of the whole apple weight. Moreover, except for chlorogenic acid, on average 50% or more of these phenolic compounds are present in the peel of apple cvs. Granny Smith, Idared, Red Rome, Jonamac, and Gloster, wherein 'Starking Delicious' having the highest (82%) levels of these phenolic compounds in the peel (Łata et al. 2009). Interestingly, anthocyanidins are only present in the peel, while flavonols are primarily found in the peel with only low levels detected in the flesh (Nezbedova et al. 2021). However, it is important to point that some of the above findings seem to vary over years and climate changes (Nezbedova et al. 2021; Mignard et al. 2021).

3 Bioavailability of Nutraceutical Compounds

Any human health-promoting benefits of bioactive compounds of a food component, such as apple fruit, are dependent on absorption, metabolism, and distribution of these compounds within a human body (Marín et al. 2015; Selby-Pham et al. 2017). In fact, bioavailability of phenolic compounds present in apple fruit, once these are absorbed and are available for biological activity, is influenced by pH, enzymatic

activity, solubility, chemical structure, free and bound forms, as well as those synergistic effects with the food matrix (Bondonno et al. 2017; Cosme et al. 2020; Nezbedova et al. 2021; Feng et al. 2021; Di Lorenzo et al. 2021).

Although absorption of phenolic compounds begins in the small intestine (Cosme et al. 2020), it is gut microbia in the large intestine that are responsible for transforming these complex phenolics into metabolites that are easily released and absorbed (Aprikian et al. 2003; Selma et al. 2009; Cosme et al. 2020; Feng et al. 2021). These phenolic compounds of fresh and processed apple can be detected in human plasma and urine (Wruss et al. 2015; Feng et al. 2021; Galvis-Sanchez and Rocha 2016).

Furthermore, as the apple fruit contains various nutrients and phytochemicals, it is also the apple's non-nutrient component, referred to as the food matrix, that plays a critical role in both absorption and bioavailability of these phytochemicals as demonstrated in several studies (Aprikian et al. 2003; Koutsos et al. 2017; Di Lorenzo et al. 2021). Apple fruit has high contents of fiber, pectins, deemed as a complex food matrix (Kaeswurm et al. 2022). It has been reported that uptake of both phenolics-rich apple extract and apple pectin enhances metabolism of gut microbiota in the large intestine, as well as metabolism of lipids more than that of phenolic compounds administered alone, thus demonstrating a positive relationship between phenolic compounds and fiber (Aprikian et al. 2003). Kaeswurm et al. (2022) have found that in a simulated oral digestion study (in vitro and ex vivo), 63–82% of total phenolic compounds are released from the flesh, while 42–58% of phenolic compounds are released from the peel. Furthermore, it has been reported that apple consumption has strong prebiotic effects wherein the fiber content supports bioaccessibility of other beneficial phytochemicals (Efimtseva and Chelpanova 2020; Williams et al. 2017; Starowicz et al. 2020). At the cellular level, fiber is present in the plant cell wall of the apple fruit wherein various phytochemical compounds are reported to bind to plant cell wall components (Williams et al. 2017). On the other hand, consumption of processed apples, in various forms such as juice, sauce, or cooked, impacts the integrity of the plant cell wall and fiber content, thereby modifying bioaccessibility, bioavailability, and phytochemical compound interactions with gut microbiota (Nezbedova et al. 2021).

4 Antioxidant Properties of Apple Nutraceuticals

Recently, there has been an interest in assessing and exploiting those bioactive compounds present in leaf tissues of apple as new raw materials for production of nutraceuticals. Wojdyło et al. (2021) evaluated contents of phenolic compounds, triterpenes, isoprenoids, amino acids, organic acids, minerals, and sugars in leaves and fruits of different cultivars of apple, as well as those of pear and quince. Moreover, they assessed these bioactive compounds for their in vitro enzymatic inhibition of hyperglycemic (α-glucosidase and α-amylase), obesity (pancreatic lipase), cholinesterase (acetylcholinesterase and butyrylcholinesterase), inflammatory (15-LOX, COX-1, and COX-2), and antioxidant capacity (ORAC [oxygen radical absorption capacity], FRAP [ferric reducing antioxidant power], ABTS [2,2-azinobis-(3-ethyl-

benzothiazoline-6-sulfonic acid)]. It is reported that apple leaves have high levels of polyphenolic compounds (about 160.65 g/kg dm), particularly of phloretin-2′-glucose and procyanidins, and these polyphenolics are known to scavenge free radicals and inhibit their production, and they are associated with other biological properties such as anti-inflammatory, cardiovascular, antimicrobial, and anti-cancer, among others. Wojdyło et al. (2021) have found that sugars and organic acids are major components of apple fruits as the sugar/acid ratio, ranging between 8.4 and 35.5, is a critical index of the organoleptic properties of the fruit, as these serve as stimuli for human taste receptors; moreover, organic acids can positively influence microflora in the gastrointestinal tract, thus enhancing their nutritional uptake and health properties. It was found that organic acids in fruits were 1.3–1.4 g/100 g dry weight with dominant acids such as malic acid, followed by quinic and citric acids, while the predominant organic acids in leaves included quinic, malic, malonic, and tartaric acids.

Apple fruit is a rich source of potassium (500–700 mg/100 g dw), serving as one of the dietary minerals that contribute to human health and prevention of human disease (Wojdyło et al. 2021). Furthermore, polyphenolic compounds are present in both apple fruits and leaves; however, apple fruits have high levels of procyanidins, followed by flavonols and then flavan-3-ols, while apple leaves have higher levels of dihydrochalcones, followed by flavonols, and then flavan-3-ols. Additionally, fruits and leaves of different cultivars analyzed exhibited wide differences in flavan-3-ols levels wherein fruits had higher contents than leaves (Wojdyło et al. 2021).

Furthermore, Wojdyło et al. (2021) have reported that the content of dihydrochalcones in different apple cultivars tested ranges between 10.9 and 12.0 mg/100 g dry weight for fruits and from 3155.7 to 3552.7 mg/100 g dry weight for leaves. Recent findings have pointed out that these dihydrochalcones along with other phenolic compounds, such as phloridzin, have a broad spectrum of biological activities including antioxidative, antibacterial, and anti-inflammatory by inhibiting COX-1 and COX-2 activities, anticancer against prostate cancer cells, and immunosuppressive potentials (Wojdyło et al. 2021; Brglez Mojzer et al. 2016). Furthermore, anthocyanin contents in apple fruits are marginal, around 2 mg/100 g dry weight, while anthocyanin contents in leaves are more diverse with significantly higher levels, up to tenfold, than those found in fruits. Anthocyanin compounds strongly absorb ultraviolet light and mainly accumulate in epidermal cells of leaf tissues. The interest in anthocyanin compounds is also attributed not only due to their biological activity, but also to their health-promoting properties (Wojdyło et al. 2021).

Triterpene is present in equal content in leaves and fruits. Of note, leaves of apples and pears most effectively inhibit COX-1, COX-2, α-amylase, and α-glucosidase enzymes (Wojdyło et al. 2021).

5 Health Benefits of Apple Nutraceutical Components

Various studies have demonstrated that phenolic compounds in apple fruit contribute to several biological functions that are beneficial for human health (Nezbedova et al. 2021). Among these various biological functions, it has been reported that these

phenolic compounds contribute to lower incidence of chronic conditions including asthma, pulmonary disease, cardiovascular disease, diabetes, cancer, and obesity, as well as of cognitive decline of normal aging, bone health, and gastrointestinal protection (Hyson 2011; Hosseini et al. 2017; Zhao et al. 2017; Gayer et al. 2019; Hyun and Jang 2016; Koutsos et al. 2015; Mahmud et al. 2018; Zou et al. 2020; Guo et al. 2017; Alam et al. 2018; Martínez-Rodríguez et al. 2020; Ulaszweska et al. 2018).

Furthermore, there are many studies reporting on the chemopreventive and chemoprotective effects of phytochemicals in apple against different forms of cancer. These effects include regulation of cell proliferation, arrest of cell cycle, apoptosis, reactive oxygen species (ROS), and anti-inflammatory activities (Alam et al. 2018; Martínez-Rodríguez et al. 2020; Nezbedova et al. 2021; Nile et al. 2021). Furthermore, these phytochemicals can modulate signaling pathways, thereby exerting epigenetic alterations, such as DNA methylation and expression patterns of microRNAs (miRNAs) (Briguglio et al. 2020).

As mentioned above, intake of apples (and of pears) is reported to reduce incidence of various forms of cancer, such as bladder, breast, lower lung, pancreatic, oral cavity and pharynx, esophagus, larynx, ovary, renal, colorectal, and prostate cancers as reported in various controlled studies conducted in the USA, Europe, China, Mexico, and New Zealand, among other countries (reviewed by Nezbedova et al. 2021). Furthermore, association of apple intake with lower incidence of cancer has also been reported in various observational studies (Fabiani et al. 2016; Reyes-Farias and Carrasco-Pozo 2019; Li et al. 2020). These collective findings are valuable in promoting dietary recommendations; however, these are based on cohort and observational studies and not on clinical intervention trials that are yet to be conducted to confirm direct linkages between apple intake and cancer incidence (Nezbedova et al. 2021).

5.1 The Role of Apple Phenolic Compounds on Cancer

As cancer, in its various forms, is a complex disease that is linked to genetic and molecular controls, cellular and tissue biology, manifestation of disease, and responses to treatment and therapy, it relies on availability of diverse experimental, technological, and computational tools that collectively yield large sets of data related to myriad pathologies of cancer (Nezbedova et al. 2021). Therefore, an integrative concept, referred to as the "hallmarks of cancer," is used to distill the complexity of cancer into a form of science that allows for a more thorough understanding of mechanisms of cancer development and malignant progression. Such hallmarks of cancer correspond to sets of functional capabilities acquired by human cells as they transition from a normal state to an abnormal (neoplastic) growth state; i.e., forming malignant tumors (Hanhan 2022). Studies have reported that phenolic compounds in apple fruit are associated with inhibition of several hallmarks of cancer, such as breast cancer cell proliferation, cell cycle arrest and apoptosis, and growth of cancer cells of lung, prostrate, oral, and colon, among others (Scafuri et al. 2016; Nile et al. 2021; Li et al. 2020; Nezbedova et al. 2021).

In general, it has been reported that phenolic compounds act on carcinogenesis via induction of cell defense systems, including antioxidant enzyme and detoxifying systems. Furthermore, these phenolic compounds are involved in inhibition of anti-inflammatory and anti-cellular growth signaling pathways that lead to arrest of cell cycle and/or to cell death. Thus, these anticancer effects of polyphenolic compounds are capable of altering the epigenome of cancer cells (Blesso 2019; Nasir et al. 2020; Briguglio et al. 2020). It has been demonstrated that dietary natural polyphenolic compounds can elicit anticancer effects via different mechanisms, including cell cycle signaling modulation, removal of anticancer agents, apoptosis, antioxidant enzymes, and cell cycle arrest (Briguglio et al. 2020).

Various studies have reported that apple phytochemicals can inhibit activities of several critical components of cell cycle progression such as growth factors, pyruvate dehydrogenase kinases (PDKs), P21, cyclin-dependent kinases (CDKs), and extracellular protein kinases (ERKs), among others (Nezbedova et al. 2021). Furthermore, phenolic compounds in apple extracts are reported to lower expression of anti-apoptotic genes such as those coding for B-cell lymphoma (Bcl)-2 and p2 proteins while increasing expression of pro-apoptotic genes such as those coding for Bcl-2-associated X (Bax) and p53 proteins (Koh et al. 2019).

Nile et al. (2021) have reported that among the major polyphenolic compounds present in apple pomace, including quercetin-3-glucoside (Q3G), coumaric acid, phloridzin, quercetin, and phloretin, it is Q3G that has the highest antioxidant and anti-inflammatory effects in vitro, as well as elicits significant cytotoxic effects of HeLa cells in a dose- and time-dependent mode. Moreover, flow cytometric analysis has revealed that Q3G induces cell cycle arrest at the S- phase in a time-dependent manner by altering CDK-2, and it induces apoptosis via chromosomal DNA degradation and increased production of reactive oxygen species (ROS) (Nile et al. 2021). In addition, Q3G influences expression of apoptosis-associated proteins by activating caspase-9/-3, upregulating the pro-apoptotic Bax protein, and downregulating anti-apoptosis protein Bcl-2 (Nile et al. 2021).

It is important to point out that these anticancer properties of apples are also attributed to synergistic effects between apple phytochemicals and the food matrix as the food matrix may likely contain other bioactive compounds present in apple extracts (Zhang et al. 2019a; Leng et al. 2018; Nezbedova et al. 2021). Moreover, Han et al. (2019) have reported that extracts of crabapples have more abundant phenolic compounds and higher total polyphenolic compounds, as well as higher antioxidant activities compared to those of apple cv. Fuji. Although all fruit extracts exhibit inhibitory effects on proliferation of different cancer cells, it is crabapple extracts that elicit significantly higher inhibitory effects on colon cancer cells, stomach cancer cells, as well as esophageal cancer cells (Han et al. 2019). Overall, it is reported that red crabapples have higher antioxidant and antiproliferative activities to cancer cells than yellow fruits, as they are richer in phenolic compounds (Han et al. 2019).

It is noteworthy to point out that various bioactive compounds can function as prooxidants, and under conditions of high levels, low pH, and in the presence of metal ions, these compounds can induce ROS production and promote cell death

(Sotler et al. 2019; Kalinowska et al. 2020). In fact, Kalinowska et al. (2020) have reported that the higher content of phenolic compounds in peels of apple fruit correlated with higher pro- and antioxidant activities, as well as in inhibition of lipid peroxidation. In cancer therapy, prooxidants may have a beneficial effect as they serve as cytotoxic agents for fast-growing cells, thus promoting death of cancer cells (Sotler et al. 2019; Fernando et al. 2019). Such prooxidant activities of various phenolic compounds have been associated with induction of apoptosis and arrest of cell cycle arrest of different cancer cells, including skin fibroblast cells (Fernando et al. 2019; Kalinowska et al. 2020). For instance, it has been reported that phloridzin exhibits prooxidant activity, while the antioxidants epicatechin and catechin can act also as prooxidants, and epicatechin induces ROS production in colon cancer cells, thereby activating pro-apoptotic enzymes and inducing apoptosis of these cells (Mendoza-Wilson et al. 2016; Nezbedova et al. 2021). Therefore, phytochemicals in apple can not only have antioxidant effects, but they can also have prooxidant effects for cancer prevention (Nezbedova et al. 2021).

5.1.1 Mechanisms of Anticancer Properties of Apple Phenolic Compounds

Details of the anticancer mechanisms of major phenolic compounds of apple and of other crops investigated in different studies are presented in recent reviews (Nezbedova et al. 2021; Briguglio et al. 2020). Therefore, a summary of the mechanisms of key phenolic compounds involved in the phenylpropanoid biosynthesis pathway is presented herein (Fig. 2).

Among the phenolic compounds that have received much attention, the flavonoid quercetin is reported to promote apoptosis and arrest of cell cycle via its regulation of the proteins p53, GADD45, and AMPK (Guo et al. 2021; Nguyen et al. 2017). Moreover, quercetin induces autophagy in lung cancer and breast cancer cells by reducing activity of the AKT-mTOR pathway (Jia et al. 2018). Furthermore, quercetin inhibits invasion and migration of colorectal and breast cancer cells by inhibiting activity of VEGFR2, thereby inhibiting angiogenesis in prostate, breast, and retinoblastoma cancer cells (Song et al. 2017).

Another group of important flavonoids found in apple include phloretin and phloridzin, a glucoside form phloretin, both metabolized into phloretin glucuronides and phloretin sulfate glucuronides in the human intestine (Choi 2019). Although there is limited knowledge of the bioavailability of phloretin, it is reported that phloretin inhibits proliferation of breast cancer and colorectal cancer cell lines by inhibiting glucose transporter 2 (Glut-2) based on in vitro and in vivo studies (Lin et al. 2016; Wu et al. 2017). Moreover, phloretin also inhibits migration and invasion (Zielinska et al. 2019). Furthermore, it is reported that phloretin inhibits cell proliferation by promoting arrest of the cell cycle, apoptosis, and ROS production and by inhibiting autophagy via mTOR/ULK1 (Min et al. 2015; Kim et al. 2020b; Chen et al. 2020; Xu et al. 2018a, b; Choi 2019). In addition, phloretin supports an anti-inflammatory environment by inhibiting expression of pro-inflammatory molecules including PGE2, IL-8, and AGE (advanced glycation end products) receptors (Zielinska et al. 2019). Recently,

Roy et al. (2022) have reported that a ruthenium-phloretin complex is capable of modulating p53 intervening apoptosis in breast cancer cells. This response is initiated by intrinsic apoptosis, facilitated by Bcl2 and Bax along with down-regulation of the PI3K/Akt/mTOR pathway and coupled with the matrix metalloproteinase-9 (MMP-9) regulated tumor invasive pathways. It is found that such a ruthenium-phloretin chemotherapy could either interrupt, reverse, or suspend succession of breast carcinoma by altering intrinsic apoptosis along with the antiangiogenic pathway (Roy et al. 2022).

Chlorogenic acid in apple fruit is metabolized in the large intestine by gut microbiota, broken down from its aglycone form into various microbial metabolites, including caffeic acid, 3-phenylpropionic acid, hippuric acid, and quinic acid (Koutsos et al. 2017). Although chlorogenic acid has low bioavailability, it is found to inhibit growth of liver and breast cancer tumors in xenograft mice in vivo (Wang et al. 2020; Zeng et al. 2021). Moreover, chlorogenic acid is reported to inhibit cell proliferation, promotes arrest of the cell cycle by modulating the miR-17 family, inhibits invasion and metastasis via downregulation of MMP-9 and MMP-2, and induces apoptosis by binding to annexin and suppressing the NF-κB pathway (Yan et al. 2017; Wang et al. 2020; Zeng et al. 2021; Hou et al. 2017; Sapio et al. 2020).

Among other phenolic compounds in apple are procyanidins, a class of pro-anthocyanidins, consisting of (epi)catechins, particularly B-type procyanidins formed by (+)- and(−)-catechin. These classes of metabolites play critical roles by preventing chronic diseases due to their antioxidant capacity (de la Iglesias et al. 2010); moreover, their bioavailability is determined by their degree of polymerization. For those procyanidins that pass through the stomach unaltered, they are degraded by gut microbiota (especially in the colon), eliciting a prebiotic-like effect (Ou and Gu 2014). More recently, it is reported that catechins and epicatechins, monomeric flavanols are found to be unstable in the gastrointestinal tract, and these are deemed weakly to moderately absorbed based on urinary excretion of human subjects (Almanza-Aguilera et al. 2021). Nevertheless, epicatechins and catechins have been demonstrated to have antioxidant, anti-inflammatory, immunomodulatory, antiviral, and antiallergic effects, and they possess various anticancer properties (Almanza-Aguilera et al. 2021; Nezbedova et al. 2021). In particular, both epicatechins and catechins exhibit inhibitory effects on cancer cell proliferation, induced arrest of the cell cycle via inhibition of CDC25A and upregulation of p21 expression, and lower invasion and migration, as well as induced apoptosis (Pereyra-Vergara et al. 2020; Thomas and Dong 2021; Nezbedova et al. 2021). The anticancer properties of epicatechins and catechin from apples are yet to be fully investigated as most of the previous studies are based on the intake of other food crops.

On the other hand, those procyanidins that are oligomeric flavanols are abundant in apples, and these are known to possess various have anticancer properties. It has been reported that bioavailability of procyanidins is variable, and this is dependent on their structure, as well as the composition of the gut microbiome, wherein low-polymerized procyanidins, such as procyanidin B1, B2, and C1, are more easily absorbed into the small intestine than those highly polymerized procyanidins (Masuda et al. 2018). It is procyanidin B1, B2, and C1 that release metabolites

that may elicit various anticancer effects (Nezbedova et al. 2021). It is reported that procyanidins have higher effects on cancer cell proliferation and apoptosis in vitro compared to other phenolic compounds (Nezbedova et al. 2021). Furthermore, it has been demonstrated, in vivo and in vitro, that procyanidins inhibit cell proliferation via both redox and non-redox regulation of the epidermal growth factor receptor (EGFR) signaling pathway, induce cell cycle arrest by inhibiting the signaling of the epidermal growth factor receptor signaling, induce ROS by inhibiting MAP kinase phosphatase activity and activating ERK1/2 and AMPK, inhibit migration, and promote apoptosis and angiogenesis (Shilpi et al. 2015; Zhu et al. 2020; Daveri et al. 2020; Na et al. 2020; Nezbedova et al. 2021).

Among other bioactive compounds in apple are triterpenoids or pentacyclic triterpenes. These triterpenic compounds are present mainly in apple peel and its associated epicuticular wax. Interestingly, pomolic, euscaphyic, maslinic, and ursolic acids are the most abundant triterpenes in ancient apple cultivars, while in current commercial apple cultivars, it is ursolic acid that is most prevalent, followed by oleanolic acid, and then corosolic acid and betulinic acid (Sut et al. 2019; Butkeviciute et al. 2021). Overall, triterpenic compounds have been reported to have low bioavailability as they are not well absorbed into the intestine (Furtado et al. 2017). These triterpenic compounds are reported to induce apoptosis, inhibit cell proliferation, modify ROS production, and inhibit invasion, metastasis, and angiogenesis via various cellular mechanisms and signaling pathways (Nezbedova et al. 2021). For instance, it has been demonstrated that ursolic acid inhibits breast cancer growth in vitro by inhibiting proliferation, inducing autophagy and apoptosis, as well as suppressing inflammatory responses via the PI3K/AKT and nuclear factor-kappa B (NF-κB) signaling pathways (Luo et al. 2017). On the other hand, oleanolic acid induces osteosarcoma cell apoptosis by inhibiting Notch signaling (Xu et al. 2018). On the other hand, betulinic acid induces apoptosis in human prostate cancer cells via p53 and NF-κB pathways (Shankar et al. 2017).

5.2 The Role of Apple Fruit Nutraceutical Components on Cardiovascular Disease

Consumption of apple has been associated with reduced risk of cardiovascular disease (reviewed by Boyer and Liu 2004). This is primarily attributed to flavonoid intake. In various observational studies, it is reported that women who ingested high amounts of flavonoids experienced 35% reduction in risk of cardiovascular events. Furthermore, consumption of apple resulted in 13–22% reduction in risk of cardiovascular risk in women (Boyer and Liu 2004). In other observational studies, it has been reported that consumption of apples (>71 g/day) by a group of Finnish women resulted in 43% reduction in coronary mortality compared to those who have not consumed apples. On the other hand, the reduction of risk of coronary mortality is 19% in a group of men consuming apples (>54 g/day) compared to those who have not consumed apples (reviewed by Hyson 2011). Furthermore, it has been demonstrated that there is an association of quercetin and apple consumption with

cerebrovascular disease (Boyer and Liu 2004). In other studies, it has been demonstrated that catechin and epicatechin, both readily bioavailable in apples, are highly inversely associated with death from coronary heart disease (Boyer and Liu 2004).

In recent studies, there has been an increased interest in identifying biomarkers associated with cardiovascular risk, particularly focusing on oxidation and lipid metabolism (Hyson 2011). It is known that overexposure to oxidants in the body can contribute to cellular damage, and such oxidative damage may likely disrupt DNA, protein, lipids, and other cellular components via ROS, thus serving to initiate several chronic diseases, such as cardiovascular disease (Hyson 2011). It is reported that dietary antioxidants contribute to the endogenous potential of the body to scavenge ROS and nitrogen-free radicals, thereby directly counteracting lipid peroxidation reactions (Hyson 2011). There are reports demonstrating that apple consumption increases total antioxidant activity in plasma by 64% within a few hours (3 and 6 h) following consumption compared to control (water) treatment (Maffei et al. 2007). Furthermore, it is reported that apple lowers ROS generated by exposure to hydrogen peroxide in lymphocytes isolated from participants in the study. In fact, it is observed that apple significantly protects against DNA damage (highest at 3 h, but this gradually drops by 24 h) in cultured lymphocytes isolated from participants following apple consumption (Maffei et al. 2007). There are several other reports, using animal feeding experiments and in vitro studies, that further demonstrate the role of phenolic compounds in apple and apple products in eliciting antioxidant activities, by inhibiting ROS-induced production of radicals, as well as in modulating lipids and lipid-related processes (Hyson 2011).

5.3 The Influence of Apple Nutraceutical Components on Asthma and Pulmonary Function

Exposure to high and steady levels of oxygen contributes to oxidative damage in lung tissues (Devereux and Seaton 2005). Such oxidant stress activates mediators of pulmonary inflammation that induce asthma (Devereux and Seaton 2005). In particular, oxidative stress can result in various deleterious effects on airway function, such as airway smooth muscle contraction, induction of bronchial hyper-responsiveness (BHR), mucus hypersecretion, epithelial shedding, and vascular exudation (Bowler 2004). Moreover, ROS can activate the transcription factor NF-κB, thus resulting in a cascade of events involving upregulation of transcription of several inflammatory cytokine genes, such as interleukin-6 (IL-6) and leading to influx and degranulation of airway neutrophils (Wood and Gibson 2009). There are a number of studies conducted in different countries that have demonstrated that apple consumption is inversely linked to asthma and it is positively associated with overall pulmonary health (Boyer and Liu 2004; Romieu et al. 2006; Hyson 2011). This reduced incidence of asthma is mostly attributed to apple flavonoids (Romieu et al. 2006). In one study, it is reported that apple and pear intake is positively associated with pulmonary function and negatively associated with chronic obstructive pulmonary disease and that it is catechin that is involved in these observed responses (Hyson 2011).

5.4 The Influence of Apple Nutraceuticals on Anti-inflammatory Responses

Oleanolic acid plays a potential role in treating drug-induced hepatic steatosis via its interaction with liver X receptor alpha and pregnane X receptor, thus reducing ligand-induced lipogenesis (Chen and Lim 2018). Furthermore, it is well known that different triterpene acids from various natural sources have anti-inflammatory effects. For instance, recent studies have reported that maslinic acid has a significant effect on inflammation, and this is partially due to its inactivation of NF-κB (Yap and Lim 2015; Fukumitsu et al. 2016). Furthermore, such anti-inflammatory and anti-arthritic effects of both maslinic and pomolic acids are also attributed to their inactivation of NF-κB (Yap and Lim 2015). Ancient Italian apple cultivars in the *Friuli* Venezia Giulia region are reported to be important sources of such compounds; thus, further investigations should be conducted to assess the potential of these compounds in having anti-inflammatory and glycemic control effects (Sut et al. 2019).

5.5 The Role of Apple Nutraceuticals on Diabetes and Weight Loss

Based on a meta-analysis of various observational studies, it is reported that consumption of apple significantly decreases risk of type 2 diabetes mellitus and body mass index (BMI), in addition to reduced risk of cerebrovascular disease and cardiovascular death (Gayer et al. 2019). Recently, Bondonno et al. (2021) have reported that there is evidence of an inverse association between higher intake of apples and type 2 diabetes for apples, as well as for other fruits including bananas, orange, and other citrus fruits. It is proposed that the beneficial effects of apple consumption (and of other fruits) on glucose regulation and diabetes risk are attributed to multiple factors. These factors include the fruit's low energy intake, low glycemic load, high fiber content, phytochemicals, vitamins, and minerals (Bazzano et al. 2003; Bondonno et al. 2021). Among the phytochemicals in apples, the high content of flavonoids is reported to enhance sensitivity to insulin, thereby decreasing apoptosis, promoting proliferation of pancreatic β cells, as well as reducing muscular inflammation and oxidative stress (Vinayagam and Xu 2015; Kawser Hossain et al. 2016). Furthermore, apple intake may indirectly influence type 2 diabetes risk by either preventing or managing excess adiposity, likely via their higher dietary fiber that contributes to satiety (Guyenet 2019).

5.6 Effects of Apple Nutraceuticals on Various Other Health Diseases

Apple polyphenolic compounds have been reported to inhibit in vitro human low-density lipoprotein (LDL) cholesterol oxidation (Thilakarathna et al. 2013), attenuate Alzheimer's disease (Chan and Shea 2009), and protect against cigarette

smoke-induced acute lung injury (Bao et al. 2013), among other health benefits (Francini and Sebastiani 2013). Koutsos et al. (2020) have reported that apple consumption lowers serum cholesterol and improves cardiometabolic biomarkers in mildly hypercholesterolemic adults. In a recent study, Ichwan et al. (2021) have found that flavonoids, such as quercetin, and 3,5-dihydroxybenzoic acid (not related to flavonoids) are pro-neurogenic, as they activate precursor cell proliferation and promote cell cycle exit, cellular survival, and neuronal differentiation in brains of test animals. Thereby, it is proposed that these compounds are likely involved in promoting adult hippocampal neurogenesis, in particular these compounds are likely involved in brain plasticity. As functional neurons are generated throughout life, these are integrated into existing circuitry; therefore, these compounds are involved in mediating some forms of learning and memory (Ichwan et al. 2021).

However, it is important to keep in mind that bioavailability of apple polyphenolic compounds is a critical factor in their efficacy as disease preventive agents.

5.7 Genetic Diversity of Phytochemical Contents in Apples

Various studies have been undertaken to evaluate the phytochemical contents in different apple cultivars used for the fresh market, as well as for processing – juice, cider, and applesauce, among others (Boyer and Liu 2004; van der Sluis et al. 2001; Escarpa and Gonzalez 1998; Guyot et al. 2002, 2003; Wojdyło and Oszmiański 2020). Studies have reported on the observed variations in total phenolic and total flavonoid contents among different apple cultivars. For example, among ten apple cultivars commonly used for fresh eating, 'Fuji' had the highest total phenolic and total flavonoid contents, while 'Empire' had the lowest (Boyer and Liu 2004). Moreover, among four apple cultivars used for applesauce, namely, 'Rome Beauty', 'Idared', 'Golden Delicious', and 'Cortland', 'Rome Beauty' had the highest phenolic and flavonoid contents, while 'Cortland' had the lowest (Boyer and Liu 2004). On the other hand, 'Idared' had the highest levels of anthocyanins than any of the other cultivars (Boyer and Liu 2004). van der Sluis et al. (2001) reported that among four apple cultivars analyzed, namely, 'Jonagold', 'Golden Delicious', 'Cox's Orange', and 'Elstar', 'Jonagold' had the highest contents of quercetin glycosides, catechins, and chlorogenic acid, followed by 'Golden Delicious'. Escarpa and Gonzalez (1998) reported that among four cultivars analyzed, namely, 'Red Delicious', 'Granny Smith', 'Golden Delicious', and 'Reinata', 'Golden Delicious' had the lowest levels of various flavonoid compounds, while 'Reinata' had the highest level of flavonoids along with 'Granny Smith' and 'Red Delicious'. In addition, Hammerstone et al. (2000) reported that 'Red Delicious' and 'Granny Smith' had the highest content of procyanidins, while 'Golden Delicious' and 'McIntosh' had the lowest.

Stushnoff et al. (2003) assessed the total phenolic content and the antioxidant capacity of a core germplasm collection of the USDA Plant Genetic Resources at Geneva, NY, also maintained at Excelsior (MN), consisting of over 300 *Malus* species, selections, and cultivars. It was found that this collection has a wide

variation for total phenolic content, ranging from 14 to 7181 mg l^{-1}, gallic acid equivalents. In particular, it was observed that the total phenolic content of the commercial cultivars clustered together generally in a narrow and low range, 15–210 mg l^{-1}, the central Asian species *M. sieversii* collection ranged from 100 to 731 mg l^{-1}, and the red-fruited taxa ranged from 151 to 5355 mg l^{-1}. Moreover, 25 taxa representing 10 different *Malus* species and various other genetic backgrounds had the highest total phenolic contents, ranging between 1000 and 7181 mg l^{-1}.

Using a large collection of 80 cultivated apples (*M.* × *domestica*) and 13 accessions of *M. sieversii*, Volz and McGhie (2011) determined levels of flavan-3-ols (catechin + epicatechin); oligomeric procyanidins; flavonols (quercetin 3-rutinoside, quercetin 3-galactoside, quercetin 3-glucoside, quercetin 3-xyloside, quercetin 3-arabinofuranoside, quercetin 3-arabinopyranoside, and quercetin 3-rhamnoside); chlorogenic acid; dihydrochalcones (phloridzin + phloridzin-2-xyloside); anthocyanin [cyanidin 3-O-galactoside (Cy3 gal)]; and total polyphenols in peel and flesh fruit tissues of these 93 apple genotypes for at least 1 year (between 2003 and 2005), grown at a single site in New Zealand. It was reported that genotypic differences for these phenolic compounds accounted for 46–97% of the total variation observed in levels of total polyphenols and for each of the individual phenol groups in both flesh and peel tissues in this germplasm pool. Moreover, it was observed that there were minimal effects for "year" and for "genotype × year" for all phenolic compounds, except for peel flavonols in the cultivated apple, *M.* × *domestica*, and for flesh flavonols in both *M.* × *domestica* and *M. sieversii*, wherein genotypic differences for flavonols accounted for less than 30% of the total variation, which was less than that observed for "genotype × year" interactions. Moreover, levels of total polyphenolic compounds among genotypes ranged between seven- and nine-fold in the flesh and four- and three-fold in peel of *M. sieversii* and *M.* × *domestica*, respectively. In addition, levels of individual polyphenol groups in flesh and peel tissues within each of *M. sieversii* and *M.* × *domestica* ranged between 2- and over a 500-fold. Overall, *M. sieversii*, all accessions originating from Kazakhstan, had higher levels of polyphenolic compounds than those in *M.* × *domestica*. Furthermore, it was found that among all *M.* × *domestica* cultivars and breeding selections originating in New Zealand (since 1990, except for two older cultivars) had lower mean total polyphenols and chlorogenic acid in both flesh and peel tissues than those cultivars originating from other countries, including the USA, UK, France, Germany, Spain, Czech Republic, Netherlands, and Canada.

5.8 Influence of Various Growth and Environmental Factors on Phytochemical Content in Apple

It is important to point out that profiles of phenolic compounds in apple cultivars are highly influenced not only by genetic control but also by growth season, growth period, and geographical location (Wojdyło and Oszmiański 2020). For instance, levels of hydroxycinnamic acids and catechins are high in early developing fruits,

but these levels decrease during fruit growth (Mosel and Herrmann 1974). Similarly, accumulation of flavonoids including flavan-3-ols, dihydrochalcones, and flavonols occurs during early fruiting, and then this drops during fruit growth and maturation (Renard et al. 2007). Likewise, levels of quercetin glycosides, phloridzin, catechins, and chlorogenic acid in 'Jonagold' and 'Elstar' are found to be highest early in the growing season, and these decrease to steady levels during maturation and ripening (Awad et al. 2001a). Furthermore, levels of anthocyanins in both 'Elstar' and 'Jonagold' are high early in the growing season, drop in mid-season, and rapidly increase prior to fruit maturation. Interestingly, such increased levels in anthocyanin content are detected in fruit hanging along the outer periphery of the tree canopy, but not within the inner areas of the tree canopy. Similarly, levels of quercetin glycosides in both 'Jonagold' and 'Elstar' are also found to be higher in fruit hanging along the outer periphery of the tree canopy (Awad et al. 2001b). Thus, sun-exposed fruits of both cultivars have higher levels of both quercetin glycosides and anthocyanins than those of shaded fruits, thereby indicating that exposure to sun light influence increased accumulation of these two phenolic compounds in apple. However, levels of phloridzen, catechin, and chlorogenic acid are not influenced by sunlight. Therefore, it is proposed that light exposure of apple fruit may enhance synthesis and accumulation of particular phytochemicals (Awad et al. 2001b).

Among other factors influencing phytochemical contents in apples is that of cultural management practices such as fertilization. Awad and de Jager (2002a) have reported that application of nitrogen fertilization is associated with drop in levels of anthocyanins, catechins, and total flavonoids in fruit and contributes to lower percentage of blush in peel of fruit of cv. Elstar. On the other hand, calcium fertilization is associated with increased levels in anthocyanins and total flavonoids in fruit of apple cv. Elstar. Furthermore, application of various growth regulators in apple orchards can also influence accumulation of flavonoids and chlorogenic acid as observed on apple cv. Jonagold (Awad and de Jager 2002b). It is reported that application of ethephon highly elevates levels of anthocyanin accumulation, but not of other flavonoid compounds and chlorogenic acid in peel of 'Jonagold', while application of ABG and gibberellic acid (GA3) significantly delayed accumulation of anthocyanin, but not that of other flavonoid compounds and of chlorogenic acid (Awad and de Jager 2002b).

5.9 Effects of Apple Fruit Storage and Processing on Phytochemical Content

It has been reported that phytochemical content in apples is not significantly affected by storage (Boyer and Liu 2004). In an early study, van der Sluis et al. (2001) have observed that levels of quercetin glycosides, phloridzin, and anthocyanin in 'Golden Delicious', 'Jonagold', 'Elstar', 'Red Delicious', and 'Cox's Orange Pippin' do not change following controlled atmosphere (CA) storage for a period of 52 weeks. However, levels of both total catechins and chlorogenic acid slightly decrease in 'Jonagold', while levels of chlorogenic acid remain stable and those of total catechin

slightly decrease in ‘Golden Delicious’. On the other hand, under standard cold storage conditions (0 °C), there is no decrease in levels of chlorogenic acid in all cultivars analyzed, while levels of catechin slightly drop in ‘Elstar’, ‘Cox’s Orange Pippin’, and ‘Golden Delicious’ following 25 weeks of storage (van der Sluis et al. 2001). Interestingly, both forms of storage have no effects on antioxidant activity in any of these tested apple cultivars (van der Sluis et al. 2001).

As apple processing is a major industry, studies have evaluated the influence of processing on phytochemical content. For instance, apple juice from ‘Jonagold’, using straight pressing and pulping, is found to have only 10% of the antioxidant activity of fresh apples. On the other hand, juice resulting from pulp enzyming has only 3% antioxidant activity, and this juice has 58% less catechin, 44% less chlorogenic acid, and 31% less phloridzin, as most of the phenolic compounds are retained in the apple pomace (van der Sluis et al. 2002). It is reported that apple phenolics, especially procyanidins, are found to bind with plant cell wall, which leads to these reduced levels of polyphenol compounds detected in apple juice (Renard et al. 2001). As apple peel contains higher levels of phenolic compounds than that of the flesh, apple peel of ‘Rome Beauty’ is turned into freeze-dried samples, and it is found that these samples have the highest levels of total phenolic and flavonoid contents, even higher than those in fresh peels (Boyer and Liu 2004; Wolfe and Liu 2003). Furthermore, apple peel powder is found to have a strong antioxidant activity and inhibits cell proliferation (Wolfe and Liu 2003). Therefore, apple peel powder may serve as a value-added product in various food products to increase their phytochemical content and antioxidant activity (Boyer and Liu 2004).

In recent studies, it has been found that genotype, tissue type, and cold storage have strong effects on bioactive compound contents in different apple cultivars. It is observed that total phenol content is greatly reduced in flesh (50%) and peel (20%) following cold storage (1 °C for 3 months) in apple cv. Braeburn (clone Hillwell), but not in apple cvs. Golden Delicious (clone B) and Fuji (clone Kiku8) (Carbone et al. 2011). Moreover, phenolic content is found to decrease slightly over storage period (1 °C for 60 days) in commercial apple cvs. Topaz, Pinova, and Pink Lady, as well as in three local (Bosnia and Herzegovina) apple cultivars, namely, ‘Ruzmarinka’, ‘Ljepocvjetka’, and ‘Paradija’ (Begić-Akagić et al. 2011).

5.10 Influence of Applications of Growth Regulator Compounds and Fruit Drying Protocols on Apple Phytochemical Content

Boyer and Liu (2004) evaluated the effects of applying various chemical compounds, used as growth regulators on apple fruit ripening and red color development, as well as the phytochemical content in these fruits. It was observed that ethephon increased anthocyanin production, but it did not increase chlorogenic acid content or the levels of any of other phytochemicals. Moreover, applications of gibberellins and (*S*)-trans-2-amino-4-(2-aminoethoxy)-3-butenoic acid hydrochloride (ABG-3168) decreased anthocyanin production in apple fruit, but these did not influence levels of other phytochemical compounds. Furthermore, application of other chemicals, such as

cycocel, seniphos, shikimic acid, plantacur-E, and galactose, did not have effects on contents of any of the phytochemical contents in apple (Boyer and Liu 2004).

Kidoń and Grabowska (2021) investigated the effects of three fruit drying methods, including convective drying, vacuum-microwave pretreatment with convective drying, and freeze-drying, on the content of phytochemicals, antioxidant activity, color, and sensory attributes of cut cubes of red-fleshed apples, *M. purpurea* or *M. pumila* var. Niedzwetzkyana. Fruits of *M. purpurea* are known to have high contents of anthocyanins both in skin and flesh tissues, rendering the entire apple either red or pink in color, as well as of various phenolic compounds, including chlorogenic acid, catechin, phlorizin, procyanidins, and quercetin derivatives. On average, levels of these phytochemical compounds are threefold higher than those found in standard apple cultivars (Rupasinghe et al. 2010; Wang et al. 2015). Kidoń and Grabowska (2021) observed that following drying, the highest levels of phenolics were detected in freeze-dried apples. In particular, chlorogenic acid was the major phenolic compound, accounting for 60% of all phenolics in both fresh and dried red-fleshed apples, while cyanidin-3-galactoside was the major anthocyanin. However, levels of anthocyanins were markedly lower in these apples following drying.

5.11 Correlations Between Apple Phytochemical Content and Antioxidant Activity

It is important to point out that variations in phytochemical contents among different apple cultivars also influence antioxidant activities. In particular, it has been reported that there is a correlation between levels of phenolic compounds and antioxidant activity (Boyer and Liu 2004). Wojdyło et al. (2008) have determined the composition of phenolic compounds in 67 apple "new" and "old" cultivars along with their antioxidant activities. It is reported that using liquid chromatography-mass spectrometry (LC-MS) analysis for phenolic contents (up to 18 compounds) in this large group of apple cultivars, including those of flavanols (catechin, procyanidin), flavonols, anthocyanins, hydroxycinnamates, and dihydrochalcones, a mean content of total polyphenols ranged between 523 and 2724 mg/100 g dry weight, depending on the apple cultivar. Moreover, it is found that flavanols (catechin and oligomeric procyanidins) account for 80% of polyphenols, followed by hydroxycinnamic acids (1–31%), flavonols (2–10%), dihydrochalcones (0.5–5%), and, in red apples, anthocyanins (1%). Furthermore, it is reported that the highest correlation (r) of total polyphenols and antioxidant activity, based on assays of free-radical scavenging ability, is detected with the 2,2′-azino-bis-3-ethylbenzothiazoline-6-sulphonic acid (ABTS) method ($r = 0.87$), followed by that for the ferric reducing/antioxidant power (FRAP) ($r = 0.84$), and 2,2-diphenyl-1-picrylhydrazyl (DPPH) ($r = 0.80$) methods. Levels of bioactive compounds in this large group of cultivars indicated that these levels are either equal or higher in new (e.g., 'Ozark Gold', 'Julyred', and 'Jester') versus old (e.g., 'Golden Delicious', 'Idared', and 'Jonagold') cultivars, and concentration of procyanidins/flavan-3-ols is the most important contributor to the in vitro antioxidant activity (Wojdyło et al. 2008).

As mentioned above, Stushnoff et al. (2003) evaluated the total phenolic content and the antioxidant activity using the ABTS method of a large collection of *Malus* germplasm. It was reported that the antioxidant activity of a subset of that collection, 103 taxa, correlated well with the total phenolic content ($r = 0.7779$ for juice and $r = 0.7181$ for freeze-dried fruit).

Recently, Mignard et al. (2021) analyzed apple fruit quality and levels of biochemical compounds (peeled fruit, i.e., flesh tissue), including total phenolics content, total flavonoids, vitamin C (ascorbic acid-AsA), and relative antioxidant capacity (using the DPPH method) of 155 accessions, consisting of 99 local (commercial cultivars and traditional landraces) and 56 foreign accessions, grown at the germplasm bank in Spain over a period of 5 years. It was found that total phenolics content widely varied among these accessions and over the years, ranging from 3.3 ('Poma de San Juan', in 2018) to 116.7 ('Camuesa Fina de Aragón', in 2015) mg gallic acid equivalents/100 g fresh weight. On the other hand, the total flavonoid content ranged from 0.7 ('Poma de San Juan', in 2018) to 142.1 ('Camuesa Fina de Aragón', in 2014) mg catechin equivalents/100 g fresh weight. Moreover, levels of vitamin C ranged from 0.4 ('Delgared infel', in 2016) to 13.2 ('Transparente', in 2014) mg AsA/100 g fresh weight. As for the relative antioxidant capacity, this varied from 1.7 ('Poma de San Juan', in 2018) to 44.6 ('Les_1 – MRF 73', in 2014) mg trolox/100 g fresh weight. Over the period of 5 years, mean values of total phenolics content varied from 15.2 ('Biscarri_1 – M 107') to 98.1 ('Camuesa Fina de Aragón') mg gallic acid equivalents/100 g FW, total flavonoid content ranged from 6.0 ('Biscarri_1 – M 107') to 89.0 ('Camuesa Fina de Aragón') mg catechin equivalents/100 g FW, whereas, vitamin C ranged from 1.4 ('Delgared infel') to 5.9 ('Reguard_1 – MRF 53) mg AsA/100 g fresh weight. Finally, mean values of relative antioxidant capacity varied from 5.9 ('Delgared infel') to 30.8 ('Les_1 – MRF 73').

Furthermore, Mignard et al. (2021) have reported that all levels of bioactive compounds and relative antioxidant capacity demonstrated significant differences between local and foreign accessions. Indeed, for all parameters analyzed, foreign cultivars such as 'Deljeni', 'Delorgue Festival', 'Akane', and 'Reineta Gris', among others, had lower values than those of local accessions such as 'Peruco de Caparroso', 'Prau Riu_5', 'Camuesa Fina de Aragón', and 'Les_1 – MRF 73', among others.

Using Pearson's correlation, Mignard et al. (2021) found that relative antioxidant capacity was highly and positively correlated with each of total phenolics content and total flavonoid content, $r = 0.901$ and $r = 0.865$, respectively. Moreover, total phenolics content was significantly and highly positively correlated with total flavonoid content, $r = 0.963$. Interestingly, vitamin C showed a significant and moderate positive correlation with total phenolics content, $r = 0.415$. In addition, significant moderate positive correlations were found between titratable acid and each of total phenolics content and flavonoid content, $r = 0.450$ and $r = 0.464$, respectively.

Using a cluster analysis, Mignard et al. (2021) revealed that foreign cultivars (those not originating from Spain) were concentrated in two groups, while local accessions could not be segregated and had very different profiles. Furthermore, it

was observed that levels of bioactive compounds tended to decrease with higher temperatures, while these levels increased with higher solar radiation; thus, it was concluded that genotypes and climate are major factors influencing variability in metabolite profiles.

Interestingly, Kidoń and Grabowska (2021) used the ABTS assay to assess the antioxidant activity in dried apple fruit cubes of red-fleshed apples (as described in the above section), and they found that apple cubes subjected to convective drying had the highest antioxidant activity, while the vacuum-microwave pretreatment with convective drying samples had the lowest antioxidant activity.

5.12 Genetic Mapping of Phytochemical Content Components in Apple

Efforts to uncover the complex genetic controls of the phenolic compound content of apples have been underway for quite some time, but these efforts have intensified in recent years.

Early genetic mapping efforts of some of metabolites in apple fruits have been undertaken with particular interest in volatile compounds that contribute to aroma. Dunemann et al. (2009) constructed a set of two parental genetic maps for apple cultivars 'Discovery' and 'Prima' using dominant amplified fragment length polymorphism (AFLP) and resistance gene analog (RGA) markers along with a set of 90 multi-allelic simple sequence repeats (SSRs), selected based on their known positions within the *Malus* genome. A total of 18 linkage groups (LGs) was constructed for 'Discovery', while the 'Prima' map consisted of 19 LGs. Hence, 17 homologous LGs corresponding to the basic chromosome number in apple ($n = 17$) were assigned in both parents and aligned with co-dominant SSRs and with segregating AFLPs. A total of 20 volatiles, including various esters, alcohols, terpene α-farnesene, and norisoprenoid β-damascenone, measured using gas chromatography–mass spectroscopy (GC/MS) over a period of 3 years, were analyzed for levels of variability in 'Discovery' and 'Prima'. It was observed that approximately 50 putative quantitative trait loci (QTLs) for a total of 27 different apple fruit volatile compounds were detected via interval mapping by using genotypic data of 150 F_1 seedlings of the mapping population of 'Discovery' × 'Prima' along with phenotypic data obtained by head-space solid phase microextraction gas chromatography. It was reported that QTLs for volatile compounds likely involved in apple aroma were detected on 12 out of 17 apple chromosomes, but these were not evenly distributed. In particular, QTLs were clustered primarily on LGs 2, 3, and 9. A lipoxygenase (LOX) candidate gene, likely involved in volatile metabolism, was mapped on LG 9 and genetically associated with a cluster of QTLs for ester-type volatiles.

With availability of various analytical tools for large-scale analysis of metabolites in an organism, the field of metabolomics has emerged as a powerful tool for pursuing functional genomics studies in various crops, including that of apple (Brizzolara et al. 2021; Han and Korban 2021). Khan et al. (2012a) investigated

the genetic basis of quantitative variations of phenolic compounds in apple fruit. They used a large segregating F_1 population of 'Prima' × 'Fiesta' to map metabolite quantitative trait loci (mQTLs). They conducted untargeted metabolic profiling of peel and flesh tissues of ripe apple fruits using liquid chromatography–mass spectrometry (LC-MS) and detected 418 metabolites in peel and 254 metabolites in flesh tissues (Khan et al. 2012a). Furthermore, using the mapping software MetaNetwork, enabling simultaneous genome-wide screening of numerous traits, they were able to detect and map 669 significant mQTLs, 488 in peel and 181 in flesh tissues. Of particular interest, they identified four linkage groups, namely, LG1, LG8, LG13, and LG16, that contained mQTL hotspots, primarily involved in regulating metabolites belonging to the phenylpropanoid pathway. Subsequently, they used the MapQTL® software to construct an integrated map of both parents, 'Prima' and 'Fiesta', and this map, containing 801 markers and spanning 1348 cM, was used for analysis of annotated metabolites to elucidate the genetics of these annotated metabolites (Khan et al. 2012a). It was observed that a number of quercetin conjugates had mQTLs on either LG1 or LG13. However, an mQTL hotspot with the largest number of metabolites was detected on LG16, wherein mQTLs for 33 peel-related and 17 flesh-related phenolic compounds were located. Furthermore, structural genes of the phenylpropanoid biosynthetic pathway were located by aligning positions of orthologous genes on all 17 chromosomes of apple to DNA sequences of structural genes of *Arabidopsis thaliana* using the genome sequence of apple cv. Golden Delicious (Velasco et al. 2010). Various metabolites that mapped onto an mQTL hotspot on LG16 locus included procyanidins (flavan-3-ols and their polymers), phenolic esters, and flavonol and dihydrochalcone derivatives, among others. All these compounds belong to the phenylpropanoids; thus, it was presumed that this mQTL was controlled by a biosynthetic gene from the phenylpropanoid pathway, or by a transcription factor controlling this pathway. In addition, an apple structural gene coding for leucoanthocyanidin reductase (LAR1), *MdLAR1*, was identified in the mQTL hotspot on LG16, as well as seven transcription factor (TF) genes.

In a subsequent study, Khan et al. (2012b) investigated expression profiles of structural and putative transcription factor genes of the phenylpropanoid and flavonoid pathways during various stages of fruit development in progeny. It was observed that it was only the structural gene *MdLAR1*, located on *LG16*, demonstrated highly significant correlation between transcript abundance and content of metabolites mapped onto the mQTL hotspot. Furthermore, it was observed that seedling progeny of 'Prima' × 'Fiesta', divided into two groups based on "procyanidin dimer II" levels of either high of low content, inheriting either one or two copies of dominant *MdLAR1* alleles (*Mm*, *MM*) had 4.4- and 11.8-fold higher levels of expression, respectively, than progeny inheriting the recessive alleles, *mm* (Khan et al. 2012b). In addition, this observed higher level of expression was associated with a fourfold increase of procyanidin dimer II as a representative metabolite that mapped within the mQTL hotspot. Although expression levels of several other structural genes correlated with expression of various structural genes and with some *bHLH* and *MYB* transcription factor genes, it was only expression of *MdLAR1* that correlated with metabolites mapped within the mQTL hotspot (Khan

et al. 2012b). Therefore, it was proposed that *MdLAR1* was the only candidate gene that could explain the mQTL for procyanidins and flavan-3-ols. However, mQTLs for other phenylpropanoids such as phenolic esters, flavonols, and dihydrochalcones that were detected at the same locus on this map have not been deemed to be dependent on LAR, as their biosynthesis did not involve LAR activity (Khan et al. 2012b). Thus, the dominant allele of *MdLAR1*, promoting increased content of metabolites of potential health benefit, was proposed to be useful in marker-assisted selection in current apple breeding programs, as well as for pursuing cisgenesis (Khan et al. 2012b).

Chagné et al. (2012) analyzed fruits from a population of 'Royal Gala' × 'Braeburn' segregating for phenolic compounds using ultra-high performance liquid chromatography (UHPLC) of extracts derived from fruit peel and flesh. A total of 23 phenolic compounds with varying levels were quantified in apple peel and flesh in 2 separate years. Furthermore, using single nucleotide polymorphic (SNP) markers to genotype individuals in this segregating population, and subsets of these SNPs were used to construct genetic maps for the two parents, 'Royal Gala' and 'Braeburn'. These genetic maps and segregating population were used to detect 79 QTLs for 17 fruit polyphenolic compounds. Of these QTLs, seven QTL clusters were found to be stable across two fruit harvest years, and these included QTLs for content of flavanols, flavonols, hydroxycinnamic acids, and anthocyanins. Following alignment of parental genetic maps with the whole genome sequence of apple cv. Golden Delicious (Velasco et al. 2010), this allowed for screening of candidate genes, coding for enzymes in the polyphenolic biosynthetic pathway, that were co-segregating with these QTLs. As observed by Khan et al. (2012a), the largest cluster of QTLs was located at the top of LG16. Using bioinformatic tools, candidate genes predicted on the basis of their involvement in the polyphenolic biosynthetic pathway were located on the whole genome sequence of cv. Golden Delicious using BLASTN analysis. Furthermore, this co-location was confirmed by genetic mapping of markers derived from gene sequences. It was found that *LAR1* co-located with a QTL cluster for fruit flavanols catechin, epicatechin, and procyanidin dimer, and five unknown procyanidin oligomers identified near the top of linkage group LG 16, while *HYDROXY CINNAMATE/QUINATE TRANSFERASE* (*HCT/HQT*) co-located with a QTL for chlorogenic acid that mapped near the bottom of LG 17. Interestingly, it was hypothesized that the mutation that drove this signal on chromosome 16 was present in the promoter region of *LAR1* and located within a site recognized by transcription factors involved in gene regulation. Furthermore, this mutation did not result in a complete loss of function of *LAR1* (Chagné et al. 2012). It was concluded that *LAR1* and *HCT/HQT* must have likely influenced levels of these phenolic compounds in apple fruit. Therefore, it was proposed that *LAR1* and *HCT/HQT* would serve as useful allele-specific markers for marker-assisted selection of fruit-bearing trees with high content of these phenolic compounds.

Verdu et al. (2014) have capitalized on marker-assisted selection to identify and select new apple cultivars with specific phenolic compounds influencing the taste of cider. Fruit and juice of individuals from a segregating population of a cross between two hybrids X5210 (derived from 'Kermerrien', a well-known French

cider apple cultivar) and X8402 (a desert apple derived from 'Florina' × 'Prima') have been analyzed for various phenolic compounds using a liquid chromatography system. The phenolic compounds including (+)-catechin, (2)-epicatechin, procyanidins B1 and B2, avicularin, hyperin, quercitrin, 5-caffeoylquinic acid, 4-p-coumaroylquinic acid, and phloridzin have been quantified in each 2 years in both fruit and juice. Other compounds (procyanidins B5 and C1, 4-caffeoylquinic acid, isoquercitrin, reynoutrin, ideain, rutin, and phloretin xyloglucoside) have been quantified in some experiments. QTLs have been detected on LG1 for flavanols, LG5 for dihydrochalcones, LG15 for flavonols, and LG16 for mean polymerization degree (DPn) of these phenolic compounds. These QTLs have demonstrated high stability between years and for apple products, fruit, and juice, with high proportion of explained phenotypic variation. Candidate genes under these QTLs for phenolic content were identified *in silico* from the apple genome sequence, and their co-localizations were confirmed by genetic mapping. For example, they identified and mapped four genes homologous to shikimate/quinate O-hydroxycinnamoyl transferase (HCT/HQT) under the QTL confidence interval for the 5-caffeoylquinic acid on the LG17. Likewise, a gene homologous to flavonoid 3′-hydroxylase (F3′H), responsible for the hydroxylation on the third position of the B ring of flavonols, dihydroflavonols, and flavanones, was identified and mapped under the quercetin glycoside cluster. Moreover, a homologue of UDP-glucose 3-glucosyltransferase (UFGT) gene was identified under QTLs for flavanols on LG1. This gene is described to catalyze the formation of anthocyanidins-3-O-β-D-glucoside from anthocyanidins and UDP-D-glucose (Verdu et al. 2014).

Verdu et al. (2014) have confirmed the importance of two regions involved in the biosynthesis of hydroxycinnamic acids on LG14 and LG17. Moreover, other regions of interest include those detected on LG1, LG5, and LG15 for flavanols, dihydrochalcones, and flavonols, respectively. These QTLs are of interest in apple-breeding programs. Furthermore, identification of candidate genes in silico has revealed interesting targets for future studies to better understand the biosynthesis of phenolic compounds. This study not only highlighted QTLs responsible for variability of major phenolic compounds involved in cider organoleptic characteristics but also those for mean polymerization degree of procyanidins. It is reported that these QTLs would aid in understanding the mechanism of procyanidin biosynthesis, which appears to be independent from the synthesis of flavanols.

In another study, a number of major QTLs regulating apple fruit mean L-ascorbate (l-AA), or vitamin C, and total l-AA levels on parental genetic linkage maps of apple cvs. Telamon and Braeburn have been detected (Davey et al. 2006). Moreover, common QTLs were localized to the same region of LGs 6, 10, and 11, accounting for up to 60% of the total observed variation in the segregating seedling population of 'Telamon' × 'Braeburn'. It was proposed that molecular markers for some of these QTL alleles could be used to select for high mean and total contents of l-AA/total l-AA contents. Moreover, a major and highly significant QTL for flesh total l-AA content on LG 17 of the 'Telamon' map was detected that co-localized not only with a QTL for dehydroascorbate (DHA) content but also

with strong QTLs for flesh browning. It is proposed that this QTL on LG 17 may be involved in regulating the redox status of fruit flesh l-AA pool, likely via the activity of polyphenol oxidases (PPOs) or peroxidases (Davey et al. 2006).

Fang et al. (2017) determined the ascorbic acid (AsA) content in mature fruits in a large collection of 30 *Malus* species and 457 accessions, consisting of worldwide cultivars. It was found that AsA concentration ranged from 10.48 to 278.48 μg/g fresh weight, with an average of 46.43 μg/g fresh weight, corresponding to more than 26-fold variation in AsA concentration among all accessions analyzed. Ascorbic acid content ranged from 22.07 to 278.48 μg/g fresh weight in fruits of wild species compared to 10.48 to 131.52 μg/g fresh weight in fruits of apple cultivars. Thereby, this suggested that fruits of wild species had wider variations in ascorbic acid content than fruits of cultivated apples. Furthermore, it was observed that ascorbic acid accumulation in fruit of cultivated apples is rapid during early fruit development, but this markedly decreases during fruit expansion, followed by a slight decline during the mature stage. In an earlier genetic analysis study, Mellidou et al. (2012) reported that four regions on chromosomes 10, 11, 16, and 17 contained stable fruit AsA-QTL clusters, and when AsA metabolic genes were mapped, it was found that within this QTL clusters, these genes co-located with orthologs of GDP-L-galactose phosphorylase (*GGP*), dehydroascorbate reductase (*DHAR*), and nucleobase-ascorbate transporter (*NAT*). Following additional analysis, it was delineated that AsA content in mature apple fruit was mainly controlled by a set of four genes, including two encoding the galactose biosynthetic pathway enzyme genes *MdGGP1* and *MdGGP3*; an ascorbic acid recycling pathway enzyme encoding gene, *MdDHAR3-3*; and a nucleobase ascorbate transporter gene, *MdNAT7-2.* When Fang et al. (2017) evaluated expression of these four genes throughout apple fruit development, it was observed that all four genes were highly expressed in fruits at stages of fruit expansion (highest levels) and maturity stages compared to early fruitlet development at the juvenile stage. Moreover, levels of expression of three genes, *MdGGP1, MdDHAR3-3,* and *MdNAT7-2*, were significantly and negatively correlated with AsA contents in fruits throughout different stages of fruit development. This suggested that low levels of ascorbic acid may induce expression of these three genes during fruit expansion and maturity via a feedback mechanism. However, in young fruitlets, expression of all analyzed genes demonstrated a positive correlation with ascorbic acid content, thereby suggesting that unusual high levels of ascorbic acid detected in early developing fruit was likely due to coordinated contribution of ascorbic acid synthesis and regeneration, as well as of ascorbic acid translocation from leaves (Fang et al. 2017).

A major locus for anthocyanin content in apple flesh has been mapped to linkage group LG 9 (Chagné et al. 2007). Expression studies have determined that this locus is controlled by *MYB10* (Espley et al. 2009). An allelic gene, *MYB1*, also located on LG 9, controls fruit skin color (Zhu et al. 2011). Subsequently, a major QTL controlling red skin coloration on LG 9, found using four segregating New Zealand populations, was screened using an apple 8-K single-nucleotide polymorphism (SNP) array, and a significant SNP marker, ss475879531, was identified (Chagné et al. 2016). This SNP marker was transformed into a marker suitable for use in a real-time PCR assay for the

red skin phenotype (Chagné et al. 2016). It was found that this marker could efficiently predict red skin coloration and it would be useful in marker-assisted selection.

5.13 Genome-Wide Association Studies and Candidate Gene Predictions

McClure et al. (2019) investigated the genetic architecture of polyphenols by combining high performance liquid chromatography (HPLC) data with ~100,000 SNPs using two apple populations, consisting of 136 cultivars evaluated in 2014 and 85 cultivars (from the larger population) evaluated again in 2016, planted in two different randomized blocks. They observed that polyphenol compound contents in fruit, of both peel and flesh, varied widely, up to two orders of magnitude across cultivars, and that much of this variation was both heritable and predicable using genetic markers. Moreover, it was observed that this wide variation was often controlled by a small number of genetic loci with large effects.

Using genome-wide association study (GWAS), McClure et al. (2019) have detected significant genotype-phenotype associations, and the proportion of the phenotypic variance (R^2) explained by the top SNPs ranges from 0.31 to 0.63. Although this relatively high effect size estimates are attributed in part to small sample size, it is suggested that expression of several polyphenolic compounds in apple is under relatively simple genetic control. Furthermore, it is reported that identified markers are in strong linkage disequilibrium (LD) with causal genetic variation that underlies expression of polyphenol compounds. Based on GWAS, it was observed that there was a clear trend for flavan-3-ols and pro-anthocyanidins, wherein there was a large peak on chromosome 16 for catechin, epicatechin, and procyanidin B1, B2, and C1. Interestingly, a highly significant SNP accounted for up to 50% of the observed phenotypic variance. As noted in the above genetic linkage mapping studies of biparental populations, this region on chromosome 16 was identified as a QTL hotspot for catechin, epicatechin, and proanthocyanidins (Khan et al. 2012a, b; Chagné et al. 2012). Although McClure et al. (2019) have detected some slight differences in the location of this most significant SNP across phenotypes, these were within the boundaries of the aforementioned QTL hotspot. Again, as *LAR1* has been identified earlier as a putative candidate gene for this hotspot, it is proposed to catalyze conversion of leucocyanidin to catechin. Moreover, this region is found to also contain several transcription factors of different classes, including *MYB*, *bHLH*, *bZIP*, and *AP2* that could also influence levels of phenolic compounds in apple fruit.

McClure et al. (2019) have found GWAS peaks for various other phenolic compounds including those for flavonol and quercitrin, on chromosome 1. Earlier studies have detected hits for flavonols on chromosome 1 and have proposed that a uridine diphosphate-dependent glycosyltransferase (*UGT*) gene and a flavonoid 3′-hydroxylase (*F3′H*) gene are potential candidate genes underlying this signal (Verdu et al. 2014; Khan et al. 2012a). McClure et al. (2019) have detected a SNP that strongly associated with quercitrin ~44 kb upstream of an apple *UGT* gene

(MD01G1148700). As *UGT*s mediate glycosylation of flavonoids, and quercitrin is produced via glycosylation of the flavonoid quercetin, such glycosylation of secondary metabolites increases both solubility and stabilization of flavonoid compounds; moreover, specific *UGT*s have been identified that glycosylate flavonoids into potent antioxidants, such as phloridzin (Jugdé et al. 2008; Zhou et al. 2017; Kim et al. 2013). Nevertheless, no specific *UGT* has been associated with the formation of quercitrin in apples; thus, it is hypothesized that the GWAS signal detected on chromosome 1 is due to variation in a specific apple *UGT* gene (MD01G1148700) that regulates levels of quercitrin and glycosylation of quercetin (McClure et al. 2019). Further studies will assess whether or not quercetin is in fact associated with this *UGT* gene. Thus, it is anticipated that markers at this locus would be exploited for marker-assisted breeding to enhance the content of quercetin in apple or that genetic variation of antioxidant content will be introduced into new cultivars via gene editing.

McClure et al. (2019) have exploited GWAS for chlorogenic acid, and two significant hits on apple chromosomes 5 and 15 have been detected, thereby suggesting that variation for this trait is controlled by two independent loci. Within this scope of these loci, three promising candidate genes have been identified at these loci including cinnamyl alcohol dehydrogenase (*CAD*; MD05G1089900), caffeoyl-CoA *O*-methyltransferase (*CCOAMT*; MD05G1083900), and 3-dehydroquinate synthase (*DHQS*; MD15G1242600). It is known that both CAD and CCOAMT are enzymes associated with biosynthesis of hydroxycinnamic acids via the phenylpropanoid pathway that also supplies intermediates for synthesis of flavonoids, tannins, and phytoalexins (Hoffmann et al. 2004). As CAD converts cinnamyl alcohol to cinnamaldehyde, it was found that a *CAD* gene was highly expressed in ripening receptacle tissues in strawberry; however, thus far no such *CAD* gene has been characterized in apple (McClure et al. 2019). While CCOAMT is not directly involved in the final step of chlorogenic acid biosynthesis, it is active upstream in its production via conversion of caffeoyl-CoA to feruloyl-CoA, and it has been associated with accumulation of chlorogenic acid accumulation in coffee (Clifford et al. 2017; Hoffmann et al. 2004). As for DHQS, it is reported to be involved in catalyzing key substrates for chlorogenic acid biosynthesis via the shikimate pathway (Maeda and Dudareva 2012). Therefore, it is proposed that all three genes, namely, *CAD*, *CCOAMT*, and *DHQS*, are likely candidates involved in chlorogenic acid production (McClure et al. 2019).

As Khan et al. (2012a) and Chagné et al. (2012) have proposed that *HCT*/*HQT* on chromosome 17 are potential candidate genes for chlorogenic acid, McClure et al. (2019) have not identified SNPs on chromosome 17 that are significantly associated with chlorogenic acid. However, a suggestive GWAS signal is identified on chromosome 17 for chlorogenic acid, and a *HCT*/*HQT* gene (MD17G122510) is found within the suggestive peak on chromosome 17.

Yet another hydroxycinnamic compound, 4-*O*-caffeoylquinic acid, produced significant GWAS hits on chromosomes 3 and 14 (McClure et al. 2019). Although candidate genes for flavonoid 3′-hydroxylase (*F3′H*) or flavonoid 3′,5′-hydroxylase (*F3′5′H*) were proposed, these genes were not located on chromosome 14.

As phenylalanine is converted to *p*-coumaroyl-CoA, with cinnamic acid and *p*-coumaric acid acting as intermediates, it is sequentially catalyzed by phenylalanine ammonia lyase (PAL), cinnamate 4-hydroxylase (C4H), and 4-cinnamoyl-CoA ligase (4CL). McClure et al. (2019) have identified an association signal for 4-*O*-caffeoylquinic acid on chromosome 3; it is proposed that phenylalanine ammonia-lyase (*PAL*; MD03G1121500) may be a candidate gene for this detected signal. PAL, the first enzyme in the phenylpropanoid pathway, is an enzyme that catalyzes the production of cinnamic acid, a precursor to hydroxycinnamic compounds. PAL plays a critical role in controlling the biosynthesis of acyl-quinic acids (Clifford et al. 2017).

In addition, a strong GWAS peak is detected for cyanidin-3-galactoside on chromosome 9, and a strongly associated SNP at this locus is also the most significantly associated SNP with total anthocyanin content in apple (McClure et al. 2019). It is reported that these associations are expected as cyanidin-3-galactoside is the most predominant anthocyanin in apples (Tsao et al. 2003), and several studies have identified a QTL for skin color that is found to co-locate to this genomic region (Zhang et al. 2019b; Amyotte et al. 2017; Chagné et al. 2016). It is reported that a SNP (ss475879531; chr9:33001375) on chromosome 9, useful in predicting skin color in apple breeding programs, is located 666 kb upstream from the most significant SNP identified by McClure et al. (2019). Moreover, Zhang et al. (2019b) have identified a retrotransposon insertion 1 kb upstream of the transcription factor *MYB1* gene (chr9:35,541,127–35,541,721) that likely elicits the red-skinned phenotype. Although this putatively causal allele is located 1.8 Mb downstream from the top GWAS hit, it is found to overlap with a broad GWAS peak detected for both cyanidin-3-galactoside and total anthocyanins.

Therefore, McClure et al. (2019) have identified several SNPs that are deemed as strong candidates for use in marker-assisted breeding. Moreover, it is reported that polyphenol compounds lacking significant GWAS are deemed as predictable using genome-wide SNPs; thus, these may be amenable for breeding using genomic selection (McClure et al. 2019). This study has demonstrated that quite often it is a relatively simple genetic architecture that underlies such observed wide variations in levels of key polyphenolic compounds in apple. These findings offer opportunities for breeding efforts in improving the nutritional value of apples using either marker-assisted breeding or gene editing.

5.14 Transcriptome Expression Profiling of Genes Involved in the Phenylpropanoid Pathway

Busatto et al. (2019) conducted a large transcriptome analysis of 16 genes involved in key steps of the phenolic biosynthetic pathway, beginning with phenylalanine all the way through anthocyanins. These genes included *Phenylalanine ammonia lyase* (*MdPAL*), *Chalcone synthase* (*MdCHS*), *Chalcone-flavone isomerase* (*MdCHI*), *Flavonoid 3-hydroxylase* (*MdF3H*), *Dihydroflavonol 4-reductase* (*MdDFR*), *Anthocyanin synthase* (*MdANS*), and *Anthocyanidin 3-O-glucosyltransferase* (*MdUFGT*).

Moreover, they investigated transcriptomes of genes involved in the synthesis of procyanidins including *leucoanthocyanidin reductase* (*MdLAR*) and *anthocyanidin reductase* (*MdANR*), as well as expression of those major genes involved in the synthesis of flavonols and phoridzin, including *flavonol synthase* (*MdFLS*), *UDP-dependent glycosyltransferase* (*MdUGT*), and *enoyl reductase* (*MdENLR*), respectively. Furthermore, expression of three different *MdUGT* genes, including *MdUGT88F1/4*, *MdMdUGT71K1s,* and *MdUGT71A15*, along with *MdENLR3/5*, that are likely to be involved in the biosynthetic pathway of phloridzin, via glycosylation of phloretin into phloridzin (Zhou et al. 2017), was also investigated. In addition, expression of genes involved in the biochemical pathway of chlorogenic acid and its accumulation and oxidation were also investigated including *p-Coumaroyl ester 3-hydroxylase* (*MdC3H*) and the *Polyphenol oxidase* (*MdPPO*), respectively. This large transcriptome analysis study demonstrated that all these genes were expressed at higher levels in skin tissues than in flesh tissues, collected during early fruit development (74 days after full bloom) and at fruit maturity (harvest time, depending on the genotype), of seven apple genotypes including two wild *Malus* species, *M. baccata* and *M. sieversii*, and five apple cultivars, 'Tyroler Spitzlederer', two clones of 'Golden Delicious' (a smooth skin and a russeted skin clones), 'Cripps Pink', and 'Braeburn'. However, there were some interesting findings wherein, during early fruit development, six genes, namely, *MdCHI*, *MdF3H*, *MdDFR*, *MdANS*, *MdUFGT,* and *MdANR*, had the highest levels of expression in the wild species *M. baccata*, but with no differences in levels of expression between the two tissues (skin and pulp), except for *MdUFGT*, whose expression was much higher in the flesh. On the other hand, transcriptome profiles of *M. sieversii* demonstrated higher levels of gene expression for *MdCHS*, *MdFLS*, *MdLAR,* and *MdENLR3/5*. Moreover, while *MdCHS* was expressed at higher levels in the fresh tissue, *MdFLS* showed higher transcript accumulation in the skin tissue (Busatto et al. 2019).

Transcriptome profiles in cultivated apples demonstrated that *MdPAL*, *MdF3H*, and *McCHI* were highly expressed in skin of the russeted cultivar 'Tyroler Spitzlederer'. Furthermore, the russeted 'Golden Delicious' clone ('Rugiada') demonstrated the highest level of expression of *MdUGT88F1/4* in the skin tissue. These findings supported the role of russeting in the pattern of phenolic compound accumulation in these genotypes due to higher induction of expression of genes in the phenolic biosynthesis pathway of secondary metabolites (Busatto et al. 2019). Furthermore, the majority of genes involved in the phenolic biosynthesis pathway were highly expressed in skin tissues of fruit collected at harvest time in the different genotypes investigated (Busatto et al. 2019). However, at harvest time, transcriptome profiles of all 16 genes were higher in cultivated apples compared to the 2 wild *Malus* species, although *MdCHS* gene in *M. sieversii* was highly expressed. Furthermore, transcriptome profiles of nine genes, namely, *MdPAL*, *MdCHI*, *MdF3H*, *MdANR*, *MdFLS*, *MdENLR3/5*, *MdANS*, *MdC3H,* and *MdUGT88F1/4*, at harvest were significantly higher than during early fruit development, with a 3.8-fold (for *MdUGTF88F1/a*) to 58 (for *MdFLS*). This could be attributed to increased fruit size and skin russeting (Busatto et al. 2019).

5.15 Enhancing Polyphenolic Contents in Red-Fleshed Apples

As noted above, interests in increasing contents of phenolic compounds and their bioavailability have prompted efforts for breeding for red-fleshed apple cultivars. It has been established that the red flesh trait has long been identified in the apple germplasm, particularly in *Malus* species, such as *M. pumila* var. Niedzwetzkyana (van Nocker et al. 2012; Wang et al. 2018). Several studies have reported that a *MYB* TF, *MdMYB10*, has been identified as a key factor responsible for increased accumulation of anthocyanin in several plant tissues and organs, including fruit, via its activation of anthocyanin pathway genes (Espley et al. 2007, 2009, 2013). In particular, owing to the higher anthocyanin contents in red-fleshed apples, compared to white-fleshed ones, particularly with higher levels of cyanidin, along with availability of molecular markers useful for marker-assisted selection for this trait, efforts have been underway to develop red-fleshed apples for its nutraceutical value (Wang et al. 2018).

Busatto et al. (2019) evaluated the phenolic contents of seven white-fleshed apple accessions (described above) along with three red-fleshed apple accessions. As with white-fleshed apples, red-fleshed apple accessions had varying fruit sizes, wherein fruits of cultivated apple (*M.* × *domestica*) and *M. pumila* var. Niedzwetzkyana had an average weight of 80.8 and 75.1 g along with fruit diameter of 6 and 5.8 cm, respectively, while fruit of *M. sylvestris* had an average weight of 17.7 g and fruit diameter of 3.1 cm. All 15 phenolic compound contents, except for anthocyanins, were found in both white- and red-fleshed apples, including neochlorogenic acid, chlorogenic acid, *trans*-piceide, *cis*-piceide, catechin, epicatechin, procyanidin B1, procyanidin B2 + B4, quercetin-3-Rha, kampferol-3-rutinoside, quercetin-3-galactoside + glucoside, isorhamnetin-3-glucoside, rutin, arbutin, and phloridzin. Moreover, levels of chlorogenic acid, epicatechin, and procyanidin B2 + B4 in red-fleshed *M. sylvestris* were significantly higher (90.2, 133, and 16.9 mg/kg fresh weight, respectively), ranging from 1.3- to 4.5-fold, compared to these levels in the two red-fleshed accessions, cultivated apple and *M. pumila* var. Niedzwetzkyana. Comparing the metabolite profiles of white- versus red-fleshed apples, it was observed that the content of phenolic compounds was significantly higher in white-fleshed ones. However, red-fleshed apples had significantly higher anthocyanin contents than white-fleshed ones, although white-fleshed apples had higher contents of all other polyphenols. Furthermore, polyphenolic accumulation in the flesh of white-fleshed domesticated and red-fleshed accessions revealed a fold-change of 17.5, 12.7, and 26.2, respectively, for procyanidins B1 and B2 + B4 and quercetin-3-Rha, and this accumulation pattern is attributed to the fact that the red color is induced by *MdMYB10* TF that activates anthocyanin-related genes in red-fleshed apples (van Nocker et al. 2012; Espley et al. 2007). It is worth pointing out that low levels of phenolic compounds, except for anthocyanins in red-fleshed apples, are noted both in skin and flesh tissues (Busatto et al. 2019). Although it has been widely reported that anthocyanins play important roles as an antioxidants, they have lower levels of bioavailability in comparison to other flavonoids, as they have been found to either degrade rather quickly or are rapidly absorbed and excreted in humans (McGhie and Walton 2007; Fernandes et al. 2014).

5.16 Structural and Regulatory Genes Controlling Critical Nutraceutical Biosynthesis Pathways

5.16.1 The Phenylpropanoid Pathway

The phenylpropanoid biosynthesis involves several structural genes, including those coding for phenylalanine ammonia-lyase (*PAL*), cinnamate-4-hydroxamate (*C4H*), and 4-coumarate–CoA ligase (*4CL*) (Fig. 2; Liu et al. 2021). This is followed by early biosynthesis genes (EBGs) of the flavonoid biosynthesis, including chalcone synthase (*CHS*), chalcone isomerase (*CHI*), flavanone 3-hydroxylase (*F3H*), flavanone 3-′-hydroxylase (*F3′H*), and flavonoid 3′5′-hydroxylase (*F3′5′H*) (Henry-Kirk et al. 2012; Davies et al. 2020). This is followed by late biosynthesis genes (LBGs) of the flavonoid biosynthesis pathway including dihydroflavonol 4-reductase (*DFR*), anthocyanidin synthase (*ANS*)/leucoanthocyanidin dioxygenase (*LDOX*), UDP-glucose flavonoid 3-*O*-glucosyl transferase (*UFGT*), flavonol synthase (*FLS*), leucoanthocyanidin reductase (*LAR1*/*LAR2*), anthocyanidin reductase (*ANR*), glycosyltransferases (*GT1/GT2*), quinate hydroxycinnamoyl (*HQT*)/hydroxycinnamoyl CoA shikimate (*HCT*), and *p*-coumarate 3-hydroxylase (*C3H*), along with other modifying genes, such as methyltransferase (*MT*), O-methyltransferase (*OMT*), and anthocyanin transferase (*AT*) (Han et al. 2007, 2012; Henry-Kirk et al. 2012; Davies et al. 2020; Liu et al. 2021).

In addition, there are four structural genes, namely, transparent testa 10 (*tt10*), transparent testa 12 (*tt12*), transparent testa 13 (*tt13*), and transparent testa 19 (*tt19*), encoding polyphenol oxidase (PPO), a secondary transport factor of the MATE (multidrug and toxic compound extrusion) family, H (+)-ATPase, and glutathione S-transferase (GST), respectively. These proteins play significant roles in modification, transport, and oxidation of anthocyanidins (Liu et al. 2021).

5.16.2 The Flavonoid Biosynthesis Pathway

The flavonoid biosynthesis pathway has been extensively investigated in several plant species (Brueggemann et al. 2010; Liu et al. 2021). It is reported that regulation of this pathway occurs mostly at the transcriptional level of those structural genes encoding enzymes. It has been found that two major groups of transcription factors (TFs) are found to be involved in all investigated plant species, and these include the basic helix-loop-helix (bHLH) and R2R3 myeloblastosis (MYB) family proteins. BHLH proteins can typically regulate target genes in multiple branches of the flavonoid biosynthesis pathway (Brueggemann et al. 2010), while specificity for regulation of a single branch is conferred by MYB factors (Brueggemann et al. 2010). Although transcriptional control of the flavonoid pathway occurs mainly with these two major groups of TFs, additional regulators are required for proper expression of structural genes (Fig. 3).

As reported above by Khan et al. (2012b) and Chagné et al. (2012), an *LAR* gene within a major QTL is deemed as a strong candidate controlling the accumulation of both flavanols and procyanidins. However, Brueggemann et al. (2010) have observed that an apple WD40-repeat gene (*MdTTG1*), a homolog of *Arabidopsis* TRANSPARENT TESTA GLABRA1 (TTG1), activated a promoter of the

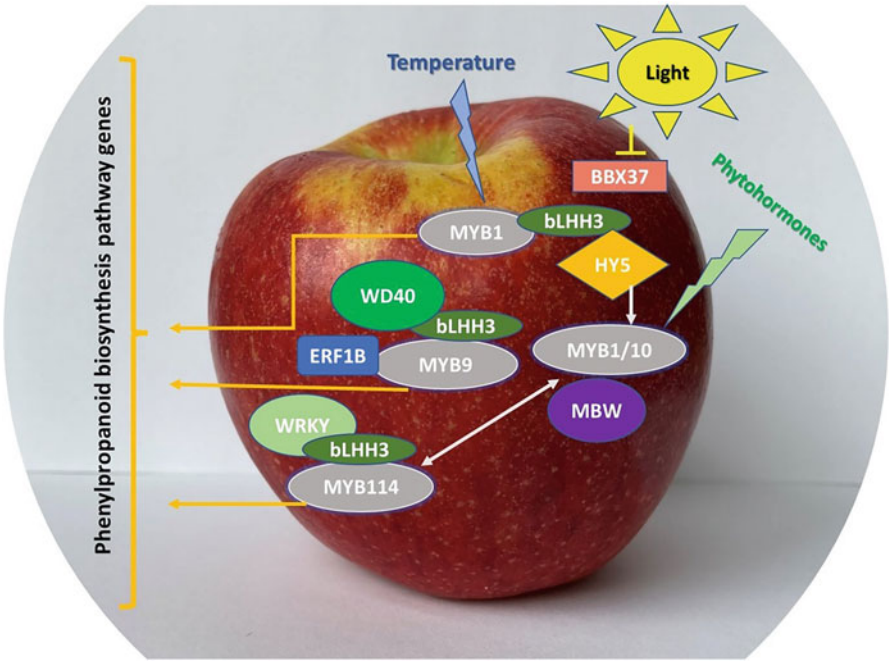

Fig. 3 A simplified schematic diagram of some of the key regulatory factors involved in the phenylpropanoid biosynthesis pathway. *BBX* B-box, *bHLH* basic-helix-loop-helix, *ERF* ethylene response factor, *HY5* ELONGATED HYPOCOTYL 5, *MYB* v-*myb* avian myeloblastosis viral oncogene homolog, *WD40* WD repeat protein, *WRKY* WRKYGQK domain, *MBW* MYB-bHLH-WD40

Arabidopsis *BANYULS* gene, *AtBAN,* along with *Arabidopsis* TT2 and TT8 in *A. thaliana* protoplasts. This suggests that proanthocyanidin (PA) accumulation in apple is likely regulated at the transcriptional level although no TFs in apple have been yet identified to be involved in regulation of PA biosynthesis.

Earlier, Han et al. (2012) investigated the functionality of the anthocyanidin reductase (*ANR*) gene family in apple, consisting of a single *MdANR1* gene on chromosome 10 and two allelic *MdANR2* genes, *MdANR2a* and *MdANR2b*, on chromosome 5. Liao et al. (2015) reported on the role of *LAR* genes in proanthocyanidins (PA), also referred to as condensed tannins, biosynthesis in apple. Expression profiles of both *LAR* and *ANR* genes were investigated in fruit skin of a single cultivated apple and three crabapples. Transcript levels of *LAR1* and *ANR2* genes were significantly correlated with contents of catechin and epicatechin, respectively, thus suggesting that these genes played active roles in PA synthesis. However, unexpectedly, transcript levels for both *LAR1* and *LAR2* genes were almost undetectable in two crabapples accumulating both flavan-3-ols and PAs. This finding contradicted an earlier finding that *LAR1* gene was a strong candidate involved in regulation of metabolite accumulation of epicatechin and PAs in apple. Moreover, ectopic expression of the apple *MdLAR1* gene in tobacco was found to

suppress expression of the late genes in the anthocyanin biosynthesis pathway, thereby leading to resulting loss of anthocyanin in flowers. Furthermore, a decline in PA biosynthesis was also observed in flowers of transgenic tobacco plants overexpressing the *MdLAR1* gene, which was likely attributed to reduced levels of expression of both tobacco genes *NtANR1* and *NtANR2* genes. This study confirmed the in vivo function of the apple *LAR1* gene (Liao et al. 2015).

5.16.3 The Anthocyanin Biosynthesis Pathway

As for anthocyanin biosynthesis, the role of regulatory genes is of critical importance. Many genes involved in regulation of the anthocyanin biosynthetic pathway consist of groups of TFs, including those of the MYB family, the bHLH family, and the tryptophan-aspartic acid repeat (WDR) family (Fig. 3) (Tian et al. 2017; Liu et al. 2021). Often, members of these three families of regulatory genes are dependent on the MYB-bHLH-WD40 (MBW) complex to elicit their roles (Hichri et al. 2010; Liu et al. 2021; Li et al. 2022). Those regulatory genes involved in upregulation of the anthocyanin pathway are members of a subclade that includes the *PRODUCTION OF ANTHOCYANIN PIGMENT1* (*PAP1*) gene, and when overexpressed in *Arabidopsis*, this results in accumulation of anthocyanins (Borevitz et al. 2000). Anthocyanin-regulating MYBs have been isolated from various plant species, including apple, among other fruit crops in the Rosaceae family (Lin-Wang et al. 2010; Vimolmangkang et al. 2013; Chagné et al. 2013; Han et al. 2010). It is observed that proanthocyanidins are synthesized from epicatechin, which in turn is catalyzed by anthocyanidin reductase (ANR), transported, and polymerized (Tian et al. 2017). Anthocyanins are synthesized on the cytoplasmic surface of the endoplasmic reticulum, and stable anthocyanins are formed via different modifications, including glycosylation, methylation, and acylation, and then transported into the vacuole where they accumulate (Tian et al. 2017; Liu et al. 2021).

Plunkett et al. (2019) have reported that accumulation of anthocyanins in plants seems to be linked to biotic and abiotic stress, with levels of anthocyanin increasing in response to these stresses. Studies on regulation of anthocyanin production have identified both biosynthetic pathways genes and major regulating TFs, comprising the MYB-bHLH-WD40 (MBW) complex (Baudry et al. 2004; Henry-Kirk et al. 2012; Albert et al. 2014). This complex binds promoter regions of anthocyanin biosynthetic genes and *MYB10* to enhance transcription, as demonstrated in various plant species including apple (Espley et al. 2009; Chagné et al. 2013; Plunkett et al. 2019). Those MYBs regulating accumulation of anthocyanin in apple have been well investigated (Allan et al. 2008; Ban et al. 2007; Espley et al. 2009; Takos et al. 2006). It is found that the alleles *MYBA* and *MYB1* are identical, sharing 98% sequence homology with *MYB10*, differing by three amino acids in the open reading frame (Ban et al. 2007). Furthermore, the R2R3 binding region of these genes and anthocyanin-related MYBs in other plant species is found to be highly conserved (Ban et al. 2007). It has been observed that MYB10, bHLH3/33, and a WD40 protein TTG1 in apple form an MBW complex that regulates anthocyanin levels in other plant systems (Allan et al. 2008; An et al. 2012).

It is also important to point out that repressor genes also play an important role in the regulation of anthocyanin production, and these repressors have been identified in various plant species, such as *Arabidopsis*, petunia, strawberry, and apple, among others (Plunkett et al. 2019). For instance, two repressors have been reported in petunia: MYB27 (R2R3-MYB), a R2R3-type MYB that interferes with the MBW complex by preventing formation or incorporation and converting the complex into a repression complex, and MYBx (R3-MYB), an R3-type MYB that competes for interaction with the bHLH component of the MBW complex (Albert et al. 2014). MYB27 contains an ethylene-responsive element binding factor [ERF]-associated amphiphilic repression domain (EAR) and a repression TLLLFR motif, both involved in conferring the capability of anthocyanin repression (Albert et al. 2014). Lin-Wang et al. (2011) have identified a family of MYB repressors of anthocyanin in apple, belonging to the R2R3 MYB family, following heat treatment, and these repressors are characterized by an EAR motif. As Lin-Wang et al. (2011) have demonstrated that heat reduces *MYB10* expression in apple skin, Xie et al. (2012) have demonstrated that low temperature induces binding of bHLH3 to *MdMYB1* and to upregulating promoters of *MdDFR* and *MdUFGT* genes of the anthocyanin biosynthesis pathway (Fig. 3).

Thus, it is clear that genes controlling the phenylpropanoid biosynthetic, flavonoid, and anthocyanin pathways in plants are mainly regulated by transcriptional changes (Plunkett et al. 2019; Liu et al. 2021).

As mentioned above, anthocyanins are important secondary metabolites, belonging to flavonoids (polyphenols) (Liu et al. 2021). Thus far, over 20 anthocyanins have been identified in nature, and these are derived from the six most common anthocyanins, namely, cyanidin (Cy), peonidin (Pn), pelargonidin (Pg), malvidin (Mv), delphinidin (Dp), and petunidin (Pt). Anthocyanins are present along with various monosaccharides, including glucose, rhamnose, galactose, and xylose, as well as with disaccharides consisting of rhamnose, gentian disaccharide, and sophora disaccharide to form glycosides. Furthermore, anthocyanins consist of α-phenylbenzopyran cations, and these are primarily composed of C6(A)-C3 (C)-C6(B) carbon skeleton structures. Depending on presence of hydroxyl groups at the 3′ and 5′ of the B-ring carbon structure, along with methoxylation, this is used to distinguish among the six anthocyanins. Thus, methylation and hydroxylation modifications at different positions of the B-ring of the molecule contribute to the development of different colors of anthocyanins.

In addition to the roles of heat and cold temperatures in regulating anthocyanin accumulation, light conditions are also required for anthocyanin accumulation in many apple cultivars, particularly following exposure to ultraviolet-B (UV-B) irradiation (Ban et al. 2007; Jakopic et al. 2009; Vimolmangkang et al. 2014; Bai et al. 2014).

R2R3-MYB TFs play critical roles in the regulation of the anthocyanin biosynthesis pathway as these can directly regulate expression of related genes, thereby contributing to tissue-specific anthocyanin accumulation (Liu et al. 2021). It has been well documented that BHLH TFs are necessary for activities of R2R3-MYBs, primarily for stabilizing the MYB complex or for promoting its transcription (Liu et al. 2021). As an

example, some MYB TFs, such as MdMYB1, MdMYB9, MdMYB10, and MdMYB114, can promote apple fruit color development via interactions with bHLH3 and WD40 (Ban et al. 2007; Jiang et al. 2021). MdMYB1 is initially found in apple fruit skin, and its product participates in photoinduction by activating the transcription activity of promoters of the structural genes *MdDFR* and *MdUFGT* (Xie et al. 2012). It has been well documented that transcript levels of *MdMYB1* are positively correlated with anthocyanin accumulation and expression of structural genes as promoters of *MdDFR* and *MdUFGT* have light-response elements, such as ACGTs and MRE or MRE-like sequences (Takos et al. 2006; Hartmann et al. 2005). Zhang et al. (2022) have reported that mdm-mir858, an miRNA with multiple functions in plant development, negatively regulates proanthocyanidin accumulation by targeting *MdMYB9/11/12* in the peel of apple fruit.

Members of the WD40 protein family have 4–10 random WD repeat domains, consisting of 40 amino acid sequences ending with tryptophan (W) and aspartic acid (D). Among the first WD40 proteins isolated from apple is MdTTG1, and this can interact with MdbHLH3 and MdMYB9 to control expression of downstream structural genes (Brueggemann et al. 2010). Some TFs such as apple MYB16 can negatively regulate anthocyanin biosynthesis by hindering formation of the MBW complex (Xu et al. 2017).

Although many TFs have been found to be involved in the regulation of anthocyanin biosynthesis, the role of light in regulating anthocyanin biosynthesis is still under study. Various investigations of specific members of the *BBX* (B-BOX) protein gene family, belonging to the zinc-finger transcription factors, in apple have revealed that UV-B light in particular upregulates *MdCOL11/BBX33* expression in a temperature-dependent manner (Liu et al. 2021). *MdBBX33* is a close homolog of *AtBBX22/LZF1 (LIGHT-REGULATED ZING FINGER PROTEIN 1)*, also known as *STH3* (Salt Tolerance Homolog 3) and *DBB3* (Double B-Box zinc finger 3) (Bai et al. 2014). Furthermore, overexpression of apple *BBX33* in transgenic *Arabidopsis* lines resulted in increased anthocyanin accumulation and revealed that expression profiles of both *BBX33* and *MYB10* are related during different temperature and light regimes (Bai et al. 2014). It is demonstrated that BBX33 upregulates the *MYB10* promoter, thus suggesting that BBX33 functions downstream of ELONGATED HYPOCOTYL 5 (HY5) and upstream of MYB10 as a component in the environmental sensing pathway, thereby resulting in anthocyanin production in apple (Fig. 3; Bai et al. 2014; Liu et al. 2021).

Liu et al. (2018) assessed the roles of 23 apple *BBX* genes in anthocyanin regulation. Several *BBX* genes, including *Arabidopsis CONSTANS* (*CO)*, *CONSTANS-LIKE1* (*COL1),* and *COL2*, are reported to undergo diurnal patterns of gene expression. Furthermore, several studies investigated diurnal expression patterns in both candidate apple *BBX* genes and anthocyanin structural genes, along with expression profiles of anthocyanin biosynthetic genes and the MYB regulator, *MYB1*/*MYB10* (An et al. 2019, 2020; Liu et al. 2019). A group of BBX proteins has been evaluated for their ability to activate the promoter of *MYB1/MYB10* (Plunkett et al. 2019).

The anthocyanin biosynthesis pathway is influenced by several parameters, including environmental factors (light, temperature, water, and sugar), phytohormones,

transcription factors, as well as epigenetic modifications (Wang and Chen 2021). For instance, it is reported that light negatively regulates anthocyanin biosynthesis in apple primarily by inhibiting expression of *MdBBX37,* as *MdBBX* reduces expression of *MdHY5* by directly targeting its promoter (Liu et al. 2019). In contrast, the transcription factors MdWRKY72 and MdWRKY11 bind to the W-box cis-element of *MdHY5* to activate its regulation of anthocyanin biosynthesis (Liu et al. 2019; Hu et al. 2020). Therefore, it is apparent that BBX proteins function in response to light-induced anthocyanin accumulation and requiring HY5 participation. Furthermore, MdHY5, a bZIP TF and positive regulator of light signaling, can enhance anthocyanin biosynthesis via direct activation of *MdMYB1/10* expression (An et al. 2019). Nevertheless, MdBBX37 hinders binding of MdMYB1 and MdMYB9 to their respective target genes, thereby reducing accumulation of anthocyanin (Ban et al. 2007; Takos et al. 2006; Liu et al. 2021).

Phytohormones such as abscisic acid (ABA), jasmonic acid (JA), auxin, and ethylene are critical for plant and development, and they play important roles in anthocyanin biosynthesis (Wang and Chen 2021). An et al. (2021) have reported that ABI5 promotes ABA-induced anthocyanin biosynthesis by regulating the MYB1-bHLH3 complex in apple. On the other hand, JA induces degradation of JAZ (jasmonate ZIM-domain) proteins in apple via direct interaction of MdJAZ with MdbHLH3, thereby interfering with the recruitment of MdbHLH3 to the promoter of *MdMYB9* resulting in repressed transcription of the MBW complexes which leads to reduction in anthocyanin biosynthesis. As it has been observed that ethylene inhibits anthocyanin biosynthesis in red pears by downregulating expression of R2R3-MYBs (including *PpMYB10* and *PpMYB114*) and LBGs (late biosynthetic genes), and as ethylene signal transduction takes place via ethylene response factors (ERFs) and ethylene-insensitive 3 (EIN3)/EIN3-like (EIL), it has been reported that MdERF1B binds to promoters of *MdMYB9* and *MdMYB11* in regulating accumulation of both anthocyanin and proanthocyanidin (Zhang et al. 2018). Furthermore, elevated auxin levels can inhibit anthocyanin biosynthesis by suppressing structural and regulatory genes, while gibberellic acid (GA) signaling interrupts anthocyanin biosynthesis via DELLA proteins, essential for GA's role in regulating anthocyanin biosynthesis (Liu et al. 2021).

Expression of structural genes during anthocyanin biosynthesis is directly under the control of the MYB-bHLH-WDR complex, and R2R3-MYB TFs are highly involved in the regulatory anthocyanin pathway as these directly regulate expression of related genes, thereby resulting in tissue-specific accumulation of anthocyanin accumulation (Liu et al. 2021). Furthermore, BHLH TFs are critical for the activity of R2R3-MYBs, by either stabilizing the MYB complex or promoting its transcription (Liu et al. 2021). For instance, some MYB TFs, such as MdMYB1, MdMYB9, MdMYB10, and MdMYB114, can promote red color development in apple fruit via their interactions with bHLH3 and WD40 (Ban et al. 2007; Jiang et al. 2021). The MdMYB1 is detected in the skin tissue of apple, and its product participates in photoinduction by activating transcription activities of promoters of *MdDFR* and *MdUFGT*. It has been observed that *MdMYB1* transcript levels are positively correlated with anthocyanin, as well as in accumulation and expression

of structural genes as promoters of both *MdDFR* and *MdUFG* have light-response elements, such as ACGTs and MRE or MRE-like sequences (Hartmann et al. 2005; Takos et al. 2006). As members of the WD40 protein family have 4–10 random WD repeat domains, consisting of 40 amino acid sequences ending in tryptophan (W) and aspartic acid (D), MdTTG1 was the first WD40 protein isolated from apple and found to interact with both MdbHLH3 and MdMYB9 in controlling expression of downstream structural genes (Brueggemann et al. 2010). As it has been observed that some MYB TFs, such as apple MYB16, negatively regulate anthocyanin biosynthesis (Xu et al. 2017; Liu et al. 2021; Li et al. 2022), interactions of such MYBs with bHLH would hinder formation of the MBW complex, as well as competing in their interactions with subunits of bHLH and MYB/bHLH (Liu et al. 2021; Li et al. 2022). As TFs of members of the same family play different roles in the regulation of anthocyanin biosynthesis, functional elucidation of these TFs remains in progress.

In addition to the above TF factors, other regulatory factors such as methylation and demethylation of DNA are also involved in the regulation of anthocyanin biosynthesis. For instance, the DNA methylation inhibitor 5-azacytidine can induce red color pigmentation in apple (Liu et al. 2021). Furthermore, microRNAs can play critical roles in anthocyanin biosynthesis. Zhang et al. (2020) have reported that expression of mdm-miR828 only increases during late red color development in the skin of apple fruit and that this miRNA is involved in a feedback regulatory mechanism associated with anthocyanin accumulation in apple. Moreover, mdm-miR828 is reported to inhibit accumulation of anthocyanin in response to high temperature (Zhang et al. 2020).

5.17 Future Opportunities and Challenges of Apple Nutraceutomics

In the past decade, there here has been a significant interest in enhancing the phytochemical content of apple fruit, particularly of various secondary metabolites involved in the phenylpropanoid, flavonoid, and anthocyanin biosynthesis pathways, as well as of vitamin C and fiber content. With availability of various biochemical analysis and metabolomic platforms and tools, as well as of molecular, genomic, transcriptomic, and bioinformatic tools and platforms, there are ongoing concerted and focused efforts in the evolving field of nutraceutomics. Nutraceuticals have been gaining more considerable interest due to their demonstrated safe, health benefit, and therapeutic effects. Many studies have focused on apple nutraceuticals, primarily of those secondary metabolites involved in the flavonoid biosynthesis pathway such as phloridzin, phloretin, and phenolic acids as they have demonstrated not only high antioxidant defense activities, as well as their critical roles in cell proliferation and gene expression, but they are also more readily bioavailable than those of other phytochemicals, particularly of anthocyanins. Therefore, nutraceuticals offer opportunities for improving human health, preventing chronic diseases, and alleviating various ailments and diseases, such as cancer, diabetes, cardiovascular diseases, asthma, pulmonary

diseases, gastrointestinal disorders, and neurological disorders, among others. The most critical role of these apple nutraceuticals is to protect against oxidative damage, as humans live in a highly oxidative environment and various metabolic processes may result in production of higher levels of oxidants. As oxidative damage accumulates, it becomes more important to protect against oxidative damage early on.

When compared to other fruits consumed in the USA, apples demonstrate the second highest level of antioxidant activity, after cranberry (Boyer and Liu 2003–2004). Apples rank second for total content of phenolic compounds. When compared to other fruits, apples have the highest proportion of free phenolics; thus, these phenolics are likely to be more bioavailable, for eventual absorption into the bloodstream. As noted above, several of the antioxidant compounds in apples have been well investigated such as quercetin, catechin, epicatechin, procyanidin, chlorogenic acid, and phloridzin.

Nutraceutomics offers new opportunities for pursuing enhancement of nutraceutical content of apple fruit in advanced breeding lines via integration of metabolome profiles, antioxidant activity, environment, and gene expression during pursuit of a genomic selection scheme(s) in an apple breeding program. Therefore, it is important that considerations of environmental influences, such as temperature and irradiation, as well as of fruit developmental factors are accounted for in gene expression analysis and in metabolic responses of these selections, as these present challenges in achieving rapid advances in nutraceutomics. Moreover, epigenetic modifications via DNA methylation can play important roles in structural and regulatory gene expression of "nutraceutical" profile(s).

However, the key factor in continued successful advances in the field of apple nutraceutomics is to develop a set of priorities of those metabolites that are likely to be highly expressed in apple fruits under varying environmental conditions, particularly in light of current conditions of climate change, and also to demonstrate high efficacies of bioavailability. This should be followed by genetic enhancement and breeding efforts via various breeding schemes and strategies. These strategies could be pursued using either marker-assisted selection, genomic selection, rapid-cycling breeding, or gene editing, among others.

6 Conclusions

Plant secondary metabolites in apple fruit have been documented to be involved in alleviating various human health diseases and conditions, and therefore there has been increased interest in enhancing levels of these nutraceutical compounds in both skin and flesh tissues of apple fruits, as well as their bioavailability and antioxidant activities (Busatto et al. 2019; Nezbedova et al. 2021; Koh et al. 2019). Various studies have assessed contents of these nutraceutical compounds in different cultivars, genotypes, and accessions, and although contents of these compounds are higher in wild versus cultivated apples, there are various opportunities to enhance accumulation of these compounds in the cultivated apple (Busatto et al. 2019). Genetic studies have been undertaken to identify and map genes and

QTLs associated with these compounds, particularly of phytochemical compounds involved in the phenylpropanoid pathway, including polyphenolic compounds consisting of phenolic acids and flavonoids (McClure et al. 2019; Brizzolara et al. 2021; Kim et al. 2020a). As marker-assisted selection efforts have become integrated in modern breeding programs, availability of molecular markers associated with various polyphenolic compounds has become highly critical in selecting genotypes with enhanced levels of these different compounds (Teh et al. 2021). Furthermore, owing to the availability of tools of apple genomics, transcriptomics, metabolomics, and other omics technologies, the field of apple nutraceutomics is a new frontier that is gaining stronger interest by apple geneticists, nutritionists, and health professionals (Korban 2021; Kidoń and Grabowska 2021; Li et al. 2020; Nasir et al. 2020).

Integrating Omic Tools to Design Nutraceutically Rich Citrus

Bidisha Mondal

Contents

Abstract

The world is facing a bipartite problem of malnutrition covering under-nutrition as well as over-nutrition. This situation is an outcome of imbalance in financial capability and inequality in food distribution. The intake of diverse nutraceutical compounds could assist in overcoming the health problems and may provide additional protection to the human communities through generation of substantial antimicrobial and antioxidant properties. The tropical and subtropical fruits and vegetables are rich source of multiple bioactive compounds and are regarded as therapeutic storehouse. In majority of the countries, the fruit by-products and

C. Kole (ed.), *Compendium of Crop Genome Designing for Nutraceuticals*,
https://doi.org/10.1007/978-981-19-4169-6_35

wastes lead to a complication of agro-waste disposal and management. The fruits, as a whole, are fascinating in production of bioactive elements. Citrus is a representative fruit having marked significance in food and fragrance sector. The nonedible parts, including peel, seed, fiber, and leaves, are potent source of health-promoting elements. The sequencing of the Citrus genome and available omics information could distinctly aid in the development of a nutraceutical database. In this chapter, the contemporary account on Citrus omics, encompassing genomics, transcriptomics, and metabolomics are critically evaluated for development of an array of sub-foods pertinent to food-omics division. The Citrus germplasm recourse and exploitable breeding strategies available till date could build a designer Neutri-Citrus appropriate for the prospering nutraceutical sector. This futuristic strategy of utilization of Citrus fruit waste and by-products in phyto-pharmaceutical industry may simultaneously encourage global agro-waste reduction and emerge as a new model contributing to circular economy.

Citrus · Omics-tools · Nutraceutical · Germplasm · Designer food · Agro-waste · Circular economy

1 Introduction

Nutraceuticals are natural dietary components found in food having health benefit and disease-fighting property. Nutraceuticals exhibit a boundary between food and drug and could be exploited to ameliorate health, slow down senescence, and maintain proper functioning of human body. A broad functional classification of nutraceuticals includes two types: potential nutraceutical and established nutraceutical. A prospective sub-food could be considered as a potential nutraceutical and could be elevated to an established designer food subject to qualifying certain clinical trials. In current time, GRAS (generally recognized as safe) status of nutraceuticals is essential for the quality assurance of products. The common food sources used as nutraceuticals are covered under multiple categories. The dietary fiber, probiotics, and prebiotics contain elements for improvement of gut health. Polyunsaturated fatty acids (PUFAs), polyphenols, antioxidants, vitamins, and spices form a category with capacity of fighting free radical led damages (Das et al. 2012).

Plants harbor bioactive compounds with health benefits beyond the basic nutritional values in the form of secondary metabolites. On the basis of chemical structure and function, the common secondary metabolites available in foods could be grouped as phytosterols, phytoestrogen, carnitine, and choline with direct cellular and tissue-specific activities. Carotenoids, dithiolthiones, flavonoids, polyphenols, glucosinolates, and taurine are equally potent modulators of physiological processes (Rodríguez-Casado 2014). Fruits and vegetables with diverse colors are quintessential source of an array of nutraceuticals. The classical examples are grape (*Vitis vinifera*), watermelon

(*Citrullus lanatus*), and banana (*Musa* spp.). Fruits like bael (*Aegle marmelos*), pomegranate (*Punica granatum*), amla-Indian gooseberry (*Phyllanthus emblica*), cranberry (*Vaccinium* spp.), orange (*Citrus sinensis*), and lemon (*Citrus limon*) are well-established sources of nutraceuticals (Dutta et al. 2017). Citrus fruits including orange, bergamots (*Citrus bergamia*), lemon, and grapefruit (*Citrus x paradisi*) are rich in bioactive compounds. The tropical and subtropical fruits are considered as therapeutic storehouse. The pharmaceutical and nutraceutical components present in fruits protect human from several diseases, increases life expectancy and reduces stress. The fruit peel, seeds, and by-products from food processing units serve as potential source of multiple bioactive compounds. These waste products could be utilized for extraction and valorization of nutraceuticals that strengthen the field of circular economy and aid in environmental waste mitigation (Fig. 1).

The phytochemistry of Citrus fruits and their by-products has gained importance in nutraceutical industry due to its impact on human health and contribution toward nutragenomics. The human gene expression, transcriptomic modulation, and protein turn-over could be regulated by Citrus bioactive compounds. In specific instances, the expression of *COX2*, microsomal cytochrome *P450 A1*, and *NF-kB* genes were guided by hesperidin, naringenin, and hesperetin, nutraceuticals that are present in Citrus. Evidence reveals that Citrus flavonoids have a regulatory effect on gene expression by coding of low-density lipoprotein receptors (LDLR). Citrus essential oil is also well known for food preservation with substantial antimicrobial, flavoring, and antioxidant properties (Mahato et al. 2018). The Citrus peel powder possesses free radical scavenging activity and could replace synthetic preservatives in the market in near future (Khan et al. 2021).

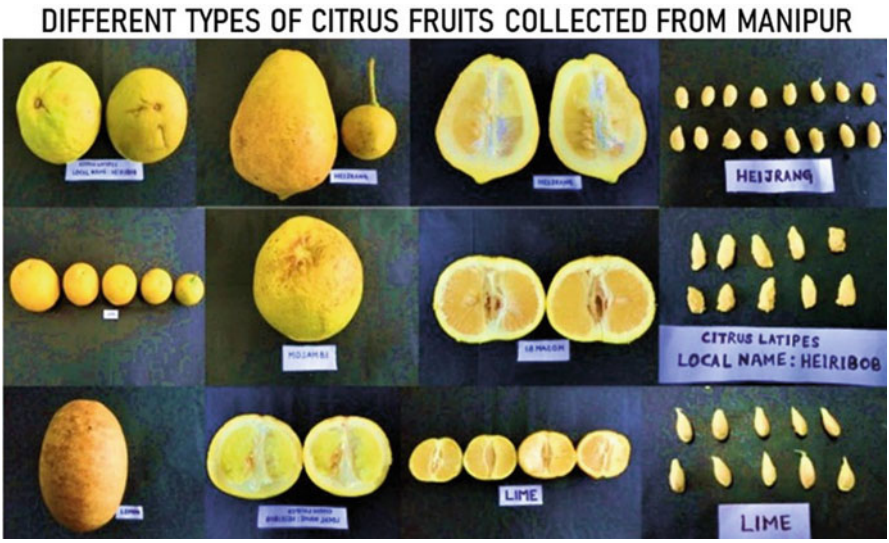

Fig. 1 Citrus fruits collected from Manipur, India (*C. latipes*, *C. medica*, *C aurantifolia*)

2 Mechanism of Nutraceutical Production in Citrus

The qualitative and quantitative variation in bioactive compounds produced in vegetatively grown plants bears epigenetic regulation. The plant genome controls production of the expected phyto-constituents, but epigenomic events change the ultimate phenotypic imagery of the genotype. Parental imprinting and epi-alleles could affect developmental switches leading to gene silencing or over-expression in some natural ecotypes, producing variants. In clonally propagated plants, the recovery of somaclones is possible due to reprogramming of the somatic embryos, carrying similar genetic architecture as sib-plants. The movement of diffusible epigenetic signals through plasmodesmata and vascular systems as well as parasites from one part to another conceivably regulates the fitness of a plant. The season, ecology, and light intensity might regulate clonally propagated plant to a larger extent than its sexually grown complements (Pikaard and Scheid 2014). Several exogenous as well as endogenous stimuli determine the survival and nutraceutical production of various genotypes (Fig. 2).

The by-products of the Citrus industry are of immense economic value. The red orange of Sicily (known as blood orange) is a reservoir of significant amount of biologically active compounds (limonoids and flavonoids). The decanted pulps were the most abundant source of highest amount of flavonoids (130 g/kg) and a high amount of limonoids (5.5 g/kg) earning the protected geographic indication (PGI) for the cultivar. In Citrus, seeds are the best source of limonoids with about 10 g/kg of expression. Low amount of anthocyanins were found only in coarse pulps and waste water of red oranges (Russo et al. 2021). Bergamot (*Citrus bergamia* Risso) contains limonoids in abundance in seeds and peels (70% and 80% of the total, respectively), while limonoid glucosides are more abundant in juices and pulps

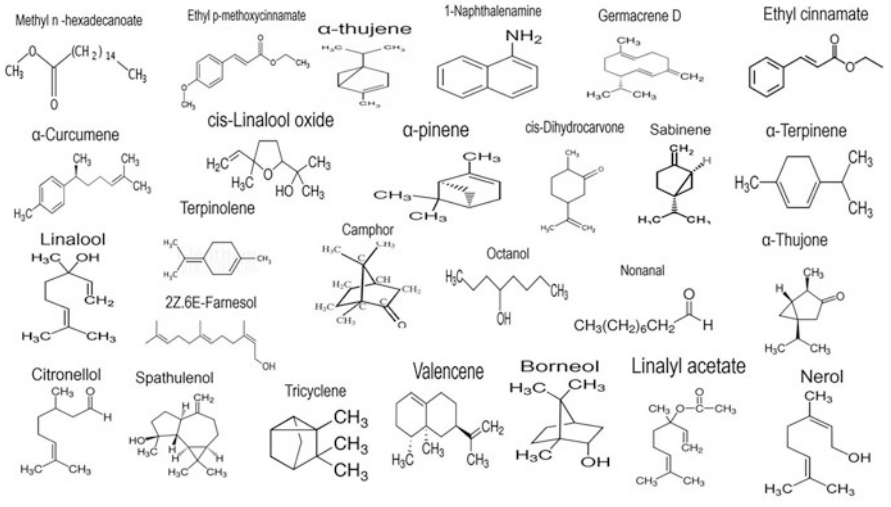

Fig. 2 Major bioactive components present in Citrus peel essential oil

(61% and 76% of the total, respectively). The limonoids are related to microbial disintegration and free radical scavenging activity (Russo et al. 2016). *C. sinensis* commonly called 'Ovale Calabrese' grows profusely in the south of Italy (Calabria region). Due to the richness of flavonoids and limonoids and high content of phenolic compounds, in particular hesperidin in the pastazzo, the fruits could be utilized for the valorization of the by-product for the development of a novel functional ingredient (Celano et al. 2019).

The lemon leaf essential oil (EO) is rich in oxygenated monoterpenes, accounting over 48% of the extracted oil. The most abundant constituent of the oil is a terpenoid identified as neryl acetate (15.3%). Geranyl acetate is a monoterpenoid and its alcohol nerol and geraniol are involved in the generation of the characteristic lemon aroma. The sesquiterpene hydrocarbons fraction in the EO was represented by β-caryophyllene representing the second most quantitatively important chemical class of compounds. Traces of β-bisabolene and bicyclogermacrene were detected in lemon EO. Principle monoterpene hydrocarbons limonene and β-pinene along with spathulenol and caryophyllene oxide, the oxygenated sesquiterpenes were found to be a possible contributor in the lemon EO. The essential oil composition of lemon leaves exhibits great variability in onto-genetics. Leaves of lemon specimens from the Mediterranean region were mainly rich in limonene with the aldehydes and acetic esters of both nerol and geraniol (Vekiari et al. 2002), while the composition of Indian lemon leaf EO exhibits the presence of (Z)-sabinene hydrate, geraniol, with a trace of α-pinene (Pal et al. 2016). The Iranian lemon oil is predominated by linalool, followed by a substantial representation of geraniol, α-terpineol, as well as linalyl acetate (Hojjati and Barzegar 2017). The geographical origin of the genotypes plays an instrumental role in the composition of the essential oil (EO) extracted from the Citrus peel.

The orange leaf essential oil was mainly dominated by oxygenated monoterpenes. The most prevalent component for this class was linalool. The acetic ester of linalool, α-terpineol, geranyl, and neryl acetate was associated with the signature aroma of the fruit. Myrcene, β-ocimene, and β-pinene belonging to monoterpene hydrocarbons were another related chemical class of volatiles found in orange fruits. The metabolic profile of oranges expresses differential outcomes subject to growth conditions and nurturing. The essential oil profile of different Citrus accessions under orange is consistent with the literature report presented earlier (Sanmartin et al. 2019).

The leaf essential oil of endemic species of Australia reveals significant variation in oil content. While *C. australasica* produced oil is predominated by bicyclogermacrene, germacrene-D, δ-elemene, and limonene, the other promising species, *C. australis* oil shows major share of α-pinene. The oil from another species, *C. garrawayi*, shows two distinct components, α-pinene and β-caryophyllene, belonging to monoterpene group. *C. glauca* contains α and β-pinene in contrast to *C gracilis* with γ-terpinene as major contributor. Another species, *C. inogora*, contains germacrene D as principal constituent. The wide variation of component availability is a comprehensible reflection of disparate epigenetic control of the same pathway (Brophy et al. 2001).

C. aurantifolia leaf and peel essential oil was characterized by 49 constituents (93.6% of the total oil), in which the dominant components were the monoterpene hydrocarbon limonene, β-pinene, γ-terpinene, and β-myrcene. *C. aurantium*

essential oil displays 15 components, with limonene as the major monoterpene hydrocarbon with successors β-myrcene and α-pinene. The oil has minor fractions of linalool and linalyl acetate, representing the oxygenated monoterpenes (Tundis et al. 2012). The oil profile of both the above-mentioned species could be utilized as natural anti-oxidants and could prevent an array of neurodegenerative diseases and aging. Bioactive compounds naturally occur in our surrounding plants, but in trace quantities. Epidemiological studies indicate that intake of bioactive food increases gastrointestinal ecology, immunity, reduces risk of cancer, diabetes, heart diseases, Alzheimer's disease, stroke, cataract, cytotoxicity, and even age-induced senescence (Saini et al. 2022). Additionally, energy boosting, wound recovery, and beauty retention are also ensured by nutraceuticals (Table 1). Limonoids exhibit antimicrobial and anticancer activities and is a recognized human health promoter with manifold pharmacological properties and potential (Brito et al. 2014).

3 Chemistry of Major Bioactive Compounds Present in Citrus

3.1 Flavonoids

Flavonoids are found in all parts of plants and form a class of polyphenolic secondary metabolites. Flavonoids contain a 15-carbon framework (C6-C3-C6). Two hexa-carbon phenyl rings form a heterocyclic ring with embedded oxygen. A variety of modifications in the heterocyclic ring of flavonoid generates several subgroups. The naringin, eriocitrin, hesperidin, and narirutin constitute flavanone group, while flavones were categorized into rhoifolin, vitexin, and diosmin. Polymethoxylated flavones with natural antioxidant property cover nobiletin, tangeritin, and 5-demethyl nobiletin. Flavonols, the colorless secondary metabolites housing kaempferol, quercetin, and rutin, are recognized developmental regulators and signaling receptors. The colorful pigment anthocyanin present inside vacuolar compartments provides numerous health benefits to humans. The anthocyanin covers the cyanidin and peonidin glucosides (Testai and Calderone 2017; Saini et al. 2022). Plant defense, cell signaling, and repair from UV associated damages were mainly regulated by the flavonoid group of bioactives.

3.2 Carotenoids and Apocarotenoids

Carotenoids are a universal accessory isoprenoid pigments involved in carbon fixation and signaling pathways. Pigment carotenoid produces two subgroups: carotenes and xanthophylls. The hydrocarbon carotenoids α-carotene, β-carotene, and lycopene act as immune-activator. While xanthophylls, the oxygenated derivatives of hydrocarbon carotenoids represented by neoxanthin, violaxanthin, lutein, and β-cryptoxanthin, were accepted as anti-phototoxic agents (Saini and Keum 2018). Apocarotenoid is

another category of pigment detected in Citrus with distinctive role in signaling and growth regulation. The origin of apocarotenoids is subject to cleavage of dioxygenase. The eco-nutritional variation of apocarotenoid is an important factor for its acceptance as a functional food. In Citrus, both β-cryptoxanthin and zeaxanthin could be the probable progenitor of β-citraurin, and the process witnesses an asymmetric cleavage of the progenitor (Luan et al. 2020).

3.3 Terpenes and Limonoids

The monoterpene hydrocarbons consist of two isoprene components and cover several subtypes. The oxygenated monoterpenes (nonanal, geranial, and neral) are known as fragrant. Terpene alcohols are olfactory markers segregated into linalool, verbenol, geraniol, carveol, and α-terpineol. Sesquiterpenes with 15 carbon and 3 isoprene units are the major chemical constituents of the volatile fractions of Citrus essential oil (Raspo et al. 2020). The total terpenoids expressed in mandarin, tangerine, grapefruit, orange, citron, and lemon essential oil were preferentially dominated by a monoterpene D-limonene. An interesting study reveals that green mandarin contains fourfold higher limonin, a tetracyclic triterpenoidin much higher amount than its yellow and red complements. Montenegrin mandarin, essential oil has γ-terpinene as a major fraction with the minor presence of citronellol, an acyclic monoterpenoid, and terpene alcohol (Rossi et al. 2020). This sparse presence of these trace signatory components favored the antioxidant activity with a property of significant decrease of cytotoxicity inside colorectal cancer HT-29 cells.

3.4 Phenolic Acids

In a study involving kinnow mandarin clearly stated the percentage of solvent in determination of final recovery of the peel extracts or peel essential oil. Among the phenolic compounds, ferulic acid and hydroxycinnamic acid were recovered with remarkable antiaging properties. Hesperidin, a flavone glycoside, was also abundant in kinnow mandarin peel extracts. A tri-hydroxybenzoic acid, gallic acid, and catechin, a poly-phenol compounds were found to remain present in high concentration in kinnow type mandarin. Trace quantities of caffeic acid, a methylxanthine, and naringenin, a flavanone, were recovered from the peel extract with anti-carcinogenic and immune-stimulant activity (Safdar et al. 2017).

3.5 Coumarin

Five coumarins and 21 fucocoumarin compounds are widely present in Citrus species. The compounds are rich in dimethylallylated and/or geranylated compounds such as bergamottin, aurapten, or imperatorin. The coumarin compounds exhibit multiple applications in skin diseases with antiviral and anticancer properties. Citrus roots are storehouse of some novel coumarins. Peroxytamarin, with antibacterial property along with cis-casegravol having antiproliferative properties were detected as major constituents. Lignan glycoside, citrusarin-A, and citrusarin-B were present in root of Citrus plants. These polycyclic compounds possess organoleptic properties with prominence as satisfactory odor and flavor agents (Ito et al. 1991).

4 Citrus Genome and Phylogeny

Citrus is a diploid genus with 18 chromosomes and a genome size ranging from 265 to 407 Mb. In *Citrus* spp., a spectrum of research has been done on germplasm characterization and management. The Sino-Indian border area is regarded as a unique germplasm conservation center of Citrus. Citrus group contains multiple species qualifying as scions (commercial varieties) and several rootstocks (wild types). The novel *Citrus* fruit types of South Asia displays diverse species, including *C. reticulata*, *C. sinensis*, *C. aurantifolia*, *Citrus indica*, *Citrus limon*, *C. aurantium*, *C. maxima*, *C. medica*, *C. limetta*, *C. latipes*, *C. jambhiri*, and *C. hystrix* (Mondal 2021). These huge ecotypic resources could act as reservoir for a number of important bioactive compounds that could play a crucial role in Indian nutraceuticals industry. The North Eastern hilly region evinces *C. indica*, *C. assamensis*, *C. macroptera*, *C. latipes*, *C. ichangensis*, *C. micrantha*, *C. medica*, *Fortunella margarita*, *F. crassifolia*, *F. japonica*, and *Poncirus trifoliata.* The analysis of the pulp, peel, and seed of this gigantic germplasm reservoir, predominantly the wild types, could manufacture unique compounds with prospects in the medicinal and pharmaceutical sectors.

In Chinese wild mandarin Mangshanju (*Citrus reticulata* Blanco), a total of 81 compounds were identified, including flavonoid glycosides, acylated flavonoid glycosides, flavones, polymethoxylated flavonoids, and limonoids, as well as four other compounds. The Citrus wild germplasm reserves are the automatic store house of nutraceuticals, and a thorough characterization of the constituents could yield an optimum product for the industry. The wild plant produces 22 polymethoxylated flavones and 10 polymethoxylated flavanones/chalcones in excess in comparison to its commercially propagated counterpart (Zhao et al. 2018). Ancient Indian Citrus species, pummelo (*Citrus grandis* L. Osbeck) harbors naringin as the predominant flavonoids irrespective of genotypes. Some selections are particularly high in naringin, and others seem promising for lycopene and phenols. Other phenolics quantified in the juice included caffeic, epicatechin, benzoic acid, neoeriocitrin, hesperidin, and narirutin. The examples cited above present the importance of germplasm characterization. The proper characterization of the wide and rich gene-pool with a nutraceutical inventory of elite cultivars could possibly assist Citrus nutraceuticals breeding program (Nishad et al. 2018).

5 Omics Understanding of Nutraceutical Production in Citrus

The omics tapestry of living organisms presents the most mysterious and interesting field of molecular research. The response of a plant genome to external stresses and the successive cellular homoeostasis are regulated by the genic and inter-genic territories of the genome. In metabolic discovery, the natural variation within the species provides significant insight into nutraceuticals production. The multiple genomic identities of Citrus, including the wild and cultivated types, influence a

range of traits covering plant defense and commercially important attributes. Due to simultaneous occurrence of natural hybridization and vegetative propagation in citrus, the mode of inheritance of metabolite production becomes complex. Most of the biosynthetic pathways leading to identification of numerous bioactive compounds mainly follow non-Mendelian inheritance. The mQTL mapping technique unravels novel genes with intense epigenetic and environmental influence in synthesis of diverse end-products. The analysis and integration of various omics tools will assist in achieving futuristic goals in Citrus nutra-omics.

5.1 Nutragenomics of Citrus

In Citrus, the multidrug and toxic compound extrusion (*MATE*) gene plays a valuable role in flavonoids and citrate metabolism in fruits and is involved in numerous allied physiological processes. The MATE proteins are a class of secondary active multidrug transporters. In *Citrus clementina*, a total of 69 MATE transporters were classified on the basis of phylogeny. Tandem and segmental duplication events were the main causes of the Citrus MATE family expansion. RNA sequencing and qRT-PCR operations in different fruit developmental stages revealed that *CitMATE* gene expression is regulated by tissue diversity and a specific developmental stage. *CitMATE43* and *CitMATE66* are involved in the transport process of flavonoids and citrate in Citrus fruit, and additionally *CitERF32* and *CitERF33* are related to activation of *CitMATE43* promoter (Liu et al. 2022a).

In a research involving the large family of plant polyphenolic secondary metabolites, it has been expressed that transgenic plants could be developed with a high production capacity for bioactive compounds. A model transgenic tomato developed with structural flavonoid genes (encoding stilbene synthase, chalcone synthase, chalcone reductase, chalcone isomerase, and flavone synthase) from different plant sources was able to produce novel nutraceuticals. Biochemical analysis showed that the tomato peel contained high levels of stilbenes (resveratrol and piceid), deoxychalcones (butein and isoliquiritigenin), flavones (luteolin-7-glucoside and luteolin aglycon), and flavonols (quercetin glycosides and kaempferol glycosides). The study involving genetic engineering of flavonoids in tomato fruit demonstrated the prospects of developing tailor-made Citrus crops with high level of plant nutrients (Abeynayake et al. 2012).

In a research involving the identification of major limonoid-producing gene in Citrus, P450s (CYP450s), MYB, and CiOSC genes were found to play a ubiquitous role in limonoid biosynthesis. The leaves, phloem, and seeds of pummelo (*Citrus grandis* L. Osbeck) express variations in limonoids' contents at different development stages. Digital gene expression profiling identified 382 putative genes from 3 conjunctive groups related to the biosynthesis of limonoids. Repetitive correlation analysis with the samples from different genotypes involving different developing tissues of the Citrus confirmed 15 candidate genes with high correlation with the contents of limonoids. The cytochrome P450s (*CYP450s*) and transcriptional factor *MYB* demonstrated significantly high correlation coefficients, validating the

importance of those genes for the biosynthesis of limonoids. *CiOSC* gene encoding the critical enzyme oxidosqualene cyclase (OSC) for biosynthesis of the precursor of tri-terpene scaffolds was responsible for limonoids production in seeds. Suppressing the expression of *CiOSC* with *VIGS* (Virus-induced gene silencing) demonstrated that the level of gene silencing was significantly correlated to the reduction of limonoids contents (Wang et al. 2017).

In Citrus cultivars, two vacuolar P-ATPase homologs, *CitPH1* and *CitPH5*, are strongly induced in highly acidic species such as lime and lemon fruits. The level of expression of these two genes is significantly reduced in acidless mutants. The cellular pH gradient is maintained by vacuolar ATPases with an array of genes: *CitPH1*, *CitPH5*, *PH3* (WRKY), *PH4* (*MYB*), and basic helix-loop-helix (*bHLH*). Citrus Noemi (*CitAN1*) transcription factors were less expressed or reduced in the mutants (Butelli et al. 2019). Homologs of *PH4*, which is a *MYB* transcription factor, have been reported to activate the promoter of the proton pumps (*PH1* and *PH5*) in Citrus. A pleiotropic gene Noemi (*CitAN1*) regulates both acidless phenotypes and loss of proanthocyanidin and anthocyanin in sweet lime, citron, sweet orange, lemon, and limetta accessions. A variation in the core promoter region of the *Noemi* gene in two limetta accessions reduces gene expression and increases the pH of the juice, indicating *Noemi* as a vital gene contributing to fruit acidity. Recent studies showed that a specific mutation in *CitAN1* is responsible for the reduced expression of *CitPH1* and *CitPH5* in acidless lemon and other acidless Citrus fruits (Strazzer et al. 2019). A complex formed of WD40-repeat proteins, MYB, bHLH, and WRKY transcription factors known as WMBW in short plays a significant role in the operation of three anthocyanin pathways. *Ruby2* and *Ruby1* genes belonging to a cluster function as anthocyanin activators, but Ruby2 operates in tender leaves and Ruby1 functions preferentially in fruits. The reduction or loss of anthocyanins may be due to the hitchhiking effect of fruit acidity selection in some domesticated types. A mutant gene, *AN1*, is a common regulator for both citric acid and anthocyanin metabolism, playing a regulatory role in fruit acidity and pigment production (Rao et al. 2021).

The National Centre for Biotechnology Information (NCBI) reveals enormous data on Citrus, categorized under 20 databases. The Citrus literature is covered under 42 bookshelves with 6 NML catalog, 2407 Pubmed, 17,780 Pubmed central information (Table 2). The data available in NCBI exhibits 110,766 terpinene, 382 limonoid, 259 alcohol dehydrogenase, 162 flavonoid, 32 limonene, 22 γ-terpinene, 67 coumarin, 60 chalcone synthase, 48 geraniol, 28 carotenoid, 8 citronellol, 7 citral, 7 quercetin, 6 trans-citral, 5 cis-citral, 5 naringenin, 3 anthocyanin gene, and 2 kaempferol associated genes in *Citrus* genera (NCBI 1988). These potential candidate genes could be utilized for qualitative as well as quantitative improvement of bioactive accumulation in pulp, peel, and seeds of Citrus.

5.2 Nutra-transcriptomics of Citrus

The accurate comprehension of the biosynthetic pathway is essential for commercial metabolite production. Transcriptomic data-mining is an efficient tool for

identification of gene families involved in certain metabolite production. In non-model plant species, a transcriptomic approach could accelerate genomic investigation. Transcriptomic analysis could efficiently identify the genetic and epigenetic factors underlying the expression of diverse bioactive compounds present in various plant species and the interplay of gene and environment influencing distinct pathways. A study involving the transcriptomic profiling of two varieties of *Citrus reticulata* expressed differences in the storage of bioactive compounds. Transcriptomic profiling of *Citrus reticulata* 'Huajuhong' (HJH) and *C. reticulata* 'Sanhuhongju' (SHHJ) reveals differences in the distinct level of bioactive ingredients in fruit peels. The total flavonoid in HJH peels was significantly higher than that in SHHJ. Messenger RNA (m-RNA) sequencing identified 203 differentially accumulated metabolites (DAMs) and 3517 differentially expressed genes (DEGs). Among the DAMs, the major components were flavonoids (104, 51.2%), followed by phenolic acids (30, 14.7%). KEGG enrichment analysis indicated the over-

expression of the flavonoid pathway. Ten glucosyl transferase genes regulated the accumulation of seven of the top ten flavonoid glycosides in HJH (Yu et al. 2022). Collectively, the higher content of flavonoid glycosides in HJH peels than SHHJ might contribute to the distinct health-promoting effect of the former and confirms its possible selection for integration in nutraceutical extraction.

In a similar transcriptomics study conducted by a group of scientists involving blood orange (*Citrus sinensis* cv. 'Tarocco') showed significant effects of diverse exogenous treatments in regulation of internal qualities of the fruit. Bagging has been widely used in fruit crops to improve fruit quality, but the result showed that bagging treatment has a significant effect on fruit quality. The treatment led to increase in total flavonoid (TFL) and total anthocyanin (TAN) concentrations, while total soluble solids (TSS), total phenolics (TPH), ascorbic acid (AsA) concentrations, and titratable acidity (TA) decreased in response to the bagging treatment. The high-throughput tag-sequencing (Tag-seq) analysis detected over 21 × 106 clean reads per library. Approximately 53.7–71.7% genic and 3.1–6.4% of intergenic clean reads were mapped onto Citrus genomic regions, respectively. About 25.2–39.9% of the clean reads failed to align with the Citrus genome. Overall, bagging treatment resulted in an increase in transcripts involved in a range of metabolic pathways rather than anabolic pathways. The tricarboxylic acid (TCA) cycle, sucrose and starch metabolism, ascorbate metabolism, and the phenylpropanoid pathway got affected through the treatment. Competition for limited amounts of substrates for the flavonoid, phenolics, and anthocyanin pathways may have led to an increase in total anthocyanins (TAN) and total flavonoid (TFL) concentrations under a variety of stresses on fruits. The gene, *bHLH* is involved in anthocyanin biosynthesis in blood orange fruit and was identified as a key player in controlling the genetic mechanisms operating in Citrus fruit in response to a bagging treatment (Sun et al. 2014).

In another, transcriptomic study on cold-induced response of *Citrus paradisie* confirms that low temperature exposure induces the elevation in the anthocyanin levels in the orange flesh. This enhancement being modulated by the transcriptional stimulation of the genes involved in the anthocyanin biosynthesis. The RNA profiling and subsequent construction of expressed sequence tag (EST) collection revealed *NAC* family of gene plays a vital role in the abiotic stress response. An EST, encoding the BRD4 bromodomain, a DNA-binding protein belonging to an extensive family of evolutionarily conserved protein originally remain associated with chromatin activity. This BRD4 plays a pivotal role in chromatin remodeling and transcriptional activation. Similarly, another gene, glutathione transferase (*Tau2*), previously identified in the leaves of blood oranges, ensures ROS scavenging activity. The storage temperature as well as the exposure tenure turned out to be critical for pigment development in flesh tissue. Though prolonged cold storage for more than 3 months, negatively influences the sensory quality of oranges due to the increase of the malodorous substance vinylphenol, whereas the standard fruit quality parameters (total soluble solids (TSS), total acidity (TA), and maturity index TSS/TA) remained unchanged between cold treated and control samples (Crifò et al. 2011).

In accessions of citron, limetta, sweet lime, lemon, and sweet orange, the acid-less phenotype is associated with large deletions or insertions of retro-transposons in the *Noemi* gene. In two accessions of limetta, a change in the core promoter region of *Noemi* is associated with reduced expression and increased pH of juice, indicating that *Noemi* is a major determinant of fruit acidity. *Noemi* in turn encodes a basic helix-loop-helix (*bHLH*) transcription factor and which controls flavonoid production as well as fruit acidity. A parallel research with 33 Citrus varieties completely unable to produce anthocyanins further reveals that acidless varieties containing functional alleles of *Ruby*, a key regulatory *MYB* gene, is essential for anthocyanin production. The two previous investigation show that both *bHLH* and *Ruby* are required for anthocyanins production. Mutation in any of the genes may affect pigmentation. *Noemi* encodes the *bHLH* protein that interacts with Ruby to control anthocyanin production in Citrus. *Noemi* and *Ruby* are both pleiotropic genes and play a regulatory role in anthocyanin production and fruit acidity (Butelli et al. 2019).

The biologists are searching for natural resistance in plants that could be a significant defense weapon for controlling biotic stresses in an environmental sustainable manner. A functional genomics approach employing cDNA microarrays with pathogen-infested flavedo tissue of Citrus fruits detected upregulation of few genes. The most highly induced genes were related to the phenylpropanoid pathway, engrossing 29 most up-regulated genes in the flavedo. Out of the 20 genes, 13 were involved in either phenylpropanoid metabolism or coumarin biosynthesis, including 7 different O-methyltransferases, isoflavone reductase, hydroxycinnamoyl transferase, 2 leucoanthocyanidin dioxygenases, and 2 SRG1 proteins. Genes related to methionine and ethylene biosynthetic processes, such as 1-aminocyclopropane-1-carboxylic acid oxidase (ACO) and proteins related to defense and response to stress were also induced in the flavedo. *EFE* and *CsACO* genes were over-expressed in tissues with direct affinity to ethylene production (Ballester et al. 2011).

The multiple examples presented in previous paragraphs unravels that transcriptome sequencing in plant is an efficient way of mining of functional genes, development of genomic markers, detection of discriminatory secondary metabolites, and analysis of related pathways (Guo et al. 2020). The advantage of RNA sequencing is that it provides distinctly different results owing to diverse developmental stages and tissues. Moreover, differential expression of genetic and epigenetic factors may be precisely estimated to provide information on diverse nutraceuticals production in Citrus and its valorization for industrial utilization (Table 3).

5.3 Nutra-metabolomics of Citrus

The quality of the Citrus fruit is directly related to the metabolic profile expressed by the plant. The primary and secondary metabolite deposition regulates the quality, taste, color, texture, flavor, appearance, and most importantly, the disease prevention property of the fruit. The color differences between Citrus varieties were associated with the carotenoid content. The Citrus color Index (CCI) value shows a significant positive correlation with the carotenoid content. Carotenoids are indispensable

molecules, providing protection against free radicals and oxidative stress (Zheng et al. 2019). Among organic acids, citric acid was the main organic acid found in Citrus flesh, followed by malic acid, acetic acid, and vitamin C. In a study of Korean Citrus varieties, significant variation was noticed among the local fruits (Hussain et al. 2017) with respect to acid content. Jeramon citrus showed the highest citric acid (482 mg/g DM) and malic acid content (60 mg/g DM), which were more or less 7–17 times and 2–9 times higher, respectively, than the other Korean varieties. Jeramon variety was developed from the nucellar embryo of a lemon plant, which excessively accumulates citric acid during fruit development. Kanpei (28 mg/g DM) and Natsumi (15 mg/g DM) had the lowest citric acid contents, while the lowest malic acid content was observed in Satsuma mandarin, Navel orange, Kanpei, and Setoka (approximately 6–8 mg/g DM). Setoka and Kanpei had the highest acetic acid content (about 6 mg/g DM), and the acetic acid content of the other varieties was approximately 2–4.8 mg/g DM. In particular, a high content of vitamin C, which has the strongest antioxidant activity in Citrus, was observed in Setoka (5.1 mg/g DM) and Jeramon (4.3 mg/g DM). These phenotypic and biochemical examinations provide a ground data for selection of germplasms and incorporation of the same for genomic and transcriptomic analysis, leading to the tracking of relevant biochemical pathways (Kim et al. 2021). The ratio of sugar content and organic acids is the main determinant of the maturity and core taste parameters in Citrus fruits. The sugar content and organic acid show a negative correlation, and the acid content declines during fruit development, resulting in a sweet taste in Citrus fruits (Smirnoff 2018).

A very interesting study elucidated the relationships between Citrus genotypes, diet, and health requirements of human subjects. Urinary metabolomic profile for volunteers identified proline betaine and flavanone glucuronides as known biomarkers, irrespective of Citrus genotypes. The study by the French research group revealed two strong discriminates identified as limonene 531 8,9-diol glucuronide and nootkatone 13,14-diol glucuronide belonging to terpene metabolite family in addition to standard markers (Pujos-Guillot et al. 2013). The unique study involving human subjects has thrown light on the recovery of nutritional biomarkers for accurate dietary assessment. Metabolome profiling could be a method to detect adulteration in fruit processing industry. The maintenance of the authenticity of food products is essential for export business. The compliance of end-products of our food industry with the international standard may lead to economic gain for the overall agro-business sector. Targeted and untargeted metabolomics could be applied for qualitative classification of authentic and adulterated samples.

According to the European Commission (2009), the addition of non-sweet orange (*Citrus sinensis*) to sweet orange juice is not allowed in the European Union countries. Codex Alimentarius guidelines state that up to 10% *orange* (*Citrus reticulata*) juice may be permitted in *Citrus sinensis* juice (Codex Alimentarius Commission 1992), while the Food and Drug Administration (FDA) permits the addition of 10% *Citrus sinensis* to pasteurized and canned orange juice, and up to 5% of *Citrus aurantium* to frozen concentrated orange juice. In proper operation of fruit industries, the assessment of adulteration is an important parameter. In this context, a scientific study led by the Indian food processing sector deserves mentioning.

Kinnow mandarin (*Citrus nobilis* × *Citrus deliciosa*), Jaffa, Mosambi orange (*Citrus sinensis*), and red blush grapefruit (*Citrus paradisi*) were collected from the Indian Agriculture Research Institute (IARI) for assessment of the authenticity of randomly collected samples with the authentic collection. Untargeted methods of ultra-performance liquid chromatography-quadrupole-time of flight mass spectrometry were applied to identify characteristic markers that could potentially be used to control Citrus fruit authenticity. The most influential markers identified were: didymin, rhoifolin, isorhoifolin, neohesperidin, hesperidin, naringin, narirutin, limonin glucoside, and vicenin-2. A targeted liquid chromatography-tandem mass spectrometry method was then optimized for the application of the identified markers. Diverse ratios among the identified phyto-chemicals act as potential biomarker for the *Citrus* juice industry. The tested biomarkers were proved authentic, with a proven record of reduction in adultery down to 2%. The study prescribed an untargeted qualitative approach with Principal Component Analysis (PCA) as a validation method for possible discrimination between authentic and adulterated samples (Jandrić et al. 2017). These integrative omics studies could accelerate the growth of nutraceutical industry and authentic biomarking of the Citrus sub-foods. The peel and seed waste of Citrus could lead to the development of a new industry with a simultaneous reduction in the global load of agro-waste.

6 Citrus Genome Database

The draft genome sequences of some *Citrus* species were available in the genomic databases of the Citrus Annotation Project (CAP) 3 and Phytozome. The bulk data of reference genomes from Citrus re-sequencing projects were available for application in population genetics, including genome-wide association studies (GWAS), evolutionary studies, and comparative genomics (Table 4). The genomic variation assists in the discovery of key quantitative trait loci (QTLs), molecular genetic markers, and genes relevant to important traits and contributes to the understanding of the origin and evolutionary relationships in Citrus. CitGVD (http://citgvd.cric.cn/home), a comprehensive database of Citrus genomic variations that provides a publicly available and free data service for scientific studies includes large sets of data on genomic variations (SNPs and INDELs) compiled from two released reference genomes for *Citrus clementina* and *Citrus grandis*, including 84 phenotypes, gene functional annotations, and informative literature. CitGVD also provides in-depth analysis, including CitTRAIT for phenotypic data statistics, CitGWAS for GWASs based on built-in data, CitEVOL for genetic evolution analysis, PCR primer design, and Gbrowse for variations and genes (Li et al. 2020).

Another Citrus Genome Database, known as CGD, is a USDA and NSF-funded resource that enables basic, translational, and applied research in Citrus (Dorrie and Sook 2018). It houses genomics, genetics, and breeding data for *Citrus* species. It is an open-source, generic database constructed on Tripal platform. The Citrus genome database contains 10 species: *C. clementina*, *C. ichangensis*, *C. sinensis*, *C. reticulata*, *C. medica*, *C. Maxima*, *C. limon*, *C. trifoliate*, *Atalantia buxifolia*,

Fig. 3 Canopy structure of *Citrus reticulata* plant taken in the orchards of Darjeeling, West Bengal, India

Fortunella hindsii, and three species of *Ca. Liberibacter* (Fig. 3). It contains 366,169 genes and 649,803 mRNAs, 25 genome assemblies, 2255 germplasm, 85 maps, 60,407 markers, 16,971 phenotypic measurements, 75 trait descriptors, 6997 publications, and 673 QTLs for 153 agronomic traits. Seven tools are available such as BLAST, CitrusCyc, JBrowse, BIMS, Map Viewer, Synteny Viewer, and Expression Heatmap in the database for in-depth study of citrus genomes.

Another contemporary platform, CitSATdb (http://bioinfo.usu.edu/citSATdb/), mostly focuses on molecular markers mined from six *Citrus* species. The database is most useful for marker assisted selection and cisgenic improvement of Citrus. Recently, an updated genome information of *Citrus sinensis* (Wan et al. 2022) and 12 new sequenced genomes were integrated to provide an all-in-one database. The published Citrus genomes including Clementine, mandarin, pummelo, Mangshan wild mandarin, citron, Ichang papeda, kumquat, Trifoliate orange, and Chinese box orange were amalgamated to construct a more comprehensive database named the Citrus Pan-genome to Breeding Database (CPBD). CPBD presents large-scale datasets of Citrus transcriptomes, genome variations, and DNA methylomes as well as practical tools for Citrus breeding. In addition to omic data tool, some new datasets for CRISPR, KEGG/GO Enrichment, and GWAS are available in the CPBD platform (Liu et al. 2022b).

7 Nutraceutical Breeding for Designer Food Development in Citrus

In *Citrus*, several internal genetic complexities along with environment create hindrance in the improvement of different traits through breeding. The occurrence of heterozygosity, sexual reproduction, apomixis, polyploidy, juvenility, as well as recalcitrant seeds makes the breeding effort less productive. The majority of the Citrus plants are vegetatively propagated with preferential selection of the polyploid

types for larger fruit size with smooth rind. The traditional *Citrus* breeding mostly depended on selection of new cultivars from wild germplasm reserve and their domestication and cultivation. In *Citrus*, most of the agriculturally important traits are polygenic in nature, and conventional breeding has developed very few cultivars and rootstocks till date (Fig. 4). The scarcity of monogenic traits in *Citrus* is responsible for the lack of improvement of commercial traits. It has been noticed that a product of hybridization is only producing apomictic seeds, often diluting the effect of hybridization. Traditional breeding sometimes produces a hybrid with weak zygotic embryo as a result of inbreeding depression through mating of near-isogenic parents. The vast juvenile stage of the plants makes *Citrus* breeding a more time-intensive, resource draining, and land-occupying venture. In *Citrus*, conventional breeding were applied in dichotomous way for the improvement of both scions and rootstocks. In selected cases, the application of mutation breeding is noticed with gamma rays and other chemical mutagens.

In scion breeding, the new cultivars are developed through controlled crosses, and later the superior selections were grafted to compatible rootstocks. Natural hybridization, chance mutation, and Somaclonal variation have played major roles in cultivar development in *Citrus*. 'Satsuma' and 'Clementine' mandarins are outcomes of bud sport mutation. In grapefruit, a commercially acceptable cultivar, 'Star Ruby', was developed from 'Hudson' through irradiation. In Citrus, the long juvenile period was effectively utilized with a significant synergistic effect in the production of

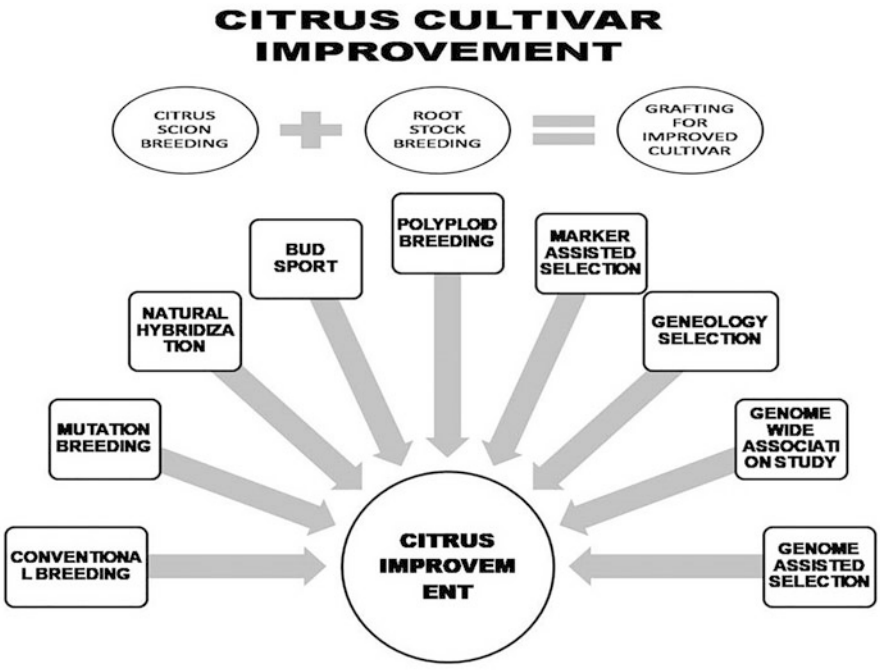

Fig. 4 Multiple breeding techniques employed for improvement of Citrus Industry

irradiated cultivars from growing scions. In sweet orange, lemon, and mandarin new varieties, 'Zhongyu No 7' (seedless), 'Kutdiken lemon' (resistant to *mal secco*), and 'Tango' (seedless) were developed respectively through the application of chemical mutagen in the juvenile stage of some scions. In scion breeding, there is a preference for monoembryonic species, inversely the rootstock propagation mostly depends on polyembryonic species, securing recovery of huge number of uniform plant-types. Root-stocks developed through inter-specific hybridization are found effective in disease resistance. Carrizo, Troyer Citranges, and Swingle Citrumelo were found to show resistance toward *Phytophthora* and nematode. Inter-specific hybrids between two species were found very effective for a third species. A hybrid between *Citrus reticulata* and *Poncirus trifoliata* was found exceptionally useful for *Citrus sinensis*. US-852, X639 are important representative of successful grafts involving three species. US early pride, UF Glow, Tango, Sugar belle, Roe tangerine, RBB7-34, Mandalate, Gold nugget, and Bingo, 950, 914 are commercially available varieties developed by the NVDMC, Citrus Research & Development Foundation (Gmitter et al. 2009). NRCC Mandarin Seedless-4, NRCC Acid Lime-7, NRCC Pummelo-5, NRCC Grapefruit-6, Cutter Valencia, Flame Grapefruit, US Pummelo-145, and Alemow were released by the Central Citrus Research Center, Nagpur, India, from the 552 indigenous and 62 core collections (Vi QRT Report-CCRI, 2018).

In agriculture, molecular marker-assisted breeding plays an effective role in improvement of crop quality and productivity. The mainstream agriculture has provided food security to the majority of global population. In the present era, a metabolomics-driven breeding could pave a way for the development of customized designer Citrus using system biology tools. The cross-talk among different biochemical pathways could produce varied nutrient elements. Application of several stress situations alters the production of nutrients in plants utilizing the same pathway. The previous discussion illuminated the differential role of multiple putative genes and transcription factors in the production of the consumer-friendly end products. Though nutraceutical breeding is an emerging technique, but few examples are available that exhibit equivalence to this futuristic breeding approach.

A study conducted on the influence of the rootstock in the production of bioactive compounds in the peels of a Mediterranean *Citrus* tree showed significant variation in the deposition of secondary compounds with respect to rootstock germplasm. Different rootstocks (Cleopatra mandarin and Troyer citrange) influenced the variable deposition of hesperidin and narirutin flavonoids. Flavanone glycosides, β-cryptoxanthin and violaxanthin, and limonene were the most abundant flavonoid, carotenoid, and limonoid identified in the peel essential oil of the grafted plants. The distinct difference in the content of bioactive compounds for the different groups of *Citrus* was in agreement with the taxonomic distinction of the rootstocks. The research highlighted that both mandarin and other hybrid orange varieties showed influence of the rootstocks in the deposition of a sizable amount of bioactive constituents, but the quantitative accumulation of individual nutrients were determined by the scion. This study concluded that different breeding programs with new rootstocks could yield conclusive outcomes for enhancement and production of desired nutraceutical according to the needs of the industry (Cano and Bermejo 2011).

In another study, examining the influence of *Citrus* rootstocks (Carrizo citrange, C-35 citrange, and F-5) in bioactive compound production on Clementine scion revealed a complex interaction between the rootstock in critical production of bioactive compounds. The species reflects a particular flavanone glycoside pattern. Six flavonoids are detected in clementines cv. 'Clemenrubí' and 'Orogrós'. The interaction between Orogrós cv and FA-5 rootstock presented the highest amounts of Api-6,8-di-C-glc, Nar-7-O-rut, and Hes-7-O-r flavonoids. Scion variety C-35 with citrange rootstock produced the heaviest and larger fruits, while the rootstock FA-5 produced the final reap with the major flavonoid content. This interesting study presents a special provision of integration of several desired agronomic and bio-chemical traits in a single plant by customized grafting techniques (Legua et al. 2017).

The genealogy research in Citrus has proven very successful in the identification of suitable breeding parents. In a study involving tropical Citrus plants, some germplasm were identified as a potential reservoir of bioactive compounds (Fig. 5). *Citrus maxima*, *Citrus grandis* L. (Pomelo), *Citrus paradisi* Macfad (Grapefruit), *Citrus sinensis* (Orange), *Citrus macroptera* (Wild Orange), *Citrus reticulata* (Mandarin), *Citrus limon* (Lemon), and *Citrus medica* L. (Citron) exhibit a varied morpho-metabolomic profile. Additionally, analysis of *Melicoccus bijugatus* Jacq. (Spanish Lime) fruit peels presented pharmacological potential and novel therapeutic proficiency. The research recommended the natural cultivation of the non-commercial Citrus for foodomics and sustainable agroforestry (Chel-Guerrero et al. 2022).

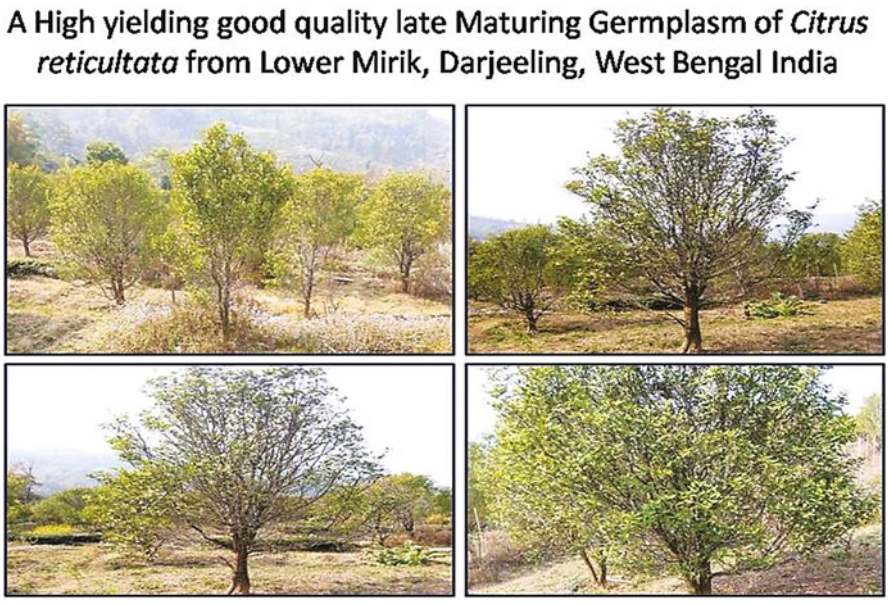

Fig. 5 Late maturing type Mandarin of Lower Mirik region of Darjeeling, West Bengal, India

The wild and endemic Citrus found in different parts of the globe may contribute toward the improvement of Citrus nutraceutical research. The gas chromatography–olfactometry (GC-O) analysis of volatiles of a wild mandarin, Mangshanyegan (*Citrus nobilis* Lauriro), and subsequent comparison with volatile profile of four *Citrus* species, Kaopan pummelo (*Citrus grandis*), Eureka lemon (*Citrus limon*), Huangyanbendizao tangerine (*Citrus reticulata*), and Seike navel orange (*Citrus sinensis*) exhibits significant distinctions. Monoterpene hydrocarbons d-limonene (85.75%) and β-myrcene (10.89%) pre-dominated the total volatile fraction. The flavor dilution factors (FD) detected eight oxygenated compounds, including (Z)- and (E)-linalool oxides specific to Mangshanyegan. The combined results of GC-O, quantitative analysis, odor activity values (OAVs), and omission tests confirms the balsamic and floral aroma of Mangshanyegan is controlled by β-myrcene and (Z)- and (E)-linalool oxides (Liu et al. 2012). These results are in consistence with the prospect of Citrus waste in the aroma and flavor industry.

A striking discovery of a new wild Citrus species native to the Ryukyu island increases the prospect of nutraceutical research in Citrus. This new species collection with eight wild Okinawan accessions forms a separate cluster, disowning their association with all previously sequenced species of Citrus. The accessions include 'tanibuta' type Citrus that is genetically distinct from tachibana and shiikuwasha described by Tanaka. Among their differences, *C. ryukyuensis* is a sexual species that produces monoembryonic seeds, while tachibana and shiikuwasha, both produces polyembryonic (apomictic) seeds. The identification of *C. ryukyuensis* as a pure species (a distinct sexually reproducing population without admixture) with low genome-wide heterozygosity (0.2–0.3%) with zygotic (sexual) reproduction forms a promising separate accession suitable as a breeding parent (Wu et al. 2021).

In a very recent study conducted in Manipur, India, confirms the origin of *Citrus indica* in the Indo-Burma border region. A wild orange morphologically resembling *C. indica* was characterized using morpho-taxonomic identifiers of Citrus. Additionally, plant barcoding using three chloroplast regions (trnL-F, psbK-I, matK-5′trnK spacer) and one nuclear (ITS) region established the identity of the Manipuri wild Citrus species as *Citrus indica*. The Dailong Village of Manipur, inhabited by the Rongmei tribes, were associated with the natural conservation and maintenance of wild Citrus known as 'Garuan-thai'. *C. indica* is known for its poor regeneration and less adaptability to new habitats. A distinct hilly microclimate is essential for its survival and existence (Fig. 6). The identification of 'Garuan-thai' in North Eastern India unveils the prospect of discovering potent genotypes for nutraceutical exploitation (Devi et al. 2022).

In recent years, several attractive breeding strategies were applied for improvement of Citrus orchard and fruit production strategies. Normally, Citrus seedlings go through a very long juvenile phase (about 3–20 years), which hinders the breeding and improvement of Citrus. Research on minimizing the juvenile phase and promotion of early flowering in Citrus was done by adoption of a transgenic breeding method. APETALA1 (*AP1*) and LEAFY (*LFY*) genes were introduced into citrange (*P. trifoliata* L. Raf. × hybrid of *C. sinensis* L. Osbeck) from Arabidopsis. Transgenic citrange plants over-expressing the *AP1* and *LFY* genes flowered early and

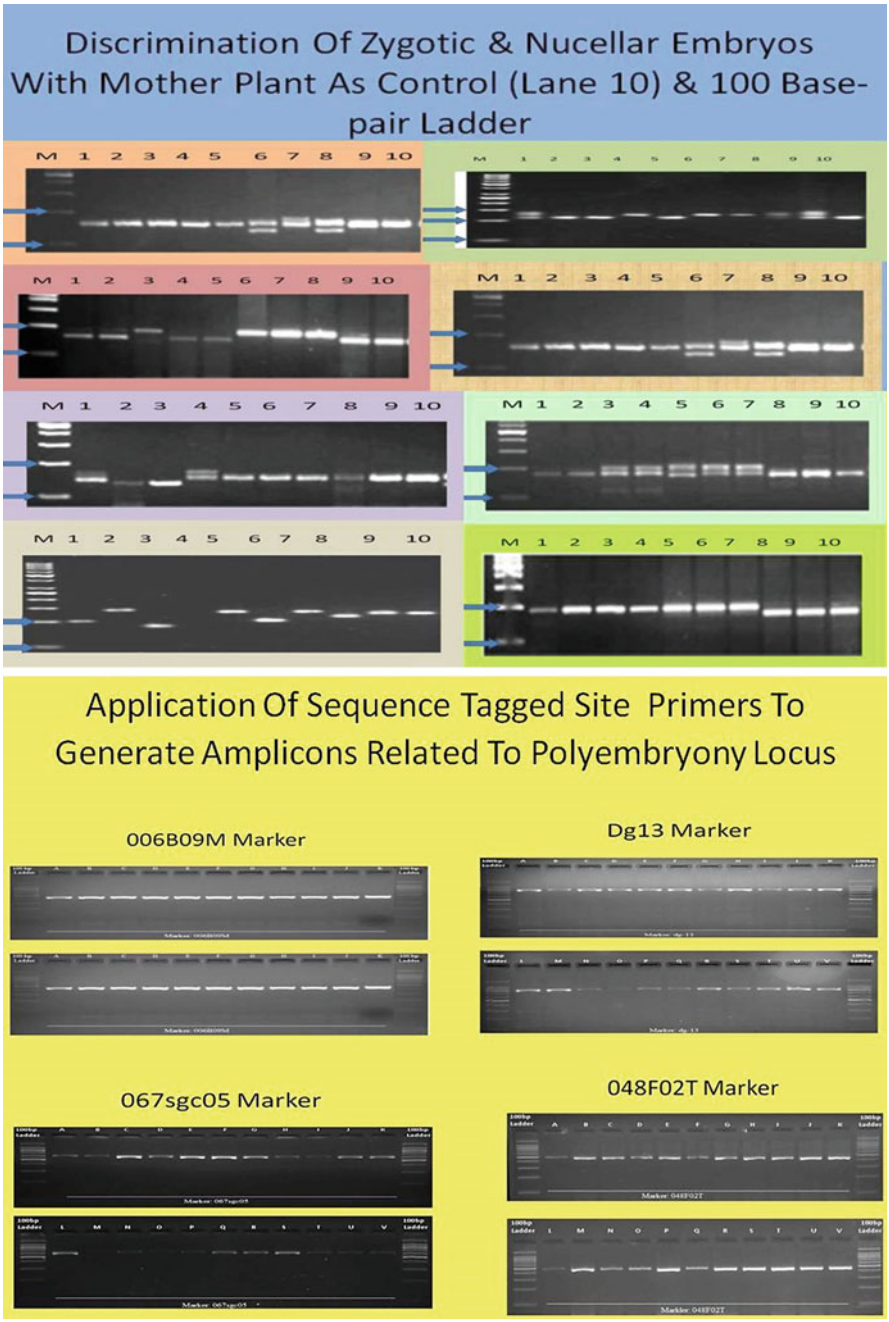

Fig. 6 Molecular Profile of some elite clones of mandarin (*Citrus reticulata*) orange collected from North Eastern Himalayan Region of Indian Subcontinent

produced fertile and normal flowers (Pillitteri et al. 2004). Fruits were obtained from first-year transgenic plants that were only 2–20 months old and bore their first flowers, significantly reducing the juvenile phase to less than 5 years in transgenic citrange compared with control plants (Peña et al. 2001). Zygotic seedlings obtained by crossing *AP1* and *LFY*-transgenic citrange also showed early flowering with normal fruit setting in the first spring, validating provisions for novel research (Rao et al. 2021). The *Citrus* genetic resource in conjecture with model and non-model plants could produce unique nutraceutical cultivar in *Citrus*. The gene co-suppression, feedback inhibition regulates metabolic inheritance in *Citrus* and transcriptomic tool could encourage anabolic biosynthesis of desired components.

In new generation *Citrus* breeding, a novel approach of genomic-assisted breeding (GAB) plays an important role. This GAB method could solve the main three constraints of Citrus improvement, meeting the commercial demand, disease resistance, and fast breeding. The GAB technique is an integration of genome wide association studies (GWAS), and genome selection (GS) is expected to increase the prediction accuracy of conventional MAS. In this method, the parents of multiple Citrus cultivars mainly natural hybrids will be confirmed. The genomic pedigree will be beneficial for selection of some unfamiliar cultivar for hybridization to assimilate novel traits in hybrid by reduction in unwanted traits. A research conducted by NARO released the current cultivars 'Aurastar', Nou No. 7, 'Nou No. 8', second-generation Trifoliate orange from a cross of 'TF Flying Dragon' and a local cultivar 'Hassaku', followed by subsequent crossing with 'Kiyomi', for transfer of Citrus tristeza resistance trait from the Banpeiyu pummelo genotype (Goto et al. 2018). The genealogy study of the cultivars is a productive approach that could accelerate the breeding pace. Several Japanese cultivars Satsuma, Hassaku, Sudachi, and Kabosu having unique traits were selected within a single cross. Elite hybrids were selected from the crossing of 'Kaikoukan' and 'tachibana' within a single generation. Screening of thousands and tens of thousands of offspring combining GAB techniques was assumed to be the new savior of dwindling orchards and the Citrus industry (Shimizu 2022).

8 Conclusion

In current times, the global nutrition sector is facing a dichotomous constraint: one is the nutritional deficit and malnutrition, and the other is anomalous nutrition associated with luxuriance in food habits. The malnutrition of children due to lack of healthy diet in developing and some developed nations is recognized as a global problem, the other condition of anomalous nutrition promotes obesity, diabetes, and coronary heart diseases in developed countries with abundance availability of high-calorie food. The imbalance in nutritional requirement could be compensated by the intake of functional foods. In tropical and subtropical countries, the fruits and vegetables are loaded with diverse nutraceuticals. A vast majority of economically

backward countries are blessed with rich biodiversity reserves. This rich plant gene-pool is a robust weapon for the countries to alleviate poverty by creation of domestic and global agri-business. In real life, these germplasm biomass produces a sizable agro-waste that becomes a concern for the under-privileged nations. Through an intelligent approach, these agro-wastes could be utilized in alleviation of nutritional inconsistencies. Citrus is one of the prominent fruit crop with immense potential to be included as raw material in the emerging nutraceutical sector. This fruit crop has a long history of cultivation and has conserved a vast wild gene reserve in tropical and sub-tropical regions of the world. The appropriate utilization of the omic tool could lead to metabolic flux of the nutritive and pharmaceutically valuable plant bio-actives. Genotype-driven measurable phenotypic changes with consequent understanding of the biochemical mechanism and pathway dynamics may assist in food-omics research. The cutting-edge technologies of new omic era could increase the metabolite heritability, leading to development of designer Citrus cultivar. Omic-guided novel designer citrus may accelerate the pace of emerging nutraceutical industry and ensure intelligent agro-waste management.

Watermelon: Advances in Genetics of Fruit Qualitative Traits

Sudip Kumar Dutta, Padma Nimmakayala, and Umesh K. Reddy

Contents

Abstract

Watermelon (*Citrullus lanatus*) belongs to the family Cucurbitaceae. The crop is grown commercially in regions with extended warm, frost-free months. Watermelon is cultivated for its colorful, tender, juicy, and sweet fruit. They are generally consumed fresh and make an excellent and delicious dessert, particularly during the summer months. Because of its smaller genome and large number of gene mutations, watermelon is a suitable crop species for genetic research. Watermelon's genome has 424 million base pairs. DNA sequencing found significant conservation, which is relevant for comparative genomics within Cucurbitaceae and other species.

There exists a huge genetic variability in the fruit quality characteristics of watermelon with respect to seed traits, fruit shape, fruit size, skin color, skin pattern, flesh color and sugar/acid composition, fruit bitterness, and many more. This chapter serves as a guide to show the prospects and advances made in the genetics of fruit qualitative traits in watermelon breeding programs depending on profitability and consumer preferences.

Keywords

Watermelon · Fruit · Genomics · Quality · Flesh color · Rind pattern

1 Introduction

Watermelon (*Citrullus lanatus* [Thunb.] Matsum. and Nakai var. *lanatus*; 2n = 2x = 22) belonging to the family Cucurbitaceae is primarily cultivated for its fresh and nutritious fruit. *Citrullus lanatus* var. *citroide*s, *C. naudinianus, C. mucosospermus*, *C. rehmii*, *C. ecirrhosus*, and *C. colocynthis* are the species of the genus *Citrullus* (Chomicki and Renner 2015). Most *Citrullus* species have their origins and genetic diversity in continental Africa (Dane and Lang 2004). One theory claims that it came from a species of *Citrullus lanatus* that is a common wild plant in central Africa, while another believes that it was domesticated from the perennial *Citrullus colocynthis* that is a common plant in ancient sites. Watermelons have been grown in Africa for over 4000 years. Watermelons were commonly planted in the Nile valley region prior to 2000 BCE, according to seeds and plant pieces found in Egyptian tombs. They were transported from Africa to India in the year 800 CE and to China in the year 900 CE, after which they expanded to other continents in the year 1500s. Annual watermelon plants have lobed leaves, long, angular vines that trail, branching tendrils, and solitary male and female flowers. Watermelon of various shapes like round, oval, or elongated can weigh anywhere between 1.5 kg and 15 kg. The rind varies in color from light to dark green and has different striped patterns. Despite the fact that the flesh may be white, green, yellow, orange, or red, customers favor inner qualities like sweetness and texture and colors like deep red, pink, or dazzling yellow. Fruit types and cultivars differ widely in size and form, and the outside skin is smooth, sutured, or netted, with a white, green, or yellow tone. Normal colors for the flesh (mesocarp) are green or orange; however, pink and white are also found. Fig. 1 is a panel displaying the variety in morphology of watermelon fruits. A small genetic background of sweet watermelon has resulted from modern breeding practices that have mostly focused on fruit quality characteristics including sugar content, flesh color, and rind pattern (Levi et al. 2017). It is uncertain how phenotypic alterations brought about by human and natural choices affected the watermelon genome. For the creation and marketing of new products, sweet watermelon fruit characteristics are essential. The pharmaceutical industry, the processing industry, and the fresh market will all profit from the novel and value-added genotypes. Pickles, jam, fruit puree, popsicles, and watermelon juice are a few examples of items with added value that are made from recently created cultivars with superior qualities. The new cultivars ought to have a range of bioactive

Fig. 1 A panel showing watermelon fruit morphological diversity

substances that are both nutritive and therapeutic in nature (Mashilo et al. 2022). A viable and alternate method for hastening the creation and release of watermelon varieties with sufficient agronomic and quality traits to meet the crop's value chains is nonconventional breeding using gene-editing technology. For instance, changing watermelon genes associated with agronomic traits using clustered regularly interspaced short palindromic repeats (CRISPR/Cas9) allowed the development of novel cultivars (Wang et al. 2021). The development of superior cultivars with higher nutritional contents, market-preferred traits, and a longer shelf life will be aided by the information on the genetic control of fruit qualities in watermelons that will be possible by gene-editing and related technologies. The goal of this chapter is to illustrate the prospects and developments made in the genetic study of fruit quality characteristics in watermelon as a guide for quality breeding based on economic and end-user qualities, taking into account the aforementioned context.

2 Organic Acids and Sugar

Sugars and organic acids have a substantial influence on organoleptic fruit quality and are key components in fruit flavor development. Contrary to staple food crops, where production is the ultimate breeding goal, watermelon places greater emphasis on flavor

and aroma, both of which are influenced by the metabolite composition of the fruit. During development, watermelon fruits go through a variety of biochemical changes, including as adjustments to sugar metabolism, an increase in organic acid and color, fruit softening, flavor, and volatile aromatic compounds (Zhu et al. 2017). In one study, researchers examined the coexpression patterns of gene networks linked to sugar and organic acid metabolism using transcriptome profiles. They found three gene networks or modules comprising 2443 genes that were substantially associated with organic acids and carbohydrates. Seven more genes involved in the metabolism of organic acids and carbohydrates were found. *SWEET*, *EDR6*, and *STP* were recognized as sugar transporters (*Cla97C01G000640*, *Cla97C05G087120*, and *Cla97C01G018840*, r 2 = 0.83 with glucose content), while *Cla97C03G064990* (*Cla97C03G064990*, r 2 = 0.92 with sucrose concentration) was identified as a sucrose synthase. *Cla97C07G128420*, *Cla97C03G068240*, and *Cla97C01G008870* were identified as malate and citrate transporters, respectively, since they displayed strong associations with malic acid (r 2 = 0.75) and citric acid (r 2 = 0.85) (ALMT7, CS, and ICDH) (Umer et al. 2020a). The two enzymes that regulate sugar metabolism in watermelon most crucially are sucrose synthase and sucrose phosphate synthase (Guo et al. 2015). The expression of gene clusters involved in sugar biosynthesis, including a-galactosidase, invertase, and urease diphosphate (*UDP*)-galactose/glucose pyrophosphorylase (*UDP-Gal/Glc PPase*), rises as the watermelon fruit ripens. The *Cla013902* gene reportedly affects how sugar is metabolized in watermelons (Guo et al. 2015). There are nine a-galactosidase genes in the watermelon genome. The nine genes are reportedly involved in the hydrolysis of stachyose and raffinose, according to studies (Guo et al. 2013). Additionally, the buildup of sugar in watermelon is influenced by five genes for insoluble acid invertase (*IAI*) (Guo et al. 2015). The watermelon fruit's extracellular sucrose degeneration, which permits fructose and glucose transfer and intercellular sugar accumulation, is linked to the IAI gene *Cla020872* (Guo et al. 2015). Recent research has identified *ClAGA2*, an alkaline a-galactosidase gene expressed in the vascular bundle, as a critical regulator of the hydrolysis of stachyose and raffinose in watermelon. *ClAGA2* controls fruit raffinose hydrolysis and reduces the amount of sugar in fully grown watermelon fruits (Ren et al. 2021). Tonoplast sugar transporter (*ClTST2*) and sugar transporter 3 (*ClSWEET3*) genes control sugar storage and transfer in watermelon fruit cell vacuoles (Ren et al. 2021). Several important genes involved in sugar production and translocation that are up- or downregulated throughout developmental processes have been found by several researches. Differentially expressed genes such NAD-dependent malate dehydrogenase (*NAD-cyt MDH*), aluminum-activated malate transporter (*ALMT*), and citrate synthase (*CS*) affect the accumulation of organic acids in watermelon (Gao et al. 2018). The reversible conversion of malate to oxaloacetate is catalyzed by the NAD-dependent malate dehydrogenase (*NAD-cyt MDH*) gene (*OAA*) (Yao et al. 2011), whereas citrate synthase (*CS*) gene controls citric acid production. Malate dehydrogenase genes and aluminum-triggered malate transporters control the regulation and breakdown of malates (Umer et al. 2020a). It is believed that the genes for citrate synthase (*Cla97C03G068240*) and isocitrate dehydrogenase (*Cla97C01G008870*) are involved in the generation and breakdown, respectively, of citric acid (Umer et al. 2020b). Malic and citric acid accumulation are linked to higher

expression of the genes for malate dehydrogenases (*Cla008235* and *Cla011268*) and citrate synthases (*Cla013500*) (Gao et al. 2018). From the sweet and sweet-and-sour genotypes, *Cla97C01G000640* (*SWEET*), *Cla97C05G087120* (*EDR6*), and *Cla97C01G018840* were shown to control glucose biosynthesis, whereas *Cla97C03G064990* controls sucrose production in watermelon (Umer et al. 2020b). *ClVST1*, a gene for a vacuolar sugar transporter, was shown to be highly expressed during the ripening of watermelon fruit and was connected to the accumulation of sucrose (Ren et al. 2021).

3 Amino Acid Compositions

The amino acid citrulline is the most abundant in ripe watermelon fruit (Joshi et al. 2019). Citrulline is a nonessential amino acid which is generated throughout the urea cycle as a metabolic intermediate (Bahri et al. 2013). This amino acid serves as a precursor to arginine, another essential amino acid contained in watermelon fruit (Joshi et al. 2019). Watermelon has many genes that are involved in citrulline metabolism. Citrulline biosynthesis in watermelon is associated with ornithine carbamoyltransferase (*OTC; ClCG05G018820*), N-acetylornithine aminotransferase (*N-AOA*; *ClCG09G003180*), N-acetylornithine-glutamate acetyltransferase (*N-AOGA*), *CPS*-1 (*ClCG11G013120*) and *CPS-2* (*ClCG09G021680*), N-acetylornithine deacetylase (*AOD-1*), N-acetylornithine deacetylase (*AOD-3*), and nitric-oxide synthase gene (*ClCG01G004960*) (Joshi et al. 2019). Citrulline catabolism is also connected to ASS, 1,2,3-argininosuccinate synthase; *ASL*, *1,2-argininosuccinate lyase*; *ARG*, *arginase*; *ODC*, *ornithine decarboxylase*; and *ADC*, *arginine decarboxylase* (Joshi et al. 2019). Citrulline biosynthesis is mediated by the genes *argininosuccinate lyase*, *N-acetylglutamate kinase*, and *ornithine decarboxylase*, whereas arginine biosynthesis and accumulation is mediated by the genes *ornithine carbamoyltransferase* (Fall et al. 2019).

4 Fruit Bitterness

Watermelons in the wild create bitter cucurbitacin molecules, a kind of highly oxygenated tetracyclic triterpene that repels pests. Cucurbitacin B (CuB), cucurbitacin C (CuC), cucurbitacin E (CuE), and cucurbitacin E-2-O-glucoside are all found in *Citrullus* fruits, leaves, roots, and stems (CuE-Glu) (Kim et al. 2018). The principal bitter ingredient in *Citrullus* fruit is CuE, commonly known as elaterinide (Matsuo et al. 1999). Despite the fact that these protective chemicals evolved in plants millions of years ago, humans have bred them to make them more appealing to our taste buds. In domesticated varieties of watermelon, a single point mutation in a transcription factor results in a faulty protein and diminished bitter compounds (Everts 2016). The genetic basis of two watermelon fruit traits were studied in a backcross generation arising from the hybridization of an interspecific F, hybrid of *Citrullus lanatus* and *C. colocynthis* with the domesticated parent *Citrullus*

lanatus. Bitterness of the fruit, which distinguishes wild *C. colocynthis*, was revealed to be governed by a single dominant gene (*Bi*) that was linked to the isozyme marker *Pgm-1* at a distance of 11.3 cm (Navot et al. 1990). In one study, it was shown that *Cla011508* (located on chromosome 1) regulates the bitterness of watermelon fruit, and the crucial mutation locus in this gene provided molecular insights for marker-assisted breeding of target characteristic (Gong et al. 2022). The dominant *Bi* gene regulates cucurbitacin production, which is responsible for bitterness in *Citrullus* fruits, whereas the recessive su (bitterness suppressor) gene regulates the presence or absence of bitterness in watermelon fruit. The *Bi* gene has been identified as an oxidosqualene cyclase (*OSC; Cla007080*) gene on watermelon chromosome 6 (Chambliss et al. 1968; Robinson et al. 1976; Navot et al. 1990; Lu et al. 2016). Furthermore, one watermelon fruit bitterness gene on chromosome 1 was found; the significant locus with the highest LOD score (58.361) was designated *qbt-c1-1*, and it explained 82.927% of phenotypic variation with a negative additive effect of −0.465 (Li et al. 2018). Watermelon breeders looking to improve their carotenoid profiles should hunt for progenies with genes that condition the carotenoid synthesis pathway.

5 Fruit Shape and Size

Fruit form and size are important horticultural sector traits that exhibit a large range of phenotypic variation, emphasizing their importance in breeding programs. The shape of watermelon fruits was assumed to be controlled by an incompletely dominant gene, resulting in elongate (OO), oval (Oo), and spherical (oo) fruits (Guner and Wehner 2004). It was also shown that a single gene regulates both spherical (Os) and oval (O+) watermelon fruits, exhibiting partial dominance when a spherical fruit inbred line crosses with an oval fruit inbred line (Tanaka et al. 1995). The similar pattern of inheritance was seen in F2 populations of 'Peerless', 'Baby Delight', 'Northern Sweet', and 'Dove' (Poole and Grimball 1945). For the dominant elongate fruit, allele *ObE* was proposed; for the recessive oblong fruit, allele *Ob*; and for the round fruit, allele *ObR* (not the same as the o gene for round) (Lou and Wehner 2016). Segregation analysis in F2 and BC1 populations derived from a cross between two inbred lines 'Duan125' (elongate fruit) and 'Zhengzhouzigua' (spherical fruit) revealed that watermelon fruit shape is controlled by a single locus and that elongate fruit (OO) is only partially dominant to spherical fruit (oo), with the heterozygote (Oo) being oval fruit and a 159 bp deletion (Dou et al. 2018). The *SUN* gene, a member of the IQ domain (*IQD*) family, has long been recognized to influence tomato fruit elongation early in fruit development, following pollination and fertilization (Van Der Knaap and Tanksley 2001). Several QTLs linked with FD (and fruit weight) and FL (fruit length) have been found in diverse genetic backgrounds; however, the genes underlying these QTLs remain unknown.

6 Flesh Color

There are many different fruit flesh colors in watermelons (Fig. 1); fruit flesh color is a key feature that influences nutritional value, customer choice, and breeder selection. The composition of chlorophyll and carotenoids in the flesh determines its color. Watermelon flesh colors have been classified as scarlet red, red, pink, orange, canary yellow, pale yellow, and white based on carotenoid levels. Watermelons with red flesh (including flaming red and pink) are high in lycopene (Sun et al. 2018). Prolycopene and carotene concentrations are considerably higher in watermelons with orange flesh (Branham et al. 2017). Watermelons with yellow flesh (canary yellow and light yellow) contain a high concentration of neoxanthin, followed by neochrome and violaxanthin (Fang et al. 2020). Watermelons with white flesh have very little violaxanthin and lutein in them (Lv et al. 2015). The idea of genetic variability in the color of watermelon fruit flesh is supported by the existence of separate mechanisms regulating carotenoid metabolism. Understanding the process of carotenoid inheritance enables for the development of cultivars with improved phytochemical component compositions. The genetics of skin color are extremely complex, with numerous genes and quantitative trait loci (QTLs) influencing carotenoid production. Genes involved in the carotenoid biosynthesis and metabolism pathway's genome-wide comparative expression study showed complex gene expression and regulatory networks that led to the accumulation of different carotenoids in watermelon fruit (Fang et al. 2020; Mashilo et al. 2022). Based on genotyping data, two Kompetitive Allele-Specific PCR (KASP) markers were created for the candidate gene *Cla97C10G185970*, which was annotated as plastid lipid-associated protein and showed a strong connection between pale green and non-pale green meat fruits (Pei et al. 2021). During fruit ripening, the carotenoid profiles of four watermelon cultivars – red-fleshed 'CN66', pink-fleshed 'CN62', yellow-fleshed 'ZXG381', and white-fleshed 'ZXG507' – were examined. It was revealed that the amounts of violaxanthin and lutein in yellow fruit were positively correlated with *CHYB* and *ZEP* transcription levels (Lv et al. 2015). *ClPAPs, Cla006670, Cla010946*, *Cla008831, Cla014416, Cla021506, Cla003468*, and *Cla003198* are plastid lipid-associated genes that are thought to be involved in the development of plastoglobules and globular and crystalloid chromoplasts (Fang et al. 2020).

7 Rind Pattern

The most common rind (or skin) colors in watermelon are solid green (dark, medium, and light), striped (narrow, medium, and large dark green stripes on a light green background), and grey. Gray is also written grey, although the names of watermelons have been standardized to the grey spelling. The expression of genes responsible for rind color and pattern does not appear to be uniform across different

genetic backgrounds. Furthermore, the inheritance of gray or medium green rind colors has not been recorded, despite the fact that they have been two of the most prevalent rind colors in watermelon breeding during the previous century. ClCG08G017810 (ClCGMenG), a protein encoding a 2-phytyl-1,4-beta-naphthoquinone methyltransferase, is linked to the production of dark green rind vs light green rind in watermelon (Li et al. 2018). For the '0901', '10909', '109905', and '90509' rind trait-segregating F2 populations, genotyping analyses were done using subsets of 188, 273, 287, and 113 probes, respectively. For the '0901', '10909', '109905', and '90509' populations, 26, 34, 30, and 15 linkage groups containing 175, 254, 269, and 79 probes were created, respectively. The genetic order of the probes is mainly collinear with the physical order on the reference genome, with a few exceptions on chromosomes 1, 3, and 11. S, D, and Dgo, together with chr4 150/chr4 249 on chromosome 4 and chr6 25767 on chromosome 6, were identified nearby (Park et al. 2016). As a consequence of genetic investigations, a team of researchers found three unique genes in watermelon. In comparison to Angeleno Black Seeded, the type line for the hue of watermelon red flesh, scarlet red flesh (*Scr*) gave more vivid red color in Dixielee and Red-N-Sweet. They suggest calling the original red skin color coral red in order to distinguish it from scarlet red. As a single dominant gene, *Scr* is inherited. A single dominant gene called *Yellow Belly* (*Yb*) was identified as the cause of Black Diamond's ground spot's transition from creamy white to dark yellow. A single recessive gene called intermittent stripes (*ins*), with the dominant allele, was found to be responsible for the difference between continuous and intermittent stripes on the rind of Navajo Sweet (Gusmini and Wehner 2006).

8 Flesh Firmness

The firmness of the flesh determines the texture and quality of watermelon fruit. Multigenes control flesh firmness as a qualitative attribute. For watermelon genetic breeding, it is crucial to identify the regulatory elements that most significantly affect the firmness of the fruit's flesh. According to localization interval transcriptome analysis, *Cla012507* (MADS-box transcription factor) may be involved in the control of fruit ripening and affect the hardness of watermelon fruit. *Cla016033* (*DUF579* family member), which may impact the cell wall component contents to alter the flesh firmness in watermelon fruit, was distinct in W1-1 and PI186490 (Sun et al. 2020). The hardness of watermelon flesh is controlled by phytohormone levels, particularly ABA (Wang et al. 2017). *Cla009779* (*NCED*), *Cla005404* (*NCED*), *Cla020673* (*CYP707A*), *Cla006655* (*UGT*), and *Cla020180* (*SnRK2*) are implicated in ABA biosynthesis in watermelon (Wang et al. 2017). *Cla009779*, *Cla005404*, and *Cla005457* were the most effective at increasing ABA accumulation. On chromosome 6 of the watermelon genome here is a significant QTL (*Qffi6.1*) for flesh firmness from *C. amarus* (Gao et al. 2016). The putative candidate gene for *Qffi6.1* is *Cla018816*, a xyloglucan endotransglucosylase/hydrolase (*XTH*) gene that is variably expressed across firm- and soft-bodied near-isogenic lines (Anees et al. 2021). Another *XTH* gene

(*Cla006648*), cellulose synthase (*Cla012351*), galactosyltransferase (*Cla006648*), pectinesterase gene (*Cla004251*), ethylene response element transcription factor 1 (*Cla004120*), and ethylene response element transcription factor 2a (*Cla007092*) all played important roles in watermelon flesh firmness, according to transcriptome analysis (Anees et al. 2021).

9 Rind Thickness and Toughness

Watermelon fruit rind breaking not only facilitates disease invasion and reduces yield, but it also degrades the fruit's exterior aesthetic value. One of the simplest methods for gauging consumer acceptance during commercial purchases is the rind of a watermelon. After crossing 97103 and PI296341, a biparental F2 population was produced. Using RAPD and SSR markers, QTL analysis showed that there were a total of two rind thickness QTLs and three fruit weight QTLs (Fan et al. 2000). Additionally, a watermelon backcross (BC) generation was developed for measuring rind hardness, and a QTL location controlling rind hardness was found on chromosome 4 (Hashizume et al. 2003). Watermelon rind hardness is correlated with the ethylene *clerf4* transcription factor genes, according to the genotyping of 349-F2 individuals from 32 germplasm. The genotyping indicated a significant ascending allelic pattern of aa (hard) bb (soft) and substantial QTL region on chromosome 10 (Liao et al. 2020). Another recent study combined the hard-fleshed and soft-fleshed watermelon lines 'PI186490' and 'W1–1', and preliminary mapping in 175-F2 individuals identified the key genes on chromosomes 2 and 8 controlling central flesh hardness using BSAseq and CAPS marker-based QTL analysis (Sun et al. 2020). Using a combinatory genomic map and bulk segregant analysis, it was possible to link variations in rind hardness to the ethylene-responsive transcription factor 4 (*ClERF4*) (*BSA*). The *ClERF4* gene on chromosome 10 also has an 11-bp InDel and a neighboring SNP, which confers cracking resistance in F2 populations with different rind hardness (Liao et al. 2020). A transcriptome study demonstrated the molecular pathways involved in the enhancement of fruit attributes including greater rind toughness by watermelon and bottle gourd grafting (Garcia-Lozano et al. 2019).

10 Ethylene and Ripening in Watermelon

A microarray and quantitative real-time PCR-based investigation was conducted to better understand the sequence of events linked to fruit growth and ripening in watermelon (*Citrullus lanatus* [Thunb.] Matsum. and Nakai var. lanatus). This study found several of the ESTs with potential roles in the growth and ripening of watermelon fruits, particularly those involving the vascular system and ethylene (Wechter et al. 2008). The researchers noted differential expression of homologs of genes involved in ethylene biosynthesis (*ACC* oxidase) and signal transduction (ethylene receptor *Cm-ETR1*, ethylene insensitive [*EIN3/EIL*]-like transcription factor, ethylene-responsive binding protein [*EREBP*], and ethylene response factor [*ERF*]) in the same

study. Fruit rind plays a major role in reducing moisture loss and disease, as well as cracking resistance, ease of transport, and storage stability quality of watermelon; an ethylene-responsive transcription factor 4 (*ClERF4*) linked with variation in rind hardness was discovered using a combinatory genetic map and bulk segregant analysis (BSA) (Liao et al. 2020). The ethylene biosynthesis and signaling pathway genes, such as ACC oxidase, ethylene receptor, and ethylene-responsive factor, showed highly ripening-associated expression patterns in the watermelon, a non-climacteric fruit, according to a comparative transcriptome profiling analysis of the cultivated watermelon 97103 and wild watermelon PI296341-FR. This suggests that ethylene may play a role in the development and ripening of the fruit (Guo et al. 2015). *XTH* gene (Cla006648), cellulose synthase (*Cla012351*), galactosyltransferase (*Cla006648*), pectinesterase gene (*Cla004251*), ethylene response element transcription factor 1 (*Cla004120*), and ethylene response element transcription factor 2a (*Cla007092*) all played important roles in watermelon flesh firmness, according to transcriptome analysis (Anees et al. 2021).

11 Conclusion

Watermelon fruit qualitative characters like seed color, seed size, fruit shape, skin color, rind pattern, flesh color and sugar/acid composition, fruit bitterness, and many more exhibit significant genetic diversity. With the advancement of genomics and availability of watermelon genome sequences, it has become possible to identify genes critical to valuable fruit quality traits. As the knowledge of the molecular mechanisms behind these characteristics improves, more effective and focused selection will enhance the efficiency of breeding of this important crop.

Abstract

Grapevine is considered the most important fruit crop cultivated in temperate regions and is acknowledged as a model species for non-climacteric fleshy fruits. From a nutritional perspective, grapes are fruits with a high content of carbohydrates, a good nutritional source of minerals and vitamins, and most importantly, they are one of the richest fruits in polyphenols and other compounds with antioxidant properties. In particular, this chapter focuses on nutraceutical compounds such as phenolic acids, stilbenes, flavonols, flavanols, tannins, anthocyanidins, monoterpenes, sesquiterpenes, carotenoids, C_{13}-norisoprenoids, and some vitamins. Their chemical structures and biosynthetic pathways are revised, and the content and diversity of these secondary metabolites in genetic resources of the genus *Vitis* (including *Muscadinia* and *Vitis* species, focusing on *V. vinifera* cultivars) are shown. In addition, QTL and association studies exploring the genetic basis of the biosynthesis of different health-related compounds in *V. vinifera* grape berries were asserted. Finally, a survey on the peculiarities and limits of traditional breeding compared to the innovative plant breeding techniques (cisgenesis and genome editing) applied to grapevine is provided. We

1 Introduction to Worldwide Wine and Table Grape Production

Grapevines are one of the most valuable horticulture crops, typically cultivated in regions with mild climate conditions, sufficient heat accumulation, and moderate winter low temperatures for proper fruit development and growth. The primary grape production areas are located between latitudes 30°–50° and 30°–40° in the Northern and Southern Hemispheres, respectively. These areas include some world-renowned winemaking regions, like Bordeaux and Burgundy in France, La Rioja in Spain, Tuscany in Italy, the Napa Valley in the USA, the Barossa Valley in Australia, or the Stellenbosch region in South Africa, to cite a few. It also embraces major table grape and raisin producers, including China, Turkey, India, the USA, and Chile (OIV 2019). In 2020, the total vineyard surface for wine grape and table grape production was estimated at 7.3 million hectares (OIV 2019). Mediterranean Sea countries, where grapevines have been cultivated for centuries, are some of the most important worldwide leading grape growers, including Spain (13.1% of the vineyard surface in 2020), France (10.9%), Italy (9.8%) and Turkey (5.9%). Outside these traditional grape-growing regions, it is worth highlighting other major grape-producing countries like China (10.7%), the USA (5.5%), Argentina (2.9%), and Chile (2.8%). These "New World" regions accounted for some of the largest vineyard surface and gross grape production increases over the last decades (OIV 2019).

Worldwide grape production is estimated at 77–78 million tons per year. About 57% of this annual yield mainly aims to sustain worldwide wine production. In contrast, fresh grape and dried grape (raisins) markets account for 36% and 7% of the total annual grape production, respectively (OIV 2019). In addition, some of these grapes are processed into jam, grape juice, vinegar, jelly, and grape seed extracts and oils, which diversify the use of grapes. Although some muscadine grapes (from *Vitis rotundifolia* cultivars and interspecific hybrids) have local relevance in the Southeastern USA (Yuzuak and Xie 2022), worldwide grape production is majorly sustained by the cultivation of *V. vinifera* cultivars. Despite the vast number of cultivars available for this species (Wolkovich et al. 2018), grape production focuses on cultivating a few genotypes (Morales-Castilla et al. 2020). In this light, only 13 grape cultivars ('Kyoho', 'Cabernet Sauvignon', 'Sultanina', 'Merlot', 'Tempranillo', 'Airén', 'Chardonnay', 'Syrah', 'Red Globe', 'Garnacha Tinta', 'Sauvignon Blanc', 'Pinot Noir',

Fig. 1 Grape clusters at maturity of 'Kyoho' (left), 'Carbernet Sauvignon' (middle), and 'Sultanina' (right). (Photos were downloaded from the *Vitis* International Variety Catalogue (*V*IVC), www.vivc.de – (accessed April 2022). Source: Ursula Brühl, Julius Kühn-Institut (JKI), Federal Research Centre for Cultivated Plants, Institute for Grapevine Breeding Geilweilerhof – 76,833 Siebeldingen, Germany)

and 'Trebbiano Toscano' (syn. 'Ugni Blanc')) account for more than one-third of global vineyard surface, and 33 cultivars for one half of it (Alston and Sambucci 2019). Attending to this list, the most widely cultivated genotype is 'Kyoho' (a black-berried table grape cultivar bred by Yasushi Ohinoue in 1935 in the Oinoue Institute for Agronomical and Biological Science, Japan), followed by 'Cabernet Sauvignon' (a black-berried wine grape cultivar), and 'Sultanina' (a seedless white-berried multi-purpose cultivar also known as 'Thompson Seedless') (Fig. 1). Collectively, these three cultivars accounted for almost one million hectares in 2015 (Alston and Sambucci 2019).

Global table grape production has increased gradually in the last decades to reach ca. 27 million tons in 2018, with four countries producing more than 50% of world production: China (9.5 million tons), Turkey (1.9), India (1.9), and Iran (1.7) (OIV 2019). Besides dominating table grape production, these countries also lead table grape consumption rates, likely due to the perishable nature of grape fruits, which tend to be consumed close to where they are grown. World raisins production and consumption have stayed relatively constant in the last decades, reaching a total production of 1.3 million tons in 2018 (OIV 2019). The two principal raisin producers worldwide are Turkey and the USA, with 381 and 263 thousand tons of gross production in 2018, respectively (OIV 2019). In contrast to table grapes, raisins can be easily transported, so they are majorly exported to other countries. In fact, although European countries are only minor producers of raisins, they account for one-third of global consumption (FAO and OIV 2016). As a result, raisins are considered valuable agricultural commodities for producing countries. Table grape production is based on cultivating a series of high-yielding cultivars with good sensory attributes and optimum commercial characteristics for packaging and

transport. On the other hand, raisin production is based on growing cultivars with berries with a good attitude towards dehydration and easy detachment from the stalk. For both uses, seedless cultivars are preferred. Some of the most cultivated cultivars for table grapes and raisins production are 'Alphonse Lavallée', 'Crimson Seedless', 'Dattier de Beyrouth' (syn. 'Afus Ali'), 'Flame Seedless', 'Kyoho', 'Muscat Hamburg', 'Italia', 'Muscat of Alexandria', 'Red Globe', 'Sugraone', 'Sultanina', and 'Victoria' (FAO and OIV 2016). As observed, modern table grape and raisins production is based on the combined cultivation of traditional cultivars (e.g., 'Sultanina', 'Muscat of Alexandria') with others obtained in more recent breeding programs aimed to achieve novel grapes with better features that fit consumers and producers' needs (e.g., 'Kyoho', 'Red Globe').

2 Grape as a Source of Nutraceutical Compounds

Grapes and raisins are grown on all inhabited continents, so they are commonly included in worldwide diets. Therefore, grapes result as one of the most regularly consumed fruits worldwide. It has been estimated that the average world consumption of grapes per year is 4.0 kg per capita (FAO and OIV 2016), although some differences between regions exist. For example, Turkey and China's annual grape consumption is much higher, estimated at 23 and 7 kg per capita, respectively (FAO and OIV 2016). Grapes are known to be one of the fruits with higher content of carbohydrates, mostly simple sugars (18.1 g per 100 g of grapes). As observed in Table 1, grapes are a good dietary source of calcium, manganese, phosphorous,

Table 1 Nutritional facts of grapes, raisins, and other relevant fruit crops. Nutritional data is referred to as 100 g servings. Information is taken from the USDA-Agricultural Research Service, FoodData Central (https://fdc.nal.usda.gov/, access: April 2022)

potassium, and vitamins B1, B6, and E compared to other relevant fruit crops. However, grapes stand out as one of the fruits richest in polyphenols and other compounds with antioxidant properties. In this line, multiple bioactive compounds with antioxidant potential have been discovered in grapes, including, but not limited to, phenolic acids, stilbenes, anthocyanins, flavonols, and flavanols (Teixeira et al. 2013; Pinasseau et al. 2017).

Nowadays, there is a growing interest in consuming food products naturally rich in antioxidants (like grapes), as they may reduce the incidence of some chronic diseases. The interest in uncovering the connection between grape consumption and its beneficial effects on human health started in the early 1990s when the so-called "French Paradox" was proposed. This concept refers to the unusually low rate of coronary heart disease observed in French people, regardless of consuming a diet rich in high saturated fats, which was initially correlated with moderate red wine intake (Renaud and de Lorgeril 1992). Later on, this phenomenon was linked to the presence of resveratrol in the skin of colored grapes and then to multiple dietary factors and life conditions that characterize Mediterranean and French lifestyles (Ndlovu et al. 2019). These findings boosted numerous research studies aimed at identifying and quantifying the most important health-related metabolites present in grapes and their derived products and analyzing their consumption's effect on human health (Catalgol et al. 2012). Numerous epidemiological, in vivo, and in vitro studies have indicated a relationship between polyphenol grape consumption and the lower incidence of some diseases and health disorders, information that has been collected in numerous reviews (Catalgol et al. 2012; Yang and Xiao 2013; Wightman and Heuberger 2014; Singh et al. 2015; Rasines-Perea and Teissedre 2017; Herman et al. 2018; Nash et al. 2018; Ko and Kim 2020). On the contrary, very few in vivo studies have considered the effects of fresh table grape intake on human health. As an example, Ammollo and colleagues reported an anticoagulant and profibrinolytic effect in healthy subjects after a 3-week table grape-rich diet (Ammollo et al. 2017). This protective role was further linked to an effect on the modulation of a series of genes implicated in critical processes like immune response, DNA and protein repair, autophagy, and mitochondrial biogenesis (Milella et al. 2020). Another study has suggested a link between the intake of fresh table grapes and a series of microRNA involved in fighting cancer development (Tutino et al. 2021).

Grape polyphenols have been linked to a lower risk of cardiovascular diseases, one of most industrialized countries' dominant causes of death. Among other cardioprotective effects, grape flavonoids (like anthocyanins, flavanols, and flavonols) are known to (i) inhibit platelet aggregation, (ii) decrease blood levels of triglycerides and high-density lipoprotein cholesterol, (iii) increase blood levels of low-density lipoprotein cholesterol, (iv) reduce oxidative stress, and (v) improve endothelial function (Wightman and Heuberger 2014). Besides, grape consumption may have a beneficial effect on type-2 diabetes, as they have one of the lowest glycemic index and glycemic load values among fruit crops (FAO and OIV 2016), and they are rich in phenolic compounds with some capability to reduce blood glycemic levels after food intake (Yang and Xiao 2013). On the other hand, grape berries are rich in resveratrol. Besides its protective effect against cardiovascular

diseases, resveratrol has been suggested to have chemopreventive and chemotherapeutic effects on different cancer types (Catalgol et al. 2012). In addition, the estrogenic activity of resveratrol has been associated with the prevention of some metabolic disorders in post-menopausal women, including the loss of bone mineral density and some alterations of the lipid metabolism pathways that might lead to the development of insulin resistance, abdominal adiposity, and dyslipidemia (Ko and Kim 2020). Lastly, grape polyphenols have been associated with some preventive effects toward developing neurodegenerative disorders, like Alzheimer's and Parkinson's diseases, and chronic traumatic encephalopathy (Herman et al. 2018). Delphinidin 3-*O*-glucoside is one of the predominant plant bioactive compounds of anthocyanins, linked to protecting against thrombosis and cardiovascular diseases, inhibiting platelet activation, and attenuating arterial and venous thrombus formation and development (Yang et al. 2012). Flavonoids can scavenge free radicals; therefore, they play a role in protecting against UV light damage. These compounds, accumulated preferentially in the skin and seeds of ripened grape berries can fulfill these functions thanks to the flavonoid scaffolds modification, which ameliorates the antioxidant capacity among other properties such as stability, solubility, and bioavailability of the resulting derivative.

Grape seeds are especially rich in proanthocyanidins, also known as condensed tannins or tannins. Given their redox potential and capability to bind target proteins and regulate cell signaling pathways, proanthocyanidins are known to have beneficial effects against different diseases (Unusan 2020). For example, in vivo and in vitro experiments have indicated that seed proanthocyanidin can inhibit metastatic processes, positively affecting the progression of lung, breast, colon, prostate, liver, pancreas, and skin cancers (Unusan 2020). In fact, proanthocyanidins have been suggested as powerful candidate drugs for cancer prevention and treatment therapy. In addition, grape seed proanthocyanidins have shown some preventive effects against cardiovascular diseases, obesity, type-2 diabetes, inflammatory bowel disease, neurodegenerative disorders, asthma, eye diseases, and osteoarthritis (Unusan 2020). Because of these potential beneficial effects on human health, grape seed oils rich in proanthocyanidins and other antioxidants have been recommended as suitable dietary supplements to prevent certain diseases (Gupta et al. 2020). Nevertheless, detailed safety analyses are needed to set the conditions of use and consumption of grape-derived ingredients in humans, especially for subjects under specific medical conditions (Singh et al. 2015).

Lastly, grapevine leaves have a long history as a traditional food in some regions, being considered a healthy food item with multiple nutritional benefits. In addition, they are often mentioned in folk medicine to treat some medical conditions, like high blood pressure, diabetes, and several circulatory system and inflammatory disorders (Pintać et al. 2019). Analyses of their chemical composition have indicated that they are rich in carotenoids (like β-carotene, lutein, and zeaxanthin) and essential minerals like calcium, potassium, iron, and zinc (Maia et al. 2021). In addition, they show a high content of flavonoids and hydroxycinnamic acid derivatives, which confer antioxidant protective activities (Pintać et al. 2019; Banjanin et al. 2020). In this regard, preliminary in vitro studies suggested that grapevine leaf extracts might

exert some promising anti-proliferative effects in human cancer cell lines due to their phenolic composition (Ferhi et al. 2019). However, further research is needed to suggest a chemopreventive and/or chemotherapeutic effect of grapevine leaf extracts, as well as before their use as ingredients in functional foods.

Biomarkers of food intake provide accurate information on the consumption of certain foods in the diet. Indeed, several protocols for identifying and confirming food candidate biomarkers have been established within the Food Biomarker Alliance (FoodBAll) Project funded by the Initiative "A Healthy Diet for a Healthy Life" (JPI-HDHL). It was developed to cover the food intake in different European populations to identify more straightforward sampling techniques for metabolomics analysis and discover dietary biomarkers. In particular, resveratrol and tartaric acid were found as candidate biomarkers for grapes intake. However, considering the putative biomarkers for berries in general (i.e., including strawberry, blueberry, blackberry, cranberry, raspberry, and blackcurrant), it was possible to identify that anthocyanins and ellagitannins are the main drivers in berries (Ulaszewska et al. 2020).

3 Polyphenolic Compounds in Grapes

Phenolic compounds significantly impact fruit and wine quality. Their biosynthetic pathways are tightly controlled by many transcription factors that modulate their expression and accumulation as a natural defense to various biotic and abiotic stresses (Kobayashi et al. 2004; Bogs et al. 2007; Terrier et al. 2009; Czemmel et al. 2009; Höll et al. 2013). In grapevine, phenolic compounds are conventionally separated into two classes: (i) non-flavonoid (phenolic acids and stilbenes) and (ii) flavonoid compounds (flavonols, flavanols, and anthocyanins).

3.1 Phenolic Acids

Polyphenol biosynthesis begins with phenylalanine. This amino acid can exert carbon competition phenomena between primary and secondary metabolites linking the shikimate pathway with the non-oxidative branch of the pentose phosphate pathway. The biosynthesis is divided into the phenylpropanoid and flavonoid/stilbene pathways. The phenylpropanoid ends with *p*-coumaryl-CoA in three reactions carried out by the phenylalanine ammonia-lyase, the cinnamate4-hydroxylase, and the 4-coumarate-CoA ligase activities (*PAL*, *C4H*, *4CL*, respectively). *p*-coumaryl-CoA is a branching compound of the phenylpropanoid pathway, and it can set up the flavonoid (with the enzymes chalcone synthase, *CHS*) or stilbene (with the enzyme stilbene synthase, *STS*) biosynthesis pathways (Teixeira et al. 2013; Falchi et al. 2019).

Phenolic acids (coumaric, caffeic, and ferulic) can be synthesized via phenylpropanoid products. When esterified with tartaric acid, they are known as *trans*-caftaric, *trans*-coutaric, and *trans*-fertaric acids, respectively (Fig. 2). They are synthesized in the berry flesh before véraison (beginning of grape ripening). Another significant phenolic acid in grapes is gallic acid (Fig. 2). It is formed from an

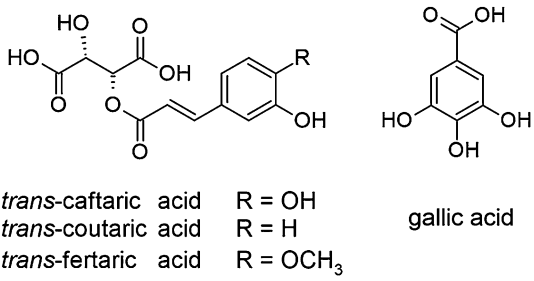

Fig. 2 Chemical structures of the primary phenolic acids in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))

intermediate compound in the upstream reactions of the shikimate pathway, thanks to the activity of a dehydroshikimate dehydrogenase (Bontpart et al. 2016). Gallic acid participates in several reactions, such as the galloylation of flavanols.

3.2 Stilbenes

Stilbenes are phytoalexins, small lipophilic compounds with well-known benefits for human health. They are naturally formed by the stilbene synthases in berries from *véraison* onwards. Stilbenes content and composition in grape berries present differences among cultivars. In addition, an enhancement of their synthesis happens concurrently with biotic and abiotic stresses (Gatto et al. 2008). Genomics analysis in *V. vinifera* indicates a remarkable expansion of the stilbene synthase gene family compared to other crops and plant model species, likely through segmental and tandem gene duplication events. In fact, up to 45 stilbene synthases have been described, with 33 coding for functional proteins (Vannozzi et al. 2012). The major stilbenes in *Vitis* are *trans*-resveratrol and its isomer *cis*-resveratrol, although the latter is less stable. Modifications of resveratrol give rise to other stilbenes present in grapes, such as the glycosylated *trans*-piceid, the methoxylated pterostilbene, or the hydroxylated piceatannol, which, if further glycosylated, become astringin. Moreover, oligomerization processes can produce the resveratrol dimer pallidol or a series of viniferins (α-, β-, γ-, δ-, ε-) with different stilbene units (Fig. 3). The genetic and metabolic mechanisms involved in such modifications are mainly unknown, except for a resveratrol *O*-methyltransferase and a resveratrol glucosyl transferase responsible for the production of pterostilbene and piceid, respectively (Hall and De Luca 2007; Schmidlin et al. 2008).

3.3 Flavonols

The flavonoid pathway leads to three major polyphenolic classes: flavonols, flavanols, and anthocyanins. First, naringenin is produced through the activity of chalcone synthases and chalcone isomerases (*CHS*, *CHI*). Then, naringenin is hydroxylated at diverse positions (3, 3′ or 3′5′) thanks to different flavanone

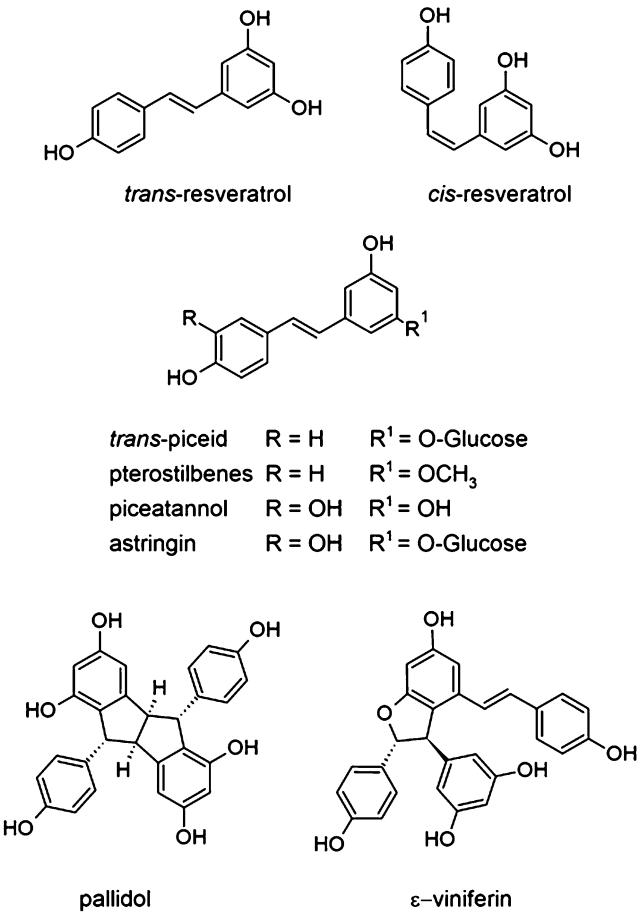

Fig. 3 Chemical structures of the major stilbenes in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))

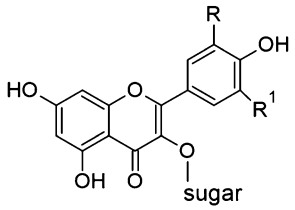
hydroxylases (*F3H*, *F3′H*, *F3′5′H*). These reactions form dihydroquercetin, dihydrokämpferol, or dihydromyricetin, respectively. Flavonol synthases (*FLS*) trigger flavonols' production by converting the previous dihydro-forms into kämpferol, quercetin, and myricetin. In addition to these three major compounds, grapes have isorhamnetin (the quercetin *O*-methylated form), laricitrin, and syringetin (the myricetin *O*-methylated forms carrying one or two methyl groups, respectively). Glycosylated flavonols are the majority metabolites found in grapes, and they can be linked to a glucoside, a galactoside, a rhamnoside, a rutinoside, or a glucuronide. In black-berried cultivars, flavonols can associate with anthocyanins, strengthening red wine color stability. In white-berried grapes, the primary flavonols are kämpferol (mono-hydroxylated), quercetin, and isorhamnetin (di-hydroxylated). In addition, myricetin, laricitrin, and syringetin (tri-hydroxylated) have been



quercetin	R = OH	R^1 = H
kämpferol	R = H	R^1 = H
myricetin	R = OH	R^1 = OH
isorhamnetin	R = OCH_3	R^1 = H
laricitrin	R = OCH_3	R^1 = OH
syringetin	R = OCH_3	R^1 = OCH_3

Fig. 4 Chemical structures of the noteworthy flavanols in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))

detected in black-berried grapes (Mattivi et al. 2006) (Fig. 4). Synthetized prevalently in grape berries skins, they are suggested to have a protective effect against UV radiation.

3.4 Flavanols

Flavanols, synthesized during the first growth phase of the berry, are derived from dihydroflavonols in two ways. They can be formed (i) in three steps via the dihydroflavonol 4-reductase, the leucoanthocyanidin dioxygenases, and the anthocyanidin reductase passing by anthocyanidins (*DFR*, *LDOX*, *ANR*) or (ii) in two steps via the dihydroflavonol 4-reductase and leucoanthocyanidin reductase (*DFR*, *LAR*) (Falchi et al. 2019).

The most abundant monomeric flavanols found in *Vitis* are catechin and gallocatechin, their enantiomers epicatechin and epigallocatechin, and the gallate ester epicatechin-3-*O*-gallate (Fig. 5). Their difference lies in their chemical modification (hydroxylation, acylation) and stereochemistry. Proanthocyanidins are the major polymeric phenolics, which differ in the number and selection of monomeric flavanols (polymerization degree) and the galloylation level (Mattivi et al. 2009). Tannins can be hydrolyzed under favorable pH conditions in gallic acid (from the gallotannins) or in ellagic acid (from the ellagitannins) (Teixeira et al. 2013).

3.5 Anthocyanins

Anthocyanins are a series of pigmented metabolites present in black-berried grapes, which are synthesized in the skin and stored in the vacuole during the second phase of berry growth. The UDP-glucose:flavonoid-3-*O*-glucosyltransferase (*UFGT*) is in

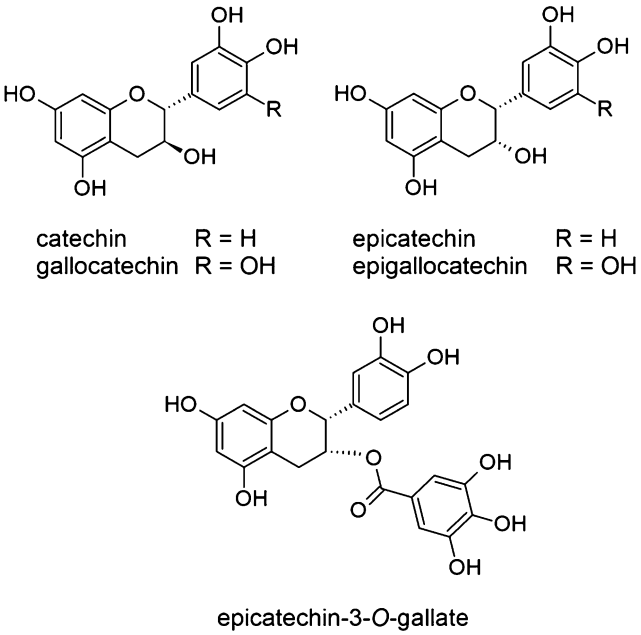


Fig. 5 Chemical structures of the main flavanols in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))

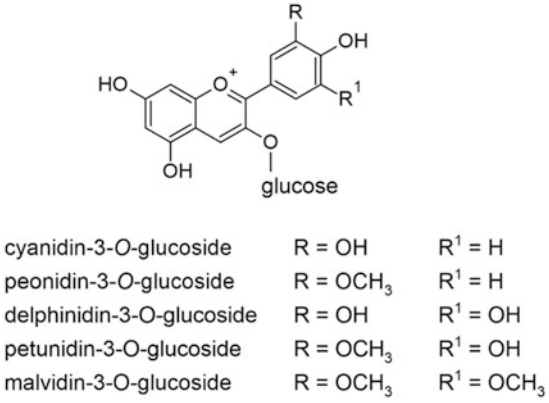
Fig. 6 Chemical structures of the most important glucosylated anthocyanins in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))



charge of their stabilization by glycosylation. The main grapevine anthocyanins are the cyanidin-3-*O*-glucoside and peonidin-3-*O*-glucoside (di-hydroxylated forms), and the delphinidin-3-*O*-glucoside, petunidin-3-*O*-glucoside, and malvidin-3-*O*-glucoside (tri-hydroxylated forms). In addition, peonidin, petunidin, and malvidin can further be methylated, increasing their stability and promptly influencing the berry color, (Fig. 6).

4 Terpenoid Compounds in Grapes

Terpenoid compounds can be obtained from two unrelated pathways: the plastid MEP (methyl-erythritol-4-phosphate) pathway or the cytosolic MVA (mevalonate) pathway. In any case, both pathways end with the synthesis of isopentenyl pyrophosphate (C5), which represents the building block of all terpenes, whose synthesis happens via specific prenyltransferases. Monoterpenes (C10) and tetraterpenes (C40) are produced in the plastid by geranyl pyrophosphate synthase and geranylgeranyl pyrophosphate synthase, while sesquiterpenes (C15) are formed in the cytosol by the farnesyl pyrophosphate synthase.

4.1 Monoterpenes

Up to 60 putatively terpene synthases (*TPS*) have been identified in the *vinifera* genome, some of them already functionally characterized (Martin et al. 2010). For more information, readers are referred to a recent review by Lin et al. (2019). Monoterpenes (C10) are compounds recognized as being involved in grape aroma, providing flower and fruity notes. The most aromatic monoterpenes in grapes are linalool (and its oxides, furanoid and pyranoid), geraniol (and its isomer nerol), citronellol, ho-trienol, α-terpineol and terpinen-4-ol, and *cis*-rose oxide (Mateo and Jiménez 2000) (Fig. 7). Monoterpenes diversity in grape berries arises from the linalool oxidative metabolism (Ilc et al. 2016), although the enzymes involved in this process have not yet been identified. In fact, geraniol can be converted to nerol or reduced to citronellol by an unknown isomerase and reductase, respectively. Moreover, hydroxylation and cyclization of citronellol can form *cis* and *trans*-rose oxide (Luan et al. 2005). The majority of monoterpenes are glycosylated in grapevine. Up to now, only three genes encoding for glycosyltransferases have been indicated to participate in this process (Bönisch et al. 2014a,b; Li et al. 2017). In their glycosylated forms, molecules are bound to sugar moiety and are not perceived, therefore, named as the nonvolatile fraction. Several hydrolysis mechanisms (acid or enzymatic) can free these bound terpenes during must fermentation or wine aging.

4.2 Sesquiterpenes

Sesquiterpenes (C15) are suggested to play a less important role in grape aroma, as they are generally found in concentrations lower than the olfactory perception threshold. Rotundone has been highly investigated in recent years (Fig. 7) due to the peppery character it confers to some black-berried (e.g., 'Cabernet Sauvignon', 'Syrah') and white-berried (e.g., 'Grüner Veltliner', 'Riesling) grape cultivars, and derived wines (Siebert et al. 2008; Caputi et al. 2011). Interestingly, the rotundone biosynthesis has been indicated to be linked to a specific terpene synthase coding for α-guaiene, the rotundone precursor (Drew et al. 2015).

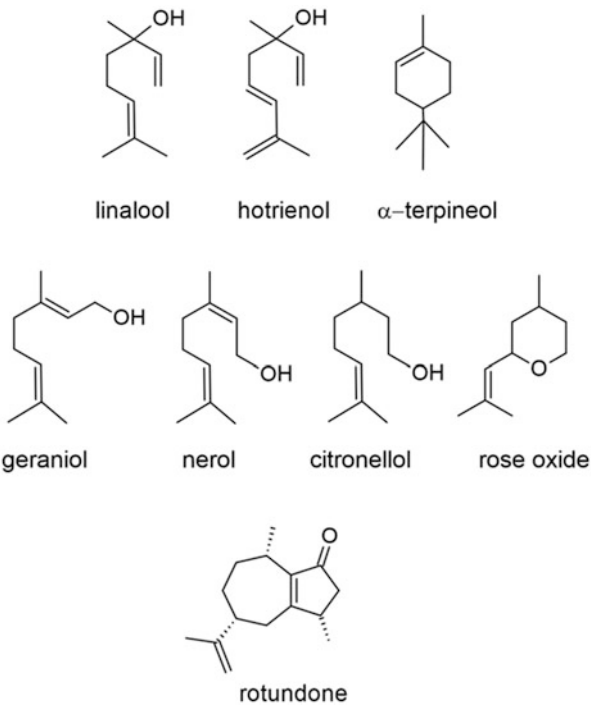


Fig. 7 Chemical structures of the major monoterpenes and sesquiterpenes in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))

4.3 Tetraterpenes

Tetraterpenes in grapes are represented by carotenoids (C40), a group of pigments commonly found in different flowers and fruits. They participate in light absorption processes and, due to their antioxidant properties, shield the photosystems from photooxidative degradation. The grapevine carotenoid metabolic pathway has been characterized by a comparative genomics approach (Young et al. 2012). Following this work, phytoene is formed by joining two molecules of geranylgeranyl pyrophosphate by phytoene synthase (*PSY*). In this regard, this first step is suggested to be the rate-limiting reaction of carotenoid biosynthesis. Then, phytoene is modified by four consecutive desaturation reactions by a phytoene desaturase, a carotene isomerase, a carotene desaturase, and a carotenoid isomerase (*PDS*/*PDH*, *ZISO*, *ZDS*, *CISO*), that end with the production of lycopene. Then, lycopene cyclases (*LBCY*) form α- and β-carotene, which triggers the formation of a series of carotenoid compounds, such as lutein and zeaxanthin, antheraxanthin and violaxanthin through different hydroxylation reactions (Fig. 8). The conversion of violaxanthin into neoxanthin represents the last reaction in the core carotenoid biosynthetic pathway, which is done by a neoxanthin synthase (*NSY*). The process of metabolite

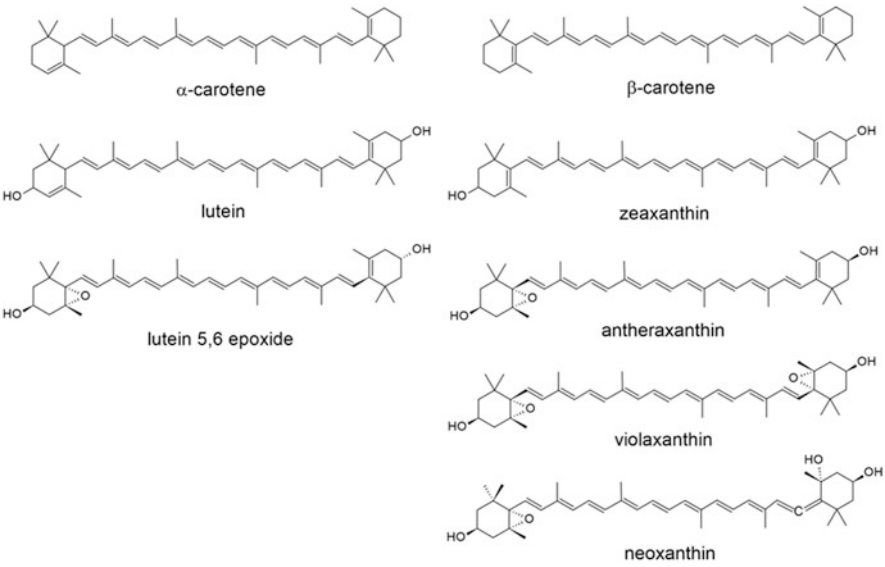

Fig. 8 Chemical structures of the major carotenoids in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))

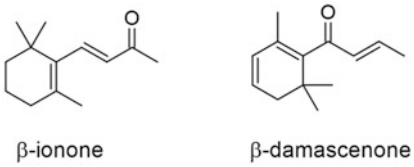
Fig. 9 Chemical structures of the representative C_{13}-norisoprenoids in grapes. (Drawn by the authors with ChemSketch (ACD/Labs))



interconversion between zeaxanthin and violaxanthin and between lutein and lutein 5,6-epoxide, named the xanthophyll cycle, is known to be involved in plant photoprotection processes. Thus, this conversion helps dissipate the excess of light energy in plant photosystems, shielding the photosynthetic apparatus. Carotenoid levels generally are higher during the first phase of berry growth, decreasing during berry ripening. Interestingly, only two carotenoids (zeaxanthin and antheraxanthin) have been reported to increase during berry ripening, reaching their maximum accumulation at harvest time.

Further modifications can occur to the end-products of the carotenoid pathway (neoxanthin and violaxanthin), which end up synthesizing compounds like abscisic acid, strigolactone, or flavor and aroma-related compounds like C_{13}-norisoprenoids (Lashbrooke et al. 2013). Within them, there are β-ionone and β-damascenone (Fig. 9), suggested to contribute to the grape floral and fruity aroma. In this regard, β-ionone is the direct cleavage metabolite of β-carotene, while 3-hydroxy-β-ionone

(a β-ionone derivative) represents the one of zeaxanthin and lutein. On the contrary, β-damascenone results from a multistep reaction starting with the dioxygenase cleavage of neoxanthin, producing the precursor ketodiol, which undergoes several acid-catalyze conversions (Sefton et al. 2011).

5 Vitamins and Other Compounds

Vitamins are of utmost importance because of their impact on human health and, above all, because we cannot synthesize them. Consequently, the only source for the human being is via dietary intake. Vitamins showing strong antioxidant potential are both water-soluble vitamins (such as vitamin C) and lipid-soluble (such as vitamin E). Ascorbic acid, or vitamin C (Fig. 10), is a major soluble antioxidant agent, supplying renewing protection against the damages inflicted by reactive oxygen species (ROS). In grapes, the content of vitamin C is relatively low compared to other fruits, like citrus. In this regard, it is known that grapevines use ascorbic acid as a precursor of tartaric acid, which belongs to the primary organic acids synthesized in grapes (together with malic acid), and the end-product of the irreversible ascorbic acid catabolism (Burbidge et al. 2021). The biosynthesis of ascorbate in mitochondria can follow different pathways. The most studied one is the Smirnoff-Wheeler pathway (known as the D-mannose/L-galactose pathway), which in grapes is highly active in immature green berries. It converts D-glucose-6-phosphate into GDP-D-mannose, then into GDP-L-galactose and L-galactono-1,4-lactone, to ultimately produce ascorbic acid. The alternative biosynthetic pathway originates from methyl-galacturonate, a pectin degradation product, that is converted into L-galactonate, re-joining the Smirnoff-Wheeler pathway intermediate L-galactono-1,4-lactone. This alternative route is suggested to be the most common one in grape berries after veraison (Melino et al. 2009).

Tocochromanols (comprised tocotrienols and tocopherols, collectively termed vitamin E) are a group of antioxidants known for preventing lipid oxidation (Fig. E). The structure of vitamin E holds a polar chromanol head group derived from the shikimate pathway and a hydrocarbon tail of isoprenoid origin. In this regard, tocotrienols and tocopherols are differentiated by containing a phytyl or a geranylgeranyl chain, respectively. Within each group of tocochromanols, molecules can be additionally distinguished in α-, β-, γ-, and δ- molecules based on the number and position of additional methyl groups present in the chromanol ring. Tocochromanols are primarily stored in the seed of grape berries (Fig. 11).

6 Genetic Resources and Extent of Genetic Diversity for Health-Related Compounds in Grapes

6.1 Diversity in the Muscadinia Subgenre

Grapes are part of the genus *Vitis*, a member of the Vitaceae plant family. According to morphological, anatomical, and cytological characteristics, species of the genus *Vitis* can be separated into two subgenera: *Muscadinia* ($2n = 2x = 40$) and *Vitis* (formerly known as *Euvitis*; $2n = 2x = 38$) (Aradhya et al. 2013). The natural occurrence of *Muscadinia* is narrowed to the Southeastern USA and Eastern Mexico (Aradhya et al. 2013), and it includes 2–3 species, of which only about 100 *V. rotundifolia* cultivars and interspecific hybrids have commercial interest (Yuzuak and Xie 2022). Fruits from these cultivars are commonly known as muscadine grapes, and they are grown for fresh fruit production and wine, juice, jam, and jelly elaboration. Muscadine grapes are suggested to have multiple health benefits, which result from their high content of phenolic compounds, namely anthocyanins and proanthocyanidins (Yuzuak and Xie 2022). Screening results suggest a high diversity in their levels of phenolic compounds, which are majorly found in grape skins and seeds (Pastrana-Bonilla et al. 2003). Through the analysis of 10 muscadine cultivars ('Carlos', 'Cowart', 'Early Fry', 'Fry', 'Ison', 'Late Fry', 'Noble', 'Paulk', 'Summit', and 'Supreme), Pastrana-Bonilla et al. (2003) highlighted the high concentration of ellagic acid, myricetin, quercetin,

kämpferol, and *trans*-resveratrol in muscadine grape skins, with concentration values ranging from 6.2 to 22.2, 1.8 to 19.6, 0.5 to 3.8, 0.2 to 3.8, and 0.1 to 0.2 mg/100 g, respectively. In seeds, epicatechin, catechin, and gallic acid dominate (Pastrana-Bonilla et al. 2003). Focusing on the ellagic acid and its precursors in eight muscadine cultivars ('Albermale', 'Carlos', 'Cowart', 'Doreen', 'Fry', 'Georgia Red', 'Nesbitt', and 'Noble'), Lee and Talcott (2004) reported a range of variation of 0.8 to 16.3, 0.7 to 11.5, and 58.7 to 190.0 mg/100 g, for free ellagic acid, ellagic acid glycosides, and total ellagic acid in the skin of ripe grapes, respectively. Regarding total anthocyanins, a wide range of variation in muscadine grapes has been indicated too, with an expected marked difference between black-berried cultivars (like 'Floriana' and 'Noble', with more than 10.0 mg/100 g dry weight) and white-berried cultivars (like 'Sweet Jenny', 'Watergate', and 'Welder', less than 0.03 mg/100 g dry weight) (Campbell et al. 2021). The overall high phenolic content of muscadine cultivars indicates their potential to develop new grape varieties with better fruit composition. However, hybrids between the *Muscadinia* and *Vitis* subgenera are generally infertile due to the discrepancy in the number of their chromosomes (Töpfer et al. 2011), limiting the usefulness of muscadine grapes in grapevine breeding programs.

6.2 Diversity Among Grape Vitis Species

The precise number of species belonging to the subgenus *Vitis* is challenging to estimate due to either hybridization between species or clinal variation within species. Thus, this subgenus is suggested to include between 60 and 70 species naturally occurring in Eastern Asia and North America and the only European grapevine species, *V. vinifera* (Péros et al. 2021). Comparative studies of the phenolic content and composition in ripe berries indicate significant differences among and within *Vitis* species. For example, the analysis of 147 grape accessions from 16 different *Vitis* species suggested that *V. rupestris* and *V. acerifolia* have the highest total phenolic concentration (20.2 mg/g and 19.2 mg/g fresh weight, respectively). On the other hand, *V. monticola*, *V. champinii*, and *V. labrusca* have the lowest concentration (3.8, 5.2, and 5.2 mg/g fresh weight) (Liang et al. 2012). Interestingly, these values are considerably higher than those reported for most of the *V. vinifera* L. cultivars analyzed by Liang et al. (2011) using the same methodology (1.4 mg/g fresh weight). A wide difference in anthocyanins content and composition between cultivars of different *Vitis* species has also been described. For example, delphinidin-derivatives might account for more than 60% of anthocyanins in species like *V. novaeangliae* and *V. champinii*, while it might be less than 20% in *V. monticola* (Liang et al. 2012). A wide range of variation for malvidin-derivatives (the dominant anthocyanins in *vinifera* cultivars (Sikuten et al. 2021) has been indicated too, accounting for up to 30% of total anthocyanins in species like *V. cinerea*, *V. palmata*, *V. vulpina*, *V. coignetii*, and *V. monticola*, to less than 2% (*V. novaeangliae*) (Liang et al. 2012). The concentration of total flavanols and flavonols also varies among species. Thus, *V. palmata* and *V. coignetii* have been indicated as some of the species with the highest content of flavanols, while

V. monticola and *V. champinii* have some of the lowest (Liang et al. 2012). Besides, *V. palmata*, *V. doaniana*, and *V. novaeangliae* are some of the species rich in flavonols, which contrasts with the low content reported in species like *V. monticola*, *V. champinii*, and *V. cinerea* (Liang et al. 2012). Substantial differences among *Vitis* species have also been indicated for stilbenes content and composition (Gabaston et al. 2020). As observed, non-*vinifera Vitis* species hold a wide range of variability for total phenolic content and individual phenolic compounds, which are of high interest for grape improvement. Nevertheless, some of these non-*vinifera* species carry certain off-flavors and undesirable aromas that, generally, are not positively perceived by consumers. As a result, the most common and realistic source of variability for developing novel grape cultivars with high fruit phenolic content is the one available within the *V. vinifera* species.

6.3 Diversity Among Wild and Cultivated *Vitis vinifera* Grapes

Most table and wine grape cultivars cultivated worldwide are part of the *V. vinifera* species, autochthonous of the Mediterranean Sea, southern and central Europe, northern Africa, and southwest and central Asia (Töpfer et al. 2011). Nowadays, two forms can still be found in these areas, the cultivated grapevine (*V. vinifera* subsp. *sativa* (or *vinifera*)) and its wild ancestor (*V. vinifera* subsp. *sylvestris*). Multiple sources indicate that the domestication process started in the Transcaucasian region during the early Neolithic Period (Myles et al. 2011). Genetic analyses based on different molecular markers indicate that the genetic diversity available in the *V. vinifera* subsp. *sativa* pool is highly structured, being linked to grape primary use (table or wine) and geographical origin (Bacilieri et al. 2013; Emanuelli et al. 2013; Laucou et al. 2018). Excluding novel grape cultivars achieved in breeding programs, these works indicate a major genetic division into four groups of cultivars: (i) table grapes from Eastern Mediterranean, Caucasus, Middle, and Far East countries, (ii) wine grapes from Western and Central Europe countries, (iii) wine grapes from the Balkans and Eastern Europe countries, and (iv) wine and table grapes from the Iberian Peninsula and the Maghreb. Further analyses indicate that this grouping correlates with significant differences in several grapevine reproductive and quality traits (Nicolas et al. 2016; Migicovsky et al. 2017). In this regard, differences in the phytochemical composition of *V. vinifera* subsp. *sativa* grapes between genetic groups have also been indicated (Teixeira et al. 2013; Sikuten et al. 2021).

In a comparative study between 11 *sylvestris* accessions from the eastern Adriatic region and three *sativa* cultivars ('Merlot', 'Plavac Mali', and 'Xinomavro'), Budic-Leto et al. (2018) indicated some significant differences in the phenolic content between subspecies, like those affecting the content of delphinidin-derivatives (higher in *sylvestris*), and of acylated anthocyanins (higher in *sativa*). Interestingly, the authors found two black-berried *sylvestris* accessions that lack acylated anthocyanins in berry skins, which agrees with previous findings by Revilla et al. (2012). The lack of acylated anthocyanins in berry skins is a rare characteristic in *sativa* cultivars, and it has only been observed in a few cultivars like the black-berried cultivar 'Pinot Noir' (and its offsprings and somatic variants) or the slightly colored

cultivar 'Gaglioppo' (Mattivi et al. 2006). Acylated anthocyanins in grapes not only increase phenolic fruit content but also stabilize the red color in wines during winemaking, leading to wines with a slight blue tint (Revilla et al. 2012). Regarding delphinidin-derivatives, delphinidin 3-*O*-glucoside was more abundantly found in *sylvestris* genotypes (on average, 22.5% of total anthocyanin content) than in the *sativa* cultivars 'Merlot', 'Plavac Mali', and 'Xinomavro' (on average, 10.3, 13.3, and 4.2%, respectively) (Budic-Leto et al. 2018).

Given its relevance for grape production, the phenolic content and composition of *V. vinifera* subsp. *sativa* cultivars have been screened in a vast number of genotypes. The analysis of the phenolic profiles of ripe berries from 344 cultivars by HPLC-MS revealed 36 phenolic compounds, including 16 anthocyanins, six flavonols, six flavanols, six hydroxycinnamic acids, and two hydroxybenzoic acids (Liang et al. 2011). Instead, the use of high-performance liquid chromatography coupled with triple quadrupole mass spectrometry analysis enabled the detection and quantification of 96 phenolic compounds, including the constitutive units of proanthocyanidins present in the skins of ripe grapes from 279 cultivars, providing highly detailed data on grape polyphenol composition (Pinasseau et al. 2017). These comprehensive analyses have suggested that polyphenol content varies among cultivars according to their primary use, with an overall higher level for all compounds (but hydroxycinnamic acids) in wine grapes than in table grapes (Liang et al. 2011). Nevertheless, the differences in phenolic content between cultivars of different use might be an indirect effect of their different behavior to factors affecting polyphenols biosyntheses, like precocity (Migicovsky et al. 2017) or the response to abiotic and biotic factors (Pinasseau et al. 2017). Considering only wine grapes, Sikuten et al. (2021) indicated that genetic and geographical background also affects the different phenolic content and composition between cultivars. These findings suggest that the evolution of the biosynthetic pathways leading to current grape phenolic content and composition might have been affected by regional environmental conditions, likely shaped by additional human-driven selection processes.

As expected, substantial differences in the total content of anthocyanins have been observed between grape cultivars of different berry colors. According to Liang et al. (2011), the average total anthocyanin content of black-berried cultivars is 30 times higher than the one found in pink-berried cultivars and 10 times higher than that of red-berried cultivars. As inferred from wine or table grapes studies, this effect is independent of the primary use of the cultivar. Regarding white-berried cultivars, only traces of anthocyanins have been detected from berry skin extracts in concentrations 5,000–60,000 times lower than in black-berried cultivars (Arapitsas et al. 2015). An interesting dietary source of anthocyanins is grapes from red-fleshed or 'teinturier' cultivars, which show an ectopic accumulation of anthocyanins in other plant organs, including berry flesh (Röckel et al. 2020). As a result, in proportion, grapes from 'teinturier' cultivars have a superior concentration of anthocyanins compared with white-fleshed cultivars (Kong et al. 2021; Röckel et al. 2020). Most of the available 'teinturier' cultivars derive from the French cultivar 'Teinturier', whose red-fleshed phenotype has been recently associated with the presence of a repetitive DNA element in the promoter of the *VviMybA1* gene (Röckel et al. 2020). In addition, other non 'Teinturier'-related red-fleshed cultivars

have been detected, like 'Gamay de Bouze', 'Gamay Fréaux' (somatic variants of 'Gamay'), and 'Pinot Teinturier' (a somatic variant of 'Pinot Noir') (Kong et al. 2021). Interestingly, cases of somatic variation causing red-fleshed berries have also been identified in table grape cultivars (Zhang et al. 2018), opening a promising sector for developing red-fleshed table grapes of higher nutritional quality.

On the contrary, berry skin color does not seem to significantly impact the content of other phenolic compounds (Liang et al. 2011). Flavanols are the major non-anthocyanin polyphenols of grapes, followed by flavonols. There is significant variability in the content of both groups of polyphenols, with up to a 100- and 176-fold variation between cultivars for flavanols and flavonols, respectively (Liang et al. 2011; Pinasseau et al. 2017). In this line, the cultivars 'Jampal' and 'Muscat St. Laurent' are suggested to be especially rich in flavanols, while 'Touriga Nacional' and 'Dornfelder' are in flavonols (Liang et al. 2011). The concentration of hydroxybenzoic and hydroxycinnamic acids has been indicated to vary widely between cultivars (Liang et al. 2011; Pinasseau et al. 2017), as does that of stilbenes (Gatto et al. 2008; Pinasseau et al. 2017). Regarding stilbene derivatives, the ratio between *trans*-resveratrol, *trans*-piceid, and *cis*-piceid also varies widely between cultivars (Gatto et al. 2008).

The characterization of different grape cultivars indicates that lutein and β-carotene are the major components of grape carotenoids, with significant differences between genotypes. As an example, the comparative analysis of nine grape cultivars grown under conventional conditions indicated a varying concentration ranging between 470.9 ± 46.0 and 825.0 ± 39.0 0 μg/kg for lutein in grape skins (for cultivars 'Aromat de Iaşi' and 'Feteascaregală', respectively), and between 229.6 ± 18.0 and 593.2 ± 35.0 μg/kg for β-carotene (for 'Napoca' and 'Muscat Ottonel' grape skins, respectively) (Bunea et al. 2012). Besides, different works indicate that vitamin content also varies significantly among grape cultivars. For example, vitamin C content varied between 11.2 ± 0.1 and 35.7 ± 0.3 mg/100 g in a group of nine Turkish table grape cultivars (Eyduran et al. 2015), a similar range to the one found in the analysis of 10 table grape cultivars from Syria (from 9.7 ± 1.2 to 30.9 ± 3.3 mg/100 g fresh weight) (Khalil et al. 2017). Regarding vitamin E content (α- and γ-tocopherols), the analysis of six table grape cultivars indicated a range of variation from 5.0 to 8.1 mg/kg fresh weight (values for 'Italia' and 'Muscat de Hambourg' cultivars, respectively) (Aubert and Chalot 2018). In the analysis of 15 wine and table grape cultivars, the total tocopherol content (α-, β-, γ-, and δ- tocopherols) was found to range from 29.2 ± 1.6 (in 'Muscat of Alexandria') to 102.7 ± 1.3 ('Syrah') mg/kg dry weight in bagasse (skin and pulp), and between 6.0 ± 1.1 ('Semillon') to 25.9 ± 1.7 ('Trakya Ilkeren') mg/kg dry weight in seeds (Tangolar et al. 2011). Following this work, the principal use of the cultivar (table or wine) does not significantly affect vitamin E content, which is dominated by α- and γ-tocopherols in grapes in both cases.

Another source of genetic variation affecting the content of health-related compounds in grapes is caused by somatic variation events. Spontaneous somatic mutations might cause changes in relevant phenotypic traits, deriving in clonal variation (Carbonell-Bejerano et al. 2019). To the interest of this chapter, different works report the identification of clones of some cultivars with significantly different phenolic content and composition (Ferrandino and Guidoni 2010; Muñoz et al. 2014; Pantelić et al. 2016; Royo et al. 2021). For example, the analysis of the

phenolic amount in ripe berries of four clones of 'Merlot' revealed a fold variation of 2.0, while that of four clones of 'Cabernet Franc' was set at 3.9 (Pantelić et al. 2016). Similarly, the maximum differences observed in the total phenolic content within 30 'Tempranillo Tinto' clones rose to 3.5-fold (Lemos et al. 2020). Following this work, the maximum fold variation in total anthocyanins was found to be 2.3, while one of the total flavonoids was 1.6.

7 Molecular Mapping Studies for Health-Related Compounds Content in Grapes

Understanding the genetic architecture of the accumulation of health-related compounds in grapevine berries implies identifying the number and location of the genomic regions (quantitative trait loci, QTLs) affecting trait variation, as well as their interaction. This information is essential for grapevine improvement, as it can be converted into practical knowledge for marker-assisted selection processes in modern breeding programs. Conventionally, QTL mapping is performed in populations segregating for the trait of interest through detecting significant associations between genetic markers segregation and trait phenotypic variation. This approach has been successfully applied over the past decades to reveal the genetic basis of traits related to the phenotypic determination of crop yield, grape quality, and adaptation mechanisms to abiotic and biotic factors. More recently, genome-wide association studies (GWAS) have also been implemented in different grapevine diversity panels to explore the genetic architecture of complex traits. Here, we focus on the works exploring the genetic basis of the biosynthesis of different health-related compounds in *V. vinifera* grape berries.

7.1 Anthocyanins Biosynthesis: The Berry Color Locus

Phenolic compounds are the most abundant and important health-related compounds in grape berries. The color of grape berries (and grape-derived products) is mainly associated with the content and composition of anthocyanins in berry skins. In addition, anthocyanin content clearly impacts the antioxidant potential of grapes. Given the relevance of berry color on fruit quality, the genetic basis of anthocyanins synthesis and accumulation in berry skins has been of great interest to the scientific community, and it can be reflected by the numerous works exploring this topic (see Ferreira et al. (2018) for a recent review). Early genetic studies in different *V. vinifera* progenies segregating for berry color indicated that this trait is mainly regulated by a single locus on chromosome 2, named *berry color locus*. The same locus was found when using quantitative data of total anthocyanins extracted from berry skins (Fournier-Level et al. 2009; Sun et al. 2020), which added evidence to support the role of anthocyanins on berry skin color determination. The oligonenic architecture of this trait has also been found in different GWAS (Myles et al. 2011; Migicovsky et al. 2017; Laucou et al. 2018), a procedure that screens functional variation in a

wider set, usually employing a panel of cultivars bearing most of the phenotypic variability existing for the target trait available at a species level.

Further molecular studies indicated that the *berry color locus* spans over a 200-kb region on chromosome 2, which encompasses a cluster of four MYB-type transcription factors: *VviMybA1*, *VviMybA2*, *VviMybA3,* and *VviMybA4* (Kobayashi et al. 2004; This et al. 2007; Walker et al. 2007; Fournier-Level et al. 2009). Different works have evidenced that both *VviMybA1* and *VviMybA2* are necessary for successfully accumulating anthocyanins in berry skins, indicating that white-berried cultivars (which lack anthocyanins in berry skins) only appear when these two genes are disrupted. This now widely accepted mechanism was first explored by Kobayashi et al. (2004) through the comparative study of the white-berried cultivar 'Italia' and its red-berried somatic variant 'Ruby Okuyama', which accumulates anthocyanins (mainly cyanidin-3-*O*-glucosides) in berry skins. Molecular and genetic studies revealed that the absence of anthocyanins in berry skins was tightly linked to the presence of a retrotransposon (called *Gret1*, from *Grape retrotransposon 1*) in the promoter of the *VviMybA1* gene sequence, which causes a non-functional allele. Thus, if this allele is found in homozygosis (as in 'Italia') it causes an absence of anthocyanins in berry skins, which derives in non-colored berries. This mechanism was then observed in a high number of cultivars of different origins and uses, which confirmed the role of *VviMybA1* on berry color variation at a species level (Lijavetzky et al. 2006; This et al. 2007). Later on, Walker et al. (2007) indicated that berry color loss is due to modifications in both *VviMybA1* and *VviMybA2*. Thus, besides the inclusion of the *Gret1* retrotransposon in *VviMybA1* first indicated by Kobayashi et al. (2004), two additional non-conservative mutations in *VviMybA2* are needed to inhibit the synthesis of anthocyanins in berry skins. Sequence analyses characterized these two mutations as (i) a single nucleotide polymorphism (SNP) causing a non-conservative amino acid substitution and (ii) a deletion of a dinucleotide that alters the reading frame in the functional *VviMybA2* allele. Considering that *VviMybA1* and *VviMybA2* are closely linked on the same chromosome region, they are usually considered part of a single MYB haplotype. This haplotype configuration determines a "white allele," which harbors non-functional alleles for both *VviMybA1* and *VviMybA2*, and two different "colored alleles," which harbor (i) *VviMybA1* functional and *VviMybA2* non-functional alleles, or (ii) *VviMybA1* and *VviMybA2* functional alleles (Ferreira et al. 2018). Functional analyses have indicated that both *VviMybA1* and *VviMybA2* are capable of inducing the *VviUFGT* gene expression (Walker et al. 2007). *VviUFGT* is the last gene of the phenylpropanoid pathway, and it has been suggested to be key for the biosynthesis of anthocyanins in berry skins and, consequently, berry pigmentation.

As previously indicated, genetic variations in *VviMybA1* have also been linked to the anthocyanin levels in the flesh of red-fleshed cultivars. After the analysis of a series of 'teinturier' cultivars, Röckel et al. (2020) associated the colored berry flesh phenotype with the presence of a 408-bp repetitive DNA element (called *Grapevine Color Enhancer*, GCE), found 338 bp upstream of the start codon in the *VviMybA1* gene promoter region. Following this work, GCE has been found with varying repetitions (two, three, and five) in different cultivars. Interestingly, the number of

GCE repeats correlates with the expression of *VviMybA1* and *VviUFGT* genes, as well as with berry flesh color intensity.

VviMybA3 sequence polymorphisms have also been significantly associated with berry color variation through a GWAS (Fournier-Level et al. 2009). However, it has been indicated that the cysteine-rich (CR) domain of the *VviMybA3* gene is truncated, deriving into a non-functional protein with poor functional evidence in the accumulation of anthocyanins in berry skins and berry skin color variation. However, it has been recently revealed that *VviMybA3* might contribute to regulating the accumulation of anthocyanins in berry flesh (Zhang et al. 2018). Finally, no associations between *VviMybA4* sequence polymorphisms and anthocyanins content variation have been described (Fournier-Level et al. 2009), sustaining the observed lack of functional activity of this transcription factor in grape berry skins (Walker et al. 2007). Beyond the *berry color locus*, Deluc et al. (2008) found that another MYB transcription factor (*VviMyb5b*, located in chromosome 6) can activate several genes of the general anthocyanins biosynthetic pathway, but not *VviUFGT*. Following this work, *VviMYB5b* has been suggested to participate in regulating proanthocyanidins biosynthesis in developing grape berries. In addition, Cardoso et al. (2012) tested the association between berry color and anthocyanins content variation and the genetic diversity detected in 15 genes that are not part of the *berry color locus* but putatively involved in the synthesis or transport of anthocyanins. Modeling results indicated some significant associations between the content of anthocyanins in berry skins and several polymorphisms found in three MYB transcription factors (*VviMYB11*, *VviMYBCC*, and *VviMYCB*). These results suggest that other genes not included in the *berry color locus* might influence anthocyanins biosynthesis mechanisms, which agrees with the additional minor QTLs for grape berry color and/or anthocyanins accumulation found in other studies (Sun et al. 2020).

7.2 Flavonols and Flavanols Biosynthesis: The Role of VviMYBF1, VviMybPA1, and VviMybPA2

The genetic basis of how flavonols are synthesized and accumulated in mature grape berries was explored by analyzing 170 individuals from a 'Syrah'×'Pinot Noir' population segregating for flavonol content and composition (Malacarne et al. 2015). According to this work, the *berry color locus* exerts a significant effect on flavonol content variation, indicating a common genetic control between flavonols and anthocyanins biosynthesis. This result agrees with previous findings that indicated that the metabolic reactions leading to the biosynthesis of these two groups of phenolic compounds are (at least) partially connected (Mattivi et al. 2006). Besides this QTL, other genomic regions associated with the fine-tuning of flavonol biosynthesis were identified, including a series of flavonol-specific QTLs that do not co-localize with genomic regions previously associated with anthocyanin biosynthesis or berry color variation. The authors found a region on chromosome 7 associated with kämpferol variation, which co-localizes with one MYB-type transcription factor gene, *VviMYBF1*. Interestingly, expression and functional analyses of *VviMYBF1* have

indicated that this transcription factor is a significant regulator of flavonols biosynthesis in developing grape berries (Czemmel et al. 2009).

Proanthocyanidins result from the polymerization of flavanol units. These compounds are secondary plant metabolites with multiple beneficial effects on human health, preferentially accumulated in berry skins and seeds. The genetic determinism of proanthocyanidin content in grape berries was first explored by considering two candidate genes: *VviMybPA1* and *VviMybPA2*. Using a series of transcriptome and functional studies, these two MYB-type transcription factors have been proposed as the central regulators of proanthocyanidins biosynthesis in grape berries (Bogs et al. 2007; Terrier et al. 2009; Carrier et al. 2013). In fact, different functional studies indicate that *VviMYBPA1* and *VviMybPA2* induce the transcription of key enzymes of the flavonoid, which triggers the biosynthesis of anthocyanins, flavonols, and proanthocyanidins in berries (Bogs et al. 2007; Terrier et al. 2009). Nevertheless, different genetic mapping studies have indicated that proanthocyanidin content might be under a highly more complex genetic control. For example, the analysis of 191 individuals from a segregating population obtained from a 'Syrah' × 'Grenache' cross revealed up to 43 and 103 QTLs for a series of skin and seed proanthocyanidins-content related traits (like total content or polymerization degree), respectively (Huang et al. 2012). These QTLs were virtually found on all chromosomes, suggesting a complex polygenic regulatory mechanism in berry skins and seeds. Interestingly, given the different numbers and positions of the QTLs identified for berry skins and seeds, results pointed out that the biosynthesis of proanthocyanidins in these two organs might be under different genetic regulation pathways. Based on a combination of QTL mapping and transcriptomic studies, Carrier et al. (2013) identified 20 genes in six chromosomes (1, 2, 3, 8, 14, and 17) as potential candidates to be involved in the proanthocyanidins biosynthetic pathway. Among them, three genes not previously associated with proanthocyanidins synthesis (*VviMybC2-L1*, *VviGAT-like*, and *VviCob-like*, in chromosomes 1, 3, and 17, respectively) were highlighted as promising candidates to be validated in subsequent works. Lastly, Huang et al. (2014) identified 21 eQTLs based on the transcript abundance of five downstream proanthocyanidins synthesis genes. Following this work, some of the more confident candidate eQTLs were related to genes linked to the general proanthocyanidins synthesis pathway, including *VviDFR* (in chromosome 18), *VviLAR1* (chromosome 1), or *VviLAR2* (chromosome 17).

7.3 Monoterpenes Biosynthesis: The 1-Deoxy-D-xylulose 5-Phosphate Synthase (DXS1) Activity

Other health-related compounds present in grape berries with antioxidant properties are monoterpenes. Grape monoterpenes have been classified into three categories: (i) free aroma compounds; (ii) free odorless polyols; and (iii) non-aromatic glycosidically bound forms of the monoterpenes (Mateo and Jiménez 2000). Given their contribution to the sweet and typical floral flavor of Muscat cultivars (Emanuelli et al. 2010), the genetic basis of the linalool, geraniol, and nerol content in grape

berries has been explored in multiple works. Different QTL mapping studies have indicated that muscat aroma (and/or geraniol, linalool, and nerol levels) is under an oligogenic control (Doligez et al. 2006; Battilana et al. 2009; Duchene et al. 2009; Wang et al. 2020). Recent GWAS have supported this genetic architecture using sets of grapevine cultivars of different origins (Migicovsky et al. 2017; Yang et al. 2017; Laucou et al. 2018; Guo et al. 2019; Liang et al. 2019). All these works indicate that geraniol, linalool, and nerol content in grapes is controlled by a key QTL on chromosome 5, which co-localizes with *VviDXS1* (Battilana et al. 2009; Duchene et al. 2009). This gene performs its action on the starting reaction of the plastidial MEP pathway (Battilana et al. 2009), whose functional role on monoterpene levels in grape berries was furtherly validated (Battilana et al. 2011). By association mapping, the causal SNP underlying this QTL has been identified (Emanuelli et al. 2010). Following this work, this SNP generates a non-neutral substitution present in the majority of Muscat-flavored cultivars. Beyond this locus, other minor QTLs have also been indicated by QTL mapping in different progenies (Doligez et al. 2006; Battilana et al. 2009; Duchene et al. 2009), suggesting the potential involvement of additional genomic regions to the final content of monoterpenes in grape berries.

7.4 Carotenoids Biosynthesis: What Gene Is Prominent?

As previously indicated, different carotenoids have been found in grapes, enhancing their nutritional value. Nevertheless, the information available on the genetic basis of their content in grape berries is limited. Using a comparative genomics approach, Young et al. (2012) identified up to 42 genes putatively involved in the grapevine carotenoid biosynthetic pathway, scattered on 16 chromosomes. More recently, after a genome-wide screening study, Leng et al. (2017) identified a total of 54 putative carotenoid metabolism-related genes, which were found to be distributed on 17 chromosomes. Altogether, these two works suggested a complex genetic architecture for grapevine carotenoid biosynthesis and provided a list of candidate genes likely involved in carotenoid accumulation. Nonetheless, specific genetic mapping analyses (either QTL mapping or GWAS, or both) are still needed to uncover the genetic basis underlying the accumulation of carotenoids in grape berries.

8 Grape miRNAs and Their Likely Impact on Human Health

Plant bioactive metabolites such as polyphenols, monoterpenes, carotenoids, and tocopherols are suggested to be responsible for the beneficial effects of consuming fruits and vegetables on human health. Plant microRNAs (miRNAs) are new bioactive molecules that migrate from plants to mammalian cells through dietary intake, regulating specific genes and pathways, and resulting in interesting candidates for dietary therapy approaches (Sanchita Trivedi et al. 2018; Li et al. 2021b).

miRNAs are endogenous, highly conserved, non-coding single-stranded RNAs. Specific miRNA genes code for these molecules, which consist of 18–24 nucleotides. At the post-transcriptional level, they can regulate gene expression by stimulating target messenger RNA (mRNA) degradation, translational repression, and chromatin modification of the corresponding target gene/s. Today, approximately half of the protein-coding mRNAs are thought to be influenced by miRNAs. miRNA gene silencing machinery is highly conserved in eukaryotes, even if notable differences exist between plants and animals concerning miRNA biogenesis, maturation, and mode of function (Achkar et al. 2016). These differences might contribute to the plant miRNA's high stability compared to their animal counterparts, explaining plant miRNA cross-kingdom abilities. Previous findings have revealed that plant miRNAs can survive adverse conditions such as low pH levels, high temperatures, ribonuclease and RNase activities, and digestive processes like food homogenization and absorption processes. In plants, adding a methyl group to the sugar present at the 3′-terminal nucleotide safeguards miRNAs from exonuclease degradation and 3′-uridylation. Moreover, the high plant miRNA GC content determines the absence of RNase digestion motifs (Yang et al. 2018). The nexus between Argonaute proteins or cofactors, such as high-density lipoproteins, with miRNA avoid miRNA decay, and combining miRNA with plant secondary metabolites creates a favorable setting that is able to inhibit RNAse activities. The packaging of plant miRNAs into microvesicles or exosomes protects their transportation before being absorbed via intestinal epithelial cells (van der Pol et al. 2012).

In recent years, plant miRNAs have attracted the attention of researchers for their cross-kingdom abilities and capability of regulating gene expression and cellular processes in humans through dietary intake. The first cross-kingdom study describing the detection of an exogenous plant miRNA (*miR168a*) in human serum was reported in 2012 (Zhang et al. 2012). Numerous other studies followed this pioneering work, and such studies can be found for diverse plant species like maize (Li et al. 2019), strawberry (Cavalieri et al. 2016), lettuce (Zhang et al. 2019), cabbage (Liang et al. 2014), spinach (Hou et al. 2018), and soybean (Chin et al. 2016). However, to our knowledge, only one cross-kingdom study has been conducted on grapes (Svezia et al. 2020). Following this work, authors proved the effects of grape miRNAs on human health by evaluating the cardioprotective role of cv. 'Sangiovese grape juice intake, using three different models: a murine model of myocardial infarction, murine coronary endothelial cells, and healthy human subjects. More specifically, they investigated the grape miRNAs impact on the natriuretic peptide system gene expression in murine coronary endothelial cells culture, representing the central auto-/paracrine signals of cardiac remodeling in infarcted patients. Remarkably, the survival of such cell lines was significantly linked to an intensified uptake of grapevine miRNAs. In the same work, for the first time, the authors detected the grape miRNAs in the human plasma of four healthy humans after seven days of 'Sangiovese' grape juice regular intake. Interestingly, the levels of two conserved plant miRNAs (*Vvi-miR159-3p* and *Vvi-miR166-3p*) increased in the bloodstream after 'Sangiovese' grape juice consumption.

To date, the ability of plant miRNAs to regulate key pathways in mammalian cells has been reported in an increasing number of studies. However, despite these promising results, works report contradicting evidence of cross-kingdom gene regulation by plant miRNAs, and the role of plant miRNAs on human metabolism regulation is still highly debated.

In plants, miRNAs are implicated in many functions related to growth and development, fruit ripening processes, signal transduction, response to abiotic and biotic stresses, and secondary metabolites modulation. In grapes, the publication of the genome sequences eased the discovery of miRNAs and their putative role in grapevine molecular regulatory networks. Many studies have evaluated the role of grape miRNA in developmental processes and stress responses. Belli Kullan et al. (2015) described the abundance of miRNAs in several grapevine tissues (including berries) at different developmental stages of the grapevine cultivar 'Corvina'. Accordingly, the distribution and abundance of miRNAs across samples are suggested to reflect the functional specificity of different organs, which ultimately aids in defining organ identity. Besides, Paim Pinto et al. (2016) compared the distribution of miRNAs in two grapevine cultivars ('Cabernet Sauvignon' and 'Sangiovese') collected in different vineyards and developmental stages. This work showed that both the developmental stage and cultivar influence miRNAs more than the vineyard. Chitarra et al. (2018) developed the first online database of grapevine miRNA candidates, called miRVIT. As a proof of concept study, this tool was successfully used to explore the response of 'Barbera' vines infected by *Flavescence dorée*, one of the most dangerous phytoplasma diseases.

The ingestion of plants with an added concentration of functional miRNAs in the diet has been recently suggested as a potential solution to face specific clinical situations (Sanchita Trivedi et al. 2018; Li et al. 2021a). However, further investigations and validations are required prior to this recommendation, and specific studies on many related topics (including how miRNAs are transported or absorbed by the human system) are needed to avoid any potential risks.

9 Applicability of Breeding Techniques in Grapevine Improvement

Improving crop traits, including nutritional value or quality, is critical to meet the growing population demands, which puts pressure on land use due to urbanization. Indeed, as a consequence of population growth and negative climate change effects on agricultural systems, there is a need to ensure food availability while maintaining (or increasing) food quality. In such context, crop breeding approaches (both conventional and modern activities) can improve crop productivity and quality features. However, some limitations have hindered grapevine breeding activities. Despite its importance, grapevine genetic improvement did not begin until the nineteenth century as a defense strategy against the arrival of powdery mildew, phylloxera, and downy mildew from North America (Töpfer et al. 2011). Although grapevine can be improved through several breeding techniques, these are difficult and time-consuming due to long generation cycles and the time required for selecting and

testing reliable progenies (juvenile stages). In addition, the grapevine is a highly heterozygous crop that exhibits inbreeding depression (Dalla Costa et al. 2019; Campos et al. 2021). Despite these limitations, grapevine improvement efforts could result in high-value products with high content of phenolic, aromatic, and vitaminic compounds that might provide beneficial effects linked to their antioxidant, anti-inflammatory, and anticancer properties, among others.

9.1 Conventional Breeding

Conventional grapevine breeding has focused on using strategies to counteract pathogens' negative effects and abiotic stressors on grapevine production. Chemical control is the most efficient way to deal with pathogens, but this approach has negative environmental, ecological, and sociological impacts. Thus, a way to reduce the use of chemicals is the development of novel resistant grapevine cultivars by the introgression of resistance R-loci from North American and Asian *Vitis* species into elite *vinifera* cultivars, developing more tolerant/resistant grapevine genotypes with high fruit quality (Töpfer et al. 2011; Pertot et al. 2017). To allow the preservation in time of the tolerant/resistant introgressed genes, gene pyramiding is used, aimed at incorporating more than one effective resistance gene (Pedneault and Provost 2016). This technique permits the parallel control of various pathogens or traits linked to grapevine resistance or tolerance. Moreover, these new genotypes might develop from multiple "back-crosses" steps with the elite cultivar, aimed to maintain a high percentage of the *V. vinifera* genome to preserve elite grape and wine quality properties. In this regard, several countries such as Austria, Chile, France, Germany, Hungary, Italy, Spain, and the USA have developed different wine and/or table grape breeding programs to obtain new cultivars with better yield and quality properties.

The development of improved genotypes holding genes from non-*vinifera* individuals while maintaining a high proportion of *V. vinifera* in their pedigree was speeded up by the use of Marker-Assisted Selection (MAS) (Pedneault and Provost 2016). In this sense, informative genetic markers associated with relevant grapevine features like berry size, acidity, color, aroma, and fruit ripening time have also been discovered in the grapevine. Most of these markers are reported in the "*Vitis* International Variety Catalogue – VIVC" website (https://www.vivc.de/docs/dataonbreeding/20220218_Table%20of%20Loci%20for%20Traits%20in%20Grapevine.pdf). Within them, some markers linked to genetic *loci* involved in the synthesis of metabolites with impact on the nutraceutical content of grapes can be found. For example, the available markers for berry color and muscat aroma (based on *VviMybA1* and *VviDXS1* gene sequences, respectively) could be used to trace the presence/absence of alleles related to increased color and increased aroma (so, to trace the presence/absence of antioxidant compounds) in breeding programs. The availability of these markers represents an interesting starting point to work on improving the nutraceutical properties of grapes via MAS.

The conventional breeding process comprises three stages: hybridization, line-fixation, and field trials. Plant breeding is an extensive logistical procedure requiring hundreds of thousands of vines in the hybridization and line-fixation stages;

however, the amount of plants is drastically lowered to small-selected vines in advanced breeding lines by the end of the breeding process. Therefore, considering the presented limitations, conventional breeding is hardly exploitable. Specifically, because of a prolonged lifecycle, severe inbreeding depression, and complex genetic control of enological properties, other genetic improvement strategies must be considered for *Vitis* (Gray et al. 2014; Litz et al. 2020).

9.2 The Potential of New Plant Breeding Techniques (NPBTs)

Over the past 15 years, biotechnological application in breeding programs has developed New Plant Breeding Technologies (NPBTs) that can modify only specific target DNA sequences without changing other regions (linkage drag) and without the need for long backcrossing stages, a limitation of conventional breeding techniques (Enfissi et al. 2021; Giudice et al. 2021). NPBTs are a new generation of techniques able to improve plant disease resistance, abiotic stress resilience, and added nutritional values (Lusser et al. 2012; Giudice et al. 2021). Compared with traditional breeding techniques, NPBTs increase the precision and accuracy of making changes in the genomes, reducing the time and efforts needed to produce novel crop cultivars that meet new requirements and potentially reducing the loss of important traits such as the biosynthesis of nutraceutical compounds. Several NPBTs make small modifications to the plant DNA and do not introduce foreign genes. Even considering the great potential of these techniques, and even when the modification is impossible to be differentiated from the ones triggered by spontaneous mutations or conventional breeding (Bortesi and Fischer 2015), their applicability has encountered legislative constraints.

The first developed NPBT strategy is called cisgenesis, which was proposed by Schouten et al. (2006). In this approach, one or more genes of interest can be isolated from a *Vitis* species that could potentially be utilized in conventional breeding and therefore transferred, maintaining its constitutional sequence composed of promoter, gene orientation, and terminator into the cultivar to be improved. There are a few examples of cisgenesis in grapevine: the proof of concept was demonstrated in 2016 using a recombinase system (Dalla Costa et al. 2016). This method allowed the production of genetically modified organism (GMO) plants that were easily selectable using conventional GMO approaches (i.e., antibiotics). Once the GMO plants containing the cisgene(s) were selected, through the activation of a recombinase system, it was possible to excise the transgene used for the detection of the transformed plants from the genomic DNA (Dalla Costa et al. 2016, 2020). Hence, the final products are plants containing only the cisgene(s), with their own promoter and terminator, without any exogenous sequence. Unfortunately, the transgene excision was never achieved completely, producing chimeric plants where the number of cells containing the transgene was limited but still present in the final product. Up to now, no real cisgenic grapevine plants have been obtained, and the difficulties related to this approach limit the application of this method.

The most recent and famous NPBT developed is genome editing (GE). GE, and specifically Clustered Regulatory Interspaced Short Palindromic Repeats (CRISPR)-Cas systems, can insert modifications in specific target DNA sequences without changing other sequences, avoiding the introduction of foreign DNA. Editing the genome is accomplished by applying three components: a protein with nuclease activity (e.g., Cas9, Cas12, Cas13, etc.), a single guide RNA (sgRNA) required to drive the Cas protein to the target sites, and a Protospacer Adjacent Motif (PAM), which is a short sequence upstream of the complementary DNA strand acting as a tag for the target site (Doudna and Charpentier 2014). Once the target sequence is identified, the endonuclease inserts a double-strand DNA (dsDNA) break and consequently stimulates the DNA repair pathway (Panda and Ray 2022), which are the two basic steps for taking advantage of the Cas systems in NPBTs. The CRISPR-Cas system could be used to obtain knock-out mutants, insert a DNA fragment using a donor vector through the homologous recombination system, base edit a target sequence to induce a specific mutation in regulatory sequences, and modify the epigenome (Vats et al. 2019; Khalil 2020; Giudice et al. 2021; Molla et al. 2021). Since the first application of CRISPR-Cas9, new advances have been achieved to improve its efficiency, versatility, and specificity (Gleditzsch et al. 2019; Giudice et al. 2021; Wang et al. 2021; Li et al. 2021b). Moreover, multiplex CRISPR-Cas9 gene editing can also be simultaneously accomplished using different gRNAs to edit a single gene and enhance editing efficiency (Najera et al. 2019), as demonstrated in a recent work where the targeting of *TAS4* and *MYBA7* genes efficiently prevented the accumulation of anthocyanins in the grapevine rootstock Milardet Grasset 101–14 (Sunitha and Rock 2020). On the other hand, genome editing applied to a gene belonging to the bZIP family allowed the over-accumulation of anthocyanin in plant tissue (Tu et al. 2022). More in detail, knocking out the *VvibZIP36* gene generated mutant plants, able to accumulate not only anthocyanin but also other secondary metabolites like naringenin chalcone, naringenin, dihydroflavonols, and cyanidin-3-*O*-glucoside. Although the potential of this technique is immense in woody plants, and specifically in grapevine, this strategy has many limitations, including the transformation method. This led laboratories to develop new delivery methods for plant systems. To date, methods such as the *Agrobacterium*-mediated transformation, nanoparticle platforms, biolistic transformation, or protoplast transfection can fulfill the role of delivering the DNA sequences encoding for Cas and sgRNA(s) into the host plant genome (Duan et al. 2021; Miller et al. 2021). In grapevine, the most used method to deliver CRISPR-Cas9 components into host cells still rely on *A. tumefaciens*-mediated transformation (Sandhya et al. 2020). This method includes the drawback of integrating the T-DNA into the plant genome (Lee and Gelvin 2008), leading to the production of edited plants.

The CRISPR-Cas approach has already been used and validated to enhance food quality, also from the nutraceutical point of view. For instance, the enhancement of provitamin A content in edible parts of relevant crops is considered an important issue and has been previously addressed (Zheng et al. 2021). Besides, genome editing techniques have been successfully applied to enhance nutrient availability

in cereals. For example, in a recent work, Ibrahim et al. (2021) used the CRISPR-Cas system to target genes implicated in the biosynthesis of phytic acid, responsible for the development of grains and involved in the bioavailability of iron and zinc in wheat, rice, and maize. Regarding the nutraceutical improvement of fruit crops, the CRISPR-Cas technology has been successfully used in 'Cavendish' banana cultivar to enhance β-carotene content by targeting the lycopene ε-cyclase (Kaur et al. 2020). Despite several limitations, these examples highlight the potentiality of CRISPR-Cas as a suitable strategy to improve grapevine nutraceutical features. Before being used, both genome editing and cisgenic approaches need the identification of suitable genes. Since these technologies work on one to a few target genes, exploiting traits under polygenic control would be challenging to achieve with the NPBTs. From the legislative perspective, plants containing exogenous DNA sequences (including marker genes necessary to confer resistance to selective chemicals for their early detection) are considered genetically modified organisms. In the case of plant species propagated by seeds, such as most of the herbaceous species (e.g., tomato, wheat, etc.), the elimination of the transgene containing T-DNA cassette could be achieved by co-transformation with different vectors and segregation of marker genes from the gene of interest in the progeny. Sadly, this approach is not applicable in vegetatively propagated plants characterized by long juvenile periods and highly heterozygous genomes. Despite these limitations, present-day plant genome editing applications remain the most versatile tool to improve the sustainability and nutraceutical features of several crops, including grapevine, but further studies are necessary to solve the abovementioned constraints.

10 Conclusion and Future Perspectives

Current grapevines show an extraordinary diversity of multiple health-related compounds, which contribute to their distinct antioxidant activities. Although some non-*vinifera* cultivars might not be a realistic source for commercial breeding programs, the high inter-cultivar variability available within the *V. vinifera* species might be a very relevant source to improve the nutritional quality of current grapes in the near future. In this process, selecting the most beneficial plant material is paramount, including, when available, the selection of the clone with the most adequate characteristics. This wide variability has aided in identifying the genetic architecture and the candidate genes responsible for phenotypic variation, which is the basis for detecting useful markers to assist breeding activities via marker-assisted selection. As summarized in this chapter, the leading role of anthocyanins in berry color and the importance of monoterpenes in muscat flavor (two traits with high relevance in breeding) led to multiple studies that ended up uncovering their genetic determinism. Then, this knowledge was efficiently used to design some genetic markers currently used in grapevine breeding activities. Nevertheless, the genetic architecture underlying the biosynthesis and accumulation of other grape health-related compounds is barely known. For example, the genetic basis of stilbene and stilbene derivatives (like resveratrol) accumulation in grape skins is unknown, although this compound is

known to have multiple positive biological effects on human health. Similarly, little is known about the genomic regions affecting the accumulation of other phenolics with high potential in preventing cardiovascular and other chronic diseases. The function of grapevine miRNA in regulating plant networks has emerged in recent years thanks to several studies, although their possible effect on humans by dietary intake of fresh grapes or juice is still unknown. This limited information is an opportunity for more intensive research studies to identify the genomic regions, genes, and miRNA involved in the biosynthesis of relevant grape health-related compounds. These studies will be benefited from the new generation of molecular tools, technologies, and computational resources available nowadays. In this line, novel genome editing technologies might be key to validating the putative role of some candidate genes on the accumulation of health-related compounds in grape berries. The information obtained from these studies is expected to speed up grapevine breeding activities in modern breeding programs, fostering the obtaining of new grape cultivars of higher nutritional value and antioxidant properties.

Mango Nutrigenomics for Nutritional Security

Nimisha Sharma, Anil Kumar Dubey, and Ramya Ravishankar

Contents

Abstract

Nutrition is all about the study of food and the intake of food to stay healthy. As the community is developing, the world is also facing substantial challenges, such as malnutrition or hyperalimentation. Due to the imbalance of nutrition, chronic disease rates are also drastically increasing in the world. Furthermore, it is leading to high rates of obesity and diabetes in cities and villages. High rise in diet-related disorders such as obesity, cardiovascular diseases, diabetes etc., have resulted in seriousness regarding "Genomics of Nutrition" research worldwide. Therefore, the present global growth of the epidemic needs to be addressed through the promises of nutrigenomics. How genes and diet jointly may affect a person's health and risk of developing the illness could be well studied by nutrigenomics. The goal of nutrigenomics is to study the interaction of nutrients with the genome, proteome, and metabolome,

and it describes the affinity between these specific nutrients and nutrient regimes for quality health. A result of consolidated analyses that comprised fruit and vegetable utilization was connected to preventing coronary artery disease, cancer, and fatality, with similar results seen when fruits were scrutinized independently from vegetables. Mango (*Mangifera indica* L.) is one of the excellent tropical fruits in the world. Most of the mango tree parts are a rich reserve of bioactive compounds, which reside in leaves, bark, and fruit (pulp, peel, and stone). Contemporary studies have proven the presence of significant bioactive components of remedies in fruit waste parts like mango peel and kernel. Mangiferin, flavonoids, catechin, phenolic acids, and gallic acid are a few of the biologically active components contained in this fruit. Hence, the study of nutrigenomics in mango is very important to mitigate malnutrition and coronary diseases.

1 Introduction

Nutrigenomics is defined as the relationship between nutrients, diet, and gene expression. It is a fascinating, upcoming field that explains the role of nutrition on gene expression. It brings together the science of bioinformatics, nutrition, molecular biology, genomics, epidemiology, and molecular medicine. The present chapter highlights the nutrigenomics research in mango. It includes the common outlook of nutrigenomics, relevant diseases, the role of single nucleotide polymorphism (SNP) in gene alteration, diet supplementation, and public consciousness in general and specifically in the fruit crop mango. It is very clear that with the accelerated changes in food habits and lifestyles, individuals are becoming more susceptible to diet-related disorders. Therefore, there is an imperative need to accelerate more research in this area so that the relationship between diet and health could be better understood and everyone could be benefitted from the genomic revolution (Neeha and Kinth 2013).

The new science of nutrigenomics teaches us what specific foods tell your genes and how food affects a person's genes and how a person's genes affect the way the body responds to food. What you eat directly determines the genetic messages your body receives. These messages, in turn, control all the molecules that constitute metabolism: the molecules that tell your body to burn calories or store them. "If you can learn the language of genes and control the messages and instructions, they give your body and metabolism, you can radically alter how food interacts with your body, lose weight, and optimize your health" (Hyman 2006; Aswini and Varun 2010). The nutritional phenotype of individuals could be more precisely accessed *via* the science of omics (Collins et al. 2003; German et al. 2011). It is cardinal to understand human health both by the role of diet in the fluctuating declaration of a genome and the role of genetics in the uncertain responses to diet (Gopalan 1992; Ghoshal et al. 2003; Ghosh 2010; Ghosh and Gorakshakar 2010). It is quite obvious and understandable that individuals respond distinctively to the same dietary consumption. The most manifest goal of actively preventing disease and improving the health of all individuals, of all ages, becomes nutrition's greatest golden chance and its strenuous provocation will be in establishing these basic relationships and implementing them (Gobard and Hurlimann 2009; Godbole et al. 2009). The comprehensive retort of metabolism to the quislings of the lifestyle and food choices, environmental oscillations, the status of nutrients, hereditary background, and epigenetic changes, within an individual at a discrete point in time (e.g., metabolic recessive) is possibly a susceptible and actionable reflection of nutritional and metabolic status (Zivkovic and German 2009). In India, some the diseases like epilepsy, type 2 diabetes, and neural tube defect disease are found to be associated with low nutrient uptake (Menon et al. 2010; Mohan et al. 2007a, b; Naushad et al. 2010). Further, nutritional status was observed in the Indian population (Rao 2001; Raj et al. 2007).

2 Need of Nutrigenomics Study for Fruit Crops Like Mango

It is a treasure house of nutrition and supports the economic stamina of the territory (FAO 2020) in newly industrialized countries, where tropical fruits are mostly grown. The acceleration in worldwide production of tropical fruits elevated rapidly from 5% to as high as 23% in 2019, based on the approximate anticipation that it will be one of the flourishing agricultural sectors (OECD/FAO 2020). Tropical fruits contain multitudinous health-promoting bioactive compounds such as phenolic acids, carotenoids, flavonoids, anthocyanins, vitamins, minerals, fatty acids, and fiber. These fruits comprise tremendously bountiful antioxidants, and phytochemicals rank them a predominant nutritional source with good medicinal properties (Rymbai et al. 2013; Acham et al. 2018; Laldinchhana Lalrengpuii et al. 2020) and assist in accomplishing nutritional security for an ever-increasing world population. As a result, to circumvent nutritional forfeiture and superior merchantability, fruits need to be harvested at the perfect phases. Postharvest deprivation is around 20–40% (Bantayehu and Alemaye 2019; Rajapaksha et al. 2021) because of their highly decaying character. Accommodating an integrated "multi-omics" perspective supports escalating the genomic knowledge and its implementation in developing improved cultivars. A study on 15,000 adults in several US communities emphasized that both high and low percentages of carbohydrates as part of routine uptake were associated with high mortality, although a 50% reduction in carbohydrate uptake lowers the risk (Seidelmann et al. 2018). Higher salt and low-quality fat due to the intake of more animal protein and decreased consumption of fruits and vegetables lead to higher mortality risk (Mazidi et al. 2019). Therefore, the nutritionist suggests to take more veggies in a routine manner as it maintains sound health. Increased intake of certain fruits like mango corresponds with a medley of beneficial health outcomes. It not only lowered the risk of obesity but also decreased chronic illness (Slavin and Lloyd 2012; Dreher et al. 2018).

Cardiovascular diseases and all-cause mortality (Aune et al. 2017) may be auxiliary with low risk with the excessive intake of fruits (apples, pears, and citrus fruits) and vegetables (green leafy and cruciferous vegetables). Studies on the intake of mango and its correlation with nutrient quality and health outcomes emphasize restricted information. Former research using NHANES 2001–2008 illustrated that the intake of mango in kids and adults corresponded with increased nutrients in comparison to those who did not consume mangoes. One cup (165 g) of raw mango give 100 kcal, 3 g dietary fiber, 277 mg potassium, 70 μg folate, DFE, 60 mg vitamin C, 90 μg vitamin A, RAE, 1060 μg beta-carotene, and 12 mg choline (USDA Database 2015). Therefore, it is considered as the supreme source of a healthy diet, although it is still less consumed in the United States. Papanikolaou and Fulgoni (2022) studied nutrient intakes, diet quality, and health results using data from NHANES 2001–2018 in children and adult mango consumers ($n = 291$; adults $n = 449$) compared with mango nonconsumers (children $n = 28{,}257$; adults $n = 44{,}574$). Children who consumed mangoes had a significantly lower daily intake of added sugar, sodium, and total fat, and a higher intake of dietary fiber, magnesium, potassium, total choline, vitamin C, and vitamin D, compared with

nonconsumers. In adults, mango consumers had significantly higher daily intakes of dietary fiber, magnesium, potassium, folate, vitamin A, vitamin C, and vitamin E and significantly lower intakes of added sugar and cholesterol, compared with nonconsumers. Mango consumption was also associated with better diet quality versus mango nonconsumers ($p < 0.0001$). Mango consumption in youngsters was associated with lower BMI *z*-scores, compared with nonconsumption. In adults, BMI scores, waist circumference, and body weight were significantly lower only in male mango consumers compared to mango nonconsumers. The key findings comprise a healthy nutrient pattern (more consumption of vegetables and fruits, whole grains, and less animal protein foods). The present data are affiliated with previously published data documenting numerous benefits associated with the inclusion of fruit within healthy dietary patterns.

3 Mango and Dietary Benefits

Mango (*Mangifera indica* L.) is a member of the Anacardiaceae family (more than 70 genera and 1000 varieties) and is known as the "king of fruits." It is widely consumed due to its exotic flavor, succulence, and sweet taste. Mango leaves, bark, and fruit (pulp, peel, and stone) are rich sources of bioactive compounds (BaCs). It contain proteins [0.36–0.40 g 100 g^{-1} fresh weight (FW) of pulp; 1.76–2.05% (w/w) of peel; 66.1 g kg^{-1} of kernel flour; and 3.0% (w/w) of leaves], vitamin A [0.135–1.872 mg 100 g^{-1} FW of pulp; 15.27 International Units (IU) in kernels; 1490 IU in leaves], vitamin C [7.8–172.0 mg 100 g^{-1} FW of pulp; 188–349 μg g^{-1} FW of peel; 0.17 g kg^{-1} DW of kernel flour; 53 mg 100 g^{-1} dry matter (DM) in leaves], carotenoids (0.78–29.34 μg g^{-1} FW of pulp; 493–3945 μg g^{-1} FW of peel), mangiferin (1690.4 mg kg^{-1} DM in peel; 4.2 mg kg–1 DW of kernel extract), phenolic compounds, dietary fiber (DF), carbohydrates, minerals, and other antioxidants known to have medicinal, nutritional, and industrial benefits. Certain diseases related to oxidative stress need several bioactive compounds due to their antioxidant properties. In mango fruit, only the pulp is used, while all other parts are relinquished that could be better utilized due to its therapeutic properties. Thus, there is an exigency to conduct research on all the bioactive constituents present in mango. These compounds not only provide substantial medical and nutritional properties but also have industrial applications, as well as role in defending the plant. The present-day, ascendant worldwide population leads to the dual challenges of nutritional insecurity and dietary disorders, engendering to health problems such as obesity, cancer, and cardiovascular disease (Clugston and Smith 2002). Mango encloses a complex mixture of antioxidants including xanthones and polyphenols whereby can help protect us from many diseases (Berardini et al. 2005). Mangoes are ingested as fresh fruit or are processed into enriched products such as nectar, puree, squash, or juice. In all instances, only the pulp is used, while the stones and peel are discarded, which results in a considerable waste of organic material. Details of nutrient composition of mango are given in Table 1.

Table 1 Nutrient composition of ripe mango pulp (Masibo and He 2008)

Component	Value (100 g–1 FW)	Component	Value (100 g–1 FW)
Water (g)	78.90–82.80	Calcium (mg)	6.10–12.80
Carbohydrate (g)	16.20–17.18	Phosphorus (mg)	5.50–17.90
Fiber (g)	0.85–1.06 Ash (g)	Iron (mg)	0.20–0.63
Protein (g)	0.36–0.40	Vitamin A (mg)	0.135–1.872
Fat (g)	0.30–0.53	Thiamin (mg)	0.020–0.073
Riboflavin (mg)	0.025–0.068	Ascorbic acid (mg)	7.80–172.00
Niacin (mg)	0.025–0.707	Tocopherol (mg)	1.12
Tryptophan (mg)	3.00–6.00	Lysine (mg)	32.00–37.00
Methionine (mg)	4.00	Lycopene (mg)	0.35

Polyphenolics: polyphenolics (PP) are the most widely distributed secondary metabolites and serve as the dominant antioxidant compounds. Gallic acid and six hydrolyzable tannins constituted 98% of the total polyphenolics. Other polyphenolics reported in mango pulp include flavonoids, xanthones, phenolic acids, and gallotannins (Berardini et al. 2005); m-hydroxybenzoic acid, vanillic acids, and apigenin (Masibo and He 2008); and hydroxybenzoic acid, m-coumaric acid, coumaric acid, ferulic acid, myricetin, mangiferin, catechins, epicatechin, quercetin, ellagic acids (EA), benzoic acid, and protocatechuic acid (Kim et al. 2007; Jasna et al. 2009; Gorinstein et al. 2011) (Table 2).

4 Therapeutic Potentials of Bioactive Compounds from Mango Fruit Wastes

Mango contains a congregation of several bioactive compounds and has been used as a significant herb in the traditional and Ayurvedic medicinal system for centuries (Shah et al. 2010). Bioactive components (mangiferin, flavonoids, catechin, phenolic acids, gallic acid, and gallic acid derivatives) of therapeutic nature were identified in the kernel and peel of mango. The medicinal value of these compounds has been assessed *in vitro* and minimal pre-clinically (Asif et al. 2016). The seed of mango is an important source of therapeutic health benefits (Momeny et al. 2012). Mango contains 20–60% seed of the whole and the kernel is 45–75% of the whole seed fruit (Maisuthisakul and Gordon 2009). Peel is a waste product of the mango processing industry. It consists of 15–20% of mango weight (Masibo and He 2008). Various important compounds are distributed in various concentrations in different parts of mango fruit like seed, peel, and pulp (Ignat et al. 2011;Ghuniyal 2015; Parvez 2016; Torres-León et al. 2016). Several polyphenols like alkylresorcinol, flavonols, gallotannins, xanthones, and benzophenone derivatives have been reported in mango fruit waste; peel and seed kernel antimicrobial (Gadallah and Fattah 2011; Shabani and Sayadi 2014), anti-inflammatory (Robles-Sánchez et al. 2009), antidiabetic (Ediriweera et al. 2017), analgesic, immune modulator (Sahu et al. 2007), and antioxidative (Khandare 2016), Wauthoz et al. 2007).

Table 2 Medicinal properties of polyphenols and vitamins present in mango

Polyphenols	Vitamins/carotenoids	Lupeol
1. Gallic acid acts as a substrate for polyphenol oxidase (PPO) in the pulp 2. Ellagitannins inhibit cancer cell proliferation *in vitro* 3. Gallic acid, mangiferin, myricetin, and flavan-3-ols (e.g., catechin and epicatechin) can prevent membrane lipid peroxidation and protect cells from Parkinson's disease 4. These antioxidants prevent coronary atherosclerosis lowering the levels of low-density lipoprotein cholesterol and triglycerides	1. Ascorbic acid is known to be a potent antioxidant that can eliminate reactive oxygen species (ROS) and maintain the membrane-bound antioxidant 2. Tocopherol, in its reduced state, act as a cofactor for the activity of a number of key enzymes and act as a substrate for oxalate and tartrate biosynthesis 3. Play roles in stress resistance and the synthesis of collagen, hormones, and neurotransmitters 4. Lower risk of degenerative diseases such as cancer, heart disease, inflammation, arthritis, immune system decline, brain dysfunction, and cataracts 5. b-carotene was the dominant carotenoid in mango plays a vital role against degenerative diseases such as cancer, cataracts, and muscular diseases, as well as neurological, inflammatory, and immune disorders	1. It is a pentacyclic triterpene. It possesses pharmacological properties, acting as a strong antioxidant, antimutagenic, anti-inflammatory, and antiarthritic agent 2. Lupeol also prevented 7, 12 dimethylbenz(a)anthracene-induced strand breaks in DNA, thereby reducing the incidence of tumors, lowering the tumor body burden, and causing a significant delay in the latency period of tumor appearance

Mango seed consists of about 29% shells, 68% kernel, and 3% testa (Diarra 2014). The composition of mango seed kernel varies according to different varieties (Barreto et al. 2008). Based on dry weight, 11% fat, 6.0% protein, 77% carbohydrate, 2.0% ash, and 2.0% crude fiber are the average composition of mango seed kernel. Mango seed kernel is high in minerals such as sodium, potassium, phosphorus, calcium, and magnesium (Sandhu et al. 2007). The mango seed kernel encompasses 52–56% unsaturated fatty acids and 44–48% saturated fatty acids (primary stearic acid). The mango seed kernel also comprehends a substantial amount of essential amino acids (lysine, leucine, and valine). Bioactive components that are embodied in mango kernel incorporate phytosterols (stigmasterol, campesterol, and also consists of vitamin K), sitosterol (β-sitosterols), tocopherols, and polyphenols (Soong and Barlow 2006).

The mango peel contains a prominent proportion of total dietary fiber (45–78%), distributed into soluble (16–28%) and insoluble (29–50%) fractions (Ajila et al. 2007). Furthermore, the mango peel also contains cellulose, hemicelluloses, pectin, lipids, proteins, carotenoids, and polyphenols. Apart from this, mango peel also has an appreciable amount of reducing sugars, and due to reducing sugars, mango peel is

also harnessed for the fermentation process, bioenergy, and various value-added products (Barreto et al. 2008). Sandhu et al. (2007) chronicled that mango peel comprises an elevated quantity of pectin (10–15%), and the soaking process before the extraction of pectin increases its yield to about 21%. The bioactive compounds or the polyphenolic connotations in 100 g of mango seed kernel comprise 20.7 mg tannin, 6.0 mg gallic acid, 12.6 mg coumarin, 7.7 mg caffeic acid, 20.2 mg vanillin, 4.2 mg mangiferin, 10.4 mg ferulic acid, 11.2 mg cinnamic acid, and 7.1 mg unknown compounds (Masibo and He 2008). Polyphenols include mangiferin pentoside, quercetin, syringic acid, and ellagic acid (Ajila et al. 2007).

5 Gene and Genomics to Study Nutrigenomics

Genomic data of both eukaryotes and prokaryotes are essential to understand the complete science of food. These genome sequences pave the way to get thorough knowledge about the composition of nutrients and their availability. Further, processing strategies and safety standards could be determined in a systematic way. It allows unlocking of a novel method to the post-genomic era that allows nutritionists to screen the genetic background and observe the omics as a whole (transcriptome, proteome, and metabolome). Genome science has resulted in development of new dietary strategies, targeted to supply the optimum nutrition for every person. These tools are the pivot of the ascending domain of nutrigenomics (Fig. 1a, b). The tools of genomics research come in to use to design markers from the candidate genes. It not only improves the health of humans but other living entities as well. Further, it accelerates the breeding efficiency of crops for quality traits and imparts better resistance against diseases (EFSA 2008; Kogel et al. 2010; Polesani et al. 2010). It allows breeders to design a genotype *in silico* based on the desired phenotype by the knowledge procured from recognizing the alleles at all places in a population. As far as the domains of food science, proteomics offers opportunities for discovering functional foods with metabolic effects. It is exceptionally pertinent in the research of proteins of fauna and flora for designer crop breeding (Agrawal et al. 2010), identifying new biomarkers (Pavlou and Diamandis 2010), and discovering therapeutic targets (Katz-Jaffe et al. 2009). By applying measurements of single biomarkers using traditional biochemical methods (Bakker et al. 2010), metabolomics is more helpful in identifying the complexities of metabolic regulation. Due to polyploidy in plants, genomes tend to be stupendous. Hence, because of the scale of the projects, the progression of entire plant genomes lags somewhat beyond other life forms. However, sequencing in a variety of agriculturally important genomes is complete or nearing completion and is forming the basis of a vital knowledge resource for food research. These genomes appraise from the frame of reference of production with agricultural nutritionists who are still struggling with the fundamental strategies for moving beyond the discovery of genes associated with essential nutrients to maximize their agricultural suitability and nutrient bioavailability under the Darwinian selection pressures that guided the organism's development (Lagaert et al. 2009). A genome of organisms represents the culmination of its evolutionary

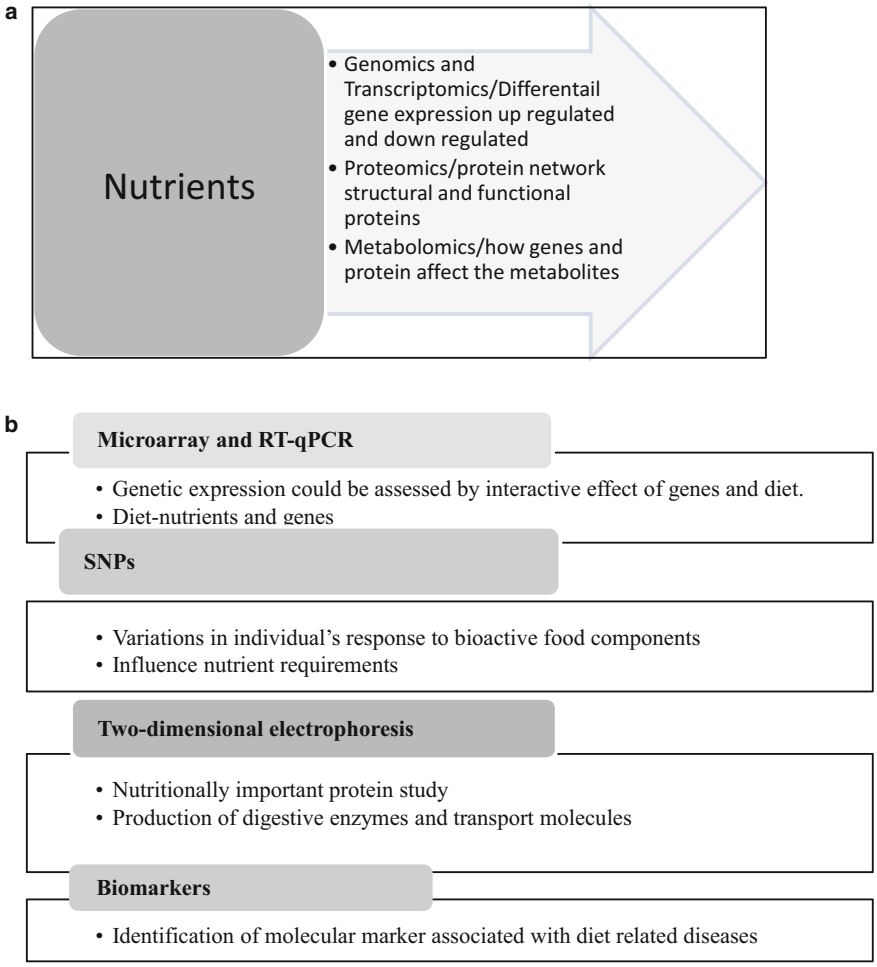

Fig. 1 (**a**, **b**) Conceptual nutrigenomics approach in mango for sound health. The model summarizes the proposed roles for various molecular tools to study the interaction among diet-nutrient and genes

history and the ensemble of genes emerging. Genetics could also influence nutrient and vitamin levels in individuals and changed gene expression. Hence, nutrigenetics emerges as a new science for unlocking the individual pedigree and their composition of nutrients. In mango, molecular markers like simple sequence repeats (SSRs) associated with fruit weight, width, volume, total soluble solid (TSS), titrable acidity, ascorbic acid, and total sugars, additionally reducing sugars, and succors will facilitate screening for varieties/seedlings with preferable fruit traits. Spongy tissue is a consequential physiological disorder influencing the palatable standard of mango drupes, producing a metabolic profile consisting of stress-related and flavor-suppressing metabolites that differ among different

stages of the fruit (Ajila et al. 2007; Masibo and He 2008). Genes also affect the absorption, transportation, and activation of nutrients and vitamins. There are studies on markers like single nucleotide polymorphisms (SNPs) which affect vitamin availability and cause deficiency (Rubab et al. 2022). Recently transcriptome-based grouping study showed the impact of mango fruit as dietary intake on cardiometabolic health that appears to have interindividual variability (Keathley et al. 2022). A study on the expression of genes involved in carotenoids and anthocyanins during ripening in fruit peel of green-, yellow-, and red-colored mango cultivars was carried out (Karanjalker et al. 2018). Various genes involved in bioactive and metabolites' production in mango like *UDP-glucose: flavonoid-Oglycosyl-transferase* (UFGT), *dihydroflavonol* (UFGT), *dihydroflavonol 4reductase*, and *anthocyanin synthase* are responsible for flavonoid synthesis (Karanjalker et al. 2018). Similarly, *lycopene-β-cyclase* is responsible for carotenoid synthesis. The gene *MiUFGT2* synthesizes cyanidine-3-O-monoglucosides and peonidin-3-O-glucosides bioactive compounds (Bajpai et al. 2018). Transcriptomes (a set of RNA) are transcribed at a cellular level. Functional products derived through RNA not only affect physiological functioning but also impart knowledge about disease progression (Passos 2015). Although, gene response may be variable, environmental interaction also change the expression of the cell. Some nutrition composition improves the health of humans *via* transcriptomic modulation. Further, "Omics" science could identify new therapeutic targets relevant to variable conditions (Chambers et al. 2019). The transcriptomic analyses provide insights to identify new metabolic pathways affected by mango consumption in individuals who responded to the intervention (Ducheix et al. 2018; Stefania et al. 2021). A network of pathways such as hydrogen peroxide, cofactor catabolic and metabolic processes, gases (oxygen, carbon dioxide) transport, and transcriptional regulation (by *RUNX1* and *TP53*) play a key role in this process. Metabolic pathways also modulated by mango consumption such as *RUNX1* have been demonstrated to be one of the most frequently mutated genes in several hematological malignancies (Sood et al. 2017). Further, *TP53* was found as expressed protein variant in human carcinoma (Khurana et al. 2016). Insulin resistance, diabetes, cardiovascular disease, and chronic diseases like cancer and kidney illness are regulated by hydrogen peroxide metabolism (Lismont et al. 2019). Previous studies with mango extracts have demonstrated beneficial health effects related to these conditions (Awodele et al. 2015; Fomenko and Chi 2016; Imran et al. 2017). Differential gene expression includes *TNFAIP3, API5*, and *TAL1*, etc., as up- and downregulated genes, that regulate the physiological processes. Based on these mechanistic findings, it appears that mango consumption could have a beneficial cardiometabolic effect. Moreover, a reduction in blood pressure following mango consumption is observed (Fang et al. 2018). Research on mangiferin component shows key inflammatory pathways involved in cancer progression (Gold-Smith et al. 2016; Imran et al. 2017; Piccolo et al. 2022). These mechanistic findings provide partial evidence supporting the anticancer potential of mangos.

6 Research Gaps and Future Prospects

The propagation of tropical fruit trees for ameliorating fruit traits is intricate due to several constraints like long gestation period, heterozygous nature, variable embryonic nature, and lack of high-quality genome sequences (Mathiazhagan et al. 2021). New advanced molecular tools supplement conventional breeding efforts. Numerous genomics strategies have recently progressed to accommodate and compliment to traditional breeding methods. DNA-based markers associated with fruit burgeoning and fruit quality characteristics were identified in perennial fruit crops. Furthermore, it could be utilized in association mapping.

7 Conclusion

With the availability of genome sequences of fruit crops, identification of SNP variants/Indels, QTLs, functional genes, etc., could be utilized in quality fruit production. Hence, the fruit superiority was accredited through multi-omics perspectives. Moreover, the recognition and measurements of transcripts involved in sugar-starch metabolism, fruit development and ripening, genomic selection (GS), and genetic modifications *via* transgenics have paved the way for studying gene function and developing varieties with improved quality traits of fruit crops by overcoming long breeding cycles.

Abstract

Not just in India, but all around the world, papaya (*Carica papaya* L.) is considered one of the most significant fruits. It is grown in tropical and subtropical areas all over the world. Over 37 nations around the world currently cultivate it. One of the biggest issues causing economic losses in the world is the papaya ringspot virus (PRSV-P). Therefore, producing resistant cultivars with good fruit quality and yield is the primary goal of papaya improvement. The fruits are abundant in vitamins, minerals, and other chemical components that have been linked to improved health. There are bioactive components in various plant parts, viz., shoots, leaves, immature and ripe fruit, latex, roots, and seeds, and these compounds possess antioxidant, anticancer, anti-inflammatory, wound–healing, and antifungal properties. The genetic resources have potential genes for both abiotic and stresses that could be exploited in the crop improvement program combining both traditional and modern molecular approaches like genetic engineering to achieve the set target.

Keywords

Papaya · Nutritional composition · Medicinal properties · Genetic resources · Genetic diversity

1 Introduction

1.1 Agricultural Importance

One of the most significant and profitable fruit crops in the world is papaya (*Carica papaya* L.). It is native to Tropical America (Central America and Mexico) and a member of the Caricaceae family. The viral disease, papaya ringspot virus (PRSV-P), and postharvest losses are the two most serious problems affecting the papaya industry globally. The postharvest losses are quite high, ranging from 30% to 60% (Prasad and Paul 2021), while the economic yield losses due to PRSV disease are as high as 95% of expected yield (Babu and Banerjee 2018), rendering papaya orchards economically unviable.

1.2 Nutritional Composition

The papaya fruit is incredibly high in minerals, including iron, calcium, potassium, magnesium, and phosphorus, as well as carbohydrates and proteins. Additionally, it is a plentiful source of vitamins, with 100 g of fruit providing 2020 IU of vitamin A, 40 mg of vitamin B1, and 46 mg of vitamin C (Alara et al. 2020). The fruit contains about 85–90% water and total sugars from 10% to 13%. It is also abundant in carotenoids, the main ones being lycopene, β-cryptoxanthin, and β-carotene (Daagema et al. 2020).

1.3 Limitations of Conventional Breeding and Rationale for Intervention of Advanced Strategies

The papaya ringspot virus (PRSV-P) is one of the major problems in almost all papaya-growing regions of the country and worldwide. Since this illness affects most cultivars of the genus *Carica*, one long-term solution is the introgression of a gene from a wild related. The other breeding objectives are to develop dwarf/semi-dwarf stature cultivars having gynodioecious nature with good fruit quality, shelf life, and dual purpose (table and processing) having resistance to major fungal diseases and abiotic stresses like cold tolerance. The conventional breeding method takes a very long period as attaining homozygosity for the specific traits takes several generations (Cortes et al. 2017). Hence, there is a need to integrate the modern biotechnological tools like marker-assisted selection (MAS), genetic engineering, genome-assisted breeding approaches like targeting-induced local lesions In genomes (TILLING), genome-wide association studies (GWAS), genomic selection (GS), and genome editing to develop superior cultivars.

2 Nutritional Composition

2.1 Chemical Composition

Approximately 60% portion of the ripe fruit is eatable per 100 g of fresh fruit and is composed of approximately 85–90% water and 10–13% total sugars. The major sugars are 29.8 g of glucose, 21.9 g of fructose, and 48.3 g of sucrose per 100 g of edible fruit. It contains an abundant amount of vitamins and minerals but is very low in calories. It has 200 kJ/100 g of energy and 10% carbohydrates per 100 g of edible fruit (Anjana et al. 2018). The sensory properties are caused by a number of volatile chemicals, including esters, hydrocarbons, terpenes, alcohols, aldehydes, benzyl isothiocyanate, ketones, and other organic acids. The highly abundant volatile compound of papaya is linalool, which occurred in 94% in solo varieties, whereas the oxide *cis*-linalool is abundant in Taiwan varieties (Serra et al. 2016). Some of the major fatty

acids present in papaya seeds are palmitic acid (13.90–19.7%), oleic acid (70.84–79.10%), stearic acid (4.20–6.68%), linolenic acid (0.17–0.90%), gadoleic acid (0.51%), and arachidic acid (0.38–1.10%) (Dotto and Abihudi 2021). According to Saeed et al. (2014), pulp contains various nutritional components like vitamin: ascorbic acid (25.07–58.59 mg); phenolics: ferulic acid (277.49–186.63 mg), *p*-coumaric acid (229.59–135.64 mg), and caffeic acid (175.51–112.89 mg); and carotenoids: lycopene (0.36–3.40 mg), β-cryptoxanthin (0.28–1.06 mg), and β-carotene (0.23–0.50 mg). Papaya has four types of cysteine protease enzymes, viz., papain (less than 10%), glycyl endopeptidase-III and IV (23–28%), chymopapain A and B (26–30%), and caricain (14–26%) (Saeed et al. 2014).

2.2 Chemical Type and Structure

Papaya leaves contain flavonoids, saponin, tannin, alkaloids, and glycosides. The fruit is also an excellent source of carotenoids with major carotenoids lycopene (0.36–3.40 mg), β-cryptoxanthin (0.28–1.06 mg), and β-carotene (0.23–0.50 mg) (Saeed et al. 2014). The root of papaya contains benzyl isothiocyanate and glucosinolates carposide. The papaya seed oil also contains flavonoids, kaempferol, and myricetin (Adachukwu et al. 2013). Papain and chymopapain enzymes occur in the unripe fruit, and there are also some enzymes present in latex and other parts of the plant, viz., caricain, papain, chymopapain, and protease omega (Teng et al. 2019). Some enzymes are reported in papaya latex, that is, chitinase, cysteine endopeptidases, and glutaminyl cyclase (Daagema et al. 2020).

Papaya leaves are also rich in a variety of bioactive compounds such as flavonoids like quercetin, kaempferol-3-rutinoside, quercetin 3-rutinoside, and myricetin 3-rhamnoside (Nugroho et al. 2017); carotenoids like lycopene, zeaxanthin, cryptoxanthin, β-carotene, and violaxanthin; and other phytochemicals such as kaempferol, myricetin, and quercetin. The leaves are rich in phenolic compounds, viz., "kaempferol, protocatechuic acid, quercetin, 5,7-dimethoxy coumarin, caffeic acid, p-coumaric acid, and chlorogenic acid" (Canini et al. 2007).

There are many compounds present in various papaya portions, viz., pulp: linalool (Daagema et al. 2020); leaves: dehydrocarpaine I and II, carpaine, psudocarpaine, and alkaloids (Teng et al. 2019); latex: glutaminyl cyclase; shoots: quercetin, chitinases class II and III, kaempferol, and cysteine endopeptidases; and roots: cyanogenic compounds. The benzyl glucosinolate and their degradation products like benzyl isothiocyanate are present in all the tissues of papaya. According to Ghosh et al. (2017), papaya seeds have a good amount of oleic acid and the antifertility compound 1,2,3,4-tetrahydropyridin-3-yl-octanoate. The papaya pericarp, pulp, and seed also contain benzyl glucosinolate and benzyl isothiocyanate.

An important nutritional quality aspect of papaya fruit is regarded to be its pulp color. Generally, the red pulp types are rich in lycopene and the yellow pulp types are rich in carotenoids. There are some phenolic compounds also identified in papaya, viz., "ferulic acid (277.49–186.63 mg), p-coumaric acid (229.59–135.64 mg), and

Table 1 Important chemical compounds present in different parts of papaya

Plant parts	Compounds	References
Fruits	Vitamins: vitamins A, C, B1, B2, and B3 Acids: malic acid, citric acids, and amino acid Volatile compounds: linalool, benzyl isothiocyanate, *cis* and *trans* 2, 6-dimethyl-3, 6 expoxy-7-octen-2-ol Alkaloid: α; carpaine and benzyl-β-d glucoside	Adedayo et al. (2021)
Seeds	Carpaine, benzyl isothiocyanate, benzyl glucosinolate, glucotropaeolin, benzyl thiourea, caricin, and myrosin	Moses and Olanrewaju (2018)
Latex	Papain and chymopapain, glutamine cyclotransferase, chymopapain A, B, and C, peptidase A and B, and lysozymes	Ngafwan et al. (2018)
Leaves	Carpaine, pseudocarpaine, and dehydrocarpaine I and II, choline, carposide, vitamins C and E	Naureen et al. (2022)
Shoots	β-Sitosterol, glucose, fructose, sucrose, and galactose	Naureen et al. (2022)
Roots	Arposide and myrosin	Singh et al. (2021)

caffeic acid (175.51–112.89 mg)" per 100 g of fresh fruit that have antioxidant and antimicrobial properties (Alara et al. 2020) (Tables 1 and 2).

2.3 Medicinal Properties

2.3.1 Dengue Fever

Dengue fever is an infectious ailment in human beings that is caused by dengue viruses and spread by mosquitoes. Because it can occasionally induce excruciating pain in muscles and joints that feel like bones are breaking, this illness was previously known as break-bone fever. The major critical condition in case of dengue fever is thrombocytopenia, which can be alleviated by the use of papaya leaves (Sarker et al. 2021). Studies conducted in vitro revealed that papaya leaf extracts have the ability to stabilize membranes and, at lower doses, reduce heat-induced and hypotonicity-induced hemolysis of erythrocytes in both healthy and dengue-infected persons (Ranasinghe et al. 2012); thus, it may be useful in preventing platelet lysis (Fig. 1).

2.3.2 Anti-Inflammatory Property

This activity found in papaya is because of the presence of enzyme cysteine proteinases. Papain was found to be safe and effective in the treatment of chronic inflammation. The anti-inflammatory property of papaya seeds was confirmed by Amazu et al. (2010)

2.3.3 Anticancer Activity

Due to the proteolytic enzymes present in papaya, which convert protein and the fibrin cancer cell wall into amino acids, the fruit possesses anticancer properties. Isothiocyanate (the degradation product of benzyl glucosinolate) is also very

Table 2 Prominent bioactive compounds present in different parts of papaya: structure and properties

Enzymes				
Papain		Unripe fruit latex	Anti-inflammation, wound healing	Azarkan et al. (2003)
Chitinase		Papaya latex	Antifungal	Azarkan et al. (2006)

Fig. 1 Health-related beneficial role and products of papaya. (Sharma et al. 2020)

effective against various cancers, viz., colon, lung, breast, pancreas, prostate, and leukemia. The aforementioned enzymes have the ability to prevent the growth and development of cancer cells (Fauziya and Krishnamurthy 2013).

2.3.4 Antifungal Activity

The latex of papaya combined with the chemical fluconazole can inhibit the growth of *Candida albicans* (Giordani et al. 1997). Antifungal activity is attributed to latex proteins, and for complete inhibition of fungal growth the minimum quantity required is about 138 mg/dl (Dwivedi et al. 2020).

2.3.5 Wound-Healing Activity

Papaya has wound-healing property due to the presence of proteolytic enzymes. Papain is very effective in the treatment of ulcer in rats by blocking the acid secretion (Chen et al. 1981). Papain is a nonspecific cysteine proteinase that can digest the substrates of necrotic tissue (pH varied from 3.0 to 12.0). These proteolytic enzymes decrease the risk of oxidative tissue damage due to the increase in hydroxyproline content; additionally, they are capable of burn-healing activities (Chen et al. 1981) (Fig. 2 and Table 3).

2.4 Agronomic and Postharvest Techniques

As well as being consumed as fresh fruit, it can also be processed into various value-added goods while retaining the nutritional value. The raw papaya fruits can be processed into tutti-frutti, pickle, jellies, and candies, while ripe fruit can be processed into canned papaya, ready-to-serve fruit beverages, nectar, pulp, fruit bar, bars, toffee, osmotically dehydrated products, minimally processed products from cut pieces of ripe papaya, and also it can be blended with other fruit pulps to use

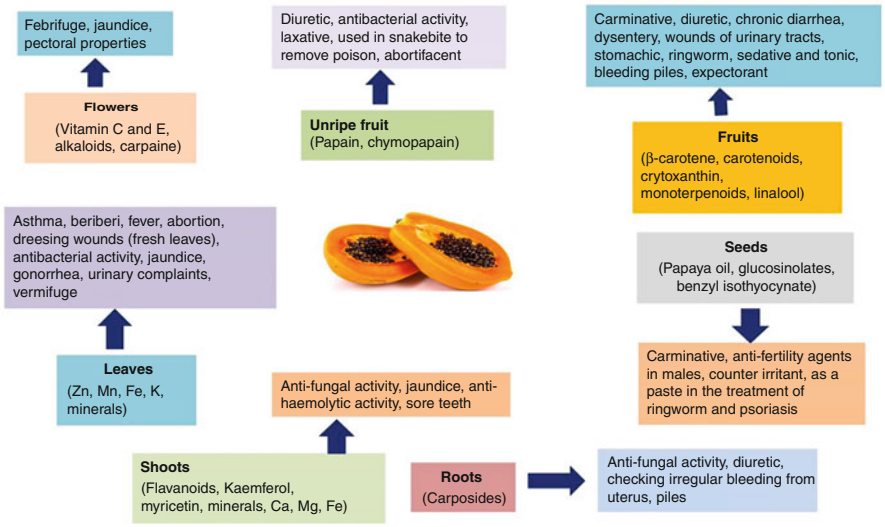

Fig. 2 Medicinal benefits of different parts of papaya

Table 3 Therapeutic benefits of various papaya portions (Anjana et al. 2018)

Part	Methods of preparation	Therapeutic uses
Peel	Use peel as a mask on your face for around 20 min	To remove skin and facial blemishes
	Peel and lemon juice apply to the scalp for 20 min	Against dandruff
	Olive, almond, and rose oil are used to stew papaya peel, and the resulting papaya oil is then used with nectar and rose water to apply onto the skin	Works as a skin tonner and skin cleanser
Fruit	Consumption of fresh fruit	Indigestion, clogging, farts, and enhanced hunger
	Apply unripe fruit on the influenced zone	Pimples, skin inflammation, and mouth ulcer
Leaves	Leaf extracts	Treating dengue fever, nervous pains, and elephantoid growth; and used to treat injuries and wounds
Root	Root infusion	Employed to treat syphilis and lessen urine concretions
Seeds	Crisp or dried seeds	Bacteriostatic, bactericidal, and fungicidal
Flowers	Flower extract	Treating jaundice
Latex	Latex of plant	Curing psoriasis, ringworm, and dyspepsia

either in juice or fruit bar. Blending of papaya to an extent of 30% produced acceptable quality of juice (Pathak et al. 2021). Papaya sauce from the extracted pulp of ripe fruits has been prepared by Ang et al. (2017). The papain is milky latex extracted from mature green fruits when lanced. It contains a protein hydrolyzing

Table 4 Utilization of different edible coatings to enhance the shelf life of papaya

Coatings	Features	References
Burkholderia cepacia B23 plus calcium and chitosan coating	The addition of $CaCl_2$ (3%) to the combination treatment raised the calcium content of the fruit (to 81%) and prolonged its shelf life	Rahman et al. (2012)
Chitosan plus peppermint essential oil	Chitosan (1%) plus peppermint essential oil (0.2%) results in less peel discoloration, good color development, and higher marketability	Picard et al. (2013)
Chitosan plus extract of propolis	Chitosan (1%) in combination with propolis ethanolic extract (5%) improved postharvest quality of fruit	Barrera et al. (2015)
Aloe vera gel	Shelf life extended up to 15 days and during storage color development improved by adding aloe vera gel coating (1.5%)	Sharmin et al. (2016)
An essential oil and carboxymethylcellulose coating (CMC)	Postharvest quality is maintained and the severity of postharvest disease is decreased when CMC is used in combination with *Lippia sidoides* essential oil	Zillo et al. (2018)

enzyme (protease or proteolytic enzyme) that has several industrial and medicinal uses. The demand for papain has significantly expanded during the last few years, and its production on commercial scale has started. The nutritional values in the processed products (tutti-frutti, pickle, jellies and candies, etc.) were estimated after 6 months of storage and found that they remain constant but the stability of dried papaya is only up to 30 days (Prasad and Paul 2021).

The use of edible coatings can improve shelf life and appearance of papaya fruit, and reduce microorganism growth and decay after harvesting, improving its postharvest quality (Prasad and Paul 2021). The quality of the fruit can be enhanced by immobilizing the fresh-cut fruit in multilayered antimicrobial coatings (chitosan and pectin) (Brasil et al. 2012). Coating of papaya fruit with chitosan (1%) plus peppermint essential oil (0.2%) results in less peel discoloration, good color development, and higher marketability (Picard et al. 2013). Fruits that are packed in HDPE and kept under evaporative cooling maintain better fresh weight and contain higher TSS and vitamin C (Table 4).

2.5 Requirement of Biotechnological Intervention

Genetic engineering is a vital approach in genetic improvement of papaya that alters one or more desirable characters in elite varieties without interfering with the prevailing traits. The development of effective gene insertion techniques to impart the desired features has helped advancements in genetic engineering. A total of 21 quantitative trait loci (QTLs) were related to seven fruit quality attributes, viz., length and breadth of fruit, sweetness and thickness of pulp, skin freckle, fruit firmness, and fruit weight (Nantawan et al. 2019). These traits could be improved through biotechnological intervention in papaya. The shelf life of papaya fruit can also be improved through co-suppression ACC oxidase genes (Lopez-Gomez et al. 2009). A bacterial color

complement test confirmed that the gene *CpCYC-b* controls papaya pulp color. Tomato chloroplast-specific *lycopene b-cyclase* and *CYC-b* is a DNA marker that is closely associated with flesh color co-localized on physical map contigs containing cDNA probes. So, papaya fruit pulp color and lycopene content can be improved through the incorporation of gene from tomato (Blas et al. 2010). The development and maturation of papaya fruit are regulated by the *CpGRFs* genes. The expression or overexpression of these genes can regulate the growth and ripening of fruit (Li et al. 2021). The markers, which are linked with many fruit quality parameters, including fruit size, pulp color, lycopene content, and carotenoid content, might facilitate marker-assisted selection and also improve quality in a short period. However, there are only a few attempts in this regard, and there is a need for more effort using modern next-generation sequencing (NGS)-based methods like QTL-seq, GWAS, etc.

3 Genetic Resources

Papaya belongs to the genus *Carica,* which is monotypic, and all the commercial varieties come under the genus *Carica*. The highly cross-pollinated nature of crop and seed multiplication is the cause of the diversity currently existing in germplasm (Chavez-Pesqueira and Nunez-Farfan 2017). Continuous research efforts made in this crop have resulted in the development of more than 25 improved cultivars. The papaya germplasm ranges from various commercial cultivars, wild types, local land races, and exotic collections. Some species of the genus *Vasconcellea* are tightly associated with *C. papaya* than others, which influence the successful use of *Vasconcellea* in papaya improvement. Commercially available cultivars are generally divided into two groups: gynodioecious (hermaphrodites and females) and dioecious (males and females). As the crop is commercially propagated through seeds, the purity is being maintained through selfing and sib mating. Several organizations around the world are involved in the conservation of germplasm in the form of seed bank and field gene banks.

However, the global germplasm of papaya has not been organized into an accessible database. The USDA site of the U.S. National Plant Germplasm System in Hilo, Hawaii, reports 153 accessions of *C. papaya* and some *Vasconcellea* spp.; EBDA, Bahia (82 accessions), EMBRAPA Mandioca e Fruticultura, Cruz das Almas, Bahia (141 accessions), and IAC Campinas, São Paulo (169 accessions); Colombia at University Nacional Medellín and CORPOICA (83 accessions) with additional accessions at other locations; and Malaysia (72 accessions) (Vincent et al. 2019). Approximately 150 papaya germplasm samples are being preserved in field gene banks in India (Indian Council of Agricultural Research – All India Coordinated Research Project or ICAR-AICRP) at a number of ICAR institutes, including the Indian Agricultural Research Institute-Research station, Pune, Maharashtra (17), TNAU-HC& RI, Coimbatore, Tamil Nadu (89), and ICAR-IIHR-National Active Germplasm Sites, Bengaluru, Karnataka (49) (http://www.aicrp.icar.gov.in) (Table 5).

Table 5 Genetic resources of different wild species as potential gene donor

Wild genetic resources	Specific traits	References
V. cundinamarcensis (syn. *V. pubescens)*	Resistant to PRSV-P, blackspot and *Erwinia* species, cold tolerant	Badillo (2000), Eeckenbrugge et al. (2014)

V. goudotiana	Resistant to *Erwinia* species, *Phytophthora,* and bacterial canker *(Erwinia papayae)*	Eeckenbrugge et al. (2014)
V. parviflora	Resistant to Paw *paw die back (Mycoplasma) and interspecies* for *V. cundinamarcensis*	Drew et al. (1998)
V. quercifolia	Resistant to PRSV-P	Badillo (2000)
V. stipulata	Resistant to PRSV-P and cold tolerance	Badillo (2000), Horovitz and Jiménez (1967)
V. candicans	Resistant to PRSV and distortion ringspot virus	Badillo (2000), Horovitz and Jiménez (1967)
V. heibornii	Resistant to PRSV and distortion ringspot virus	Horovitz and Jiménez (1967)
V. monoica	Monoecious, leaves as vegetable	Swingle (1947)
V. pentagona	Resistant to frost	Singh (1964)
V. pentandra	Cold tolerant	Hamilton and Robinson (1937)

4 Classical Genetics and Traditional Breeding

Traditional breeding and classical genetics made significant advancements and generated information for a variety of quantitative and qualitative characteristics. Superior cultivars have been developed through a variety of breeding techniques, including plant introduction, inbreeding and selection, hybridization and selection, mutation, backcross breeding, and marker-assisted selection.

4.1 Genetics of Health-Related (HR) Genes

The knowledge of various genes and their controlling mechanism, which affects economic traits, will be helpful in the selection of superior genotypes for imparting specific traits. Thus, once information about genetic pattern is generated, breeding programs are initiated with the aim of incorporating a particular desirable trait. Fruit weight has direct positive correlation with fruit size and is controlled by multiple alleles. However, the heterosis in fruit weight is demonstrated over the superior parent in the presence of overdominant gene action (Chan 2001). Total soluble solids

(TSS) and flavor are governed by a single homozygous recessive allele, which are important traits for taste and quality of fruit while there are some reports indicating that the trait TSS is determined by quantitative genes with additive effects (Rimberia et al. 2018). Pulp color is an important trait in relation to fruit quality and is controlled by a single gene. The yellow color (*R*) is predominating over red (r) and different shades of pink may be attributed to the influence of modifier genes. All red pulp (*rr*) varieties will breed true for pulp color. The green color of fruit peel is controlled by a single dominant gene (*G*) and yellow (*gg*) is governed by double-recessive gene (Aryal and Ming 2014).

Traditional breeding has been used effectively to improve qualitative traits that are directly associated with other traits, for example, carotene is linked with orange flesh color (Rimberia et al. 2018), gynodioecious is linked with fruit shape (Ming et al. 2007), and parthenocarpy is linked with seedless; these are typical examples of selection using morphological markers.

4.2 Breeding Objectives

Current breeding goals in papaya develop gynodioecious-type cultivars that are dwarf or semi-dwarf in stature and good fruit quality (high TSS, less cavity percent, good shelf life, and high pulp recovery) coupled with resistance to major fungal, viral diseases, and abiotic stress like cold tolerance.

4.3 Limitations of Conventional Breeding and Rationale for Molecular Breeding

The selection of traits, which is primarily based on morphological parameters that are affected by environmental factors, is the primary drawback of traditional breeding (Jat et al. 2021). Traditional breeding has paved the way for the development of important quantitative traits like fruit size, early maturity, and fruit yield, which is the most effective method for selection of multiple allele traits. PRSV is the major problem faced by the papaya industry, and attempts are being made to develop PRSV-resistant types through traditional breeding by incorporation of resistance from the wild relative, viz., *Vasconcellea cauliflora, V. stipulata, V. cundinamarcensis,* and *V. quercifolia*. Resistance genes from wild relatives are typically difficult to incorporate into cultivars due to cross-incompatibility between the two genera, early embryonic abortion, nonviability, lethality, and sterility of hybrid seeds. However, the postfertilization barrier to intergeneric crosses can be overcome by using growth hormones and nutrient solution to reduce embryo abortion. Sucrose at 5% was noticed to break the intergeneric barriers by promoting pollen germination (Pujar et al. 2019).

Due to their nondisruptive nature, ability to evaluate many characteristics simultaneously, and ability to eliminate trait-related environmental variation, molecular markers have the potential to overcome the constraints of conventional breeding

techniques. But in molecular-assisted breeding, the traits that are important must be identified during marker identification and a segregating population must be created in order to produce the traits. Recently, many advanced technologies of genome sequencing, linkage disequilibrium (LD) mapping, or genome-wide association studies (GWAS) have been developed for the identification of trait of interest and their important QTL regions (Zhu et al. 2008). As PRSV is the major problem in the papaya industry, molecular breeding and genome editing technologies (CRISPR Case-9) can help us to overcome the problem.

5 Genetic Diversity Analysis

The germplasm of papaya shows considerable genetic variability for various horticultural importance traits. There are various criteria that can be used in the assessment of genetic variability, including pedigree records, morphological characteristics, and molecular markers. According to Baxy (2009), comparable external morphological features that are specific to the environment and developmental stages have historically been the basis for plant taxonomy. The fact that molecular markers can be found in all plant tissues and are unaffected by environmental changes makes them ideal for plant identification. Inter-simple sequence repeats (ISSRs) are significant molecular marker that are widely used to identify various plant species and cultivars (Ahmad et al. 2010).

5.1 Phenotypic Diversity Analysis

Phenotypic characterization using descriptors related to leaf size and shape, types of flowers and inflorescence, and fruit size and shape has assisted in understanding the divergence of papaya germplasm and identifying suitable cultivars to enhance the genetic gain in papaya improvement programs (Silva et al. 2017). The flower and fruit traits are the most economically distinctive phenotypic traits used as the selection criteria for a genotype. According to the sex type of the tree, the inflorescence and flowers vary, and cultivars are basically either gynodioecious or dioecious. The female plant's inflorescence peduncle is short (2.5–6 cm long) than the male inflorescence peduncle (60–90 cm to 150 cm). The female inflorescences bear spherical- to ovoid-shaped fruits. Hermaphrodite plants have short inflorescence peduncles, are intermediate to unisexual in nature, and produce pear-shaped fruits with varying degrees of neck constriction as per the variety (Santa-Catarina et al. 2020).

As mentioned, the fruit shape corresponds to the flower type, and the flower type corresponds to plant sex. Fruit size typically ranges from 10 to 50 cm in length, depending on the shape of the fruit, which can be spherical or pear-shaped. Fruits ranged in weight from 0.35 kg to 3.6. The most divergence traits are fruit weight, number of fruits, firmness of pulp, and TSS (Santa-Catarina et al. 2020), plant height, canopy diameter, stem diameter, the average number of leaves, and an insertion height of first fruit (Silva et al. 2017).

5.2 Diversity Analysis Using DNA Markers

SSR marker libraries have been used in research, and their applications have helped in molecular-assisted selection and genetic variability evaluation. Genetic diversity analysis using 20 simple sequence repeat (SSR) markers was carried out on 164 accessions from Costa Rican and 20 known cultivars from the U.S. Department of Agriculture (USDA) (Brown et al. 2012). Genetic diversity was assessed using two SPAR (single-primer amplification reaction) techniques, that is, random amplified polymorphic DNA (RAPD, 16 primers), ISSR (12 primers), for 13 cultivars and lines, and they found a great similarity among these cultivars, Pusa delicious and Pusa Giants, Pusa Dwarf and CO-7, and Pusa Nanha and CO-2 (Sabara and Vakharia 2018). In another study, analysis of morphological traits (fruit yield traits) revealed significant diversity among the 20 genotypes of papaya, with a total of 89 polymorphic and 45 monomorphic alleles being found out of a total of 134 alleles. The diversity of morphological attributes is closely resemblance to molecular diversity analysis (Suvalaxmi et al. 2019).

5.3 Relationship with Other Cultivated Species and Wild Relatives

Papaya is a member of the Caricaceae family and is divided into six comparatively small genera such as *Carica*, *Vasconcellea*, *Horovitzia*, *Jacaratia*, *Jarilla*, and *Cylicomorpha* (Badillo 2000). The best-known and most significant species in terms of economic importance belong to the genus *Carica*, which has just one species (*Carica papaya*). The largest genus, *Vasconcellea,* has 21 species and was recently reclassified as a separate genus rather than a subgenus of the genus *Carica* (Badillo 2000). Accurate species identification can be difficult as natural interbreeding between species in the genus *Vasconcellea* is easy. The existence of hybrid *Vasconcellea* × *heilbornii and* its several variants, not all of which have been characterized, may provide an explanation. The commercially grown varieties of *V. cundinamarcensis* and *V.* × *heilbornii* cv. *babaco* possess untapped potential as sources of the proteolytic enzyme papain and genes for genetic improvement of papaya (Badillo 1993).

Many molecular studies indicated that there is a large genetic gap between *Vasconcellea* and *Carica*. Studies on intraspecific relationship among *Vasconcellea* genus showed that intraspecific *cpDNA* variation was observed in *V. microcarpa*, and *Vasconcellea* × *heilbornii* was the most diverged species (Droogenbroeck et al. 2004). Intergeneric hybridization of the *Vasconcellea* and *Carica papaya* species has shown that Arka Prabhath proved to be a good combiner with *Vasconcellea* spp. (Pujar et al. 2019).

5.4 Relationship with Geographical Distribution

According to Rimberia et al. (2018), papayas are commonly planted throughout the world's tropical and subtropical regions and are native to Mexico or South Central America. They are also said to be able to adapt to a broad spectrum of environmental

variables. Although it thrives between 36°N and 36°S, the majority of papayas are produced between 26°N and 26°S. The geographical distribution of the papaya population, both wild and cultivated, can be used to find the collection locations for their utilization and conservation. The geographical distribution of papaya is widespread in Mexico. Variable climate (latitude, altitude, temperature, and rainfall) had the greatest influence on the ecological and geographic distribution of papaya. Papaya distribution has been better understood by the identification of 16 eco-geographical areas based on climatic and edaphic geophysical characteristics (Salinas et al. 2022). The promising dispersal of papaya species in Mexico covered a total area of 114,546.5 km^2, with the coasts of Chiapas and the Gulf of Mexico possessing the highest potential. Three zones, namely the coast of Chiapas, the north part of Guerrero, and the southern region of Veracruz, are described as the highly promising spreading areas of cultivated papaya. This is done to gather genetic material and discover the many types of adaptations that exist in Venezuela's various geographical regions. The *Vasconcellea* species distribution zones have been known using the FloraMap software (Trujillo et al. 2018). DIVA-GIS software has also been used to know the distribution zones and patterns of 21 *Vasconcellea species*.

6 Molecular Mapping and QTLs for HR Genes

There have been numerous papaya genetic molecular linkage maps created during the past 70 years. Hofmeyr produced the first genetic molecular map in 1939, and it was based solely on three morphological markers, that is, flower color, types of sex, and stem color. The initial map covered a region of 41 cM and revealed that stem color is associated with flower color at a distance of 17.3 cM between the loci and distantly associated with sex type at a distance of 41 cM. This map could not be used to predict sex type due to its poor resolution. It took over 60 years for the next genetic map to be created. A second genetic molecular map was based on 62 RAPD markers and created a sex-type locus on linkage group 1. A total of 999.3 cM and 11 linkage groups (LGs) were covered by the 62 markers, with a mean distance of 19.6 cM between contiguous markers (Sondur et al. 1996). The heterozygote genotype was suppressed due to the dominant character of RAPD markers, which led to increased map distances between markers. Nevertheless, using eight more markers, the sex-type locus, *Sex1*, was finally mapped for the first time on Linkage Group 1. There was no evidence of recombination suppression in the linkage groups, including the one carrying the sex locus. The third genetic molecular map was produced based on the morphological markers such as sex type and pulp color, which comprised 1498 AFLP markers and PRSV-P coat protein marker (Ma et al. 2004). Compared to the previous linkage map, which had 19.60 cM average distance between the markers, this map represented a tremendous improvement. The flesh color of fruit served as a morphological marker and was included in the most current high-density genetic map, which had 706 SSR markers. Twelve linkage groups were created by the map (9 major and 3 minor), totaling 1068.9 cM with an average distance of 1.5 cM between the markers (Chen et al. 2007) (Table 6).

Table 6 An overview of papaya's five genetic molecular maps

Types of genetic maps and number of markers												
Stem color	Sex type	Flower color	Fruit flesh color	PRSV coat protein	RAPD	AFLP	SSR	No. of loci	Total cM mapped	No. of LG	Average distance (cM)	References
1	1	1	–	–	–	–	–	3	41	n/a	20.5	Hofmeyr (1939)
–	1	–	–	–	61	–	–	62	999	11	19.6	Sondur et al. (1996)
–	1	–	1	1	–	1498	–	1501	3294	12	2.2	Ma et al. (2004)
–	–	–	1	–	–	–	706	707	1069	12	1.5	Chen et al. (2007)
–	–	–	1	–	–	277	712	990	945	14	1.5	Blas et al. (2009)

The results of the QTL study are anticipated to show that the alleles for fruit size may control cell division and growth, while the allele for fruit shape may influence floral development (Blas et al. 2012). Genetic linkage map was constructed in which 21 QTLs were observed for seven fruit quality characteristics, viz., length and breadth of fruit, thickness and sweetness of pulp, fruit weight, skin freckle, and fruit firmness. The QTLs were unable to forecast the fruit shape and size in individuals of the F1 and F2 progenies from the intraspecific hybrids. However, there are no studies related to fruit qualities and nutrient content.

7 Marker-Assisted Breeding

7.1 Germplasm Characterization

Papaya cultivars cannot often be identified by using morphological markers till the fruit production (Nishimwe et al. 2019). The papaya cultivars and accessions were characterized by using the 65 agronomic and morphological parameters. The morphological characterization of 60 Kenyan papaya germplasm has been carried out, and results revealed that some traits showed great variability, viz., tree habit, flower color, fruit diameter, fruit shape, and leaf size (Nishimwe et al. 2019). Molecular germplasm characterization of papaya has been done using different molecular markers AFLP (Oliveira et al. 2011), SSR (Pirovani et al. 2021), and ISSR (Hassan et al. 2022).

Using ten polymorphic simple sequence repeats, 31 papaya genotypes from Spain, Brazil, Ecuador, China, Taiwan, India, and multiple spots in Bangladesh were genotyped. The P3K1024CC and P6K900CC markers had the largest numbers of alleles, great gene diversity, and polymorphism information richness (Hasibuzzaman et al. 2020). Based on the microsatellite markers, molecular characterization was done using SSR markers of 23 elite lines of papaya (Pirovani et al. 2021). In a study involving various genera of Caricaceae, the cultivated type of *Carica* is closely associated with the genus *Jarilla* and *Horovitzia* but diverged from the *Vasconcellea* species.

7.2 Marker-Assisted Gene Introgression

With a density of one per 0.7 kb, microsatellites are the most prevalent kind of tandem repetition in the papaya genome. However, it merely makes up 0.19% of the papaya's whole genome (Wang et al. 2008). Using WGG (whole-genome genotyping) and the Illumina Miseq platform, a total of 28,451 SNPs with a Transition/Transversion (Ts/Tv) ratio of 2.45 and 1982 small InDels (insertions/deletions) were recognized in order to forecast the effects of the identified variants and produce a list of ripening-related genes (RRGs) with associated variants. A total of 106 RRGs were identified to be linked with 460 variations; these variations might be converted into PCR markers to facilitate the genetic improvement of papaya through marker-assisted selection (MAS) for particular traits (Bohry et al. 2021).

Microsatellite markers were used to examine the first backcross generation of papaya (BC1S) to assess the parental genomic ratio, degree of homozygosity, and gene or allele transfer that imparts the golden fruit color traits (Pinto et al. 2013). Markers are linked to HR traits such as pulp color (marker CPFC1), sex type (CPM1815Y52 marker), lycopene content, ripening-related genes, and other fruit quality traits (Bohry et al. 2021). The MAS helped to improve the health-related traits, viz., lycopene, pulp color, sweetness, and carotenoid content.

8 Map-Based Cloning

The genome size of papaya is quite small (372 Mbp) because of this, which makes it an ideal fruit crop for genetic study (Sharma et al. 2016). Information on map-based cloning in relation to the nutritional qualities of papaya is lacking. High-density genetic maps are necessary to isolate and clone desirable genes, deconstruct genomes, and MAS. The enzyme that promotes the conversion of lycopene to beta carotene, papaya *lycopene-b-cyclase* or *CpLCY-b,* was cloned by Blas et al. (2010). However, there was no difference in the expression of *CpLCY-b* between yellow and red pulp fruit. A chloroplast-specific *CpLCY-b* was expressed seven times more in leaves than in fruit. The pulp color locus was located at the end of LG-5 on a high-density genetic molecular map employing SSR markers, with the adjacent marker being 13 cM distant.

The crystal structure of the complex between papain and cystatin B served as the basis for the design and synthesis of the tripodal synthetic papain inhibitors. The tripodal molecular construct was created by synthesizing it using the tri-azacyclophane (TAC) scaffold, simulating the discontinuous cystatin B epitope that is related in the interaction with papain. A b-hairpin loop, an N-terminal peptide segment, as well as C-terminal peptide segment are the three distinct peptide segments that help cystatin B bind to papain. When *CysTACtins* 5, 7, and 9 were examined for their ability to inhibit papain, *CysTACtin 9* demonstrated outstanding papain inhibition with a Ki of 12 nm, which is similar to cystatin B's inhibitory efficacy (Ki = 0.12 nm) (Zoelen et al. 2007).

9 Recent Concepts and Strategies

Introduction of germplasm is vital in the growth and development of papaya. Various breeding approaches were followed for varietal improvement. Selection and sib mating has been the most successful method. Also, hybridization and selection to achieve homozygosity for the traits have given considerable success. Now the focus is on the development of PRSV disease-resistant cultivars using the wild genus *Vasconcellea* as a source of resistance. Genetic engineering will assist in the speedy development of novel variety by facilitating the direct introduction of genes into elite lines as conventional breeding requires a lot of time and effort (Alvarez et al. 2021). This is done to create new cultivars with better nutritional qualities by either decreasing the level of a particular antinutrient or increasing the concentration of essential

ingredients like vitamins and carotenoids (Sabbadini et al. 2021). Recent developments in molecular methods paved the way for the discovery of potential genes that regulate specific classes of nutrient components in papaya, viz., *"CpCYC-B, CpLCY-B, CpPDS2, CpZDS, CpLCY-E, CpCHY- B"* are for carotenoids (Sabbadini et al. 2021); CpLIS1 and CpP450-2 for linalool and linalool oxide (Zhou et al. 2021).

9.1 Genome Editing

Genome editing is one of the most significant recent advancements in genetic improvement of crop, and methods based on the adaptable CRISPR/Cas9 technology have been developed for a variety of features, including improvement in yield, improving resistant or tolerant to abiotic, abiotic stresses and pests, and alteration of genetics of plants for quality fruit. The TILLING technology is used for improved storage life with better fruit quality of papaya (Gauffier et al. 2016). The *V. pubescens* chloroplast genome was constructed and sequenced using Oxford Nanopore Technology. According to Lin et al. (2017), the genome size is 158,712 bp in length, which is less than the chloroplast genome of *C. papaya* (160,100 bp). These two structural haplotypes, *LSC IRa SSCrc IRb* and *LSC IRa SSC_ IRb,* were observed in the chloroplast genomes of *V. pubescens* and *C. papaya*. The chloroplast genome of *C. papaya* has 46 RNA editing locations with an approximate RNA editing effectiveness of 63%. The chloroplast genome, together with the nuclear and mitochondrial genomes, is an essential part of the plant genomes in a species, facilitating adaptation, diversification, and the emergence of plant lineages. Based on the above finding, *V. pubescens* can contribute to crop improvement in *C. papaya*. To create a visually scoreable albino phenotype in altered tissue, Brewer and Chambers (2022) used CRISPR/Cas9 to target the putative "*C. papaya* L. *phytoene desaturase* (*CpPDS*)" gene. A total of 73 plant lines were successfully transformed using the CRISPR construct *pAC0025*, which targets the *CpPDS* gene. 59 of them (81%) were entirely albinos. Ten *pAC0025* (*CpPDS* construct) lines, one untransformed control line, and one transformed line with the negative regulation construct *pAC0026* were genotyped for the targeted area in *CpPDS* (no *gRNA* construct). All three *gRNA* target locations showed mutations. Overall, high frequency of mutations found at *CpPDS gRNA* target locations and the high percentage of recovered albino plants point to a successful genome editing procedure that may be utilized to enhance papaya at the genetic level. However, there is no information available on work related to improvement of fruit quality.

9.2 Nanotechnology

Nanotechnology has been one of the most dynamic and emerging areas of science. In comparison to other physicochemical approaches, using the plant material fabrication of nanoparticles (NPs) results in more well-specified sizes and morphologies. Because plant materials operate as capping and reducing agents, which frequently aid in minimizing NPs' agglomeration, plant extracts utilized for the creation of

nanoparticles are more favorable than chemical synthesis. ZnO NPs have been synthesized using *Carica papaya* L leaf extract and characterized using UV-V in spectrum, X-ray diffraction, etc. The seeds of chickpea were treated with various concentrations of ZnO NPs, and the seed germination, shoot length, root length, and antioxidant enzyme were studied (Dulta et al. 2021). Green chemistry-based strategies for creating NPs have become a reality in recent years. Using papaya peel bio waste, the copper oxide NPs (CuO NPs) have been developed. These NPs were used as a photocatalyst to help palm oil mill effluent degrade when exposed to UV light (Phang et al. 2021). NPs based on extract derived from different parts of papaya have been extensively put into use as a green technology.

10 Genetic Engineering

The very first prerequisite for genetic engineering is the availability of plant regeneration protocols. It was effective to use premature zygotic embryos and juvenile seedling tissues in the papaya regeneration process developed by Fitch (2005). In order to obtain nutritionally rich papaya, it has to be grown in a disease-free condition. Two PRSV (papaya ringspot virus) resistant cultivars 'SunUp' and 'Rainbow' have been developed using a concept called parasite-derived resistance wherein the coat protein-mediated gene silencing mechanism is used (Gaskill 2001). Another significant problem with papaya is fast fruit ripening, and this problem has been addressed by downregulating "*1-aminocyclopropane-1-carboxylate (ACC)* synthase" enzyme involved in the biosynthesis of ethylene. In papaya, the ACC synthase enzyme, which is an important precursor in the biosynthesis of ethylene, has been downregulated to delayed fruit ripening. The genetics of papayas have undergone yet another modification to the ethylene perception pathway to postpone fruit ripening (Fitch 2005). A low-temperature stress tolerance was brought about by transgenics overexpressing *CBF1 gene*. This gene is responsible for the expression of *COR genes* that give freezing tolerance to papaya plants.

11 Role of Bioinformatics as a Tool

The multidisciplinary field of bioinformatics combines "biology, computer science, mathematics, and statistics." It is used to extract, analyze, integrate, and present the biological data generated by omics platform technologies. There are several biological databases and bioinformatics tools available to other researchers working in related subjects.

11.1 Gene, Genome, and Comparative Genome Databases

The genome of the papaya has been sequenced. 90% of the euchromatic sections and 75% (277.4 Mb) of the genome (372 Mb) were represented by the sequences. 16,362

unigenes were included in the assembled EST unigene set, and the assembled entire shotgun sequences matched 92.1% of them. The transcribed sequences accounted for 48% of the genic area and 3.6% (13.4 Mb) of the whole genome in the WGS (Ming et al. 2008). Unfortunately, there has not been any progress in the genome data sequences. With the aid of this database, we can locate promising genes related to fruit quality, growth, and development.

The papaya genome sequence can be searched through these databases: "NCBI, PlantGDB, Phytozome, and PLAZA." To examine the similarity and homology of the sequences, two initiatives have been introduced: HMMER and BLAST. "InterProScan, SMART, and Pfam" tools were developed to identify the gene family, domain association, and motif sequence, respectively. PLACE and PlantCARE tools are designed to identify the *cis*-regulatory elements and promoter of the desirable genes (Alok et al. 2019).

The papaya genome sequence can be retrieved from open-access databases to start a comparative genomics investigation. The abovementioned databases are also used for the comparative genomics analysis. The gene sequences are also aligned using the multiple sequence alignment programs ClustalX and MAFFT. The MEGA tool is often used to create phylogenetic trees (Kumar et al. 2018).

11.2 Gene Expression Databases

These are the EBI ArrayExpress (EBI AE) and the NCBI Gene Expression Omnibus in an MIAME-compliant way. Contrary to the International Nucleotide Sequence Database, these two gene expression databases have not been exchanging information. As of 2017, AE no longer imports data from GEO. Furthermore, the DNA DataBank of Japan (DDBJ) recently started a similar repository called the Genomic Expression Archive (GEA). The proteomics data of MS origin can be submitted to a public database like the "ProteomeXchange Consortium" in order to promote reproducibility of proteomics data (Abidin et al. 2021) (Fig. 3).

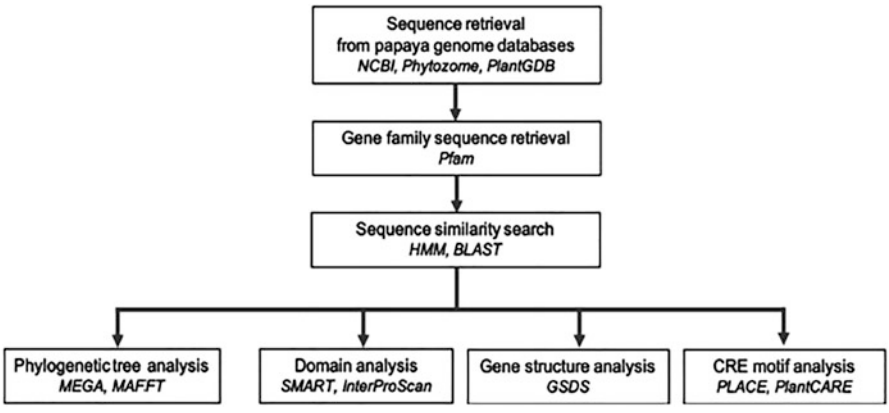

Fig. 3 Schematic approaches for comparative genomics analysis of papaya. (Abidin et al. 2021)

11.3 Protein or Metabolome Databases

There are some protein databases for papaya such as UniProt comprises UniProtKB for protein knowledge, UniRef for sequence cluster, UniParc for sequence archive, and another section is proteomes; NCBI; PlantGDB comprises CpGDB for papaya genomes; and RCSB PDB for the structure of a protein (1D–3D view) along with electron density (Abidin et al. 2021).

12 Social, Political, and Regulatory Issues

The nutritional security of expanding global population can greatly benefit from the health advantages of papaya plants. The major issues faced by papaya growers involve unfavorable weather, pest and disease incidence, nonavailability of disease-resistant good commercial cultivars, lack of processing and storage facilities, and huge postharvest losses. Awareness toward its nutritional and health benefit including the market potential of papaya is needed to boost its cultivation besides its use as a nutritious alternative. More importantly, developing postharvest techniques and value-added products that retain the phytochemicals and antioxidants present in the fresh fruit could be a boon to the industry and consumer market. Further, regulatory issues related to its biomedical application, nanotechnology, and alternative therapies need to be streamlined for its safe usage.

13 Future Prospects

Due to the significant genetic diversity that exists in papaya germplasm around the world and its importance as a fruit crop, it is possible to use this germplasm to develop a variety of improved traits. Though the crop has very good pharmacological value, viz., antioxidant, anticancer, anti-inflammatory, wound healing, antifungal and dengue cure, sufficient information is not available on these aspects and needs to be generated. There is a need to improve whole-genome sequencing data and develop a papaya genome database for easy access to genomic information. Integration of conventional breeding approach with recent biotechnological intervention like marker-assisted selection (MAS), marker-assisted introgression (MAI), association studies, genomic selection, genome editing, and transformation for health-related traits in addition to disease resistance needs to be intensified. Papaya cultivation for processing and papain production has become a profitable venture in a few countries that can be extended to other papaya-growing regions also. Very limited literature is available on map-based cloning and genomic libraries pertaining to health-related traits at present that needs more focus. Adoption of efficient production technologies like water budgeting and carbon sequestration, and integrated crop protection techniques for major fungal and viral diseases are some of the pressing needs that should be looked into and studied.

14 Conclusions

Papaya is one of the most important fruit crops of India as well as other tropical countries all over the world. The fruits are rich source of vitamins, minerals, and other bioactive compounds, which are linked to improve the health-related traits. It has wide genetic diversity, which is contributing toward the development of improved varieties with desirable horticultural traits with improved fruit quality, including resistance to viral disease like papaya ring-spot virus. As the traditional breeding has some limitations, use of molecular approaches like MAS, genome-wide association studies (GWAS), transgenic approaches, and genome editing methods like CRISPR/Cas can help to speed up the results in improving various agronomic and health-related traits in addition to resistance or tolerance to biotic and abiotic stresses.

Avocado: Agricultural Importance and Nutraceutical Properties

A. Talavera, J. J. Gonzalez-Fernandez, A. Carrasco-Pancorbo, L. Olmo-García, and J. I. Hormaza

Contents

Abstract

The avocado is a subtropical evergreen tree crop originated in Mesoamerica presently cultivated worldwide in more than 60 countries. Avocado fruits were consumed by Native American cultures as early as 10,000 years ago, and they are experiencing increasing popularity globally as highly nutritious and healthy food. In this chapter, we review the agricultural importance of the crop, compositional

Avocado · Genomics · Nutraceutics · Lauraceae · *Persea americana*

1 Introduction

1.1 Agricultural Importance of Avocado

The avocado (*Persea americana* Mill.) is a subtropical evergreen woody perennial tree crop, member of the family Lauraceae in the order Laurales. The center of origin of avocado can be located in Central America, in a wide geographical region that expands from the highlands of Mexico, Guatemala, and Honduras to the Pacific coast (Popenoe et al. 1997). According to archaeological findings, native cultures in Mexico already consumed avocados at least 10,000 years ago, as remains dating back to that time have been found in the Coxcatlan Cave, in Tehuacan (state of Puebla) (Knight 2002). Originally, the word avocado derives from the ancient nahuatl word "ahuacatl" that the Spaniards transformed into "aguacate" from which the English word "avocado" transliterated. As other trees native of the Americas that produce large fruits, it is likely that the avocado coevolved with the presently extinct American megafauna that probably was the main disperser of the fruits before humans arrived to the continent (van Zonneveld et al. 2018). From its center of origin in Central America, avocado was probably dispersed to South America in pre-Columbian times. In fact, the first description of avocado after the European arrival to America was made in Colombia in 1519 (Fernandez de Enciso 1519). Soon, the European explorers dispersed avocados to other regions of the world, and the first description outside the Americas was made in 1576 by the botanist Charles de l'Écluse (Carolus Clusius) (Clusius 1576), who observed a blooming avocado tree in a botanical garden in Valencia (Spain), established by Joan Plaza, a professor of "herbs and other simple medicines" at the University of Valencia (Lopez-Terrada 2011). Clusius named the tree Persea due to its resemblance to a traditional North African tree with that name (*Mimusops laurifolia*, Sapotaceae) (Schroeder 1977); this will later become the name of the genus (Miller 1754).

At least eight botanical varieties or subspecies that have evolved in different edaphoclimatic conditions and geographically isolated from each other are usually recognized in the species *Persea americana*. Three of them, also called horticultural races, have agronomic importance (Schaffer et al. 2013): West Indian (*P. americana* var. *americana*), from the lowland tropics; Guatemalan (*P. americana* var. *guatemalensis*), from the valleys of the Central American mountain ranges; and Mexican (*P. americana* var. *drymifolia*), from the tropical highlands of Southern

Mexico. Thus, the three horticultural races differ mainly in botanical characteristics and edaphoclimatic preferences. The Guatemalan and Mexican subspecies are better adapted to cooler subtropical climates although the Guatemalan subspecies is more vulnerable to low temperatures than the Mexican subspecies. The West Indian subspecies is more adapted to tropical climates. The three horticultural races are sexually intercompatible, and, in fact, most of the presently cultivated avocado commercial varieties in subtropical and Mediterranean climates are interracial Mexican x Guatemalan hybrids. Avocado is presently cultivated in most countries with subtropical and tropical climates all over the world and is grown commercially in more than 60 countries worldwide.

Avocado international market and trading have seen an exponential increase in the last couple of decades, and global avocado world production in 2020 reached over eight million tons (FAO 2022). Mexico, Dominican Republic, Peru, Indonesia, Colombia, and Brazil contribute most of the production. Mexico is the most important avocado-producing country with approximately 30% of the global production (over two million tons in 2022). Most avocados in the international trade are exported from those main producing countries to big consumer regions, mainly USA and Western Europe, while the rest is predominantly consumed in local markets. Thus, the avocado can be considered as a staple fruit in most countries with tropical and subtropical climates, especially in the Americas, but also in some African and Asian countries. Local landraces that usually do not reach the export markets are very popular in most of those countries. Encouraging smallholder farmers to grow avocados together with other crops could, thus, help to reduce malnutrition and help to increase food security (Hakizimana and May 2018).

1.2 Relationship with Other Species and Wild Relatives

The Laurales, in addition to the Canellales, Magnoliales, and Piperales, form the magnoliid clade that is considered as a sister clade to the eudicot and monocot angiosperms (APG IV 2016; Chase et al. 2016). The order Laurales includes seven families: Atherospermataceae, Calycanthaceae, Gomortegaceae, Hernandiaceae, Lauraceae, Monimiaceae, and Siparunaceae. The Lauraceae is a monophylic family with more than 50 genera and between 2500 and 3000 species with a worldwide distribution, mainly in tropical and subtropical climates. Most of the species of the family are evergreen woody trees or shrubs, and, in addition to avocado, a few other species in the Lauraceae have agronomic and/or economic interest. Among them, the most important are spices, such as the camphor (*Cinnamomum camphora* [L.] J. Presl), the cinnamon (*Cinnamomum verum* J. Presl), or the laurel (*Laurus nobilis* L.); timber trees such as those of the genera *Chlorocardium, Eusideroxylon*, *Mezilaurus, Nectandra*, *Ocotea*, and *Phoebe*; and ornamental trees such as *Persea indica*. About 150 species are recognized in the genus *Persea*, 70 of which are distributed in America and 80 in Southeastern Asia, and a single species, *P. indica*, is endemic to the Macaronesian islands in the Atlantic Ocean. The genus possibly first evolved in African Gondwanaland, from where it dispersed to North America and Asia through

Europe; by the Paleogene, the genus reached South America via Antarctica, and it was reunited thanks to the land bridge that during the late Neocene connected North and South America.

Three subgenera are usually considered in the genus *Persea*: *Machilus*, *Persea*, and *Eriodaphne*, although *Machilus*, restricted to Asia, is treated as a separate genus by many authors. The 70 American species of *Persea* are divided in two subgenera (Kopp 1966): *Eriodaphne* (primarily with a South American origin) and *Persea* (primarily with a Central American origin). The subgenus *Persea* includes at least three species, although additional species are added by some authors (Chanderbali et al. 2013): *P. pallescens*, *P. schiedeana*, and *P. americana*, the avocado.

2 Description on Nutritional Constituents

2.1 Products/Parts with Nutritional Interest

Avocado fruits develop from flowers that are produced as panicles of cymes. A mature avocado tree may produce more than a million flowers, although less than 1% remain on the tree at harvest, which results in a very low fruit-to-flower ratio (Alcaraz and Hormaza 2021). The fruit of avocado is botanically a pyriform or globose fleshy drupe that contains one seed surrounded by the pericarp. The pericarp is formed by the outer skin (exocarp) with a variable thickness and color depending on the horticultural race and the variety, the pulp (mesocarp) that constitutes the edible part, and a thin endocarp, next to the two papery seed coats (Cummings and Schroeder 1942). The pericarp color and texture are highly variable, and the color at ripening can be black, brown green, or purple with intermediate intensities of each one depending on the genotype. The fruit shape and size are also variable and can range from spherical to different pear or egg shapes.

The avocado fruit developmental process can be divided in two main phases: fruit maturation that takes place on the tree and that, depending on both the environmental conditions and the genotype, can last between 6 and 18 months and postharvest ripening that takes place after the detachment of the fruit from the tree and during which the mesocarp softens changing the organoleptic characteristics of the fruit. The avocado fruit is climacteric, and, consequently, during the ripening process after harvest, respiration levels related to ethylene production increase. The fruits are harvested when physiological maturity (the ability to ripen after harvest) is reached. Edible ripeness takes place several days after harvesting; the length of the phase between physiological and edible maturity is variable depending on the variety, the time of harvesting, and the conservation temperature after harvesting. The visual determination of the stage of physiological maturity is difficult in avocado, since no clear external changes are observed during this process. This topic has been addressed by a number of works (Stahl 1933; Lee et al. 1983; Landahl et al. 2009) resulting in the development of different approaches to accurately assess avocado physiological fruit maturity; among the most used is the correlation between dry matter and oil contents (Gamble et al. 2010).

As avocado fruits develop on the tree, total mesocarp oil content increases, and, thus, oil content in the fruit can be used to establish the different fruit developmental stages in order to decide when physiological maturity has been reached (Lee 1981). Avocado is one of the few examples in which high amounts of triacylglycerols are accumulated in the mesocarp of the fruit (Kilaru et al. 2015). Although in the 1920s in California a minimum empirical value of 8% oil content was established for harvesting, this value was later considered as too low. In any case, determination of oil content is a cumbersome process, and, consequently, alternative determination methods were necessary. During avocado fruit development, as oil content increases, since oil replaces the water present in the fruit, water content decreases concomitantly. Then, during this process, the increase in both oil and dry matter contents is correlated. Consequently, measurement of dry matter (defined as the solid content of the fruit minus its water content) is an indirect indicator of oil content and, thus, of maturity and a reliable indicator of flavor. Dry matter measurements are easy to perform either using microwave or other ovens to dry avocado fruit slices or, more recently, using near-infrared (NIR) technologies. The minimum dry matter value for harvesting is variable depending on the variety and the region of production, but the standard value for 'Hass' avocado ranges from 21% to 23%.

Most avocados are consumed fresh but also in salsas (such as guacamole), soups, and other elaborations, such as in Brazil and different Asian countries in which avocados are consumed sweet mixed with sugar and condensed milk, in milk shakes or as ice cream. In addition, increasing interest is being put into using the edible oil extracted from the avocado flesh in addition to the more traditional use of the avocado oil in the cosmetic and beauty industries.

Although the main interest of this crop is the fruit consumed mainly fresh, in some cases, the leaves of the avocado trees (mainly of genotypes of the Mexican race which have a distinctive anise aroma) are also used in some traditional cuisines. Also, avocado leaves are used in some regions in traditional medicine against coughs or skin bruising. Other parts of the avocado fruits after processing (such as for guacamole production) that are usually considered as waste (peels, seeds, paste) could also be a source of interesting bioactive substances (Dalle Mulle Santos et al. 2016; Araújo et al. 2018). Exploiting the phytochemical properties of those byproducts will increase the added value of the avocado industry helping to improve sustainability of avocado production worldwide.

2.2 Detailed Chemical Composition

Avocado is a calorie-rich fruit with high levels of unsaturated fatty acids. The avocado fruit is particularly rich in ascorbic acid (vitamin C), vitamin B6, β-carotene, vitamin E, and potassium, and it also contains phytosterols and carotenoids, such as lutein (which represents about 70% of the carotenoids of avocado [Dreher and Davenport 2013]) and zeaxanthin. For a standard 'Hass' avocado, we can consider that about 72% of the flesh is water, although this percentage is variable depending on the location and on the stage of fruit development. Avocado

composition of the edible flesh for the most important macro- and micronutrients per 100 g of 'Hass' avocados is shown in the following Table 1 (USDA 2018).

Compared to other vegetables with high oil content, the avocado fruit shows high levels of monounsaturated fatty acids (such as oleic acid), whereas the levels of polyunsaturated fatty acids (such as linoleic and linolenic acids) are low. It also contains small proportions of additional fatty acids (stearic, palmitic, myristic, or arachidonic acids).

For 100 g, it can be considered that 2.13 g corresponds to saturated fatty acids, whereas 9.8 g corresponds to monounsaturated fatty acids (about 70% of total fats) and 1.82 g to polyunsaturated fatty acids (USDA 2018).

We can highlight some of the main health-related nutrients of avocado fruits as follows:

- Relevant levels of monounsaturated fatty acids.
- Relevant levels of dietary fiber, of which about 70% correspond to insoluble fibers and 30% to soluble fibers (Marlett and Cheung 1997).
- Low sugar content compared to other fruits, mainly in the form of the heptose *D*-mannoheptulose and its reduced form, the sugar alcohol perseitol.

Table 1 Most important macro- and micronutrients per 100 g of 'Hass' avocado

Water (g)	72.3
Macronutrients (g)	
Lipids	15.4
Proteins	1.96
Total carbohydrates	8.64
Dietary fiber	6.80
Minerals (mg)	
Calcium	13.0
Copper	0.17
Iron	0.61
Magnesium	29
Phosphorous	54
Manganese	0.15
Potassium	507
Selenium	0.40
Sodium	8
Zinc	0.68
Vitamins	
Niacin (mg)	1.91
Pantothenic acid (mg)	1.46
Riboflavin (mg)	0.14
Thiamin (mg)	0.075
Vitamin A (IU)	147
Vitamin B6 (mg)	0.29
Vitamin C, ascorbic acid (mg)	8.80

- High potassium and low sodium content, which can help to control blood pressure levels.
- High magnesium levels.
- High levels of antioxidant C and E vitamins.
- High levels of B vitamins.
- High levels of phytosterols, mainly β-sitosterol, followed by campesterol and stigmasterol (Duester 2001).

Significant changes can be observed in the concentrations of some of these compounds along the harvesting season and also during ripening after harvest (Lu et al. 2009; Hurtado-Fernández et al. 2016; Serrano-García et al. 2022). Hence, the levels of saturated fat decrease, whereas those of monounsaturated oleic acid increase (Slater et al. 1975; Lu et al. 2009). The levels of carotenoids also increase along the avocado harvesting season (Lu et al. 2009).

Avocado fruits also show high levels of certain types of nonnutritive compounds, such as alkanols, amino acids, carotenoids, or phenolics, which account for some of their organoleptic properties and that could also be relevant in improving human health.

The first works in which powerful tools and ambitious analytical methods were used to characterize the avocado pulp exhaustively – considering many substances not described in the food composition databases – were performed by Hurtado-Fernández et al. (2011a, b). After that, other works have been published addressing the study of the substances present not only in the avocado pulp but also in the avocado peel and seeds (López-Cobo et al. 2016; Figueroa et al. 2018a, b).

2.3 Medicinal/Physiological Properties and Functions in Relation to Human Health

Avocado is considered as an excellent source of different macro- and micronutrients, and significant health benefits of avocado pulp and oil consumption have been described in different works (Bhuyan et al. 2019). Among them, we can include lowering risks of cardiovascular diseases, cataracts and other age-related macular degenerations, metabolic syndromes, prostatic hypertrophy, and prostate and other tumors, as well as blood cholesterol regulation, weight management, diabetes control, anti-inflammatory effects, and prevention and treatment of osteoarthritis, among others (Salazar et al. 2005; Dreher and Davenport 2013; Bhuyan et al. 2019). Those benefits are probably related to the presence of different phytochemicals in the avocado fruits including phenolic compounds, chlorophylls, carotenoids, or anthocyanins (Ashton et al. 2006; Ding et al. 2007) as well as to the high levels of monounsaturated and low levels of saturated fats that result in a similar healthy oil profile to that of the olive oil (Bhuyan et al. 2019).

Most of the studies performed in the avocado fruit have been focused on the pulp, consumed either fresh or processed as oil, which often is cold-pressed, and, consequently, most of the bioactive compounds are preserved (dos Santos et al. 2014). In

fact, there is a huge potential to improve the use of avocado as a high-quality oil, since generally all the breeding and selection of varieties in this crop have been focused on fruit quality for the fresh market and the diversity present in this species for oil production has not been studied in detail. Moreover, displacing the production of cooking oil from annual plants to perennial crops could have an overall impact on sustainability, similar to the case of the olive tree in the Mediterranean region, helping to reduce soil erosion and fertilizer and pesticide runoff while providing a more sustainable agricultural landscape (Bost et al. 2013). In some markets, fruits of West Indian and of hybrid Guatemalan x West Indian varieties that show a lower oil and calorie content than 'Hass' are marketed as "light avocados."

In addition to the monounsaturated acids, recent interest has been devoted to other fatty acid derivatives present in the avocado fruit, such as lauraceous acetogenins that show different interesting bioactive properties (Rodríguez-López et al. 2017; Colin-Oviedo et al. 2022). These substances were first reported in avocado leaves several decades ago (Chang et al. 1975).

A recent work (Sánchez-Quezada et al. 2021) shows that nutraceutical properties of avocado seeds (which are responsible for about 16–22% of the avocado fruit weight and are often a byproduct from the guacamole industry) correlate positively with the fruit ripening process; as the fruit ripens, seed moisture decreases, and the antioxidant capacity increases due to an increasing concentration of phenolics.

2.4 Cultural Methods for Nutraceutical Improvement

Although avocado international trade is mainly based on a single variety, 'Hass' (Fig. 1), which allows the availability in the markets of an externally very

Fig. 1 Fruits of the avocado variety 'Hass' hanging on a tree before harvesting

homogeneous fruit all year round from different origins, pre- and postharvest management factors play a relevant role on 'Hass' avocado fruit quality and nutritional composition. Preharvest factors include fruit origin, which, in turn, is mostly related to edaphoclimatic conditions, especially soil type and chemical status, light intensity, relative humidity, temperature fluctuations during fruit development, harvest date along the harvesting season, and agronomic management, especially irrigation regimes and fertilization programs. Postharvest management includes handling at harvesting time, during transport to cooling facilities, and at packing operations, storage length and conditions, and processing and transport to final destination markets.

Although very few works have addressed the influence of all those factors on avocado nutraceutical properties, the understanding and control of those factors are highly relevant in order to optimize avocado fruit quality and composition. One example is the length of the harvesting season of fruits derived from the same flowering period that, in some avocado-producing regions, can be extended up to 6 months with differences in fruit composition depending on the harvest time (Hurtado-Fernández et al. 2016) or the geographical origin (Pedreschi et al. 2022). In this sense, differences in avocado fruit composition in the same variety related to the growing area, ripening stage, and postharvest fruit storage conditions have also been described (Donetti and Terry 2014).

Regarding crop management, key aspects that can explain heterogeneous ripening in avocado include mainly irrigation and pruning of fertilization practices (Rivera et al. 2017). In this sense, a recent work combining proteomic and metabolomic studies revealed clear differences after heat treatments between avocados from early and mid-harvesting seasons; those differences seem to depend on the fruit physiological stage at harvest (Gavicho-Uarrota et al. 2019). Heat treatments can improve the homogeneity of the ripening process by increasing the amount of soluble sugars (such as galactose or sucrose) and of some stress-related enzymes. Regarding postharvest management, a careful fruit handling has to be performed avoiding not only mechanical injuries but also controlling environmental conditions that could alter normal fruit maturation and avoiding fruit disorders or postharvest diseases that could affect final fruit quality and nutraceutical properties.

Although, as discussed above, differences can be found in fruit composition in the same cultivar depending on the edaphoclimatic conditions and pre- and postharvest management procedures, the overwhelming use of 'Hass' in the international avocado market is a limiting factor to exploit the natural diversity present in this crop. Some studies have shown differences among avocado varieties in fruit composition (Hurtado-Fernandez et al. 2015; Di Stefano et al. 2017); this will allow in the future to combine the production of different varieties increasing the avocado production period; in some cases, such as in Spain and other countries with a Mediterranean climate, it is possible to produce avocados all year round with a combination of four or five varieties. In other countries with subtropical climates (Colombia or Mexico), different flowering periods can take place all year round allowing the production of fruits from the same variety during the whole year.

On the other hand, in countries with Mediterranean climates where the pressure of pests and diseases is low compared to regions with tropical high humidity conditions, avocado organic production is relatively easy to perform with the consequently improvement of healthy food production due to the lack of application of toxic chemicals for pest and disease control.

3 Molecular Tools for Genetic Improvement of Nutraceuticals

3.1 Limitations of Conventional Breeding and Rational for Next-Generation Molecular Breeding

The avocado is highly heterozygous and shows a long juvenile period and, as stated before, with an extremely low fruit set due to massive flower abscission and immature fruit drop (Alcaraz and Hormaza 2021). Avocado is characterized by the presence of a synchronous protogynous dichogamy system in which each hermaphrodite avocado flower opens twice during two consecutive days, first functionally as a female flower and, during the second opening, as a functionally male flower. Avocado genotypes have been traditionally classified in two different types (A or B) depending on whether in the first day of the flowering cycle the flowers open in the female stage in the morning (type A cultivars) or in the afternoon (type B cultivars). This flowering behavior promotes outcrossing, since self-pollination in the same cultivar can only occur during the limited number of hours in which closing female flowers in the first day of the flowering cycle and opening male flowers in the second day of the flowering cycle can be found on the same inflorescence, tree, or cultivar. The length of this overlap is highly dependent on temperature and on the avocado genotype.

Conventional breeding programs have been moderately successful to release new avocado varieties and rootstocks, although the majority of the most important commercial cultivars worldwide are derived from open pollinations and spontaneous interracial hybridizations. In general, the objectives of avocado breeding strategies have focused on (i) high consistent yield, (ii) high fruit quality, (iii) expanded harvesting season, and (iv) longer shelf life (Lahav and Lavi 2013). The most important avocado cultivar present in the international markets is ‘Hass’ that produces fruits with a black rough epicarp, followed, to a much lesser extent, by varieties such as ‘Fuerte’ that produce fruits with a green smooth epicarp. This has not always been the case, since ‘Fuerte’ was the leading avocado variety in the international markets until the 1970s. Several cultivars similar to ‘Hass’ in appearance have been released during the last decades, and some of them are cultivated in some regions, such as ‘Lamb Hass’, ‘Carmen’ (a mutation of ‘Hass’), or ‘Maluma’. Other interesting cultivars that ripen in green are ‘Reed’ (type A, as ‘Hass’) and ‘Bacon’, ‘Edranol’, or ‘Zutano’ which are type B and are used as pollinizers for ‘Hass’.

In spite of the growing importance of avocado production worldwide, significant bottlenecks that limit breeding and development of new high-quality avocado varieties still remain worldwide. Among the main limiting factors, we can include the lack or scarce availability of molecular resources, the absence of adequate phenotypic data for many cultivars and environments, and the very limited germplasm used in most avocado breeding programs. There is an increasing demand to develop new high-quality avocado cultivars, since about 90% of the world avocado production is based on 'Hass', a variety that was developed in the 1920s in California (USA) from a chance seedling and, in fact, all presently cultivated 'Hass' trees derive clonally from that single tree patented in 1935 (Crane et al. 2013). Therefore, any pest or disease that affects this cultivar could threaten avocado production worldwide. Moreover, the present scenario of climate change requires adapting the breeding programs to rapidly changing environmental conditions. As in other crops, it is expected that the increasing availability of molecular data derived from high-throughput sequencing technologies will speed up avocado breeding in the next years.

3.2 Molecular Genetics and Genomics of Nutraceuticals

The avocado is a diploid ($2n = 2x = 24$) species with a haploid genome size of 896 Mb (Arumuganathan and Earle 1991). Different molecular markers have been used in this crop for fingerprinting, paternity assessment, diversity and phylogenetic analyses, development of genetic linkage maps or screening, and selection of traits of interest in avocado breeding programs. As with other crops, in avocado isozymes were the first genetic markers used (Torres and Bergh 1980) followed more recently by the development of different DNA-based markers.

Early markers based on DNA included minisatellites (Lavi et al. 1991), variable number of tandem repeats (VNTRs) (Mhameed et al. 1996), random amplified polymorphic DNA (RAPDs) (Fiedler et al. 1998), and restriction fragment length polymorphism (RFLP) (Furnier et al. 1990; Davis et al. 1998). Later, codominant and highly polymorphic single sequence repeats (SSRs) or microsatellites were also specifically developed in avocado and widely applied for cultivar fingerprinting and genetic diversity studies (Sharon et al. 1997; Schnell et al. 2003; Ashworth and Clegg 2003; Ashworth et al. 2004; Borrone et al. 2007; Alcaraz and Hormaza 2007; Gross-German and Viruel 2013; Guzmán et al. 2017; Boza et al. 2018; Ge et al. 2019b; Juma et al. 2021; Ruiz-Chután et al. 2022). The more recent development of high-throughput new-generation sequencing technologies has enabled the use of single-nucleotide polymorphism (SNP) markers that are increasingly being considered as the preferable type of marker for genetic studies in different crops for diverse objectives such as the construction of genetic linkage maps, the characterization of quantitative trait loci (QTL), association studies with traits of agronomic interest, marker-assisted selection (MAS), or genomic selection (GS) (Scheben et al. 2017; Le Nguyen et al. 2019). SNPs show several advantages that are especially relevant in woody perennial crops, such as avocado, in which breeding programs are

characterized by long generation times: the possibility of developing a large number of markers at increasingly reduced costs, their bi-allelism that results in a high accuracy in the analyses, or their high replicability.

New-generation sequencing approaches in avocado have so far mostly been focused on transcriptome analyses and SNP development. In general, these studies have been applied to study disease resistance, plant development, stress tolerance, and genetic diversity (Ibarra-Laclette et al. 2015; Kilaru et al. 2015; Liu et al. 2018; Vergara-Pulgar et al. 2019; Ge et al. 2019a; Kuhn et al. 2019a, b; Ge et al. 2019c; Rubinstein et al. 2019; Talavera et al. 2019; Chabikwa et al. 2020; Pérez-Torres et al. 2021; Kämper et al. 2021; Fick et al. 2022; Hernández et al. 2022). However, recently, several avocado nuclear genome sequences have been published. Rendón-Anaya et al. (2019) developed genomic sequence drafts of 'Hass' as well as of a wild accession of the Mexican horticultural race. The 'Hass' assembly was anchored to a genetic map, and the generated genome consisting of 915 scaffolds covered approximately half (46.2%) of the estimated avocado genome. Furthermore, ten genomes representing the three avocado subspecies, as well as Hass-related cultivars and *P. schiedeana*, were resequenced helping to better understand the genetic diversity and the evolutionary history of avocado. Subsequently, another 'Hass' genome reference has been generated by Sharma et al. (2021). In this last work, the reference genome resulted in an assembly of 788 Mb representing approximately 88% of the avocado genome size. However, this assembly was not anchored into scaffolds. These new genomic resources in avocado will probably make a qualitative change in future avocado breeding. But additional efforts are needed to find solutions to new challenges, since the molecular knowledge of avocado lags far behind other crops.

3.3 Molecular Mapping, QTLs, and Gene Identification

The increased availability of saturated genetic maps in many crops has accelerated different breeding programs in recent years. These maps have been extensively applied in QTL mapping, MAS, and comparative and genome structure analyses allowing the identification of a large number of genes through QTL fine mapping studies (Jaganathan et al. 2020). However, in avocado, the number of linkage maps constructed to date is still low. The first avocado genetic linkage map was developed with 50 SSRs, 23 minisatellite DNA fingerprints (DFPs), and 17 RAPD markers, using the progeny from a cross between 'Pinkerton' and 'Ettinger'. This map represented the 12 avocado linkage groups and covered 352.6 cM (Sharon et al. 1997). Later, a new linkage map was constructed by Borrone et al. (2009) using 715 F1 individuals (456 from the cross 'Tonnage' x 'Simmonds' and 259 from the reciprocal cross 'Simmonds' x 'Tonnage'). This map was developed using SSR makers, and 12 linkage groups were also detected, but, in this case, the total map length was longer (1087.4 cM). More recently, a linkage map was constructed using SSRs and single-nucleotide polymorphisms for a 'Gwen' x 'Fuerte' progeny. The

resulting linkage map covered 1044.7 cM distributed along 12 linkage groups. In this last study, a high number of molecular markers located in linkage group 10 showed remarkable association with flowering type, and a marker on linkage group 1 was associated with a QTL related to β-sitosterol fruit levels and a region on linkage group 3 with vitamin E (α-tocopherol) fruit levels. Unfortunately, the limited population size used restricted the possibility of developing a robust linkage map and detecting additional QTLs (Ashworth et al. 2019).

Although the genetic maps generated so far are useful resources, new efforts are needed to develop more saturated genetic maps in avocado in order to optimize and boost breeding programs for specific traits. Several mapping populations have been developed in spite of the difficulty of this crop with a long juvenile period, the low yield obtained after natural or hand pollination, and the dichogamy system. However, larger populations, higher molecular resources, and phenotypic data will be required in order to detect QTLs and develop marker-assisted programs.

As a result of those limitations, the examples of the identification of health-related genes are still scarce in avocado. Those examples include the studies on oil accumulation in the mesocarp of avocado fruits. Kilaru et al. (2015) performed a comparative transcriptome analysis of some lipid metabolic pathways in 'Hass' and compared this with other species showing a similar oil biosynthesis patterns (avocado, oil palm, rapeseed, and castor bean) suggesting the conservation of these metabolic pathways during angiosperm evolution. However, some unique features were also detected in avocado. Similarly, comparative transcriptomic analyses of the mesocarp and seeds revealed higher expression levels of 17 carotenoid biosynthesis genes in the mesocarp than in the seed along five avocado fruit developmental stages (Ge et al. 2019a).

3.4 Genetic Engineering

As in other crops, genetic engineering could play an important role in future avocado breeding programs. Significant advances have been obtained using *Agrobacterium rhizogenes* and *Agrobacterium tumefaciens* (Pliego-Alfaro et al. 2020). Genetic transformation has been successful in a few cases to study some genes that affect different horticultural traits. Examples include the manipulation of the *S*-adenosyl-l-methionine (SAM) hydrolase (SAMase) gene to block ethylene production (Efendi 2003) or the study of genes involved in pathogenesis such as β-1,6-glucanase, chitinase, and the antifungal protein (AFP) gene (Raharjo et al. 2008) or targeting chloroplast RNA to avoid the replication of the avocado sunblotch viroid (ASBVd) in chloroplasts (Perea Arango et al. 2010). Transient gene expression has also been accomplished using biolistics in avocado embryogenic cultures (Chaparro-Pulido et al. 2014). In addition, as in other crops, CRISPR/Cas can make a qualitative change in avocado gene edition in the future. However, efficient regeneration protocols from single cells in this crop are still lacking in order for the approach to be effective.

4 Future Prospects

This chapter has summarized relevant information about avocado, covering aspects such as the agricultural importance of the crop, description of compositional profile, genetic diversity, and molecular tools. Although the composition of this fruit has been described in considerable depth, there is still a long way to go, making use of recent advances in metabolomics, proteomics, sequencing, transcriptomics, and genomics. Thus, in spite of the importance of several compounds present in avocado fruits with nutritional and health benefits, such as carotenoids, lipids, sugars, proteins, minerals, or vitamins, avocado lags behind other crops in the breeding or varieties to take advantage of those excellent properties. Several studies have shown the exceptional nutritional and phytochemical composition of avocado fruits and their potential in the control and prevention of different human diseases, but additional in vitro, in vivo, and clinical studies are needed to understand the mechanisms of action of avocado phytochemicals in order to use this fruit in therapeutic and nutritional applications. However, recent advances in sequencing and transcriptomics together with gene editing can make a qualitative change to take advantage of the still underused genetic diversity present in this crop. It is expected that additional genes coding for important nutraceutical properties of avocado will be identified in the next years. This knowledge is crucial to use molecular breeding to improve classical breeding approaches as well as to provide appropriate material for the generation of DNA-edited plants with desired traits of interest.

5 Conclusion

The fruits of the avocado including several of their byproducts show interesting nutraceutical properties that can be different depending on the genotype and the preharvest and postharvest management of the crop.

Melon Nutraceutomics and Breeding

Prashant Kaushik

Contents

Abstract

Nowadays, people are preferring consumption of fresh fruits and vegetables with delicious taste. Further fruits and vegetables have high nutritional values, since they are enriched in minerals, vitamins, protein, fiber, and some other beneficial components for human health. Compared with other fruits, melon has more antioxidant properties and is beneficial for human health. Melons are considered a good source of vitamins C, B6, and K, and a maximum of potassium and copper is found in the pulps of melon, after using the fruits. Melon seeds are dried and powdered to be consumed to get maximum health benefits. In addition, there are many phytochemicals and useful components in melons, which were identified to be antifungal, antibacterial, antiviral, and anti-inflammatory. These compounds present in the melons promote health in humans by maintaining good source of

vitamins in the human body. To achieve the desired yield and enriched beneficial nutritional compounds for human health, conventional breeding can be started, but it takes too long time, and so to overcome the challenges of conventional breeding, a new approach, namely, molecular breeding has been started. In molecular strategy, the approaches, namely, marker assisted selection MAS, quantitative trait analysis, next-generation sequencing, genome-wide association mapping, genomic selection, high-throughput analysis, and structural and functional genomics have been started recently.

Melon · Nutritional value · Nutraceutomics · Conventional breeding · Homologous recombination and molecular breeding

1 Introduction

Melons are unique yet important fruits consumed around the world. These fruits are known for their dietary fiber, vitamins, and minerals and are a good source of water. Melons are also known as summer fruits or summer melons. The fruits of these melons are referred to as pepo, a kind of berry. The melons belong to the Cucurbitaceae family and are sweet and fleshy, making them easy for consumption. Melons are native to Africa and are present in the southwest valleys of Asia, especially India and Iran. Later, the importance of the fruit was understood by the European countries and they spread to almost all parts of the world (Manchali et al. 2021).

The name melon is derived from the Latin word "melo pepo." The melons are used and adapted in a wide range of conditions with maximum diversity all around the world. The production of melons is topped by China, followed by Turkey, and India occupies the fourth place, behind the USA. In India, especially Uttar Pradesh and then Andhra Pradesh and Tamil Nadu are known to have the maximum area under melon production. Also, in the USA, California contributes to a maximum of 58% of total melon production, followed by Arizona, which contributes around 28% of the total melon production. Not only the aforementioned countries, but also many more countries cultivate melons, and increase of their production is due to their numerous beneficial and useful properties in promoting human health (Fraga et al. 2019).

There are numerous benefits of melon cultivation, which can provide a good source of income for farmers who begin melon cultivation. This crop needs a maximum of 85–95 days from sowing to harvest and is fully packed with nutritional benefits. Therefore, melon cultivation, which has been popular in recent years, has become highly important in the agriculture field under proper supervision and care (Sharma et al. 2020).

There are many species of melons with varied genome sizes, among which cantaloupe, watermelon, and honey dew are the best-known melons consumed in almost all parts of the world due to their sweet taste and flavor, along with added

health benefits. As stated, melons contain many useful properties, providing good health upon consumption. Melons are considered a good source of vitamin C, B6, and K. Also, a maximum of potassium and copper are found in the pulps of melons. Along with this, the seeds of these melons are dried and consumed or powdered and consumed to get maximum health benefits. Most importantly, these melons contain maximum water content; hence, they are called summer fruits, making them profitable to farmers for production in summer and consumption for added health benefits (Gómez-García et al. 2020). Not only the fruits but also the seeds of the melons are highly healthy, containing many benefits. The seeds of these melons contain high vitamin B, minerals, and fats and are a good source of dietary fiber. These seeds are also known to regulate blood pressure, boosting energy levels while keeping the skin healthy and glowing. Apart from these, the melon fruits are known to cool the body after consuming them as a juice, whereas the seeds keep the human body active with their nourishing properties. Some recent studies revealed that watermelons contain lycopene, which is a phytochemical compound having antioxidant and anti-inflammatory properties, keeping chronic diseases at bay (Fraga et al. 2019).

Proper diet, physical health, and a calm mind are always recommendable to promote health and to fix many internal health issues. With their nutritional properties, these melons were known to promote mental calmness and, more importantly, to cure malnutrition in humans and children. A healthy diet will always fix malnutrition problems by providing the body with all the needed elements for growth. Along with starchy grains, dairy, other fruits, and vegetables, melons are also recommended to be added to the diet to keep many health issues at bay. It is recommended that a person should consume at least five fruits per day, which should include melons, as a must. Due to the lower carbs and total fats in the fruit pulp, melons can be consumed for dieting and regulating weight (Sánchez et al. 2021). Also, the lower sodium content is good for promoting proper brain functioning and is good for maintaining blood pressure. Along with this, the seeds of melons are known to contain maximum health benefits, especially in lowering the cholesterol in the blood vessels, thereby promoting a healthy lifestyle. Due to the presence of folate in these melons, they are considered good for bone health and bone mineral density. Also, the presence of lutein and zeaxanthin in the melons makes them good for eyesight and vision. The above factors, i.e., water content, dietary fiber, vitamins, minerals, especially vitamin C, less sodium, lower cholesterol, and improving bone density and vision, make melon a wonderful crop with all the daily required nutrients useful for a healthy human being and protect one from the symptoms of malnutrition (Thakur et al. 2019).

Also, certain melon species like watermelons, honey dew, and cantaloupes are very healthy in promoting a wonderful diet and keeping away severe maladies. The phytochemicals and bioactive compounds, especially in watermelons, help in improving health by increasing the availability of antioxidants to the body. The lycopene, present not only in watermelons but also in tomatoes and pink guava, is a potential antioxidant that helps in reducing the growth and development of cancerous cells. Therefore, the presence of lycopene in watermelons has become the limelight in studying its antioxidant properties, making this species of melon very useful in arresting chronic diseases like cancer (Rolbiecki et al. 2021).

There are many conventional breeding methods in melons, which include intra-specific crosses that generate variations; pedigree methods, which include selection of two parents and producing hybrids with diverse characteristics, etc., which were not very successful in melons, as these hybridization methods have not changed for many years, and similar procedures in all the crops may not be successful always. The breeding procedures can be carried out only when the plants are sexually compatible, and the insertion of new traits is also possible if the plants are sexually mated with each other. Also, a major limitation in conventional breeding is that during crossing of the plants, many unwanted genes are also transferred along with the desirable traits showing reduction in yields. Therefore, the use of these methods needs to be supplemented and new methods need to be employed in order to achieve proper growth, yields, and nutritional qualities in plants (Sultana et al. 2014).

Therefore, the use of next-generation methods like high-throughput genotyping will improve the nature of the crop and yields as well. Certain gene editing techniques help in improving allelic variations in plants. Also, automated throughput phenotyping and bioinformatic tools help in improving the genotypes of the plants. The genome-wide single nucleotide polymorphism (SNP) discovery in nonmodel organisms also helps in developing suitable melon species that are highly beneficial to farmers and breeders. The above newly emerging next-generation methods help in understanding the genetic nature of the crops and promote the development of new varieties, thereby increasing the production and productivity of the crops (Yashiro et al. 2005).

In this chapter, we will describe the importance of melon and its many useful health properties in improving the immunity of humans and keeping chronic or harmful diseases at bay. The nature of conventional methods in how they affect the crops and the ability of next-generation methods to improve the production of the crops are also discussed, along with the genetic manipulations and the biotechnological tools to be implemented in order to increase the yields and the nutritional quality of melons.

2 Description on Nutritional Constituents

Melons were considered as useful sources of nutrition due to their properties and their nutritional constituents. The melons even though of different types contain varied nutritional parameters like minerals, vitamins, etc.

The nutritional components in the fruits and the seeds of melons include many important compounds useful for human health with the abundance of water (Tables 1 and 2). Not only the water content, melon fruits contain high amount of vitamin C which is around 36.5 mg followed by vitamin A, i.e., 169 μg. The most abundant minerals found in the fruits of melons are potassium and magnesium, i.e., 267 mg and 12 mg, respectively. Not only the fruits but also the dried seeds contain high content of nutrients like proteins, around 27.40%, followed by useful fiber, around 25% adding up the importance of melon seeds along with the fruit. Therefore, the nutritional components in the seeds and the fruits of different melons make them good for consumption as they are packed with a whole lot of nutrition useful to human body on a daily basis. Due to the presence of these important compounds in melons, they were recommended for intake on a daily basis for extreme health benefits.

Table 1 Nutritional constituents in melon fruits

Components	Quantities in 100 g of raw fruit
Water	90.5 g
Proteins	0.84 g
Carbohydrates	8.15 g
Total fats	0.18 g
Dietary fiber	0.8 g
Sugars	0.9 g
Vitamin C	36.5 mg
Vitamin A	169 μg
Potassium	267 mg
Magnesium	12 mg

Table 2 Nutritional constituents in melon seeds

Components	Quantities in raw fruit
Moisture	7.15%
Oil	30.55%
Proteins	27.40%
Ash	4.81%
Carbohydrates	29%
Fibers	25%
Phenolic compounds	Less quantities

Compared to all the other biochemical and nutrient molecules present in the melon fruits, glucose and fructose were the most abundant, which are converted into easily available sugar sucrose. These sugars or the biochemicals help in maintaining the metabolism of the plants and provide food for the growth of the fruits. The sucrose content directly corresponds to the sweet taste of the fruits, which is a major parameter for increasing the market value of fruits (Kolayli et al. 2010). Therefore, the production of glucose to carry out the plant's physiological functions is given in a flow chart in Fig. 1.

The available sucrose present in the plant system is utilized along with raffinose and stachyose, which is formed into fructose, glucose, and galactose that are considered as major biochemical compounds in melons and are again synthesized into simple sugars like sucrose, which is made available to the plants and also known for enhancing the sweet taste of the fruits.

3 Medicinal Properties in Relation to Human Health

There are many phytochemicals and useful components in melons, which were identified to be antifungal, antibacterial, antiviral, and anti-inflammatory. These compounds present in the melons promote health in humans maintaining good source of vitamins in the human body. Certain studies revealed that these medicinal

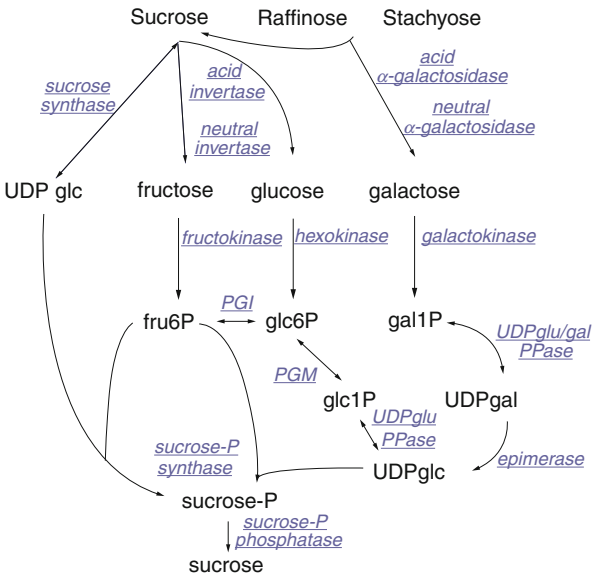

Fig. 1 A schematic diagram of the process of glucose production in plants

properties in the melons were useful in reducing many chronic diseases or the entry of such disease-causing agents can be arrested and killed immediately after it enters human body (Rajasree et al. 2016).

Melons provide maximum water content to the human body as they are abundant in water maintaining the cellular osmosis levels and promoting osmotic balance in human body. Moreover, the fruits of melons include important nutrients such as lycopene and citrulline, which are present because of the high levels of vitamins A and C. The lycopene is well-known to impart the red color to certain species of melons. Therefore, these red melons available in the market are well-known to have major health properties like reducing heart problems, arresting muscle soreness and treating inflammation in the human body wherever needed.

Certain physicians and doctors recommended that the intake of melon seeds helps in solving kidney problems, urinary bladder issues, and lowers high blood pressures thereby improving human health. The lycopene, which is a well-known antioxidant, helps in scavenging the free radicals in human body caused by radiations. The lycopene increases the body's tolerance ability toward sicknesses and ill health. Therefore, considering the above factors melons are considered as important sources of nutrition for humans to maintain balanced body weight and health (Manchali et al. 2021).

4 Genetic Resources of Health-Related (HR) Genes

The presence of particular genes in plants and the expressions of those genes have been shown to have a beneficial effect on human health. The presence of these genes in plants and the expressions of those genes have been shown to increase the

nutritional qualities of the plant, which in turn benefits the consumer. There were certain evidences of the presence of genes whose expressions can trigger and create phytomedicine synthesis in melons. The secondary gene pool of melons contains closely related plant species and hybrids. These cultivars are used for crossing and are known to produce fertile offspring. The interchange or crossing between the cultivars of this gene pool with primary gene pool is considered difficult because such crosses lead to the production of weak, sterile hybrids. Therefore, recivering the chromosomes of better parent becomes difficult. Finally, the tertiary gene pool produces completely sterile hybrids upon cross with the primary gene pool, because this gene pool is distantly related to the primary gene pool. Some special techniques are needed to transfer genes from wild gene pool to other gene pools, especially the primary one. These techniques are embryo rescue, chromosomal doubling, and bridge crosses with plants from the secondary gene pool (Pavan et al. 2017).

Cucumis melo, commonly known as melon, is a diploid plant species with a wide range of phenotypic diversity and economic importance. Melon fruits contain various nutraceuticals, such as carotenoids, flavonoids, vitamin C, and antioxidants, that have beneficial effects on human health (Garcia-Mas et al. 2012). The genetic basis of nutraceutical content in melon is not fully understood, but some candidate genes have been identified by GWAS and transcriptome analysis. For example, a gene encoding phytoene synthase (PSY), which catalyzes the first step of carotenoid biosynthesis, was found to be associated with β-carotene content in melon flesh (Pandey et al. 2016). Another gene encoding 9-cis-epoxycarotenoid dioxygenase (NCED), which regulates abscisic acid (ABA) synthesis from carotenoids, was found to be differentially expressed between climacteric and nonclimacteric melons. ABA is a hormone that influences fruit ripening and sugar accumulation. Moreover, some gene pools or germplasm collections of melon have been reported to have higher nutraceutical content than others. For instance, a wild relative of melon from India (*Cucumis melo* subsp. *agrestis* var. *momordica*) showed higher levels of antioxidants and phenolics than cultivated varieties (Zhang et al. 2022). Similarly, a landrace of melon from China (*Cucumis melo* var. *makuwa*) showed higher levels of metal ions than other types. These gene pools may provide valuable resources for breeding new varieties with improved nutraceutical content (Lotti and Fernández-Silva 2019).

5 Brief on Genetic Diversity Analysis

Melons were known for the differences in their phenotypical characters. These characters differ from one species to another in shape, size, and color of the fruits. Regarding melons, many studies previously suggested the changes in the phenotypic characters show diversity in their morphological parameters. Certain diversified traits were identified in case of melon's sex expression, fruit color, shape, number of sutures, layer around the seeds, flesh color, and the number of placentas. In case of seeds, the melons were observed to have small seed size, less seed weight, sometimes seedless in some fruits like watermelons, etc. The presence of such traits differing from the wild relatives and land races was observed due to inter-crossing or gene transfer techniques. Therefore, new methodologies and techniques help in

understanding the diversification in plants which ultimately leads to the changes in the phenotypic nature of the plants where sometimes these diversifications lead to positive changes, but sometimes they may be negative (Sensoy et al. 2007).

For example, Al-Zaher et al. (2016) characterized 50 snake melon accessions from Palestine using 17 phenotypic characters and found significant variation among them. They also identified four distinct groups of snake melons based on their morphological traits. Similarly, Yetisir et al. (2006) evaluated 56 Turkish melon genotypes using 12 phenotypic characters and found high diversity among them. They also classified the Turkish melons into six groups according to their botanical varieties. Other studies have used molecular markers such as RAPD3, SNP4, and SSR5 to complement phenotypic data and reveal more details about the genetic relationships and population structure of melon collections (Sharma et al. 2014). Phenotypic characters are useful for assessing genetic diversity in *Cucumis melo*, but they may be influenced by environmental factors and human selection. Therefore, combining phenotypic and molecular data can provide a more comprehensive picture of the genetic variation and evolution of this crop (Kimura-Kawakami et al. 2021).

5.1 Relationship with Other Cultivated Species and Wild Relatives

These melons, which were originated in South Africa, were cultivated in different parts of the world. The changes in the names and appearance of the melons make them different from each other. These melons contain different cultivated species which differ from each other, i.e., cucumber differs from gherkins where both these fruits belong to the same family. Likewise, these melons which belong to Cucurbitaceae family are closely related to each other. It was also observed that the taste, shape, and sizes of each melon species differ from each other which does not imply that they belong to different families. Therefore, the melons which were cultivated now in one area have a close relationship in sharing genes, characters, and pedigree with the other cultivable species in the same family (Mliki et al. 2001).

As India started the cultivation of melons long back, it was observed that many unexplored land races and wild relatives of melons having several useful characters were still unused. The accessions of such wild relatives were kept in store for future purpose as these wild relatives of any plants were known to contain many useful characters improving the yields, resistance against stresses, and the quality of the fruits. Understanding hybrid cultivars is a complex process. These cultivars come from crosses between wild relatives and cultivable species. This process takes a lot of time and effort. However, we can do this more efficiently now. We use techniques like marker-assisted breeding and genetic engineering. Although, some of the wild relatives of melons were explored to having many useful characters like maximum yields and stress resistance, many were yet to be explored as the process was time consuming (Endl et al. 2018).

Melons belong to the Cucurbitaceae family and have several wild relatives within the same genus, such as *C. amarus*, *C. mucusospermus*, *C. colocynthis,* and *C. zeyheri* (Zhang et al. 2019). These wild species are genetically very diverse and can provide useful genes for improving cultivated melons in terms of pest and disease resistance, drought tolerance, fruit quality, and other traits (Lotti and Fernández-Silva 2019).

Plant breeders have successfully crossed cultivated melons with some of these wild species, such as *C. amarus*, to introduce beneficial alleles into the melon gene pool. However, there are also challenges and limitations in using wild relatives for melon improvement, such as reproductive barriers, linkage drag, and genetic diversity loss (Guo et al. 2019). A comprehensive genome variation map of 1175 melon accessions and nine related species was recently published, which revealed the domestication history, population structure, and genetic diversity of melons and their wild allies. This resource could help identify novel genes and QTLs from wild species that could enhance melon-breeding programs (Zhao et al. 2019).

5.2 Relationship with Geographical Distribution

Melons are believed to have originated in Central Eastern Africa, and they spread throughout the world, possibly due to animals, humans, or birds carrying them. Musk melons come under Cucurbitaceae family with differences in their species, shapes, and sizes (Kerje and Grum 2000).

Certain species of melons called winter melons, *Citrullus,* and water melon were known to have originated in Africa and distributed to all over the world. Whereas, horned melon which originated in Africa was immediately grown in Australia, New Zealand, and Chile. Also, cantaloupe melon was cultivated in Italy. Honey dew and honey melon cultivars were cultivated in some parts of China. Mirza melon was cultivated in central Asia. Sharilyn melons, Galia, and Northern American cantaloupes were cultivated in European countries. There were many other cultivars which were grown in different parts of the world. Therefore, the above distribution of different melons all around the world in different countries provides an insight regarding the positive relationship of melons with respect to geographical distributions (Pavan et al. 2017).

5.3 Extent of Genetic Diversity

Melons are diploid species with $2n = 2x = 24$ chromosomes believed to be originated mostly in Africa and certain parts of Asia. After a few years, the melons' domestication was observed in Egypt, Europe, Middle East, China, and Afghanistan, whereas some other species of melons were imported from one country to another. Even though Africa is known to be the center of origin for melons, China was considered as the maximum producer and exporter of different hybrid melons. On an

average, these melons contain nearly 800 species or more under cultivation in different parts of the world (Nuñez-Palenius et al. 2008).

Several diversified characters and forms of melons were observed in different areas which include size ranging between 5 and 20 kgs, flesh color – orange, pink, red, white, etc., rind color – green white, yellow, red, etc., and form – round, flat, elongated, etc., based on different variations observed among different melon species. The changes in the sexual nature of the species, sex expression, and productivity of melons differ from species to species where some species gave low quality compared to the others. Even though many plant-breeding techniques emerged in melon cultivation they were observed to be less successful compared to newly emerging marker-assisted breeding and genetic transformation methods. These methods were also known to increase the diversity among the species by developing new, tolerant, and high-yielding cultivars in all the species of melons. Therefore, it was observed that the presence of maximum species of melons with less yields and low quality previously, the changes in the techniques for improving the yield, and other parameters gave rise to highly improved cultivars which were able to tolerate any stress up to a certain level, and such species were adaptable in different environmental conditions which was purely attained by the developed techniques under molecular biology (Guliyev et al. 2018).

6 Biotechnological Intervention for Health-Related Traits

Even though melons contain high nutrients, their shelf life, pollination, and storage create many problems in reducing the market value of the fruits.

Many scientists conducted experiments in melons to modify the fruits to be beneficial for consumption, and a few were successful in improving the yields and storage life of the fruits. Therefore, certain melon species were genetically modified for their ethylene biosynthesis in order to reduce the ripeness of the fruits to increase the shelf life for longer storage. On the other hand, seedless watermelons were developed by crossing male and female flowers. Also, certain gene modification in watermelons increased the sucrose content ultimately the sweetness of the fruits and the lycopene content, i.e., the antioxidant nature of the fruits so that they can be beneficial for consumption (Ezura et al. 2000).

There are many other aspects through which the melon fruits can be improved and made beneficial not only for consumption but also to increase the market value of the fruits. Therefore, it was understood that the implementation of molecular biology and biotechnology techniques in the improvement of melon fruits for different aspects was proven to be beneficial and useful in meeting the nutritional requirements after consumption. Biotechnology makes crop improvement faster and more accurate. It's a good alternative to traditional breeding methods, which take a lot of time (Ahmar et al. 2020).

Cucumis melo is a highly diverse crop with many cultivars and landraces that differ in morphological and agronomic traits. Several studies have assessed the

genetic diversity of melon collections based on phenotypic characters, such as fruit shape, size, color, texture, flavor, and yield.

6.1 Molecular Mapping for Health-Related Traits in Melon

Molecular mapping for health-related traits in melon is a technique that uses molecular markers to locate genes or quantitative trait loci (QTLs) that affect traits such as fruit quality, disease resistance, antioxidant content, or seed size. Molecular markers are DNA sequences that can be detected by various methods such as polymerase chain reaction (PCR), restriction fragment length polymorphism (RFLP), amplified fragment length polymorphism (AFLP), simple sequence repeat (SSR), or single nucleotide polymorphism (SNP). These markers can be used to construct genetic linkage maps that show the relative position and distance of the markers on each chromosome (Diaz et al. 2011). By comparing the linkage maps of different individuals or populations with different phenotypes for a trait of interest, it is possible to identify the regions that are associated with the trait variation (Kumar and Sharma 2018). These regions are called QTLs, and they may contain one or more genes that influence the trait expression (Zhang and Liu 2017). Molecular mapping can help to identify candidate genes or regions that control these traits and facilitate marker-assisted selection or gene editing for improving melon breeding. Marker-assisted selection is a method that uses molecular markers to select individuals with desirable genotypes for a trait without relying on phenotypic evaluation (Leng and Xu 2017). Gene editing is a technique that uses engineered nucleases such as CRISPR-Cas9 to introduce targeted mutations or modifications in specific genes or regions of interest. Molecular mapping can also reveal the genetic diversity, population structure, and linkage disequilibrium of melon germplasm and provide insights into the evolution and domestication of different melon types (Liu and Zhang 2020). Genetic diversity is the amount and distribution of genetic variation within and among populations. Population structure is the pattern of genetic differentiation among populations due to factors such as geographic isolation, migration, selection, or drift. Linkage disequilibrium is the nonrandom association of alleles at different loci due to physical linkage or historical recombination events. Evolution and domestication are processes that shape the genetic and phenotypic changes in organisms over time due to natural or artificial selection pressures (Pandey and Saxena 2013).

6.2 Molecular Breeding and Genomics for Health-Related Traits in Melon

Molecular breeding and genomics for health-related traits in melon is a research field that aims to improve melon varieties by using molecular tools and genomic information. Health-related traits include disease resistance, fruit quality, antioxidant content, seed size, and other traits that affect human health and nutrition (Liu et al. 2020).

Molecular tools include molecular markers, genetic linkage maps, quantitative trait loci (QTLs), candidate genes, genome editing, and gene expression analysis. Genomic information includes genome sequences, transcriptomes, proteomes, and metabolomes of different melon types (Zhang and Liu 2017). Molecular breeding and genomics can help to identify genetic variation, dissect trait inheritance, select desirable genotypes, and modify target genes or regions for improving melon breeding (Pandey and Saxena 2021).

Molecular breeding and genomics are powerful tools for improving health-related traits in melon (*Cucumis melo* L.), such as disease resistance, fruit quality, and nutritional value (Chikh-Rouhou et al. 2023). Melon is a highly diverse crop with a wide range of morphological and physiological characteristics, making it a model plant for studying various aspects of plant biology. Several genomic resources have been developed for melon, including genome assemblies, molecular markers, gene expression data, and genetic maps (Liu et al. 2022). These resources enable the identification and characterization of quantitative trait loci (QTLs) or candidate genes associated with health-related traits in melon. For example, QTLs for resistance to Fusarium wilt, powdery mildew, cucumber mosaic virus, and melon necrotic spot virus have been mapped and validated in different melon populations (Zhao et al. 2021). Similarly, QTLs for fruit quality traits such as sugar content, flesh color, aroma, and antioxidant activity have been identified and used for marker-assisted selection (MAS) in melon-breeding programs. Moreover, genomics allows the discovery of novel genetic diversity and functional variation in melon germplasm collections that can be exploited for enhancing health-related traits in melon (Gonzalo et al. 2005). In addition to conventional breeding methods such as hybridization and selection, molecular breeding techniques such as MAS, genomic selection (GS), gene pyramiding (GP), and genome editing (GE) can be applied to improve health-related traits in melon by increasing the efficiency

+and accuracy of selection (Boualem et al. 2016). Molecular breeding and genomics have thus contributed significantly to the advancement of knowledge and innovation in melon research and development.

7 Conclusions

In conclusion, melons are delicious fruits with high nutritional value that offer numerous health benefits. They are packed with minerals, vitamins, fiber, and beneficial compounds, making them an excellent choice for a healthy diet. Melons, such as cantaloupe, watermelon, and honeydew, contain vitamins C, B6, and K, as well as potassium and copper. The seeds of melons also provide health benefits, including regulating blood pressure and promoting healthy skin. Additionally, melons possess medicinal properties, such as antioxidant and anti-inflammatory effects. Through molecular breeding approaches, researchers aim to enhance the growth, yields, and nutritional qualities of melons. Incorporating melons into our daily diet can contribute to overall well-being and protect against malnutrition.

Guava: A Nutraceutical-Rich Underutilized Fruit Crop

Malarvizhi Mathiazhagan, Vasugi Chinnaiyan, and Kundapura V. Ravishankar

Contents

Abstract

Psidium guajava L., commonly known as guava, is native to the tropical and subtropical regions. It is one of the important commercial fruit crops rich in nutrients and phytochemicals that have many medicinal and nutritional benefits. It is now being recognized as "super fruit" due to the attractive color and compounds, which are known to be active as neutralizers of free radicals and are beneficial to human health. Guava fruit, leaf, bark, and seeds contain bioactive compounds that can

function as antioxidants and anti-inflammatory agents, thereby helping in alleviating different types of cancer, diabetes, and infectious diseases and promoting overall health. Guava genetic resources are diverse, with more than 400 germplasm and cultivars available around the world. Morphogenetic and molecular studies have improved our understanding of the guava germplasms. This chapter discusses in detail about the health benefits of phytochemicals, as well as genetic and molecular studies for improvement of health-related traits in guava.

Keywords

Guava · Phytochemicals · Bioactive compounds · Molecular markers · QTL · Nutraceutical

1 Introduction

Guava (*Psidium guajava* L) is widely grown across the tropical and subtropical countries of the world. Increased public awareness toward balanced diet along with nutrient benefits of guava has resulted in a global market demand for the fruit. In addition to the fruit, leaf, bark of stem, root, and seeds are also rich in phytochemicals, vitamins, and minerals. Because of their antioxidant, antidiabetic, anti-inflammatory, anticancerous, and antidiarrheal properties, many parts of the plant are found to be beneficial to human health (Shanthirasekaram et al. 2021; Blancas-Benitez et al. 2022) (Fig. 1). Further, because of its climacteric nature, the shelf-life of the fruit is less and

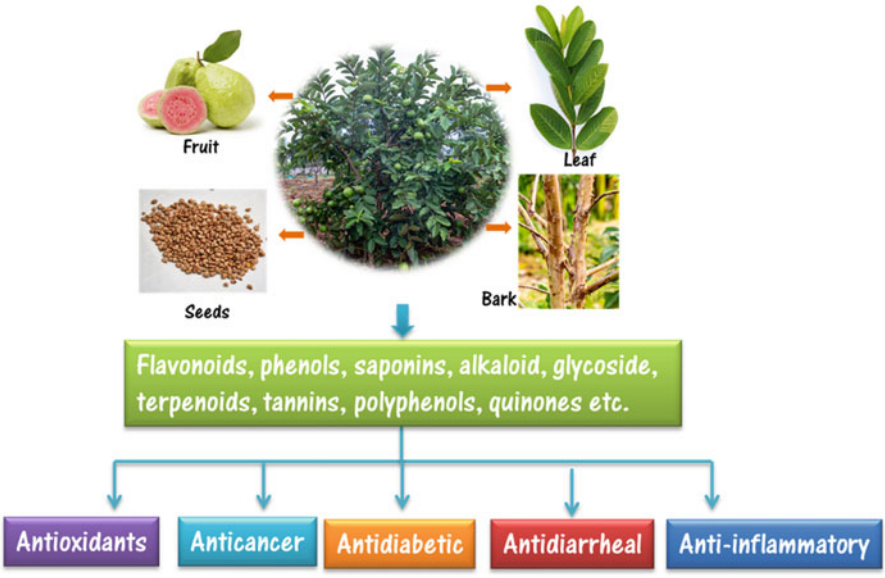

Fig. 1 Benefits of different parts of guava for human health

warrants immediate consumption. Hence, to mitigate this post-harvest loss, a variety of processed and functional food products like guava purees, jams, jellies, RTS beverages, ice creams, tea, etc. have been developed, which preserve the bioactive compounds found in the fruit and thereby catering the nutritional needs of the consumers (Sampath Kumar et al. 2021) have been developed by various workers. In order to exploit the genetic resources available in guava, morphological and genetic diversity studies play a major role. Different molecular markers have been employed to characterize and analyze the variability of guava accessions and cultivars (Pavani et al. 2022; Usman et al. 2020). Because it is an underutilized crop, there have been little efforts to understand the quantitative trait loci (QTLs) or genes controlling the important fruit quality and health-related traits. In addition, application of marker-assisted selection (MAS) and genome-assisted breeding approaches such as genome-wide association studies (GWAS), genomic selection (GS), and genome editing has not been understood in guava. With the advancements in sequencing technologies and metabolomics, efforts to identify health-related traits like vitamin C content, lycopene content, shelf-life, etc. are expected to accelerate in the future.

2 Phytochemicals with Nutraceutical Properties

Various studies on the physical, chemical, and sensory attributes of guava fruit, leaf, seed, and stem bark have been undertaken all over the world. The fruit is a rich source of vitamin C (which is four times higher than orange) and other vitamins like vitamin A (retinol), vitamin B_1 (thiamine), vitamin B_2 (riboflavin), vitamin B_3 (niacin), and vitamin B_6 (pyridoxine) (Kumari et al. 2018); minerals like calcium, magnesium, phosphorus, potassium, zinc, and iron; proteins; carbohydrates; dietary fiber (5.2 g/100 g); and lycopenes and carotenes (USDA 2019; Pandian and Jayalakshmi 2019). It's also a good source of pectin (0.5–1.9%). Many pharmacological studies have shown that the phytochemicals found in different parts of the guava plant possess various health benefits and have medicinal applications. The composition and concentration of several chemical compounds present in guava differ among the cultivars and are also influenced by the horticultural practices adapted.

2.1 Guava Leaf

The leaves are simple, opposite, oblong to elliptic with an entire margin, and have a specific aroma when crushed, which comes from an essential oil and smell depends on the cultivar. Because of its antioxidant potential and numerous phytochemicals which can boost health and ameliorate the effects of ailments or diseases, guava leaf tea is a better herbal tea alternative to commercial tea. The leaves have long been used in traditional medicine to treat diarrhea (Birdi et al. 2020) and other gastrointestinal ailments and infections. The leaf extracts have been used to treat a variety of pathogenic bacteria and viruses as natural antimicrobial agents. Some Ethiopian guava cultivars were found to have good antagonistic activity against *Salmonella*

typhi and *Shigella boydii* (Oncho et al. 2021), whereas various commercial guava cultivars with high phenols, flavonoids, and increased antioxidant activity were found to have a high level of inhibition against *Escherichia coli* and *Bacillus subtilis* (Melo et al. 2020). Guava leaf extracts are more effective against Gram positive than Gram negative bacteria in many studies (Abdullah et al. 2019). In addition, guava leaf tea has been demonstrated to be effective in suppressing influenza H1N1 viruses (Sriwilaijaroen et al. 2012). The antimicrobial activity of the leaf extract was found to differ based on the solvents used for extraction (Biswas et al. 2013). The multitude of phytochemicals such as flavonoids, phenols, saponin, alkaloid, glycoside, terpenoids, tannins, polyphenols, and quinones found predominantly in the guava leaf extracts were found contributing to its plethora of health benefits (Shanthirasekaram et al. 2021). In addition, guava leaf extracts can also act as natural immune stimulants, enhancing our immune system's ability to fight infections (Laily et al. 2015).

The mouthwash of leaves was effective for aphthous ulcers in terms of reduction of symptoms of pain and faster reduction of ulcer size (Guintu and Chua 2013). The presence of functional compounds or the bioactive poly-phenolic compounds like quercetin, caffeic, ferulic, ascorbic, and gallic acids acts as antioxidants in the treatment of numerous diseases (Denny et al. 2013). The leaf extract has been found to be promising as a herbal medicine to treat hyperglycemia. The leaves were shown to possess antidiabetic activity in diabetic mice, protective activity on liver cells (Zhu et al. 2020), reduced oxidative stress, inhibition of inflammation, and β-cell death (Jayachandran et al. 2018). The bioactive substances such as triterpenoids, monoterpenoids, flavonoids, and phenolic compounds have been discovered as important components in the regulation of type 2 diabetes mellitus (Jiang et al. 2021). These compounds control the insulin secretion and thereby lower the blood glucose level. Furthermore, due to their high free radical scavenging activity, polysaccharides from guava leaf have shown potential to be used as an antidiabetic or antioxidant compounds (Luo et al. 2019). Guava leaves also have anticancer activity and show growth inhibition of cancer cells and inducing apoptosis. Kampferol in guava leaves have been proven to have scavenging and antiproliferative activity on thyroid cell lines (Kim 2011), betulinic acid on human cholangiocarcinoma cell lines (Phonarknguen et al. 2022), polyphenols on breast, lung, and prostate cancer cell lines (Alhamdi 2019).

As an alternative, because of their antiproliferative, antioxidant, and antibacterial properties, essential oils from guava leaf have also been used for treating various diseases (Rakmai et al. 2018). The guava leaf oil is a rich source of volatiles like Caryophyllene, 1, 8-Cineole, Limonene, a-Pinene, and different proportions of terpenes and hydrocarbons (Soliman et al. 2016). As the leaves possess antimicrobial compounds, leaf extracts and essential oils are commonly used as a medicine against gastroenteritis.

2.2 Guava Fruit

The fruit is a berry with a thick pericarp and pulpy seed cavity, emitting a strong, sweet, musky odor when ripe. The shape ranges from glucose to sub-globose,

spherical, oblong, ovate, and pyriform, with four or five protruding floral remnants (sepals) at the apex weighing up to 500 g depending upon the cultivars. The fleshy mesocarp is of varying thickness and has a softer endocarp with numerous small, hard yellowish-cream seeds embedded throughout (Malo and Campbell 1994). The skin is thin, and the color of ripe fruit varies from pale yellow to dark yellow or blushed with pink, sometimes completely pale green or dark purple, depending upon the cultivars. The pulp color may be white, creamy white, creamy yellow, pale pink to dark red, purple to orange, slightly juicy, acid, sub-acid, or sweet and flavorful. The fruits are rich sources of carbohydrates (12.16%), proteins (2.3%), fats (0.7%), ascorbic acid (241.86 mg/100 g), fiber (4.8%), and minerals like calcium (17.63 mg), iron (0.24 mg), and zinc (0.21 mg/100 g), and moisture content (84.31%). The calorie yield is around 68 calories/100 g of fruit (Bogha et al. 2020). Among the pulp colors, the pink/red pulp types are more nutritious due to the presence of higher amount of phytochemicals and secondary metabolites like phenolic compounds, flavonoids, carotenoids, and tannins, which contribute to its antioxidant potential (Suwanwong and Boonpangrak 2021) than the white pulped fruits. The whole fruit is generally consumed, as the peel is rich in ascorbic acid and phenolic compounds compared to pulp (Musaa et al. 2015; Emanuel et al. 2018). The pink or red pulped guava fruits have shown to be a promising therapeutic alternative due to their increased antioxidant potential and high levels of lycopene and vitamin C (Nwaichi et al. 2015).

Numerous studies have emphasized the importance of using lycopene-rich guava fruit extract for treating different ailments, including reducing oxidative stress damage in human dermal fibroblasts (Alvarez-Suarez et al. 2018); ameliorative effects on cigarette smoke-damaged pulmonary tissues (Meles et al. 2021); cytostatic and cytotoxic effects on breast cancer cells (Dos Santos et al. 2018); modulating colon health (Blancas-Benitez et al. 2022); inhibition of intestinal resorption of glucose (König et al. 2019); frailty reduction and health promotion (Ruangsuriya et al. 2022). Pharmacological studies on pink-pulped guava fruits recorded increased hemoglobin levels in pregnant women (Sormin et al. 2020); antiplatelet activity (Rojas-Garbanzo et al. 2021); and apoptosis induction in breast cancer cells (Liu et al. 2020; Polinati et al. 2022). Guavinoside B, a biologically active compound found in guava fruit, displayed inhibitory activities on α-glucosidase, thereby providing a new therapeutic possibility for people with diabetes (Xu et al. 2022). Additionally, guava pulp, seed, and leaf phenols have shown to improve the diabetic parameters in albino rat model (Shabbir et al. 2020). Presence of high amounts of ascorbic acid, flavonoids, and polyphenols makes guava fruit a suitable candidate as a natural therapeutic agent.

2.3 Guava Seed

The seeds are good source of proteins, fats, dietary fiber, phenolics, flavonol, glycosides, tannins, saponins, and vitamins. They possess free radical scavenging activities due to the presence of phenolic compounds like chlorogenic acid, apigenin and its glycosides, caffeic acid derivatives, quercetin, phytosterols and fatty acids

like ethylpalmitate, linoleic acid, stigmasterol, and campesterol, and dietary fiber (Prommaban et al. 2020; Emanuel et al. 2018). Additionally, the polysaccharides from guava seeds were also found effective in immunomodulation and inhibition of breast cancer cell growth (Lin and Lin 2020) and prostate cancer cell growth (Lin and Lin 2021). Further, the seed oil has exhibited wound healing properties and also demonstrated growth inhibition of human erythroleukemic cells (Prommaban et al. 2019). In addition, the seed protein hydrolysates displayed α-amylase inhibition, thereby making it a suitable plant peptide-based antidiabetic agents (Jamesa et al. 2020). The seeds, generally obtained as a by-product of processing industry, have the potential to be utilized as a functional food, food additives, or structural modulators in addition to their nutraceutical applications. An elaborate review on the uses of guava seeds in food processing and nutraceutical applications is available for further reading (Kumar et al. 2022).

2.4 Guava Bark

Along with the leaves, guava stem bark has been used in traditional medicine to treat diarrhea, dysentery, and fever. The presence of bioactive phenolic compounds like gallic acid, chlorogenic acid, caffeic acid, and ellagic acid and flavonoids like catechin, rutin, quercetin, and luteolin renders guava stem bark with good antimicrobial (Gurmachhan et al. 2020), antidiabetic, antinephrolithiatic (Irondi 2020), and other health benefits (Table 1). The presence of flavonoids, tannins, alkaloids, and saponins in the root barks of guava was also reported to have antimicrobial and antioxidant activities (Kuber et al. 2013).

2.5 Post-Harvest Techniques

The fruits are climacteric, ripens fast with increase in rate of respiration and metabolic activities due to which the shelf life of fruits does not last for more than 5–7 days and making them unpleasant and commercially undesirable. Hence, there is a need for processing raw fruit into ready-to-eat products with a longer shelf life coupled with enhanced nutritional attributes. It is processed into wide an array of products like juice, jam, jelly, puree, concentrate, cheese, toffee, fruit flakes, squash, syrup, nectar, powder, wine, and vinegar, as well as ready-to-eat snacks, drinks, ice cream, biscuits, dehydrated, and canned products (Kumari et al. 2018; Sampath Kumar et al. 2021; Kumar and Gupta 2021). The by-products obtained from pulp industries are generally used as food additives, pharmaceuticals, biofuels, etc. (Iha et al. 2018; Anjali and Manjul 2021; Hoyos et al. 2022) and serve as promising functional foods due to the presence of a large number of phytochemicals (da Silva Lima et al. 2019).

Guava leaves, fruits, and seeds have become functional foods due to their health benefits. Biscuits made from guava seeds and pulp have been reported to have a significant effect in reducing the blood glucose levels in diabetes patients

Table 1 Prominent bioactive compounds present in guava

Bioactive compounds	Structure	Plant source	Properties	Reference
Phenolic and poly-phenolic compounds				
Chlorogenic acid		Leaf, seed, bark	Antioxidant, antimicrobial	Prommaban et al. 2020; Gurmachhan et al. 2020
Myricetin		Fruit, seed	Antioxidant	Emanuel et al. 2018
Ellagic acid		Seed, bark	Antioxidant	Prommaban et al. 2020; Gurmachhan et al. 2020
Caffeic acid		Leaf, bark	Antioxidant	Denny et al. 2013; Gurmachhan et al. 2020
Ferulic acid		Leaf	Antioxidant	Denny et al. 2013

(continued)

Table 1 (continued)

Bioactive compounds	Structure	Plant source	Properties	Reference
Ascorbic acid		Leaf, fruit	Antioxidant, anti-inflammatory	Suwanwong and Boonpangrak 2021
Gallic acid		Leaf, bark	Antioxidant	Melo et al. 2020; Gurmachhan et al. 2020
Guavinoside B		Fruit	Antidiabetic	Xu et al. 2022
Tannins		Leaf, bark	Antioxidant, antimicrobial	Oncho et al. 2021
Flavonoids				
Apigenin		Fruit, seed	Antioxidant and antimicrobial	Prommaban et al. 2020; Melo et al. 2020

Myrcetin		Fruit	Antioxidant and antimicrobial	Shukla et al. 2021
Quercetin		Leaf, bark	Antioxidant, antidiarrheal	Emanuel et al. 2018; Gurmachhan et al. 2020
Gallocatechin		Fruit, leaf	Antioxidant	Blancas-Benitez et al. 2022
Procyanidin B		Fruit	Antioxidant	Prommaban et al. 2020

Oleic acid		Seed	Antioxidant	Prommaban et al. 2020

Palmitic acid		Seed	Antioxidant	Prommaban et al. 2020
Stigmasterol		Seed	Antioxidant	Prommaban et al. 2020
Campesterol		Seed	Antioxidant	Prommaban et al. 2020
Alkaloids				
Saponins		Leaf, bark	Antioxidant, antimicrobial	Oncho et al. 2021

(Kaushik 2019). Further, guava seeds have found applicability in anti-acne face wash gels that harnesses their antioxidant and antimicrobial properties (Kamble et al. 2019). Similarly, guava purees rich in vitamin C and polyphenols have been reported to have a positive effect on the hyperglycemic and hypercholesterolemic rats (Pérez-Beltrán et al. 2017). Guava acts as a prebiotic and improves the flavor and nutritional value of traditional dairy products like yogurt, whey beverages, mousse, and smoothies (Chauhan et al. 2015).

In addition to adding value, post-harvest packaging techniques are critical for maintaining the fruit quality and nutritional attributes for an extended period of time (Etemadipoor et al. 2020). Different packaging techniques like modified atmosphere packaging (MAP) (Mangaraj et al. 2021), controlled atmosphere packaging (CAP), edible packaging (Murmu and Mishra 2018), antimicrobial/antifungal packaging (Elabd 2018), and nano packaging (Kalia et al. 2021) are available to extend the shelf life with minimal changes to the physiochemical properties of the fruit. Overall, post-harvest management, value-addition and processing in guava has gained significance in recent years with different kinds of functional foods being introduced into the market. However, in order to preserve the fruit's functional properties in the processed goods, the guava processing technologies must be improved, and in-depth research is needed.

2.6 Biotechnological Interventions to Improve Nutraceutical Properties

Besides some phytochemical analysis and basic pharmacological studies, the information on the mechanism of action of bioactive compounds and their antioxidant pathways are scarce in guava. In order to speed up guava breeding efforts, research on molecular markers, genes, and QTLs linked to nutraceutical properties such as vitamin C, lycopene content, shelf life, etc. are essential. Further, gene expression studies, association mapping, prediction modeling (genomic selection), and genome editing techniques can help expedite the efforts in identifying and breeding new guava cultivars with enhanced nutritional and therapeutic applications.

3 Genetic Resources

Guava is an important commercial crop in the tropical and subtropical countries and is cultivated in India, Mexico, Brazil, Thailand, Spain, Portugal, Southern France, Israel, Panama, EI Salvador, Costa Rica, Nicaragua, Bolivia, Malaysia, Kenya, the USA (Hawaii, California, and Florida), New Zealand, the Philippines, China, Indonesia, Cuba, Java, Venezuela, Pakistan, Australia, and some African countries, with India contributing around half the world's guava production. From tropical American countries, guava reached Asian and African countries through its colonizers like Spain and Portugal. It is reported that there are more than 400 guava cultivars are available around the world, majority of which belongs to the cultivated species,

Psidium guajava L. There are other wild species that has a wide variability in fruit shape, size, and flavor. Some important species which are used in breeding program for imparting resistance to biotic and abiotic stresses are: Guinea guava or Castilian guava or Brazilian guava (*Psidium guineense* Sw syn: *P. Molle* Bertol, *P. Araca* Raddi, *P. Schiedeanum* O.Berg.), Strawberry or cherry guava or cattley guava or Chinese guava (*P. Cattleianum* Afzel. ex Sabine syn; *Psidium littorale* Raddi, *P. littorale* (Raddi) var. *longipes* (O.Berg.), *P. cattleianum* var. littorale (Raddi) Mattos, *P. cattleianum* var. Purpureum Mattos, *P. Cattleianum* var. Pyriformis Mattos), Costa Rican guava or Cas guava (*Psidium friedrichsthalianum* (O.Berg) Niedenzu, syn: *Calyptropsidium friedrichsthalianum*) (Rajan and Hudedamani 2019). Prominent guava cultivars around the world for commercial and breeding works are listed here (Table 2).

Guava fruit quality parameters like shape, size, TSS, acidity, peel color, pulp color, pulp recovery, pectin content, ascorbic acid, phenols, dietary fiber, and shelf life vary greatly among guava germplasm collections around the world. Some of the traditional and modern cultivars rich in health-related traits are listed in Table 3.

4 Genetics and Traditional Breeding

Information on the genetics and inheritance of genes related to commercial traits is limited due to the perennial nature and heterozygosity of the guava plant. Guava breeding programs have generated segregating populations/progenies by crossing contrasting cultivars to understand the segregation phenomenon governing important quantitative traits like fruit peel color, pulp color, seed characters, fruit weight, yield, TSS, acidity, leaf characters, and tree characters. But only a small portion of the genetic diversity available in the crop has been utilized for commercial purpose, and the good amount of diversity that exists in the wild progenitors needs to be explored.

When it comes to pulp color, red was reported to be dominant over white pulp, with a segregation ratio of 3:1. In addition, red pulp has shown strong linkage with large and hard seeds, whereas white pulp has been linked with small and soft seeds (Subramanyam and Iyer 1990). The fruit quality traits like TSS in guava appear to be due to non-additive gene effects, while fruit weight and seed hardiness exhibited a negative association at the phenotypic and genotypic levels (Dinesh et al. 2017). The characters like fruit yield, fruit weight, outer flesh thickness, acidity, number of seeds per fruit, seed weight, plant height, phenol, and pectin content were governed by additive gene action and had high heritability combined with high genetic advance as percent of mean (Patel et al. 2015; Singh et al. 2015a; Gupta and Kour 2019). Further, a few studies have reported a low genetic variability and a high phenotypic variability for characters like fruit mass, fruit width, sepal size, length of stalk, external flesh thickness, internal flesh thickness, and external/internal flesh thickness ratio. This indicates the influence of environmental conditions over the phenotypic variability of individual progenies in a population. In contrast, the length of fruit and the ratio of diameter of calyx/fruit had a very high heritability due to additive effects

Table 2 Prominent guava cultivars grown around the world

Country	Cultivar name	Reference
Australia	'Northern Gold', 'Thai White' ('Glom Sali'), 'Common', 'Cherry', 'Allahabad Safeda', 'Beaumont', 'Sardar', 'KaHua Kula'	Mitra and Thingreingam Irenaeus 2016; Rajan and Hudedamani 2019
Bangladesh	'Swarupkathi', 'Mukundapuri', 'Kanchannagar', 'Kazi'	Rajan and Hudedamani 2019
Brazil	Paluma', 'Rica', 'Pedro Sato', 'Seculo XXI' 'Sassaoka, 'Yamamoto', 'XXI Century', 'Kumagai'	Mitra and Thingreingam Irenaeus 2016; Rajan and Hudedamani 2019
China	'Pearl', 'Red Heart', 'China pear'	Tan et al. 2020; Jaleel et al. 2021
Cuba	EnanaRoja', 'Cubana', 'EEA 1-23', 'Supreme Roja'	Mitra and Thingreingam Irenaeus 2016
Egypt	'Bassateen El Sabahia', 'Bassateen Edfina', 'Allahabad Safeda'	Rajan and Hudedamani 2019
India	'Allahabad Safeda', 'Swetha', 'Dhawal', 'Apple Colour', 'Lucknow-42', 'Lucknow-49', 'Safeda', 'Seedless', 'Red Fleshed', 'Lalit', 'Lalima', 'Red Supreme', 'Red-flHybr', 'Banarasi Surkha', 'Chittidar', 'Harijha', 'Sardar', 'Arka Mridula', 'Arka Amulya', 'Arka Kiran', 'Nagpur seedless', 'Hisar Surkha'	Dinesh and Vasugi 2010
Indonesia	'Kristal', 'Bangkok merah', 'Kamboja', 'Dadu1', 'Dadu 2', 'Pipit', 'Susupith'	Mayadewi et al. 2016
Malaysia	Jambubiji', 'Gu-5', 'Beaumont Semeyih', 'Beaumont Sungkai', 'Hongkong Pink'	Mitra and Thingreingam Irenaeus 2016
Mexico	'Media China', 'China'	Mitra and Thingreingam Irenaeus 2016
Pakistan	'Safeda', 'Allahabad', 'Lucknow-49', 'Red Fleshed', 'Seedless', 'Kerala', 'Apple Colour'	Mitra and Thingreingam Irenaeus 2016
South Africa	'Fan Retief', and 'TS-G2', 'Glom Toon' 'Klau', 'Khao Boon Soom Vietnam Xalynghe', 'Ruothong da lang'	Mitra and Thingreingam Irenaeus 2016; Rajan and Hudedamani 2019
Taiwan	'Jen-Ju', 'Di Wan', 'Pearl', 'Rainbow', 'Media China', 'China'	Mitra and Thingreingam Irenaeus 2016
Thailand	'Kim Ju', 'Pan Si Thong', 'Sa Li Thong'	Mitra and Thingreingam Irenaeus 2016
USA	'Homestead', 'Barbi Pink', 'Blitch', 'Hong Kong Pink', 'Patillo', 'Crystal', 'Lotus', 'Supreme', 'Webber', 'Beaumont', 'KaHua Kula'	Mitra and Thingreingam Irenaeus 2016
Vietnam	'Le Dai loan', 'Nu hoang', 'Khong hat', 'Xa li nghe', 'Ruot do', 'Se', 'Tim'	Mitra and Thingreingam Irenaeus 2016

of genes and with less environmental influence, which makes them a suitable candidate for improvement and positive selection (Pelea et al. 2012). Seed hardiness, which is an important fruit trait, is negatively correlated with the number of seeds per fruit but positively correlated with 100 seed weight of the fruit (Rajan et al. 2012).

Table 3 Some guava cultivars rich in nutritional values

HR traits	Cultivar name	Reference
High vitamin C	'Jen Ju', 'Di Wan' and 'Rainbow', 'Supreme', 'Jambubiji', 'Allahabad Safeda', 'Fan Retief', 'Lucknow-49', 'Media china', 'Sangam', 'Cotorrera', 'Microguayaba', 'H-118', 'H-138', 'H-153', ' H-345', 'Selection 106', 'Selection 126', 'BG 76-8', 'BG 76-14', 'Darío 18-2', 'BG 76-21', 'Red fleshed', 'Seedless', 'G. Vilas Pasand', 'Pant Prabhat', 'Mirzapur seedling', 'EC 162904', 'G-6', 'Chakaiya Ruthmanagar', 'Dhareedar'	Mitra and Thingreingam Irenaeus 2016; Medina and Herrero 2016; Dinesh and Vasugi 2010; Pommer 2012
Shelf life	'Yilan Red', 'Arka Amulya', 'Sardar', 'Swetha', 'Arka Mridula'	Mitra and Thingreingam Irenaeus 2016; Dinesh and Vasugi 2010
High Lycopene content	'Arka Kiran'	Mitra and Thingreingam Irenaeus 2016
High Phenolic content	'Allahabad Safeda ', 'Fan Retief', 'Lucknow-49', 'Sangam'	Medina and Herrero 2016
High Carotenoid content	'Cortibel 1'	Medina and Herrero 2016
High dietary fiber	'Allahabad Safeda ', 'Lucknow-49', 'Sangam', 'Lalit'	Medina and Herrero 2016
High Pectin content	'Allahabad Safeda ', 'Arka Mridula' 'Lucknow-49', 'Sangam', 'Lalit', Selected genotype no. 2'	Medina and Herrero 2016

It is interesting to see that fruit characters like fruit yield, number of fruits and fruit mass are unaffected by vegetative characters like plant height, stem diameter, and canopy volume. In contradiction, a high genetic correlation was observed between fruit yield with number of fruits; fruit weight with fruit length, width, fruit core diameter, number of seeds per fruit and seed weight which facilitate concurrent selection for these traits (Santos et al. 2017; Shiva 2017). Moreover, the total chlorophyll content has a positive correlation with Vitamin C content of the guava fruit. In case of leaf characters, leaf length and breadth had a positive correlation with leaf area, but were negatively correlated to stomata number (Shiva 2017). Further, high genotypic variance was observed in terms of width of leaf, whereas low variability for leaf length and length/width ratio (Nagar et al. 2018). More number of studies on heritability and genetic gain of important fruit traits with health benefits like vitamin C, TSS, phenolic and pectin content, flavonoids, and carotenoids are needed to improve the available germplasms and for the selection of progenies. Overall, the traditional breeding approaches in guava take a long period and require large parcels of land for progenies. Hence, adapting modern breeding

methods employing molecular markers and prediction tools will have an immense impact in terms of progeny screening, marker-assisted selection (MAS), genetic diversity analysis, association studies, genome editing, and genetic engineering.

5 Analysis of Genetic Diversity

Assessing the genetic diversity of guava germplasm can aid in crop improvement for traits of our interest, especially in the selection of parents for effective hybridization programs. Diversity analysis using phenotypic, biochemical, and genetic methods have been applied to study the available guava genetic resources in different countries (Singh et al. 2015b; Usman et al. 2020; Krause et al. 2021). Phenotypic characterization using descriptors related to tree, leaf, fruit, seed, and yield characters have assisted in understanding the divergence of guava germplasm and to identify suitable cultivars to enhance the genetic gain in breeding programs (Krause et al. 2021; Singh et al. 2015b; Pavani et al. 2022). Further, digital phenotyping has been applied to study the seed characters like texture, geometry, and color through digital image analysis to understand the genetic diversity among inbred guava lines (da Silva et al. 2021; Krause et al. 2017). Biochemical characterization consisting of health-related traits like Total soluble solids (TSS), total acidity, total sugars, sugar acid ratio, total flavonoids, total phenols, ascorbic acid, β-carotene, lycopene, and anti-oxidant activity have been studied to apprehend the divergence pattern among different white pulped cultivars (Usman et al. 2020) and different guava accessions (Santos et al. 2011).

Although many morphological characters are used for discriminating genotypes, they fail to differentiate between closely related genotypes. Thus, DNA markers or molecular markers were utilized for genetic diversity analysis of guava based on different origins, pulp color, vitamin C content, and cultivars. Markers like PCR-based, hybridization-based, and sequence-based have been used for diversity studies. Markers like Amplified Fragment Length Polymorphism (AFLP) (Thaipong et al. 2017), Random Amplified Polymorphic DNA (RAPD) (Ahmed et al. 2011), Inter simple sequence repeat (ISSR) (Sharaf et al. 2020), Inter-primer binding site (iPBS) (Mehmood et al. 2016), and sequence-related amplified polymorphism (SRAP) (Youssef and Ibrahim 2016) have been used to study the variability among the guava cultivars. Simple Sequence Repeat (SSR) markers have been predominantly used to study the genetic diversity of accessions/germplasms in different countries like India (Kumari et al. 2018; Kherwar et al. 2018), Kenya (Chiveu et al. 2019), China (Ma et al. 2020), United States (Sitther et al. 2014), Pakistan (Kareem et al. 2018), Bangladesh (Alam et al. 2018), Mexico (Sánchez-Teyer et al. 2010), and Venezuela (Aranguren et al. 2008). Genomic SSRs developed from cultivar 'Allahabad Safeda' through microsatellite-enriched libraries were found suitable for genetic diversity studies, population structure analysis and also had high cross-species transferability among *Psidium* species (Kumar et al. 2020). SSRs developed from *Psidium guajava* have had a high cross transferability potential to members of Myrtaceae family like *E. citriodora*, *E. camaldulensis*,

C. lanceolatus, and *S. aromaticum*, which can be utilized for inter- and intra-species genetic diversity analysis (Rai et al. 2013). Further, SSR markers have found its utility in studies assessing sexual compatibility among the *Psidium* species (Mulagund et al. 2021) and DNA fingerprinting (Chaithanya et al. 2017). Lately, due to advancements in next generation sequencing (NGS) and construction of draft genome assembly in guava, development of sequencing-based single nucleotide polymorphisms (SNPs), InDels, and transcriptome-based SSR markers from different peel and pulp-colored cultivars have become feasible. These markers have high applicability in population structure analysis, genetic diversity studies, and in breeding programs (Thakur et al. 2021). In addition, SNP markers identified using DArTSeq-based genotyping among different native Psidium species have shown high interspecific diversity (Grossi et al. 2021). The development of SNP-PCR and transcriptome-based SSR markers strongly associated with health-related traits can aid in precise identification of the cultivars, accessions, and wild species suitable for breeding programs in guava.

6 Molecular Mapping and QTL Identification for HR Genes

Various molecular markers like AFLP, SSR, RAPD, and SRAP were used for molecular mapping studies in guava. Genetic linkage maps were developed by mapping populations derived from heterozygous parents. Polymorphic markers were used to construct individual parental linkage maps and then assembled into an integrated map (Lepitre et al. 2010). Further, integration of phenotypic data with the marker data has helped in identifying QTLs that are correlated to different quantitative traits in guava (Ritter et al. 2010a).

The first molecular linkage map of guava contained 167 AFLP markers in the integrated map, which helped in the identification of 15 QTLs for vegetative characters (Valdés-Infante et al. 2003) (Table 4). A genetic linkage map utilizing 220 polymorphic AFLP markers was constructed along with the identification of QTLs for leaf length, leaf width, petiole length, height, fruit weight, acidity, total soluble solids, vitamin C content, and pulp thickness utilizing a mapping population derived from dwarf cultivar 'Enana Rojacubana' as the female parent (Rodriguez et al. 2005). Later, Ritter et al. (2010a) constructed an integrated parental linkage map in three guava mapping populations ('Enana' × 'N', 'Enana' × 'Suprema Roja' and 'Enana × 'Belic L-207') using AFLP and SSR markers. They obtained 11 linkage groups (LGs) corresponding to the haploid guava genome of 11 chromosomes for each parent. The integrated maps contained markers between 408 and 850 and were covering 1885–2179 cM, in length, respectively. Further, Ritter et al. (2010b) had conducted a QTL analysis using the linkage maps constructed for three mapping populations in their previous study. Sixteen different traits related to leaf and fruit characteristics and yields were recorded in both the parents and progenies of the three-mapping population. A total of 75, 56, and 59 QTLs for all the traits studied were detected in populations MP1 ('Enana' × N'), MP2 ('Enana' × 'Suprema Roja') and MP3 ('Enana' × 'Belic L-207'), respectively. Some QLTs were found

Table 4 Genetic linkage maps and QTLs identified in guava

Mapping population derived from crosses	Number of segregating individuals	Type of linkage map	Molecular markers employed	No. of QTLs identified	References
'Enana' × 'N6'	81	Integrated	AFLP	15 QTLs for vegetative traits	Valdés-Infante et al. (2003)
'Enana' × 'N6'	81	Integrated	SSR	Fruit weight – 3, fruit width – 3, acidity – 3, TSS – 2, Vit. C content – 2, pulp thickness – 2, seed number – 1, seed weight – 5	Rodriguez et al. (2005)
'Enana' × 'N6' 'Enana' × 'Suprema Roja' and 'Enana' × 'Belic L-207'	100–120	Integrated	AFLP and SSR	75, 56, and 59 QTLs in each mapping population respectively	Ritter et al. (2010a, b)
'Enana' × 'N6'	80	Integrated	AFLP and SSR	–	Lepitre et al. (2010)
'Kamsari' × 'Purple local'	94	Parental	SSR, SRAP, and RAPD	One major QTL for average fruit weight, four QTLs for seed strength (hardness/ softness)	Padmakar et al. (2015, 2016)

to be linked to SSR markers, which could be used for marker-assisted selection of progenies with desired traits in conventional breeding.

A similar type of study was conducted by Lepitre et al. (2010) in a guava mapping population derived from a cross between two heterozygous guava cultivars ('Enana' × 'N6'). A total of 1364 AFLP and SSR markers were used for linkage mapping. The integrated map length was 2179 cM and had an average linkage group length of 198 cM/chromosome. Further, high throughput genotyping of 94 guava F1 progenies using SSR and SRAP markers had generated scorable polymorphic markers, that were used for the construction of parental (Cultivar 'Kamsari' and 'Purple local') genetic linkage maps using a LOD score of 4.0 (Padmakar et al. 2015). Padmakar et al. (2016) have also identified one major QTL linked to fruit weight and two major and two minor QTLs for seed strength based on linkage map enriched further using RAPD markers. These studies have shown some insight into the QTL regions responsible for health related traits like vitamin C, TSS, and acidity, along with other fruit and leaf-related quantitative and qualitative traits. However,

adapting NGS-based genotyping methods like Genotyping by sequencing (GBS) becomes vital for exact identification of QTLs or genes linked to health-related traits.

In addition, an RNA-Seq based transcriptome analysis of genotypes with contrasting peel and pulp colors at different stages of ripening has set the stage for the functional genomics of traits like colored pulp and peel (Mittal et al. 2020) in guava. The study has identified 68 candidate genes that are involved in peel and pulp color development in guava fruits. These genes involved in ethylene biosynthesis, phenylpropanoid, and monolignol pathways, along with the QTLs identified, have the potential to be used as predictive markers in marker-assisted selection (MAS) in conventional breeding. Interestingly, even though there is a dearth of NGS-based research in this crop, guava got its first chromosome-level genome assembly for the cultivar 'New Age' recently (Feng et al. 2021). This development will aid in reference-based genotyping, thereby assisting in construction of high-density linkage map, genome-wide association studies (GWAS), and Genomic selection (GS) in guava.

7 Nanotechnology

Nanoparticles (NPs) are produced through a complex physico-chemical reaction which involves release of toxic wastes, unsafe by-products, and a high level of energy intake. Hence, an alternate and safe method for metal nanoparticle synthesis can be achieved through green biosynthesis of NPs utilizing plant sources. Guava leaves rich in phytochemicals like flavonoids, phenols, polyphenols, tannins, saponins, terpenoids, ascorbic acid, and proteins can mediate the redox reactions, thereby reducing the salts/ions, stabilizing and capping the nanoparticles formed. Several metal nanoparticles synthesized using guava leaf extracts were reported to possess antimicrobial properties. The aqueous extracts of guava leaves have been used in the preparation of iron oxide, silver oxide (Dildar et al. 2022), and Zinc oxide (Jyoti et al. 2020; Balalakshitha and Kolanjinathan 2021; Ramya et al. 2022) nanoparticles that exhibited radical scavenging and antimicrobial activities against pathogenic Gram positive and Gram negative bacterial strains. Similarly, the silver nanoparticles synthesized from guava extract coated with polymeric micelles possessed high antifungal activity against *Candida albicans* (Suwan et al. 2019). In addition, these silver NPs presented high level of antioxidant, antibacterial, and cytotoxicity against the colon cancer cells (Sandhiya et al. 2021). The copper NPs synthesized using aqueous guava extract comprised of high antibacterial activity against bacterial pathogens, *E. coli* and *S. aureus* due to the presence of antioxidant compounds like polyphenols and ascorbic acid in the guava extract (Caroling et al. 2015). Likewise, aqueous and ethanol extracts of guava leaves have yielded gold NPs due to the involvement of flavonoids present in the leaf extracts (Raghunandan et al. 2009; Putri et al. 2021). Furthermore, a lipophilic nano-emulsion containing purified lycopene from red guava had shown potential as a drug delivery system because

of its successful delivery of the lycopene to liver, kidney, and prostate organs of mice and also for enhancing the cytotoxicity against the prostate cancer cells (Vasconcelos et al. 2021).

Another interesting application of nanotechnology is for the improvement of shelf life of guava fruits using nanoparticle-based coating materials. The edible coatings, like Zinc oxide NPs combined with chitosan and alginate (Arroyo et al. 2020) and solid lipid NPs (Zambrano-Zaragoza et al. 2013), were shown to increase the shelf life of the guava fruits. In addition, incorporation of guava puree in chitosan nanoparticle-based edible films for packaging has imparted favorable color and odor for these films (Lorevice et al. 2012). The nano-technological application of guava leaf extracts in synthesis of metal NPs can prove to be a cost-effective and safe method with a wide biomedical application.

8 Social, Political, and Regulatory Issues

The health benefits of guava plants can immensely contribute to the nutritional security of the growing population. Unfavorable weather conditions, pests and diseases, unavailability of good commercial cultivars, lack of processing and storage facilities, and post-harvest wastages are the major problems faced by guava growers. Awareness toward the market potential of guava fruit is needed to boost its cultivation among the farmers of the tropical and subtropical countries. Moreover, popularizing guava fruit and its benefits among the public can provide consumers with a cheaper and nutritious alternative. More importantly, developing post-harvest techniques and value-added products that retain the phytochemicals and antioxidants present in the fresh fruit could be a boon to the industry and consumer market. In order to ensure its safe deployment, regulatory issues related to its biomedical application, nanotechnology, and alternative therapies need to be streamlined.

9 Future Prospects

The tropical and subtropical regions are home to *Psidium guajava*, which is highly diverse and spread across the world. Studies have proved the antioxidant, anticancerous, antidiabetic, antidiarrheal, and anti-inflammatory potential of this highly nutritious commercial fruit crop. Although there are a few conventional breeding efforts, application of modern breeding techniques using precise molecular markers for marker-assisted selection (MAS), marker-assisted introgression (MAI), association studies, genomic selection, genome editing, and transformation studies are lacking in guava. Using high-throughput sequencing techniques like NGS can help in identifying SNP and SSR markers for important health-related traits in guava and thereby assist in speed breeding of superior guava cultivars and hybrids. Also, there is a need to develop strong international collaborations, industrial and academic interactions to ensure adequate public and private funding of projects which helps in faster outcome.

10 Conclusion

Nutraceutical properties present in guava plant is being utilized in the traditional medicine practices of different countries. From leaf to seed, the potential benefits provided by this underutilized crop can help cure and mitigate various ailments as documented by different studies. On the other hand, it is essential to develop breeding materials and value-added products and popularize its benefits among the general public for a sustainable growth in guava production and utilization.

Abstract

Date palm (*Phoenix dactylifera* L.) is one of the oldest fruit trees known where a significant amount of breeding has been carried out to improve various agronomic and nutritional characteristics. Numerous studies have been done to improve the nutritional composition and quality of the fruit due to its significant biological properties. Various strategies have been formulated for improving the agronomic characters through biofortification as well as preserving through postharvesting techniques. Modern breeding practices using molecular markers have significantly helped to identify the phenotypic, as well as genotypic, diversity for the selection of superior date palm cultivars, advanced agronomic characters like nutritional quality, disease resistance, and yield. Availability of the whole genome sequence, organellar sequence, and genetic map of date palm has helped breeders in modification and improvement of the characteristics. With the availability of bioinformatic tools and gene editing knowledge, the nutritional composition of date palm can be effectively manipulated to develop better crops along with good agronomic characters and resistance to diseases. The authors have compiled the nutritional composition of date palm fruits and detail the strategies to edit the genome and improve nutritional quality.

Date palm · Nutritional composition · Molecular markers · Whole genome · Bioinformatics · Genetic map

1 Introduction

Date palm (*Phoenix dactylifera* L.) trees are one of the cultivated plants for centuries and its fruits served as a staple human food since time immemorial. In the world, date palm cultivation varies from region to region. There are in total more than 2000 cultivars of date growing around the world some of which are available elite varieties with good fruit qualities (Ahmad Mohd Zain et al. 2022).

Date fruits are consumed in both their fresh and dry states. Date palm fruit production volume in the world has surpassed 9.45 million mt (https://www.statista.com/statistics/960213/date-palm-market-value-worldwide/). Dried fruits of date can be stored for a long duration at ambient climatic conditions at exceptionally low cost. Date fruits have a worldwide market; primary exporters are Iran, Egypt, Saudi Arabia, Iraq, and Algeria. World-class date fruit exporters need to take some important steps with respect to good physical and chemical properties, date types, quality and size of package, main requirements of the importing countries, and transport mode (Al-Khayri et al. 2018).

As a part of traditional nutritional therapy and religious practice, date fruits have been consumed all over the world for thousands of years by millions of people. Dates are rich in carbohydrates which give instant energy to the human body. Dates are composed of vital minerals such as Fe, Mg, Ca, P, Zn, Se, K, and Mn which are important to improve their nutritional values (Aljaloud et al. 2020). Fruits contain various vitamins such as β-carotene, thiamine, ascorbic acid, riboflavin, and folic acid niacin (El Hadrami et al. 2011; Aljaloud et al. 2020). Date fruits also supply essential amino acids like histidine, valine, aspartic acid, proline, arginine, serine, methionine, threonine, lysine and alanine, glycine, leucine, tyrosine, phenylalanine, and isoleucine (Assirey 2015). Bioactive compounds are the important ingredients of date fruits including caffeic, gallic, syringic, protocatechuic, vanillic, p-coumaric, and o-coumaric acids, quercetin, kaempferol, ferulic acid, and luteolin (Vayalil 2012; Ahmad Mohd Zain et al. 2022). The superfluity of nutrition composition of date fruits makes them highly medicinal and therapeutically important crop plants.

Conventional breeding and biotechnological tools were used together to improve the quality of the date fruits, for quick growth, to develop resistance against a variety of stresses and diseases. Height reduction is one of the important objectives in the date palm breeding. In Kuwait, scientists have developed a seedless fruit by crossing tall female cvs. and a dwarf palm (*Phoenix pusilla*), combining both conventional breeding and tissue culture techniques (Sudhersan et al. 2010). Various chronic diseases of date palm reduce date fruit production. One such deadliest disease is bayoud, caused by *Fusarium oxysporum* f. sp. *albedinis*, which causes great losses in Morocco and Algeria (Sedra and Lazrek 2011). To control the disease, various control measures were applied including chemical and biological applications, but among them all, developing resistant varieties is the most promising way to fight against the bayoud disease. Date palm cv. Taqerbucht from the oases of Salah and Tidikelt, Algeria, is found to be the best resistant cultivar against bayoud (Bouguedoura et al. 2015). In Tunisia, a new disease named brittle leaf disease has destroyed around 40,000 date trees in a short time span due to leaf wilting; the cause of the disease is still unknown (Triki et al. 2003). The date palm crop has a breeding limitation due to its growing environmental conditions where the plant must survive extreme salt and drought stress. Another problem is sex determination; until the onset of fruiting, it is not possible to identify the sex of the plant which matures at 5–7 years of age. Farmers are using traditional and rudimentary agricultural techniques from past generations. Water scarcity, a primitive level of farm and crop

management, applying traditional methods of irrigation, limited use of advanced breeding tools, lack of skilled labor, and a low level of mechanization are some constraints to date palm breeding (Al-Khayri et al. 2015).

2 Chemical Composition and Biochemical Pathways

2.1 Chemical Composition

The plant species of the family Arecaceae, *Phoenix dactylifera*, has been a staple food in the Indus valley region and Middle East since before than sixth millennium BCE. Extensive research has been conducted on its nutritional composition and related molecular biochemistry. The overall chemical composition of date palms suggests that it consists of a very large number of nutrients and associated molecules. Due to this long list of nutritional chemicals, the benefits of date palm consumption are many. Starting from its activity as an energy booster, it is also credited with elevating the iron content in the body. It helps in digestion and has various pharmacological activities. Due to their appropriate balance in composition, they have also been regarded as being sufficient for consumption during fasting. All these activities are credited with the presence of innumerable chemicals in the plant. The overall list of contents in various species of date palms is comprehensively reviewed in the following section.

Almost every organ of the plant is rich in a variety of nutritional compositions. The stem of date palm consists of important nutritional compounds such as stilbene (Fernández et al. 1983a). Along with this, the same part of the plant also contains important steroid, polysterol, and stigmastane molecules (Fernández et al. 1983b). In addition, the stems also possess sterols such as ergosterol along with aromatic carboxylic acids like benzoic acid and its derivative like 3,5-dihydroxy-4-methoxy benzoic acid (Fernández et al. 1983a). Triterpenoids have already been tested and found to be very crucial anti-inflammatory, anti-pyretic, and hepatoprotective agents in medicine. For conditions associated with weight loss and reduction of cholesterol levels, it is also highly necessary to reduce the risk of heart attacks which are aided by the presence of plant sterols like campesterol.

The seeds of date palm plants also consist of a variety of important phytochemicals that boost the immunological capabilities of humans. The long list starts with the presence of amino acids like alanine in seeds which help in metabolic activities in the human body (Hussein and El Zeid 1975). It relates to the muscle and improvement of physical functioning in humans. Notably, the concentration of amino acids is higher in the unripe stages of the seeds as compared to the ripe ones, as arginine, glutamic acid, aspartic acid, leucine, lysine, and serine were the highest in unripe stages, while proline and glycine were the highest in ripe stages (Auda et al. 1976). The seeds of the date palm are home to mostly several SFAs (Jindal and Mukherjee 1970; Mossa et al. 1986) (Table 1, Fig. 2). Pivotal agents to nutrition include the presence of saccharides obtained from plants as they help magnify nutrition levels, prevent blood clotting, and are one of the major products consumed as staple food in

Table 1 Chemical composition and health benefits of date palm

Plant Part	Chemical	Specification	Health benefits	Reference
Stem	*Cis*-3,5,3′,5′-tetrahydroxy-4-methoxystilbene	Stilbene (olefin)	Antioxidant benefits	Fayadh and Al-Showiman 1990

Table 1 (continued)

Plant Part	Chemical	Specification	Health benefits	Reference
	Manganese	Essential mineral	Metabolism of various amino acids, carbohydrate, bone formation, anti-inflammatory, blood clotting	Ibraheem 2021
	Magnesium	Essential mineral	Energy promotion, maintenance of normal nerve functioning, immune system	Uddin and Nuri 2021
	Iron	Essential mineral	Essential for blood production and healthy skin, bones, and hair, immune system booster	Lamia and Mukti 2021
	Ascorbic acid	Vitamin C additive	Collagen formation, wound healer, cartilage, teeth, bones, repair of body tissues	Rajan et al. 2021
	Iso-chlorogenic acid	Phenolic acid	Lowers blood pressure, blood sugar, and weight	El-Far et al. 2016
	γ-Aminobutyric acid (GABA)	Neurotransmitter	Brain neurotransmitter, anxiety reducer, pain reliever	López-Córdoba 2021
	Vitamin A	Vitamin	Normal vision, reproductive ability, helps organs work well	Hinkaew et al. 2021
	Thiamine	Vitamin additive	Pyruvate metabolism, conversion of carbohydrates to energy, nerve signal transmission	Shehzad et al. 2021
	Riboflavin	Vitamin additive	Fat and protein metabolism, conversion of carbohydrates to energy	Awofadeju et al. 2021
	Nicotinic acid	Vitamin additive	Triglyceride and cholesterol improvement	Tawfek et al. 2021

our diets (Noorbakhsh and Khorasgani 2022). As far as seeds of date palm are concerned, they contain a large number of saccharides, essential for human life such as rhamnose, xylose, D-mannose, lactose, glucose, D-galactose, and most importantly, the sweetest sugar, fructose (Jindal and Mukherjee 1969; Mahran et al. 1976; Al-Whaibi et al. 1985). Zinc, phosphorus, potassium, aluminum, manganese, and iron are a few of the beneficial elements found along with other chemicals in the seeds (Sawaya et al. 1982; El-Shurafa et al. 1982; Hamad et al. 1983).

The pollen of date palms also has been found to contain a few important biomolecules like β-sitosterol, which resembles cholesterol molecules and helps to reduce hypercholesterolemia (Mahran et al. 1976; Kikuchi and Miki 1978; Fernández et al. 1983b). Another fascinating glycoside, formed by the combination of flavonol quercetin and disaccharide rutinose, rutin is found in the pollen of the plant (Mahran et al. 1976). It is chiefly used in the production of medicines which has a similar function as that of sitosterol, in lowering cholesterol levels. In addition, it is also used to reduce arthritis pain and prevent blood clotting. The flavonoid quercetin is also present in the pollen along with female sexual hormones like estrogen and estrone (Hassan and Abou El Wafa 1947; Bennett et al. 1966; Mahran et al. 1976; Mossa et al. 1986). Estrone in the body is converted to estrogen when needed; thus, the former serves as a repository for hormone estrogen in females. A triterpenoid, i.e., β-amyrin, is also found in pollen that is responsible for the improvement of glucose tolerance owing to its anti-inflammatory and antioxidant effects (Mahran et al. 1976).

The most important and maximum number of phytochemicals exists in the edible part – "fruit." Nearly all amino acids like alanine, arginine, etc. and saccharides like fructose, glucose, and sucrose (Auda et al. 1973; Hussein and El Zeid 1975; Auda et al. 1976; Sawaya et al. 1983b) are present. Elements like Ca, Fe, Mg, Mn, P, K, and Zn with vitamin additives like ascorbic acid, nicotinic acid, riboflavin, thiamine, and vitamin A are also found (El-Shurafa et al. 1982; Sawaya et al. 1983; Mossa et al. 1986). Natural products with pharmaceutical potentials like neurotransmitter γ-aminobutyric acid (GABA) and iso-chlorogenic acid are added compositions (Cadi et al. 2021; Hattori et al. 2021) (Table 1).

2.2 Chemical Type, Structure, and Biochemical Pathways of Production

Date palms have a plethora of important nutrients and chemicals in their composition ranging from vitamins to amino acids and fatty acids. The extensive details about all the parts of the date palm containing the respective nutrients have already been explained. Specifically, when the leaf fiber extracts of date palm were studied, constituents obtained in decreasing order of their percentages were α-cellulose (58%) to pectin (2.3%) (Pandey and Ghosh 1995). In fact, a good replacement for synthetic fibers exists through the microcrystalline cellulose extracted from the fruit fibers of the date palm. Lignin and hemicellulose were also isolated from the date palm fiber, indicating their richness in nutraceutical properties (Hachaichi et al. 2021).

The list of important therapeutic and immune condition-boosting biomolecules present in the fruits of the date palm is long, as already mentioned. The range commences at amino acids like alanine and terminates at nicotinic acid and other vitamin additives. Amino acids are structurally identical, except for the -R group which determines the nature of the molecule (Figs. 1 and 2). They are zwitter ionic

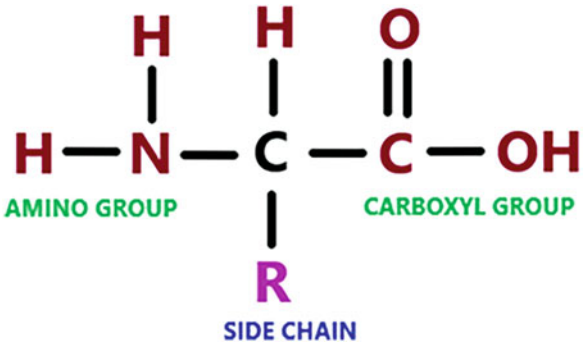

Fig. 1 General structure of amino acids

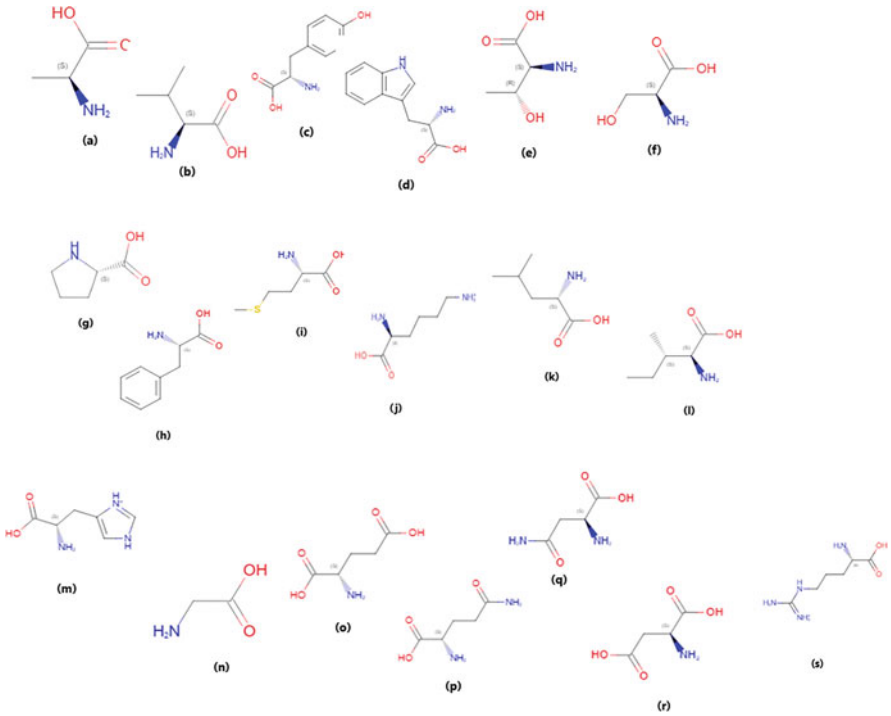

Fig. 2 Structures of a few amino acids found in the fruits of date palm. (Source: PubChem) [a-Alanine, b- Valine, c- Tyrosine, d- Tryptophan, e- Threonine, f- Serine, g- Proline, h- Phenylalanine, i- Methionine, j- Lysine, k- Leucine, l- Isoleucine, m- Histidine, n- Glycine, o- Glutamic acid, p- Glutamine, q- Asparagine, r- Aspartic acid, s- Arginine]

molecules that exhibit the acidic and basic character simultaneously at a given set of environmental conditions.

Other parts of the plant are also rich in several important pharmaceutical biomolecules and guarantee a healthy immune system when consumed on a regular basis. One of the major reasons why date palms are included in our diet during a very physically demanding fast is because of the availability of enormous amounts of carbohydrates and fats, which is also the reason why date palms exist under "Ojas" or energy-giving food in Ayurveda (Haas 2015). Moreover, high amounts of soluble fibers (Maou et al. 2021) and the alkaline nature of fresh date palms (Alghamdi et al. 2019) further increase the beneficial properties of its consumption because it increases colon performance and compensates for the increased stomach acidity, respectively, after fasting. The "sattvic" nature of soft and succulent fresh dates as described in Ayurveda aids in cooling down the heated body after a long fast. Other important biomolecules present in date palms are stilbenes (Fig. 3a), steroids (Fig. 3b), phytosterols (Fig. 3c), minerals like calcium (Fig. 3d), saccharides (Fig. 3e), saturated (Fig. 3f) and unsaturated fatty acids (Fig. 3g), vitamins (Fig. 3h), triterpenoids (Fig. 3i), flavonoids (Fig. 3j), and carboxylic acids (Fig. 3k), as listed in Table 1.

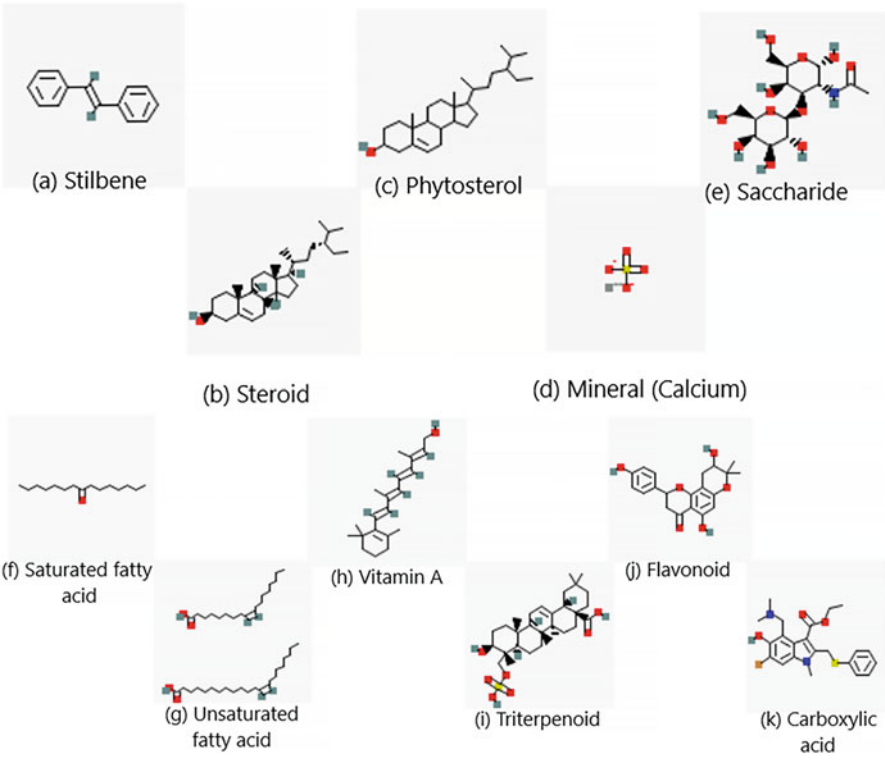

Fig. 3 Structure of a molecule from each group of biomolecules present in different parts of date palm. (Source: PubChem)

The biochemical pathways to produce biomolecules generally follow a distinct cascade of reactions in the organism. In the case of date palms, there are a wide range of biomolecules present in almost all organs as mentioned. When focusing on stems, olefins are present in the majority, which are produced by a variety of reactions like hydrogenation, dehydration, hydro-deoxygenation, or steam cracking. It has been found that almost all the important olefins are ultimately produced from the intermediates obtained from the basic metabolic cycles in respiratory pathways such as glycolysis or citric acid cycle. An example of such a pathway has been found starting from glucose to olefins like stilbene and various other secondary metabolites in plants (Fig. 4).

Very interestingly, it has been observed that there are different changes in the amount and number of metabolites in the context of amino acid biosynthesis in date palms when subjected to UV-B light irradiation (Agwa 2021). There is a cascade of reactions that give rise to multiple metabolites in between two steps that can be significant to humankind, both in terms of economy and nutrition. The saccharide biosynthesis in date palms occurs through another series of reactions and biochemical pathways, as in any other fruit species as depicted by researchers already.

Not only date palms have the biochemical pathways to produce metabolites, but they have been studied in other species, such as in maize. Sharma et al. (2012)

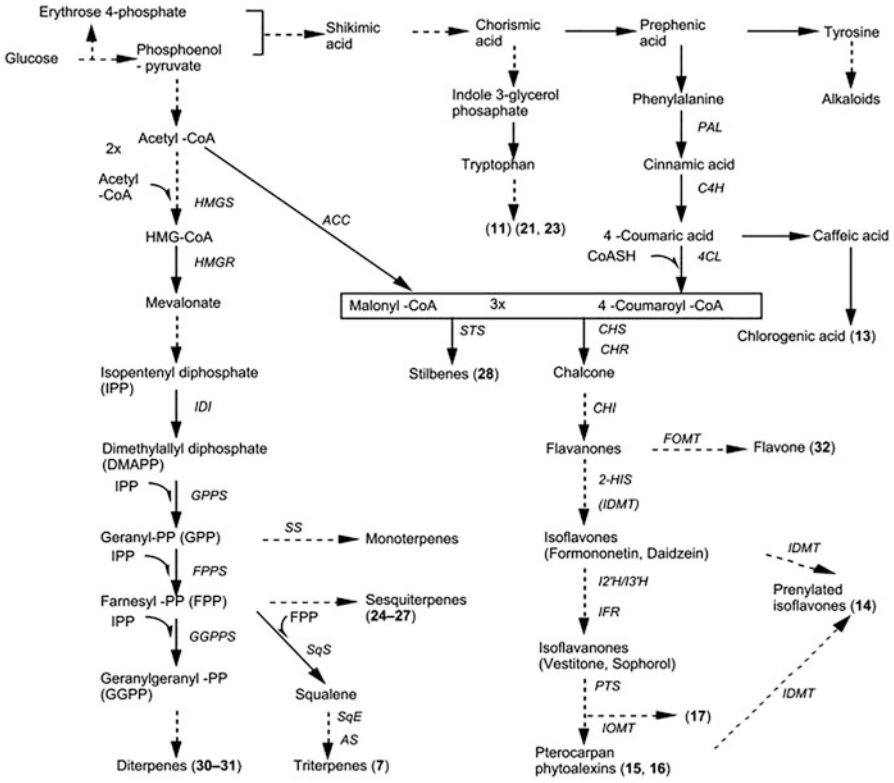

Fig. 4 Biosynthesis of various olefins in plants by metabolic pathways. (Modified from Bacigalupa et al. 2018)

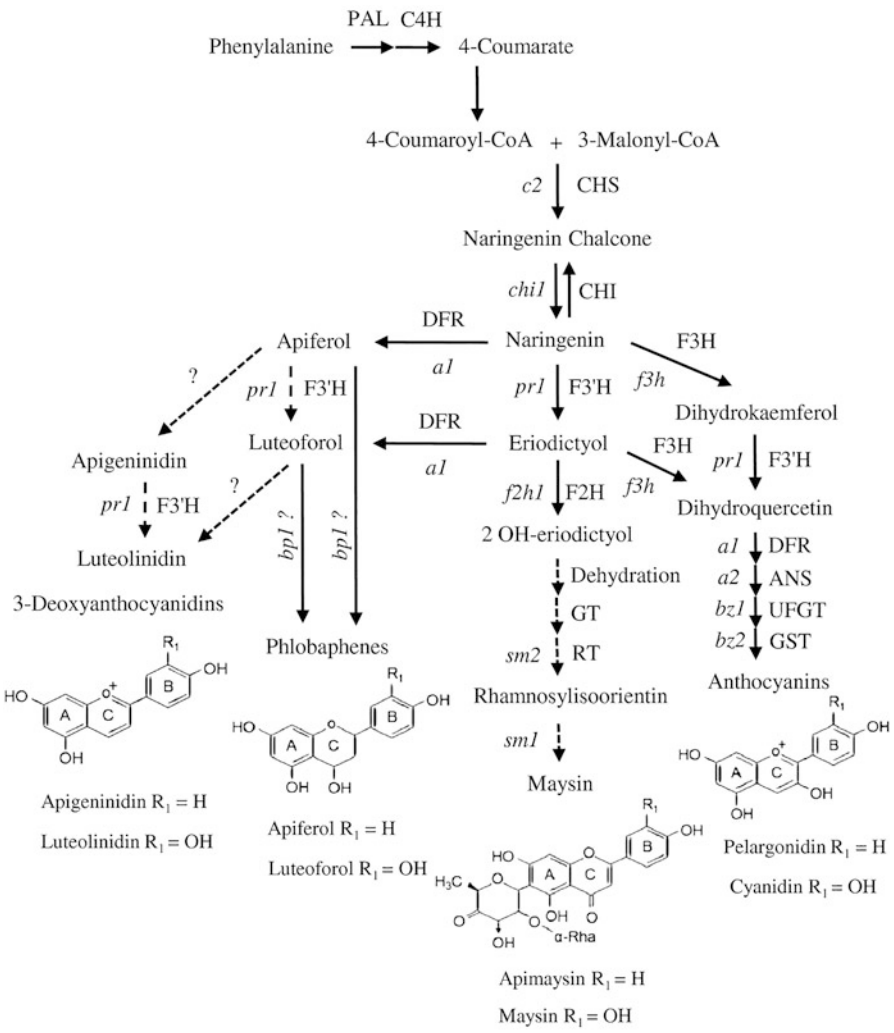

Fig. 5 Flavonoids' biosynthetic pathway in maize (Sharma et al. 2012)

reported on flavonoid biosynthesis in maize (Fig. 5). Identification of crucial genes responsible for the authentic metabolism of raw products is important. In date palms, extensive research is ongoing on its biochemical pathways of metabolite production.

2.3 Medicinal/Physiological Properties and Functions in Relation to Human Health

Date palms are also consumed by humans because of their restorative and curative properties. The medicinal properties of the plant range from the simplest of

Fig. 6 Protective activities of *Phoenix dactylifera* against various ailments

symptoms like cold and fever to life-threatening diseases such as liver cancer and bronchial catarrh (Fig. 6). The credit for being a remedy to this long list of ailments goes to the enormous number of phytochemicals present in the plant. The main biomolecules present in the plant are vitamins, minerals, flavonoids, carbohydrates, steroids, alkaloids, and many others (Ahmad Mohd Zain et al. 2022). Some of the important medicinal properties of the date palm are listed in Table 1.

2.3.1 Anticancer Activity

One of the leading causes of death today is cancer and an extensive number of research is being done to prevent and treat this disease. The plant under study contains a good number of anticancerous agents and studying the effects of those molecules in rat models can increase its use for therapeutic purposes. For the prevention of hepatocellular carcinoma, restoration of antioxidant enzymes in the liver to accurate levels is very important, which can be performed using biomolecules like quercetin, luteolin, or glucans already existent in date palm (Lamia and

Mukti 2021). For mammary cancer in humans, the effect of various concentrations of water extracts of Jordanian dates was assessed on MCF-7 breast cancer cell lines. On analyzing the effect of anticancerous agents using the MTT assay and calculating the percentage of inhibition, it was found that 100 mg/ml was the most effective in exhibiting the maximum inhibition (Al-Sayyed et al. 2021). Acetone extracts of date fruit (Ajwa variety) demonstrated cytotoxic effect on oral squamous cell carcinoma cell lines by inhibiting their growth and proliferation and inducing cell death by apoptosis (Shahbaz et al. 2022). Apart from these, the consumption of dates also increases the health condition of colon cells by colon cancer cell growth inhibition and enhancing beneficial bacterial growth in the colon (Eid et al. 2014). Various extracts of ethanol, acetic acid, and acetone using date palm have also reduced the proliferation of pancreatic stellate cells (PSC) in vitro. In addition, it also reversed the fibrotic phenotype of PSCs, thereby reducing fibrosis (Al Alawi et al. 2020). Thus, on further research, there is a high capacity for date palm to serve as a potential anticancerous agent, and isolation of the novel phytochemicals responsible for the same can be done on a commercialized scale for treatment purposes.

2.3.2 Anti-diarrheal Activity

Diarrhea can be acute or chronic depending on the immune system of the individual. When castor oil was used to induce diarrhea in Wistar rats, it was observed that extracts of date palm used in the concentration of 1000 and 1500 mg/kg of body weight were successful in reducing the intensity of diarrhea (Agbon et al. 2013). The results were almost the same in another experiment when loperamide was administered as a control agent (Megbo et al. 2017). Comparatively, date palm aqueous extracts possessed completely nontoxic anti-diarrheal activity when used on male Wistar rats. Phytochemical screening and spectrophotometric methods revealed the high crude ash, carbohydrate contents with saponins, tannins, and flavonoids along with a low anti-nutrient concentration in date palm extracts.

2.3.3 Anti-ulcer Activity

When gastric ulcer was introduced in rats using ethanol, different extracts of both dialyzed and undialyzed date fruits were administered to check the effect of dates on gastric ulcers in humans, at 4 ml/kg for 14 days. It was observed that both aqueous and ethanolic extracts could work successfully toward the reduction of severe gastric ulcers in rats (Al-Qarawi et al. 2005). The presence of the ethanolic extract of undialyzed date palm fruit could reduce the level of gastric mucin, histamine, and gastrin in the rats. The effect of date palms on peptic ulcer conditions was further affirmed when the report of Gangwar et al. (2014) suggested that chloroform extract of its leaves contained gastroprotective activity. This was supported by the inhibition of ulcer index, mean ulcer score, and reduction in gastric content when the pH increased and acidity levels, both free and total, decreased, along with doses. Thus, it has already been proven that painful sores can easily be removed by the consumption of date fruits, which become hard to remove even sometimes using synthetic molecules.

2.3.4 Anti-hepatotoxic Activity

As of 2021, diabetes ranks as one of the major reasons of the death of humans in the world due to a high cholesterol diet and eventually brings with it associated disorders. Liver health deterioration is a concern for people, irrespective of age, which can further be responsible for chronic illnesses, and thus, treatments for the prevention of this disease are the need of the hour. It has been observed that when date palm's hydroalcoholic extracts were administered to rats having hepatotoxic effects due to diabetes, comparatively healthier sinusoids and hepatocytes were found (Zheng et al. 2021). On the other hand, when liver diseases were untreated, severe histopathological conditions such as dilated portal veins, fatty degeneration, and necrotic nuclei were seen. Since this observation was a remarkable advancement as conducted in 32 adult rats, further clinical research is solicited for the execution of the hepatoprotective activity of date palms on humans. In addition, Onyilo et al. (2021) reported the hepatoprotective potential of date palm's aqueous extract when fat-induced damaged liver cells in adult Wistar rats were found to be reversed and Kupffer cells activated with changes in the level of hepatic enzymes as well as hepatocyte configuration.

2.3.5 Antioxidant Activity

Antioxidants are important chemicals needed to protect the body against free radicals produced by catabolism and capable of causing cancer (Moslemi et al. 2022). They are necessary substances in the body and have been found in great abundance in date palms (Zihad et al. 2021). High quantities of phenolic, tannin, and flavonoid contents were recorded in three varieties of date palms, namely, Ajwah, Sakkari, and Safawy, using UPLC-QTOF-MS assays. Radical scavenging activity, both DPPH and hydroxyl, was found in all of them along with a total antioxidant capacity of IC_{50} 87–192 μg/ml. Results were obtained, almost along the same lines when antioxidant and total phenolic levels were compared among methanolic extracts of four different date palm varieties (Bensaci et al. 2021). Folin-Ciocalteu and DPPH test along with superoxide anion and reducing power test exhibited the highest antioxidant levels of 0.006 mg/ml in the Chtaya variety using the cyclic voltammetry method. Thus, consumption of the fruit can also aid in keeping deadly diseases like cancer at bay, as proved in the literature already.

2.3.6 Anti-inflammatory Activity

Out of the many visible therapeutic activities of date palms, one of the most important is its anti-inflammatory effect. In a report by Barakat et al. (2020), it has been proven that date palm seeds could exhibit anti-inflammatory effects on inflammation induced by LPS in RAW 264.7 cells. This was mainly done against the nitric oxide release and subsequent iNOS protein expression. In addition, suspensions of date palm pollen have been shown to improve immune-histochemical and histopathological conditions in rats with hyperplasia (Elberry et al. 2011). The presence of inflammation was confirmed due to the presence of chemical messengers like IL-6, IL-8, TNF-α, and IGF-1. Along with upregulation of autocrine or paracrine receptors, the date palm has been shown to modulate cytokine expression through a

protective effect by suppressing inflammation. Cellular proliferation was accompanied by a reduction in apoptosis in the ventral prostate of rats with hyperplasia on the administration of date palm.

2.3.7 Antimicrobial Activity

The term "viral infection" needs no new introduction in the present-day scenario of 2021 where the entire world fought and is fighting against the deadly coronavirus pandemic. At this juncture, it is highly essential that the availability of the number of antiviral commodities is increased as much as possible. For the same, the leaf extract of date palm had been tested in vitro using an MTT assay on the embryonic fibroblast cells of NIH/3 T3 mouse. Takdehghan et al. (2021) reported a significant decrease in CRP levels as well as elevation in partial pressure of oxygen levels in those patients administered with date palm leaves five times daily along with the recommended dosage of medicines as compared to the patients strictly on routine medication. When checked on days 7 and 14 post-administration, the inference was drawn and thus was recommended as a safe add-on along with the daily dosage of treatment. The efficiency of date palms against bacteria, both Gram-positive and Gram-negative, has also been studied when Ghosh (2021) reported that methanolic extracts of its seeds have exhibited antibacterial activities against *Klebsiella pneumonia* and *Escherichia coli*. Along with that, it has also reduced the side effect on the testosterone and muscles of rats and improved other hormonal functions.

2.3.8 Antihyperlipidemic Activity

Due to the possibility of developing a heart disease, it is necessary to maintain a low blood lipid level or triglyceride. Lipoproteins are essential for providing energy in the body but only up to a certain level, because beyond that level, the severity of medical conditions can escalate to diabetes, alcoholism, kidney disease, and other chronic cases too. Date palm possesses antihyperlipidemic activity as has been reported by Innih and Lorliam (2021) in an experiment where it was determined whether date palm has hyperlipidemic properties, owing to the phytochemicals present in the plant. Against hyperlipidemia induced by margarine in rats, the differential blood count and lipid profile analysis revealed a decrease in cholesterol and LDL levels whenever date palms were used as a part of the therapeutic routine. The results were further confirmed when Silabdi et al. (2021) explained the reduction in total and LDL cholesterol along with that in triacylglycerol while the level of HDL in the blood of rats increased. These results were obtained from three different varieties of Algerian date palms, namely, Deglet Nour, Ghars, and Degle Baida. Date palms play a crucial role in keeping lipid and other lipid-related levels such as SGPT, ALT, LDH, and GOT at a normal level without any other side effects compared with synthetically derived products.

2.3.9 Anti-nephrotoxic Activity

To keep one ailment at bay, the chemical medications may invite other illnesses. For severe diseases like lymphoma or leukemia, doxorubicin is a widely used drug with a high therapeutic index, linked with causing nephrotoxicity in patients as a side effect.

Wang et al. (2019) reported the activity of date palm extract on the nephrotoxic effects caused by doxorubicin in patients. Levels of cardiac markers like LDH-1 were seen to decrease and nephrotoxicity was seen to be reversed on the administration of date palm extract. As far as nephroprotection is concerned, there was amelioration in the urine flow rate and a significant increase in the urine sodium-potassium ratio due to the activation of Na^+/K^+ ATPase in the presence of date palm extract. In addition, there can also be an improvement in the functioning of nephrons using its antioxidant potential on proximal tubular damage. On further investigation, the reason for the observed nephroprotective activity of date palm alluded to elevation in the level of antioxidant enzymes which possessed the capability of free radical scavenging (Al-Qarawi et al. 2008). Dates were already known to act as strong antioxidants for their mechanism of counteraction of free radicals. Hence, nephroprotection is a major function of date palms owing to their radical scavenging capacity.

2.3.10 Antimutagenic Activity

The presence of any external agent or any other factor might be responsible for transformations in organisms, which can even be fatal in some cases and are phenotypically invisible. To safeguard or inhibit such a process from occurring, it is crucial that an intensive number of research is done on the naturally present antimutagenic substances. Vayalil (2002) reported the antimutagenic property of date palms on *Salmonella* tester strains TA-98 and TA-100. The property was tested for His^+ revertant formation in the strains which exhibited 50% dose-dependent inhibition of benzo(α)pyrene-induced mutagenicity on the administration of date palms. Not only in this case but date palm's antimutagenicity was also examined against N-nitroso-N-methylurea by the activity of chromosome aberration and other DNA fragmentation assays. On administration of date palm extract, it was seen that the DNA damage caused by the mutagen was restored back to its normal conditions (Diab and Aboul-Ela 2012). This was proven by the reduction in the chromosomal aberration and micronuclei in the bone marrow, and no further DNA fragmentation in hepatic cells was seen when date palm extracts were introduced before and after the treatment by intraperitoneal injection in mice. Furthermore, research on the medicinal properties of date palm might open doors to more innovative and therapeutic discoveries helpful to the economy and human health.

2.4 Methods of Biofortification: Agronomic and Postharvest Techniques

2.4.1 Agronomic Biofortification

The procedure of application to increase the nutritional content in plants during their growth phase naturally through agronomic methods is termed biofortification. This is essential to maximize the mineral uptake by plants or nutrient availability while consuming the fruits and can be done by application of several mineral fertilizers to the plant parts or soil. To date, there have been numerous trials to improvise the mineral and nutrient values in several species of plants, but there is also huge

potential for the same in the remaining plants (Stangoulis and Knez 2022). In date palm too, efforts were made to increase its nutritional value. However, the level of research conducted is very limited and needs more attention. With the advent of newer strategies and scientific advancements like insertional, somaclonal, and site-directed mutations, biofortification in plants has become easy. Along with that, provisions for targeted and more accurate mutagenesis have also increased with the discovery of CRISPR-Cas gene editing and base editing systems in engineering date palm genomes (Sattar et al. 2017).

There are several issues associated with breeding a plant, including both biotic and abiotic factors. Abiotic components include the issues of dry soil, inadequate mineral contents, scarcity of water, or insufficient root activity in a few cases. All of them can be improved by advanced techniques of agronomic biofortification like the usage of NPK, potassium sulfate, nitrate, silicate, iron sulfate, urea, zinc sulfate, etc. nutrients externally. Numerous studies have been conducted on the foliar spray of date palm for improvement of mineral composition in the date palm plant. Starting in 2007, the effect of urea (N 46%) has been observed when sprayed on the plant in different concentrations (0.5% and 1%) and in different stages of the plant (Khalal and Kimmri stages) (Abbas et al. 2007; Khayyat et al. 2007; Shareef 2011a, b). Positive traits of plant growth on the same included an increase in the pulp weight, nitrogen content, fruit length and diameter, dry matter, percentage of fruit ripening, and sugar content while decreasing dropping down of fruits from the plant. Similar results were obtained using 300–600 ppm zinc sulfate in terms of yield and quantity of fruits. Total soluble solids calculated were higher using 1500–2500 ppm boric acid along with the increased concentration of boron content in the fruits. Moreover, other nutrients like 1000–2000 ppm of calcium chelate were responsible for the increase in plant height, girth, and the number of new leaves (Jasim et al. 2016). An overall increase in fruit length and diameter, along with the increased percentage of sucrose and total dissolved solutes, was obtained by application of 125 and 250 mg/L phosphorus (Fasal et al. 2014).

It is essential that extra importance is laid on the status of nutrition of any crop and biofortification plays an added role in this process. A constant effort to elevate nutritional content in date palms has been initiated by several scientists across the globe, and one of the many noteworthy discoveries includes the introduction of (0.01–0.02%) sodium selenite for improvement in growth, bunch weight, and quality of fruits in the plant (El-Kareem et al. 2014). Nitrogen, phosphorus, and potassium (NPK) are mixed in various ratios to fasten plant growth and for other beneficial properties. In the cultivation of date palms too, NPK was prepared in the ratio of 20:20:20 and in 2.5% concentration which provided beneficial effects like increase in total yield; soluble solids; sugars; percentage of fruit ripening; chlorophyll content; soluble carbohydrates; potassium, phosphorus, and nitrogen content; chlorophyll a; fruit yield; and dry weight and decrease in the number of fruit drop (Shareef 2011a, b; Attaha and Al-Mubark 2014; Altememe et al. 2017; Jubeir and Ahmed 2019). Thus, usage of NPK is beneficial to a high commercial extent but the side effect of chemical pollution and chemical fertilizers always persists in this case, which may prove harmful for human consumption. It is well-known that the role of

potassium in plants ranges from the transport of minerals, water, and carbohydrates and the production of protein, starch, and adenosine triphosphate to the improvement of drought resistance and others. In addition, various salts of potassium have been tested on the growth of date palms in various concentrations such as potassium sulfate, silicate, nitrate, and others. Potassium nitrate when used in the concentration of 1500 ppm exhibit a notable increase in the number of new leaves and clusters along with the increase in the content of ascorbic acid, abscisic acid, indole acetic acid, carbohydrates, gibberellin, and zeatin (Shareef 2019). When potassium silicate was used in concentrations of 0.01% and 0.02%, an increase in bunch weight and percentages of specific minerals in leaves, yield, and leaf area was noted (El-Kareem et al. 2014). Among pigments, there was higher chlorophyll a, carotenoid, and total chlorophyll when the same was applied. Similarly, the utility of iron compounds in the production of chlorophyll and other chloroplast maintenance activities in plants cannot be ignored. Iron sulfate itself when used in 250 ppm concentration can lead to a good increase in yield along with a decrease in the number of fruit dropping (Abbas et al. 2007). Again, when the same compound is used in 20–40 ppm, it results in an increase in weight and volume, diameter, length of fruits and flesh, carbohydrates, total soluble solids, reducing sugar, and dry weight (Abass et al. 2012). Apart from iron sulfate, Faisal et al. (2017, 2018) have reported that the usage of chelated iron compounds in date plants has led to an increase in the overall total soluble solids, reducing sugar, weight, and diameter of fruits.

The list of agronomic biofortification methods continues to include the usage of 8–16 cm^3/L seaweed as a biostimulant in date palm plants (Attaha and Al-Mubark 2014). It produced an increase in a long list of parameters such as soluble carbohydrates, potassium, phosphorus, as well as chlorophyll content. When the same biostimulant was used in the concentration of 4–8 ml/L, the effects observed in the fruits included elevated levels of chlorophyll, K, Mn, ascorbic acids, organic solutes, indole-3-acetic acid, zeatin, K^+/Na^+ ratio, and other ions as compared to that without seaweed (Taha and Abood 2018; Shareef et al. 2020). Shareef et al. (2020) also reported that 4 g/L *Saccharomyces cerevisiae* can bring about almost the same effects with an additional benefit of increase in plant height, new leaves, offshoot girth, and leaf area. Apart from this, the gelatinous milky white secretion produced by worker bees, also called "royal jelly," is responsible for the production of high nutrient content like N, P, K, and Mg along with good quality fruits and increased growth (Al-Wasfy 2013). Refaai (2014) reported that using 0.5–2% wheat seed sprouts increase growth characteristics, plant pigments, total yield, nutrients, bunch weight, and carbohydrates along with improvement in characteristics of fruits – both physical and chemical. Macro and micronutrients together are essential for the plants to grow healthy and the higher the quantity of nutrients available to the plants, the better growth it exhibits. Through biofortification, the level of mineral uptake is maximized in plants and one such effort was put forward by combining many micronutrients like Fe, Zn, Cu, Mn, B, and Mo and chelating with EDTA. Here, boron and molybdenum are used in completely soluble form, under the name of "Fetrilon Combi," and is commercially available as an agronomic biostimulant in crops (Altememe and Mahdi 2015). Using the product shows a remarkable increase

in the invertase activity, ripening percentage, and ionic concentration of sucrose and water content in fruits. Another commercialized biostimulant available in the name of "Drin" (2–4 ml/L) helps date plants to synthesize free amino acids and readily uptake nitrogen content from the soil. Catalase activity is increased along with total chlorophyll content as this liquid organic solvent contains a high proportion of amino acids and organic nitrogen that activates the biochemical pathways in crops. Like many other biostimulants, addition of 4–8 ml/L humic acid is not only seen to increase the amount of N, P, and K but also the overall content of chlorophyll a (Altememe et al. 2017). Obtained from animal bones, 5–10 ml/L sugar chitosan is a good source of increasing K, Mn, amino acids, and dry weight of fruits in date palms (Taha and Abood 2018). Recent investigations also reveal the usage of 1.5 g/L commercialized Biocont-T in date palms shows benefits like increased bunch weight, yield, and percentage of fruits and 800 or 1600 mg/L potassium fertilizer by Alqawafel shows notable increases in fructose, glucose content, and fruit size with reduced sugar (Ressan and Al-Tememi 2019; Al-Hajaj et al. 2020).

Date palm is an essential source of food in areas where there is water scarcity and thus demands a good number of postharvest techniques for their growth and biofortification. Among a wide range of technologies available, storing at −18 °C and application of apple vinegar treatment have proven to be the most useful in effect (Kahramanoglu and Usanmaz 2019). Next effective in line are the treatments of grape vinegar followed by commercialized Ethephon; the former is credited with an increase in total soluble solids in the fruits, while the latter slightly affects the ripening of fruits due to reaction with tannins.

2.4.2 Postharvest Techniques

After harvesting a crop, it is essential to protect and conserve the agricultural produce with minimum handling and effective management. This is mainly done using postharvest management strategies and employs many advanced scientific and technical processes. A good harvesting procedure and management can lead up to 100 kg of dates annually where the average economic life of a date garden can be around 150 years. While harvesting, it has been found that usage of blue and black polythene bags has increased the percentage of fruit ripening (Awad 2007). Similarly, it is advisable to implement the bagging process to protect the plants from birds, sunburn, and heavy rain (Zaid and de Wet 2002b). The grower's experience plays a big role in deciding the time of harvest of the fruits depending on their texture and appearance which are connected to sugar content and moisture. If decided correctly, the timing of harvesting reduces chances of skin cracking, attacks by insects and pests, or extreme dehydration. In fact, when selectively harvested early, it also leads to higher prices in the market and avoids disadvantages of harvesting late such as adverse weather conditions, attacks by pests, yielding good quality dates at matured stages, etc. However, in case the dates fall on the ground, they are not supposed to be considered fit for human consumption as there are higher chances of microbial contamination and soil particles entering the date fruit (Kader and Hussein 2009).

Artificial Ripening

It is very important that the fruits harvested are taken for appropriate ripening if they are picked immature for any purpose. Ripening can be carried out either indoors or outdoors, where the former requires a room with adequate air-conditioning to keep temperatures at 45–46 °C and 70% relative humidity, for dates with thick flesh to ripen in about 2–4 days (Hyde 1948). However, the latter is a cheaper technique and comes with many disadvantages such as adverse conditions or external attack. Apart from this, the quality of ripening further increases when fruits are treated with chemicals like 1% ethanol and 2% acetic acid +1% NaCl or acetaldehyde (Asif and Al-Taher 1983). It has also been observed that freezing at −35 to −50 °C is beneficial for the plants as it prevents damage to cell membranes (Kader and Hussein 2009).

Hydration

The step necessary to soften the few hard fruits refers to the hydration process which includes dipping them in cold or hot water for around 4 to 8 h at 60–65 °C (Kader and Yahia 2011). The relative humidity maintained in the same is around 100% to convert the dried dates into glossy ones. Maintaining a constant rate of temperature and relative humidity is essential through forced air circulation, which is also the method of controlling the growth of microorganisms. The methods of treatments vary from one country to another, depending on the climatic conditions. Chemicals like alkaline ammonium sulfate help in improving quality of acidic but hydrated dates (Yahia et al. 2014). The additional step of hydration is necessary only when the dates are unripe and not overdried. Pasteurization is an exclusive process in the postharvest treatment of date palms which is executed at 72–80 °C for 2.5 min (Martínez Vega et al. 2014). It was also reported that maintenance of almost 15–70% of relative humidity is best, when keeping the fruit mass loss and sweetness index in mind along with the coloration of dates becoming darker when skin temperature reached around 66 °C (Casagrande et al. 2021). Thus, hydration is essential only when the moisture content of the fruits is low and can be continued using the same solutions as applied during the harvest procedure (Dole John and Faust James 2021).

Initial Transportation and Sorting

Large boxes of wood, plastic, or cardboard capable of carrying 200–450 kg fruits are essential to prevent any postharvest losses while transferring the fruits to the packing station. The process is better when faster and speedy transportation can be done as that prevents microbial infection as fruits are more susceptible to pests during the postharvest period (Abd Elwahab et al. 2019). The transportation process is ideally carried out at cooler temperatures (0–2 °C) to prevent spoilage and atmospheric heat damage to plants. Specifically, forced air cooling proves to be more efficient than hydrocooling, which is the removal of excess moisture and its disinfection before packing and the usage of perforated plastic lining adds to the technicality of the process (Kader and Hussein 2009). Further, dates are fumigated in closed chambers and transferred to shakers for primary washing followed by the removal of excess water from the fruits. Then they are sorted manually through visual inspection

according to whether they are ripe or unripe and are discarded if they are damaged due to transportation, microbial infections, heat, or other external factors, so that only the fresh lot of fruits is kept (Sarraf et al. 2021). This is one of the most time-consuming stages of all postharvest procedures because sorting and grading depend on either manual means or through a mechanized visual system where color values and sugar range play an important role in differentiating various types of dates.

It is essential to remove those dates which are either unfertilized or disfigured or contain some blemishes or foreign particles. This can be executed manually or using a machine according to physiological parameters like color, shape, size, and others. Immature, overripe, diseased, parthenocarpic, and partially or completely damaged dates are ideally discarded in this stage and only fresh ones are sorted according to their quality. Date fruit colors range from yellow to brown, and consistency of flesh ranging from soft to dry; these are the two most essential characteristics at this point (Sarraf et al. 2021). The accuracy of grading was improved using automated systems like date quality analysis by near-infrared imaging of two-dimensional view (Lee et al. 2008). More advanced techniques are also being developed for the differentiation of a variety of species since the time of maturation of all fruits is not the same, which will hasten the entire process of sorting and transportation to the packing house.

Advanced Automation and Robotics in Fruit Handling

Keeping in mind the disadvantages of water and soil unavailability, it is always advisable to make the optimum use of advancements in technology and automation, which not only increases the rate of accuracy but also speeds up the entire procedure in a limited area. Cull fruits can be discarded or storage of fruits for a longer period can be controlled by automated systems and algorithms fixed in advance. This highlights the necessity of attaching technology to agriculture, forming agri-tech and taking the help of GPS, the Internet, robots, sensors, and a many other electronic devices to execute the agricultural processes in a more organized, smart, and accurate manner (Rose and Chilvers 2018). The remarkable possibilities of the Internet going digital are well-known in the twenty-first century and in the whole world; thus, it is time to transform conventional procedures into smarter and faster techniques. Near-infrared spectroscopy has long been helping in the analysis of fruit colors and textures (De Jager and Roelofs 1996). Not only this, but the advancement has also reached to the level that packing lines containing several sensors and cameras attached to visible and infrared probes help in analyzing the different qualities and parameters of fruits (Walsh et al. 2020). A track record can be maintained for easy accessibility (Njoroge et al. 2002) of the intricate details of the fruits like color, shape, size, grower name, and others by consumers to guarantee the safety and security of the fruits. Furthermore, computer models are used for correct decision-making and 80% accurate grading of fruits according to RGB images produced (Al Ohali 2011). There can be no end to the innovation and technology when it comes to applying robotics and artificial programming for both consumer's and manufacturer's ease of transaction.

Nanotechnology Utilization in Packaging

The application of nanotechnology has become a well-researched topic in almost every sphere of life, from physics to the biomedical world. For the packaging of date fruits, nanotechnology can play a major role in packaging, coatings, and films for date fruits. There are various types of nanoparticles – metallic, nonmetallic, or synthesized – working as antifungal agents in the preservation of fruits. There is a provision for creation of edible packages also using chitosan-based nanoparticles, which helps in the reduction of postharvest decay in fruits (Chaudhary et al. 2020; Kumar et al. 2020). Additionally, respiration and transpiration rates can be controlled in date fruits by using nanotechnology materials with smart packaging and innovative technologies for increasing the shelf life of fruits when stored for long periods (Acharya and Pal 2020; Alfei et al. 2020). Thus, overall application of nanotechnology using nano-fertilizers can also aid in the process of postharvest management of date palms to minimize the losses incurred by it.

Adding Surface Coatings

It is essential to identify the presence of any metal particles or xenobiotic compounds present on the fruit that might have come from the environment. This is followed by the improvement in the appearance of dates by introducing polished surface coatings and reducing stickiness. In addition, a solution of 5–6% soluble starch can be used as a dipping agent, 3% methylcellulose, 6% vegetable oil, 2% mixture of butylated hydroxyanisole and hydroxytoluene, 90% water, and finally a wetting agent. Ethanol vapors or immersing the dates in water for 10 h has hastened the process of ripening as compared to the controls, and neither had any negative effect on the quality of fruits (Awad 2007). For the surface coating preparation, solutions of date syrup, vegetable oil, corn syrup, and sorbitol or glucose syrup can also be used.

Cooling and Packaging

As mentioned, hydrocooling, which affects the rate of microbiological and biochemical changes in temperature and maintaining date palms at an average temperature of 0–10 °C, is always desired and recommended for further long-term storage under 65–75% relative humidity. Once removal of excess water and disinfection is done, dates can be cooled to 0 °C in 10–20 min, based on their initial temperature. Hydrocooling delays the rate of spoilage caused by microbes and increases the shelf life of food products (Djihad et al. 2021). Maintaining the temperature is important as it affects physiological parameters like sugar crystallization and that is affected by the moisture content in the fruit, as water above 20% affects the fruits adversely (Glasner et al. 1999).

Before commercialization, it is essential that the date palms are packed in suitable containers or packages so that they are protected from any further microbial attack or damage due to mishandling and transportation prior to consumption. Only those date palms that are packed and available in intact airtight packets are accepted for further research and analysis in the marketing sector (Kabir et al. 2021). Consumer packages and large cartons including transparent film bags and plastics include the containers for storing date palms apart from other bottles with metal caps and bottoms. Small

packages suited to carry 50–60 g date palms are also used along with cardboard boxes weighing 5 kg, in countries like the USA, Jordan, Saudi Arabia, and others. It is very important to mention particulars about the specifications on the labels such as date of packaging, grower industrial details, nutritional benefits, date of expiry, country of origin, and other details so that consumers can get a glimpse of the overall status of the fruit.

2.5 Requirement of Genetic Biofortification

Fortification of any consumable product refers to deliberately making it enriched and more nutritious than normal by means of either the addition of micronutrients or bringing about modification genetically. It is done either through conventional techniques which are slower and vulnerable to bacterial invasions or through modern biotechnological approaches that are quicker, more reliable, and easier to obtain. Such an approach toward the biofortification of any consumable is essential when judged from the perspective of enriching the nutritional status of any country's population. Processes of agronomic practices, food processing, and others fall under conventional fortification techniques, but for genetic modification of plant germplasm, selective breeding comes under modern biofortification tools and techniques. It is aimed toward the enrichment of a nutritional density of a plant, increasing accessibility to rural areas without the slightest drop in the overall yield of the crop. Especially after the COVID-19 pandemic, it has become essential to support the underdeveloped and developing countries in terms of food security and uplift their standards of living in terms of nutrition and health to prevent loss of life from malnutrition. Moreover, institutions like ICRISAT and CIMMYT in association with Harvest Plus have taken initiatives to scale up biofortification procedures to improve the nutrition and public health by providing and promoting higher iron content in pearl millets and zinc content in wheat available to the general population (https://www.harvestplus.org/where-we-work/india). India ranks tenth out of 117 countries and third out of 128 countries, respectively, as suitable place to grow iron pearl millet and zinc wheat. Increasing food security and the quality of life of people in developing countries and decreasing nutrition-related disorders, mortality, and morbidity are the main goals of biofortified crop production.

When crops are genetically engineered to produce high micronutrient-enriched products, they are referred to as genetically fortified. One of the most common examples of genetically biofortified crops is the Golden Rice that was modified to produce and accumulate vitamin-A enriched genes (β-carotene), giving it a golden colored appearance. Rice being the staple food of a good portion of the entire world population, if targeted to be genetically biofortified, can automatically benefit a lot of people who might not get the required nutrients due to the reduction in zinc and iron, especially after milling. So, one of the most promising solutions brought very recently toward the mitigation of this problem is the production of genetically biofortified rice along with iron and zinc, and in addition special features were kept in mind, for the decrease in arsenic contamination in rice grains (Viana et al.

2021). Not only rice, but there are also reports of wheat biofortification as wheat is also consumed by another major part of the population. Identification of Fe/Zn QTLs is an important step of biofortification, and a versatile domain is promised by the usage of biofortification tools and techniques in genetic engineering and molecular biotechnology field (Tong et al. 2020). Genomic selection has been considered as a good process for biofortification of Fe/Zn QTLs, but incorporation of the QTLs into the models as a fixed effect is questionable. The answer to why crops need to be genetically biofortified can be alluded to targeting the rural population which has restricted accessibility to nutritious foods and minerals or those who have almost no opportunity of genetic interventions like biofortification. Another reason is the requirement to meet a specific quantity of calories needed by the body to sustainably live.

As of recent reports, Egypt has recorded the world's highest date palm consumption of about 1.6 million mt, followed by Oman, United Arab Emirates, and Algeria (https://www.mordorintelligence.com/industry-reports/date-market). Africa and Middle East alone hold 70% of the entire consumption of date palm fruits worldwide and the trend increases daily. So, with the increase in date fruit consumption, the necessity to biofortify the fruit increases and achieving the target of uplifting lives in rural areas with micronutrient-enriched date fruits automatically becomes easier. The proteins like cell number regulator (CNR) play an important role in the genetic biofortification of *Triticum aestivum* by TaCNR5 expression in shoots of wheat analyzed under Cd, Mn, or Zn metal treatments (Qiao et al. 2019). Activity of these heavy metals as micronutrients in the biofortification of cereals, moderated using the expression levels of TaCNR5, can open a new avenue of research and development in the nutrition elevation. As of 2021, not enough research has been executed for the genetic biofortification of date palm, but the techniques are being studied and more possibilities are being discovered by plant biotechnologists. In their first book, Al-Khayri et al. (2021) provided comprehensive information on various proteomics and metabolomics technologies applicable for the genomic improvement of date palm fruits. The genomic stability of in vitro date palm plants and diversity of genomes with DNA barcoding processes along with genomic approaches for resistance to all stress factors have been reported already. At this juncture, this chapter proposes the urgency and essence to identify the possible genetic biofortification procedures applicable for date palm because that itself serves as one of the major mechanisms for nutrient level improvement in the world population.

The requirement of genetic biofortification alludes to the necessity of nutritional security in a country, with respect to enhancement of the micronutrient status in the soil. Transgenic biofortification is a route that can answer the same question and curtail the issue of micronutrient deficiency in soil. At this juncture, microbes with plant growth-promoting benefits are beneficial to improve the nutritional quality of the soil. Reports of using *Arthrobacter* sp. (DS-179) and *Arthrobacter sulfonivorans* (DS-68) for the nutritional improvement of zinc and iron in the soil have been studied (Singh et al. 2017). Biofortification, depending on the insert type, can be classified into conventional and transgenic biofortification. The former type involves the introduction of artificial additives along with it and is thus largely limited to the

developed countries only, due to the necessity of high infrastructure and machinery (Díaz-Gómez et al. 2017). There are various disadvantages connected to the introduction of added minerals to the food crop like taste, etc., but the brighter side includes a higher percentage of necessity, when focusing on the nutritional requirements among the masses. The importance and necessity of genetic biofortification, though well-known to scientists and researchers, has not much been implemented in the field of date genomics. This void needs to be filled through advanced research as soon as possible and that demands our attention to elevate the standards and processes that are linked with enhancement of mineral constitution in the plant at study.

3 Breeding Using Molecular Markers for Genetic Improvement

Molecular breeding via molecular biology and marker-assisted DNA analysis by considering phenotypic character and diversity is an effective strategy to analyze genetic polymorphism in breeding programs. Molecular breeding includes marker-assisted selection (MAS), quantitative trait loci (QTL), genetic engineering, etc. Molecular markers with support of phenotypic data are involved in species and cultivar identification, diversity and phylogenetic relationships, and many breeding activities.

3.1 Diversity Analysis

3.1.1 Phenotypic Diversity

Phenotypic diversity is seemingly a date palm diversity indicator. It is also a basis for selection, conservation, and improvement for sustainable utilization. There are 19 known or reported *Phoenix* species; however, 12 species (Zabar and Borowy 2012; Abul-Soad et al. 2017) are often considered as valid as there is still confusion regarding the exact number of *Phoenix* species. *P. dactylifera*, *P. acaulis*, *P. canariensis*, *P. paludosa*, *P. reclinata*, *P. rupicola*, and *P. sylvestris* are the most widely accepted species. *P. dactylifera* is the most commercially cultivated *Phoenix* species. Pinnate leaves and conduplicate leaflets with acute apex are the distinguishing characteristics of this genus (Uhl and Dransfield 1987). *P. dactylifera*, *P. atlantica*, *P. canariensis*, *P. theophrasti*, and *P. sylvestris* are closely related in overall appearance. However, they have been reported as separate species by molecular marker studies (Henderson et al. 2006).

P. dactylifera is the original Middle Eastern wild representative and is distributed in different parts of South Asia and Africa. The domesticated date palm grows more than 30 m in height. It has a clustering trunk, but in cultivated varieties, it appears as a single trunk due to the removal of offshoots. The fruits are the largest among the *Phoenix* spp. reaching to a maximum of 100 × 40 mm in size. The other wild relatives like *P. theophrasti* have a restricted distributional range especially in coastal

areas of Southwest Turkey, *P. atlantica* growing near the Atlantic shores of North Africa, which represents the feral populations of *P. dactylifera* (Rivera et al. 2008), and *P. iberica* with glaucous leaves, stout stem, and small fruit with thin flesh growing in the Mediterranean coast of Spain which is considered as an intermediate between *P. theophrasti* and *P. sylvestris*. *P. chevalierii* has greener leaves compared to *P. dactylifera* and is an Iberian-Moroccan group of cultivars grown in southeastern Spain (Rivera et al. 2008). *P. reclinata* has a bushy habit and seen in the southern parts of Arabia and Sahara Desert (Tengberg 2012), and *P. sylvestris*, the rain palm, is a nonsuckering 20 m tall tree adapted to tropical climates especially the Indus Valley (Zohary and Hopf 2000). *P. canariensis*, usually cultivated as an ornamental, has a 20 m high stout trunk which is adapted to moderate climate and is endemic to the Canary Islands (González-Pérez et al. 2004). However, *P. rupicola*, known as the cliff palm is about 7 m in height and has a thin trunk and is native to the northern parts of India. Similar in morphology is the *P. pusilla* palm but with a shorter trunk and is found in the southern parts of India and Sri Lanka. The Senegal date palm *P. reclinata* with 10 m thin clustering trunk is used as an ornamental and is native to tropical Africa. Ornamental palms *P. paludosa* (mangrove date palm) and *P. reclinata* have similar appearance and are found in the swampy regions of southeastern Asia. *P. roebelenii* (pygmy date palm), grown as an ornamental, has a single trunk and is native to Southeast Asia; *P. acaulis*, *with* short clumping stems, is found in northern India and Burma; and *P. loureiroi*, often confused as *P. acaulis*, has short stems and is found in northern India and southern China (Barrow 1998; Zohary and Hopf 2000).

Thousands of cultivars have been reported from all over the world. These have been developed by various selection methods to improve crop yield and quality and to tolerate environmental stress, etc. Morphological description of characters like form of the tree, fruit (shape, size, weight, color, texture), fruit stalk, and leaf, especially leaflets and spines, is an important parameter for identification of cultivars (El-Houmaizi et al. 2002; Al-Yahyai and Al-Khanjari 2008; Ould Mohamed Salem et al. 2008; Elshibli and Korpelainen 2009; Markhand et al. 2010). Jaradat and Zaid (2004) have reported up to 5000 date palm cultivars. However, based on botanical descriptions, 1000 cultivars in Algeria, 450 in Saudi Arabia, 400 in Iran, 400 in Iraq, 250 in Tunisia, 244 or 453 in Morocco, 95 in Libya, 400 in Sudan, 250 in Oman, 321 in Yemen, 52 in Egypt, and 300 in Khairpur, Pakistan (Benkhlifa 1999; Bashah 1996; Hajian and Hamidi-Esfahani 2015; Zabar and Borowy 2012; Zaid and de wet 2002a, b; Sedra 2015; Battaglia et al. 2015; Osman 1984; Elshibli 2009; Al-Yahyai and Al-Khanjari 2008; Al-Yahyai and Khan 2015; Ba-Angood 2015; Rabei et al. 2012; Mahar 2007; Markhand et al. 2010; Abul-Soad et al. 2015;) along with other cultivars in different growing regions have been reported.

Chemical characters of fruits and ripening stages of fruits are some of the apparent factors for the identification of cultivars (Elshibli and Korpelainen 2009, 2010). Numerous documented reports are available for date palm cultivars using vegetative, flowering, and fruit characters. In Saudi Arabia, 17 date palm cultivars were evaluated for vegetative parameters, flowering and yield characters, and fruit attributes (Al-Doss et al. 2001). Among five Sudanese date palm cultivars,

physicochemical differences with respect to weight of fruit, and seed, thickness of flesh, fruit length, and phytochemical constituents were reported (Sulieman et al. 2012). Prominent fruit characters were reported among 85 cultivars from Pakistan (Markhand et al. 2010). Twenty-six date palm cultivars have been studied to identify descriptors (leaf, pinnae, and spine) for early-stage date palm characterization other than fruit characters (Elhoumaizi et al. 2002). Fruits of date palm have been classified based on texture as soft, semidry, and dry types (Barreveld 1993). Ecological distribution of soft and dry dates is reported only from Sudan. However, they also exist in different growing countries (Barreveld 1993; Zaid and de Wet 2002a). Although there is huge diversity in the cultivar of date palm, most information is unpublished or unavailable due to ownership of cultivars.

3.1.2 Genetic Diversity Using DNA Markers

Phenotypic characterization has been utilized extensively for the identification and selection of various cultivars. However, it is difficult to identify the date cultivars without observing the fruiting stage. Molecular biology techniques and molecular marker-based selection have helped breeders to accurately select specific cultivars. The extent and distribution of genetic diversity is an important measure for genetic conservation of existing germplasm (Jubrael et al. 2005). The availability of nuclear and chloroplast genome sequence of date palm is an added advantage for assessment of genetic diversity (Yang et al. 2010; Al-Dous et al. 2011; Soumaya et al. 2014). In addition, molecular markers can be effectively used for genetic diversity assessment and constructing genetic maps for identification, genetic improvement, and conservation of true-to-type elite material (Eissa et al. 2009; Khierallah et al. 2011).

Random Amplified Polymorphic DNA (RAPD)

RAPD marker-based PCR techniques have been extensively used for identification of date palm cultivars as they are cost-effective and do not require blotting or radioactive materials (Mirbahar et al. 2014; Emoghene et al. 2015). Numerous studies have reported genetic diversity in date palm cultivars using RAPD markers in Saudi Arabia, Tunisia, Algeria, Iraq, Egypt, Bahrain, Syria, Nigeria, Morocco, India, and Pakistan (Al-Khalifah and Askari 2003; Al-Moshileh et al. 2004; Abdulla and Gamal 2010; Munshi and Osman 2010; Benkhalifa 1999; Jubrael 2001; Al-Khateeb and Jubrael 2006; Khierallah et al. 2014; Trifi et al. 2000; El-Tarras et al. 2002; Adawy et al. 2004; Soliman et al. 2006; Younis et al. 2008; Moghaieb et al. 2010; Pathak and Hamzah 2008; Haider et al. 2012; Sedra et al. 1998; Sedra 2013; Emoghene et al. 2015; Mirbahar et al. 2014; Toor et al. 2005; Singh et al. 2006; Rani et al. 2007). However, due to lack of dominance and detection of heterozygosity, these markers are relatively less used than other molecular markers.

Amplified Fragment Length Polymorphism (AFLP)

Large intervarietal polymorphism in date palm cultivars has been reported by various workers using AFLP markers (Mueller and Wolfenbarger 1999; Elhoumaizi et al. 2006; Khierallah 2007). These markers have also been effectively employed for making high-density linkage maps. There are several reports showing the detection

of polymorphism in date palm cultivars. In Spain, Diaz et al. (2003) reported diversity and polymorphism of date palm cultivars using AFLP markers. Using AFLP markers, El-Khishin et al. (2003) characterized five date palm cultivars from Egypt. The genetic diversity of Egyptian date palm from eight locations was studied. Twenty-eight accessions and a few accessions from California were classified and found to represent the major date palm germplasm of North Africa (El-Assar et al. 2005). Genetic diversity and phylogenetic relationships among various Iraqi cultivars have been reported (Jubrael et al. 2005; Khierallah et al. 2011). AFLP markers have been also employed for assessing genetic variations that are seen in offshoots of tissue-cultured date palms (Saker et al. 2006).

Restriction Fragment Length Polymorphism (RFLP)

RFLP markers are locus-specific markers which can be used as important tools for identification between closely related species. Being codominant they show strong molecular differentiation. Date palm cultivars have been differentiated using these RFLP markers. In Tunisian date palms, 43 accessions have been utilized for identification of genotype and genotypic polymorphisms (Sakka et al. 2003). Shoot tips used to initiate tissue culture of five elite date palm cultivars were utilized to determine the polymorphism using RFLP markers (Cornicquel and Mercier 1994). Cornicquel and Mercier (1997) generated cultivar-specific hybridization using RFLP in four date palm cultivars. PCR-RFLP-based markers were utilized for sex determination in date palm (Al-Mahmoud et al. 2012).

Intersimple Sequence Repeats (ISSR)

Microsatellite-based primers are utilized to amplify intersimple sequence DNA repeats and have been also utilized for studying inter- and intraspecific genetic variations in date palm. The genetic diversity of date palm in different growing regions has been assessed by various workers in Egypt, Iraq, Iran, India, Morocco, Pakistan, Tunisia, Egypt, Saudi Arabia, Algeria, and Ethiopia (Younis et al. 2008; Khierallah et al. 2014; Sharifi et al. 2018; Srivastav et al. 2013; Bodian et al. 2012a; Mirbahar et al. 2013; Ahmad et al. 2020; Zehdi et al. 2002, 2004a, b, 2005; Karim et al. 2010; Zehdi-Azouzi et al. 2011; Hamza et al. 2012; Younis et al. 2008; Kumar et al. 2010; Munshi and Osman 2010; Sabir et al. 2014a; Boudeffeur et al. 2021; Takele et al. 2021).

Microsatellites or Simple Sequence Repeats (SSR)

SSR markers are codominant, species specific, and highly polymorphic, making them suitable markers for cultivar identification, genetic diversity assessment, and construction of linkage maps and gene-based maps in date palm. Akkak et al. (2003) have isolated simple sequence repeats from genomic library and detected high polymorphism in the analyzed samples. Researchers have reported genetic diversity and polymorphism in Tunisia (Zehdi et al. 2004a, b, 2006), Qatar (Elmeer and Mattat 2012), Iraq (Khierallah et al. 2011), Libya (Racchi et al. 2014), Saudi Arabia (Yusuf et al. 2015; Al-Faifi et al. 2017), Qatar (Ahmed and Al-Qaradawi 2009; Elmeer and Mattat 2015), Mauritania (Bodian et al. 2012b), Pakistan (Naeem et al. 2018), and

Sudan (Elsafy et al. 2016). SSR markers have been developed for specific identification of gender in date palm for breeding (Maryam et al. 2016).

Expressed Sequence Tags (EST)

28,889 EST sequences were analyzed from date palm genome database to develop gene-based markers, i.e., EST-SSRs (Zhao et al. 2012). One third of the primers designed detected polymorphism to differentiate the date palm cultivars used. In date palm, large-scale collection and annotation of gene models were also developed (Zhang et al. 2012). ESTs were also generated for understanding the high performance and quality of commercial cultivar (Al-Faifi et al. 2017).

Single Nucleotide Polymorphisms (SNPs)

High-density genetic maps are created using potential markers like SNPs. They are now widely used to study date palm genome sequences. The first draft genome of palm cultivar was assembled using EST markers (Al-Dous et al. 2011). SNP analysis by sequencing the mitochondrial DNA sequence of Saudi Arabian date palm cultivars revealed close phylogenetic relationships among the studied cultivars (Sabir et al. 2014b). In a study of date palm cultivars from different countries using generated SNPs, the date palms were segregated based on genetic background into two main regions, i.e., North Africa and Arabian Gulf (Mathew et al. 2015). Based on whole genome sequence of date palm, a catalog of about seven million SNPs from 62 cultivars was developed (Hazzouri et al. 2015).

3.2 Sex Determination

In dioecious trees, identification of male and female sex is a complex process, as it is not possible to identify the plants in the seedling or early growth stage. Date palm being dioecious takes 5–7 years before it starts flowering and fruiting, which is a limiting factor with respect to traditional breeding programs. It not only causes economic loss to farmers but also makes it difficult for the breeders to select the superior lines from the existing elite cultivars. The genetics of sex determination in date palm is fully understood, but attempts have been made at morphological level, biochemical level, and molecular level to determine the sex of the plant at the early development stages (Awan et al. 2017).

3.2.1 Morphological Markers

Morphological features of the plant are usually taken into consideration to determine the sex of the plant. However, such characters can be applicable at maturity. Being laborious and the effect of environmental factors make it difficult to study. Identification of genotype of date palm is based on female tree morphology and characters of fruits. Date palm cultivars from Saudi Arabia have been identified based on morphological characters (Al-Khalifah et al. 2012). Similarly, male plants from elite cultivars have been identified based on morphological markers (Soliman et al. 2013). There are

numerous reports stating that the leaf and leaflet characters can be utilized for identification (Ahmed et al. 2011; Hammadi et al. 2009; Haider et al. 2015).

3.2.2 Biochemical Markers

Peroxidase serves as an important marker for the identification of male and female plants, as the diversity of peroxidase varies between male and female inflorescences. Researchers have reported lower peroxidase and acid phosphatase activities in male than in female date palm plants (Qacif et al. 2007; Bekheet et al. 2008). Moreover, glutamate oxaloacetate activity is higher in female than in male plants. Polypeptides specific to male plants which were isolated from the leaves were also reported. These also serve as a gender biomarker in date palm (Sonia et al. 2013). Chemical composition of leaves has also been a distinguishing parameter, where female leaves have higher concentration of pigments, phenolic acids, amino acids, and sugars, whereas male leaves have higher concentrations of proline and ash (El-Yazal 2008). Higher levels of sugar have been reported in male trees compared to female trees (Rao et al. 2009). Similarly, phenolic acid content is higher in male than in female plant saps (Makhlouf-Gafsi et al. 2016).

3.2.3 Molecular Markers

Due to the limitations of the morphological and biochemical markers, molecular markers based on RFLP, RAPD, AFLP, and SSR markers were developed for the identification of gender in date palm. Numerous attempts to identify the male and female gender in date palm using RFLP (Al-Mahmoud et al. 2012), RAPD (Ben-Abdallah et al. 2000; Soliman et al. 2003; Ahmed et al. 2006; Al-Khalifah et al. 2006; Bekheet et al. 2008), ISSR (Younis et al. 2008; Al-Ameri et al. 2016a), AFLP (Atia et al. (2017), SCAR (Al-Qurainy et al. 2018; Dhawan et al. 2013; Al-Ameri et al. 2016b), and SSR markers (Elmeer and Mattat 2012; Maryam et al. 2016) have been made. A putative sex chromosome was identified using the constructed date palm genetic map (Mathew et al. 2014). Date-SRY gene and GWAS mapping of sex determination locus are some of the important tools for sex determination in postgenomic era (Hazzouri et al. 2019; Mohei et al. 2019).

3.3 Genomics

Sequencing and analysis of the genome have important applications in determining genetic diversity, systems biology, evolutionary process, etc. The sequenced genome of date palm has been used for developing genetic map (Al-Dous et al. 2011; Al-Mssallem et al. 2013; Mathew et al. 2014; Sabir et al. 2014b; Hazzouri et al. 2015). Sequencing technologies like pyrosequencing, ligation-based sequencing, etc. have been utilized for sequencing the nuclear genome (Al-Mssallem et al. 2013), chloroplast genome (Yang et al. 2010), and mitochondrial and plastid genomes (Sabir et al. 2014b). In addition, to understand the genomics of date palm, various projects have been undertaken for sequencing the whole genome like the Date Palm Genome Project (DPGP) by King Abdulaziz City for Science and Technology (KACST), Riyadh, Saudi Arabia, in association with Beijing

Institute of Genomics in 2008. Weill Cornell Medical College, Qatar, using next-generation sequencing technology, sequenced the whole genome of date palm (https://qatar-weill.cornell.edu/research-labs-and-programs/date-palm-research-program/date-palm-genome-data). The genome contains 500 Mbp.

3.4 Computational Analysis

Gene regulation has been highly influenced by micro-RNAs (mi-RNAs) during the development of the plant. The 276 novel date palm-specific mi-RNAs involved in regulating genes for fruit development and ripening have been characterized by using high-throughput sequencing and bioinformatics predictions (Xin et al. 2015). Similarly, 153 homologs of conserved miRNAs, 89 miRNA variants, and 180 putative novel miRNAs in date palms that can play an important role in salt tolerance were identified (Yaish et al. 2015).

3.5 Genetic Manipulation of Date Palm

Date palm has been genetically modified to incorporate new genes to improve the commercial value of the crop. Transformation via *Agrobacterium-mediated* and direct gene transfer using particle bombardment has been utilized for the transfer of specific genes of interest. *Agrobacterium*-mediated transfer utilized GUS (β-glucuronidase) as the reporter gene. Saker et al. (2009) reported the first case of successful infection of embryonic cells in date palm and a system was developed for the transfer. Aslam et al. (2015) reported detection of strong GUS activity and integration of *uidA* (*GUS)* and *npt II* genes into transgenic plants in cultivar Khalasah via somatic embryogenesis. Various researchers were involved in the transformation via particle bombardment, but pioneering work was using the Iranian cv. Khorma (Habashi et al. 2008). Likewise, factors affecting transformation via particle bombardment in Egyptian cv. Sewi were optimized (Saker et al. 2007). Mousavi et al. (2014) developed an efficient transformation for gene delivery in date palm. Somatic embryos of Estamaran cultivar were utilized for transient transformation of the uidA gene. Physical and biological parameters were optimized, and tissue bombarded with constructs having the uidA gene. Similarly, for introducing date palm resistance to pests, a construct with the cholesterol oxidase (*ChoA*) gene was introduced into embryonic callus of date palm by particle bombardment (Allam and Saker, 2017).

4 Recent Concepts and Strategies Developed

4.1 Gene Editing

Prevention and treatment of diseases in organisms using genome corrections or modifications refers to gene editing and is gaining ground today as conducted by researchers and scientists. Mainly for therapeutic purposes, gene editing is known

for somatic body cells and germline – reproductive cell-based therapies. The applicability of gene editing is not only limited to animals or humans but also finds an extensive range of applications in plant biotechnology. Gene editing in plants, referring to the alterations in DNA and ultimately affecting the phenotype and associated traits in the plants, involves the use of various enzymes for the insertion and replacement of various DNA sections. Instead of random insertion and deletion of genes like traditional ways in organisms, gene editing targets the site-specific editing at specific locations only and is of immense interest in the treatment and cure of diseases like sickle cell anemia, cystic fibrosis, and others.

The creation of herbicide-resistant, disease-resistant, or nutrient-rich crops is no longer a dream for scientists as they can be constructed even with specific alterations in the plant's own DNA instead of the introduction of new or foreign genes. Both with and without plant tissue culture methods, the creation of identical copies from simple plant tissue is possible with the advancement in technology (Kim 2020). Out of the many techniques available, the two most applied ones in the construction of an edited plant include the addition of *Streptococcus pyogenes* cas9 protein-encoding DNA and a guide RNA using nature's genetic engineer, *Agrobacterium*. CRISPR-Cas9 systems have revolutionized the entire world of plant editing genome and its associated areas. Knock-ins and other methods of delivery for CRISPR and other editing tools require a deeper understanding and knowledge of the processes for finer targeted procedures (Mao et al. 2019). It has been reported that not all CRISPR constructs and variables are successful owing to the differences in specificity required for the expression of Cas9 DNA nuclease, and such a comparison in levels of editing has been exhibited by *Arabidopsis thaliana* (Shockey 2020). Unwanted mutations can also be expected to be observed on introspection at the genomic level as nuclease activity was observed at locations that were targeted using single guide RNAs that were imperfectly matched.

There are processes available that include genetic transformation even without the involvement of DNA, and one of the major concerns includes its cellular genome integration. This often becomes a hurdle in the experimental settings and practical modes, which often drives a reason for developing novel methods of gene editing without the necessity to transform or use DNA delivery (Tsanova et al. 2021). Few of the processes include the formation of ribonucleoprotein complexes, utilization of secretory systems in bacteria for Cas/gRNA delivery, or even application of viruslike particles. For the former option, *Agrobacterium* plays a major role in the CRISPR/Cas9 cassette delivery. Although this method is gaining ground owing to its ease of techniques, low cost, and flexibility, there are a number of obstacles in transformation using genome editing of polyploid crops and germline gene expression (Vats et al. 2019). More precise technologies like promoter bashing, methylome, or gene editing can also be referred to as techniques for advancement in plant sciences and editing.

As far as *Phoenix dactylifera* is concerned, gene editing reports revolve mostly around determination of genetic basicity. Measurable phenotypes as controlled by a set of genes and their interaction with the environment, referred to as quantitative traits, are primarily concentrated on when it comes to gene editing in date palms.

Specific chromosome regions of that control continuous traits are referred to as quantitative trait loci (QTLs). The phenotypic evaluation might not be the ultimate method to identify QTLs, but they can be mapped to identify the location of complex traits as well. In addition, for the identification of QTLs, both genotype and phenotype play a major role by either linkage disequilibrium or overall structure of population or prediction of relatedness in the category of genotypes. CRISPR-associated protein 9-based approaches have been applied in fruit trees; they are cumbersome and practically difficult to apply in date palms due to their higher genome complexity and structure and high outcrossing and heterozygosity rate. The disadvantages of genetic instability owing to high frequency rate of single nucleotide polymorphisms are common in the same. Despite these issues, several approaches using CRISPR/Cas-9 for gene editing in date palms have been enlisted in a report by Sattar et al. (2017). Along with that, various prospects of genome editing tools have also been discussed in date palms.

An array of experiments has been conducted on the genomic content of date palms alone. They have revealed the presence of 38 proteins, 3 ribosomal RNAs, and 30 tRNAs which make up 6.5% of the complete genome and are completely coding, whereas the remaining is noncoding and chloroplast-derived, consisting of tandem and long repeats with a constitution of 0.33% and 2.3%, respectively (Fang et al. 2012). This places the mitochondrial genomic data of date palms at the fourth position based on genomic length. Evolution along parallel lines can be well documented according to a report by Hazzouri et al. (2019) where domesticated species showed diversification in the evolutionary trend. A comprehensive genome assembly of the *P. dactylifera* genome has been made by the group that extends up to 772.3 Mb lengthwise with an 897.2 Kb contig N50, which is further used to execute genome-wide association studies (GWAS) of fruit traits or sex-determining region. It has also been reported that there are 18 polycistronic transcription units and three exclusive genes that are highly expressive in nature, namely *atpF*, *rrn23*, and *trnA-UGC*, as per information from RNA sequencing in date palm chloroplast genome. As observed in most angiosperms, the date palm genome also exhibits 112 unique genes along with 19 duplicated fragments in the inverted repeat regions. There is a typical similarity of date palm genomics with that of tobacco with slight rearrangements in genetic order, as reported by Yang et al. (2010). Major intravarietal polymorphisms as observed include 78 single nucleotide polymorphisms within the chloroplast genome, mostly in genes with vital functions. To get a comprehensive idea about the complications of dioecy and long-time generation, the draft genome for Khalas variety was executed by Al-Dous et al. (2011), constituting a 380 Mb sequence with gene models of more than 25,000, covering 60% of genome and 90% of genes.

4.2 Nanotechnology

The study and application of extremely small objects, being classified on a scale between one and a hundred nanometers on the meter range, refers to the branch of nanotechnology. Currently, it is one of the most developing branches in the

scientific world and rightly gaining prominence among the scientists due to its promising avenues for study of almost any division of research world. The application of nanotechnology has been extended to biological systems especially to create new medicines for combating upcoming challenges in the world of diseases, along with preventing blood clot formation. The most important fluids maintaining the overall physiological conditioning of body, blood, and its components – erythrocytes, leukocytes, and platelets – are accessible to the nanoparticles through the induction of phosphatidylserine on erythrocyte membrane, thereby altering the hemorheological membranes (Zain et al. 2022). An increasing resonance has been found in the application of nanotechnology in the production of secondary metabolites in plants, especially in the usage of silver nanoparticles that possess both hermetic and antimicrobial properties (Rahmawati et al. 2022). This increased applicability is mostly due to microbial decontamination capabilities and elevation in the overall quantity of secondary metabolite content. Detection mechanisms are conducted using nano-biosensors and chips that provide a cheaper, reliable, portable, and faster method for sustainable agricultural procedures (Sellappan et al. 2022). This has already been applied to the detection of microbes, especially viruses in plants as higher pollution was observed on introduction of pesticides in the fields. The never-ending industrialization and urbanization have led to the overall rise in environmental pollution, and application of nanotechnology has helped in the bioremediation processes and decontamination measures taken up by the research centers and industries. In association with nanoparticles, the environmentally friendly and reactivity nature of nanotechnology has helped elevate the quality of bioremediation tasks aided with responsibility in keeping surroundings clean and green. Nyika (2022) has reported various examples where nanotechnology has hastened the process of environmental bioremediation measures that were apparently challenging owing to chemical reactions like photocatalysis, filtration, and other invasive chemical reactions.

For the preparation of nanoparticles, until now several plant extracts have been used as reducing agents, and greener methods of production are more preferred over synthetic ones. Thus, in a report by Batool et al. (2021), nanoparticles were created using *Phoenix dactylifera* as the reducing agent and iron sulfate heptahydrate was the respective substrate to work on. Very interestingly, the nanoparticles have exhibited high antimicrobial activity with a zone of inhibition of about 25 ± 0.360 mm against *Bacillus subtilis*, *Klebsiella pneumoniae*, *Escherichia coli*, and *Micrococcus luteus*. Apart from that, seeds of date palm were used for the same in another experiment by Sirry et al. (2020) for the synthesis of silver nanoparticles. Applications in the biomedical field were checked using the nanoparticles so formed, and extraction was mostly focused on with the usage of several solvents like acidic and alkaline media, ethanol, methanol, and water – both boiling and at normal temperature. In all cases, applicability of water was at a higher efficiency level as compared to other solvents, and anti-inflammatory efficiency was studied by inhibiting albumin denaturation to a higher extent as compared to that using piroxicam alone loaded onto silver nanoparticles.

As explained earlier, almost all the parts of the plant are useful in some way or the other for scientific application. Apart from seeds, leaves of the plant have found applicability in the formation of zinc oxide nanoparticles, where FTIR, TEM, XRD, and UV-visible spectrophotometry are few techniques that have aided in its characterization (Salih et al. 2021). These nanoparticles so formed elevated the physiological characteristics necessitated for growth and development of callus of *Juniperus procera*, as analyzed using GC-MS. Further, there was an upliftment in the quality of biochemical parameters such as chlorophyll a, total flavonoid, and phenol, apart from improvement of total protein and SOD, CAT, and APX activity. In addition, aqueous extract from fruits of date palm have been exclusively used in the preparation of silver nanoparticles and further characterized and evaluated for their in vitro antimicrobial activities (Zafar and Zafar 2019). Potential studies about the cytotoxic activities of the nanoparticles obtained using fruits have been studied in breast cancer cell lines (MCF-7), and cytotoxicity has been found through apoptosis, necrosis, or mechanisms to suppress mitochondrial functioning that can lead to disruptions at various stages in cell cycle. Similar experiments have been performed by Farhadi et al. (2017) using date palm fruits as an extract to produce spherical silver nanoparticles using low-cost and eco-friendly approaches for the preparation of reducing and stabilizing agent from the same. The elemental or crystalline property of nanoparticles was characterized using EDX and XRD techniques, whereas their spherical nature was confirmed using scanning electron microscopy and transmission electron microscopy. Along with that, functional groups as found in biomolecules of date palm fruits are the major reasons for the reduction or stabilization property of nanoparticles, respectively.

There are several active components in *Phoenix dactylifera*, also referred to as date pits, which include L-glutamic acid, gallic acid, or sinapic acid that can function as reducing agents, in accordance with manganese trioxide nanoparticles so synthesized (Sackey et al. 2021). These active compounds have helped in the nanoparticle preparation, and several advanced techniques such as HR-TEM, energy-dispersive detector, high resolution-scanning electron microscopy, and cyclic voltammetry have revealed the efficiency of computationally and experimentally synthesized nanoparticles. Apart from the protocols being cheap, another reason for the preference of green synthesis over synthetic ones includes its environment-friendly nature. Characterization of nanoparticles was conducted using advanced technologies such as UV-visible spectrophotometry showing a peak at 275 nm, indicating the presence of copper oxide. Berra et al. (2018) also confirmed the application of X-ray diffraction and scanning electron microscopy for the crystalline nature and aspherical shape of copper oxide nanoparticles, respectively.

5 Bioinformatics of Date Palm

Bioinformatics is the scientific discipline of collecting and storing biological information in searchable databases and handling the data effectively to draw significant conclusions. Data generated by omics approaches is understood by in silico tools to draw implications about mechanisms of the biological processes in date palm.

To understand the DNA of date palm, whole draft sequence assemblies of nuclear, plastid, and mitochondrial genomes are being generated, and to understand the RNA, protein, phenotype, and chemotype, transcriptomes, proteomes, phenomes, and metabolomes have been generated, respectively.

5.1 Genome Analysis

Date palm is diploid (2n = 36) and several studies have been carried out for the estimation of nuclear genome and organellar genome sizes (Al-Dous et al. 2011; Fang et al. 2012; Al-Mssallem et al. 2013; Sabir et al. 2014a; He et al. 2017; Gros-Balthazard et al. 2018; Thareja et al. 2018; Chaluvadi et al. 2019; Hazzouri et al. 2019; Mohamoud et al. 2019;). Date palm genome assembly draft was analyzed and microsatellite motifs were screened using a script in Perl software, which showed 321,278,327 bases (Hamwieh et al. 2010). Transcriptome sequences were identified and 1000 SSR loci were utilized for developing new markers. 166,760 SSR regions with a density of 1 at every 2.2 Kb in the date palm genome were found (Manju et al. 2016). Xiao et al. (2016) observed at a density of 1 in every 1.36 Kb, 371,629 SSRs. As many as new 264,655 SSR loci were located when 62 cultivar genomes of date palm were re-sequenced and when compared them with known reference genome assemblies available in online database. Pathway annotation work carried out in date palm by using SSR regions and BLAST2GO methods showed 23 enzymes involved in metabolism of starch and sucrose and 16 enzymes involved in metabolism of amino/nucleotide sugar (Mokhtar et al. 2016).

A database has been generated to show the SNP variation, using re-sequenced and known genomes of date palm (He et al. 2017). A density of 1 SNP per 217 bases was seen by date palm genome (Al-Dous et al. 2011). SNP peaks associated with sex-determining loci were found at linkage group (LG) 12 (Mathew et al. 2014; Hazzouri et al. 2019).

5.1.1 Organellar Genome (Chloroplast and Mitochondrial Genome)

Various assembling software like CLC Genomics Workbench (CLC bio, Denmark) were used to assemble the NGS datasets from the pyrosequencing and Illumina systems of date palm chloroplast DNA (Khan et al. 2010). NOVOPlasty program was used for de novo assembly of chloroplast DNA from NGS data along with ORF Finder (http://www.ncbi. nlm.nih.gov/projects/gorf/), and Dual Organellar Genome Annotator (the DOGMA server) was employed for the annotation of chloroplast genomes (Wyman 2004; Dierckxsens et al. 2017; Rasheed et al. 2020). Also, tRNAscan-SE was carried out for annotation of some tRNAs (Lowe and Eddy 1997), and description of repeat sequences was carried out by using the REPuter program after searching for sequence similarity with annotated plastomes (Kurtz et al. 2001). Bioinformatics tools including the GenomeVx online and Gene Order tool were used for the circular genome map of date palm, and chloroplast genome and gene order were investigated (Celamkoti 2004; Conant 2008). mVISTA comparative genomics server was used for the construction of multiple sequence alignments of chloroplast genomes (Frazer et al. 2004). MEGA4 program was utilized for

parsimony-based phylogenetic tree construction (Tamura et al. 2007). Various bioinformatics software had been used to examine and infer the date palm cp DNA sequence, and it showed a close association with the broad leaf cattail (*Typha latifolia* L.). The mitochondrial genomes of date palm are the circular DNAs of sizes ranging from 585,493 bp to 715,120 bp. In *Phoenix dactylifera* (NC016740), *P. dactylifera* (MH176159), and *P. dactylifera* cv. Naghal, the protein-coding sequence is composed of 5.35, 4.6, and 4.6% gene content, respectively. However, the noncoding region possesses only 1.8% in the unverified mitochondrial genome of *P. dactylifera* (MG257490). The gene content is similar among these mt genomes. In *P. dactylifera* (NC016740), in total 43 protein-coding genes were found.

5.1.2 Whole Genome

Numerous web-based date palm databases have been constructed to map the date palm genome. Most databases available today are intended to help researchers and breeders to recognize predominant date palm cultivars by selecting highly specific polymorphic markers. These databases help researchers to search genetic variations among different date palm cultivars, thus helping in further breeding and genetic studies. The following are the databases used to map the date palm genome.

Date Palm Genome Database (DRDB)

DRDB was developed as a platform to help researcher and breeder in observing and recognizing different date palm varieties or cultivars using polymorphic markers using search functionalities that can be accessed freely – http://drdb.big.ac.cn/home (He et al. 2017). The database has sequenced genomic data of 62 different cultivars from different parts of the world, with 246,445 SSRs and 6,375,806 SNPs annotated in the genome assembly. Phylogenetic tree developed from these cultivars based on the geographic location shows three subclades. The database also helps in identifying and retrieving the SSR and SNP data sheets of specified cultivars, which can be customized based on requisite parameters. In addition, markers can be selected at cultivar, regional, or country level. The database also provides information associated with SNP annotation, etc. Information for external sources like UniProt is also available. The data can be accessed freely and downloaded.

Plant Genome and System Biology (PGSB)

PGSB is an online database comprising the databases of various plants. The date palm genome database can be accessed directly at http://pgsb.helmholtz-muenchen.de/plant/pdact/ index.jsp or https://qatar-weill.cornell.edu/ research/research-highlights/date-palm-research program. Date palm genome sequence and genome annotation is available at date palm draft sequence version 3.0. Shotgun next-generation DNA sequencing was utilized for creation of date palm genome draft assembly with an estimated genome size of ca 650 Mb. Over 3.5 million high-quality SNPs distributed among nine date palm genomes and the Khalas cv. as a reference genome is available. 90% of genes and 60% of the genome sequences including repetitive sequences and the chloroplast genome account for 381 MB of assemble sequences. Contig tables and genetics elements are placed as separate sections which can be accessed by name/id or free text methods. Information is available freely and can be

downloaded from http://qatar-weill.cornell.edu/research/research-highlights/date-palm-researchprogram/datepalm-draft-sequence.

Date Palm Molecular Markers Database (DPMMD)

DPMMD contains information useful for basic and applied research that can be accessed freely at http://dpmmd. easyomics.org/index.php. DPMMD provides information of more than 3,611,400 DNA markers in addition to genetic linkage maps, KEGG pathways, DNA barcodes, and date palm markers related to articles indexed in PubMed journals. In DPMMD, a list of SSR and SNP primers is integrated from some previously published data (Al-Dous et al. 2011; Mokhtar et al. 2016) and compiled in a relational database using MySQL environment. Information of SSR markers is categorized into Genic SSR, Genic SSR-SNP, SNP markers, intergenic SSR-SNP and R-gene SSR markers, and DNA barcode. In addition, it has Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway where database 896 SSR markers were mapped to 111 pathways. DPMMD also contains the first ever constructed date palm genetic linkage maps of 1293 cM distance.

NGS-Based Sequencing

Gene functions and their involvement in pathways of date palm were determined by NGS-based sequencing techniques coupled with omics technologies (Safronov et al. 2017). The prospects of genetic mapping as a complementary method for the identification of QTLs related to abiotic stress have also been identified (Hazzouri et al. 2020).

5.2 Gene Annotation and Promoter Motifs

By using bioinformatics approaches, abiotic stress-responsive genes were analyzed. Bioinformatics methods were used to find the desaturases of date palm and their role in stress response (Sham and Aly 2012) and motif abundances in abiotic (heat, drought) stress-induced genes (Safronov et al. 2017). In aquaporin gene PdPIP1, two regions of date palm indicated abundant abiotic (drought and salinity) stress-inducible motifs in its 2 Kb promoter region and occurrence of four groups of aquaporins in date palm genome in 40 members (Patankar et al. 2019). Phytoremediation by date palm of polluted sites to remove toxic metals especially Cd, Cu, Pd, and Cr and harmful dioxins has shown promising results (Hanano et al. 2016; Al-Najar et al. 2019; Sivarajasekar et al. 2019). Phytochelatin synthase (PdPCS1) was investigated in silico distributed in eight exons intervened by seven introns and was about 5.7 Kb long (Zayneb et al. 2017).

5.3 Gene Mapping for Trait-Linked Attributes

5.3.1 Sex-Linked Attributes

Several studies were carried out to determine the sex of date palm seedlings by using markers (Heikrujam et al. 2015; Awan et al. 2017). XY sex determination pattern is seen in date palm. The sex-linked SRY region which is specific to male plants

possesses recombination arrest mechanism. Analysis using bioinformatic tools was carried out to understand the gene, SSR, and SNP variation using transcriptomes and whole genomes of date palm (Hamweih et al. 2010; Al-Dous et al. 2011; Torres et al. 2018; Arunachalam 2021) to differentiate between sexes. The sex-determining region of the date palm having a size of approximately 6–13 Mb is present in the telomeric region of the long arm of linkage group (LG) (Mathew et al. 2014; Cherif et al. 2016; Hazzouri et al. 2019). SSR markers, SCAR marker, etc. have been developed for the identification of sexes (Billotte et al. 2004; Arunachalam 2021). The physical mapping of the genes and genomic regions on date palm LG 12 chromosome was developed by Mathew et al. (2014) to understand genomic arrangement and the evolution of sex by *in silico* methods (Premkrishnan and Arunachalam 2012; Thiel et al. 2003).

5.3.2 Attributes

Fruit color differs in different cultivars of date palm. For example, dominant negative mutation suppresses purple color anthocyanin pigment to cause yellow peel color of the date fruit (Hazzouri et al. 2019). The pericarp color of the date fruit is determined by R2-R3-MYB transcription factor (VIR locus) virescence gene, etc. (Hazzouri et al. 2015). Similarly, change in color from purple to yellow is caused by retrotransposon insertion of 397 bp size in the exon region leading to truncation of R2-R3-MYB gene (Hazzouri et al. 2019). Deletion of copies of invertase gene can lead to changes in the content of sucrose, fructose, and glucose among cultivars (Ghnimi et al. 2017; Hazzouri et al. 2019; Malek et al. 2020).

5.4 MicroRNA Prediction

Gene expression at the posttranscriptional stage is regulated by microRNA (miRNA) molecules. An eightfold increase in galactose content in heat- and drought-stressed date palm in metabolome of date palm has been observed (Safronov et al. 2017).

5.5 Image Analysis and Molecular Structure Analysis

Fluorescence microscopy is used for phenotyping of date palm varieties like leaflet anatomy (Arinkin et al. 2014), size, and shape of the seed (Terral et al. 2012). The phytochelator synthase gene structure of date palm was predicted using the available structure of a similar gene from the cyanobacteria genus *Nostoc* as a template (Zayneb et al. 2017).

6 Conclusion and Prospects

Date fruit is highly nutritious compared to any other fruits. Several varieties of date fruits can be consumed which are associated with any metabolic syndrome and related diseases. Dates being a good source of antioxidants have a vital role in

regulating human health. Hence, date fruit can be considered as a remarkable medicinal fruit due to its nutritive, bioactive, and therapeutic potentials. But there is a strong need to explore the nutra-pharmaceutical and health benefits of dates on the basis of their functional components and elucidate the mechanisms of action of such bioactives.

The available genomic resources of date palm are useful for finding out bioinformatics approaches to understand the genomic variations among cultivars in different geographical regions. Availability of the whole genome sequence, organellar sequence, and genetic map of date palm have helped breeders to modify and improve various agronomic characteristics by manipulating the genome, to improve nutritional components of the fruits. The date palm genome provides scope to understand several other biological processes with unique features. Genes and markers linked to iron content in fruit in different cultivars of date palm need to be explored. Identified SNP markers till now in nuclear and organelle genomes of date palm provide potential for developing SNP chips for molecular marker-assisted selection of date palm. Molecular modeling and docking studies will improve our understanding of the gene structure, binding sites, and crucial residues. The data on the status of research by material and software used for in silico studies on date palm omics provided here can help to identify drawbacks, to further plan investigation on the nutritional value and iron content of fruits in different varieties of date palm, to develop new cultivars, and to promote the consumption and utilization of date palm worldwide in place of several staple food used at present.

Acknowledgments The authors express their appreciation for the support provided by the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, Saudi Arabia [Grant No. GRANT3173].

Abstract

Sweet cherry is a highly appreciated fruit by the consumer because of its attractiveness and flavor. But it is also a nutritious fruit and an excellent source of bioactive compounds associated with health benefits. These molecules include nitrogenous and phenolic compounds like melatonin, serotonin, anthocyanins, or hydroxycinnamic acids. Numerous studies have associated their consumption with health-related properties, such as blood pressure regulation, anti-inflammatory properties, or cancer prevention. The concentration of these compounds has been evaluated in several cultivars, and a wide range of variability has been reported, which has been used as a starting point for genetic and molecular studies that have allowed identifying QTLs and candidate genes associated with bioactive compound concentration. At the same time, more recent transcriptomic and metabolomic studies are providing light into understanding their regulation and role during fruit development. Agricultural and postharvest practices are also showing useful to improve bioactive content. In this chapter, most relevant results of these works are reviewed.

1 Introduction: Sweet Cherries and Health

Sweet cherry (*Prunus avium* L.) is a temperate climate fruit tree species with a high commercial value in national and international markets due to its attractive appearance, delicious taste, and rich nutritional value, which is related to the presence of vitamins, fiber, minerals, fatty acids, and sugars (Gonçalves et al. 2017; Serradilla et al. 2017). Additionally, sweet cherries contain other secondary metabolites with high biological value, like flavonoids such as anthocyanins, hydroxycinnamic and hydroxybenzoic acids, flavanones, flavonols, and flavan-3-ols (Ballistreri et al. 2013; Serradilla et al. 2016; Gonçalves et al. 2017; Martini et al. 2017). These compounds exhibit high antioxidant activity that helps in combating cell damage, reducing inflammation, and promoting overall health (McCune et al. 2011; Martini et al. 2017). Therefore, cherry consumption is linked to beneficial and health-promoting effects (Nawirska-Olszańska et al. 2017). Specifically, sweet cherry consumption exhibits a reduced risk of gout and arthritis attacks and a reduction in gout-related pain (Singh et al. 2015). On the other hand, it also exhibits other health-related properties linked to blood pressure reduction, body weight control, diabetes, and the prevention of degenerative diseases like Alzheimer's (Wu et al. 2014; Kent et al. 2016; Gonçalves et al. 2017). Additionally, the health effects of sweet cherry

consumption and its derivatives have focused on physiological aspects related to anti-inflammatory and anticancer activities, protection against cardiovascular diseases, anti-obesity and antidiabetic activities, and neuroprotective factors (Blando and Oomah 2019). Moreover, these beneficial effects of sweet cherries are associated with the anti-inflammatory capacity shown by anthocyanins, inhibiting the production of nitric oxide and other pro-inflammatory factors, as well as improving vision, brain function, and sleep quality (Tsuda 2012; Garrido et al. 2013). Additionally, the consumption of sweet and sour cherry has been associated with regulating the sleep-wake cycle, mood performance, sleepiness, and jet lag symptoms, thanks to molecules like melatonin (González-Gómez et al. 2009; Howatson et al. 2012). The use of biostimulants or elicitors, both preharvest and postharvest, with salicylic acid and its derivatives, methyl jasmonate, oxalic acid, and, recently, melatonin, has been found to increase the content of these bioactive compounds that can improve fruit quality and also bioactive capacity (Yao and Tian 2005; Giménez et al. 2014, 2015; Martínez-Esplá et al. 2014; Sharafi et al. 2021; Carrión-Antolí et al. 2022).

2 Chemical Composition

The scientific community has extensively studied the chemical composition of cherries (Usenik et al. 2008; Correia et al. 2017; Serradilla et al. 2017; Papapetros et al. 2018). Cherries are characterized by a low-calorie level (around 63.0 kcal [263.34 kJ] per 100 g), high water content (approximately 80%), and the absence of sodium (Serradilla et al. 2017; Gonçalves et al. 2017). Water content varies according to genotype and ripening stage, ranging from 75% offered by the late ripening cultivar 'Starkrimson' to 88% shown by the mid-season ripening cultivar 'Sunburst' (Gonçalves et al. 2021). Regarding inorganic matter or ash content, values from 0.44%, shown by the mid-season ripening cultivar 'Skeena', to 2.88%, measured by the early ripening cultivar 'Burlat', were reported (Gonçalves et al. 2021).

2.1 Sugar Content

One of the parameters that have the most significant influence on consumer acceptance is sweetness (Crisosto et al. 2003; Serradilla et al. 2016). This trait depends on the soluble solid content (SSC) and soluble sugars. This content is influenced not only by genotype but also by agronomic practices, climatic conditions of the production area, and even rootstock (Hrotko 2008; Usenik et al. 2010; Correia et al. 2017; Serradilla et al. 2017). A broad range of SSC has been reported in the literature depending on cultivar and geographic localization. In the northern hemisphere, this range varies from 11.9 °Brix in the cultivar 'Celeste' to 24.5, led by the cultivar 'Salmo' (Girard and Kopp 1998; Gonçalves et al. 2021). Similarly, in the southern hemisphere, values ranging from 16.8 ('Santina') to 23.9 °Brix ('Bing') have been described (Param and Zoffoli 2016). On the other hand, SSC tends to

increase during fruit ripening (Serradilla et al. 2012). Cherries are characterized by different soluble sugars, such as disaccharides like sucrose, maltose, and trehalose and monosaccharides or reducing sugars like fructose, glucose, and especially D-glucose (Serradilla et al. 2017; Chen et al. 2022). In addition, other sugars, or polyols, such as sorbitol, are also present in cherries (Blando and Oomah 2019). The glucose content ranges from 6 to 10 g/100 g of fresh weight (FW), while the fructose content ranges from 4.6 to 6.7 g/100 g of FW. These values are influenced by genotype, rootstock, soil, climatic conditions, and fruit ripening stage (Serradilla et al. 2017).

Like other stone fruits, the ripening process in cherries is characterized by a double sigmoid curve (Serrano et al. 2005), where three stages of development are identified. The first stage is mainly based on cell division and elongation when the fruit is entirely immature or green; the second stage is the endocarp hardening, which leads to the formation of the nucleus and fruit color appearance; the third stage is the period of exponential growth caused by cell enlargement, in which physiological and biochemical changes in sugar, organic acid, and color occur drastically (Blando and Oomah 2019; Chen et al. 2022). During this process, soluble sugars show a trend consistent with changes exhibited by SSC: an initial increase, followed by stabilization, and a further increase in the last stage of the ripening process (Chen et al. 2022). Generally, during ripening, disaccharides are cleaved into their monomers, such as glucose and fructose. The latter two tend to accumulate during fruit ripening, while sorbitol concentration does not show any significant changes at the end of ripening (Teribia et al. 2016; Serradilla et al. 2017; Chen et al. 2022). All these changes during fruit development result from the joint action of multiple metabolites and genes (Yang et al. 2021a).

2.2 Organic Acids and Total Acidity

The sweet cherry flavor is mainly defined by sweetness and sourness (Serradilla et al. 2017). Sourness is expressed as titratable acidity (TA), which depends on genotypes and ripening stages. In the sweet cherry germplasm, TA ranges from 0.48 (‘Garnet’) to 0.96%, shown by ‘4–84’ and ‘Sweetheart’ cultivars (Gonçalves et al. 2021), reaching maximum values of TA at the end of the ripening process (Teribia et al. 2016). Cherries are generally considered medium acidity fruits, with pH ranging from 3.49 to 4.5 depending on cultivars and ripening stage (Ballistreri et al. 2013; Teribia et al. 2016; Gonçalves et al. 2021). Organic acids contribute to the flavor and pH of the fruits and, therefore, their sensory characteristics (Serradilla et al. 2017; Yang et al. 2021a). Among the primary organic acids found in cherries, malic acid, a predominant acid in the *Prunus* genus, stands out. Malic acid concentration depends on the cultivar and varies between 300 and 1100 mg/100 g of FW (Usenik et al. 2008; Serradilla et al. 2016); thus, some cultivars are more acidic than others. The following most crucial organic acids are citric acid, with values between 5 and 300 mg/100 g of FW, and succinic acid, which varies from 4 to 32 mg/100 g of FW (Serradilla et al. 2016). Other organic acids like oxalic, fumaric, and shikimic acid

have also been identified, showing concentrations below 8 mg/100 g of FW (Usenik et al. 2008; Serradilla et al. 2016). Like soluble sugars, malic acid content decreases at the beginning of ripening and then increases at the end of the process (Serrano et al. 2005). The balance of organic acids and sugars, defined by the SSC/TA ratio, affects cherry flavor and, consequently, customer acceptance (Crisosto et al. 2003; Serradilla et al. 2017). Gonçalves et al. (2021) found that this ratio ranged from 17.07 ('Sweetheart') to 32.33 ('Starkrimson'). However, Picota-type cultivars that show peduncle excision and late ripening time, like 'Ambrunés', can reach values close to 40 (Serradilla et al. 2012).

2.3 Nitrogenous Compounds

Cherries have also acquired great importance because their composition contains nitrogenous compounds of great bioactive value, such as indolamines, including melatonin (N-acetyl-5-methoxytryptamine), serotonin (5-hydroxytryptamine), and its precursor, the amino acid tryptophan. Within them, melatonin, a signaling molecule that regulates a wide range of physiological processes in plants and human circadian cycles, is a relevant compound in cherries (González-Gómez et al. 2009; Carrión-Antolí et al. 2022). Both melatonin and serotonin are synthesized from the essential amino acid tryptophan via the shikimic acid pathway. Similarly to other compounds, the melatonin and serotonin content depends on the cultivar and ripening stage of the fruits. For melatonin, concentration ranged from 0.6, shown by the Picota-type cultivar 'Pico Negro Limón', to 22.4 ng/100 g of FW of the early ripening cultivar 'Burlat'. Likewise, serotonin concentration ranges from 2.8 ('Pico Negro') to 37.6 ng/100 g of FW in 'Ambrunés'. Regarding the impact of the ripening stage, melatonin increased during ripening, while serotonin showed a less defined behavior (González-Gómez et al. 2009).

2.4 Phenolic Compounds

In addition to nitrogenous compounds, cherries, like other fruits, have acquired great importance in recent years due to the great content of bioactive compounds of phenolic nature that present high antioxidant activity against free radicals, which are related to beneficial properties for human health (Serra et al. 2011; Chockchaisawasdee et al. 2016; Correia et al. 2017; Serradilla et al. 2017; Blando and Oomah 2019; Gonçalves et al. 2021). The content of total phenols shown by cherries varies from 44.3 to 192 mg/100 g of FW depending on cultivar, ripening stage, and soil and climatic conditions (Serradilla et al. 2016). Among phenolic compounds present in cherries, flavonoids (anthocyanins, flavonols, and flavan-3-ols) and phenolic acids (hydroxycinnamic acids and hydroxybenzoic acids) are the most abundant (Fig. 1) (Serra et al. 2011; Ballistreri et al. 2013; Serradilla et al. 2017). Within phenolic acids, cherries stand out for hydroxycinnamic acids, especially neochlorogenic and p-coumaroylquinic acids, although chlorogenic and

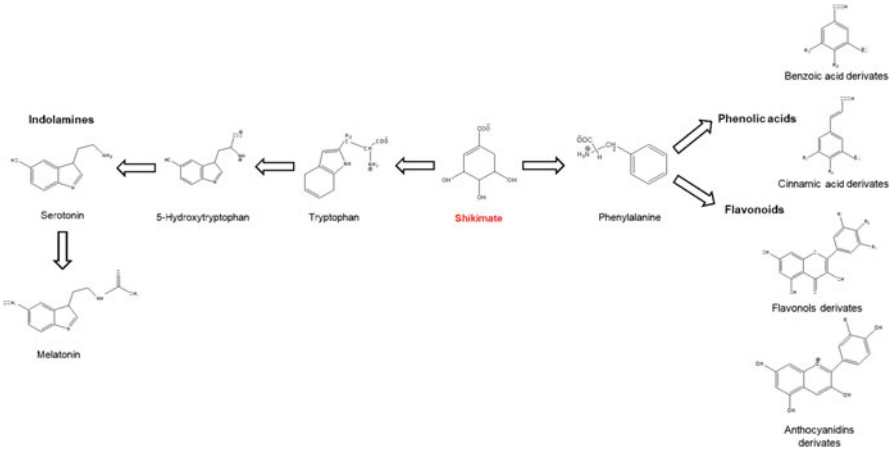

Fig. 1 Main phenolic compounds and indolamines present in sweet cherry fruits derived from shikimic acid (red) via different metabolic pathways

caffeoylquinic acids were detected in lower amounts (Serradilla et al. 2017). The concentration of these compounds is defined by genotype. For neochlorogenic acid, cultivars are classified based on concentration as low (4–20 mg/100 g of FW) like 'Burlat', 'Lapins', and 'Sweetheart'; medium (20–40 mg/100 g of FW) like 'Ferrovia', 'Blaze Star', and '0900 Ziraat'; and high (40–128 mg/100 g of FW; 'Bing') (Ballistreri et al. 2013). For p-coumaroylquinic acid content, intervals from 0.77 ('Lapins') to 131.45 ('Sam') mg/100 g of FW were reported in the bibliography (Serradilla et al. 2016). Moreover, the ratio of these two primary hydroxycinnamic acids is characteristic of each genotype (Mozetič et al. 2006).

Among flavonoids, cherries stand out for their high content of anthocyanins. These pigments are responsible for skin and flesh color and, therefore, for one of the most critical organoleptic characteristics that define consumer purchase (Serradilla et al. 2017; Gonçalves et al. 2021; Carrión-Antolí et al. 2022). Anthocyanins are characterized as water-soluble pigments present in the vacuole. They have a basic structure called aglycone or anthocyanidin (flavylium 2-phenyl-benzopyrylium) to which one or more sugars are attached by glycosidic bonds forming anthocyanins (Serradilla et al. 2016). The main anthocyanin identified in cherry has been cyanidin 3-*O*-rutinoside followed by cyanidin 3-*O*-ruthinoside and, in lower concentrations, peonidin 3-*O*-rutinoside, peonidin 3-*O*-glucoside, pelargonidin 3-*O*-rutinoside, and delphinidin 3-*O*-rutinoside (Serra et al. 2011; Ballistreri et al. 2013; Serradilla et al. 2017; Gonçalves et al. 2021). The cyanidin 3-*O*-rutinoside represents between 77% and 96% of the total anthocyanins, with light-colored cultivars showing average anthocyanin values between 2 and 47 mg/100 g of FW, while dark cherries can reach up to 297 mg/100 g of FW (Serradilla et al. 2016). Anthocyanins tend to accumulate during fruit ripening (Serrano et al. 2005; Serradilla et al. 2011).

Other flavonoids present in cherries, considered as noncolored phenolic compounds, are flavonols, remarkably quercetin 3-*O*-rutinoside or rutin, which concentration ranges

from 1.84 ('Van') to 51.97 mg/100 g of FW led by cultivar 'Lapins' (González-Gómez et al. 2010; Martini et al. 2017). Rutin content also increases during fruit ripening (Serradilla et al. 2011). Recently, Gonçalves et al. (2021) identified other flavonols such as quercetin 3-*O*-hexoside, kaempferol 3-*O*-rutinoside, kaempferol hexoside (3-gluc), and the kaempferol hexoside derivative 2, with concentrations strongly influenced by genotype. Other flavonoids listed as noncolored phenolic compounds are flavan-3-ols. In cherries, mainly epicatechin and catechin have been identified but also polymeric procyanidin (Blando and Oomah 2019). These represent less than 11.29% of the total noncolored compounds (Gonçalves et al. 2021), and their ratio is strongly influenced by genotype (Serra et al. 2011). Cherries are notorious for their high epicatechin content compared to catechin content, although this ratio also varies depending on the cultivar (Serra et al. 2011). Epicatechin levels range from 0.43 to 13.38 mg/100 g of FW, while catechin content ranges from 2.92 to 9.03 mg/100 g of FW (Serradilla et al. 2016). However, in the case of polymeric procyanidins, found in a few cultivars, levels of 20 mg/100 g of FW have been described, as is the case of the cultivar 'Royal Ann' (Chaovanalikit and Wrolstad 2004).

3 Genetics and QTL Analyses

In the last decade, several quantitative trait loci (QTLs) determining the genetic variation of the most relevant agronomic and fruit quality traits have been identified in sweet and sour cherry (Sooriyapathirana et al. 2010; Zhang et al. 2010; Dirlewanger et al. 2012; Rosyara et al. 2013; Castède et al. 2014; Quero-García et al. 2014; Campoy et al. 2015; Cai et al. 2019; Quero-García et al. 2019, 2021; Calle et al. 2020, 2021; Calle and Wünsch 2020; Branchereau et al. 2022; reviewed in Quero-García et al. 2022). Most of these works focused on physical traits like size, weight, firmness, and color (Sooriyapathirana et al. 2010; Zhang et al. 2010; Rosyara et al. 2013; Quero-García et al. 2014; Calle et al. 2020; Calle and Wünsch 2020). Despite the variation of nutritional and health-related compounds is well documented in sweet cherries during harvest and postharvest, as described above, few studies have investigated the genetics or carried QTL analyses of these compounds in sweet cherries (Quero-García et al. 2019; Calle et al. 2021).

3.1 Sugar Content and Total Acidity

Three works have focused on the genetics of sugar content and acidity in sweet cherry (Zhao et al. 2014; Quero-García et al. 2019; Calle and Wünsch 2020). These studies investigated sugar content, evaluated as SSC using a refractometer, TA, and pH (the latter only in Quero-García et al. 2019). Zhao et al. (2014) used 3-year phenotypic data from 601 pedigree-related individuals that included F_1 seedlings, breeding parental and commercial cultivars in a combined way for QTL analyses. Two major QTLs were identified on linkage groups (LGs) 2 and 4, with a minor QTL on LG7 for SSC. Quero-García et al. (2019) used an F_1 population

('Regina' × 'Garnet', N = 117) and 3-year data. This work identified SSC QTLs on LGs 1 and 3 by multi-year analysis, explaining from 6 to 10% of the variation. Later, in the multifamily QTL analysis conducted by Calle and Wünsch (2020), including 411 individuals from six populations of related pedigree and 2-year data, a major QTL for SSC, explaining nearly 30% of the phenotypic variation, was mapped on LG4. This QTL region overlapped with maturity and firmness QTLs on the same plant material. Also, a positive correlation among these traits was observed, with the latter maturing genotypes presenting a higher SSC value (Calle and Wünsch 2020). The results suggested the near presence of genes regulating sugar content and maturity, or genes with pleiotropic effects on these traits in this genome region (Calle and Wünsch 2020). In the same work, another minor SSC QTL was mapped on LG3, overlapping with the QTLs in the same region detected previously by Quero-García et al. (2019). For fruit acidity, high variability in QTLs detected between environmental years and populations was reported in these works, with QTLs on LGs 1, 2, 4, and 6 (Zhao et al. 2014; Quero-García et al. 2019; Calle and Wünsch 2020). Of them, only the genomic region at chromosome 6 seems stable across environments and plant materials for TA regulation in sweet cherry.

3.2 Fruit Color

Initial studies of the genetics of health-related compounds in sweet cherry were carried out indirectly by investigating fruit color. Sweet cherry color varies from yellow to mahogany or almost black, depending on the anthocyanin content profile (Gao and Mazza 1995; Jin et al. 2016; Calle et al. 2021). Fruit color was initially investigated as a relevant trait for sweet cherry breeding since different color fruits are preferred in different consumer markets (Crisosto et al. 2003). Furthermore, fruit color segregates in many breeding populations (Schmidt 1998). The cross of two red cultivars may result in blushed to dark cherries, and marker-assisted selection of this trait is desirable for breeders. By analyzing color segregation in sweet cherry progenies, the earliest studies showed that fruit skin color is determined by a major gene, in which alleles for red color are dominant to yellow or blushed (Fogle 1958; Schmidt 1998). The presence of minor genes exhibiting the epistasis effect was also proposed. More recently, research on the genetic control of skin and flesh color in sweet cherry by QTL analyses was carried out by Sooriyapathirana et al. (2010). In this work, fruit and skin color QTLs were mapped using a progeny from a cross of two cultivars with different flesh and skin color, blush-skinned and yellow-flesh 'Emperor Francis' and dark mahogany-skinned and red-fleshed 'New York 54' (Sooriyapathirana et al. 2010). The QTL analysis was conducted in 190 individuals that were phenotyped using a colorimeter, through a pseudo-testcross mapping strategy of a consensus map of 198 markers (102 SSR, 61 AFLP, 28 gene-derived markers, and seven SNP; Olmstead et al. 2008). A major QTL, explaining a large percentage of the phenotypic variation for skin and

flesh color, was identified on LG3. Also, minor QTLs were reported on LGs 6 and 8. This work confirmed that sweet cherry color was determined by a major regulatory gene (Sooriyapathirana et al. 2010). In a later study focused on deciphering the molecular mechanisms regulating fruit color, Jin et al. (2016) also mapped skin color using another sweet cherry F_1 segregating population. In this population ('Wanhongzhu' × 'Lapins'), both parents are dark red, and a 3:1 (dark red and blush fruits) segregation was observed for the 465 hybrids, confirming the regulation model by a major gene with dominance for dark red. In this case, specific-locus amplified fragment (SPAF) markers were used, and fruit color was mapped at a narrowed QTL (70.4–70.5 cM) on LG3. More recently, Calle et al. (2021) mapped skin and flesh color QTLs using 161 individuals of an F_1 population derived from the cross 'Vic' × 'Cristobalina' and genotyped with the RosBREED Cherry 6 + 9 K Illumina Infinium® SNP array (Vanderzande et al. 2020). The QTL analysis, using genetic maps of 910 ('Vic') and 789 ('Cristobalina') single nucleotide polymorphisms (SNPs) (Calle et al. 2021), also revealed a major QTL region for sweet cherry color on the same LG3 region previously reported by Sooriyapathirana et al. (2010) and Jin et al. (2016). This QTL region corresponds to chromosome 3, between 9.3–13.5 Mbp in *Prunus avium* v1.0.a1 (Shirasawa et al. 2017) and 11.1–15.4 Mbp of *Prunus avium* Tieton v1.0 genome (Wang et al. 2020). An additional minor QTL for flesh color was identified on LG4, explaining 15% of phenotypic variation when colorimeter data was used for QTL mapping (Calle et al. 2021).

3.3 Anthocyanins

QTL analyses of anthocyanin content in sweet cherry were also carried out by Calle et al. (2021) in the same work as previously reported for skin and flesh color QTLs. Anthocyanin compounds were extracted and quantified by high-performance liquid chromatography (HPLC) from 15 mature fruits of each progeny hybrid. Four anthocyanins (cyanidin 3-*O*-glucoside, cyanidin 3-*O*-rutinoside, peonidin 3-*O*-glucoside, and peonidin 3-*O*-rutinoside) were identified and quantified. The use of these data for QTL mapping revealed the most significant QTLs for the four anthocyanins on the same genomic region of chromosome 3 (Fig. 2) where fruit color had been mapped by Sooriyapathirana et al. (2010), Jin et al. (2016), and in the same population (Calle et al. 2021). The percentage of phenotypic variation explained by these QTLs ranged from 12 to 23%, and these results confirmed fruit color and anthocyanin biosynthesis have the same genetic determinants. In addition to this main QTL region on LG3, other minor anthocyanin content QTLs were also mapped on LG7 for cyanidin 3-*O*-glucoside, cyanidin 3-*O*-rutinoside, and peonidin 3-*O*-glucosideexplaining up to 10% of phenotypic variation and on LG4 for peonidin 3-*O*-rutinoside (Fig. 2) in the same region where a color QTL was also mapped in the same population (Calle et al. 2021). These results indicate that beyond a major gene in chromosome 3, other genes in chromosomes 4 and 7 also contribute, to a lesser extent, to anthocyanin content regulation in sweet cherry.

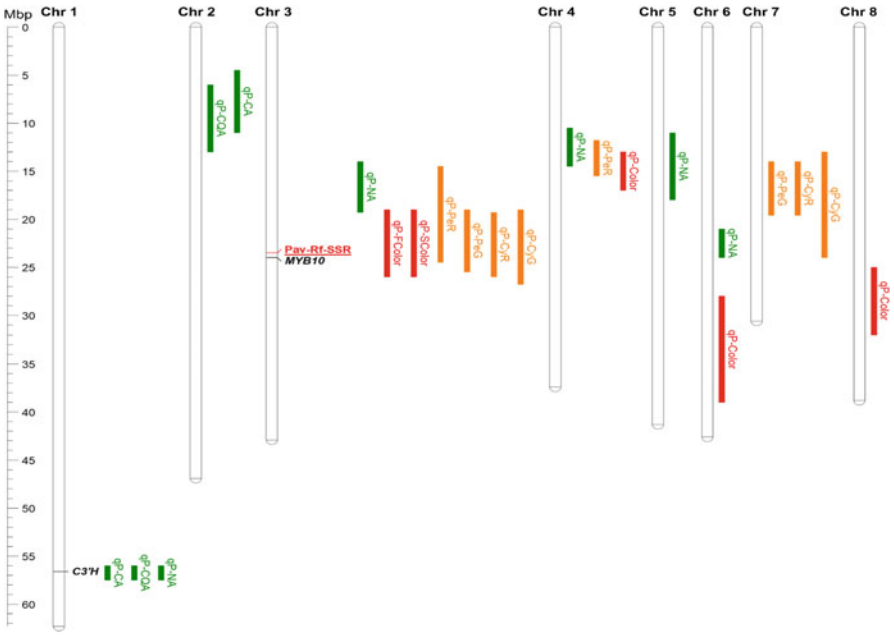

Fig. 2 Physical position in the *Prunus avium* L. genome ('Tieton' v2.0; Wang et al. 2020) of QTLs (Sooriyapathirana et al. 2010; Jin et al. 2016; Calle et al. 2021) associated with health-related (HR) compounds identified in the species. Fruit color QTLs (*qP-Color*) are shown in red, anthocyanin content QTLs (*qP-CyG*, cyanidin 3-O-glucoside; *qP-CyR*, cyanidin 3-O-rutinoside; *qP-PeG*, peonidin 3-O-glucoside; and *qP-PeR*, peonidin 3-O-rutinoside) in orange, and hydroxycinnamic acid QTLs (*qP-NA*, neochlorogenic acid; *qP-CQA*, *ρ*-coumaroylquinic acid; *qP-CA*, *ρ*-coumaric acid) in green. Position of candidate genes associated with HR-compound biosynthesis (*C3'H*, coumarate 3-hydroxylase and *MYB10*) are also included (Sooriyapathirana et al. 2010; Calle et al. 2021). Physical position of Pav-Rf-SSR marker for fruit color prediction is also included (Sanderful et al. 2016)

3.4 Hydroxycinnamic Acids

The genetics of hydroxycinnamic acid content was also investigated in sweet cherry by Calle et al. (2021). Three compounds, neochlorogenic acid, p-coumaroylquinic acid, and p-coumaric acid, were also detected and quantified by HPLC and analyzed for QTL mapping using the same population and maps as for color and anthocyanin content in Calle et al. (2021). In this case, a major QTL was detected at the bottom region of LG1 (Fig. 2) for the three compounds (141.34–141.63 cM; 46.67–47.17 Mbp in the peach genome v2.0.a1). These QTLs were highly significant (logarithm of the odds: LOD $>$ 20) and explained a substantial percentage of the phenotypic variation (60–78%; Calle et al. 2021). Other less significant QTLs were found on LGs 3, 4, 5, and 6. These were associated with minor variations in the concentration of these compounds (4–11% of phenotypic variation). Similarly, two additional minor QTLs for p-coumaroylquinic acid and p-coumaric acid were found on the same region of LG2

(Fig. 2) (2.24–6.09 Mbp; peach genome v2.0.a1) (Calle et al. 2021). The results of this work showed that a major gene also regulates the concentration of these compounds and is likely located at the bottom of chromosome 1.

4 Candidate Genes

4.1 Sugars and Organic Acids

Genetic regulation of sugars and organic acids in cherries remains largely uncharacterized. Only a few studies investigated changes during fruit development related to the biosynthesis of these compounds (Beaver et al. 1995; Gao et al. 2003; Yang et al. 2021a). Initial studies in sour cherry revealed two *sorbitol transporter* genes (*SOT1* and *SOT2*) that were expressed during fruit development playing a major role in sorbitol accumulation in the species (Gao et al. 2003). In a more recent study by Yang et al. (2021a), transcriptomic analysis during the fruit development period of the sweet cherry cultivar 'Black Pearl' revealed genes like *SOT*, *PFK* (phosphofructokinase), *NINV* (neutral invertase), or *SUS* (sucrose synthase) highly upregulated during early stages of fruit development and another set of genes like *PGI* (phosphoglucoisomerase), *UGP* (UDPG-pyrophosphorylase), *PGM* (phosphoglucomutase), and *SPS* (sucrose-phosphate synthase) upregulated during the late stage of fruit development when sucrose accumulation was enhanced. Six additional genes of the *SWEET* family were identified, showing different expression patterns related to sugar transports (Yang et al. 2021a). Regarding organic acids, just a few genes like *PEPC* (phosphoenolpyruvate carboxylase) and one *MDH* (malate dehydrogenase) that were downregulated during fruit development were observed to keep acid content low by decreasing malate acid during cherry development (Yang et al. 2021a). In this same study, other genes responsible for the metabolism of organic acids like *GOGAT* (glutamate synthase) and *GDH* (glutamate dehydrogenase) increased their expression during fruit development, reaching the highest transcription close to harvest time (Yang et al. 2021a).

4.2 Fruit Color and Anthocyanins

Most of the genetic and molecular studies involving health-related compounds in sweet and sour cherries focused on anthocyanin content regulation. Transcription factors (TFs) are known to be critical regulators of anthocyanin biosynthesis in cherries (Lin-Wang et al. 2010; Jin et al. 2016; Chen et al. 2022). The complexes of TFs containing an R2R3 MYB, a WD40, and a basic helix-loop-helix (bHLH) were observed in other species to promote anthocyanin accumulation through binding to genes involved in the flavonoid pathway (Allan et al. 2008). In sweet cherry, various studies indicated that the R2R3-MYB TF *PavMYBA/PavMYB10* interacts with two other TFs (*PavbHLH3* and *PavWD40*) to form an MBW complex (MYB-bHLH-WD40) that regulates the expression of two key genes associated with the

anthocyanin pathway (*PavANS* and *PavUFGT*) (Shen et al. 2014; Starkevič et al. 2015; Jin et al. 2016; Guo et al. 2018). This MYB TF (*MYB10*) is located at the primary color, and anthocyanin QTLs reported in sweet cherry chromosome 3 (Sooriyapathirana et al. 2010; Jin et al. 2016; Calle et al. 2021), supporting its relevance. This transcription factor was first cloned by Lin-Wang et al. (2010) in sweet and sour cherry. Based on additional expression analysis by qPCR, a clear correlation between anthocyanin content and gene expression was confirmed (Lin-Wang et al. 2010). Later works found the same correlation in the dark red cultivar 'Hong Deng' (Shen et al. 2014). These studies confirmed *PavMYB10* as one of the key genes associated with variation in flavonoid content in the species, and it was the basis for developing a DNA test (Pav-Rf-SSR) to predict fruit color in sweet cherry (Fig. 2) (Sanderful et al. 2016). Additionally, various alleles for *PavMYB10* were associated with different ranges of flavonoid accumulation and fruit coloration in sweet cherry (Sooriyapathirana et al. 2010; Jin et al. 2016). Other TFs belonging to 22 different families, specifically bZIP, C2C2-Dof, NAC, bHLH, and R2R3-MYB, were also observed to mediate in anthocyanin regulation in response to light in the 'Rainier' cultivar (Guo et al. 2018).

4.3 Hydroxycinnamic Acids

The study by Calle et al. (2021) suggested a candidate gene for the regulation of the main hydroxycinnamic acid content in sweet cherries. The gene, *ρ-coumarate 3-hydroxylase* (*C3H*), located within LG1 QTL confidence interval identified in the same work, was considered the strongest candidate gene for hydroxycinnamic acid regulation in sweet cherry (Calle et al. 2021). This enzyme was previously observed in other species and is involved in the hydroxycinnamic acid biosynthesis pathway (Chagné et al. 2012; Kim et al. 2019). The LG1 region in which sweet cherry had the most significant QTLs for hydroxycinnamic acids was found to be syntenic to LG15 in apple (Illa et al. 2011), where also a major QTL for hydroxycinnamic acid content had been identified in apple (Chagné et al. 2012), leading to the identification of this candidate gene by Calle et al. (2021) and suggesting a common mechanism for the regulation of these phenolic acids.

5 Gene Expression and Functional Analyses

In sweet and sour cherry, strong correlations between the expression of structural and regulatory genes have been associated with health-related compound biosynthesis pathways (Lin-Wang et al. 2010; Liu et al. 2013; Shen et al. 2014; Starkevič et al. 2015; Wei et al. 2015; Guo et al. 2018). Within health-related compounds, anthocyanin biosynthesis was the widest studied in cherries. These compounds are synthesized through the flavonoid pathway (Winkel-Shirley 2001), in which most of the genes related to the regulation and biosynthesis of anthocyanins are well characterized in model plants (Allan et al. 2008). Initial studies were conducted to find candidate genes associated with anthocyanin biosynthesis in cherries by real-time PCR (RT-PCR)

targeting some candidate genes reported in other species. Lin-Wang et al. (2010) analyzed the expression level of two genes (anthocyanidin synthase [*ANS*] and chalcone synthase [*CHS*]) potentially involved in the anthocyanin biosynthesis pathway through RT-PCR. Two cultivars, 'Stella' (red coloration) and 'Rainier' (bicolor coloration), were used for comparison of expression profiling during fruit development, in which expression of *ANS* and *CHS* genes showed upregulation correlated with anthocyanin content (Lin-Wang et al., 2010). Similarly, the expression level of six anthocyanin biosynthesis genes (*ANS*, *CHS*, chalcone isomerase [*CHI*], flavanone 3-hydroxylase [*F3H*], dihydroflavonol 4-reductase [*DFR*], and UDP glucose: flavonol 3-O-glucosyltransferase [*UFGT*]) was analyzed by RT-PCR in high-anthocyanin-content cultivars ('Hongdeng' and 'Caihong' by Liu et al. (2013); 'Kitayanka', 'Irema BS', 'Werdersche braune', and 'Belobokaya rannyaya' by Starkevič et al. (2015)). In these studies, as previously reported by Lin-Wang et al. (2010), all investigated gene expression manifested a significant correlation with anthocyanin content, in which the expression level of these genes increases through fruit development.

Whole genome transcriptome analyses have complemented these findings. Wei et al. (2015) sequenced and annotated a reference transcriptome of sweet cherry to identify genes associated with anthocyanin biosynthesis. In this study, they sampled total anthocyanin content during four stages of fruit development (from 20 to 55 days after pollination) and sequenced the transcriptome of yellow ('13–33') and dark red ('Tieton') cultivars for comparison. The biological pathway analysis of these transcripts revealed 72 genes related to anthocyanin biosynthesis during fruit development, including key genes like *ANS*, *CHS*, *CHI*, *F3H*, *DFR*, *UFGT*, phenylalanine ammonia-lyase (*PAL*), 4-coumarate-CoA ligase (*4CL*), and flavanone 3′-hydroxylase (*F3'H*) involved in anthocyanin pathway (Wei et al. 2015). As observed in the RT-PCR studies, these genes were highly upregulated in the dark red cultivar ('Tieton') and downregulated in the yellow fruits of '13–33' (Wei et al. 2015). Guo et al. (2018) also performed RNA sequencing (RNAseq) analysis of anthocyanin biosynthesis in sweet cherry to investigate the anthocyanin accumulation mechanism further. The transcriptomes of two contrasting cultivars, 'Hongdeng' (dark) and 'Rainier' (bicolor), were sequenced during fruit development, and as observed in previous studies in cherries (Starkevič et al. 2015; Wei et al. 2015; Shen et al. 2014; Lin-Wang et al. 2010), genes encoding enzymes like *CHS*, *CHI*, *F3H*, and *F3'H* were significantly upregulated in dark fruits. Similarly, results were reported by Yang et al. (2021b) in which weighted gene co-expression network analysis (WGCNA) indicated similar expression patterns of *4CL2* and *ANS* with 11 TF (*bHLH13/74*, *DIV*, *ERF109/115*, *GATA8*, *GT2*, *GTE10*, *MYB308*, *PosF21*, and *WRKY7*). Additionally, another set of genes related to hormone and light signaling, like *protein phosphatase 2Cs*, *PHYTOCHROME INTERACTING FACTOR 3* (*PIF3*), *phytochromes*, and *ELONGATED HYPOCOTYL 5* (*HY5*), were also significantly differentially expressed between dark- and light-colored fruits and therefore associated with anthocyanin biosynthesis (Guo et al. 2018). Together, gene expression analyses have shown significant differences in transcript accumulation between cultivars with high and low anthocyanin accumulation, which are especially significant in expression for *UFGT* and *CHS* (Shen et al. 2014; Starkevič et al. 2015; Wei et al. 2015).

In addition to the genes directly involved in the anthocyanin pathway, various studies suggested that genes related to the signaling pathways of phytohormones like abscisic acid (ABA) and gibberellic acid (GA) play essential roles in the accumulation of health-related compounds (Sun et al. 2010; Jia et al. 2011; Guo et al. 2018; Chen et al. 2022). Shen et al. (2014) reported that silencing a gene (*PavNCED1*) essential for ABA biosynthesis (Zhang et al. 2009) blocked anthocyanin biosynthesis in sweet cherry, suggesting a complex interaction of genes regulating anthocyanin pathway beyond enzymes involved in the flavonoid pathway. In the same way, Guo et al. (2018) identified 32 genes required for plant hormone biosynthesis that were regulated in response to light exposure. In this study, differentially expressed genes related to ABA, GA, auxin, and ethylene pathways were modulated by light, being ABA and GA the only phytohormones that correlated with expression profiles of *HY5* and *PIF3* genes, suggesting that ABA and GA might be the main light-dependent hormones associated with anthocyanin biosynthesis (Guo et al. 2018).

6 Future Prospects and Conclusions

The works reviewed here show that sweet cherries are a health-valuable fruit, which is also highly appreciated by consumers, including children, making them an excellent source of health-related compounds. Therefore, it is important that the healthy quality of sweet cherries is known and communicated so it can be further consumed and produced. At the same time, sweet cherries are highly perishable and seasonal, which complicates their availability throughout the year and to markets far from the cultivation area. Agronomic practices, breeding, and postharvest technology research are allowing to improve these drawbacks, and sweet cherry production, quality, and availability (in time and space) have largely improved in the last years. Extensive efforts are being made in these areas, which have resulted in remarkable improvement, but it is essential not to lose the healthy qualities of sweet cherry in the way. In fact, breeding for a healthier cherry is still lacking, and a more extensive evaluation of HR compounds in sweet cherry collections would be needed. As healthy nutrition is more evident every day and society more aware of it, it is necessary to move forward to obtain a healthier fruit, if possible, or a designed fruit that can help mitigate diet deficiencies or fight specific diseases. The availability of new technologies will help to move forward in this direction. In this sense, agronomic and postharvest practices are useful in improving sweet cherries' health qualities.

energy, potato tubers contain compounds with nutraceutical properties including minerals, vitamins, proteins, and specialized metabolites. Therefore, we outlined this chapter devoting a significant space to both genomic and biotechnology studies addressed, respectively, to identify genomic sequence and genes influencing the amount nutraceutical molecules accumulated and to increment/introduce existing nutraceutical molecules or novel nutrients in the tuber. Before entering in the core of the chapter, we made an extensive introduction to the nutraceutical molecules which have been investigated in potato tubers. Then, we focused on innovative approaches, including gene editing and organelle transformation, with great potential for the nutraceutical bio-fortification of the potato. The *leitmotiv* of the chapter is the biodiversity of potato germplasm (including wild tuber-bearing species), which is a key aspect in potato tuber bio-fortification. The critical review of the literature suggested us to conclude pointing out the current scientific challenges for fully exploiting potato as a "vibrant feedstock for nutraceuticals."

1 Potato: Introduction to an Outstanding Food Crop for Nutraceuticals

The tubers of the cultivated potato (*Solanum tuberosum*) play a significant role in human nutrition and represent an established source of starch for the food industry. The worldwide production of potato stands 359 million tons, and its cultivation occupies 20 million hectares of farmland globally (FAOSTAT. In: FAO [online]. http://www.fao.org/faostat/). The biochemical composition of potato tubers varies according to the variety, agronomic practice, soil and climate, and storage condition. Because of the high concentration of carbohydrate in the form of starch (more than 60% of the dry matter), potato tubers are considered a rich energy providing food. One hundred grams of boiled tuber (that can correspond to a tuber of average size) provides about 110 Kcal, with less of 0.5 g of lipids (Burgos et al. 2020). However, potato is not only starch. A single tuber can also provide 50% of the recommended daily allowance of vitamin C and also balanced proteins of high biological value (i.e., the proportion of absorbed proteins which are incorporated into protein of the human body) (Burgos et al. 2020; Singh et al. 2020). The current research direction is toward valorizing the presence of important vitamins and phytochemicals (belonging to the primary and specialized metabolites) and exploiting potato proteins for several technological purposes (Hussain et al. 2021).

There are numerous valuable papers and book chapters which have analyzed or reviewed the nutraceuticals and biochemical composition of potato tubers (Burgos et al. 2020 and Singh et al. 2020 just to mention the most recent). All these works emphasized potato tubers as "vibrant feedstock for nutraceuticals" (to use the words

of Stewart and Taylor 2017), with a large biochemical variability enclosed in more than 10,000 varieties (Dolničar 2021). Polyphenols, vitamin C, vitamins of B group, and carotenoids have been particularly reviewed in these works which also underlined that many of these molecules are greatly accumulated in tuber peels, a typical by-product of food and starch industries. Another important aspect which is covered by studies dealing with potato nutraceuticals is the effect of cooking methods on these molecules (D'Amelia et al. 2022). Potatoes are not commonly consumed as fresh, and, therefore, the presence of toxic glycoalkaloids is one of the reasons why potato is needed to be cooked before consumption. Fortunately, these latter compounds are not generally stable at high temperature (D'Amelia et al. 2022); however, potato glycoalkaloids, which are especially accumulated in the peels, may even have positive function as anticancer and antiviral drugs (Hellmann et al. 2021).

Many of the minerals and molecules contained in potato tubers are indeed considered nutraceuticals, whose accumulation and bio-fortification can contribute to reach the nutritional and medical or health benefits in different countries, including the prevention and treatment of disease. Potato being the world's third most important crop in terms of human consumption, it is the perfect food crop to be enriched with functional molecules. Although the cultivated potato displays complex genetic features (a tetraploid – $2n = 4x = 48$ – nature, a high level of heterozygosity, a tetrasomic inheritance, and a severe inbreeding depression), there have been several genomic and metabolic engineering research studies aimed at the bio-fortification of its tubers with healthy molecules. Its metabolic and proteomic repertoire has also been exploited for different industrial applications.

The purpose of this chapter is to review these major researches and to identify novel cutting-edge technologies which can open new horizon of research in nutraceutical bio-fortification of potato. This first and second section of this chapter introduce to the metabolic and proteomic repertoire that characterize potato tubers from wild and cultivated species and to the genomic studies carried out to identify the regulation of nutraceutical molecules. The third section is the core of the chapter, where nuclear and organelle cis/transgenic along with next generation biotechnologies are reviewed. We concluded the chapter by providing critical perspectives on the exploitation of these technologies, underlining current challenges for potato tuber bio-fortification. We are not going to consider in detail aspects related to agronomic practices and conventional breeding approaches, which have been extensively described in the chapter of Bradshaw (2019), previously published in the book titled *Improving the Nutritional Value of Potatoes by Conventional Breeding and Genetic Modification*.

2 Nutraceutical, Metabolic, and Proteomic Repertoire in Potato Germplasm

Before the nineteenth century, potato was consumed mostly by Andes population, and then it was introduced to Europe to supply secure food for the large demographic growth. Today, population is expected to increase by two billion in 2050, and in view

of higher food demand, potato is again attracting great attention as food security crop since tubers supply nutrients at lower cost than other vegetables and fruits. The scientific communities are actively involved in maximizing potatoes' nutritional value.

From a nutraceutical point of view, potato skin is rich in dietary fibers, and the flesh provides carbohydrates and several vitamins such as vitamin C (ascorbic acid), vitamin B1 (thiamine), vitamin B3 (niacin), vitamin B6 (pyridoxine), vitamin B9 (folate), riboflavin, and pantothenic acid. Moreover, a relevant presence of minerals in the tubers, such as calcium (Ca), phosphorus (P), magnesium (Mg), sodium (Na), potassium (K), chloride (Cl), sulfur (S), and iron (Fe), concurs to the whole-body homeostasis maintenance. The nutritional composition of potato tubers is summarized in Fig. 1. Tables 1 and 2 report the dietary reference values according to EFSA (European Food Safety Authority) reports (EFSA NDA Panel (EFSA Panel on Dietetic Products 2015)). An adequate macro- and micronutrient uptake is necessary for human health; indeed, insufficient intake of vitamins and minerals can affect disease resistance, cognitive development, and physical growth and can lead to serious metabolic disorders and even death.

"Hidden hunger" refers to the deficiencies of multiple micronutrients in the diet, which is associated not only to poverty but also to bad dietary habits commonly due to the lack of diversification in food consumption and to diet rich in energy but poor in nutrients. By looking at the latter aspect, several programs are currently oriented toward fruit and vegetable bio-fortification, and this is also true for potato tubers (Ierna et al. 2020). Potato bio-fortification programs have been followed by the International Potato Center (CIP) for the past 15 years, by launching breeding

Zinc	Adults (LPI 1200 mg/day)	NA	10.2 mg/day	12.7 mg/day	25 mg/day	

For adults, ARs and PRIs for zinc are provided for four levels of phytate intake (LPI): 300, 600, 900, and 1200 mg/day

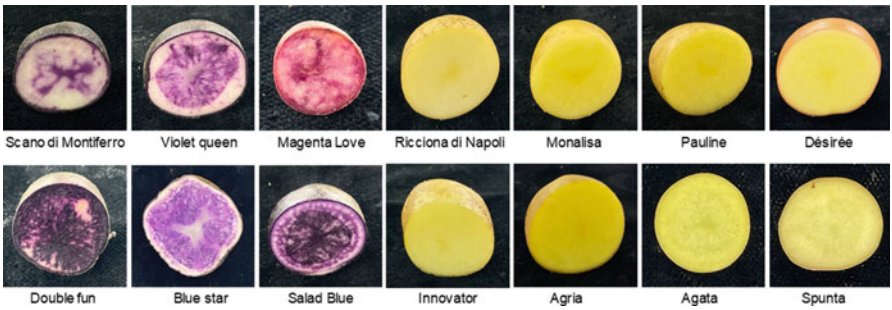

Fig. 2 Examples of commercial potato varieties and Italian landraces showing variable coloration of the flesh due to the different content of anthocyanins (purple/red) and carotenoids (yellow/orange)

programs oriented to increase the concentration of Fe and zinc (Zn), which raised almost of the doubled amount. However, the concentration of all these minerals and phytonutrients, besides being naturally different according to the varieties and agronomical practices, can be influenced by several other factors. For example, the amount of potato vitamins can be especially affected by pre- and postharvesting conditions. It should also be considered that the effective intake of potato nutraceuticals in the diet is largely influenced by their bioavailability. As matter of fact, cooking potatoes, without peeling off the skins, can guarantee a good intake of minerals and dietary fibers, but vitamins are largely reduced after cooking (Singh et al. 2020, 2022).

Carotenoids and polyphenols can be considered nutraceuticals, and these molecules are noteworthy present in potato tubers. Indeed, antioxidants in foods are key players against degenerative processes, cardiovascular diseases, and aging. Besides high-quality proteins, these antioxidants have probably been among the few nutraceuticals which domestication, breeding, and selection of potatoes have been addressed to. Carotenoids and anthocyanins characterize the color of potato tuber flesh. Commercially available, there are white, yellow, red, and purple fleshed potatoes (an example is reported in Fig. 2), whose flesh color intensity mirrors the amount of "dye" antioxidants. Yellow fleshed potatoes are richer in lutein and zeaxanthin carotenoids, whereas red and purple potatoes have a notable content in anthocyanins. These varieties can be ranged among the "functional foods."

2.1 Potato Nutrients: Starch, Sugars, and Lipids

Potato starch content is highly variable according to the genotype, environmental condition of growth, and agronomical practices. In general, fresh potatoes contain about 80% of water; 60–80% of the dry matter consists of starch. Potato starch is composed by amylopectin and amylose, with amylopectin ranging from 70% to 80% of the starch amount. The ratio between amylose (linear glucose polymers) and

amylopectin (highly branched glucose polymers) influences the degree of digestibility of starch, since amylose-rich starches are digested more slowly as opposed to starches with a high amylopectin content. The ratio *amylose/amylopectin* influences the glycemic index, which is a value indicating how much a specific food affects human blood sugar level (glucose). Starch is the major storage for carbohydrates, but potatoes have also free sugars mostly represented by the monosaccharide glucose and fructose and the disaccharide sucrose. Tubers of the tetraploid potato *S. tuberosum* have a total sugar amount up to a maximum of 300 mg 100 g^{-1} fresh weight (FW), while almost three times more (of about a maximum of 700 mg 100 g^{-1} FW) have been reported in tubers of diploid *S. phureja* (Duarte-Delgado et al. 2016). Potato sugar content is strongly dependent on the genotype. However, pre- and postharvest factors may play a crucial role. For example, particularly important are tuber maturity, growing temperature, agricultural conditions such as soil minerals and irrigation, mechanical stresses, and storage conditions. Sugar content in potato tubers is indeed particularly important since the high temperature of baking, frying, and roasting usually employed to cook potato, although are food safety measures, can also determine the formation of toxic molecules such as acrylamide. Acrylamide formation, which is considered a potential carcinogen, is present at elevated concentrations in different types of heat-treated foods, and it is formed during cooking at high temperature as reaction products of Maillard reaction between amino acids and reducing sugars. Therefore, a high basal level of potato sugars, as acrylamide precursors, and the specific processing conditions put potato in the group of food products with the highest level of acrylamide. In order to avoid acrylamide formation (probably carcinogenic to humans), the content of reducing sugar should be maintained below a level of 100 mg 100 g^{-1} FW (Liyanage et al. 2021).

Lipids are present in a relatively low amount, in a range of 0.1–0.5 g 100 g^{-1} FW. Phospholipids (47%), glycol, and galactolipids (22%) are the most represented. Their localization between the peel and the vascular ring of the tuber makes their content even reduced if the potatoes are thickly peeled. The composition in fatty acids of total lipids is mostly constituted of polyunsaturated fatty acids, e.g., linoleic and linolenic acids. Therefore, potato lipid composition is particularly "safe," since it is known that omega-3 fatty acids are beneficial against cardiovascular diseases and might also reduce the risk of type 2 diabetes.

Finally, potatoes contain fibers in the cell wall of the peel. These dietary components represent the portion of indigested carbohydrates which can be fermented in the large intestine. One hundred grams of potatoes cooked with the skin provide 2.1 g fiber, whereas for the same amount without skin the amount of fiber is reduced to 1.8 g. By way of comparison, potatoes contain less fiber than whole-grain cornmeal but more than white rice or whole-wheat cereal (1.6 g 100 g^{-1}).

2.2 Vitamins

Vitamins are molecules with different organic skeleton derived from various precursors. For example, vitamin C is a small soluble carbohydrate whose biosynthesis starts from glucose, and vitamin B complex belongs to pyridinecarboxylic acid

group of compounds. These molecules are not synthesized by humans, and their intake can occur only thought the diet. Deficiency of vitamin C causes scurvy, and the common symptoms of a poor vitamin C diet are fatigue, sore legs, and arms. The recommended dietary allowance (RDA) of vitamin C, as reported in Table 2, is about 90 mg daily for men and 80 mg for women and even more in particular condition such as pregnancy and for smokers. Potato, among vegetables, is a rich and inexpensive source of vitamin C, and its average content ranges from 84 to 145 mg 100 g^{-1} dry weight (Kawar 2016). Vitamin C content can vary according to the genotype, but the factor mostly influencing its content reduction is the oxidation. This can be caused by washing, peeling, slicing, cooking at high temperature, freezing, cooling, and storage (Sonar et al. 2020). Another important group of potato vitamins belongs to the B complex. Members of this group are vitamin B1 (thiamin), vitamin B2 (riboflavin), vitamin B3 (niacin or niacin amide), vitamin B5 (pantothenic acid), vitamin B6 (pyridoxine), vitamin B7 (biotin), vitamin B9 (folic acid), and vitamin B12 (cobalamins). The RDA for thiamin is 1.2 mg/day and 1.1 mg/day for adult man and woman, respectively, and potato varieties contain approximately 10 mg of thiamin in 100 g of tubers. Niacin can be assumed through the diet, but it can be also synthesized from the tryptophan. Its deficiency can cause pellagra, whose symptoms can be diarrhea, skin inflammation, and loss of memory (Fu et al. 2014); this disease is highly diffused among those populations relying on a maize based diet. It is estimated that potatoes can provide about one-tenth of adult's daily requirement of niacin considering that RDA values for niacin are 14 mg/day and 16 mg/day for men and women, respectively. Vitamin B5 and B6 are present in potato with similar amount, less than 1 mg for 100 g of potato, and RDA for vitamin B5 is close to 5 mg/day for both adult men and women and for vitamin B6 is about 2.0 mg/day and 1.6 mg/day for men and women. Both vitamin B5 and B6 vitamins are resistant to cooking and high temperatures. In this group of vitamins, vitamin B9 (folate) deserves particular attention because its deficiency is becoming a global dietary issue. Folic acid deficit promotes cell oxidation processes, and it causes DNA genomic instability. For this reason, increasing dietary intake of folate is particularly important during pregnancy, and folate based food supplements are recommended to reduce the risks of congenital disabilities (Wierzejska and Wojda 2020). Potato can provide about the 1–2% of the daily RDA for folic acid, which is about 0.2 mg.

Finally, K naphthoquinone is the last group of lipophilic antioxidant vitamins present in potato. Vitamin K has some essential beneficial properties deriving from its capability of blood clotting properties. Vitamin K is a group of chemically related compounds known as naphthoquinones and named vitamins K, K1, K2, and K3. One hundred grams of potatoes can contain from 1.5 to 3.0 micrograms of vitamin K, which is almost the 2–4% of the daily recommended value for an adult.

2.3 Specialized Metabolites

In industrialized countries, potato is erroneously associated to bad diet habits, mostly because of the consumption of french fries and chips. However, potato is recognized

by the Food and Agriculture Organization of the United Nations (FAO) as a staple and sustainable food for the growing world population (http://www.fao.org/potato-2008/en/aboutiyp/index.html, accessed on 2022). This is not only for the nutritional properties previously described but because it has a plethora of specialized metabolites whose consumption in the diet beneficially promotes human health. The high content of antioxidant compounds, mainly carotenoids and phenylpropanoids, makes tubers an optimal functional food. Carotenoids in plants are more than 700; they are isoprenoid-based compounds typically represented by a tetraterpene skeleton. The modification of this backbone influences color and antioxidant activities of tubers. Carotenoid content ranges from 2.7 to 7.4 μg g^{-1} FW in commercial white potatoes. The highest amounts of carotenoids are present in yellow- and orange-fleshed potatoes. Zeaxanthin is the carotenoid most responsible for orange color, whereas lutein is responsible for yellow. Andean cultivated landraces have been reported to accumulate a very high content of carotenoids; the concentration of lutein/zeaxanthin may reach up to 18 μg g^{-1} DW and about 2 μg g^{-1} DW of β-carotene (Milczarek and Tatarowska 2018). Similarly, diploid *S. stenotomum* and *S. phureja* may contain up to 20 μg g^{-1} FW of zeaxanthin (Brown et al. 2019). Through metabolic engineering approaches, β-carotene content in Désirée was increased in up to about 50 μg g^{-1} DW (Diretto et al. 2007a). Although this strategy resulted very efficient to produce what is referred as "golden potato," its consumption is limited to few European and American countries due to specific regulatory limitations and also consumer acceptance.

Among antioxidants, hydroxycinnamic acids are the most abundant with chlorogenic acid (CGA) as the most accumulated. In white and yellow potatoes, CGA can constitute 90% of tuber total soluble phenolics, with 5-*O*-caffeoylquinic acid being the most abundant CGA. Two hundred grams of potatoes could provide over 250 mg of CGA, which is much more than the amount found in a cup of coffee (the most known source of CGA) (Lu et al. 2020). Interestingly, red and purple potatoes produce an even higher quantity of CGA than white-fleshed tuber. Tubers also contain flavonoids, including anthocyanins and flavonols. Flavonoids have a C6-C3-C6 backbone; acylation, hydroxylation, methylation, and glycosylation of this skeleton give rise to thousands of compounds. Anthocyanins are synthesized in the general flavonoid pathway, and the first committed step in the anthocyanin pathway is catalyzed by dihydroflavonol reductase (DFR). The conversion from colorless leucoanthocyanidins to anthocyanidins by anthocyanidin synthase is the coloring reaction of the biosynthetic pathway. The six major anthocyanidins in potato are cyanidin, delphinidin, malvidin, pelargonidin, peonidin, and petunidin; the degree of hydroxylation/methoxylation of the B-ring influences the color of the tuber. For example, B-ring hydroxylation increases blue color, whereas methylation can turn the tuber red. Higher hydroxylation on the B-ring positively influences the antioxidant activity.

2.4 Glycoalkaloids

Another class of important and characteristic solanaceous specialized metabolites is glycoalkaloids. These molecules, due to their toxicity, play an important defensive

role in plants against pathogens and predators (Cárdenas et al. 2019). Main glycoalkaloids in cultivated potato are α-solanine and α-chaconine, where the latter is usually present in higher amounts than solanine (D'Amelia et al. 2022). These molecules consist of a lipophilic steroid nucleus, which is extended by two fused nitrogen-containing heterocyclic rings at one end and bound to a polar water-soluble trisaccharide at the other. The level of toxic glycoalkaloids in potatoes varies depending on the variety, growing conditions, storage and transportation, temperature, cutting, sprouting, and general exposure to any biotic or abiotic stress. Glycoalkaloids are present at high concentration in the skin of tubers, and higher concentrations are found around the potato eyes and wounded areas and in the sprouts. On average, a potato tuber can contain about 12–20 mg kg^{-1} of glycoalkaloids, while a green and germinated tuber reaches 250–280 mg kg^{-1}. It is worth to mention that a toxic dose has been estimated at approximately 2–5 mg kg^{-1} body weight, whereas a lethal one is around 3–6 mg kg^{-1} of body weight (Schrenk et al. 2020).

2.5 Potato Proteins and Peptides

Potato protein content ranges from 1% to 1.5% of tuber fresh weight. Despite the low content in tubers, these proteins have high nutritional value because they are rich in essential amino acids such as lysin, threonine, tryptophan, and methionine (Kärenlampi and White 2009). Therefore, they are nutritionally superior to those of many other plants (Kärenlampi and White 2009).

Potato proteins are obtained as by-products of the starch industry and are commonly divided into three groups: (i) patatin, (ii) protease inhibitors, and (iii) high-molecular-weight proteins (Kowalczewski et al. 2019). Patatin, also known as tuberin, is a 40–45 kDa glycoprotein that represents 40% of total soluble proteins (TSP) in potato tubers (Lehesranta et al. 2005). It occurs in multiple isoforms being encoded by two multigene families, and different potato varieties show distinctive patterns of putative patatin isoforms. As an example, Désirée showed nine isoforms, whereas Bintje four (Lehesranta et al. 2005). Protease inhibitors (PIs) also account for 40% of TSP and are the structurally heterogeneous group with broad range of antifungal and antimicrobial activities (Bártová et al. 2019). PIs are classified into seven different families, based on their target, structural properties, and mechanism of action: protease inhibitors I (PI-1) and II (PI-2), potato cysteine protease inhibitors (PCPI), potato aspartate protease inhibitors (PAPI), potato Kunitz-type protease inhibitor (PKPI), potato carboxypeptidase inhibitors (PCI), and other serine potato protease inhibitors (Meenu Krishnan and Murugan 2016). The third group of potato proteins consists of high-molecular-weight proteins mainly involved in starch biosynthesis that have not been fully studied.

Potato proteins are gaining increasing interest in food industry applications for their well-known functional features. These include activities that are strictly linked to food processing such as emulsifying, foaming, gel forming, antifungal, antimicrobial, and antiviral properties. They also show multiple health promoting

properties. Particularly, patatin demonstrated antioxidant and lipase activities (Wu et al. 2021). These have been associated to protection against oxidative stress in chronic degenerative disease, anticancer activity, and anti-obesity effects (Wu et al. 2021). Similarly, protease inhibitors showed anticarcinogenic activity through three main mechanisms: interfering with tumor-cell proliferation, forming hydrogen peroxide, and blocking solar ultraviolet (UV) irradiation (Sitjà-Arnau et al. 2005). Potato protease inhibitors also increased the level of the peptide cholecystokinin that increases satiety via trypsin inhibition, thus reducing food intake in humans (Komarnytsky et al. 2011). Other studies have demonstrated that peptides obtained from potato protease inhibitors positively affect serum lipids (e.g., cholesterol) through their sterol binding properties (Liyanage et al. 2010). Tuber proteins can be hydrolysate (e.g., Alcalase treatment) to produce bioactive peptides with multiple and enhanced pharmacological functions. Potato protein hydrolysate (PPH) revealed several beneficial effects: antihypertensive, through the enhanced inhibition of the angiotensin converting enzyme I (ACE); protective against hepatic and cardiac functions, through lipolytic activity; and anti-inflammatory by the activation of AMPK, a major signaling molecule controlling the pathways of hepatic metabolic homeostasis (Boudaba et al. 2018). High-quality, allergy-free, and clear activity against various disease conditions described supports the promising usage of potato proteins and peptides in novel therapeutic food products.

3 A Glance on Potato Conventional Breeding: Mapping of Gene/QTLs

As previously stated, conventional breeding approaches, addressed at improving the nutritional value of potato tubers, have been largely reported by the recent work of Bradshaw (2019). Here, we have summarized few aspects related to the limit of conventional breeding and the mapping of QTLs for potato, aspects which extend also to the bio-fortification.

Most crops are polyploids and potato is among these ensuring fulfilling food demand. Due to its complex genetics, potato breeding is a heavy task. The introduction of favorable traits in potato by means of conventional breeding techniques is very laborious and time consuming. The polyploidy offers several advantages such as heterosis and gene redundancy but also produces high heterozygosity which translates in broad segregation for many traits during breeding (Bonierbale et al. 2020). Cultivated potatoes *Solanum tuberosum* (ssp. *tuberosum*) is an autotetraploid ($2n = 4x = 48$), and four homologous chromosomes are matched pairs during meiosis process. This genetic conformation results in a tetrasomic inheritance which complicates the studying of locus interactions, allelic combinations, and genetic effects, and these effects become even more complicated for quantitative (polygenic) traits such as the amount of nutritional compounds and proteins. In this context, the pyramiding of desirable alleles in a potato breeding line or population requires screening of a progeny of thousands or even million seedlings for the identification of the desirable traits into a single clonal line, thus discouraging

progress in breeding improvements for tetraploid potatoes. In the last 10 years of the last century, various molecular markers were made available such as random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), inter simple sequence repeats (ISSR), inter-retrotransposon amplified polymorphism (IRAP), and simple sequence repeats (SSR), and lately high-throughput assays, such as single-nucleotide polymorphism (SNP) markers, have become increasingly important in genetic studies for several crops. However, in autotetraploid genetic mapping technique, such as linkage and quantitative trait locus (QTL) analysis, the genomic complexity can limit assessing correctly allelic dosage (difficulty to determine the correct allelic combination and frequency of recombination between loci), thus jeopardizing proper linkage map construction and quantitative trait loci (QTL) mapping (Bradshaw 2019). In this regard, for SNP array in polyploids, two important platforms, Illumina Infinium and Affymetrix Axiom, have been developed. The development of a potato array provided a genome-wide set of single-nucleotide polymorphism (SNP) markers which, along with the development of statistical models and suitable software, have significantly increased the power of SNP data (Hackett et al. 2017). Further, the development of Tetraploid SNP Map, a user-friendly software specifically designed to analyze SNP markers in polyploid germplasm (Hackett et al. 2017), encouraged implementation of QTL analysis with tetraploid mapping populations of potato. At present, the hybridization based SNP array and next generation sequencing (NGS) enabled the use of genotyping by sequencing (GBS) as the most popular high-throughput genotyping platforms.

Table 3 reported a summary of QTL studies related to quality traits in potato carried on biparental population, selected for their allelic variation affecting the trait of interest.

Table 3 Summary of QTL mapping studies related to quality traits of potato

Traits	Markers	QTL
Tuber starch content (TSC)	DArT RFLP	QTL on chr 1
Tuber starch and tuber starch content	AFLP and SSR	QTLs on chr 5, 8, 9, 10, 12
Tuber starch	RFLP, AFLP	QTLs on all chromosomes
Dry matter content (DMC)	AFLP and SSR, SNPs	QTLs on chr 2, 3, 5, and 7, 8, and 11
Specific gravity (SG)	RFLPs, RAPDs, AFLP, and SSR	QTLs on chr 1, 2, 3, 5, 7, and 11
Cold induced sweetening	AFLP and SSR	QTLs on chr 5 and 1 on chr 8
Amylose content	AFLP and SSR	QTLs at chr 2, 3, 5, 7, and 10
Sugars	RFLP, AFLP	QTLs on all chromosomes
Glucose and fry color	SolCAP 8 K SNP array	QTLs on chr 4, 5, 6, 10, and 11
Skin texture	AFLP and SSR	QTL on chr 2, 6, and 12
Tuber flesh color	AFLP, CAPS, SSR	QTLs on chr 5, 8, and 9
Tuber carotenoids	AFLP, SSR, and DarT	QTLs on chr 3 and 9

Modified from Naeem et al. (2021) and reference therein

Although several candidate genes and QTLs were identified, the detected QTLs represent small haplotype blocks since it is restricted only to the diversity of the two parents. To obtain more stable and reliable QTL, it is necessary to enhance mapping resolution.

Currently, efforts have been started to produce diploid potato parental lines for breeding. The use of diploid based inbreed lines may open potato breeding to more sophisticated mapping population such as recombinant inbred lines (RILs), introgression lines (ILs), and multi-parent advanced generation intercross (MAGICs) populations to identify gene-trait association. In this perspective, the work of Zhang and collaborators published on *Cell* is a smart example of how to develop diploid potato inbred lines and vigorous F1 hybrids by using genome design approach. Surely, this approach could be also used in the future to remodel the potato nutraceutical value.

4 An Overview of the Genomic/Transcriptomic Strategies to Help Nutraceutical Bio-Fortification in Potato Tubers

The sequencing of the potato genome, together with the successive re-annotations (http://spuddb.uga.edu), allowed scientists to carry out several transcriptomic (e.g., microarray, RNA sequencing) and genomic studies (e.g., single-nucleotide polymorphism (SNP) genotyping, genome-wide association studies (GWAS), comparative genomics) that have been strategic for examining the genetic diversity of potato germplasm (among recent papers, see Tang et al. 2022; Zhang et al. 2022). The sequencing of a vast number of plant genomes allowed to perform comparative analyses of nucleotide sequences to evidence similarities and diversity between related species and uncover evolutionary relationships. Wild potatoes, for example, have been used in the past to introgress novel traits, and related genes, in the cultivated potatoes. However, these species have been used to a limited extent for improving the nutritional value of cultivated potatoes (Bradshaw 2019). It is only in recent years that breeders have considered the increment of nutraceuticals as target trait in breeding programs (e.g., https://potatoes.colostate.edu/potato-breeding/; https://potato.tamu.edu/program/); in this scenario, genomic resources provide an important contribution in identifying genes involved in the accumulation of nutraceutical molecules. As genome sequencing has revolutionized all research approaches, in this paragraph we are going to concentrate to those studies that exploited the sequence of the potato genome to identify genes (or classes of genes) with a direct/indirect effect on the accumulation in the tubers of compounds recognized as nutraceuticals.

4.1 Mineral Elements

Mineral elements are important supplements in human diet. Variability in the amounts of mineral elements is present in potato germplasm. Differences are present

between modern varieties especially for N, P, K, S, Ca, Mg, Cu, Fe, Mn, and Zn; between Andean landraces as regards Ca, Fe, and Zn; and between tuber-bearing wild species as regards Ca (Bradshaw 2019). Though the amount of mineral elements that accumulates in potato tubers showed good heritability, bio-fortification through breeding is not sufficient to increase the concentration of certain elements, and it is needed to be complemented with fertilization strategies (Kromann et al. 2017). Moreover, with the aim to increase the content of mineral elements, it should be taken into account that a complex network of homeostasis mechanism guarantees an adequate and not toxic level of mineral elements and that an important regulation between source and sink is present. For example, Mengist and colleagues (Mengist et al. 2018) showed that the accumulation of Zn in tubers is regulated by stems and also identify a QTL controlling the correlation between Zn and Cd, the latter being toxic to humans (Mengist et al. 2018). A reverse genomic approach can be an alternative to resolve the complex network governing mineral uptake. For example, by analyzing on nucleotide sequences which encode for transporters with important function on mineral accumulation, it could be possible to identify allelic variants with a higher efficiency in increasing the mineral element concentration in tubers or to be used as candidate gene in biotechnological approaches. Twenty-three putative transporters with specific affinity for K (belonging to the family of High-Affinity Potassium transporter (HKT), Potassium Proton Antiporters (KEAs) and Proton-coupled potassium transporters (KUP/HAK/KTs), 8 genes encoding for high-affinity transporter of phosphorus (PHT1) family (Cao et al. 2020; Azeem et al. 2021), and 12 SULTR involved in sulfur transportation (Vatansever et al. 2016) have been identified in potato. Transporters with wider affinity for minerals have been also characterized. For example, 36 gene members of heavy metal ATPase (HMA) family and 21 of zinc/iron-regulated transporter-like (ZIP) gene family were systematically analyzed (He et al. 2020; Li et al. 2020). Aquaporins are also important proteins involved in the transcellular membrane transport of water and other small solutes like silicon (Si). For these transporters, 41 encoding genes have been found within the potato genome (Venkatesh et al. 2013).

4.2 Vitamins

Vitamin C, B6, and folate (vitamins B9) are the most represented vitamins in the potato tubers. These vitamins showed a very diversified concentration among varieties and wild species. Several have been the breeding efforts addressed to increase the content of vitamin C. Though the first evidence for the genetic basis of vitamin C has been reported more than 30 year ago and studies are still coming along showing the differences of concentration of this vitamin within potato germplasms, the literature regarding the identification of major loci or marker affecting vitamin C accumulation specifically in tubers is quite rare. However, there is a great interest to increase the accumulation of vitamin C in the tubers of potato, and substantial efforts have been made through biotechnological approaches

(described later in this chapter) involving genes of the vitamin C pathway (Goo et al. 2008; Hameed et al. 2018). As regards other vitamins, the literature reviewed indicates interest of plant scientists to use genomic tools to identify loci involved in their accumulation. For example, Bali et al. (2018) identified a total of 497 significant SNPs associated with folate (vitamin B9) in a diploid segregating population developed from *S. boliviense*. Eighteen of these markers were directly associated with folate metabolism. The sequenced potato genome allowed also the identification of genes encoding for proteins forming the multimeric complex necessary for vitamin B6 biosynthesis. These proteins were identified in a potato cDNA library by using an *Arabidopsis thaliana* pyridoxal biosynthesis (PDX) protein as bait in a *yeast two hybrid* screening (Mooney et al. 2013). However, no studies have been carried out so far to understand differences at genomic level that are responsible for the different accumulation of vitamin B6 in tubers.

4.3 Specialized Metabolites

In the last 15 years, a high number of researches have been dedicated to identify genomic regions affecting or associated with the accumulation of carotenoids and phenylpropanoids in potato. Specific markers associated to accumulation of carotenoids tubers of potatoes have been developed by using diploid populations. SNP analyses in both diploid and tetraploid populations marked one dominant allele of beta-carotene hydroxylase 2 (*CHY2*) (Y locus on chr3) having a major effect in changing white into yellow flesh color. *CHY2,* when combined with a recessive *Zeaxanthin epoxidase* (*zep*) allele, produced orange-fleshed tubers that accumulated large amounts of zeaxanthin (Sulli et al. 2017). In another diploid population, genome-wide QTL mapping combined with expression QTL (eQTL) analyses was used to identify another major carotenoid locus on chr9 and a potential gene candidate annotated as *early light inducible* protein (Campbell et al. 2014). Phenylpropanoids represent probably the class of healthy compounds mostly studied in potato tubers. In particular, anthocyanins and chlorogenic acid followed by hydroxycinnamic acids and flavonols have been subjected to different genic, molecular, genomic, or transcriptomic researches (e.g., D'Amelia et al. 2018; Bao et al. 2022). Being anthocyanins visible at naked eyes, earlier genetic investigations were particularly focused on the inheritance of loci influencing the presence or absence of red and purple pigmentation of tuber skin and flesh (De Jong et al. 2004). Anthocyanin regulatory elements (mainly characterized by the complex of R2R3 MYB, bHLH, and WD40 transcription factors) activate the genes encoding for relevant enzymes of the pathway. In potato, genes having these roles have been largely characterized by genetic, transcriptomic, and genomic approaches. The utility of RNA data resides in the fact that they evidenced the structural genes differently expressed between fleshes of pigmented and white tubers or between purple- and red-fleshed tubers. Consequently, lists of genes mainly involved in anthocyanin accumulation or in anthocyanin post-biosynthetic modifications (decorations of molecules to produce the different anthocyanin fractions) have been obtained (Ahn et al. 2022).

Compelling genomic outcomes are those which revealed noncoding RNAs showing a regulatory activity on the expression of both regulatory and structural genes. For example, a microRNA (miR828) was identified to influence the biosynthesis of anthocyanins in tuber flesh by targeting a R2R3 MYB transcription factors (Bonar et al. 2018). Another work, though carried out by using leaf materials, revealed potential long noncoding RNA (lncRNA) regulating the expression of genes encoding for important enzymes of phenylpropanoid pathway (i.e., phenylalanine ammonia lyase, flavanone 3-hydroxylase, and chalcone synthase) (Bao et al. 2022). Chlorogenic acids largely contribute to the antioxidant repertoire of potato tubers. However, genomic results on this compound came out mainly from studies conducted for investigating anthocyanins. A strong metabolic flux connection is present between anthocyanins and chlorogenic acids, and a molecular co-regulation is also hypothesized as side of anthocyanin works (Rommens et al. 2008). In recent work of Yang et al. (2021), a natural variation of the major isoform of chlorogenic acid was screened in diploid populations including 40 wild species and 374 landraces. The authors revealed the presence of 18 SNPs associated with this compound. Considering that consumers prefer white-fleshed varieties of potato rather than colored flesh (Barlagne et al. 2021), the possibility to increase the presence of this important antioxidant also in not purple/red potatoes is attractive.

4.4 Protein Content

Hereditability of total protein content is moderate, and it is a particularly complex regulated trait influenced by inter-locus interactions and environmental factors (Klaassen et al. 2019a, b). Genome sequencing coupled with transcriptomic and proteomic studies allowed to dissect the genetic architecture influencing this trait and to identify loci that can be used in breeding or biotechnology programs. Main outputs of these studies have been the identification of QTL, eQTL, and proteomic QTL (pQTL). Acharjee et al. (2018) used diploid potatoes and a proteomic approach to map pQTLs for over 300 different protein spots on every chromosome. Klaassen et al. (2019a) mapped QTLs on chromosomes 1, 3, and 5 using a biparental tetraploid population genotyped through SNPs. The QTL on chromosome 5 was then confirmed by a study which used a panel of tetraploid varieties in a GWAS (Klaassen et al. 2019b).

5 Metabolic Engineering for Nutraceuticals

Potato is among the most widely consumed vegetable in the world. Because of it is adaptability to different environments and its yielding capacity, potato plays an important role in worldwide food security. Potato tubers are rich in carbohydrates, high-value proteins, vitamins (vitamin c, above all), and also antioxidant molecules (e.g., anthocyanins and chlorogenic acid). However, the concentration of most of these compounds is often not sufficient, especially after cooking treatment, to satisfy the RDA for those populations where a diversity of diet is limited. Metabolic engineering

approaches accelerate the bio-fortification of crop with nutraceuticals compared to conventional breeding process or when natural variation in sexually compatible germplasm is insufficient to achieve satisfactory level (Van Der Straeten et al. 2020).

In this paragraph, examples of genetic engineering approaches to accelerate bio-fortification will be described. With the aim of meeting different readers' expertise, we will introduce various concepts related to the genetic transformation (trans−/intra−/cisgenesis), giving also a general idea of the techniques. We will also discuss non-conventional methods (such as organelle transformation) and gene editing as alternative or emerging techniques.

5.1 Conventional Genetic Transformation

Genetic transformation consists in the targeted manipulation of specific plant characters using genes from a range of sources. Through genetic engineering techniques (named transformation techniques), foreign genetic material can be added within a plant genome. Nowadays, several transformation techniques have been tuned in potato. The most used are the DNA uptake into isolated protoplasts mediated by chemical procedures and the *Agrobacterium*-mediated transformation in leaf explants. The frequency of stable transformants is higher when the *Agrobacterium*-mediated transformation is used. It is, indeed, the most commonly used method for plant genetic engineering. The pathogenic soil bacteria *Agrobacterium tumefaciens* that cause crown gall disease have the ability to introduce a tumor-inducing (Ti) plasmid into the nuclear genome of infected plant cells. Biotechnologists were able to engineer the Ti plasmid introducing the gene of interest within the transfer DNA or tDNA containing a regulatory sequence (including the promoters), the gene of interest, and the selection marker gene.

Various protocols based on *Agrobacterium*-mediated transformation available in potato and transgenic potato varieties have been approved for planting and commercialization. Potato GM varieties, approved for public uses, are listed in The International Service for the Acquisition of Agri-biotech Applications database at the Internet website www.isaaa.org. In most cases, these varieties have been withdrawn from the market because of low sales due to consumer/farmer rejection (Mi et al. 2015). For this reason, during the last decades, alternative methodologies of genetic transformation, such as cisgenesis and intragenesis, have been set up in metabolic engineering. Cis- and intragenesis are based on the exclusive use of genetic material from the same species or genetic material from closely related species capable of sexual hybridization. This is in contrast to transgenesis where one or more genes and DNA sequences can derive either from any organism or from a sexually incompatible donor plant. In detail, intragenesis and cisgenesis is a genetic transformation where genes are transferred from the same plant or a close relative plant species and any transgene, such as a selection marker gene and vector-backbone genes, is absent in the progeny. The main difference between intragenesis and cisgenesis is based on the concept that in the former methodology, the combination of genetic element through in vitro rearrangement is allowed. The topic of the use of metabolic

engineering approaches to increase nutrients in potato tubers has been reported by (Bradshaw 2019); more recently, several metabolic engineering approaches for the enhancement of potato nutritional value have been reported (Upadhyaya and Bagri 2021). In this chapter, a number of representative transgenic and cisgenic approaches have been itemized in Table 4, detailing the origin of the gene of interest and the potato variety used for the transformation. To obtain a successful bio-fortification of potato tubers by genetic transformation, it is fundamental to select the correct promoters. Indeed, this will drive a correct spatial and temporal expression of the selected gene/s. Therefore, in Table 4, we also summarized the promoters chosen by previous researchers in potato genetic transformation experiments.

Numerous studies have been addressed to increase the level of several types of carotenoids in the flesh of potato tubers, and many studies were particularly interested in the β-carotene, the precursor of vitamin A (Table 4). The earliest strategies attempted to modulate the flux of precursors through the introduction of either genes encoding for enzymes of the primary metabolism or belonging to early carotenoid biosynthetic steps. An important increment (sixfold) in β-carotene was obtained by introducing the gene encoding for the bacterial phytoene synthase (*CrtB*) under the control of the tuber-specific B33 promoter (Ducreux et al. 2005). However, the most successful approach was accomplished by the coordinated expression of genes isolated from *Erwinia herbicola.* In particular, under a tuber-specific promoter, genes encoding for the CrtB, the phytoene dehydrogenase (CrtI), and the lycopene β-cyclase (*CrtY*) were introduced (Diretto et al. 2007a). The authors developed the "golden tubers," where the provitamin A β-carotene increased by 3600-fold (about 47 mg g^{-1} of dried weight). More recently, Campbell et al. (2015) combined β-carotene ketolase (CrtW) and β-carotene hydroxylase (CrtZ) from bacteria with the *Orange* (*Or*) gene from cauliflower leading to substantial increment of the concentration of astaxanthin and also total ketocarotenoids. *Or* was identified from the spontaneous cauliflower orange mutant which accumulates high level of β-carotene in chromoplasts (Lu et al. 2007). Orange protein regulates carotenoid accumulation by posttranscriptionally regulating phytoene synthase, promoting the formation of chromoplast, and also preventing process of carotenoid degradation (Osorio 2019). The cauliflower *Or* was also overexpressed alone in potato, and the obtained transgenic tubers showed chromoplast neoformation and more than tenfold as much β-carotene as the level of non-transgenic cold-stored tubers (Lopez et al. 2008). Overall, these latter studies suggest that there is still a large possibility to further increase the total carotenoids or specific molecules in potato by combining the expression of biosynthetic genes and their regulators. Several regulatory genes of carotenoid pathway have been characterized in tomato (e.g., D'Amelia et al. 2019; Tang et al. 2022). Considering the phylogenetic relatedness between the two Solanaceae species, it is likely to have some success in the increment of carotenoid content by transgenically expressing these tomato genes in potato tubers.

Vitamin E and vitamin B6 have been also successfully increased through transgenic approaches (Table 4) (Crowell et al. 2008; Bagri et al. 2018). The strategy used by Qin et al. (2011) and De Lepeleire et al. (2018) to increase the content of vitamin C and folate (vitamin B), respectively, is quite interesting to discuss. The former can

be considered a cisgenic approach because the authors activated the gene encoding for dehydroascorbate reductase directly in potato. Moreover, the authors found that the increment of vitamin C was reached only by overexpressing the cytosolic isoform of the enzyme and not the chloroplastic one, reminding that also the selection of the right protein with the correct motif and signal peptide is fundamental if a specific tissue expression is desired. The work of De Lepeleire et al. (2018) is a smart example of synthetic biology approach in potato. By combining *Arabidopsis* and rice genes encoding for mitochondrial enzymes of folate biosynthetic pathway, under the control of a specific tuber promoter, they managed to get up to 12-fold increase in folate content in mature tubers. A similar result is quite difficult to reach by exploiting the natural variation of potato folate content (De Lepeleire et al. 2018).

The four most significant minerals in terms of nutrient deficiency are Fe, Zn, Si, and Ca. In the last decades, there has been an increasing interest in the development of crops tailored to provide all these limiting nutrients simultaneously. In potato, much attention has been drawn on Ca. In this context, the target genes for Ca increase in tubers are Ca2+ transporters such as calcium exchanger 1 (*CAX1*) and 2 (*CAX2*). Kim et al. (2006) induced an activation of *A. thaliana* CAX2 in *S. tuberosum* var Daejiree obtaining tubers containing 50–65% more Ca than wild-type tubers. Concerning Fe accumulation in potato, nowadays there are no studies on activation or repression of genes for Fe accumulation. Singh et al. (2022) suggested a list of candidate genes for future studies. Very few metabolic engineering researches aimed to biofortify potato tubers with specialized metabolites like anthocyanins and, generally, phenylpropanoids. Indeed, as discussed in previous paragraphs, purple potato varieties already have an important amount of anthocyanins and other phenolics like chlorogenic acids. Moreover, these compounds become quite stable at domestic cooking method (D'Amelia et al. 2022). Most of the studies on purple potatoes were conducted for the characterization of genes encoding for key enzymes of the phenylpropanoid pathway. Among the *plethora* of studies available, Kostyn and collaborators (Kostyn et al. 2013) were the few which tested the nutritional power of DFR-transgenic and non-transgenic *S. tuberosum* cv. Desiree tubers on 20 rats. Their results demonstrated the positive impact of flavonoids on lipid profile. They observed that the level of toxic glycoalkaloids (α-chaconine and α-solanine) increased for about 70% in the DFR-overexpressing tubers. As regards other compounds with nutraceutical value, there are very few studies in potato. For example, lipids (and in particular fatty acids) have been principally studied to increase tolerance to biotic and abiotic stressors. To the best of authors' knowledge, antisense-mediated silencing of lipoxygenase isoforms has been used in *S. tuberosum* to increase tolerance to insects, while no studies for bio-fortification of tubers have been released (Table 4).

5.2 Targeted and Innovative Methods: Organelle Transformation and Genome/Gene Editing

Over the past decades, the expression of transgenes in the plastid genome attracted biotechnologists because it offers several potential advantages compared to the

transformation of the nuclear genome, such as the precise integration of transgenes in the host genome by homologous recombination, the high expression levels and the biological containment of transgenes and recombinant products, the cellular compartmentalization of compounds harmful to the plant, and the possibility of co-expressing several transgenes in prokaryotic like operons. Notwithstanding the potential advantages of this technology, not all attempts have been successful. Many factors (e.g., choice of expression elements, coding region, integration sites, etc.) and parameters (e.g., host plant, growth conditions, tissue, etc.) can affect the achievement of a promising result. In most crops, the efficiency of the tissue culture, selection, and regeneration procedures is considered the most serious bottleneck to plastid transformation (Scotti et al. 2013). Another important limitation in some crops is the generally inefficient gene expression in nongreen plastids, due to deficiencies in the expression machinery of nongreen plastids compared to leaf chloroplasts (Valkov et al. 2009). The first attempts of potato plastid transformation were carried out using vectors developed for tobacco and are characterized by low transformation frequencies and low transgene expression in tubers of transplastomic plants (Thanh et al. 2005). A strong increase in plastid transformation efficiency in potato (one shoot per bombardment), comparable to those obtained with tobacco, was achieved using a combined strategy based on an optimized selection/regeneration procedure and species-specific vectors (Fig. 3) containing potato homologous flanking sequences and regulatory sequences to improve transgene (*gfp*) integration and expression in amyloplasts (Valkov et al. 2021). Although protein accumulation in amyloplasts was low, the GFP protein obtained in tubers using *clpP* regulatory sequences (i.e., promoter and 5′ untranslated region, UTR) confirms its positive effects on transgene translation in

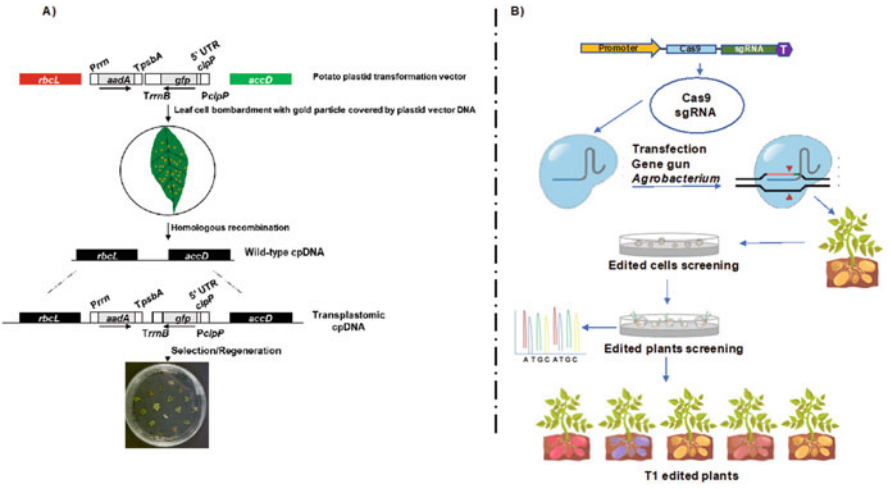

Fig. 3 Schematic representation of unconventional and innovative methods for metabolic engineering. (**a**) Improved chloroplast transformation in potato based on the use of an optimized selection/regeneration procedure and species-specific vector containing potato homologous flanking and regulatory sequences. (**b**) Gene editing strategy based on CRISPR/Cas9 and *Agrobacterium*-mediated transformation

nongreen plastids, with *clpP* being one of the less downregulated genes in tubers compared to leaves (Valkov et al. 2009). To increase protein accumulation (up to 1.3% total soluble protein, TSP) in potato amyloplasts, Yu et al. (2019) developed a different regulatory approach based on a variant of the maize RNA-binding protein PPR10, which activates the expression of the plastid *atpH* gene by binding to a cis-element in the *atpH* 5′ UTR increasing the translation efficiency, and a cognate binding site upstream of *gfp*. Attempts to increase other nutraceutical molecules by means of organelle transformation have been made in particular for specialized metabolites. Indeed, several metabolic pathways occur within the plastids producing, for example, precursors of phenylpropanoid and isoprenoids (through, respectively, the shikimate and methylerythritol 4-phosphate pathways). In tomato, a closely related potato species, Lu et al. (2013) obtained an increase of up to tenfold in vitamin E by including, in the synthetic operon construct, a binding site for an RNA-binding protein from the pentatricopeptide repeat (PPR) family (the intercistronic expression element, IEE). Methods for organelle transformation are not of recent origin, but these can be considered more unconventional than nuclear transgenesis and with a great potential for metabolic engineering of potato. The above reported results suggest that the use of these regulatory sequences may be sufficient to manipulate the expression of enzymatic proteins for metabolic engineering purposes in order to biofortify potato tubers.

More innovative for plant is the genome editing. A group of advanced biotechnological tools are becoming very useful for targeted mutagenesis. These tools can be fully exploited in crop also to improve the production of nutraceuticals through gene knockout or by modifying nucleotide sequences (Hameed et al. 2018). Among these technologies, today, much attention is being paid to the RNA-guided nuclease clustered regularly interspaced short palindromic repeats (CRISPR)-associated (Cas), which is handier technology than to previous methods of editing such as zinc finger nucleases (ZFNs) and transcription activator-like effector nucleases (TALENs). The CRISPR/Cas system has two main components, the single guide RNA (sgRNA) and the endonuclease Cas. The former is complementary to the target DNA sequence that must be immediately followed by an adjacent protospacer motif recognized by the Cas protein. Once the CRISPR/Cas system recognizes the target DNA, Cas generates a double-stranded break that can be repaired by the non-homologous end-joining (NHEJ) or by the homology-directed recombination (HDR). In particular, NHEJ causes random mutations, while HDR can introduce specific mutations with the help of an additionally provided donor DNA carrying the desired mutation (reviewed by Gonzalez-Salinas et al. 2022). There are few examples of applications of CRISPR/Cas-mediated mutagenesis, and in general of the gene editing approach, addressed to positively impact the nutraceutical potential of potato tubers. Recent studies have been mainly focused to improve the efficiency of these technologies in potato. The gene *GBSSI*, encoding for granule bond starch synthase I enzyme, has been particularly targeted to assess the technology. *GBSSI* is a single copy gene and its knockout produces an easily identifiable phenotype (amylose-free starch). From the nutraceutical point of view, the low value of amylose/amylopectin ratio caused by the de-functionalization of *GBSSI* is not a desirable trait since it is associated with a higher glycemic index of the starch. In this regard, results obtained by the CRISPR/Cas9 editing approach of Tuncel

et al. (2019) can be considered of nutraceutical interest since the authors managed to edit the gene *SBE* (Y08786) that, opposite to *GBBSI*, is responsible for amylopectin formation in tubers and consequently produces an increment of the amylose/amylopectin ratio. Zheng et al. (2021) mutated the sterol side chain reductase 2 encoding gene (*SSR2*) obtaining a reduction of more than half of the content of toxic steroidal glycoalkaloids accumulated in the peel and the tubers of wild-type potato.

Several works have fixed important technical features that will allow to perform efficient CRISPR/Cas-mediated mutagenesis in potato. A doubling in editing frequency of regenerated potato plants has been reached by using endogenous potato U6 promoter, driving the expression of RNA guides, rather than the standard *Arabidopsis* one (Andersson et al. 2017). By using the endogenous promoter to drive CRISPR/Cas components, mutation in all four alleles for 35% tetraploid ex plants was also observed (Johansen et al. 2019). Indeed, the chance to get mutation in all four alleles during the first edited generation is fundamental to reduce or even avoid selfing or backcrossing which is more complicated in tetraploid potato. Furthermore, crossings are also needed to eliminate vector cassette containing both nuclease and the sgRNA. A successful alternative approach consists in the delivering of CRISPR/Cas9 as ribonucleoproteins (RNPs) into cells, with the added potential of generating transgene-free targeted genome edits efficiently (Woo et al. 2015). Indeed, RNPs are more specific than vectors delivering CRISPR/Cas and act more rapidly because they do not need intracellular transcription and translation. A clear reduction in off-target mutations has also widely been demonstrated. Among all, González et al. (2020) developed potato varieties with reduced enzymatic browning in tubers by the specific RNP-based editing of a single member of the *StPPO* gene family (polyphenol oxidases). Their selected edited lines displayed mutations only in the *StPPO2* gene (U22921.1), with no alteration in the coding sequences of other members of the *StPPO* gene family. Another peculiar strength of RNP-based editing is the avoidance of transgene integration in the cellular genome, which reduces the regulatory burden in some countries and allows the edited plants to be labeled as "GMO-free." But "all that is gold does not glitter"! The weaknesses of RNP-based editing are the protoplast transformation methods, which are laborious and require expensive enzymes, and the onset somaclonal variations in edited plants due to much longer culture periods. However, in comparison with the protoplast method, the *Agrobacterium* system (used for CRISPR/Cas vector delivering) is less expensive and needs shorter time frame for regenerant production, reducing the occurrence of somaclonal variations. For this reason, the scientific community is moving forward a CRISPR/Cas variant with reduced DNA cleavage off-targets such as the SuperFi-Cas9 (Bravo et al. 2022).

6 Future Challenges for Increasing Nutraceutical Molecules in Potato

Potato is a perfect candidate for nutrient bio-fortification. The literature reviewed showed that there has been great deal of interest in characterizing the variability of the biochemical composition of potato tubers, but genomic and biotechnological

studies dedicated to biofortify potato tubers are still limited compared to other relative species. For example, relatively few genome-wide studies have been dedicated to identify and characterize structural variants of genes associated to the production of specific metabolites, and most of these concern with the anthocyanin biosynthesis. Association between genomic variants and amount of minerals, vitamins, or carotenoids is still rare, limiting the development of specific markers to improve the content of these compounds by classical breeding approaches. Biotechnological reports (i.e., metabolic engineering approaches) are also relatively few. In our opinion, there are three main challenges that should be considered when developing new breeding programs addressed to potato bio-fortification:

- A considerable increment of nutraceuticals is needed for potato, compared to fresh consumed vegetables, to counterbalance the reduction caused by heat treatments. Potato tubers need to be cooked before consumption, and cooking methods may degrade phytochemicals with nutraceutical properties. There are different studies that checked the stability of these phytochemicals in tuber skin and flesh after different domestic cooking methods (D'Amelia et al. 2022). Anthocyanins and chlorogenic acids have been reported to be stable, while other compounds, such as vitamins (vitamin C and folate) and flavonols, showed a consistent reduction in the total amount (Stewart and Taylor 2017). The storage of tubers may also lead to the reduction of instable compounds. Therefore, another challenge in the field of tuber bio-fortification regards the possibility to drive post-biosynthetic modification of main molecules to stabilize them over time. For example, it is known that hydroxylation negatively influences anthocyanin stability; instead, methoxylation/acylation positively affects stability.
- There are several side effects evaluated in the bio-fortification of the tuber flesh. For example, a high tendency of tuber flesh with improved CGA to browning during cutting and cooking because of CGA oxidation has been observed (Ali et al. 2016). It has also been observed that the level of toxic glycoalkaloids (α-chaconine and α-solanine) increased by about 70%, along with anthocyanins, in the DFR-overexpressing tubers (Kostyn et al. 2013). Hence, an accurate selection of the promoter, besides genes and relative alleles, is important to drive a well-balanced expression.
- The tetraploid genetic asset of the cultivated potato *S. tuberosum* is an aspect which discourages breeders and biotechnologists working in the field of food bio-fortification. The tetrasomic inheritance makes genetic studies and breeding programs addressed to introduce new traits quite complicated and time consuming compared to those of a diploid plant. There are also additional noteworthy constraints. In fact, depending on gene-centromere distance, alternative segregation patterns in the gametes are possible. Besides normal chromosome segregation, the possibility exists that portions of two sister chromatids merge in the same gamete. This occurs when recombination happens between a locus and the centromere. Due to this phenomenon (called double reduction), a triplex AAAa individual can produce aa gametes, with a frequency proportional to the distance between the locus and the centromere. In addition, as any clonal crop, the

cultivated potato is highly heterozygous, and homozygous genotypes are difficult to obtain upon selfing due to inbreeding depression. The recent development of self-compatible diploid potatoes makes it possible to obtain homozygous parental lines to use in creating F1 hybrid diploid potatoes (Zhang et al. 2021).

Abstract

Tomato (*Solanum lycopersicum*) is a popular crop due to its versatility and nutritional quality. In addition to its nutritional content, tomato is rich in various phytochemicals that are known to have beneficial effects on human health. These bioactive components include pigments like lycopene and β-carotene, ascorbic acid (vitamin C), phenolic compounds, polyamines, and glycoalkaloids. Tomato metabolites have various bioactivities such as antihypertensive, antioxidant, anticancer, anti-inflammatory, antidiabetic, antiallergenic, antiatherogenic, anti-thrombotic, and antimicrobial effects. Research aimed at improving tomato for many of these specific activities is still in its infancy; however, a foundation of knowledge has been established for health-related (HR) traits in the crop. In this chapter, previous works surveying tomato germplasm for HR traits, conventional breeding, and genetic investigation of these characteristics are described. We also

discuss research aimed at HR gene mapping and isolation as well as efforts to improve these traits via genetic engineering and genome editing.

Keywords

Antioxidants · Ascorbic acid · β-carotene · Glycoalkaloids · Lycopene · Phytochemicals · *Solanum lycopersicum*

1 Introduction

1.1 Agricultural Importance

Tomato (*Solanum lycopersicum*) is in the Solanaceae family which includes potato, eggplant, and pepper. Cultivated tomato evolved from an ancestor with small green tomatoes and its domestication began in Mexico (Peralta and Spooner 2007). Today, the crop is cultivated worldwide because of its versatility, nutritional quality, and economic importance (Kim et al. 2021). Tomato is grown in the field and greenhouse with different cultivars grown for processing and fresh consumption (Campos et al. 2021). Cultivars vary widely for shape, size, and color (Fig. 1). According to Food and Agriculture Organization (FAO) statistics, the annual global production of tomatoes was approximately 187 million tons in 2020 (https://www.fao.org/faostat/en/#data). Tomato is an important part of the diet and is one of the most consumed vegetable crops worldwide. It is used fresh or processed as sauce, soup, juice, or paste (Ali et al. 2020).

Fig. 1 Example of the wide array of phenotypic diversity available in cultivated tomato. Color, size, and shape variation have been associated with some HR traits. (Photo credit: Mehmet Ülger, MULTI Tarim Seed Co.)

For many years, the improvement of agronomic traits, especially yield, was the main focus of tomato breeding. For this reason, breeding programs often concentrated on development of disease-resistant cultivars (Kim et al. 2021). However, yield gains are often associated with decreased fruit quality (Goff and Klee 2006). More recently, quality traits such as color, flavor, and nutritional quality have become popular breeding targets due to consumer demand and the knowledge that fruits and vegetables make significant contributions to human health (Kusano and Fukushima 2013). Although consumer demands are constantly changing, most people want to consume more nutritious products that also contribute to better health and well-being. This increased interest in health-related (HR) traits in tomato has galvanized the scientific community to gain a greater understanding of the underlying genetic factors and metabolic pathways that control HR traits.

Tomato is a model species for scientific research due to its moderate genome size (950 Mb), diploidy, self-fertility, ease of manipulation, growth under different cultivation conditions, and relatively short life cycle (Kim et al. 2014; Campos et al. 2021). Moreover, the tomato genome has been sequenced and re-sequenced and these data are available online (https://solgenomics.net/).

1.2 Nutritional Composition

A balanced diet consists of certain amounts of vitamins, minerals, proteins, and fats, many of which are found in plants (Ali et al. 2020). In addition, plants are rich in bioactive phytochemicals which have been used to treat or prevent several human diseases (Rao 2003; Giampieri and Battino 2020). Tomato is a good source for the human diet because it is rich in both nutritional and bioactive compounds (Table 1). The nutritional content of tomato mainly consists of a critical amount of soluble and insoluble dietary fibers, carotenoids, phenolic acids, vitamins, proteins, minerals, essential and other amino acids, and fatty acids including monounsaturated fatty acids (Delzenne et al. 2020; Merenkova et al. 2020; Ali et al. 2020). In addition to these nutritional compounds, tomato organs including the fruit contain alkaloids which are antinutritional bioactive compounds (Chaudhary et al. 2018). Tomatoes are considered part of a healthy diet because they contain low fat and cholesterol and harbor significant amounts of specific HR compounds such as lycopene, β-carotene, certain phenolic acids, vitamins C and A, folate, and potassium (Tan et al. 2010). The presence of these HR compounds makes tomato a good source of protection against some diseases such as blindness, respiratory disorders, cardiovascular diseases, and some forms of cancers (Chaudhary et al. 2018). These phytochemicals can also help prevent mutations in DNA and have anti-inflammatory, antimicrobial, and other beneficial activities.

The content of tomato fruit is not constant and varies with many factors like variety, growth conditions, developmental and ripening stage, environmental conditions, and post-harvest and storage conditions (Hall et al. 2008; Manganaris et al. 2018; Boz and Sand 2020). For instance, water-soluble antioxidant activity is high when the fruit are green and decreases when the fruit are ripe, while lipid-soluble antioxidant activity, which is mostly related to lycopene content, increases at the red ripe stage (Cano et al. 2003). Lutein is found at high levels at the red stage but not when fruit are unripe

Table 1 Nutritional composition of 100 g raw, red, ripe tomatoes (USDA FoodData Central)

Compound	Amount
Proximates	
Water	94.5 g
Energy	18 kcal, 74 kJ
Protein	0.88 g
Total lipids	0.2 g
Ash	0.5 g
Carbohydrates	3.89 g

Minerals	
Calcium	10 mg
Iron	0.27 mg
Magnesium	11 mg
Phosphorus	24 mg
Potassium	237 mg
Sodium	5 mg
Zinc	0.17 mg
Copper	0.059 mg
Manganese	0.114 mg
Fluoride	2.3 μg
Vitamins	
Ascorbic acid, total	13.7 mg
Thiamin	0.037 mg
Riboflavin	0.019 mg
Niacin	0.594 mg
Pantothenic acid	0.089 mg
Vitamin B6	0.08 mg
Folate, total	15 μg
Choline, total	6.7 mg
Betaine	0.1 mg
Vitamin A, RAE	42 μg
β-carotene	449 μg
α-carotene	101 μg
Lycopene	2570 μg
Lutein + zeaxanthin	123 μg
Vitamin E	0.54 mg
Vitamin K (phylloquinone)	7.9 μg
Lipids	
Fatty acids, total saturated	0.028 g
Fatty acids, total monounsaturated	0.031 g
Fatty acids, total polyunsaturated	0.083 g

(Chaudhary et al. 2018). Phenolic acid content increases during the early stages of ripening but decreases after the pink stage (Nour et al. 2014) and is negatively affected by solar UV radiation (Sharma et al. 2018). Phenolic acid, vitamin, and glycoalkaloid

contents are also affected by the type of cultivar (Chaudhary et al. 2018). Moreover, bioavailability and the levels of tomato constituents, such as lycopene, can be altered by processing such as cooking. However, genetic architecture or genotype is the major factor determining HR trait variation within species (Manganaris et al. 2018). Improvement of the nutritional and HR composition of tomato is complex because these traits are under polygenic control, have quantitative inheritance, and are affected by environmental conditions (Fernie et al. 2006).

1.3 Importance in the Face of Chronic Diseases and Malnutrition

The world's human population is predicted to reach more than nine billion within 30 years (Gerten et al. 2020). Rapid population growth causes hunger and malnutrition. According to a 2019 FAO report on food security, one in every ten people suffers from malnutrition (FAO 2019). In order to cope with malnutrition, it is not enough to increase agricultural production. The nutritional content of crops and dietary diversity must also be improved (Manganaris et al. 2018). These factors also affect disease incidence because it is well known that malnutrition and diseases (e.g., cancer, cardiovascular problems, blindness) are closely related (Baldermann et al. 2016). Poor nutrition can also result in increased body mass index which is a causal factor of diseases like obesity and type 2 diabetes (Trujillo et al. 2006). Therefore, a balanced, diverse, and healthy diet may prevent many diseases.

Examination of the effects of nutrition and diet on human health has gained popularity in recent years (Campestrini et al. 2019). Although it is known that nutrients affect gene expression in humans, most chronic diseases are controlled by more than one gene, and the exact mechanisms are not known (Hall et al. 2008). However, it is clear that maintaining cell and organ homeostasis is related to maintaining human health. Bioactive compounds support human health by helping to maintain this homeostasis. Plants are especially valuable sources of metabolites and contain more than 200,000 compounds with huge structural diversity (Hall et al. 2008). Many of these metabolites are associated with the prevention of various diseases. In the last decade, the nutrient and bioactive compound content of tomato has been extensively studied. It has been discovered that tomato metabolites have various bioactivities such as antihypertensive, antioxidant, anticancer, anti-inflammatory, antidiabetic, anti-allergenic, antiatherogenic, antithrombotic, antimicrobial, vasodilator, and neuro and cardioprotective effects (Ramos-Bueno et al. 2017; Ali et al. 2020). Regular and adequate consumption of tomatoes is reported to prevent certain human diseases and increase lipid peroxidation levels (Ilahy et al. 2016).

1.4 Limitations of Conventional Breeding and Rationale for Alternative Approaches

Conventional plant breeding relies on selecting useful agronomic traits based on phenotype (Phan and Sim 2017). Germplasm is screened for the desired traits, and

selected parental lines are crossed to combine these traits in a new genotype (Ishitani et al. 2004). In this method, selection of parents and progenies is mainly according to their appearance/morphology. The progeny carries genes/traits from each parent, but their effects on phenotype may not be detected until the plant is grown and the crop harvested. The main disadvantages of conventional breeding are its intensive use of labor and time and the ineffectiveness of subjective phenotyping for many traits (Moose and Mumm 2008). Despite these disadvantages, conventional breeding has been very successful in improving yield, some quality parameters, and stress resistance in tomato (Dalal et al. 2006). In addition, compared to other approaches, conventional breeding is more acceptable to consumers because it seems more natural.

On the other hand, genotype-based selection and breeding are more precise, rapid, and cost-effective than conventional breeding (Yang et al. 2016). Next-generation sequencing (NGS) platforms provide high-throughput and cost-effective DNA sequencing which allows identifying the relationship between genotypic and phenotypic variation (Barabaschi et al. 2016). In this context, whole genome sequencing and re-sequencing techniques are being used to breed new crop cultivars that are rich in nutritional compounds (Phan and Sim 2017). Re-sequencing of different varieties helps to identify single nucleotide polymorphisms (SNPs) which enable genome-wide association studies (GWAS). Thus, quantitative trait loci (QTLs) can be identified with virtually no limitation on marker availability and can be used in marker-assisted selection (MAS) studies (Barabaschi et al. 2012, 2016; Phan and Sim 2017). MAS provides some advantages over conventional breeding methods. MAS is relatively cheap and rapid, can be applied at seedling stages, and is independent of environmental influences (Collard and Mackill 2008). Moreover, the availability of genome sequence information provides thousands of markers for genomic selection, allows analysis of genetic diversity, and enables site-specific mutagenesis by genome editing (Barabaschi et al. 2016; Phan and Sim 2017). The integration of NGS technologies and other multidisciplinary platforms should accelerate crop improvement and allow the manipulation of more complex traits.

2 Description of Nutritional Compounds

2.1 Chemical Composition, Structures, and Biochemical Pathways

Tomato is rich in nutritional and bioactive compounds. In addition to its proximate composition, the main nutritional and medicinal components found in tomato are carotenoids, phenolic acids, vitamins, polyamines, GABA, and glycoalkaloids. The composition and concentrations of those compounds in tomatoes vary depending on many factors such as the tomato variety/cultivar, part of the fruit (peel, flesh, seed), extraction process, analytical approaches, and environmental conditions (Ali et al. 2020; Lu et al. 2019) as described in Sect. 5.

2.1.1 Proximate Composition, Dietary Fiber, Minerals, and Amino Acids

The proximate constituents of tomato are protein, fat, moisture, ash, and carbohydrates. Proximates and dietary fiber are especially important for determining quality parameters and regulatory processes in the food industry (Thangaraj 2016). Proteins are important biological macromolecules with different cellular functions, and their analysis is important for nutritional labeling in foods (Ali et al. 2020). Protein is mostly found in tomato seeds with only 0.88 g/100 g serving in ripe fruit (Table 1, USDA FoodData Central 2019). Tomato also has very little total lipids and ash. Moisture content of ripe fruit is 94.5% with 3.89 g of carbohydrates/100 g serving.

Fiber consists of carbohydrates (oligosaccharides, polysaccharides, and lignins) that are digested in the large intestine. Tomato is reported to have lower crude fiber content than other popular vegetables (e.g., sweet pepper, cabbage, lettuce, spinach, and potato), with approximately 0.3 g fiber/100 g dry weight (DW) or 1.2 g/100 g fresh weight (FW) (Hanif et al. 2006; USDA FoodData Central 2019). Dietary fiber is mainly found in tomato peel (Elbadrawy and Sello 2016). According to recent reviews, the dietary fiber content of tomato peel varies between 1.32 g and 88.53 g/100 g DW (Lu et al. 2019; Ali et al. 2020).

According to USDA data, ripe tomato fruits contain ten different minerals (USDA FoodData Central, Table 1). Tomatoes are considered to be good sources of potassium, phosphorus, and calcium. They also contain 18 different amino acids including those that humans must obtain through diet. The only amino acids not present in tomato are asparagine and glutamine.

2.1.2 Carotenoids

Carotenoids are polyphenolic pigments found in the plastid membranes of leaves, flowers, and fruits. They are produced by the isoprenoid biosynthetic pathway (Martí et al. 2016). Several carotenoids are found in tomato including lycopene, β-carotene, α-carotene, γ-carotene, δ-carotene, phytoene, and lutein (Chaudhary et al. 2018). Carotenoid structures vary in terms of the presence of oxygen atoms and end group cyclization (Rao and Rao 2007). Lycopene is the immediate precursor of β-carotene with lycopene β-cyclase catalyzing this conversion. Thus, red-fruited cultivars have lower activity of this enzyme than orange-fruited ones.

Carotenoids are one of the most important compounds found in tomatoes due to their contribution to tomato's antioxidant capacity. Among carotenoids, lycopene is the most abundant carotenoid with β-carotene, also known as provitamin A, ranking second (Ilahy et al. 2017). Red tomatoes have predominantly lycopene (Kabelka et al. 2004), while orange tomatoes have mainly β-carotene (Manoharan et al. 2017). Thus, the red-fruited *S. pimpinellifolium* contains lycopene at high levels (Sharma et al. 2008), and the orange-colored wild relative, *S. cheesmaniae*, contains β-carotene at high levels (Stommel 2005). Tomato provides almost 85% of the lycopene consumed in the human diet (Rao and Rao 2007). Lycopene content increases with ripening and is found at the highest levels when ripe (Boz and Sand 2020). This increase is primarily the result of increased phytoene synthase-1 enzyme activity which catalyzes the first step of lycopene synthesis (Fraser et al. 1999).

Other carotenoids occur at low concentrations and include lutein and zeaxanthin (Raiola et al. 2014). Although the USDA database indicates that 100 g ripe tomato contains 2.57 and 0.45 mg of lycopene and β-carotene, respectively, a recent review reported that lycopene content varied from 7.8 to 18.1 mg and β-carotene content varied from 0.1 to 1.2 mg (Table 1, Martí et al. 2016). In another review, Ali et al. (2020) reported values of lycopene content from 5.0 to 11.1 mg/100 g and β-carotene content from 3.7 to 10.2 mg/100 g.

2.1.3 Phenolic Compounds

Phenolic compounds are secondary metabolites that are common in plants and are produced via the shikimate, pentose phosphate, and phenylpropanoid pathways (Lattanzio 2013; Lin et al. 2016). All phenolic compounds have at least one benzene with attached hydroxyl groups in their structure. Phenolic acids have one aromatic ring and include caffeic, ferulic, and chlorogenic acids. Polyphenols have more than one ring and include carotenoids, flavonoids, anthocyanins, and lignins.

Both phenolic acids and polyphenols make major contributions to the antioxidant capacity of tomatoes (Stratil et al. 2006). Most studies in the literature have focused on total phenolic content instead of specific phenolic acids or flavonoids. Common phenolic acids in tomato are caffeic acid, chlorogenic acid, ferulic acid, and p-coumaric acid (Ramos-Bueno et al. 2017; Sharma et al. 2018). Tomato also contains a good level of flavonoids. The most abundant flavonoids in tomato are rutin, quercetin, kaempferol, and naringenin (Ramos-Bueno et al. 2017; Sharma et al. 2018).

It is challenging to summarize the phenolic content of tomato because it varies with cultivar and environmental and physiological conditions. For instance, Martí et al. (2016) reported that 100 g of fresh tomato contains 0.9–18.2 mg naringenin chalcone, 0.5–4.5 mg rutin, 0.7–4.4 mg quercetin, 1.4–3.3 mg chlorogenic acid, 0.1–1.3 mg caffeic acid, and 0–1.3 mg naringenin. Total phenolic content was reported in the range of 21.34–31.23 mg chlorogenic acid equivalent/g extract, and total flavonoid content was reported in the range of 3.06–6.36 mg quercetin equivalent/g extract (Ali et al. 2020). Phenolic compound content is highly, positively correlated with antioxidant capacity (Stratil et al. 2006). The antioxidant capacity of tomato is difficult to compare because it changes based on the measurement method (ferric-ion reducing power, DPPH radical scavenging activity, ABTS radical cation scavenging activity) and extraction solvents and methods. Moreover, carotenoids and vitamin C and E also contribute to the antioxidant capacity of tomato (Ali et al. 2020).

2.1.4 Vitamins

The most abundant vitamins in tomato are ascorbic acid (vitamin C), provitamin A (described in Sect. 2.1.2), and vitamin E. Ascorbic acid is mainly synthesized by the L-galactose pathway in plants (Mellidou et al. 2021). It is a water-soluble antioxidant compound that neutralizes free radicals. The oxidized forms of ascorbic acids are recycled via the ascorbate-glutathione cycle. The name vitamin E encompasses four (α, β, δ, γ) tocopherols and the corresponding four tocotrienols (Raiola et al. 2015). These compounds are lipid-soluble antioxidants and only synthesized by plants. The precursors of tocopherols and tocotrienols are phytyl pyrophosphate and

geranylgeranyl pyrophosphate, respectively, which are produced in the isoprenoid pathway in plastids (Raiola et al. 2015; Mène-Saffrané 2017).

Ascorbic acid is the most significant vitamin in tomato with 13.7 mg found in 100 g fresh fruit (Table 1). During domestication, ascorbic acid levels decreased; thus, wild relatives of tomato contain higher levels of this vitamin than cultivated tomato (Mellidou et al. 2021). Ascorbic acid content is affected by various factors. Its levels increase during maturation and decrease during ripening (Chaudhary et al. 2018). Moreover, ascorbic acid levels are greatly affected by genotype. Ali et al. (2020) reported ascorbic acid levels ranging from 10.86 to 85.00 mg/100 g.

Another vitamin that contributes to the antioxidant capacity of tomato is vitamin E. The most abundant structural form of vitamin E is α-tocopherol (Raiola et al. 2015). The USDA reports the vitamin E content of tomato as 0.54 mg in a 100 g fruit. In a review, Ali et al. (2020) reported α-tocopherol levels varying from 0.59 to 0.88 mg/100 g. Folate is another nutritional compound found in tomato. Humans cannot synthesize this phytochemical, so it must be consumed in the daily diet (Vats et al. 2022). Folate content varies in the range of 4–60 μg/100 g FW (Upadhyaya et al. 2017), while in another study it was found in the range of 4.1–35.3 μg/100 g (Iniesta et al. 2009). The USDA reports folate levels of red ripe tomato as 15 μg/100 g (Table 1).

2.1.5 Polyamines

Polyamines are small aliphatic amines that occur in free, conjugated, and covalently bound forms in plants (Fortes and Agudelo-Romero 2018). The main plant polyamines are putrescine, spermidine, and spermine. Polyamine synthesis occurs in the cytoplasm. Putrescine is synthesized from the amino acid arginine and can then be converted to spermidine which can then be converted to spermine. Polyamine biosynthesis has been linked to a larger network involving abscisic acid, nitric oxide, and tricarboxylic acid cycle as well as GABA. Polyamines are important metabolites for plants due to their roles in fruit ripening and stress conditions and for humans due to their beneficial effects on health. Putrescine, spermidine, and spermine are abundant polyamines in tomato (Fortes and Agudelo-Romero 2018). Spermidine and spermine are reported to have roles in water stress tolerance (Montesinos-Pereira et al. 2014). During tomato fruit maturation, putrescine levels increase while spermidine and spermine levels decrease (Tsaniklidis et al. 2016; Gutierrez et al. 2021). Moreover, polyamine content differs based on the cultivar (Montesinos-Pereira et al. 2014).

2.1.6 Gamma-Aminobutyric Acid (GABA)

GABA is a non-proteinogenic amino acid and has been attracting attention in recent years for its health benefits. GABA is produced by the GABA shunt (Takayama and Ezura 2015). The precursor of GABA is glutamate and biosynthesis occurs in the cytoplasm. Tomato accumulates GABA at high levels. During fruit development GABA levels increase at the mature green stage but decrease during red ripe stage (Takayama and Ezura 2015). Depending on factors such as genotype, environmental conditions, and post-harvest treatment, Gramazio et al. (2020) reviewed GABA concentrations in tomato as 0.35–2.01 mg/g.

2.1.7 Glycoalkaloids

Unlike polyamines and GABA which occur throughout the plant kingdom, glycoalkaloids are nitrogen-containing compounds found in only a few species and are used in defense (Zhao et al. 2021). Solanaceous species like tomato contain steroidal glycoalkaloids (SGAs). SGAs have nitrogenous aglycone and glycoside residues and are derived from acetyl CoA via cholesterol. The two main tomato SGAs are α-tomatine and dehydrotomatine. Although they are toxic, glycoalkaloids can be used in medicine for disease treatment (Chaudhary et al. 2018). One of the important factors that affect the glycoalkaloid accumulation in tomato is fruit maturation. α-tomatine is found at high levels at green stage and decreases at the red ripe stage due to increasing enzymatic activity that metabolize the glycoalkaloids (Friedman 2002). In a review, Friedman (2002) reported that α-tomatine levels varied between 10 and 548 mg/kg at the unripe green stage and between 0.3 and 11 mg/kg at the red ripe stage in different tomato varieties.

2.2 Medicinal and Physiological Properties in Relation to Human Health

Tomato has a large part in the human diet. It is very popular due to its culinary versatility and because it is well known to contain bioactive compounds. The most abundant bioactive compounds found in tomato are carotenoids, phenolic compounds, vitamins (especially ascorbic acid), polyamines, GABA, and glycoalkaloids (Chaudhary et al. 2018). These diverse bioactive compounds play different roles in the maintenance of human health. For instance, dietary fiber has positive effects on cancer, diabetes, obesity, hyperlipidemia, and coronary heart disease (Hasegawa et al. 2017; Ali et al. 2020). Protein is essential in our daily diet because insufficient protein intake is related to risks of frailty, sarcopenia, and immunodepression (Wu 2016).

Tomato is a source of powerful antioxidants due to its rich and varied content of carotenoids, phenolic acids, ascorbic acid, and vitamin E. In addition to their antioxidant properties, these molecules have diverse bioactivity. A diet rich in carotenoids prevents certain types of cancers (Botella-Pavía and Rodriguez-Concepción 2006). Among carotenoids, lycopene has anticancer, anti-inflammatory, and immunostimulatory properties and positive effects on colitis and cardiovascular diseases (Fawzi et al. 2000; Gouranton et al. 2011; Holzapfel et al. 2013; Cheng et al. 2019). β-carotene helps in the prevention of atherosclerosis, photooxidative processes, and congestive heart disease (Stahl and Sies 2003; Karppi et al. 2013; Miller et al. 2020). It is also the precursor of vitamin A, thus preventing vitamin A deficiency (Fernández-García et al. 2012). The other minor carotenoids, lutein and zeaxanthin, protect humans against cataracts and age-related macular degeneration (Gale et al. 2003). Phenolic compounds are another category of powerful antioxidant molecules. Phenolic acids have antioxidative, antimicrobial, antiallergic, antimutagenic, anti-inflammatory, and anticancer properties (Martínez-Valverde et al. 2002; Ramos-Bueno et al. 2017). Flavonoids are a predominant type of phenolic compound in tomato and have anti-inflammatory effects and reduce cardiovascular

diseases and cancer (So et al. 1996; Tomlinson et al. 2017). Among the vitamins, ascorbic acid and vitamin E play roles in the prevention of certain cancers (Ramos-Bueno et al. 2017). Moreover, ascorbic acid has antiatherogen effects and plays role in the regulation of inflammation and insulin metabolism (Tousoulis et al. 2003). Vitamin E is important in preventing type II diabetes, cardiovascular diseases, and age-related muscular degeneration and has anti-inflammatory affects (Montonen et al. 2004; SanGiovanni et al. 2007; Cordero et al. 2010). In addition to vitamins C and E, folate also exhibits HR properties. It helps regulate the metabolism of homocysteine and reduce anemia (Solini et al. 2006; Castellanos-Sinco et al. 2015).

Polyamines, especially spermidine, also have positive effects on human health (Dala-Paula et al. 2021). Spermidine helps control blood pressure and the incidence of heart disease, has anti-aging properties, and is important for the synthesis and stabilization of nucleic acids and proteins (Eisenberg et al. 2016; Madeo et al. 2018; Muñoz-Esparza et al. 2019). GABA is another important molecule that helps to reduce blood pressure, induce relaxation, and enhance immunity (Takayama and Ezura 2015). Glycoalkaloids are important in protection against human pathogens (Chaudhary et al. 2018). Glycoalkaloids also have anticancer properties and antimicrobial activities (Iijima et al. 2013). Phytosterols play roles in the prevention of some cancer types such as colon cancer and heart disease (Ramos-Bueno et al. 2017; Uddin et al. 2018).

2.3 Methods of Nutraceutical Improvement: Agronomic and Postharvest Techniques

Plant breeding helps to improve the quality, yield, flavor and aroma, and nutritional and medicinal contents of crop plants. In addition to genotype, the levels of HR components are greatly affected by agronomic practices and environmental factors. Agronomic techniques include the regulation of UV radiation, cultivation temperature, adequate irrigation, salt stress, and cultivation methods. UV radiation (UV-B, 280–315 nm) causes DNA damage, and plants can increase the synthesis of antioxidant molecules to cope with this damage (Huché-Thélier et al. 2016). During fruit ripening, very high (>30 °C) temperatures and altered light profiles cause increased levels of both lycopene and phenolics (rutin and caffeic glucoside) (Gautier et al. 2008; Dzakovich et al. 2016). It is also reported that low (<12 °C) temperatures cause increased lycopene content (Luthria et al. 2006; Dzakovich et al. 2016). Water stress causes decreased levels of lycopene and β-carotene but increased levels of chlorogenic acid (Atkinson et al. 2011) and polyamines (Hano et al. 2017). In addition, organic pharming practices may influence the production of polyamines (Rapa et al. 2021). Salt stress may cause increased levels of phenolic acids and carotenoids due to osmoregulation (Sumalan et al. 2020).

Postharvest treatments and storage also affect the nutritional composition of tomato. After harvest, tomatoes should be stored at appropriate temperatures (4–12 °C) to maintain their nutritional quality (Chomchalow et al. 2002). Very low storage temperatures cause low levels of lycopene but high levels of putrescine

content (Tsaniklidis et al. 2021). The type of material used to coat tomatoes can also change the levels of bioactive compounds. Chitosan coating may change the anthocyanin and flavonoid content (Ortega-Ortiz et al. 2007), whereas gum arabic maintains phenolic compound and carotenoid levels (Ali et al. 2013). In addition, natural preservatives can be applied instead of chemical preservatives. Melatonin is a natural preservative and its application may induce phenolic compound synthesis (Dewanto et al. 2002).

2.4 Requirement for Biotechnological Intervention

Plants produce approximately 25,000 metabolites that significantly contribute to the human diet (Go et al. 2005). Thus, improving the nutritional quality of crops is a valuable but difficult goal of breeding strategies. Although HR traits are related to the improvement of the plant's biochemical composition, research on nutritional quality is limited (Kusano and Fukushima 2013). Moreover, genetic diversity is essential for trait improvement (Chaudhuri et al. 2022). If this diversity is not present in the crop or its relatives, the gains provided by breeding can be limited. Thus, while a mutation present in a plant's gene pool can be used to increase the content of a HR trait, the introgression of random mutations used in conventional breeding can be nonspecific and less effective than other approaches (Hartwell et al. 2018; Mao et al. 2019). Advances in genomics, transcriptomics, proteomics, and metabolomics allow the identification of biochemical pathways and expose the genetic bases of these pathways. This knowledge allows prediction of breeding value and development of selection and deployment criteria (Natalini et al. 2021). Moreover, the integration of omics technologies allows us to predict unknown gene functions (Kusano and Fukushima 2013) and understand and manipulate plant metabolism (McGloughlin 2010). Because metabolic pathways and their regulation are very complex, qualitative and quantitative profiling of metabolites using metabolomic approaches is very important. In addition, by comparison with wild relatives, this approach can reveal alleles that have been lost or silenced during domestication (Hall et al. 2008). These traits can be recovered by cross-hybridization with wild relatives or by biotechnological techniques like metabolic engineering, genome editing, and transgenesis.

Metabolic engineering and genetic manipulation methods like gene editing and transformation can be used to target specific HR traits. Metabolic engineering involves increasing the synthesis of a target compound, producing new compounds, and degrading unfavorable compounds by interfering with a key enzyme in a biochemical pathway (McGloughlin 2010). Genetically modified crops (GMOs) can also be used to overcome the disadvantages of conventional breeding. However, there are still reservations about the use of GMOs due to putative negative effects on human health and the environment (Chaudhuri et al. 2022). The major concern with GMOs is that the transgene with its viral promoter or terminator sequences remains integrated in the plant's genome often times accompanied by an antibiotic or herbicide resistance gene (Li et al. 2019). To eliminate these concerns, next-generation genome editing methods like the clustered regularly interspaced short

palindromic repeats/Cas9 (CRISPR/Cas9) system can be used. Because this genome editing tool causes mutations by inserting or deleting a small number of nucleotides within the target gene itself, these alterations are considered to be more like natural variations (Huang et al. 2016).

3 Genetic Resources of Tomato

3.1 Section *Lycopersicon*

Cultivated tomato belongs to the *Lycopersicon* section of genus *Solanum*. According to Peralta et al. (2008), wild tomato consists of 12 species in section *Lycopersicon*. These wild tomatoes include both red- and orange-fruited species: *Solanum pimpinellifolium*, *Solanum cheesmaniae* and *Solanum galapagense*. The remaining species have green or purplish-green fruits: *Solanum pennellii*, *Solanum chmielewskii*, *Solanum* chilense, *Solanum peruvianum*, *Solanum habrochaites*, *Solanum neorickii*, *Solanum arcanum*, *Solanum corneliomulleri*, and *Solanum huaylasense* (Peralta et al. 2008; Grandillo et al. 2011; Caicedo and Peralta 2013). It is possible that additional species may be added in the future as both *S. arcanum* and *S. huaylasense* were only recognized as distinct species in 2005 (Peralta et al. 2005). While all of the aforementioned species are considered crossable with *S. lycopersicum*, not all combinations result in viable seeds and fertile hybrids (Rick 1980; Díez and Nuez 2008). For instance, crosses between the red- and orange-fruited species are highly compatible; however, embryo rescue is usually required to obtain progeny from interspecific hybridization between cultivated tomato and *S. peruvianum* or *S. chilense* (Rick 1980). In addition to embryo rescue, success in interspecific hybridization has been associated with various factors including the use of *S. lycopersicum* as the female parent (Rick 1980), selection of more compatible accessions within a species (Rick 1983), and the use of pollen mixtures and bridge lines (Picó et al. 2000).

3.2 Section *Lycopersicoides*

Beyond species in section *Lycopersicon*, cultivated tomato is also crossable with *Solanum lycopersicoides* and *Solanum sitiens* in section *Lycopersicoides* (Caicedo and Peralta 2013). Both of these species have morphologies that are intermediate between tomato and potato (Knapp and Peralta 2016). Initially, hybrids of *S. lycopersicum* and *S. lycopersicoides* obtained via embryo rescue were male sterile and unilaterally incompatible if used as the female parent in backcrossing with cultivated tomato (Rick 1951). However, later work resulted in male fertile hybrids allowing introgression of *S. lycopersicoides* traits into cultivated tomato (Chetelat et al. 1997). Hybrids between cultivated tomato and *S. sitiens* were obtained using *S. lycopersicum* × *S. lycopersicoides* bridge lines (De Verna et al. 1990). Other tomato-like Solanums include *Solanum juglandifolium* and *Solanum ochranthum* in

section *Juglandifolia* which are woody and vining plants (Knapp and Peralta 2016). These species are not crossable with *S. lycopersicum* (Grandillo et al. 2011).

3.3 Germplasm Collections

Tomato germplasm has been assiduously collected, characterized, and preserved in multiple collections throughout the world. According to Genesys (https://www.genesys-pgr.org/) which consolidates data on germplasm collections, over 36,000 tomato accessions are available worldwide. The C.M. Rick Tomato Genetics Resource Center at the University of California, Davis, has approximately 4500 accessions including more than 900 wild species entries encompassing sections *Lycopersicon*, *Lycopersicoides*, and *Juglandifolia* (Chetelat 2022, https://tgrc.ucdavis.edu/). The Asian Vegetable Research and Development Center in Taiwan curates over 8500 accessions (https://genebank.worldveg.org/). The Northeast Regional Plant Introduction Station Plant Genetic Resources Unit in Geneva NY has 6600 tomato accessions representing 15 species (https://www.ars.usda.gov/northeast-area/geneva-ny/plant-genetic-resources-unit-pgru/docs/tomato-collection/). Other sizable tomato germplasm collections are found in Spain, France, Russia, the Netherlands, Australia, and Bulgaria (Díez and Nuez 2008). These collections have been and continue to be valuable resources for tomato improvement.

4 Traditional Breeding and Classical Genetics of HR Genes

Like many fruits and vegetables, the breeding of tomato has undergone different stages as defined by breeding methods and goals. The modern era of tomato breeding began during the late nineteenth century at which time landraces were available in a variety of colors indicating variable carotenoid content (Bai and Lindhout 2007; Scott et al. 2013). Since the 1940s, breeders have used wild tomatoes as a source of insect, disease, and abiotic stress resistance as well as to improve fruit quality by increasing soluble solids content (Rick 1973; Rick and Chetelat 1995). The first tomato hybrid was released in 1946 and, since then, hybrids have come to dominate the market (Bai and Lindhout 2007).

4.1 Breeding Goals

Breeding goals have shifted from a focus on yield and shelf life in the 1970s and 1980s to taste and nutrition since the 1990s. Despite this, the primary aim of most breeders is to produce a high-yielding, high-quality crop at low cost. Hence, taste and nutrition breeding will nearly always be secondary to yield and disease and abiotic stress resistance traits. Specific breeding goals also vary depending on the type of tomato. For processing tomato, the emphasis is on deep red external and internal color and high soluble solid content (4–6 °Brix). To achieve a deep red color, the lycopene

content of skin and flesh is important as are the presence and amounts of other carotenoids that alter the shade of red from yellow to orange (Díez and Nuez 2008). In the 1990s, Heinz released a series of processing cultivars with high and very high lycopene content (Scott et al. 2013). For fresh market tomato, the focus is on yield, fruit size and shape, and biotic stress resistance. In general, this has led to reduced internal fruit quality. In addition, various colors of fresh market tomato have been bred including white, yellow, orange, pink, red, purple, black, and striped (Bai and Lindhout 2007; Díez and Nuez 2008) (Fig. 1).

4.1.1 Breeding for Color

The genetic resources for color breeding include landraces and heirloom varieties as well as wild species such as *S. pimpinellifolium*, *S. habrochaites*, and *S. pennellii* for various colors and increased lycopene content (Grandillo et al. 2011). During the 1940s, the control of tomato external and internal color was described to be the result of different combinations of genes in flesh and skin (Young and MacArthur 1947). For instance, red-fruited tomatoes were described as the result of red flesh and yellow peel, while pink tomatoes have red flesh and colorless peel. In their monograph on tomato horticultural traits, Young and MacArthur (1947) listed five single genes controlling fruit color: *R* for red flesh (*r* for yellow), *t* for tangerine color, *Y* for yellow peel, m_{1-4} for modification of red color, and *G* for inhibiting the development of red color. Since then, many more carotenoid pathway and modifier genes have been identified and placed on tomato's classical linkage map (Tanksley 1993; updated in Scott et al. 2013). In 1986, Tigchelaar (1986) described seven genes that had been introgressed into tomato to breed color: *B* for high beta-carotene and its allele og_c for interior crimson color, *gs* for green stripe on ripe fruit, *hp* for high lycopene pigment, *r* for low total carotenoid content, *t* for tangerine color, and *y* for colorless peel. Since then, the repertoire of introgressed genes has expanded to include *Del*, *dps*, and *gh* for orange color; *at* for apricot color; additional *hp* genes (*hp-1* to *hp-3*) and I_p for deep red; *r* for yellow color; *ry* for red color in yellow fruit; *gf* and *Gr* for green flesh and ripe fruit; and Mo_B for modification of *B* expression (Kabelka et al. 2004; Díez and Nuez 2008). As a result of these introgressions, the carotenoid content of modern cultivars varies from deep red varieties with very high levels of lycopene to orange and yellow types with predominantly beta or delta-carotene. High pigment (*hp*) genes have been employed for enhancing dietary and HR quality because, in additional to increased lycopene and carotenoid levels, these genes are associated with improved ascorbic acid, phenolic, and flavonoid content (Levin et al. 2003). Unfortunately, such cultivars have not been widely accepted because of their reduced yield (Scott et al. 2013).

4.1.2 Breeding for Other HR Traits

Compared to carotenoid content, very little traditional breeding has addressed other nutraceutical traits. The only exception is ascorbic acid. Lincoln et al. (1943) recognized the importance of this vitamin as well as beta-carotene (provitamin A) in tomato as far back as the 1940s. Berger et al. (1966) crossed cultivated tomato with *Lycopersicon minutum* (now known as *S. chmielewskii*) and found that the hybrids had 3.5-fold more ascorbic acid than the cultivated parent. F_2 plants had highly variable concentrations

which prevented the researchers from determining the exact inheritance pattern of ascorbic acid content. This is not surprising given the quantitative nature of this trait. Variation in ascorbic acid content was also detected in more wild species (Stevens 1986), and Stevens and Rick (1986) crossed *S. peruvianum* with cultivated tomato to improve ascorbic acid content. However, to our knowledge, this work did not result in a commercial cultivar and none of the most popular processing and fresh market cultivars over the past 50 years are notable for their vitamin content (Scott et al. 2013).

As with other crops, the difficulty of studying and improving most nutraceutical traits in tomato lies in their quantitative nature. These traits are often the result of complex metabolic pathways involving multiple structural and regulatory genes. Color traits are also controlled in a complex manner; however, their visual phenotype allowed selection of single-gene mutants over thousands of years since initial domestication. Tomato's other nutraceutical components do not have the advantage of obvious phenotypes; hence, research into these compounds has only exploded with the advent of tomato molecular genetics.

5 Phenotype-Based Diversity Analysis of HR Traits

Tomato is a significant vegetable for human heath due to its high levels of crude protein and fiber in its proximate composition, as well as being rich in carotenoids, phenolic acids, vitamins, and other antioxidant compounds such as polyamines and GABA. Variation in these traits was briefly mentioned in Sect. 2.1. However, because many studies have characterized and quantified HR phytochemicals in both cultivated and wild tomato genotypes, the reported diversity in these traits is more fully described in this section.

5.1 Protein and Crude Fiber Diversity

As already mentioned, most of the protein in tomato fruits is found in the seeds. Lu et al. (2019) found that the protein content of tomato seeds varied from 23.6 to 40.9 g/100 g DW. On the other hand, the protein content of the tomato peels is much lower. For instance, Grassino et al. (2016) reported up to 1.85 g/100 g DW, while Elbadrawy and Sello (2016) found 10.50 g/100 g DW protein in tomato peel. Crude fiber is composed of cellulose, hemicellulose, and lignin. Several studies have focused on the fiber content of tomato seeds and peel. These byproducts of tomato processing can be used as ingredients in the food industry, and their high fiber content was reported by Herrera et al. (2010). Variation of fiber content in tomato germplasm was also investigated. In one study, seven tomato cultivars from the Guinea Savanna zone of South West Nigeria were characterized for fiber content, and high variation was reported with a CV (coefficient of variation) value of 133.91% (Olaniyi et al. 2010). In addition, the fiber content of three tomato cultivars (Monika, Isabella, and cherry) was investigated, and significant differences between ripening stages were reported. Cherry cultivars had the highest fiber content (Opara et al. 2012).

The most comprehensive study was performed by Al Said et al. (2014). In this study, fiber content of 54 tomato accessions grown in Oman ranged from 0.34% to 1.05%. High variation in the fiber content of 20 genotypes (0.3–1.27% range variation) was also described by Anjum et al. (2020). In addition to cultivated genotypes, wild tomato species were also evaluated for fiber content. The genetic potential of *S. pennellii* was investigated for lignin, cellulose, hemicellulose, and saccharification content using an introgression line (IL) library, and fiber content showed high variation among the tested ILs (Caruso et al. 2016). Such variation suggests that improvement of this trait in tomato fruit via breeding is possible.

5.2 Carotenoid Diversity

Lycopene and β-carotene are the most important carotenoids in tomato. Due to their significance for fruit color and high antioxidant activity, genetic variation of carotenoids was evaluated in several studies. Although these studies were performed in limited numbers of tomato genotypes (up to 53 tomato genotypes), they make it clear that genotype, ripening stage, and fruit type (green, red, and black) all affect carotenoid accumulation (Adalid et al. 2010; Roselló et al. 2011; Salunke et al. 2012; García-Valverde et al. 2013; Flores et al. 2017). Adalid et al. (2010) studied 49 accessions including local Spanish cultivated tomato, *S. lycopersicum* var. *cerasiforme* and *S. pimpinellifolium* lines. Remarkably, one of the seven *S. pimpinellifolium* accessions had ninefold the normal levels of lycopene. Roselló et al. (2011) reported that lycopene and β-carotene were affected by mainly genotype (G) effect followed by environment (E) and G × E interaction. Salunke et al. (2012) characterized 18 red and 12 orange tomato genotypes for β-carotene content and found that orange ones had the highest β-carotene content. García-Valverde et al. (2013) analyzed four fresh market tomato cultivars at different stages (green, breaker, pink, red) and five processing cultivars at the red stage for carotenoids. Tomatoes harvested at the red stage had the most lycopene and β-carotene. In addition, Flores et al. (2017) identified the effect of tomato shape (oblate to round to oblong and pyriform), color (yellow, pink, and red), and size on carotenoids. The most lycopene, β-carotene, phytoene, and phytofluene contents were measured in pink and red tomatoes, while the most lutein, violaxanthin, neoxanthin, and chlorophyll contents were found in darker-colored fruits. In another study, 69 local tomato accessions belonging to 8 cultivar groups from València (Spain) were characterized for lycopene and β-carotene as well as proximate composition traits, major sugars (glucose and fructose), and citric acid (Figàs et al. 2015). As a result, high diversity was determined among accessions. The cherry- and Penjar-type cultivars had higher values for most traits, including β-carotene dry matter, soluble solid content, titratable acidity, and taste.

5.3 Phenolic Compounds and Total Antioxidant Activity Diversity

Tomato is known for its high levels of phenolic compounds which contribute to its high antioxidant activity (Hanson et al. 2004). Flavonoids are important members of this

family of phytochemicals with a variety of different flavonoids found in various tomato cultivars (Slimestad et al. 2008; Fattore et al. 2016). Most of the studies focused on a limited number of tomato cultivars for phenolic acid composition and antioxidant traits. These studies reported significant variation in terms of phenolic acids and pointed out that the predominant phenolic acid in tomato is chlorogenic acid followed by caffeic acid, chlorogenic acid derivatives, ferulic acid, kaempferol-3-O-rutinoside, rutin, and p-coumaric acid (Martínez-Valverde et al. 2002; Minoggio et al. 2003; Spencer et al. 2005; Luthria et al. 2006; Barros et al. 2012; García-Valverde et al. 2013; Asensio et al. 2019). The most comprehensive study was performed by Bhandari et al. (2016) using 119 cherry and non-cherry genotypes including both cultivars and germplasm materials. The study revealed that total phenolic and antioxidant activity had lower variation than carotenoid, ascorbic acid, and flavonoid content. According to Figàs et al. (2015), cherry and Penjar tomatoes had higher total antioxidant and phenolic content than other types of tomatoes grown in València, Spain. In another study, 54 genotypes (cultivars, commercial hybrids, cherry tomatoes, wild species, interspecific hybrids, and backcross lines) were screened for antioxidant levels and quality. Wild species and interspecific hybrids between LA1777 (*S. habrochaites*) and an elite genotype were found to have the highest antioxidant capacity, as well as high phenolic and flavonoid contents (Kavitha et al. 2014). Other studies also highlighted the genetic potential of wild tomato species as resources for the improvement of antioxidant capacity and phenolic compounds (Kavitha et al. 2014; Top et al. 2014). A study performed by Top et al. (2014) reported that the wild tomato species *S. pimpinellifolium* (LA1589), *S. habrochaites* (LA1223), and *S. peruvianum* (LA2172) generally had higher content than cultivated tomato for water-soluble antioxidant activity and total phenolic content. Among the wild species, *S. peruvianum* had the highest values for these traits.

5.4 Vitamin Diversity

Tomato is an important dietary source of ascorbic acid. This vitamin's content is highly variable in tomato (Bhandari et al. 2016) with this variation mainly attributed to genotypic rather than environmental factors (Roselló et al. 2011). This observation was reinforced by Martí et al. (2018) who found that genotype was more important than farming method (conventional vs. organic) for the accumulation of HR compounds like ascorbic acid. Ilahy et al. (2017) reported an ascorbic acid level of 20 mg/100 g FW, and Mellidou et al. (2021) measured values from 6 to 23 mg/100 g FW in different cultivars. Among cultivated tomato types, cherry tomatoes are reported to have higher ascorbic acid content (Adalid et al. 2010; Figàs et al. 2015). For example, Adalid et al. (2010) measured ascorbic acid content in 28 *S. lycopersicum* var. *cerasiforme* accessions and identified two lines with three times the levels found in control lines. The wild tomato species *S. pimpinellifolium*, *S. habrochaites*, and *S. peruvianum* also have more ascorbic acid than cultivated tomato with *S. pimpinellifolium* (LA1589) having the highest ascorbic acid content among these three species (Top et al. 2014). In addition to the above studies, much research on ascorbic acid content in tomato has examined the effect of processing on this vitamin as well as other HR compounds (e.g., Chanforan et al. 2012; Koh et al. 2012; Badin et al. 2021).

Vitamin E content is affected by many factors. Vitamin E levels increase during ripening (Dumas et al. 2003), by the use of rainwater instead of irrigation (Pék et al. 2014), under high light intensity, at low temperature, and under salinity stress (Skłodowska et al. 2009). Vitamin E content also varies based on the tomato variety (Lenucci et al. 2006; Marsić et al. 2010). For instance, Marsić et al. (2010) recorded twofold variation in different cultivars grown in different locations. Frusciante et al. (2007) reported an α-tocopherol level of 0.62 mg/100 g FW.

5.5 Polyamine Diversity

Polyamine content is a trait which has been the focus of limited work in terms of germplasm characterization in tomato. In early work using a single line, putrescine was found to be the major polyamine at early stages of fruit development with much less spermidine and spermine (Morilla et al. 1996). The content of all three polyamines decreased throughout development and ripening. Yahia et al. (2001) also examined a single tomato cultivar and found that while spermine content decreased with fruit maturation, spermidine content remained unchanged. In the most recent and comprehensive work, Gutierrez et al. (2021) analyzed the polyamine content of eight genotypes from the green to red ripe stage. Different genotypes had significantly different polyamine contents with two Bolivian lines identified as having the highest levels at the green and red stages. No clear correlation was observed between the content of individual polyamines and maturation stage (Tsaniklidis et al. 2016; Gutierrez et al. 2021).

5.6 GABA Diversity

GABA is another HR compound that has been examined in diverse tomato material. San Marzano tomatoes were metabolically profiled and found to have high GABA content (Loiudice et al. 1995). Saito et al. (2008) screened 61 accessions including cultivars and 3 wild species and derived lines for GABA content. Content was found to vary greatly between years with a 13-fold difference between the lowest and highest accessions. In addition, fresh market cultivars had the highest levels compared with processing types, wild materials, and derived lines. Interestingly, GABA content is usually highest at the mature green stage and found in lesser amounts in ripe fruit (Akihiro et al. 2008; Saito et al. 2008; Takayama and Ezura 2015). In addition, its levels vary depending on the variety, environmental conditions, under stress conditions, and during post-harvest treatments (Gramazio et al. 2020).

5.7 Glycoalkaloid Diversity

Glycoalkaloids are an important toxic secondary metabolite in tomato. For this reason and because these toxic effects can be used to control the growth of various types of

cancers, tomato germplasm has been screened for this HR trait. In early work, Leonardi et al. (2000) examined glycoalkaloid and antioxidant content in cherry, cluster, salad, and elongated types of tomato. The elongated line had approximately fourfold more total glycoalkaloids than the other types, while cherry tomatoes had the highest antioxidant levels. Kozukue et al. (2004) analyzed glycoalkaloids in three normal and two mini-tomato cultivars from Japan. Glycoalkaloid content varied with genotype and in different tissues. On average, 11-fold more α-tomatine than dehydrotomatine was present in green fruits; however, neither compound was detectable in ripe fruits. Choi et al. (2010) monitored glycoalkaloid content during different growth stages and also found that they decreased significantly during ripening. It was reported that the α-tomatine level was 500 mg/kg FW in green fruits and then decreased to 5 mg/kg FW when the fruits were red (Friedman 2013).

In the most comprehensive work done to date, glycoalkaloids were profiled in eight accessions including cultivated tomato and the wild species *S. lycopersicum* var. *cerasiforme* (LA2213), *S. pimpinellifolium* (LA1589), *S. pennellii* (LA716), *S. habrochaites* (LA1777), *S. neorickii* (LA2133), and *S. cheesmaniae* (LA1414) (Iijima et al. 2013). A total of 123 different glycoalkaloids were found in the different accessions with distinct profiles in some of the lines. The highest levels of total glycoalkaloids were measured in *S. lycopersicum* var. *cerasiforme* and *S. cheesmaniae.* Schwahn et al. (2014) examined four of the same wild accessions as Iijima et al. (2013) but also included *S. chmielewskii* (LA1028), *S. peruvianum* (LA1274), and *S. cheesmaniae* (LA1414). They detected 169 different glycoalkaloid peaks with fruits of *S. peruvianum* and *S. chmielewskii* containing more different types than the other species. In other work, 14 Italian landraces from three broad fruit classes, one French landrace, and three F1 hybrids were analyzed for glycoalkaloids, phenols, and amino acids. While round/elongate types had more glycoalkaloids, flattened types had more phenolic compounds and amino acids (Baldina et al. 2016). Thus, in some cases, fruit type and shape can be rough indicators of health value. However, more precise prediction of phenotype for phytochemical traits requires knowledge of plant genotype. Such knowledge can be gained using molecular markers or by genome sequencing.

5.8 Other HR Compound Diversity

In addition to the compounds described above, tomato contains many other known or potential beneficial HR phytochemicals which have received less attention for one reason or another. For example, anthocyanins have anti-inflammatory, anticancer, and antimicrobial effects (Chen et al. 2021); however, anthocyanins are only produced at significant levels in fruits of a few tomato cultivars and genetically modified lines. There are also not many studies evaluating the phytosterol content of tomato cultivars. In one study, the phytosterol content of tomato seed oil (a waste product of sauce processing) extracted from three Italian processing tomato varieties (Principe Borghese, Rebelion F1 and San Marzano) was investigated. Principe Borghese had the most β-sitosterol content (Giuffrè and Capocasale 2016a). The same cultivars

were also characterized for fatty acid composition, and a study revealed their high variation in seed oil (Giuffrè and Capocasale 2016b).

5.9 Molecular Diversity

In addition to phytochemical diversity, the genetic diversity of tomato has been extensively investigated using molecular markers. Twenty years ago, such studies were performed mainly with RAPD (random-amplified polymorphic DNA) markers (Archak et al. 2002; Carelli et al. 2006; Huh et al. 2011). Germplasm characterization then began to encompass other molecular marker systems such as AFLP (amplified fragment length polymorphism) and SSR (simple sequence repeat) markers (Park et al. 2004; Cebolla-Cornejo et al. 2013; Korir et al. 2014; Zhou et al. 2015). Several genetic linkage maps derived mainly from related species such as *S. pennellii*, *S. pimpinellifolium, S. habrochaites*, and *S. chmielewskii* were constructed using molecular markers. All genetic and physical maps can be found on the Sol Genomics Network (https://solgenomics.net/cview/index.pl).

Next-generation sequencing of tomato germplasm has revealed a more complete picture of genome variation. From this perspective, a pan genome of tomato was developed by sequencing 725 phylogenetically and geographically representative accessions (Gao et al. 2019). The pan genome project revealed the absence of 4873 genes in the tomato reference genome and the negative selection of genes during tomato domestication. Structural variant data for 100 diverse tomato genotypes, assemblies, and annotations for 14 of these genotypes are available on the Sol Genomics Network (https://solgenomics.net/projects/tomato100/). The pan genome of tomato will be an invaluable tool for understanding the genetic diversity of health-related traits in this species.

6 Brief Account of Molecular Mapping of HR Genes and QTLs

Once tomato genetic resources for health-related compounds are evaluated, it is then possible to determine the molecular mechanism of their synthesis. Because HR compounds are quantitative traits, they are controlled by many loci in the genome and often with significant environmental control. This section comprises the identification of the single genes and QTLs that control HR using genomic and transcriptomic approaches.

6.1 Genomic Approaches

6.1.1 Biparental Mapping

Early studies focused on the identification of genes and QTLs controlling lycopene and β-carotene content in tomato as discussed in Sect. 4. Other studies in tomato have focused on fruit quality traits such as phenolic compounds, flavonoids, and total antioxidant activity. The first study was performed by Rousseaux et al. (2005).

In this work, ascorbic acid, phenolics, lycopene, and β-carotene contents and water-soluble antioxidant activity were measured in fruits from an IL library developed using *S. pennellii.* A total of 20 QTLs controlling the related traits were identified. The same *S. pennellii* IL library was used to map QTLs controlling the antioxidants carotenoids and tocopherols as well as molecular signatures for 2000 compounds. Introgressions from chromosomes T3, T6, T8, and T12 were associated with carotenoid and tocopherol content (Perez-Fons et al. 2014). In other research, a BC2F2 population derived from *S. habrochaites* was used to map the QTLs for total water-soluble antioxidant capacity, ascorbic acid, total phenolics, flavonoids, and lycopene contents. As a result, 48 QTLs were mapped (Ökmen et al. 2011). In terms of antioxidant traits, the most comprehensive study was performed by Çolak et al. (2020). In this study, an IBL (Inbred Backcross Line) population derived from *S. pimpinellifolium* was genotyped with GBS (genotyping by sequencing)-based SNP (single-nucleotide polymorphism) markers, and QTL mapping was performed for carotenoids, ascorbic acid, vitamin E, glutathione, and phenolic acid contents. As a result, 64 QTLs were detected with candidate genes identified for several of the loci. In addition, a RIL (recombinant inbred line) population developed from *S. pimpinellifolium* was used to map QTLs for soluble solids, acidity, sugars, organic acids, ascorbic acid, and carotenoid contents. Several QTLs were mapped and, most importantly, a fruit size QTL (*frw7.1*) was found to be co-localized with QTLs controlling soluble solids, ascorbic acid, and glucose contents, dry weight/fresh weight, and a sucrose phosphate synthase gene. Moreover, two candidate genes (*1-deoxy-D-xylulose 5-phosphate synthase* and *tocopherol cyclase*) were identified for β-carotene and ascorbic acid contents (Capel et al. 2015).

Ascorbic acid is an important health-related compound, and several studies were performed to reveal the molecular mechanism of its synthesis in tomato. In a study performed by Zou et al. (2006a), cDNA clones of two genes [dehydroascorbate reductase (*DHAR*) and ascorbate oxidase (*AO*)] with roles in ascorbic acid synthesis were isolated and 14 genes were mapped to 15 loci using a *S. pennellii* (LA716) IL library. In another study, QTLs controlling ascorbic acid content were mapped using populations from two wild tomato species (an IL library of *S. pennellii* and an advanced backcross population of *S. habrochaites*) and a subspecies (a RIL population developed from a cross between cherry and large-fruited lines) (Stevens et al. 2007). Consensus QTLs were determined on chromosomes 2, 8, 9, 10, and 12. In a recent study, GBS and RNA-seq analysis revealed that subline R182, a *S. pennellii* IL with high ascorbic acid content, had 39 wild alleles replacing 33 alleles in the IL's genetic background (cv. M82). An upregulated gene for a major facilitator superfamily protein was identified in the study and is a promising candidate for increased ascorbic acid content.

In addition to nutritional compounds that are associated with good health, tomato contains secondary metabolites like glycoalkaloids which have anticancer properties. A recent study identified QTLs controlling glycoalkaloid and flavonol content using a *S. pennellii* IL library. As a result, a total of 338 QTLs were detected. Two QTLs for flavonols and one for steroidal glycoalkaloids were confirmed using IBL populations. Cross-validation revealed that the steroidal glycoalkaloid QTL was co-localized to a glycoalkaloid gene cluster on chromosome 7 in tomato (Alseekh et al. 2020).

6.1.2 Association Mapping

Association mapping in tomato for HR traits has been more limited than biparental population QTL mapping. The most comprehensive study was performed by Ruggieri et al. (2014). In this work, 96 tomato lines were genotyped with 7720 SNP markers and used as an association panel for identification of QTLs controlling ascorbic acid, β-carotene, trans-lycopene, cis-lycopene, and phenolic contents. As a result, while two markers were linked to phenolics, three markers were associated with ascorbic acid, β-carotene, and trans-lycopene. In another study, an association panel containing 174 tomato lines was genotyped using SSR markers (Zhang et al. 2016). As a result, 4 and 15 markers were found to be associated with lycopene and β-carotene contents, respectively.

6.2 Transcriptomic Approaches

In addition to genomic research such as gene mapping, analysis of the transcriptome can be used to reveal the mechanisms controlling HR traits. For example, a transcriptomic study was performed for identification of genes with roles in phenolic compound accumulation (Di Matteo et al. 2013). In this study, a microarray hybridization method was used to identify DEGs (differentially expressed genes) between M82 and *S. pennellii* IL 7-3, which has a higher level of phenolic accumulation. As a result, a MATE-transporter, a vacuolar sorting protein, and three GSTs were found to be upregulated, and two ethylene responsive factors (*ERF1* and *ERF4*) were found to be associated with phenolic accumulation. In addition, a TILLING (Targeting Induced Local Lesions IN Genome) assay revealed a mutation in the *ERF1* gene which reduced the phenolic content (Di Matteo et al. 2013). Another transcriptomic study revealed the positive role of abscisic acid (ABA) in carotenoid biosynthesis (Mou et al. 2015). The most recent transcriptomic study to identify DEGs controlling ascorbic acid and phenolics synthesis was performed by Sacco et al. (2019). In this study, transcriptomic changes during the ripening of two tomato cultivars were investigated using a RNA-seq approach. This study reported that pectin methylesterase and L-ascorbate oxidase played roles in ascorbic acid synthesis and that the chalcone synthase (*CHS*) gene had a role in phenolic accumulation. In other works, comparative transcriptome analysis of tomato and potato glycoalkaloid content allowed the identification of ten genes involved in biosynthesis (Itkin et al. 2013). These genes are located into two clusters on chromosomes 7 and 12 in tomato. Comprehensive profiling of glycoalkaloids in different tissues of eight different species also allowed refinement of the biosynthetic network that controls their production in tomato (Schwahn et al. 2014).

6.3 Limitations in Studies to Date

While many studies have mapped loci and explored the differential expression of genes controlling carotenoid, ascorbic acid, phenolic, and flavonoid contents, such work has not yet been performed for other health-related traits such as fiber, phytosterol, and fatty acid composition. Moreover, although a significant number of QTL mapping studies

have been done for certain HR traits in tomato, to our knowledge, none of the major or stable QTLs have been employed as breeding tools. High-resolution QTL mapping approaches such as association mapping and candidate gene mapping targeting pathway and regulatory genes should be performed to elucidate the molecular genetic mechanism of nutritional compound accumulation. Such approaches can accelerate the identification of functional SNPs that can be used in selection to increase nutritional compound content via breeding. Moreover, it must be noted that utilization of the identified QTLs in breeding can be difficult due to the effects of genome background and environment on phenotype. As a result, genomic selection models should be developed for efficient selection of genotypes with high HR compound content without the need for extensive and expensive metabolite analysis (Cappetta et al. 2020).

7 Marker-Assisted Breeding for HR Traits

As previously mentioned, health-related traits in tomato are quantitative traits and affected by the environment (Schauer et al. 2008). As a result, breeding for HR characteristics is difficult. While several QTLs controlling HR traits have been mapped in the tomato genome as described in Sect. 6, the utilization of these QTLs in breeding depends on their stability in different environments and genomic backgrounds. When stable loci are identified, linked markers can be used in MAS (marker-assisted selection) for the trait of interest (Chaïb et al. 2006). To our knowledge, the first marker-assisted breeding strategy for HR traits was applied by Lecomte et al. (2004). In this work, five previously identified QTLs for organoleptic quality (soluble solids, reducing sugar, acidity, and pH), originating from a cherry tomato (Cervil) with good taste and aroma attributes, were introgressed to a fresh market recipient parent using a marker-assisted backcross (MABC) strategy. As a result, three improved BC3S3 lines were developed. In another study, two introgression lines (IL7-3 and IL12-4) developed from *S. pennellii* with QTLs for increased ascorbic acid, phenols, and soluble solids were crossed to the recurrent parent M82 (Sacco et al. 2013). In addition, F1 hybrids were developed by crossing two ILs. Molecular marker analysis of the F2 lines from these hybrids allowed identification of four individuals that carried the two introgressions in the homozygous state. Selfed F3 lines had high contents of ascorbic acid, phenols, and soluble solids. Moreover, fruit extracts of these lines and ILs (IL7-3 and IL12-4) showed selective cytotoxic effects on cancer cells (Rigano et al. 2014). Despite these significant studies, utilization of MAS for HR traits is in its infancy, and more studies are needed to identify stable QTLs and allow better integration of molecular marker technologies in breeding.

8 Map-Based Cloning of HR Genes/QTLs

Tomato is a model organism for the implementation of map-based cloning due to the abundance of genome mapping studies. Despite these studies, the genes cloned in tomato are mainly related to disease resistance (reviewed by Foolad 2007). However, several studies have also been performed for fine mapping and cloning of HR genes.

8.1 Carotenoid Genes

Early studies for fine mapping of genes with agronomic importance used subNILs from wild species near-isogenic lines (NILs) to pinpoint the locations of QTLs (Monforte and Tanksley 2000; Frary et al. 2003; Yates et al. 2004). Of this early research, only Yates et al. (2004) analyzed subNILs for HR traits such as lycopene. In this work, overlapping introgressions for portions of chromosome 4 from *S. peruvianum* and *S. hirsutum* were examined. As a result, a subNIL containing a 3 cM introgression was found to increase lycopene content. Also, a 4 cM introgression increased organic acid, total titratable acid, and total sugar contents.

Although the generation of subNILs increases the resolution of QTL mapping, it is inefficient for gene cloning. Thus, map-based cloning strategies were developed for positional cloning of genes. This approach was initially used for cloning genes for color traits such as carotenoid content. In early work, the *LYCOPENE* δ-*CYCLASE* (*CRTL-E*) gene that changes lycopene into δ-carotene and leads to orange color in the *Delta* mutant was cloned using a cDNA sequence from *Arabidopsis thaliana* as a probe in a cDNA library of tomato. The *CRTL-E* gene co-segregated with *DELTA* on chromosome 12 (Ronen et al. 1999). Another study focused on the *BETA (B)* gene for increased β-carotene content and *OLD-GOLD* (*OG*) which decreases β-carotene and increases lycopene content (Ronen et al. 2000). In this work, a yeast artificial chromosome (YAC) containing the region of interest was identified and screened with the markers TM16 and TG275. It was found that the *BETA* gene encodes lycopene β-cyclase which converts lycopene to β-carotene and that *og* is an allele of *BETA*. In another study, the *tangerine* locus which causes accumulation of pro-lycopene instead of all-trans-lycopene was cloned using bacterial artificial chromosomes (BACs) after identification of a co-segregating marker in an F2 population (Isaacson et al. 2002). The study showed that *tangerine*, re-designated *CRTISO*, encodes a carotenoid isomerase with a function in carotenoid desaturation. Another single recessive gene, *YFT1*, causing yellow tomato fruits was cloned after fine mapping to an 88.2 kb interval on chromosome 9 in an F2 population (Gao et al. 2016). Among the 12 identified candidate genes in the region, *Solyc09g007870*, annotated as encoding the ETHYLENE INSENSITIVE2 (EIN2) protein, was the most likely candidate gene. The study also showed that reduced expression of the *EIN2* gene in the *yft1* mutant resulted in abnormal carotenoid production. Another single recessive gene, *YFT2*, associated with yellow-fruited cherry tomato on chromosome 3 was cloned by Chen et al. (2019). In this work, fine mapping of the locus was performed using 1898 F2 plants and 10 cleaved amplified polymorphic sequence (CAPS) markers. The locus was mapped to a target interval of 95.7 kb, and annotation of the interval revealed 11 candidate genes with *PSY1* (*Solyc03g031860*), annotated as a phytoene synthase (*PSY1*), as the most likely candidate. Overexpression of this fruit-specific gene increased carotenoid content and resulted in red fruit.

8.2 Ascorbic Acid Genes

In addition to cloning genes involved in carotenoid synthesis, several studies have cloned genes for ascorbic acid synthesis. Firstly, a GDP-D-mannose pyrophosphorylase

(*GMP*) gene involved in ascorbic acid biosynthesis was cloned in tomato using the potato GMP cDNA sequence as a query against the tomato EST database (Zou et al. 2006b). As a result, a total of 65 homologous ESTs were identified in tomato. Assembly of the ESTs and RACE-PCR (rapid amplification of cDNA ends) revealed the full 1086 bp *GMP* gene sequence. The RACE-PCR method was also used to clone dehydroascorbate reductase (*DHAR1* and *DHAR1*) and ascorbate oxidase (*AO*) genes (Zou et al. 2006a).

8.3 Glycoalkaloid Genes

Glycoalkaloid content of tomato fruit affects their palatability. As a result, this trait has been the subject of research to identify the genes responsible for fruit bitterness. Fine mapping and resequencing of 650 tomato accessions showed that the *GORKY* gene is responsible for exporting α-tomatine from the vacuole to the cytosol in tomato (Kazachkova et al. 2021). Once in the cytosol, the α-tomatine is converted to non-bitter compounds. Bitter tomato genotypes were discovered to have deletions in this gene.

9 Editing of HR Traits

As explained in a Sect. 7 of this chapter, although several genes and QTLs controlling HR traits have been mapped in the tomato genome, integration of these loci in tomato classical and molecular breeding strategies is limited. Thus, alternative approaches were developed for efficient breeding of tomato cultivars with improved HR traits. Genome editing tools such as RNA interference (RNAi), insertional mutagenesis, and CRISPR/Cas9 editing provide great opportunities, not only for verification of candidate genes but also for improvement of cultivars for various traits. CRISPR/Cas9 is especially popular in crop plants including tomato. Genome editing has been successfully used in tomato for increasing abiotic and biotic stress resistance (reviewed by Chandrasekaran et al. 2021; Salava et al. 2021; Xia et al. 2021). In addition, it has been used for improvement of HR traits in several studies.

9.1 Carotenoid Content

Color traits such as lycopene and carotenoid content are major targets of genome editing. In early work, downregulation of the photomorphogenesis regulatory gene, *DET1*, using RNAi gene editing technology increased carotenoid and flavonoid content without affecting other fruit quality traits (Davuluri et al. 2005). In work by Sun et al. (2012), RNAi-mediated suppression of the *SlNCED1* gene, which has a role in ABA biosynthesis, provided higher levels of lycopene and β-carotene.

In addition to RNAi, CRISPR/Cas9 technology has also been used to modify HR content in tomato. Gene editing of *LEAFY-COTYLEDON1-LIKE4* (*L1L4*), a transcription factor with functions in development, seed storage, and protein and fatty

acid synthesis, was performed with a ZFN-mediated genome editing tool (Hilioti et al. 2016; Gago et al. 2017). Editing resulted in increased β-carotene content as well as enhanced antioxidant activity. In a study aimed at demonstrating the efficiency of the system in tomato, two carotenoid-related genes, *PSY1* and *CRTR-B2,* were successfully edited using CRISPR/Cas9 (D'Ambrosio et al. 2018). Li et al. (2018a) targeted five genes (*SGR1*, *LCY-E*, *BLC*, *LCY-B1*, and *LCY-B2*) involved in the metabolic pathway for converting lycopene to other carotenoids. The expression of these genes was knocked down by the CRISPR/Cas9 system. As a result, lycopene content increased by 5.1-fold. In other works, four genes, *SELF-PRUNING (SP), OVATE (O), FRUIT WEIGHT 2.2 (FW2.2)*, and *LYCOPENE BETA CYCLASE (CYCB)*, were edited in the wild tomato *S. pimpinellifolium* (Zsögön et al. 2018). These genes were selected to mimic the process of domestication. Editing resulted in increased fruit size and number and improved lycopene level by fivefold.

9.2 Vitamin Content

In early work, RNAi was used for downregulation of a mitochondrial APX (*mitAPX*) gene in tomato to increase ascorbic acid content (Zhang et al. 2011a). Gene editing of the *L1L4* transcription factor was also associated with higher levels of ascorbic acid (Hilioti et al. 2016; Gago et al. 2017). In perhaps one of the most exciting developments in genome editing, Li et al. (2022) knocked out the activity of a *7-DEHYDROCHOLESTEROL REDUCTASE* isoform (*Sl7-DR2)* in tomato. This enzyme normally converts 7-DHC to cholesterol preparatory to α-tomatine synthesis. By modifying phytosterol biosynthesis in this way, the researchers induced the accumulation of provitamin D3 in ripe fruits with no negative effects on growth or yield. It is important to note that ripe tomato normally contains no provitamin D3. In this way, knowledge of complex, interacting metabolic pathways was leveraged to develop a new biofortified crop.

9.3 Other Compounds: GABA, Glycoalkaloid, and Anthocyanin Contents

GABA content of tomato has received considerable attention in gene editing studies. Early work by Koike et al. (2013) used RNAi to knock down expression of three GABA catabolism genes. While constitutive downregulation of these genes was associated with a sevenfold increase in ripe fruit, the plants were phenotypically abnormal. The use of a fruit-ripening promoter resulted in normal plants with a 2.5-fold increase in GABA at the red ripe stage. GABA content was also increased up to 15-fold by removing inhibitory domains in two *GLUTAMATE DECARBOXYLASE* (*GAD*) genes; however, some of the edited plants had reduced height, delayed or no flowering, and reduced fruit size and set (Nonaka et al. 2017). Li et al. (2018a) targeted five genes in the GABA pathway using the pYLCRISPR/Cas9 system.

Similar to previous work, while significant gains in GABA content were achieved, negative effects on plant phenotype were also observed.

Glycoalkaloid content in tomato hairy roots was modified by knocking out a pathway gene using CRISPR/CAS9 (Akiyama et al. 2019). Reduced *SlS5αR2* (a DET2 homolog) expression was associated with decreased accumulation of α-tomatine and increased levels of dehydrotomatine.

Anthocyanin content of tomato has also been altered using genome editing tools. The *FEEBLY* (*FB*) gene was mutated using transposon-mediated mutagenesis and anthocyanin content increased significantly (van der Biezen et al. 1996). In another study, the anthocyanin gene (*ANT1*) was overexpressed using TALENs and CRISPR/Cas9. Both methods showed similar efficiency, and overexpression of the gene resulted in higher anthocyanin content and purple tissue (Salava et al. 2021).

10 Genetic Engineering of HR Traits

In addition to genome editing studies, transgenic approaches such as overexpression of genes have been successfully used to improve HR traits in tomato. This method can use genes that are already found in tomato (cisgenesis) or those from other species (transgenesis). In both cases, the resulting transgenic individuals are considered to be genetically modified organisms (GMOs) and, therefore, subject to regulatory control.

10.1 Carotenoid Content

The most popular HR trait in transgenic studies is carotenoid content. Early studies focused on the role of the *BETA-CYCLASE* (*β-LCY*) gene in the carotenoid pathway. The first study transformed this gene into tomato using both overexpression (OE) and antisense (AS) constructs (Rosati et al. 2000). While overexpression led to higher levels of β-carotene, the antisense construct decreased *β*-carotene content. Fruit-specific expression of lycopene *B-CYCLASE* (*β-LCY*) and *L-CAROTENE HYDROXYLASE* (*β*-CHY) genes resulted in increases in *β*-carotene, β-cryptoxanthin, and zeaxanthin contents (Dharmapuri et al. 2002). In a similar work, overexpression of lycopene *β-LCY* in tomato verified the importance of this gene by increasing β-carotene content 4.1-fold in transgenic tomato (Guo et al. 2012). In another study, plastid expression of the *β-LCY* gene improved content of *β*-carotene and provitamin A by fourfold (Wurbs et al. 2007). Apel and Bock (2009) transferred *β-LCY* genes from *Erwinia herbicola* and *Narcissus pseudonarcissus* to the plastid genome. Although the eubacterial enzyme did not affect carotenoid accumulation, the plant enzyme increased *β*-carotene and provitamin A levels in fruits. In a more recent study, overexpression of the *β-LCY* gene increased β-carotene content and was associated with increased ABA content and extended shelf life (Diretto et al. 2020). Some of the previously developed transgenic lines overexpressing lycopene *β-LCY* (from studies by D'Ambrosio et al. 2004; Wurbs et al. 2007; Apel and Bock 2009) were further tested for their metabolic profiles (Mi et al. 2022). The transgenic lines had altered

hormone content including changes in ABA, gibberellins, cytokinins, auxin, and jasmonic acid levels. The plants also had enhanced xanthophyll and provitamin A contents and increased abiotic stress tolerance.

In addition to *LYCOPENE β-CYCLASE*, *PHYTOENE SYNTHASE* and *TAXADIENE SYNTHASE* genes isolated from the bacterium *Erwinia uredovora* and the yew tree *Taxus baccata*, respectively, were overexpressed in tomato. The transgenic plants had increased total carotenoid content and also contained taxadiene (Fraser et al. 2002; Kovacs et al. 2007). Taxadiene is usually not synthesized by tomato but is valuable as a precursor of taxol, an important anticancer agent.

Transcription factors have also been used to increase carotenoid content in transgenic studies. In one study, upregulation of a *R2R3-MYB* transcription factor (*VVMYB5B*) in tomato reduced phenylpropanoid metabolism and increased the β-carotene content in tomato (Mahjoub et al. 2009). Overexpression of a brassinosteroid (*BR*) (response transcription factor) in tomato also enhanced carotenoid content and resulted in improved soluble solid, soluble sugar, and ascorbic acid levels (Liu et al. 2014). Overexpression of *SlPRE2*, a *bHLH* transcription factor, reduced chlorophyll and carotenoid abundance in tomato (Zhu et al. 2017). In addition, overexpression of the non-heme di-iron carotene betahydroxylase-encoding gene (*CRTR-B2*) increased xanthophyll content in tissues containing chloroplasts and chromoplasts (D'Ambrosio et al. 2011). In addition to transcription factors, the positive effects of plastid chaperones such as *ORANGE* (*OR*) and *HSP70* on carotenoid accumulation has been demonstrated (D'Andrea and Rodriguez-Concepcion 2019; Yazdani et al. 2019).

10.2 Flavonoid Content

Transgenic approaches have also been implemented to increase flavonoid content in tomato. The first study demonstrated that overexpression of the biosynthetic pathway genes *CHALCONE ISOMERASE*, *CHALCONE SYNTHASE*, and *FLAVONOL SYNTHASE* increased total fruit flavonols (Verhoeyen et al. 2002). In another study, the introduction of structural flavonoid genes (*STILBENE SYNTHASE*, *CHALCONE SYNTHASE*, *CHALCONE REDUCTASE*, *CHALCONE ISOMERASE*, and *FLAVONE SYNTHASE*) produced fruit peels with increased phytochemical content including flavonols and flavones (Schijlen et al. 2006). Transgenic approaches have also revealed the role of transcription factors in controlling the accumulation of flavonoid compounds. In one study, overexpression of the maize transcription factor genes *LC* and *C1* resulted in increased flavonols (Bovy et al. 2002). *AtMYB12* originating from *Arabidopsis* was also upregulated in tomato and was associated with increased levels of flavonols and chlorogenic acid in both leaf and fruit (Pandey et al. 2015).

10.3 Ascorbic Acid Content

The transgenic approach has also been implemented for improvement of ascorbic acid content in tomato. In one study, transgenic plants overexpressing the *SlGME1 and*

SlGME2 genes from the ascorbic acid biosynthesis pathway increased total ascorbic acid in leaves and fruits (Zhang et al. 2011b). Overexpression of two genes, *MONODEHYDROASCORBATE REDUCTASE* (*MDHAR*) and *DEHYDROASCORBATE REDUCTASE* (*DHAR*), encoding ascorbate recycling enzymes was performed by Haroldsen et al. (2011). In this work, overexpression of *DHAR* increased ascorbic acid content, but *MDHAR* overexpression was associated with reduced content. In a similar research, overexpression of a *DHAR* gene increased DHAR activity and ascorbic acid content in both leaves and fruits (Li et al. 2012). Upregulation of the *L-GULONO-Γ-LACTONE OXIDASE* (*GLOase*) gene boosted ascorbic acid content by 1.5-fold and also improved abiotic stress resistance (Lim et al. 2012).

In some cases, an increased level of a HR compound is a benefit of engineering aimed at another metabolite. For example, a *STILBENE SYNTHASE* cDNA involved in resveratrol synthesis and isolated from grape (*Vitis vinifera*) was overexpressed in tomato (Giovinazzo et al. 2005). As a result, transgenic fruit accumulated trans-resveratrol and had increased levels of ascorbate and glutathione, another water-soluble antioxidant.

10.4 Polyamine Content

Polyamines were an early target of efforts to increase their content via transformation methods. In 2002, Mehta et al. introduced a yeast *S-ADENOSYLMETHIONINE DECARBOXYLASE* (*SPE2*) gene with a ripening promoter into tomato. In addition to significantly higher amounts of spermidine and spermine, ripe fruit also had an unexpected threefold increase in lycopene content. A similar construct was transformed into tomato by Mattoo et al. (2007) who noted that the increased polyamine content was accompanied by reduced levels of some amino acids and sugars. Further analysis of the transgenic plants indicated that they had increased shelf life, higher levels of lycopene, and an obovoid fruit shape (Nambeesan et al. 2010). In a similar work, introduction of a human *S-ADENOSYLMETHIONINE DECARBOXYLASE* gene with a fruit-specific promoter was associated with enhanced levels of polyamines, lycopene, ascorbic acid, and soluble solids (Madhulatha et al. 2014). The use of an apple *SPERMIDINE SYNTHASE* gene driven by a constitutive promoter was equally effective at increasing both polyamine and lycopene contents in tomato (Neily et al. 2011).

10.5 GABA Content

GABA content has also been engineered in tomato. Constitutive overexpression of *SlGAD3* had fivefold more GABA than nontransgenic plants at the red ripe stage (Takayama et al. 2015). Interestingly, unlike the edited plants, the transgenic plants did not have abnormal phenotypes. In a continuation of this work, Takayama et al. (2017) co-expressed *SlGAD3* with a copy of the same gene missing the C-terminal

autoinhibitory domain. This approach yielded fruits with 18-fold higher GABA content but which had orange instead of red fruit.

10.6 Glycoalkaloid Content

Only a limited number of studies have been aimed at engineering glycoalkaloid content in tomato with much more work centered on potato. Overexpression of a *JASMONATE-RESPONSIVE ETHYLENE RESPONSE FACTOR* transcription factor (JRE4) in tomato led to a 1.8-fold increase in α-tomatine level in leaves (Nakayasu et al. 2018). Based on this work, JRE4 was determined to be a primary master regulator of glycoalkaloid synthesis. Overexpression of a *α-TOMATINE 23-HYDROXYLASE* (*Sl23DOX*) caused the accumulation of the pathway intermediates neorickiioside B and lycoperoside C in tomato leaves (Nakayasu et al. 2020). Silencing of the same gene resulted in increased α-tomatine levels. In this way, the glycoalkaloid biosynthetic pathway can be manipulated to produce a compounds of interest.

10.7 Anthocyanin Content

Anthocyanin content has been a popular target of genetic engineering in tomato due to its HR benefits and the fact that tomato normally produces very little of this pigment in its fruits. For instance, expression of two transcription factors (*DEL* and *Ros1*) isolated from snapdragon significantly increased tomato anthocyanin accumulation resulting in dark purple fruit (Butelli et al. 2008). This study also showed that cancer-susceptible *Trp53* mutant mice fed with the tomato had extended life spans. Overexpression of the same transcription factors by virus-induced gene silencing (VIGS) also yielded purple fruit due to higher anthocyanin content (Orzaez et al. 2009). In another work, introduction of *MYB* transcription factor (*ANT1)* alleles from *S. chilense* and *S. lycopersicum* resulted in increased anthocyanin pigments (Schreiber et al. 2012). When the effects of the two alleles were compared, higher pigmentation was achieved with the *S. chilense* allele. In a similar work, overexpression of a different MYB-type transcription factor (*SlMYB75*) resulted in increased anthocyanin accumulation and aroma volatiles (Jian et al. 2019). Moreover, overexpression of the *AtMYB90* gene from *Arabidopsis thaliana* in tomato increased anthocyanin accumulation in all plant organs (Li et al. 2018b). Thus, both transgenesis and cisgenesis have been successfully used to produce tomatoes high in anthocyanins.

11 Bioinformatics as a Tool

While databases such as NCBI, Ensembl Plants, and UniProt have an abundance of data related to the tomato genome and its products, several gene, genome, expression, and metabolite databases have been established specifically for tomato. These

resources and the tools they offer are important for mining of molecular and phenotypic data and integration of data from different studies. While not all of the resources described in this section contain health-related traits, they are described here for completeness. Moreover, these databases are continually updated to include information that is useful for those studying such traits in tomato.

The Sol Genomics Network houses whole genome data for many tomato varieties as well as phenotypic data and tools with which to analyze the data (Mueller et al. 2005; Fernandez-Pozo et al. 2015). The site also provides access to the Tomato Expression Atlas (https://tea.solgenomics.net/) that has both expression and anatomy viewers for the high-resolution map and various tomato tissues and organs (Fernandez-Pozo et al. 2017). The Tomato Functional Genomics Database (http://ted.bti.cornell.edu/) contains RNA-Seq data, microarray analyses, and metabolite information for various compounds primarily from wild species introgression lines (Fei et al. 2011). The Kasusa Tomato Genomics Database (KaTomicsDB, www.kazusa.or.jp/tomato/) has both nuclear and organellar genome sequences and extensive marker databases (Shirasawa and Hirakawa 2013; Kuwabara et al. 2021). The Tomato Genomics Resource Database (http://223.31.159.9/tomato2/) has information that overlaps somewhat with other databases but provides an attractive graphical format and search features that should be useful to users (Suresh et al. 2014). TOMATOMICS (unfortunately, not available from the published link at the time of writing this chapter) is another multi-omic database with DNA and mRNA sequence and gene structure, expression, and annotation data for the cultivars Micro-Tom and Heinz 1706 (Kudo et al. 2017). Public RNA-Seq data for tomato is integrated and normalized on the TomExpress platform (http://tomexpress.toulouse.inra.fr/) which also provides tools to mine these data (Zouine et al. 2017). The Co-expressed Pathways DataBase for Tomato (http://cox-path-db.kazusa.or.jp/tomato/) allows prediction of gene function based on co-expression profiles of genes with known function (Narise et al. 2017).

A metabolome database for tomato fruit was established more than 15 years ago (Moco et al. 2006). The Metabolome Tomato Database (MoTo DB, http://appliedbioinformatics.wur.nl/) encompasses data gleaned from the literature as well as that obtained from LC-MS analysis of 96 different tomato cultivars. The Plant Metabolic Network database (https://plantcyc.org/) contains biochemical pathways and metabolic data from 126 species including tomato (Hawkins et al. 2021). The Sol Genomics Network hosts an entryway to this database through the hub, SolCyc (http://solcyc.solgenomics.net/), with a family-specific, manually curated database for the nightshades, SolanaCyc (Foerster et al. 2018) and LycoCyc for cultivated tomato. A recent metabolome database (TOMATOMET, http://metabolites.in/tomato-fruits/) based on MS analysis of mature fruits of 25 cultivars is also available online (Ara et al. 2021).

Ruggieri et al. (2016) provided an excellent example of the integration of transcriptome, metabolome, and protein database information for analysis of a health-related trait. In this research, bioinformatics tools were used to elucidate the ascorbic acid metabolic network in tomato using gene expression analysis combined with data from the UniProt Knowledgebase, the Kyoto Encyclopedia of Genes and

Genomes (KEGG), and the metabolic pathway databases, MetaCyc and LycoCyc. More than 200 genes were found to play roles in the network including biosynthesis, translocation, and recycling.

12 Future Prospects

Tomato has always been at the forefront of studies in genetics, genomics, transcriptomics, proteomics, and metabolomics. As a result, a solid foundation of knowledge about the control of numerous phytochemical traits exists for this crop. Tomato breeders were early adapters of molecular-assisted selection techniques which have greatly facilitated improvement of some traits. In addition, genetic engineering and genome editing tools are now well established in tomato and allow manipulation of traits that are too complex for conventional and molecular breeding. Thus, the time is ripe for an explosion of research aimed at HR traits in tomato. Such research will be aimed not only on improvement of HR traits in fresh and processed tomato for human consumption but also on the development of cultivars for use by the pharmaceutical industry. It is hoped that such advances will help enhance human health and also be available in a fair and impartial manner for those who wish to benefit from them.

Abstract

Vegetables are rich in dietary nutrients, antioxidants, and phytoceuticals that are beneficial to health, thereby contributing to food security and ensuring nutritional security. *Brassica* vegetables are rich in dietary fiber and β-carotene, and most of them are also rich in folate, potassium, and calcium. These crops are also abundant in sulfur compounds, which vary crop by crop and provide distinctive flavor. Presence of specific glucosinolates in *Brassica* vegetables correlates with their anticarcinogenic ability. Vitamin C (cabbage and broccoli), vitamin A (broccoli), β-carotene (orange cauliflower), and anthocyanin are the most important bioactive substances found in *Brassica* vegetables (red cabbage, purple broccoli, purple cauliflower, and purple knol khol). Carotenoids serve a vital role in supporting human health, which has encouraged researchers to develop a deeper understanding of the molecular processes that regulate carotenoid production and accumulation. The *Or* gene is a unique carotenoid gene mutation that generates a high concentration of β-carotene in orange cauliflower's edible curd. The *Or* gene transformants are capable of causing carotenoids accumulation by inducing the formation of large carotenoids sequestering sheets as a carotenoid deposition sink. Anthocyanins are a kind of positively charged flavonoids prevalent in a broad spectrum of vividly colored fruits and vegetables, from orange to blue-violet. The three highest prevalent anthocyanidins are cyanidin, pelargonidin, and delphinidin. Glucosinolates are the most prominent secondary metabolites found in *Brassica* crops. Due to the vast array of health-promoting properties they possess, these glucosinolates play an important role both in plant defense and human health. Higher levels of beneficial glucosinolates (glucoraphanin and glucoiberin) and lower levels or complete elimination of progoitrin are interesting areas for quality breeding in *Brassica* vegetables. Using of association mapping, linkage disequilibrium (LD) mapping, and genome-wide association study (GWAS) was useful for

elucidating the molecular genetic foundation underpinning natural phenotypic variation. Through this several causal allele(s)/loci that had not been found in QTL mapping populations were identified. The technology of gene editing provides essential technological foundations for plant functional gene research and agricultural genetic modification. Apart from sequence analysis and assembling of DNA in *B. oleracea,* research on proteomics, transcriptomics, and metabolomics has revealed patterns of gene expression. This review also presents brief account of societal, political, and regulatory issues besides putting forth future nutritional quality improvement prospects of vegetable Brassicas.

1 Introduction

1.1 Importance of Vegetable Brassicas

Vegetables represent a large group of diverse culinary herb species and are a common component of both traditional and contemporary balanced diets. They are rich in dietary nutrients, antioxidants, and phytoceuticals that are beneficial to health, thereby contributing to food security and ensuring nutritional security. Vegetable crops played a significant role in reducing the prevalence of hidden hunger (i.e*.,* micronutrient deficiency), especially in marginal communities in vulnerable regions. The role of vegetables in maintaining the redox homeostasis of free radicals within the human body is emphasized by health professionals. This physiological process is facilitated by a variety of antioxidants and cofactors found in plant foods. However, inadequate consumption of fruits and vegetables is one of the top ten causes of the high prevalence of noncommunicable diseases (NCDs) worldwide. Low vegetable consumption is associated with anemia (iron deficiency), night blindness (vitamin A deficiency), weight loss, malnutrition-related child mortality, and susceptibility to diseases and disorders. Inadequate intake of vegetables increases chances of being overweight and obese. Vegetables are high in dietary fiber, which is essential for proper bowel movements. Brassicas are rich in glucosinolates (GSLs), which are B-thioglycoside-N-hydroxysulfates and the most abundant class of sulfur-rich secondary metabolites. Their hydrolysis products contribute to plant defense and human health. Anticancer, antibacterial, antifungal, and antioxidant properties are possessed by the GSLs. They exhibit cytotoxic and apoptotic activities that serve as cancer preventatives and reduce the risk of degenerative diseases. Inducing phase 2 enzymes by promoting anti-proliferative activity, GSLs induce phase 2 enzymes. Some glucosinolates contribute to the flavor and taste (along with sugar) of Cole crops, thereby influencing consumer preference. However, some glucosinolates, such as progoitrin, pose health risks due to

their interference with iodine absorption. To combat numerous soil-borne diseases including nematodes, the biofumigant function of GLSs is being investigated.

All of these *Brassica* vegetables are rich in dietary fiber and β-carotene, and most of them are also rich in folate, potassium, and calcium. These crops are also abundant in sulfur compounds, which vary by crop and provide distinctive flavor. These nonstarchy vegetables are regarded as healthful because of their low caloric content (about 19 calories per 12 cup raw amount) and high dietary fiber content (2.5 g per 12 cup piece). It has been shown that the presence of specific glucosinolates in *Brassica* vegetables correlates with their anticarcinogenic ability. Vitamin C (cabbage and broccoli), vitamin A (broccoli), β-carotene (orange cauliflower), and anthocyanin are the most important bioactive substances found in *Brassica* vegetables (red cabbage, purple broccoli, purple cauliflower, and purple knol khol).

Due to the presence of health-promoting antioxidants such as anthocyanins in red cabbage, purple cauliflower, purple broccoli, knol khol, and β-carotene in orange cauliflower, the various hues of *Brassica* crops attracted popular attention. In addition, *Brassica* vegetables are rich in vitamins, carbohydrates, protein, and minerals. Vegetable Brassicas possess natural variety and are capable of interbreeding, therefore there is potential to increase their nutritional value. For breeding high nutraceuticals and bioactive chemicals, such as β-carotene, anthocyanin, and glucosinolates, conventional, molecular, and genetic engineering methods are available (Kalia 2009).

The worldwide area and production of vegetable Brassicas are provided in two groupings, "cabbage and other Brassicas" and "cauliflower and broccoli," since cabbage and cauliflower are important Cole crops. The yearly output of Cole crops is 96.39 million tonnes over an area of 3.77 million hectares. Cabbage and other Brassicas contribute 70.86 million tonnes from an area of 2.53 million ha, while cauliflower and broccoli contribute 25.53 million tonnes from an area of 1.36 million ha. As indicated on worldwide distribution maps, cauliflower is cultivated in 131 nations whereas cabbage is produced in 141 nations (Fig. 1a and b). Nonetheless, China and India account for a disproportionate share of the area and production of both crops. These nations account for approximately 48.3% and 12.99% of the global cabbage and cauliflower acreage, respectively. China and India contribute nearly the same amount to global cauliflower production, with 37.4% and 34.6%, respectively. The collective proportion of these crops ranks 13th in global area and fourth in vegetable crop output. The cabbage and other Brassicas have greater average productivity (29.35 MT/ha) than world average of total vegetable crops (19.69 MT/ha). In case of cauliflower, the global average of production is 18.81 MT/ha. However, in India, the average production from these two well-known vegetable *Brassica* crops (i.e., cabbage and cauliflower) is more than the country's entire vegetable productivity (15.5 t/ha). Notably, the majority of nations have cauliflower and cabbage yields below the worldwide average.

1.2 Nutritional Composition of Vegetable Brassicas

Proximate analysis covers water, carbohydrates, protein, ash, lipid, dietary fiber, sugars, and energy value. Table 1 presents the approximate composition of *Brassica*

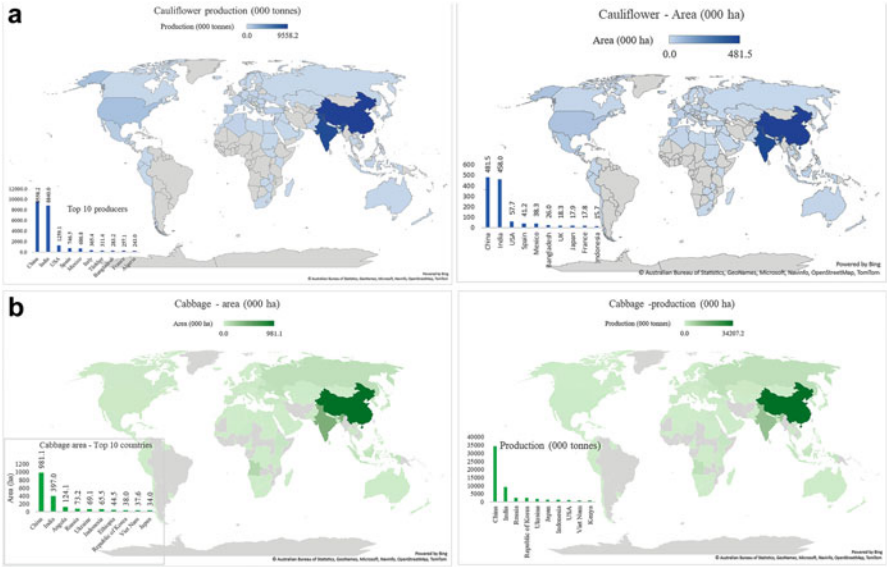

Fig. 1 (**a**) Global distribution of area and production of cauliflower and broccoli. (**b**) Global distribution of area and production of cabbage and other Brassicas. (Data source: FAOSTAT 2020)

vegetables. The vegetable Brassicas contain water in the range of 84.39–93.19%, minimum in knol khol leaves and maximum in Chinese cabbage (Table 1). Proteins are crucial macromolecules and brussels sprouts, red cabbage, collard greens, and mustard leaves are rich sources. Cauliflower curd and cabbage contain 2.15% and 1.36% proteins, respectively. Ash content refers to inorganic matter which remains after complete oxidation of organic matter and water through heating in muffle furnace. Dietary fibers are important for water retention and absorbance of organic materials in gut, thus they play role in bowl regulation, inhibition of fat accumulation, and absorbation of minerals (Jha et al. 2017). All *Brassica* vegetables have higher content of insoluble fibers than soluble fibers. Total dietary fibers in cauliflower curd portion are 3.71% and in cabbage heads it is 2.76%. Carbohydrates content and energy were low in these vegetables. Fructose is prominent sugar in Chinese cabbage, collard, cabbage, and cauliflower while sucrose in brussels sprouts and pak choi leaves.

Carotenoids content in *Brassica* vegetables are presented in Table 2. Mustard leaves, pak choi leaves, and brussels sprouts are the richest sources of lutein which contain 2939 μg, 2655 μg, and 1653 μg per 100 g of fresh weight, respectively. Similarly, β-carotene content in these crops is 2619 μg, 2450 μg, and 360 μg, respectively. Leaves of cauliflower also contain β-carotene (146 μg) but curd portion is almost devoid of it as it is just 1.59 μg/100 g of fresh weight. Among *Brassica* vegetables, mustard leaves (6397 μg/100 g fw) and pak choi leaves (5111 μg) are the richest sources while brussels sprouts (3564 μg/100 g) is top among the Cole vegetables. Red cabbage has higher content of lutein (44.50 μg), b-carotene (31.17 μg), and

total carotenoids (339 μg) than cabbage (green), i.e., 3.98, 20.48, and 273 μg/100 g fw, respectively. Ergocaciferols, α-tocopherol, and phylloquinones are important for human health, and these are reported to be high in cauliflower leaves, mustard leaves, and knol khol leaves.

Brassica vegetables are fair source of thiamin (0.01–0.8 mg per 100 g fw), riboflavin (0.05–0.22 mg), pantothenic acid (0.24–0.62 mg), pyridoxine (0.13–0.96 mg), niacin (0.21–0.86 mg), and biotin (1.08–13.57 μg) (Table 3). Not only the iron deficiency, but the prevalence of anemia is also contributed by deficiencies of folate and vitamin B12. *Brassica* vegetables are good sources of folate, particularly mustard leaves (110 μg), pak choi (98.5 μg), brussels sprouts (85.01 μg), and collard greens (63.46 μg). However, the two prominent Cole vegetables, namely cabbage (46.36 μg) and cauliflower (45.95 μg), were at intermediate level among the *Brassica* vegetables for folate content. Brussels sprouts (89.45 mg), knol khol leaves (71.11 mg), knol khol (64.7 mg), and mustard leaves (60.32 mg) were among the prominent sources of total ascorbic acid in *Brassica* vegetables.

According to the data provided by Longvah et al. (2017) and given in Table 4, *Brassica* plants are a rich source of dietary nutrients, much as other vegetables. Leafy *Brassica* vegetables contain high amount of calcium, iron, manganese, phosphorus, potassium, selenium, and zinc. The richest sources (100 g FW) among these are mustard leaves for calcium (191 mg), magnesium (66.0 mg), and selenium (10.5 μg) and pak choi for iron (3.78 mg) and zinc (0.68 mg). Potassium is highest in Brussels sprouts (639 mg) and the ratio of potassium to sodium in these crops was in the range of 7.41 in cauliflower to 34.52 in Brussels sprouts. Pak choi leaves also have a favorable K:Na ratio (21.06) followed by cabbage (15.55) in *Brassica* vegetables. These ratios are better than the recommended levels of 2.3 potassium to 1 sodium which facilitates the maintenance of normal fluid and neuronal homeostasis.

Amino acids profile of *Brassica* vegetables indicates fair content of two important sulfur-containing amino acids, namely cysteine and methionine (Table 5). Of these crops, pak choi leaves were the richest sources of cysteine (1.12 g/100 g) and methionine (1.96 g/100 g). Brussels sprout (1.34 g), cabbage green (1.06 g), and cauliflower curd (1.01 g) are also rich sources of amino acids among the prominent Cole vegetables. The *Brassica* vegetables contain all the nine essential amino acids and arginine content was present in the range of 4.15–7.63 g per 100 g. These vegetables have healthy profile of amino acids with high digestibility of protein fraction.

Oxalate is one of the antinutritional factors in *Brassica* vegetables (Table 6). In 100 g fresh edible portion, the oxalate content was highest in cauliflower leaves (172 mg) followed by Chinese cabbage (16.55 mg), pak choi leaves (14.35 mg), and brussels sprouts (12.4 mg). Insoluble oxalate has a predominant fraction in cauliflower leaves, Chinese cabbage, pak choi leaves, cabbage, and collard, while in the case of knol khol and mustard leaves the soluble fraction of oxalate is predominant. Phytate was in the range of 11.7–47.33 g in vegetable Brassicas, however, in major crops, namely cabbage and cauliflower it was estimated as 11.7 g and 18.48 g, respectively.

1.3 Rising Significance Due to Long-Term Diseases and Malnutrition

Inadequate consumption of fruits and vegetables ranks among the most common causes of death from noncommunicable diseases (NCDs). The secondary metabolites in these foods contribute as antioxidants in neutralizing the free radicals and balancing the redox homeostasis. Vegetable Brassicas contain antioxidants such as vitamin C, carotenoids, and anthocyanins (purple/red), which directly act as antioxidants. They contain almost all the essential dietary minerals and amino acids, hence they have role in human nutrition. Glucosinolates in Brassicas are major health beneficial compounds. Exploiting natural mutants for new compounds, namely anthocyanins, β-carotene, and chlorophyll, through conventional breeding further enhance the scope of these crops in consumer health. These crops are good sources of Ca, Fe, and Zn, which are crucial for public health. Presence of adequate levels of vitamin C in Brassicas vegetables enhances the bioavailability of dietary minerals.

1.4 Drawbacks of Conventional Breeding and Rationale of Nutrition Genomics

Conventional breeding has played instrumental role in the creation of diverse genetic resources and varieties/hybrids in *Brassica* vegetables. However, it has limitations of handling the complex traits such as nutritional quality traits, because the success of conventional breeding for quality in *Brassica* vegetables depends upon (i) availability of genetic diversity in genepool 1 and 2 for the target trait(s); (ii) chances of linkage drag(s) or transfer of undesirable traits during breeding activities; and (iii) breeding behavior and ease of performing breeding procedure in the crop in target environment. Further, the benefit realization from improved varieties for health compounds depends

on bioavailability and response of the body. Nutrition genomics, on the other hand, describes how genetic diversity impacts the body's natural dietary intake (nutrigenetics) and also how nutrients regulate gene activity (nutrigenomics) (Guasch-Ferré et al. 2018). The term "nutrigenomics" refers to "the study of how diet may affect the expression of genetic information in an individual, and how an individual's genetic makeup affects the metabolism and response to nutrients and other bioactive components in food." This is the definition of "the study of how diet may affect the expression of genetic information in an individual" (Simopoulos 2010). It aims to (i) identify genetic variants that may be crucial for understanding genetic retorts to diet; (ii) identify genes associated with diet-related diseases; (iii) identify effective nutritional strategies to avoid or cure infections; and (iv) enhance population-level nutritional recommendations (Guasch-Ferré et al. 2018). The genetics play a key role in diet-disease relationship. Corella et al. (2013) observed that people who consumed a Mediterranean diet had improved intermediate risks for cardiovascular disease and had a reduced chance of stroke once compared to those who consumed a low-fat diet. Additionally, people who possessed the transcription factor 7–like 2 (TCF7L2) genotype that increases the chance of type 2 diabetes had a decreased probability of contracting the disease. The early stages of common illnesses and the identification of people or population groups that are at risk may assist with the appropriate design of preventative and treatment methods that are successful. The study of nutrition genomics is especially important in plant foods that are hailed as "superfoods" and recognized as important sources of certain compounds that are helpful to human health. *Brassica* vegetables are the only common source of glucosinolates which are in common use. Additionally, anthocyanin and β-carotene content are other compounds in Brassicas which have significance in human health. Thus, nutritional genomics have strong relevance for finding the target population at risk for certain dietary deficiency diseases which can be taken care of through the regular consumption of these compounds, namely glucosinolates, anthocyanin, and β-carotene, through *Brassica* vegetables. The breeding of improved genotypes of *Brassica* vegetables rich in these compounds can serve better to prevent or reduce the prevalence of target disease in human population.

2 Nutritional Elements/Compounds in Vegetable Brassicas

2.1 Chemical Composition: Content and Their Variation

2.1.1 Carotenoids in Vegetable Brassicas

Carotenoids are a category of fat-soluble chemical that gives several plant species their red, orange, and yellow colors. Because of their photoprotective and antioxidant capabilities, all photosynthetic organisms need these natural plant pigments (Lohr 2009). They protect cells from oxidative damage produced by active oxygen elements by neutralizing free radicals in the body. *De novo* synthesis in differentiated plastids of roots, flowers, fruits, and seeds is related to the dispersal of carotenoids in plants (Nagarajan et al. 2017). Chloroplasts (green plastids), chromoplasts (yellow, orange,

and red plastids), amyloplasts (plastids transporting starch), elaioplasts (plastids containing lipids), leucoplasts (colorless plastids), and etioplasts (dark matured chloroplast precursors) are all impacted by the accumulation of oxygen radicals (ROS) (Cazzonelli 2011). Carotenoids provide protection against free radical chain reactions, which may be caused by aging, smoking, pollution, and other forms of stress. A precursor of vitamin A, beta-carotene, as well as lutein and zeaxanthin has been attributed to preserving the macular degeneration from age-related neurodegeneration. In addition to protecting against macular degeneration and cataracts, carotenoids enhance eyesight and eye function. One of the "big four" vitamins, β-carotene deficiency affects billions of people, mostly women and children. Customers overwhelmingly approved of the new colors.

Carotenoids: Contents and Their Variations

The term "carotenoids" refers to a set of more than 750 naturally occurring colors that are created by plants, algae, and other photosynthetic microorganisms. These pigmented molecules are what give many different plant species their yellow, orange, and red colors. The majority of the 40–50 different carotenoid pigments present in the human diet are derived from plant foods, namely fruits and vegetables. α-carotene, beta-carotene, lycopene, lutein, β-cryptoxanthin, and zeaxanthin are the types of carotenoids that are found in foods the most often. It's possible for the body to convert the provitamin A carotenoids alpha-carotene, beta-carotene, and zeaxanthin into retinol (Fig. 1). Because they are incapable of being converted into retinol, lutein, zeaxanthin, and lycopene are classified as nonprovitamin A carotenoids (Fig. 2).

β-carotene Content in *Brassica* Vegetables

Brassica leafy greens are considered as nutritional carotenoid providers (USDA Nutrient Database 2008; Longvah et al. 2017). The carotenoid content of kale is the highest of any leafy vegetable crop, including spinach and collard greens (Sommerburg et al. 1998). Broccoli also reported as important contributor in β-carotene (1300 μg) and lutein ((1839 μg) in North American diet (Rao and Rao 2007). Among *Brassica* vegetables, cauliflower became center of attraction after identification of a natural orange mutant. The orange mutation was found in a normal, white curded autumn crop of *cv.* extra early snowball (self-compatible) growing in Bradform, Ontario, Canada, in 1972 (Crisp et al. 1975). However, the orange color in cauliflower could not attract larger section of consumers except those who could realize its nutritional importance. As a result, β-carotene-biofortified cauliflower varieties are yet to become part of diet for general public depriving them of nutritional benefit. The detailed characteristic features of the exotic parental line "EC625883," a source of *Or* gene, wild white parental line DC 18–19, an improved Indian cauliflower recipient parent, and the biofortified variety Pusa Kesari VitA-1 developed through marker-assisted backcross breeding at ICAR-IARI, New Delhi, India, are given in Table 7.

Chemical Type, Structure, and Biosynthesis Pathway of Carotenoids

Carotenoids possess main constituents that include a polyisoprenoid form, a lengthy double-bond linked network, and almost bilaterally symmetrical around the core

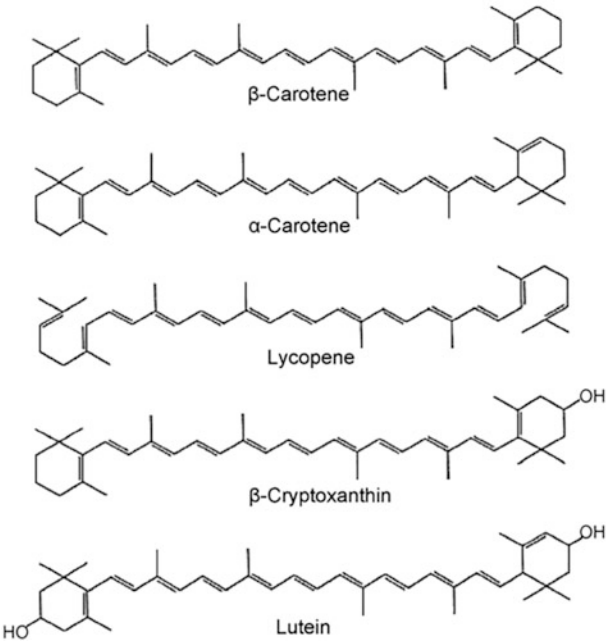

Fig. 2 Structure of some major carotenoids (Rao and Rao 2007)

Table 7 Characteristic features including β-carotene content (ppm) in white and orange cauliflower

	Cauliflower curd			
Source	DC-18-19	Pusa Kesari VitA-1 (orange*)	EC625883 (*Or* gene source genotype)	Targets for breeding program

β-carotene content (ppm)	0.6 ppm	8–12 ppm	18–20 ppm	8–12 ppm

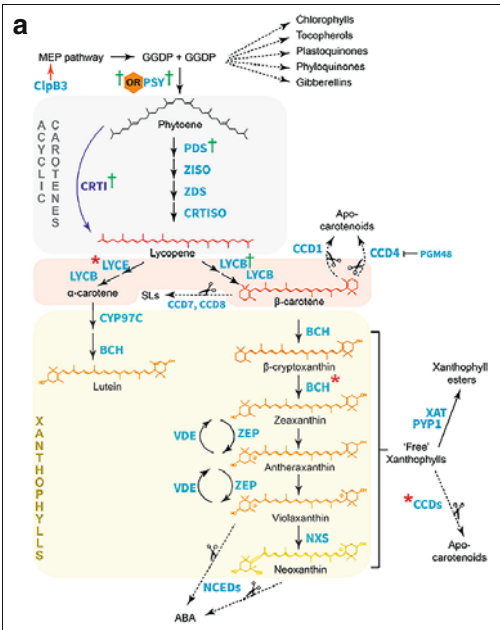
double bond (Britton 1995). Their distinct colors and antioxidant properties are the consequence of I cyclization of the end groups and (ii) the incorporation of oxygen functions into the base structure. Figure 2 depicts many typical carotenoids structures. The presence of conjugated double bonds promotes carotenoids cis-trans isomerization. In spite of the fact that trans-isomers are more prevalent and tenacious

in foods, little is established about the biological importance of carotenoid isomerization for the wellbeing of humans (Rao and Rao 2007).

In plant system, the carotenoid biosynthesis is an essential pathway for want of photosynthetic and protective pigments production, plant stress hormones, and volatile or olfactory pigments for reproductive support (Shumskaya and Wurtzel 2013; Watkins and Pogson 2020). Hence, it is considered as one of the conserved pathways in plant system, however, the accumulation of carotenoids in plants can be increased through two ways, namely: (i) altering conventional pathway as in case of most of crop plants and (ii) creating a sink area (i.e., in cell) to allow accumulation of carotenoids as in case of orange cauliflower. Thus, the present understanding about carotenoids accumulation can be explained through following four mechanisms: (i) altering biosynthesis pathway to direct synthesis for increased flux of a specific carotenoid (β-carotene or lycopene), or (ii) by raising the genes that are expressed early in the carotenoid biosynthetic pathways, substrates for specific carotenoids can be improved. (iii) Creating sink site through conversion of plastids to chromoplast which is a storage site for sequestration of β-carotene (as in case of cauliflower) and (iv) increasing the stability of produced carotenoids through changing localization within the cell or by effectively decreasing the expression enzyme(s) just below the target component known to trigger carotenoids breakdown. Researchers explained two common theories for carotenoid accumulation (or biofortification) as "push" (Sun et al. 2018) and "block" theories (Strobbe et al. 2018). According to Watkins and Pogson (2020), the "push" approach involves upregulating alleles early in the carotenoid biogenesis to drive more carbon into the beta-carotene pathways, whereas the "block" strategy involves suppressing alleles downstream of bioactive components (typically β-carotene or lycopene) or enzymes competing for the same substrate.

Carotenoids serve a vital role in supporting human health, which has encouraged researchers to develop a deeper understanding of the molecular processes that regulate carotenoid production and accumulation. Numerous details have been compiled on the genes involved in carotenoid production (Cunningham and Gantt 1998; Hirschberg 2001; Bramley 2002). Understanding the regulatory components involved in the management of carotenoid accumulation in plants is also crucial for enhancing the carotenoid status of any plant (Cunningham and Gantt 2002). This was shown by the results of Li et al. (2006), who examined carotenoid production by measuring phytoene accumulation in the presence of norflurazon, a potent phytoene desaturase inhibitor. They created calli from immature seedlings of wild-type and *Or* mutant plants (which display a high degree of carotene accumulation in tissues ordinarily devoid of carotenoids). They discovered that the calli generated from seedlings of the wild type were pale green in color. While the calli produced from *Or* seedlings had a vibrant orange hue. In addition, *Or* calli accumulated substantially more carotenoids than their wild-type counterparts. Both the wild type and *Or* calli produced considerable levels of phytoene when treated with norflurazon. The accumulation of phytoene was equivalent between the wild type and *Or* calli, and there were no significant alterations in the expression of carotenogenic genes. Their findings indicated that *Or*-induced β-carotene accumulation is not due to an increase in carotenoid biosynthetic ability.

Watkins and Pogson (2020) elaborated the sequestration mechanism as important mechanism to enhance carotenoid accumulation in plant tissues (Fig. 3a). No difference in gene amplicons from orange and white was observed by Li et al. (2006) and shown as monomorphic pattern (Fig. 3b). Nevertheless, the carotenoid-sequestering ability of the sink tissue has an effect on the number of enzymes linked with carotenoid metabolism, the chloroplast type, and the size of the storage region. The *Or* gene has an effect on the chloroplasts' response toward the source. Initially discovered in



Plant Canonical Carotenoid Biosynthesis and Regulation. GGDP-geranylgeranyl diphosphate, MEP - methylerythritol 4-phosphate (MEP) pathway, CCD-carotenoid cleavage dioxygenase, SL- strigolactone, ABA-abscisic acid, NCEDs -nine-cis-epoxy carotenoid dioxygenases, PGM48 - plastoglobule-localised metallopeptidase 48, OR- ORANGE protein. (Adapted from Li et al. 2006).

Fig. 3 (**a** and **b**) Carotenoid biosynthesis and sequestration in cauliflower (**a**) and amplification of genes in white and orange genotypes (**b**)

cauliflower, this gene provides instructions for making a plastid-localized *DnaJ* cysteine-rich protein (2006). The *Or* gene regulates differentiation process of plastids to chromoplast in cauliflower which is essential to carotene biosynthesis. The process was also demonstrated in different β-carotene-containing melons (Lopez et al. 2008; Tzuri et al. 2015) and transgenic potatoes generated using cauliflower *Or* gene (Chayut et al. 2017; Zhou et al. 2015). Watkins and Pogson (2020) summarized the role of *Or* gene in plastid differentiation or chromoplast biogenesis is not known yet, but the mechanistic studies showed the role of *Or* in two ways: in the plastid, the *Or* protein possesses chaperone action wherein it operates by actively engaging with PSY to posttranscriptionally control its activity (Chayut et al. 2017; Welsch et al. 2018).

PSY is an important regulator and rate-limiting step in the carotenogenesis pathway. The stroma contains both an active membrane-bound and an inactive soluble form (Lätari et al. 2015; Watkins and Pogson 2020). Zhou et al. (2015) may have discovered the "*Or – PSY*" system, in which the *Or* protein interacts with PSY to improve membrane attachment and enzyme activation. It also keeps PSY folded properly, decreasing turnover through the Clp protease complex (Welsch et al. 2018). Because PSY is a rate-limiting step in numerous biological processes, this sheds light on the increase in carotene caused by *Or* genetic alteration. Furthermore, *Or* prevents additional carotenoid metabolism by inhibiting hydroxylation and/or degradation (Chayut et al. 2017).

Orange outnumbers white, although orange individuals come in a variety of shades. As a consequence of this, it would seem that the *Or* gene regulates a number of different cellular processes, having an effect on a great deal of other genes and proteins. As a result of the additional phenotypic alterations that the *Or* mutant carries, it has a pleiotropic influence on the development and growth of the plant. Plants with the dominant homozygous *Or* gene (*OrOr*) mature later and weigh much less than plants with the heterozygous *Or* gene (*Oror*), which matured later than the homozygous recessive gene (*oror*). Homozygous plants produce small, stunted curds with secondary leaves. These plants are often referred to as abnormal. The *Or* gene also promotes petiole elongation (through the *BoeRF1* genes), delays flowering, and decreases flowering shoot growth. It also gives the shoot meristem, stem pith, and vasculature at the base of the petioles an orange color.

In this pathway, plastidial methylerythritol 4-phosphate (MEP) pathway produces geranylgeranyl diphosphate (GGDP) which serves as substrate for phytoene biosynthesis (Ruiz-Sola et al. 2016). The phytoene is converted into β-carotene *via* series of desaturation and isomerization reactions (Fig. 1). In cauliflower, the pathway genes did not show any polymorphism between white and orange curding phenotypes, highlighting the conserved nature of the pathway. Here, Li et al. (2003) could establish the difference between two phenotypes, which was due to genesis of site of storage (i.e., chromoplast) in place of plastids and leucoplast in orange cauliflower. Thus, the β-carotene accumulation in orange cauliflower follows a different pathway than the conventional mechanism in other crop plants.

Plastids: Site of Carotenoids Synthesis

Carotenoids are synthesized from scratch in plastids. They are concentrated in green and nongreen tissue chloroplasts and chromoplasts, respectively. This mechanism

appears to be plant specific and substantially retained among plant species. The orange color of cauliflower is due to the existence of enormous sheet-like components in chromoplasts, but not chloroplasts (Lu et al. 2006). The orange (*Or*) gene allows curd tissue leucoplasts to convert into chromoplasts, resulting in orange curds. Plastid fusion and/or translocation factor (*BoPftf*) engages in vesicle fusion and remodels plastid internal membranes during the chloroplast-to-chromoplast transition in pepper. Figure 4 depicts the pathway of plastid-to-chromoplast conversion for β-carotene accumulation in orange cauliflower.

The *Or* gene mutation results from the insertion of a copia-like long terminal repeat retrotransposon (LTR) (4.7 kb) into exon 3 of the *Or* allele. Therefore, the *Or* mutation in cauliflower is a mutation with an obtain for β-carotene accumulation. In-frame deletion (*BoOR-Del* and *BoOR-LD*) and insertion (*BoOR-Ins*) occurred from transposition introduction into the *BoOR* region (Lu et al. 2006).

Or gene encodes a protein that is linked with the plastid and has a DnaJ cysteine-rich zinc finger motif. This protein is crucial for substantial carotenoids being deposited in tissues that are ordinarily low in coloration. *Or* has a functional role in the transformation of proplastids or other noncolored plastids into chromoplasts, providing a sink for carotenoids sequestration and storage (Zhou et al. 2008). As a result, rather than directly directing carotenoid production, the *Or* gene controls carotenoid accumulation by encouraging the growth of chromoplasts, so providing a metabolic sink to sequester and deposit carotenoids. Li et al. (2006) presented the following five evidences regarding the role of *Or* in chromoplast formation.

Lu et al. (2006) used the *Or* transgene to alter white cauliflower, revealing that Or plays a role in accelerating the conversion of proplastids and other noncolored plastids into chromoplasts for carotenoid synthesis. Furthermore, Lopez et al. (2008) discovered that the *Or* transgene expression in transgenic potatoes did not result in substantial changes at the transcript level of endogenous carotenoid biosynthetic genes and was not directly involved in regulating carotenoid synthesis. It suggested the creation of

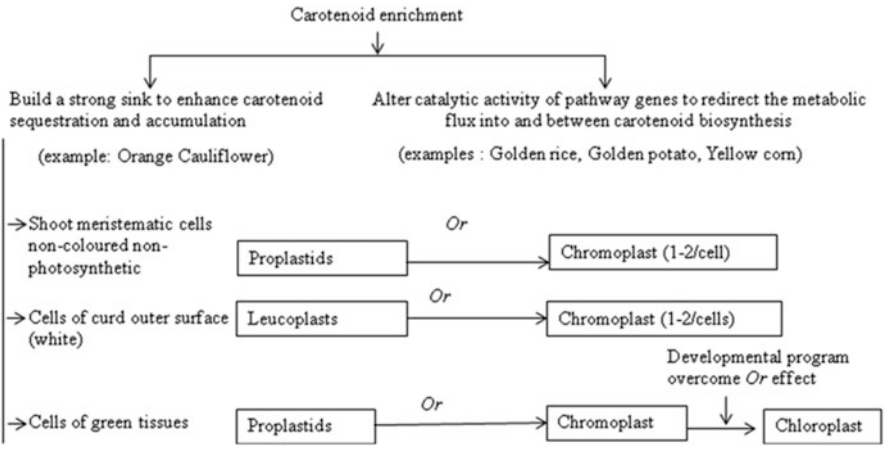

Fig. 4 Carotenoid biosynthesis processes in plants with special reference to β-carotene accumulation in orange cauliflower

chromoplasts with carotenoid sequestering structures in a heterologous system. As a result, both studies on transgenic cauliflower curd and potato tubers show that the *Or*-induced rise in carotenoid is linked to the formation of a metabolic sink.

Lopez et al. (2008) created a transgenic potato for the *Or* gene and discovered three novel metabolite intermediates of carotenoid pathways, namely phytoene, phytofluorene, and zea-carotene. Desaturation processes were restricted after the expression of the *Or* transgene. Furthermore, compared to controls, long-term cold storage boosted the carotenoid concentration of *Or* transgenic tubers tenfold. These structures were not seen in the tubers of carotenoids-rich potato types. These results show that the *Or* gene controls chromoplast differentiation and that chromoplast production regulation has a major impact on carotenoids accumulation in plants.

The *Or* protein participates in both the posttranslational regulatory oversight of phytoene synthase (PSY) that performs a frequent role in the production of carotenoids, and the maintenance of PSY proteostasis with the assistance of the plastid Clp protease network (Welsch et al. 2020). Proteostasis is the regulatory network for a balanced and functional proteome in this scenario. This network consists of competing and interrelated biological processes inside cells that govern extracellular protein production, folding, trafficking, and degradation. With 15 nuclear-encoded members and one plastid-encoded member, the Clp (caseinolytic protease) system in *Arabidopsis* is the most abundant and sophisticated soluble protease system in the plastid (Olinares et al. 2011).

Welsch et al. (2020) exploited these three differently spliced transcripts to identify three cauliflower *Or* mutant variants. Except for *BoOR-LD*, all versions produced *OR* dimers. The deletion of the first of two adjacent transmembrane domains in *BoOR-LD* inhibited *Or* dimerization and shifted the C-terminal zinc finger domain to the opposite side of the membrane. While splicing does not change the N-terminus of *BoOR*, which mediates its interaction with *PSY, BoOR* variants continue to interact with *PSY. BoOR-Del* and *BoOR-Ins* both increased BoOR protein levels in comparison to BoOR-wt, although *BoOR-Ins* did so more significantly. Furthermore, the research thus far provides the following evidence to indicate the role of the *Or* gene in carotenoids accumulation through chromoplast formation.

1. The *Or* has a considerable impact on carotenoids accumulation in proplastid- and leucoplast-rich tissues such as apical shoot meristems and the curd's outer perimeter.
2. The *ORWT* protein has been associated to nongreen plastids, and the gene is highly expressed in these tissues.
3. The existence of *Or* causes the formation of one or two large chromoplasts in each afflicted cell. It was determined that chromosomes are nothing but plastids in orange cells.
4. The *Or* mutant exhibits enhanced production of the *Pftf* gene's cauliflower homolog (*BoPftf*), which is recognized to be important in red pepper chromoplast formation.
5. Similar to the *Arabidopsis* plastid division mutant *arc6*, which has just one or two large chloroplasts in the shoot's apical meristem, *Or* halts plastid division. In

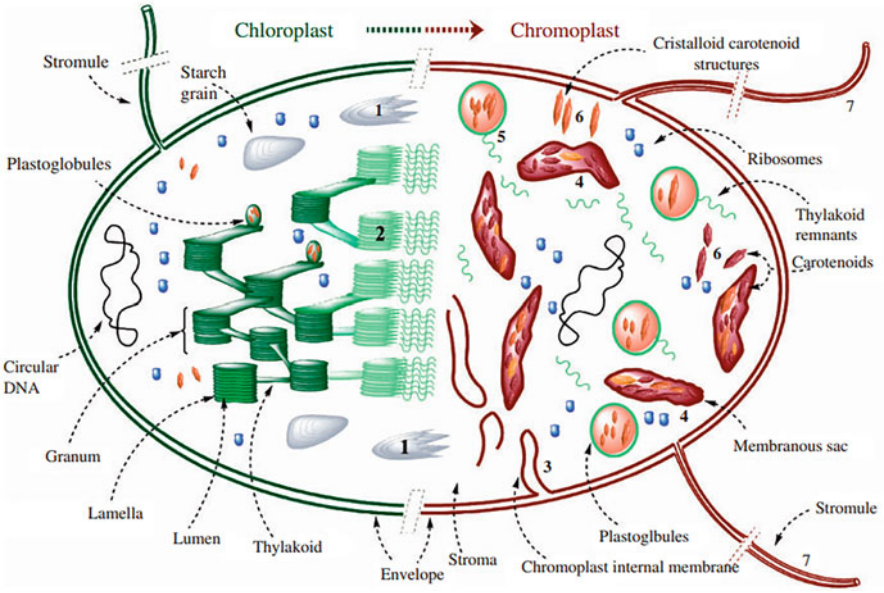

Fig. 5 The chloroplast-chromoplast transition is shown schematically. The scheme depicts the breakdown of starch granules (1) and grana and thylakoids (2); the synthesis of new membrane structures from the plastid's inner membrane envelope (3), leading to the formation of carotenoid-rich membranous sacs (4); the increase in the number and size of plastoglobules (5); the appearance of carotenoid-containing crystalloids (6); and the increase in the number of protrusions (7)

contrast to the arc6 mutant, which also has 1–2 large chloroplasts in leaf mesophyll cells, the *Or* mutant has a normal number of chloroplasts in its leaves, demonstrating that leaf growth mitigates the effects of *Or*. Figure 5 depicts the chloroplast-chromoplast transformation.

Medicinal/Physiological Properties and Functions of Carotenoids in Relation to Human Health

Carotenoids play a crucial part in the prevention of diseases as well as the upkeep of physical wellbeing. Many carotenoids, in addition to being potent antioxidants, also provide vitamin A to the body. Carotenoids' health benefits were investigated by Rao and Rao (2007). They evaluated the prophylactic effect of carotenoids in chronic disorders, as shown in Fig. 6, as well as their biological activities. Evidence supports a relationship between higher tissue concentrations of carotenoids in the human body and a reduced risk of chronic diseases, as well as a lower incidence of eye issues (Ribaya-Mercado and Blumberg 2004). It has been argued that carotenoids' antioxidant capacities are the principal method through which they exert their beneficial effects. According to Rao and Rao (2007), these phytochemicals also modulate gene expression, immune response, and Stage I and Stage II drug-metabolizing activities. β-carotene and β-cryptoxanthin have the added advantage of converting to vitamin A, which is essential in preventing disease and beginning.

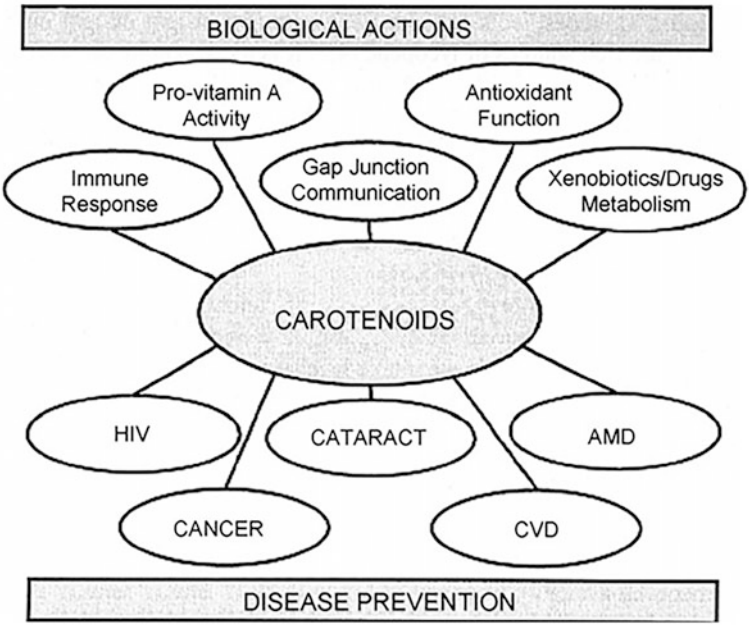

Fig. 6 Carotenoids'contribution to the fight against chronic diseases. (Adapted from Rao and Rao 2007)

However, beta-carotene increased the UVA-induced activation of hem oxygenase-1 at a dosage of 0.2 M, which indicates that it has a prooxidant impact (Obermuller-Jevic et al. 1999). In colon cancer and leukemia cells that were cultivated *in vitro*, the formation of oxygen radical (ROS) species as well as the levels of oxidized glutathione was increased when beta-carotene was present at a concentration of 10 M. Paolini et al. (2001) found that rats had a prooxidant effect and enhanced oxidative stress activity, as well as increased phase 1 enzyme activity in the liver, kidney, and gut. The Alpha-Tocopherol Beta-Carotene Cancer Prevention Study Sample (ATBCPSS) from 1994 found that supplementation with β-carotene at pharmaceutical levels led to an increased risk of lung cancer in smokers. This study also found an increased risk of death from cardiovascular disease in a sample of people who smoke, former smokers, and asbestos-exposed individuals (Omenn et al. 1996). Thus, the findings suggest that a balanced intake of β-carotene is necessary to gain the health advantages of this vitamin while avoiding the negative consequences of high amounts.

2.1.2 Anthocyanins in Vegetable Brassicas

Anthocyanins are a kind of positively charged flavonoids prevalent in a broad spectrum of vividly colored fruits and vegetables, from orange to blue-violet. The three highest prevalent anthocyanidins are cyanidin, pelargonidin, and delphinidin. Others include malvidin, peonidin, pelargonidin, and petunidin. Vegetable Brassicas

has richness of genetic resource potential for anthocyanins (Jahangir et al. 2009). Particularly red cabbage and purple cauliflower are rich sources of anthocyanins. Cauliflower and red cabbage anthocyanin profiles differed: cyanidin-3, 5-diglucoside was absent in cauliflower, but plentiful in red cabbage, coupled with the characteristic anthocyanin of the *Brassica* genus (cyanidin-3-sophoroside-5-glucoside). The p-coumaryl and feruloyl esterified forms of cyanidin-3-sophoroside-5-glucoside predominated in cauliflower, but the sinapyl ester predominated in red cabbage (Scalzo et al. 2008). Sicilian violet cauliflower landraces had less total anthocyanins, lacked cyanidin-3,5-diglucoside, and contained an isomer of cyanidin-3,5-sophoroside-5-glucoside present in red cabbage.

Anthocyanin Content

The prominent anthocyanins and reported range in *Brassica* vegetables is as below:

a) Cabbage: 1.82 mg/g FW: 36: anthocyanins: $C_{33}H_{41}O_{21}$+ (Cyanidin-3-diglucoside-5-glucose)
b) Cauliflower: 3.75 mg/g FW: $C_{30}H_{33}O_{19+}$ (cyanidin-3-(coumaryl-caffeyl) glucoside-5-(malonyl) glucoside)
c) Kohlrabi: 0.63 mg/g FW: 12: $C_{33}H_{41}O_{21}$+ (cyanidin-3-(sinapoyl)-diglucoside-5-glucoside); $C_{42}H_{47}O_{22+}$ (cyanidin-3-(caffeoyl)-p-coumaroyl-(sinapoyl) diglucoside-5-glucoside)
d) Sicilian purple: 0.48 mg/g FW: $C_{30}H_{33}O_{19+}$ (cyanidin-3-(coumaryl-caffeyl) glucoside-5-(malonyl)glucoside)

The varieties developed in vegetable Brassicas for anthocyanin content are given in Table 8.

The differences in Sicilian purple and purple cauliflower are presented hereafter (Fig. 7):

Chemical Type, Structure, and Biosynthesis Pathway of Anthocyanin

The plant anthocyanin production system is a network that has been retained in various plant species (Fig. 8). *MYB-bHLH-WD40* (MBW) is a ternary transcriptional activation complex comprising of *MYB* proteins, basic helix-loop-helix (*bHLH*) proteins, and a WD40 protein that controls structural gene expression in anthocyanin biosynthesis. Anthocyanin is governed by a single semidominant gene, *Pr*, in purple cauliflower. *Pr* expresses a tissue-specific *R2R3 MYB* transcription factor, which matches the mutant's abnormal anthocyanin accumulation pattern. Upregulation of Pr preferentially activated a *bHLH TF* and a subset of anthocyanin structural genes expressing *F3'H*, *LLDOX,* and *DFR,* to produce ectopic pigment accumulation in purple cauliflower. *Pr* gene activation is facilitated by Harbinger DNA transposon insertion into the 370 kb proximal promoter sequences of the *BoMYB2* genes. This changes the plant's phenotype. The purple sepal feature of purple broccoli is inherited by a single major gene and two secondary loci. Potential genes for the purple hypocotyl color have been discovered as *BoMYC1.1, BoMYC1.2, BoMYB114, BoTT8, BoPAL, BoDFR,* and *BoTTG1*. *BOTT8* expression was much

Table 8 Varieties developed in vegetable Brassicas for anthocyanin content

Crop	Anthocyanin content (mg/100 g FW)	Varieties of anthocyanin content	India
Cauliflower	375.0	Graffiti (3.75 mg/g FW), purple Cape, Violet Queen, Violetta Italia	KTPCF-1 (48 mg/100 g FW)
Sicilian purple	48.0	Sicilian purple	PC-1 (a line) (40 mg/100 gFW)
Cabbage	111.0.0–178.0	Premiero (1.09 mg/g), Cairo (0.8–1.53 mg/g), Red Express (1.82 mg/g), Royale (1.4 mg/g), Cardinal (0.51 mg/g), Azurro (1.44 mg/g), Bandolero (1.65 mg/g), Buscaro (1.70 mg/g)	Kinner Red Pusa Red Cabbage Hybrid-1 (7.9 mg/1gg g FW)
Purple kale	35.5	Red Dove	–
Broccoli	30	Viola, early purple sprouting, Claret	Palam Vichitra
Kohlrabi	63	Purple Vienna, Kolibri, Rapid

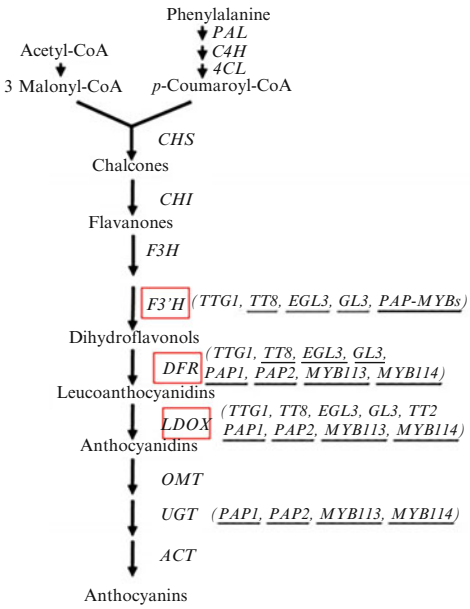

Fig. 8 Anthocyanin biosynthesis pathway in plants

greater in purple hypocotyls than in green hypocotyls. The structural genes *CHS, DFR, F3H, F3OH, GST,* and *LDOX* were constitutively upregulated at all phases of vegetative development in red types. Along with the upregulation of genes associated, the transcript levels of a bHLH gene, *BoTT8*, and a MYB transcription factor, *BoMYB2*, both went up at the same time. Furthermore, the downregulation of BoMYB3 demonstrates an equilibrium in MYB gene group components' modulation of anthocyanin production in red cabbage. The modification or deletion of the promoter of BoMYBL2-1 resulted in a purple tint in cabbage. Purple kale (*Brassica oleracea* var. *acephala* f. *tricolor*) contains total anthocyanin (1.73 mg/g), giving the mutant phenotype a vibrant purple coloration. All anthocyanin biosynthesis genes were transcribed at considerably greater quantities in the purple genotype compared to the white genotype, particularly DFR and ANS, which were hardly detectable in the white germplasm. *BoPAP1*, a *BoMYB1*, was shown to be very upregulated in purple kale and to be a necessary component for the abundant anthocyanin accumulation produced by low temperature (Zhang et al. 2012). Although *BoPAP1* was activated by light factor, the majority of anthocyanin biosynthesis genes and two transcription factors (*BoTT8* and *BoPAP2*) were considerably upregulated in the purple tissues compared to the colorless tissues in the two cultivars of knol khol. In

both cultivars' purple peel, transcript levels for late biosynthetic genes, in notably *BoF3′H, BoLDOX, BoDFR,* and *BoGST*, are significant, but hardly perceptible in other tissues (Zhang et al. 2015). Despite the expression of *BoMYBL2.2* (a negative regulator of anthocyanins) being in the opposite direction, it was discovered that *BoPAP2* and *BoTT8* were more expressed in the purple cultivar's peel than its green counterpart.

The transcriptional control of three main genes – basic helix loop helix (bHLH) proteins, WD40 proteins, and R2R3MYB transcription factors – appears to be this system's key regulatory mechanism (Broun 2005; Gonzalez et al. 2008). These genes are *bHLH* proteins (Glabra3, Enhancer of Glabra3, and Transparent Test8), *MYB113*, *MYB114*, *PAP1* (Production of Anthocyanin Pigment1), and *PAP2* (Production of Anthocyanin Pigment2) as well as the anthocyanin accumulation in *Arabidopsis* vegetative tissues (Nesi et al. 2000). The MYB transcription factor is essential for anthocyanin formation because it controls the transcription of structural genes. The *R2R-MYB* transcription factor is naturally encoded by the *Pr* gene mutation found in cauliflower, and it expresses tissue specifically (Chiu et al. 2010). They discovered that the variance in anthocyanin deposition in the 'Graffiti' cauliflower is regulated by the insertion of the Harbinger DNA transposon into the proximal promoter region of the *Pr-D* gene. (i) The kind of visible anthocyanins and (ii) the content value for case-by-case genetic investigations vary among botanical species and genotypes. MYB factors need a bHLH to control anthocyanin production in certain plants, such as *Arabidopsis* (Gonzalez et al. 2008), while in others, such as maize, they may activate transcription independently (Grotewold et al. 2000).

Medicinal/Physiological Properties and Functions of Anthocyanins in Relation to Human Health

The purple color is determined by anthocyanins, a specific type of flavonoid molecules with key biological processes in defending crops from both biotic and abiotic conditions. In addition, they contain antioxidant and anti-inflammatory characteristics that may lessen the risk of various chronic diseases in humans, including as cancer. Research indicates that anthocyanins have a role in cardiovascular disease, some forms of cancer, diabetes, disorders, osteoporosis, and allergies (Fernandes et al. 2019). Lee and Lee (2019) investigated blackcurrant extract and found it to be efficient in decreasing the pro-inflammatory M1 polarization of mouse bone marrow–derived macrophages and human THP-1 cells in response to LPS stimulation of murine macrophages. Furthermore, anthocyanins may decrease carbohydrate digestion and glucose absorption. Pancreatic lipase, β-glucosidase, and α-amylase inhibitory activity is associated with decreased gastrointestinal fat and sugar absorption. These substances combat obesity and type 2 diabetes (Castro-Acosta et al. 2016). Charron et al. (2007) examined the anthocyanin absorption rate of red cabbage in 12 volunteer groups by giving them 100, 200, and 300 g of steamed red cabbage (containing 1.38 mol anthocyanins per gram of cabbage) containing 1.38 mol anthocyanins per gram of cabbage in order to determine how well the anthocyanins were absorbed into the bloodstream. Out of 6 nonacylated and 30 acylated anthocyanins, they discovered three nonacylated, eight acylated, and

four metabolites in red cabbage. Nonacylated anthocyanins were recovered in urine at a rate four times that of acylated anthocyanins.

2.1.3 Glucosinolates in Vegetable Brassicas

Glucosinolates, also known as GSLs, are the most prominent secondary metabolites found in *Brassica* crops. Due to the vast array of health-promoting properties they possess, these glucosinolates serve an important role in both plant defense and human health. The GSLs also influence consumer preference due to their role in taste and flavor. These compounds received a lot of attention due to their perceived association with health-promoting properties (Traka and Mithen 2009; Halkier 2016). These properties are associated with *Brassica* vegetables irrespective of the kind of species, however, broccoli got special attention due to anticancer properties of "sulforaphane," a degradation product from GSLs "glucoiberin and glucoraphanin," most prominent in broccoli (Zhang et al. 1994). The breakdown products of certain specific glucosinolates possess properties which act against carcinogenesis and metastasis and also impart other health benefits through anti-inflammatory (Fahey et al. 2001; Verkerk et al. 2009), antibacterial (*Helicobacter pylori*) (Mithen et al. 2000), antifungal and antioxidant properties (Traka and Mithen 2009; Connolly et al. 2021). The GSLs reduce the risk of myocardial infraction and play role in the protection of cells from redox imbalance. These are responsible for characteristics flavor and contribute in taste (with sugar) of *Brassica* crops. Although *Brassica* vegetables also contain other health beneficial constituents, such as carotenoids, minerals, phenolics, and vitamins, but their predominant biological activity is due to glucosinolates. Some glucosinolates in oilseed Brassicas behave as growth inhibitory factors and considered as antinutritional factors (Mailer et al. 2008). Sinigrin and progoitrin are also responsible for the bitter flavor of the crucifers which influence consumers' acceptance and affect public health (particularly progoitrin). Vegetable Brassicas are known for their distinctive flavor, which is due in part to the metabolic by-products of the chemicals; however, some studies indicate little correlation between glucosinolates and flavor as in the case of broccoli (Baik et al. 2003). The GSLs are useful for soil biofumigation against various soilborne pathogens and nematodes.

These breakdown products can include isothiocyanates, thiocyanates, nitriles, epithionitriles, and oxazolidines depending on the pH levels, the presence of ferrous ions, the amount and activity of epithiospecifier protein, and the substrate. Other possible breakdown products include thiocyanates, nitriles, and epithionitriles (ESP). At neutral pH, the primary degradation component of GSL is isothiocyanates, however, at lower pH, nitriles predominate. Thiocyanates are synthesized from allyl-, benzyl-, and 4-(methylthio) butyl GSLs. There is a possibility that these substances act as inhibitors of iodine absorption in the thyroid, and elevated levels may be associated with adverse consequences on the liver (Traka 2016). The alkenyl GSLs give rise to epithioalkanes in the presence of epithiospecifier protein (Lambrix et al. 2001). Myrosinase and epithiospecifier proteins, in particular, have a lower thermal tolerance (70 and 60 degrees Celsius, respectively) (Matusheski et al. 2004). Thus, the cooking processes have been extensively researched to maximize the higher recovery of ITCs (Bongoni et al. 2014; Dosz and Jeffery 2013; Rungapamestry et al. 2006).

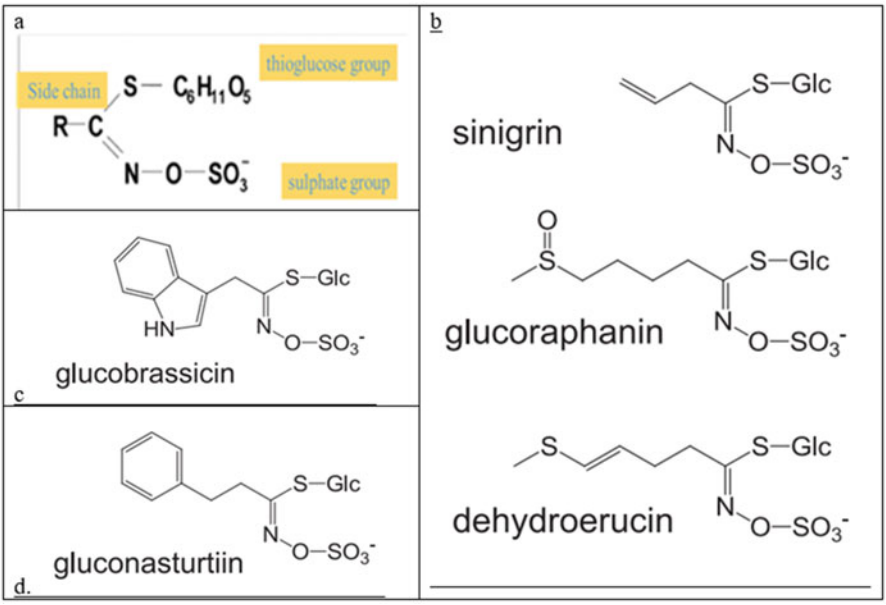

Fig. 9 Basic chemical structure of glucosinolates (**a**), indole (**b**), aromatic (**c**) and aliphatic (**d**)

The glucosinolates have a variable side chain (R), β-thioglucose moiety, and a sulfonated oxime moiety, that is produced from an amino acid as its constituent parts (Fig. 9). Basic structure of GLSs comprises a glucose residue, a sulfate group, and a variable aglycone. The sulfate group is normally balanced by a (potassium) cation. The side chain R (amino acid derived) determines whether the GLS is aliphatic (nonaromatic), indole (very stable, cyclic), and aromatic. Giamoustaris and Mithen (1996) postulated that the indolic GSLs from tryptophan, aliphatic GSLs are originated from methionine and aromatic GSLs derived from phenylalanine or tyrosine. All four of these amino acids – alanine, leucine, isoleucine, and valine – are precursors to aliphatic glucosinolates. In *Brassica* plants, methionine-derived glucosinolates are the most common (making up about half of all glucosinolates), and the breakdown products of these molecules have been shown to have metabolic activity (Mithen 2003). However, the biological activity of phenylethyl- and benzyl-GSLs (aromatic GSL breakdown metabolites) and indole GSLs have also been documented. In 1956, the compositions of sinalbin and sinigrin were the initial glucosinolates to be determined (Ettlinger and Lundeen 1956). In 1961, the word "glucosinolate" was introduced for the first time (Ettlinger and Kjaer 1968).

Glucosinolates

In 16 dicotyledonous plant families, about 136 distinct GLs structures have been identified (Clarke 2010; Agerbirk and Olsen 2012). Glucosinolates are prevalent in plants because the sugar component is easily modified by a variety of side chain modifications, *viz*. alkenylation, hydroxylation, S-oxygenation, etc. and acyl

conjugation (Halkier 2016). There are significant quantities of up to four unique glucosinolates in every plant species (Fahey et al. 2001). Investigating families other than the Brassicaceae regularly yields new data, but there is no database that tracks these studies. Bennett et al. (2004) have studied Brassicaceae plants previously.

The glucosinolate concentration of a number of *Brassica* vegetable tissues is approximately 1% of dry weight (DW), whereas it has been observed to reach 10% in the seeds. The discovery of large amounts of glucoraphanin (4-[methylsulfinyl] butyl isothiocyanate) in broccoli drew attention among cultivated Brassicas. The concentrations of the most prevalent glucosinolates are listed in Table 9. Brassicas contain the glucosinolates isothiocyanate (cauliflower, cabbage, and knol khol), sulforaphane (broccoli – most essential in cancer prevention), glucobrassicin (cabbage and broccoli), gluconasturtiin (cabbage), indole-3-carbinol (cabbage), and sinigrin (brussels sprout and broccoli). 4-(methylthio) butyl glucosinolate, 3-(methylthio) propylglucosinolate, and 2-phenethylglucosinolate were the predominant glucosinolates in kohlrabi (Macleod and Macleod 1990). Breeding cultivars, which produce a large amount of glucosinolates, lead to the production of sulforaphane compared to those that produce nitriles. Introgressed *Brassica villosa* chromosome segments led to an increase in glucoiberin levels. The introgressed region also determined whether hydrolysis produces iberin or sulforaphane. These findings suggest that broccoli with a high concentration of glucosinolates may be beneficial for increasing consumption.

Table 9 Major glucosinolates (GLSs) in commercial *Brassica* vegetables

Crucifer vegetables	Glucosinolates groups	Aliphatic glucosinolates (GLS) Range (mg/100 g fw)
Green broccoli	Glucoraphanin	11.6–34
Purple broccoli	Glucoraphanin	6.7
White cauliflower	Glucoiberin	0.5–6.6
Green cauliflower	Glucoiberin	1.2–27.7
Purple cauliflower	Glucoraphanin	11.6
	Glucoiberin	4.6
Red cabbage	Glucoraphanin	4.0–18.2
	Glucoiberin	4.0–13.6
	Sinigrin	3.0–16.7
Savoy cabbage	Glucoiberin	10.4–21.2
	Sinigrin	15.5–18.6
Brussels sprouts	Sinigrin	22.0–25.3
	Glucoiberin	6.4–13.9
Kale	Sinigrin	2.2–22.7
	Glucoiberin	13.4–16.0

Adapted from Verkerk et al. (2009)

Glucosinolate Content in Some Tissues

Fahey et al. (2001) collated information on GSLs for a range of species, but did not provide numerical data. Brassicaceae family members of high commercial value, including as cauliflower, broccoli, cabbage, brussels sprouts, and root crops like as radish and turnip, are the GSL domesticated plants that have been studied the most thoroughly. McNaughton and Marks (2003) and Verkerk et al. (2009) established a database including the total GSLs of raw, frozen, boiling, and cooked cruciferous vegetables. The principal GSLs, GSL content, and influence of cruciferous vegetables on human health were examined. Bennett et al. (2004) undertook an exhaustive examination of the GSLs found in seed. Based on GSL content, our exhaustive screening of seeds revealed the following categories:

(i) Arylaliphatic GSLs characterized by widespread substitution (such as 3,4-dimethoxybenzyl, 3,4,5-trimethoxybenzyl GLs and 3, 4-dihydroxybenzyl).
(ii) There are only aliphatic GLs with lengthy chain lengths.
(iii) Only aliphatic GLs with shorter (C-3) to medium (C-4) chain lengths are allowed.
(iv) There can only be simple arylaliphatic GSLs (2-phenylethyl (21), benzyl (20), and 4-hydroxybenzyl (22), GSLs).

The prominent glucosinolates in *Brassica* vegetables are mentioned in Fig. 10.

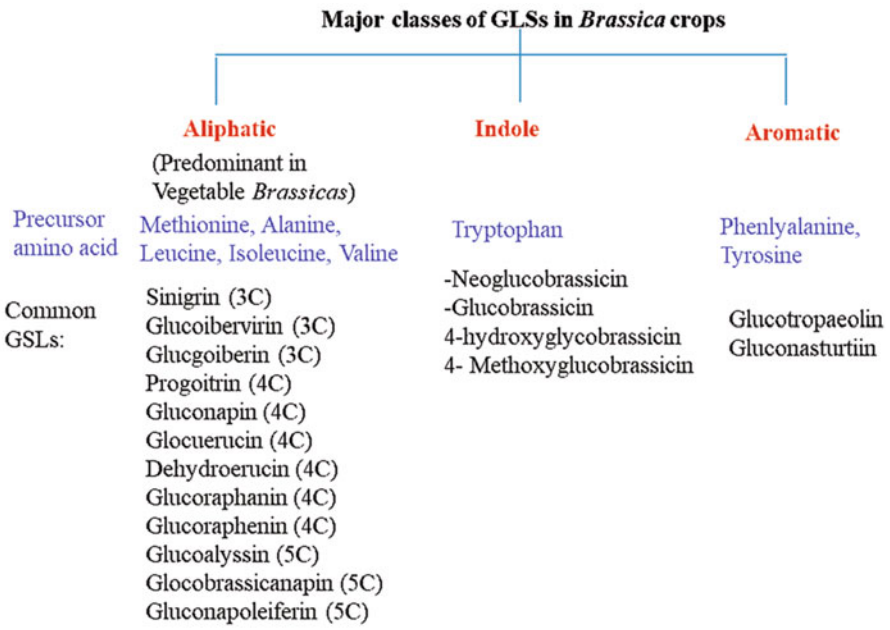

Fig. 10 Major glucosinolates in *Brassica* vegetables

Factors Determining Glucosinolates Content

The GL content of plant cultivars, individual plants, and plant parts is controlled by genetics, the environment, and plant nutrients. The greatest concentration of GLs is found in the plant's juvenile tissues. Identification and determination of phytochemical composition in plant tissues such as seed and leaf give a full understanding of these substances' potent bioactive application in agriculture as potentially insecticides and as functional nutraceuticals in animal and human diets (Berhow et al. 2013). Specialized extraction methods may be capable of separating a few GLs from acceptable plant material, but chemical synthesis is often required to get large amounts of GLs (Rollin and Tatibouët 2011). These variables impact the variation of glucosinolates:

i. Plant species: Each plant species in the Brassicaceae family has a distinct GLS profile made up of major GLSs. It also varies across genotypes within a species. Broccoli GLS contributors include *Brassica villosa*, *Brassica atlantica*, and *Brassica drepanensis*.
ii. Broccoli GLS include: Glucoraphanin: 2.2–18.4 mmol g^{-1} Aliphatic: 3.0–24.1 mmol g^{-1} Indolic: 1.0–4.9 mmol g^{-1}.
iii. Plant organ or part: Although the great majority of GLSs are present in all plant organs, the concentration and content of GLSs may vary significantly and alter during plant development. The concentration of GLSs in the roots of many Brassicas was higher than in the shoots.
iv. 4-mercaptobutylglucosinolate and 4-methylsulfinylbutylglucosinolate are found in the leaves and flowers of *Eruca* species, respectively.
v. Plant age: From transplanting to harvesting, the GLS concentration in pak choi and potherb mustard dropped. Sinigrin levels decreased from seedling to early flowering, increased during late flowering, and then decreased until seed maturity. It was higher in immature, less developed broccoli heads than in well-established broccoli heads due to a decrease in indole GLSs (Fig. 11).
vi. Plant development stages: GLS concentration was highest in the second development stage (42 DAT) with low sulfur fertilization and lowest in the third development stage with rich sulfur fertilization; afterward, GLS concentration decreased until the overmaturation stage. Sulforaphane (SFN), a GLS glucoraphanin breakdown product, flourished in broccoli until the seventh commercial maturity stage.
vii. Other (nongenetic) variables include: Soil, climate, damage, and fertilization, as well as determination processes, and so on.

Chemical Type, Structure, and Biosynthesis Pathway of Glucosinolates

The GSLs are most investigated pathways and represent a successful example of introgression of genomic regions (QTLs) for biofortification of beneficial GSLs (glucoraphanin and glucoiberin) in broccoli from a wild species *Brassica villosa* (Faulkner et al. 1998; Sarikamis et al. 2006). It is a genetically complex trait governed by several pathway genes and phenotyping of the population is also difficult and costly process. Although, some sensory attributes are related with glucosinolates content (Baik et al. 2003) but this evidence lacks strong correlation for use in breeding programs. Thus, use of alternative but robust tools such as

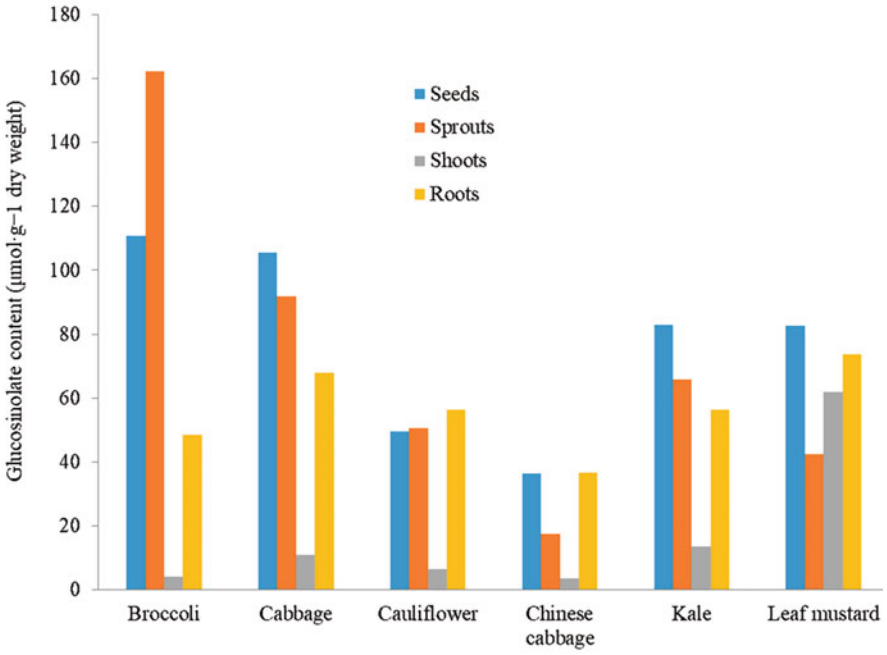

Fig. 11 Variation in GSLs content in Cole crops and their parts. (Data source: Bhandari et al. 2015)

molecular tools are more promising in tracking the introgression of gene(s) for desirable glucosinolates in *Brassica* vegetables.

Chemical Type, Structure, and Biochemical Pathways of Glucosinolates Production

The building blocks of glucosinolates are a variable side chain (R), a sulfonated oxime moiety, and a β-thioglucose moiety originating from an amino group (Fig. 12). Basic structure of GLSs comprises a glucose residue, a sulfate group, and a variable aglycone. The sulfate group is normally balanced by a (potassium) cation. The side chain R (amino acid derived) determines whether the GLS is aliphatic (nonaromatic), indole (very stable, cyclic), and aromatic. The aromatic GSLs derived from tyrosine or phenylalanine and aliphatic GSLs are derived from methionine, indolic GSLs from tryptophan (Giamoustaris and Mithen 1996). Aliphatic glucosinolates are also derived from isoleucine, leucine, valine, and alanine. Most glucosinolates in *Brassica* plants come from the amino acid methionine (nearly half of all glucosinolates), and their bioactivity is dependent on the metabolic by-products (Mithen 2003). However, the biological functions of oxidation of aromatic GSLs such as benzyl and phenylethyl GSLs, as well as indole GSLs, have also been documented. In 1956, the properties of sinigrin and sinalbin, two glucosinolates, were determined to be the first to be understood (Ettlinger and Lundeen 1956). In 1961, the word "glucosinolate" was coined for the first occurrence (Ettlinger and Kjaer 1968).

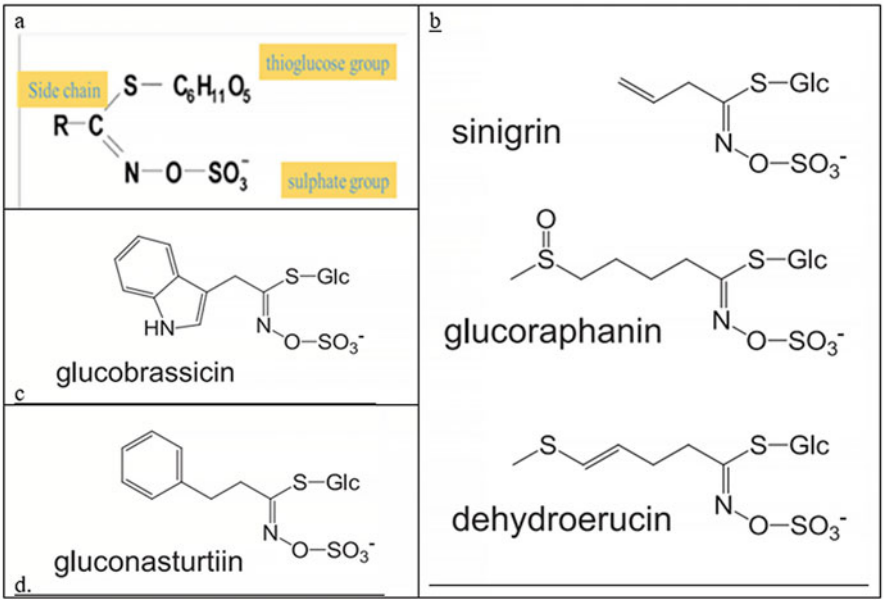

Fig. 12 Basic chemical structure of glucosinolates (**a**), indole (**b**), aromatic (**c**), and aliphatic (**d**)

Glucosinolate Biosynthesis in *Brassica* Vegetables

Extensive study has been conducted on the formation of glucosinolates, mostly employing *Arabidopsis* (Grubb and Abel 2006). Based on the precursor amino acid, glucosinolates are biosynthesized from aliphatic (mostly methionine), indole (from tryptophan), and aromatic amino acids (phenylalanine or tyrosine). Three distinct processes compose the glucosinolate synthesis routes: I chain elongation, (ii) assembly of a fundamental glucosinolate molecule, and (iii) alteration in the second stage (Fig. 13) (Sønderby et al. 2010). Ishida and collegues (2016) detailed the method for generating GSL from Brassicaceae plants. Aliphatic GSLs contain many side chains of varying lengths that are determined by periods of chain elongation. First, branched-chain amino acid aminotransferase transforms amino acids like methionine into the necessary 2-oxo acids for chain elongation (BACT). These 2-oxo acids serve as precursors in the elongation of methylene groups. The elongation is caused by the enzymes isopropylmalate isomerase (IPMI), isopropylmalate dehydrogenase (IPMDH), and methylthioalkylmalate synthase (MAM). BCAT converts the extended 2-oxo acids into their respective amino acids.

Medicinal/Physiological Properties and Functions of Glucosinolates in Relation to Human Health

The structural feature retained by intact glucosinolates and diverse breakdown products is seen in Fig. 14. Traka (2016) analyzed the results of epidemiological research on glucosinolates. Consumption of vegetable Brassicas, which are an important source of glucosinolates, has been linked to a considerably lower risk

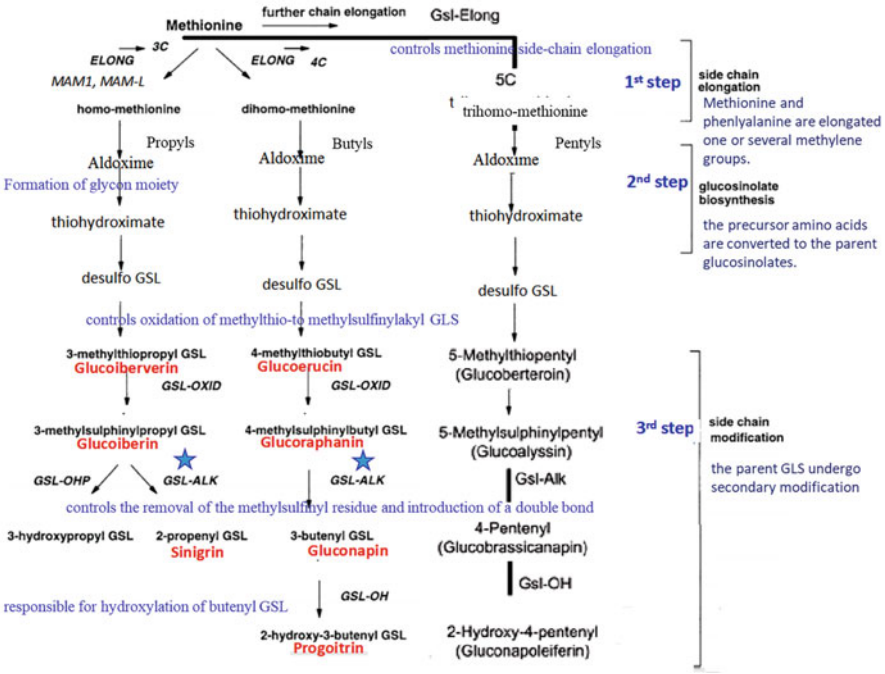

Fig. 13 Biosynthesis of glucosinolates in *Brassica* vegetables

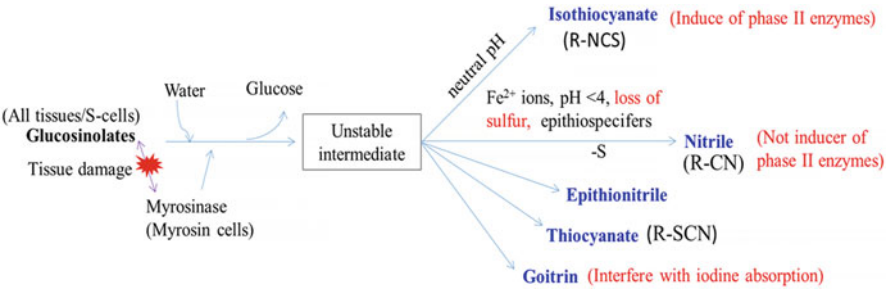

Fig. 14 Glucosinolates-myrosinase system (aliphatic GSL)

of cardiovascular disease (Giovannucci et al. 2003; Spitz et al. 2000), stomach (London et al. 2000, lung , prostate (Hansson et al. 1993; Seow et al. 2002), and rectal cancers. Richman et al. (2012) demonstrated that ingesting foods rich in glucosinolates, such as broccoli, is involved with a decreased chance of advancing from a less aggressive type of prostate cancer to a more aggressive cancer of the disease (Halkier and Gershenzon 2006). This implies that glucosinolates contribute to health improvement even after the onset of sickness. The hydrolytic product of glucosinolate and metabolic products operate as chemoprotective agents against chemically induced carcinogens by inhibiting the beginning of

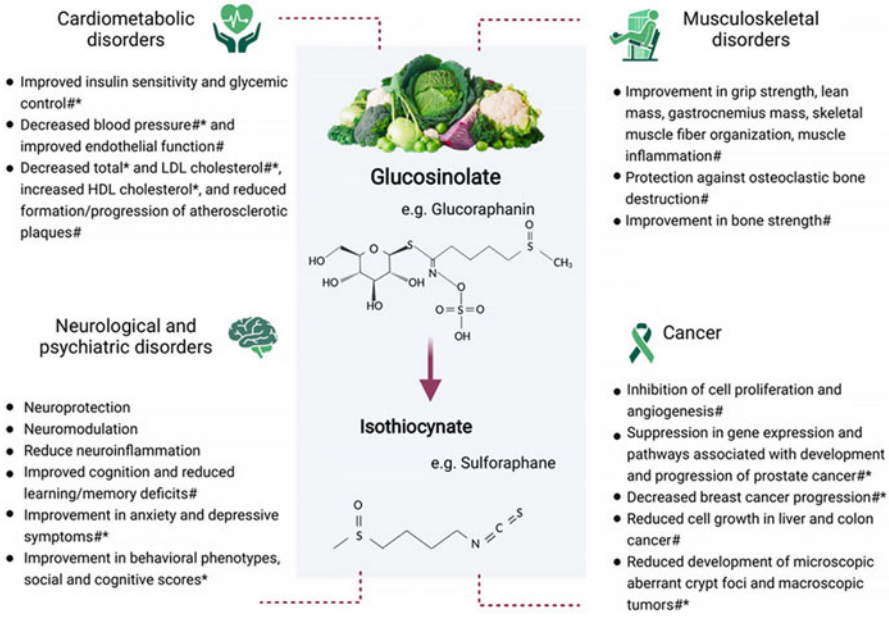

Fig. 15 Health benefits of glucosinolates from vegetable Brassicas. (Adapted from Connolly et al. 2021)

tumors in several rodent organs, including the liver, colon, mammary gland, pancreas, etc. (Fig. 15).

Suforaphanes from *Brassica* Vegetables

The cytotoxic and apoptotic function of GSLs in damaged cells acts as a cancer preventative and reduces the incidence of degenerative disorders. By stimulating antiproliferative action, they activate phase 2 enzymes. The GSLs 3-methylsulfinylpropyl (glucoiberin) and 4-methylsulfinylbutyl (glucoraphanin) are present in *Brassica* crops, with broccoli having the highest concentration (Fig. 16). The lack of a functional allele at the *GSL-ALK* gene is responsible for this. Sulforaphane is the most effective GSL breakdown product derived from glucoraphanin, which stimulates phase 2 enzyme and is believed to have a significant role in the detoxification of xenobiotic substances when ingested with food (Fahey et al. 2001; Rosa et al. 1997). Sulforaphane is the most effective naturally occurring inducer of phase 2 enzymes. It is implicated in apoptosis activation, cell cycle arrest induction, and NFB inhibition (Tortorella et al. 2015). In addition, they hypothesized that sulforaphane may target epigenetic changes in some cancers, correcting abnormal alterations in transcriptional activation through global demethylation, microRNA manipulation, and histone deacetylase suppression.

Evidence Suggesting Role of Isothiocyanates in Human Health

The breakdown product sulforaphane is important because it induces phase 2 (detoxification) enzymes *viz.* UDP-glucuronosyl transferases, glutathione-S-transferases,

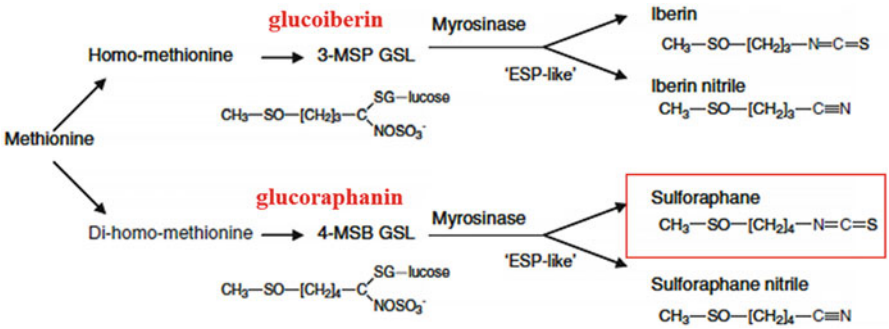

Fig. 16 Structure and degradation of 3-methylsulfinylpropyl (3-MSP) and 4-methylsulfinylbutyl (4-MSB) glucosinolate. The ratio of the two glucosinolates is determined by the extent of methionine elongation, determined by genes within the introgressed segments on O_2 and O_5. The ratio of isothiocyanates and nitriles produced depends upon the activity ESP. (Adapted from Sarikamis et al. 2006)

and quinone reductase, *via* ARE-mediated transcription which play role in neutralizing toxic electrophilic metabolites of carcinogens and ROS and serve as anticarcinogens early in the process of carcinogenesis. The cell cycle of many different kinds of cells, including prostate, lyphocyte, colon, and mammary, can be inhibited by sulforaphane's availability. It induces apoptosis in a range of cell lines. The mechanism implicated in apoptosis is JNK (c-Jun NH (2)-terminal kinase) signal transduction pathway and activation of caspases (a family of protease enzymes play essential roles in programmed cell death). Sulforaphane and synthetic cyclic isothiocyanate analogues block mammary tumor development in Sprague-Dawley rats treated with 9, 1O-dimethyl-1,2-benzanthracene (DMBA) (Huggins et al. 1961; Zhang et al. 1994; Welsch 1985). Methylsulfilalkyl isothiocyanates are known to be effective causative agents of phase 2 detoxifying enzymes in murina hepatoma *Hepa1c1c7* cells in culture. These enzymes are related with a decreased sensitivity of humans and mammalian tissue samples to the toxic and neoplastic effects of carcinogens (Faulkner et al. 1998). Administration of sulforaphane (75 or 150 μmol per day for 5 days) in Sprague-Dawley rats treated with 9,10-dimethyl-1,2-benzanthracene (carcinogen) around the time of exposure the incidence, multiplicity, and weight of mammary tumors were significantly reduced, and their development was delayed (Zhang et al. 1994).

Myrosinase: Enzyme for GSL Breakdown

The GSLs coexist with myrosinase (thioglycosidase) in a system called "glucosinolate-myrosinase," but they are kept physically apart in plants. The GSLs are believed to be mostly stored in the vacuoles of S cells and are water soluble. The S cells are referred to as sulfur-rich cells because their cell sap contains up to 350 mM S, with GLS accounting for 84% of the sulfur, or around 146 mM GSLs. It should be noted that while the GSLs are thought to be biologically inert chemicals by themselves, mechanical injury, infection, or insect assault cause the GSLs to be hydrolyzed, which produces a variety of physiologically active molecules (Bones

and Rossiter 1996). Myrosinase catalyzes the hydrolysis, resulting in the breaking of the thio-glucose link and the production of unstable thiohydrosimate-O-sulfonate, which is then rearranged to form a number of compounds (Bones and Rossiter 1996). It primarily generates isothiocynate (ITC), which controls the bioactivity of *Brassica* plants, particularly their anticancer capabilities. Other products of the hydrolysis include thiocynates, nitriles, and elemental sulfur.

Plants have the enzyme myrosinase, which, in the presence of water, separates the glucose group from a glucosinolate. When the remaining molecule rapidly converts into an isothiocyanate, nitrite, or thiocyanate, the active components are produced (Traka et al. 2008). Some of these breakdown products include isothiocyanates, thiocyanates, epithionitriles, epithioalkanes, nitriles, and oxazolidine-2-thiones (Grubb and Abel 2006). At a higher acidic pH, nitriles are produced, while isothiocyanates predominate at physiological pH (Halkier and Du 1997). It has long been known that some glucosinolate breakdown products used as feed and food components offer special benefits for plant defense and human nutrition. This characteristic has led some people to consider *Brassica* plants as possible functional foods. "Functional foods" are defined as those that, as regular dietary components, may provide enough quantities of bioactive components that are advantageous for improving health (Carlson et al. 1987b; VanEtten et al. 1976). Studies evaluating the glucosinolate proficiencies of cruciferous crops reveal considerable differences (Ciska et al. 2000). Cartea and Velasco (2008) previously posted an overview of the major glucosinolates discovered in common vegetable Brassicas, *viz*. *B. oleracea*, *B. napus*, and *B. rapa*. In *Brassica* plants, it has been discovered that the amounts of indole and aliphatic glucosinolates, as well as the glucosinolate profile, alter significantly according to the developmental phase, biological makeup, and external conditions (Velasco et al. 2007). Numerous epidemiological investigations have shown a substantial link between diet and cancer. Numerous research conducted over the last 30 years have shown that naturally occurring substances like glucosinolates, which have anticancer properties, are present in fruits and vegetables (Rosa et al. 1997; Talalay and Fahey 2001; Block et al. 1992; Smith et al. 2005). As a result, interest in cruciferous vegetables for their potential role in treating cancer has increased over the past several years (Anilakumar et al. 2006; Farnham et al. 2004). Numerous studies have shown that the chemopreventive properties of the *Brassica* vegetable family have an effect on both the initiation and advancement stages of the carcinogenic process. This concept is supported by similar findings from clinical trials and epidemiological studies (Zhang and Talalay 1994). Isothiocyanates and indoles are two important subclasses of the autolytic degradation products of glucosinolates with anticancer properties. These substances have been attributed to both the stimulation of detoxifying activities (phase II enzymes) and the inhibition of initiation enzymes in in *vivo* and *in vitro* studies of the origins of cancer (phase I enzymes) (Fahey et al. 2002). Glucosinolates are sulfur compounds that give these plants their distinctive flavor and odor in addition to their medicinal properties. Although the relationship between glucosinolate content and sensory characteristics is complex, isothiocyanates produced from glucosinolates give *Brassica* products their bitter, pungent flavor and sulfurous aroma (Padilla et al. 2007).

Myrosinases are, thus, glycoproteins that are thought to be produced in the rough endoplasmic reticulum, glycosylated in the Golgi apparatus, and then stored in the vacuoles (or myrosin grains) of myrosin cells. The thioglucoside glucohydrolases known as myrosinases catalyze the hydrolysis of the thioglucosidic link. Together with other glycosidases, they belong to the glycoside hydrolase family 1, which is involved in plant defense. Two identical, extensively glycosylated 55–65 kDa polypeptides make up the myrosinase. Two conserved residues from each monomer tetrahedrally coordinate a $Zn2^{+}$ to maintain the dimeric structure (Fig. 15).

Common properties of myrosinase are:

(i) Resistance to heat (temperature optimality up to 70 degrees Celsius).
(ii) The activation of these compounds by modest concentrations of ascorbic acid (1–2 mM).
(iii) Depending on the species, the optimal pH range might be either wide or tight.
(iv) Differ in their affinities for the various GLS as well as the efficiencies with which they convert.
(v) Species that have GLS might have a variety of myrosinase isoforms, each of which could have unique enzymatic activity as well as distinct patterns of temporal and spatial expressions.

Evidence for Role of GSLs in Human Health

In the human body, GSLs are hydrolyzed into ICTs at two sites: (i) in the mouth by plant myrosinase and (ii) in the human distal intestine by myrosinases generated by intestinal bacteria. Passive diffusion absorbs the ITCs. The glutamine in ITCs conjugates naturally and is enhanced by glutathione-S-transferases such as Mu (*GSTM1*), which is considered the key determinant of ITC metabolism, *Theta* (GSTT), and *Pi* (GSTP1) (Hayes et al. 2008). With the aid of MRP1 and MRP2 (multidrug resistance–associated proteins) and p-glycoproteins (Pgp-1), the glutathione component is rapidly released extracellularly. After that, the metabolites of the ITC are delivered to the liver via the liver's portal vein so that they may be processed by the mercapturic acid process. Following that, enzymatic changes such as glutamine and glycine cleavage generate cysteine-glycine conjugates and cysteine conjugates, which are then acetylated to form N-acetyl-cysteine (NAC) conjugates that are eliminated in urine, as detailed by Brüsewitz et al. (1977). Traka (2016) revealed various mechanisms by which free ITCs and their compounds are absorbed by hepatocytes and transported to the plasma systemic circulation. In the blood systemic circulation, they may enter periphery organs at lower quantities than in the liver (Traka 2016). The metabolic fate of GSLs in humans after consuming broccoli has been the subject of a significant amount of research. Epidemiological studies have shown that the preventative benefits of eating crucifers may vary owing to variations in glutathione S-transferases (GSTs). There are several polymorphisms in the genes that belong to the GSTs family, including null mutations in GSTM1 and GSTT1, which result in the lack of a gene product that is functional (Traka 2016). Cotton et al. (2000) discovered differences in *GSTM1* homozygous null genotype rates ranging from 30–63%, whereas *GSTT1* homozygous null genotype rates varied from 10–21% for Caucasians and up to 64% for certain Asian races. The

polymorphism has also been found in the *GSTT1* gene, where around 20% of Caucasians and up to 60% of Asians have a homozygous deletion. Similarly, the GSTM1 null genotype was common in Caucasians (47–57%), Asians (42–54%), and Africans (16–36%). In contrast, the *GSTT1* null genotype was uncommon in Caucasians (13–26%), but common in Asians (35–52%) (Garte et al. 2001; Suthar et al. 2018). Hemlata Singh et al. (2022) found variance among inter- and intra-Indian ethnic groups in Himachal Pradesh, India, while Sharma et al. (2014) found variation among Delhi residents.

According to an analysis of epidemiological data conducted in the USA, broccoli (Wang et al. 2004) and crucifer vegetables provide *GSTT1*-positive people more cancer protection than null mutants (Spitz et al. 2000). Persons with GSTM1-positive status who ingested one serving of broccoli per week had a significantly lower prevalence of colorectal adenomas than those who did not eat broccoli. However, bigger intakes of broccoli may minimize the risk of adenomas in people. GSTM1 and GSTT1 nulls in Asian cultures may have stronger resistance to Chinese cabbage than GSTM1 and GSTT1 positives, according to research that used dietary frequency questionnaires (Zhao et al. 2001; Fowke et al. 2003) or detected ITCs in urine (Gasper et al. 2005). In those with a functioning *GSTT1* allele, Cornelis et al. (2007) found that eating *Brassica* plants was related with a decreased risk of heart infection. ITC metabolism or excretion is slowed down by having a GSTM1 or GSTT null genotype because GSTs are in charge of conjugating ITCs for excretion. Mercapturic acid is responsible for the metabolism of sulforaphane to a greater degree in persons with a deficiency in GSTM1 than in those with an abundance of GSTM1 (Steck et al. 2007; London et al. 2000). Because plasma has a low glutathione environment, GSTM1 activity may cause ITC and glutathione to be conjugated after being exported from epithelial cells (Traka 2016). SNP analysis was utilized by Armah et al. (2013) to examine genome-wide associations and identify an unique interaction between diet and genes. Participants who consumed glucoraphanin-rich broccoli in this study had their metabolic profiles affected by polymorphisms in the poly-A polymerase gamma (*PAPOLG*) gene.

There is a clear connection between the health advantages of increasing the amount of GSLs in one's diet and the findings of experimental studies on the relevance of GSL-rich diets in the prevention of sickness. GSL-rich diets improve carcinogen detoxification, affect critical metabolic processes, and alter signaling pathways that induce sickness. GSL-rich broccoli sprouts significantly increased carcinogen excretion in test participants in Qidong (China), a place with a high incidence of air pollution, especially in GSTT1-positive persons, implying that these individuals' phase 2 detoxifying potential was enhanced (Kensler et al. 2012; Egner et al. 2014). It has been shown that consuming broccoli that is rich in glucoraphanin may reduce bad cholesterol in those who are at risk for heart disease. Following a diet rich in glucoraphanin for a period of one year has a considerable effect on the fundamental transcriptional mechanisms driving carcinogenesis, such as the insulin signaling molecules and the transforming growth factor (TGF) transcription factors. (Traka et al. 2008). Sulforaphane was shown to be a dose-dependent inducer of selective cytotoxicity in *HeLa* cells by Sharma et al. (2011). Because of this, the activation of the genes *IL-1, COX-2,* and *Bcl-2*

that are associated with apoptosis and inflammatory processes may be drastically reduced. Kim (2021) investigated the impact of sulforaphane in the treatment of Alzheimer's disease utilizing preclinical indicators of amyloid, inflammation, and oxidative stress. Sulforaphane was also investigated by Kaiser et al. (2021) as a phytochemical with potential cancer-preventive effects.

3 Genetic Resources for Health-Related (HR) Genes

3.1 Carotenoids

Brassica vegetables, except white cauliflower, are a strong source of β-carotene. Kopsell et al. (2004) observed that genotype variation for β-carotene varied from 3.8–10.0 mg/100 g. For either lutein or β-carotene, there was no significant genotype-by-season interaction. It is also abundant in broccoli, where levels varied between 0.4 and 2.4 mg/100 g FW (Kurilich et al. 1999). In addition, a little amount of a-carotene was identified, although <0.1 mg/100 g FW. β-carotene is abundant in orange cauliflower, which is the most intriguing and alluring Cole vegetable (Crisp et al. 1975; Dickson et al. 1988). This feature was seen in cauliflower groups with snowball (or late) development, hence its initial utilization in other cauliflower ecotypes was limited. Cauliflower is a very thermosensitive crop due to its curdling behavior, which restricts the economic viability of the trait to a narrow age group. To maximize the potential of this natural mutant, it is necessary to introgress the trait into genotypes of various age groups. Through the process of crossing orange-curded *OrOr* plants from the heterozygous line with orange-curding genotype line 6932, Dickson et al. (1988) were able to develop three orange high-carotene cauliflower inbreds. These inbreds were given the names NY 163, NY 165, and NY 156. The NY 165 and NY 163 cultivars were derived from distinct F_2 plants from the same cross, whereas the NY 156 cultivar originated from a cross between an *OrOr* plant and a white cauliflower, NY 9120 GL.

Kalia et al. (2020) launched a drive to increase carotene content in popular Indian cauliflower cultivars by introducing a spontaneously dominant *Or* mutant gene. They hybridized *Or* lines in Indian cauliflower using the donor source of the *Or* gene, EC625883, as well as Pusa Meghna, CC14, and DC 41-5 from the early maturity group and Pusa Sharad, CC35, and DC 18-19 from the mid-maturity group.

Kalia et al. (2020) examined Indian cauliflower containing *Or* gene in advanced lines. The donor source of the *Or* gene, EC625883, as well as the recipient parents Pusa Meghna, CC14 and DC 41-5 from the early maturity group and Pusa Sharad, CC35 and DC 18-19 from the mid-maturity group participated in a hybridization procedure for this purpose. Figure 17 depicts the β-carotene concentration of top plants at BC_2F_1 with various genetic backgrounds in the early and intermediate maturity groups. In the background of Pusa Meghna (early maturity group), Pusa Sharad (DC309), and CC-35 (mid-maturity group), the β-carotene content of individual plants in the backcross generation BC2F1 ranged from 4–9 ppm. However, in the background of DC41-5 (early maturity group) and DC18-19 (mid-maturity group), the

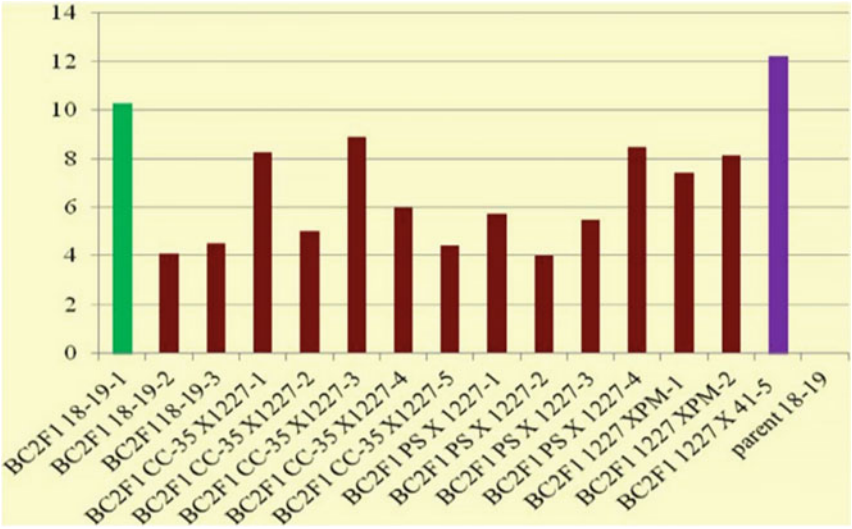

Fig. 17 BC_2F_1 elite selects for β-carotene content (ppm) in different genetic backgrounds of early (PM, 41-5) and mid-maturity (PS, CC35, 18-19) group with donor 1227 (EC625883). (Adapted from Kalia et al. 2020)

highest level was 12 and 10 ppm, respectively, when compared with the white wild parent. According to their findings, the β-carotene concentration of backcross progeny varied widely. The range of β-carotene concentration in the dark-orange category was DC 309 × EC625883 (2.03–14.64 g/g), CC-35 × EC625883 (7.03–15.99 g/g), and DC 18–19 × EC625883 (4.52–18.60 g/g) (Kalia et al. 2018). They reported combination of high recurrent parent genome in two plants with high β-carotene content, namely 18-19-1-7-7 (18.60 g/g) and 18-19-1-3-6 (17.94 g/g). BC1F1 was found to have more than 10 g/g β-carotene in these promising advanced lines.

In nine broccoli genotypes, lutein is the most abundant carotenoid, with concentrations ranging from 65.3–139.6% g/g dry matter (DM) of edible part. Violaxanthin was also observed in higher concentrations (17.9–35.4% g/g DM) than lutein. β-carotene and neoxanthin were found in concentrations comparable to violaxanthin (Farnham and Kopsell 2009). Since lutein is also crucial for human health, a decent breeding program should pay enough attention to lutein. Kopsell et al. (2004) identified *Brassica oleracea* L. var. *acephala* as the greatest source of lutein and β-carotene among *Brassica* vegetables. They investigated 23 cultigens and found that lutein concentrations varied from 4.84 mg/100 g fresh weight (343-93G1) to 13.43 mg per 100 g fresh weight (Toscano), while β-carotene accumulations ranged from 3.82 mg (30343-93G1) to 10.00 mg/100 g fresh weight (FW) (Toscano).

Kopsell et al. (2007) studied the carotenoids pigments of all six genetically related members of U's triangle. *Brassica rapa* has the greatest concentrations of antheraxanthin (0.79 mg/100 g fresh weight), lutein (8.89 mg/100 g fresh weight), and zeaxanthin (0.75 mg/100 g fresh weight). *B. juncea* had the greatest levels of total chlorophyll, and β-carotene at 125.9 and 4.41 FW mg/100 g, respectively.

Significant carotenoids in *Brassica nigra* were 5, 6-epoxylutein (0.41 mg/100 g FW), and violaxanthin (2.28 mg/100 g FW). The greatest concentration of neoxanthin (2.10 mg/100 g FW) was found in *B. oleracea. B. carinata* and *B. napus*, among the amphidiploids, collected much fewer carotenoids than the diploid species and *B. juncea*. *Brassica* plants provide distinctive health benefits when ingested. The data will be valuable for breeding programs aiming to boost carotenoids in *Brassica*.

3.2 Anthocyanin

Anthocyanin content in *Brassica oleracea* is due to natural mutant and probably transferred through natural crossing between these purple mutants and traditional color types (Volden et al. 2008). Because all the members of the *Brassica oleracea* are easily crossable and found in same localities (Piccaglia et al. 2002). In red cabbage, anthocyanins were in the range of 1.38 mg/g FW in red cabbage originated from the UK, 1.25 mg/g FW in Italian red cabbage, 1.14 mg/g in Norwegian fresh red cabbage, and 0.14–0.91 mg Cy/g fm in five tested varieties (Wiczkowski et al. 2014). Scalzo et al. (2008) detected a lower amount of anyhocyanins (0.77 mg/g FW) in red cabbage from Northern Italy (0.77 mg/g FW). The greatest concentration of these red pigments (3.22 mg/g FW) was found in American-collected red cabbage (Wu et al. 2006; McDougall et al. 2007). Strauch et al. (2019) analyzed 29 red cabbage genotypes for anthocyanin content and found a range of 11.3–30.1 mg/g, but Ahmadiani et al. (2014) reported 8–14 mg/g DW.

3.3 Glucosinolates

Wang et al. (2012) conducted research on five prominent Chinese cultivars and reported that the amounts of glucoraphanin in cultivated varieties ranged from 1.57–5.95 mol/g, but the levels in inbred lines ranged from 0.06–24.17 mol/g. The distribution of goitrin concentration in cultivars is about 1.77–6.07 mol/g with an average of 3.20 mol/g. Individual glucosinolates concentrations and the distribution of glucosinolate classes vary significantly among populations of broccoli. Wang et al. (2019) studied glucosinolates in the seeds of 32 pure lines and six commercial broccoli cultivars and discovered that aliphatic glucosinolates accounted for more than 90% of total glucosinolates. Glucoraphanin and glucoerucin were abundant in 27 samples, whereas progoitrin was prominent in seven samples. 4-(methylsulfinyl)butyl isothiocyanate and 5-(methylsulfinyl)pentanenitrile concentrations varied from 2.6–91.1 mol/g fresh weight and 0–35.4 mol/g fresh weight, respectively. Klopsch et al. (2018) discovered 23 GLS breakdown products in 91 genotypes of *Brassica rapa,* including nine isothiocyanates, ten nitriles, and four epithionitriles. Epithionitriles were the most common breakdown products because to the abundance of alkenyl GLSs. The researchers Sun et al. (2011) found that the levels of glucosinolate in the sprouts, rosette leaves, and bolting stems of each of the 27 different types of Chinese kale were distinct from one another. The overall and individual glucosinolate amounts of the

different plant species' edible portions varied. According to Cartea et al. (2008b), the total glucosinolate content ranged from 11.0–53 mol/g dw in kale, but from 10.9–27 mol/g dw in cabbage. They also discovered a temporal difference in total glucosinolate concentration, which ranged from 22 m/g dw during spring planting to 13 m/g dw during autumn sowing. Li et al. (2021) looked at eight developmental organs from 80 broccoli genotypes and found 12 GSLs in florets with concentrations ranging from 0.467–57.156 mol/g dry weight (DW). Lee et al. (2014) measured total GSL concentrations in 62 Chinese cabbage varieties ranging from 2.83–48.53 mol/g DW. Bhandari et al. (2015) investigated nine different *Brassica* varieties, including cabbage, cauliflower, broccoli, cabbage radish, pak choi, Chinese leaf mustard, kale, and baemuchae. Broccoli seeds and sprouts had the most total GSL (110.76 mol/g and 162.19 mol/g, respectively), whereas leaf mustard shoots and roots contained the least (61.76 mol/g and 73.61 mol/g, respectively). The total glucosinolate content of 36 *Brassica napus pabularia* group cultivars ranged from 1.4–41.0 mol g1 dw at one location and from 1.2–7.6 mol g1 dw at the other (Cartea et al. 2008b). Investigation of glucosinolate content of 65 *Brassica oleracea* accessions included broccoli (50), brussels sprouts (4), cabbage (6), cauliflower (3), and kale (3). The primary glucosinolates found in broccoli were glucoraphanin, gluconapin, and glucobrassicin. The content of glucoraphanin in broccoli varies between 0.8–21.7 mol/g dry weights depending on the variety. Sinigrin (8.9, 7.8, 9.3, and 10.4 mol g-1 DW) and glucobrassicin were the most abundant glucosinolates in brussels sprouts, cabbage, cauliflower, and kale (3.2, 0.9, 1.3, and 1.2 mol g-1 DW). Furthermore, brussels sprouts contained high amounts of gluconapin (6.9 mol/g DW). Branca et al. (2002) showed that Sicilian cauliflower types with colored curds contained higher levels of glucosinolates, namely glucoraphanin, than commercial cultivars with white curds. Carlson et al. (1987b) investigated the glucosinolates profile of *Brassica* vegetables, which ranged from 13.89–16.39 mol/g DW in broccoli, 13.0–14.17 mol/g fresh weights in brussels sprouts, 10.28–17.20 mol/g fresh weight in cauliflower, 14.61–21.72 mol/g FW in collard, 15.61–21.72 mol/g FW in kale, 18.50 μmol/g FW in mustard green, and 19.39 μmol/g FW in kohlrabi.

The GSL profiles of the screened wild Brassicas differed, with *B. macrocarpa* having a relatively high level of sinigrin and *B. rupestris* presenting a profile comparable to the crops investigated by Branca et al. (2002). *B. macrocarpa, B. villosa* var. *drepanensis*, and *B. atlantica* leaves were discovered to have high amounts of total GSL (11.88 M/g fresh weight) and sinigrin. Among the wild species, *B. macrocarpa* exhibited the highest GSL content (10.20 M/g FW leaves). The GSL concentration of *B. rapa* accessions varied from 1.49–3.06 M/g fresh weight (FW) leaves, whereas *B. rupestris* accessions had a GSL content of 1.71 M/g FW leaves. Leafy *B. rapa* subsp. *oleifera* is being used to breed *B. napus* oilseed cultivars with low glucosinolate concentration. Glucosinolates in wild *Brassica* species such as *B. montana* (2.17 mol/g fresh weight), *B. incana* (4.37–11.27 mol/g fresh weight), *B. rupestris* (11.88 mol/g fresh weight), *B. depranensis* (4.73 mol/g fresh weight), and *B. macrocarpa* (3.76 mol/g FW). 3-methylsulfinylpropyl, 3-methylthiopropyl, and 2-propenyl were the main glucosinolates in *B. villosa, B. drepanensis,* and *B. atlantica*, respectively are presented in Table 1. Differences

in glucosinolate profiles were attributed to changes in alleles at the *GSL-OXID* and *GSL-ALK* loci (9). Faulkner et al. (1998) investigated the glucosinolate profiles of three wild *Brassica* species while introducing beneficial glucosinolates into chromosomal areas. They discovered that the most prevalent glucosinolate in *B. villosa* was 3-methylsulfinylpropyl (glucoiberin) (119.0 moles/g dry weight), followed by 3-methylthiopropyl (glucoiberverin). These substantial glucosinolates account for about 95.9%, 82.4%, and 97.4% of total glucosinolates, respectively.

Several studies have assessed alien species of *Brassica* crops and identified certain of them as potential donors of quality traits (Table 10).

4 Classical Genetics and Traditional Breeding in Vegetable Brassicas

4.1 Genetics of HR Genes: Inheritance and Mode of Action

4.1.1 Genetics of Carotenoids Accumulation in Cauliflower Exploitation of *Or* Gene in Indian Cauliflower Improvement

Crisp et al. (1975) selfed the plants of clones of orange mutant which segregated and the following observations were reported: (i) three plant phenotypes were having white curds, plants with orange curds resembled parent plants, and plants with very small loose curds have more intense orange color in the ratio of 1:2:1, (ii) a semidominant (incomplete) gene action for orange curd trait and (iii) orange color was present in all the tissues of the curd except the pith and the color was due to xanthophylls and carotene. The plants with *OrOr* genotype showed intense orange color, whereas *oror* types were white. The gene for orange curd phenotype was designated as "*Or*" (after the color of curds).

Cauliflower as Ideal Crop for β-Carotene Biofortification

Following points highlight the significance of cauliflower as an ideal crop for β-carotene biofortification to counter the global problem of β-carotene deficiency, particularly through food-based approach:

1. Cauliflower is one of the ideal crops for public nutrition because its annual production is 25.53 million tonnes, predominantly in region of vitamin A

deficiency (Fig. 9). It has high productivity both in terms of per unit area and time scales.
2. The *Or* gene is a native spontaneous mutant in cauliflower itself, so it is not a transgene. Thus, it eliminates any prohibition and restrictions (as in case of transgenics or genome-edited crops) for commercial release and consumer acceptance. Thus, the biofortified varieties will have immediate reach to the end users and can show the health benefits in target group.
3. The phenotype of *Or* gene expresses in meristematic tissues of curd part which constitute the maximum share of edible portion. The harvest index (curd weight/gross plant weight) ranges from 0.40–0.55 kg in fully developed curds which highlight high recovery of the orange curd part, thereby β-carotene from a unit area.
4. Cauliflower has seven ecotypes, namely Italians or originals, Cornish, Northerns, Roscoff, Angers, Erfurt and snowball, and Indian cauliflower which are grown across the world. Additionally, Australians were also separated out from European types. This widespread distribution and natural evolution of crop highlights the immediate cultivation of *Or*-biofortified local ecotypes.
5. It is very common and grown at large scale in developing world which has major chunk of vitamin A–deficit human population. Thus, biofortified cauliflower can serve in a better way to the vitamin A vulnerable population in this region, a malnourished population.
6. Globally, it has large consumer base and have better transportability which highlights its scope for covering farming and nonfarming population.
7. The cooking processes of cauliflower include oil which enhances bioavailability of β-carotene as it is a fat-soluble vitamin.
8. White cauliflower is considered as bleached type and contains only glucosinolates as major functional compound while introgression impart additional health compound (i.e., β-carotene).
9. Despite nutritional significance, the orange cauliflower represents only a fraction of the traditional white cauliflower market, and still confined to specific markets as a niche product.

4.1.2 Genetics of Anthocyanin in *Brassica* Vegetables

Cabbage Head Color

Anthocyanin pigmentation in red cabbage was the subject of several genetic researches, and it was shown that this feature is passed from a single gene (Yarnell 1956) to multiple genes (Kristofferson 1924; Dickson and Wallace 1986). The red color of cabbage is influenced by at least two additional factors in addition to an increase in anthocyanin content (Kristofferson 1924). A single locus has several alleles for two dominant color components that are complementary to one another in order to explain earlier findings. The interaction of the genes *A* and *D* results in the production of red cabbage. *A* third gene, *B*, which produces the dark violet midrib when paired with *A*, produces the brilliant red midrib. While *C* is colorless on its own, combining it with *A* results in a violet midrib. Although *C* has the same effect

as *B* alone, *E* intensifies the dark violet color that *B* produces. Therefore, green cabbage with a red midrib is *daBCE* whereas crimson cabbage is *DABce* (Magruder and Myers 1933). Clearly, these studies and others demonstrate the existence of the quantitative traits of color inheritance (Kwan 1934).

Cauliflower Curd Color

The four major curd colors of cauliflower are white, green, purple, and orange. In purple cauliflower 'Grafitti' and Sicilian purple 'PC-1', this phenoptype is governed by a partly single dominant allele (Chiu et al. 2010; Singh et al. 2020). Purple Sicilian cauliflowers, which are broccoli and cauliflower hybrids (Gray 1992), on the other hand, exhibit recessive purple when mated with white cauliflower. Three additional "bleaching genes" are thought to be responsible for the whiteness of sun-exposed white curd (Crisp and Tapsell 1992). A spontaneous mutation of a single semidominant gene, *Pr*, resulted in a mutant cauliflower with intense violet colors (purple gene).

The major flavonoids derivative in the mutant's various tissues was cyanidin-3-(coumaryl-caffeyl)-glucoside-5-(malonyl)-glucoside. Curd, premature seedlings, premature leaves, premature flower buds, siliques, and seed endosperm are all rich purple, but adult leaves, stems, flower petals, and siliques are all colorless. The *Pr* gene provides instructions for making a tissue-specific R2R3 MYB signaling pathway, which is associated with the abnormal aggregation profile of anthocyanin in the mutant. The curds contained around 3.75 mg g-1 cyanidin-diglucoside (Chiu et al. 2010). Singh et al. (2020) examined the genetics of the 'PC-1' genotype established by repeated segregation of Sicilian purple material. The $173F_2$ population was segregated, showing that a gene dominant over the white allele governed the curd's purple color, although only partly. This was shown by the fact that the purple coloration was only partially exhibited. The vast selection of anthocyanin concentration in F_2 (3.81–48.21 mg/100 g fresh weight) was substantiated by the fact that now the purple coloration of the curds varied from extremely faint to vivid. This demonstrated that the anthocyanin level varied widely. In the F_2 population, co-segregation was not seen. The transcription of the BoMYB1 gene was greater in the purple curd genotypes 'PC-1' and 'Graffiti' than in the 'DC-466' genotype, but the synthesis of the *BoMYB2* gene was more in the genotype 'PC-1' than in the genotype 'Graffiti'. The existence of "broccoli-type" F_2 individuals and the genetic longevity of these individuals in $F_{2:3}$ imply that 'Sicilian purple' is an interim form between cauliflower and broccoli (Calabrese). It seems that the PC-1 and Graffiti genes behave differently since there is no correlation between the color of the curd and the coloration on the apical stem and leaf sections.

Broccoli Head Color

Broccoli contains anthocyanin, a substance with important antioxidant characteristics that may boost health, increase life expectancy, and prevent illness (Chaudhary et al. 2018). The accumulation of anthocyanins in broccoli inflorescences, especially in septals, provides a green/blue to violet tint. 'Purple Sprouting Early' is bred for its high anthocyanin content, which results in strikingly purple flower heads.

Cauliflower, cabbage, broccoli, and possibly knol khol all exhibit a variation of the *MYB DOMAIN PROTEIN 2 (BoMYB2)* gene that contributes to the purple coloration of *Brassica oleracea* (Yan et al. 2018). However, green-purple broccoli cultivars are not as desirable as the fully green variety, particularly in the Chinese market (Yu et al. 2019). This green-purple cultivar is climate sensitive, with cold temperatures inducing and intensifying the purple tint. Yu et al. (2019) used a DH population and SLAF sequencing to identify the purple sepal feature; three QTLs were discovered, with qPH being the dominant locus. C01-2, which is located on LG1, as well as two qPH loci. C01-4 is used in conjunction with qPH. C01-5 is just close to qPH. C01–2 (Reshma et al. 2018).

Other *Brassica* Vegetables

Chinese cabbage and pak choi are the most popular types of the *Brassica rapa* vegetable genus in China and other East Asian countries (*Brassica rapa* L. ssp. *chinensis*). There are several red or purple *B. rapa* cultivars, including multiple varieties of pak choi, turnip, and zicaitai. Notable was the purple leaf trait of Chinese cabbage transmitted from a lineage of *Brassica juncea* (Sun et al. 2006). In the fast-cycling *Brassica rapa*, a nonpurple mutation was recessive (Burdzinski and Wendell 2007), and the purple allele anl was initially identified on the Chinese cabbage linkage group R09. On the A09 linkage group, a significant gene influencing the purple petiole phenotype of Chinese cabbage was identified, and partial dominance for the trait was shown in flowering stalk (*Brassica campestris* L. ssp. *chinensis* var. *perperea* Hort) (Zhang et al. 2008). Two significant QTLs, BrEGL3.1 and BrEGL3.2, were discovered on the A09 linkage group (Guo et al. 2015). Purple gene from pak choi (*Brassica campestris* L. ssp. *chinensis* [Lour.] var. *cammunis* Tsen et Lee) was governed by a single dominant allele (Zhang et al. 2011), and this gene was mapped on A03 linkage group (Liu et al. 2013) and then fine-mapped on 54.87 kb interval. Anthocyanins have been identified as *B. rapa's* purple pigments. A comparison of the completed genome of *A. thaliana* and *B. rapa* led to the identification of anthocyanin biosynthetic genes (ABGs). Anthocyanin production pathways including 73 genes have been identified in *B. rapa*. *BrABGs* were created in many copies by whole genome duplication (WGD) and retained synteny with their *A. thaliana* orthologs. However, gene loss during whole genome triplication (WGT) led to the majority of genes having less than three copies. The upstream structural genes of the anthocyanin biosynthesis pathway have been retained more than their downstream counterparts. On the basis of the existence of these comparable structural genes, the anthocyanin production pathway in *B. rapa* was later discovered. Comparing copy numbers suggests more negative regulatory genes than positive have survived (Guo et al. 2014).

4.1.3 Chlorophyll-Rich Green Cauliflower

Zhou et al. (2011b) showed that combining colored curd to cauliflower improves both its appearance and nutritional value. Cauliflower is green due to the aberrant improvement of chloroplasts in its curd tissue. A partially dominant gene, according to genetic theories, is determinant for the green color (Crisp and Angell 1985).

However, it remains unknown what the inherited biological basis seems to be. Tan et al. (2020) employed QTL-seq analysis to locate genome areas crucial for the cauliflower green curd feature and to restrict targeting intervals for putative specific genes. The F_2 population is the result of a hybridization between a Stovepipe and an ACX800 (white curd × green curd) cauliflower plant. Two quantitative trait loci (QTLs) were identified on chromosome group of 7 (Gr7.1) and 5 (Gr5.1) using SNP analysis and complete DNA resequencing of green and white F_2 bulks (Gr7.1). Using CAPS markers and traditional genetic mapping, Gr5.1 was identified as a large QTL, but Gr7.1 had a little effect. Utilizing additional CAPS markers, high-resolution mapping of Gr5.1 in the second large F_2 generation reduced the target region to 0.3 cM and 236 Kbp, respectively (Chi et al. 2012). There are 35 genes in this region, four of which are UMP kinase and DEAD-box RNA helicase (Schmid et al. 2019). This is owing to the discovery that other plants with UMP kinase mutants and DEAD-box RNA helicase mutants form chloroplasts and have pale leaves (Chen et al. 2018b).

4.1.4 Genetics of Glucosinolates in *Brassica* Vegetables

Genetics of Aliphatic Glucosinolates

Four different studies were conducted and published in the 1990s under the title Genetics of Aliphatic Glucosinolats (GSL) (GSL I, GSL II, GSL III, and GSL IV) (Giamoustaris and Mithen 1996). Within the scope of these studies, models of the primary loci that control aliphatic GSL synthesis in *Brassica* were developed (Parkin et al. 1994; Mithen et al. 1995). This study's first section examined how distinct recombinant populations of *B. napus* displayed distinct patterns of glucosinolate properties (Magrath et al. 1994). Pentyl and butyl GSLs are synthesized by alleles at two extra loci, while propyl GSLs are formed by the side chain extension of amino derivatives (GSL-ELONG-A and GSL-ELONG-C), which is determined by genes at a GSL-PRO locus. The same population of *Brassica napus* provided evidence that supported a hypothesis in which genes at a simple Mendelian control the occurrence or absence of propyl G. Parkin et al. (1994) explored at the hydroxylation of alkenyl GSLs and found two alleles implicated in this process in both leaves and seeds. The *GSL-OH-A* locus in LG 3 has a much less impact than the *GSL-OH-C* locus in LG 13. Mithen et al. (1995) established that chromosome 4 alleles are responsible for two distinct types of side chain modifications in *A. thaliana*. First, methylsulfinylalkyl GSLs are changed into alkenyl GSLs (GSL-ALK), and subsequently methylsulfinylpropyl GSLs are transformed into hydroxypropyl GSLs (GSL-AL) (GSL-OHP). In 2001, Li et al. designed a conceptual framework for GSLs with three to four carbons. The GSL-PRO allele results in three carbon-containing GSLs, while the *GSL-ELONG* allele results in four carbon-containing GSLs (4C) (3C). By sequencing a homolog of the *Arabidopsis* GSL-ELONG gene present in the *B. oleracea* plant in 2002, the presence of 4C GSL was determined (Li and Quiros 2002). Key GSL genes in *B. oleracea* were identified and sequenced by mapping a BAC from this plant to its analogous area in *Arabidopsis*. This comparison was conducted to identify the presence or absence of the genes (Gao et al. 2004). All three 2-oxoglutarate-dependent dioxygenase (AOP) genes

Table 11 Genes involved in GSL biosynthesis in *Brassica* vegetables

Loci	Function	Broccoli	Purple cauliflower	White cauliflower
BoGSL-PRO	Regulate the production of propyl GSL (3C)	–	–	+
BoGSL-ELONG	A gene for side chain elongation that causes 4C GSL	+	+	–
BoGSL-ALK	Gene plays a role in the desaturation of the GSL side chain	–	+	+

Adapted from Li and Quiros (2002)

in *Arabidopsis* are essential for the generation of GSL. These genes are designated *AOP1 (null allele), AOP (GS-ALK),* and *AOP3 (GS-OHP)*. There are many copies of *AOP2.2 (BoGSL-ALKb), AOP3, AOP1.2, AOP1.1,* and *AOP2.1 (BoGSL-ALKa)* in *B. oleracea*, however, only two of these genes are absent. Table 11 displays the evolution of genes responsible for the formation of glucosinolates in three closely associated plants: broccoli, Sicilian purple, and cauliflower.

Glucosinolate side chains are oxidized and hydroxylated by the BoGSL-ALK, *BoGSL-OXID*, and *BoGSL-OH* genes, respectively. On their own, BoGSL-ELONG and *BoGSL-PRO* separate. One of the most essential genes influencing the quantity of glucoraphanin in *Brassica* plants is the *A. thaliana AtAOP2* homolog, *BoGSL-ALK*, which produces a 2-oxoglutarate-dependent dioxygenase requisite for the transition of methylsulfinylalkyl GSLs to their alkenyl derivatives. Total GSLs are calculated when methionine enters the pathway controlled by MAM genes at *GLS-ELONG* loci. The allelic variation at the *GLS-OX, GLS-ALK,* and *GLS-OH* loci is then used to determine the GLS profiles. Profile selection is possible because *B. oleracea* generally exhibits a higher degree of variation at these loci than *B. rapa*.

The transformation of a methylthioalkyl GSL structure into a methylsulfinylalkyl structure is carried out by the GSL-OX gene (Mithen et al. 1995). Numerous modifier loci were detected during a forward genetics screen of *Arabidopsis* mutants, which complicated genetic attempts to pinpoint the source of this characteristic (Kliebenstein 2009). Hansen et al. (2007) identified a considerable variety of possible key genes that co-expressed with genes previously known to be involved in the aliphatic GSL production pathway using accurate variation mapping. It was discovered that a group of five flavin monooxygenases peculiar to vegetable Brassicas governs the transformation of methylthioalkyl to methylsulfinylalkyl GSL. Through the use of *Arabidopsis* sequence analysis, Chinese cabbage, an EST library, a *B. rapa* cultivar, and BAC microarrays, Zang et al. (2009) were able to determine the genes involved in GSL synthesis and regulation. Apart from *CYP79F2, FMOGS-OX2,* and *AOP3,* they discovered 44 *Arabidopsis* homologues. These genes are available in a variety of copies. Although the numbers of genes had evolved between the two species, they found considerable intercorrelations in the GSL. This highlights the development of the link between *B. rapa* and *Arabidopsis* (Zang et al. 2009). The *B. rapa* genome sequence was then put to use in a more thorough investigation (Wang et al. 2011). Every one of the 102 GSL-producing

alleles in *B. rapa* were linked to a single chromosome, as determined by the scientists. The majority of the duplicated *Brassica* GSL genes share synteny with those in *B. rapa* and *Arabidopsis* (93%). Additionally, a triplication event in *B. rapa* is associated with variation in copy number in these genes, and GSL gene content may account for both GSL profiles and accumulation in *B. rapa* (Wang et al. 2011). Comparative genomics using the *Arabidopsis* genome sequence was used to find the bulk of *Brassica* GSL gene sequences. In recent years, several studies have examined the significance of the most important GSL genes in *Brassica* crops. From the leaves of pak choi (*B. rapa*), the genes *CYP83A1* and *CYP83B1* were synthesized, and their expression in various tissues was analyzed. These genes catalyze oximes to produce aliphatic, aromatic, or indole GSLs. There was a link between the expression patterns of these genes and the aggregation of GSL in many genotypes and cells of this species (Zhu et al. 2012). Another study used homologous recombination to genetically modify aliphatic GSL backcross lines (Hirani et al. 2013). In each backcross generation, a resynthesized *B. napus* line was crossed with a Chinese cabbage–doubled haploid line, and nonfunctional genes were discovered using marker-assisted selection (BC_3F_2). Recurrent parent progenies bearing the *GSL-ELONG* gene showed a decrease in 5C GSLs, viz. glucoalyssin, gluconapoleiferin, and glucobrassicanapin (aliphatic GSL). The experimental analysis showed that the functional allele was switched for the nonfunctional *B. oleracea GSL-ELONG* allele. Augustine et al. (2013) revealed that the chromosomes of *B. juncea* (AABB), *B. nigra* (BB), and *B. rapa* (AA) each have four *MYB28* homologues. Four genes are responsible for encoding the functional *MYB28* proteins, which results in the production of aliphatic GSL with a comparable structure and composition. Subsequently, they found four CYP83A1 homologues and utilized functional studies to demonstrate that each of these four CYP83A1 homologues preserved extensive, interconnected, but different transcriptional activity across a vast array of *B. juncea* cell and tissue types. This was accomplished by demonstrating that each of those four CYP83A1 homologues sustained wide-ranging, interrelated, but distinct expression patterns (Meenu et al. 2015). In a second study, quantitative real-time PCR was utilized to analyze the transcription of multiple aliphatic GSL regulating sequences, including the *BrMYB29* and *BrMYB28* genes, across different tissues and morphogenesis of *B. rapa* ssp. *pekinensis* (qRT-PCR). An overlapping gene regulation pattern was noticed between BrMYBs and the genes downstream from them at different stages of embryonic development (DSGs). At most stages of embryonic development, the *BrMYB29.1* and *BrMYB28.3* genes were present in greater numbers than the other *BrMYB* paralogs. These genes comprised paralogs of the *BrMYB29* and *BrMYB28* genes. This was true for all of the *BrMYB* paralogs (Baskar and Park 2015). The function of the GSL genes in *B. oleracea* was not understood until relatively recently. A comparative analysis of databases, Ensemble and Bolbase, identified that 84 genes in *B. oleracea* are orthologous to those in *B. rapa* and are involved in GSL production, regulation of gene expression, and degradation. It was determined that these genes are orthologous to one another. Yi et al. (2015) examined the levels of gene expression in a total of 12 unique *B. oleracea* genotypes that belonged to four distinct groups. It has been shown

that each of these genes may manifest itself in a distinct tissue type. Only eight of them came out as cauliflower florets that were produced in kohlrabi stems; the rest of them came out as cabbage or kale leaves.

Indole Glucosinolates

Brassicaceae plants employ indolic GSLs, a kind of secondary metabolite generated from tryptophan, as a chemical weapon in their arsenal. *Arabidopsis* has contributed as a paradigm for dramatic improvements in indolic GSL synthesis, transport, and performance characteristics in recent years (Naur et al. 2003). *Brassica* biogenesis genes were found in *B. oleracea* (Gao et al. 2014), *B. rapa* (Yun-Xiang et al. 2008; Frerigmann and Gigolashvili 2014), and *B. napus* (Pfalz et al. 2011; Hirschmann and Papenbrock 2015; Klein et al. 2006) by using EST sequencing, BAC libraries, whole-genome sequence information, and metabolic profiling. Tryptophan is transformed into indole-3-acetaldoxime, an aldoxime, as a precursor amino acid by the *CYP79B2* or *CYP79B3* gene products (Wittstock and Halkier 2000). The enzymes *CYP83A1* and *CYP83B* transform aldoximes into activated chemicals (either acid nitro compounds or nitrile oxides). With the use of metabolic engineering on *B. rapa*, scientists investigated the role of this CYP gene family that is thought to be involved in the early stages of the process. With cDNA expressing *Arabidopsis CYP79B2/CYP79B3* and *CYP83B1* Chinese cabbage plants were altered. They found that activation of *CYP79B3* or *CYP83B1* had no effect on the accumulation of indole GSL by analyzing the total GSL of different acessions transformed with each triple and double construct. When *CYP83B1* was stimulated alongside *CYP79B3* and/or *CYP79B*2, methoxyglucobrassicin hydroxyglucobrassicin and glucobrassicin levels increased. The expression of two more enzymes must be coordinated in order to change *B. rapa*'s production flow toward indole GSL. Additionally, overexpression of the *CYP79B2* or *CYP79B3* genes results in a rise in indole-3-acetic acid (IAA), indicating that these genes are crucial for the production of both auxin and indole GSL. When *BrCYP83B1* was identified and described in the pak choi leaves (*B. rapa*), researchers looked at the sequence of its transcriptional activation in a variety of pak choi genotypes and tissues (Zhu et al. 2012). Recent transcriptome experiment by Gao et al. (2014) identified the CYP family of genes (*BoCYP79B2/BoCYP79B3/BoCYP83B1*) in *B. oleracea*. These important GSL synthesis genes were found to be substantially conserved across the Brassicaceae family by the researchers using amino acid sequence analysis and sequence alignment. Thiohydroximic acids are converted to desulfoGSLs by the glucosyltransferases *UGT74B1* and *UGT74C1* of the *UGT74* family (Grubb et al. 2004). Indolyl methyl-thiohydroximate is changed into indolyl methyl desulfo GSL by the enzyme UGT74B1 along the indolic GSL biogenesis. When BnUGT74B1 upregulation in *Brassica napus* strains elevated aliphatic and indolic GSL levels, the severity of disease symptoms and tissue damage in reaction to an infection with *Sclerotinia sclerotiorum* and *Botrytis cinerea* was reduced. This was seen in both cases (Zhang et al. 2015). However, the homologues of this gene that are found in *B. oleracea* were not present in the BAC or cDNA libraries of *B. rapa* (Gao et al. 2014). Sulfotransferases (SOTs) accelerate the last stage of GSL production, which is a crucial part of GSL biosynthesis. There are three SOTs in *Arabidopsis*, SOT16,

SOT17, and SOT18. Despite the fact that the three enzymes' affinities vary, all three employ desulfoGSLs as substrates (Klein et al. 2006). In this specific model plant, the substrate indolic desulfoGSLs is SOT16's first preference (Klein et al. 2006). The recent release of the full sequencing of *B. napus* enables it to conduct an in-depth study of the SOT family of proteins in its entirety (Chalhoub et al. 2014). Four *Arabidopsis* SOT16 homologues were discovered in the *B. napus* genome by Hirschmann and Papenbrock (2015) using sequencing. Studies of the substrate preferences of BnSOT16 *in vitro* revealed similarities to *Arabidopsis* orthologs. On the side chains of indole GSLs, hydroxylations and methoxylations are catalyzed by a number of enzymes. An unidentified methyltransferase transforms glucobrassicin from *CYP81F2* to hydroxyglucobrassicin, which is subsequently converted to metoxyglucobrassicin (Pfalz et al. 2009). The significance of two CYP81F4 isoforms found in the *Brassica rapa* genome was determined through heterologous complementarity and functional studies of the matching *Arabidopsis* variation (Wiesner et al. 2014). Additionally, a *B. oleracea* transcriptome investigation discovered the existence of the genes *BoCYP81F4, BoCYP81F1*, and *BoCYP81F3* (Gao et al. 2014). *MYB34, MYB51,* and *MYB 122* are part of a complex network of TFs that control the synthesis of indolic GSL in *Arabidopsis* (Hirschmann and Papenbrock). *MYB51* largely controls indolic GSL production and is associated with biotic stress responses, but *MYB34* and *MYB122* also promote auxin biosynthesis (Celenza et al. 2005; Gigolashvili et al. 2009). Using *BLAST N* and *BLAST P* on the drought *B. rapa* genome and annotated genes, Wang et al. (2011) revealed comparable *Arabidopsis* MYBs linked to indolic GSLs. Each transcription factor from *B. rapa* shared more than 70% of the sequence with transcription factors from *Arabidopsis*. Researchers found *BoMYB51* in broccoli seeds (Araki et al. 2013) and sprouts and *BoMYB34* in kale using RNA-seq analysis and EST data (Gao et al. 2014). In addition, in response to environmental signals, TFs may alter plant metabolism. Using signaling molecules and mechanical stress, GSL levels have been raised in a number of *Brassica* species. There is evidence from several studies on *Arabidopsis*, *Brassica oleracea* (broccoli) (Koritsas et al. 1991; Bodnaryk 1992), *Raphanus sativus* (Red radish [Doughty et al. 1995] and China Radish rose [Brader et al. 2001]), *Brassica rapa* (turnip), and *Brassica napus* (rutabaga, cabbage, and oilseed rape) that methyl jasmonate and wounding may affect indolic GSL levels (Baenas et al. 2014). Hormone therapy enhances TFs in *B. rapa* MYBs encoding indolic GSLs, per prior *Arabidopsis* findings (Frerigmann and Gigolashvili 2014). The experimental analysis of Chinese cabbage seedlings with jasmonate, salicylic acid, ethanol, and abscisic acid increases *MYB34* and *MYB122* expression, which alters the expression levels of SOT16 and CYP79B3/CYP79B2 resulting in an increase in the accumulation of indolic GSLs (Thiruvengadam et al. 2015). As a result, the types and quantities of indolic GSL in diverse plant organs are greatly influenced by environmental conditions.

Modifying GSL Content in Vegetable Brassicas

In recent times, there has emerged a considerable amount of fascination with the creation of procedures and techniques that can modify the levels of specific GSLs in *Brassica* plants. This interest can be attributed to the fact that these techniques and

procedures have the potential to improve crop yields. This is due to the fact that although certain GSLs have desired qualities such as flavors, biofumigation, resistance to insects, and anticarcinogenic, others have unfavorable qualities such as harshness and goiter disease. In addition, some GSLs have desirable properties such as preventing cancer (van Doorn et al. 1998). One goal of improving *Brassica* is to increase the amount of positive GSLs and decrease the number of negative GSLs (Traka and Mithen 2009). Either this is done in an effort to grow crops with a high value and improve the overall quality of food, or it is done in an effort to collect data that can be utilized to investigate how these compounds influence living things (Fahey et al. 2001; Cartea et al. 2008a). In addition to structural variety, the genetic similarity level (GSL) diversity that exists across families, genera, species, subspecies, and subspecies accessions is considerable (Cartea et al. 2008b; Kushad Mosbah et al. 1999; Bradshaw and Wilson 2012). Because of this variety, it is now possible to design new sorts that have GSL content and composition that is acceptable. It has been shown to be possible to adjust the GSL content of cruciferous vegetables via a variety of techniques, including as classical breeding techniques and genetic manipulation. This modification has been shown to be practical. In recent years, this goal has been accomplished.

4.2 Breeding Objectives: Positive and Negative Selection

Higher crop yield, adaptation to wide climatic conditions, and resistance to common diseases and pest are major aims of breeding *Brassica* vegetables. In quality traits, higher levels of β-carotene and anthocyanin in edible portion of *Brassica* vegetables are attracting growers and consumers. Higher levels of beneficial glucosinolates (glucoraphanin and glucoiberin) and lower levels or complete elimination of progoitrin are interesting areas for quality breeding in *Brassica* vegetables. In addition to these, higher levels of other antioxidants such as ascorbic acid, lutein, dietary minerals and vitamin A are also targeted by the quality breeders for public health. Increase in chlorophylls is required for better consumer acceptance. It is also essential to increase the sugar fraction in *Brassica* vegetables so that the taste can be further improved, particularly, in higher temperature conditions when bitterness detracts many consumers.

4.3 Classical Breeding Achievements: Composition and Contents

4.3.1 Breeding for Carotenoids

To obtain 100% heterozygous plants (*Oror*), the following two ways can be adopted: (i) use combination of white homozygous recessive (*oror*) SI/CMS line × homozygous dominant (*OrOr*) as male or (ii) dominant homozygous (*OrOr*) orange as SI/CMS line × homozygous recessive (*oror*) as male. For this, the *Or* gene need to be transferred to a self-incompatible/CMS line of a respective maturity groups. Since, originally the *Or* genotypes were found in snowball group, and now since it

has been introgressed in all the maturity groups of Indian cauliflower in an attempt to develop β-carotene-rich cultivars to tackle prevalent malnutrition in Indian population, its utilization in hybrid development needs three-step activities. First, introgression of *Or* gene into a fertile non-SI line of the target maturity group; second, convert the *Or* line into a CMS lines; and third, explore/utilize the homozygous orange CMS lines in hybrid development. Alternatively, the fertile non-SI *OrOr* lines developed after first phase can be used as male parent along with white curding (*oror*) CMS lines of respective maturity groups to develop hybrids. The use of SI^{r} or CMS^{r} as one of the parents in hybrid breeding is essential because hybrid seed production in cauliflower is entirely dependent upon these genetic mechanisms.

4.3.2 Development of Open-Pollinated Varieties

Crisp et al. (1975) suggested to exploit the *Or* gene using hybrid breeding only because the *Or* gene in homozygous state confront with curd phenotype reducing their market value. Since the orange curd phenotype is governed by a single semidominant (partial dominant) *Or* gene, it has penalties on different morphological, developmental, phonological, and yield traits. Thus, the only plants heterozygous for *Or* gene have commercial value and the hybrid seed production is abundant. During seed production, the occurrence of homozygous plants (*OrOr*/*oror*) in open-pollinated varieties (OPV) will give undesirable phenotypes, particularly homozygous orange (*OrOr*) plants. The white curding plants are removed at curding stage and marketed from the seed production block to avoid contamination. These homozygous orange plants rarely produce satisfactory seeds. The curds of these plants remain very small (30–40 mm or less in diameter; <80 g in comparison to normal curd of 150–200 mm), deformed, and unmarketable (Dickson et al. 1988; Singh and Kalia 2021). The homozygous recessive (*oror*) plants produce white curds which are normal in shape and of full size as per the parental line, hence they have proper market for them as white curds. Thus, only heterozygous orange color plants are advanced for seed production in case of open-pollinated varieties. In the next year, this OP variety seed lot produces plants of three different types as white full size curds: intermediate orange full size curds: intense orange very small size curds in a ratio of 25:50:25, respectively. Thus, from such varieties, almost 75% plants are marketable, of them 50% are orange and 25% are white.

4.3.3 Development of Orange Hybrids in Cauliflower

Four F_1 hybrids by using white self-incompatible (SI) F_1 (90, 91, 95, and 96) of two isogenic lines differing in incompatibility alleles and a high carotene orange curd line as male parent. The female lines were four early white SI hybrids of two isogenic lines differing by incompatibility alleles. The orange curd hybrids so developed showed a variation in β-carotene content which ranged from 70.6–293.4 μg/100 g fresh curd tissues. The orange hybrid 95 × orange inbred line and 96 × orange inbred line had maximum β-carotene content (293.4 μg/100 g fw), which was almost 14.7 times higher than the white curd female parent, but around 3.6 times less than the orange male parent (1060 μg/100 g fw). Out of four orange hybrids, two were from female parental F_1s 90 and 91 (isogenic SI hybrids). These had lesser β-carotene content of

Fig. 18 CMS-based promising orange F_1 hybrids in early group of Indian cauliflower. (Photo: Shrawan Singh)

139.7 and 70.6 μg/100 g fw, respectively, than another set of orange hybrids 95 × orange inbred line (293.4 μg/100 g fw) and 96 × orange inbred line (155.2 μg/100 g fw). The author's group also observed strong influence of female parent on intensity of orange color and β-carotene content in Indian cauliflower.

Ding and Jian (2010) developed an orange-colored cauliflower hybrid 'Jinyu 60' using a white curding cytoplasmic male sterility (CMS) CMS92-60 as female parent and an orange-colored inbred line 93-4 as male parent. The F_1 hybrid was superior to the parental lines for both nutritional quality and commercial traits. The hybrid 'Jinyu 60' produce orange curds and the β-carotene content was 31.3 μg/g in dry curds, which was almost 10.8 times higher than that of the white curd. However, the vitamin C, dietary fibre, protein, and mineral elements were nearly equivalent to those of white cauliflower parental line. The curd weight was reported to be in the range of 800–1000 g and maturity period is about 60 days after transplanting.

The author's group at ICAR-IARI, New Delhi, India, also developed orange-colored cauliflower hybrids, namely *DCEH-15419* and *DCEH 529819*, using white curding CMS lines as female parent and intense orange-colored fertile inbred lines as male parents in tropical Indian cauliflower (Fig. 18). Both hybrids produce all orange curds at a higher mean temperature range (20–25 °C), hence promising for growing in tropical regions. The yield potential of these promising hybrids is around 18 t/ha with standard crop management practices (IARI Annual Report, 2021). Several hybrids in market are available, particularly in European-type cauliflower; some of them worth mentioning are 'Cheddar', 'Orange Burst', and 'Orange Bouquet'.

4.3.4 Breeding for Anthocyanin

Recurrent Breeding

Select heterozygous individuals from F_2 population generated from cross between white and purple genotypes. Reject intense purple, if they have parent-type plant morphology. If the purple curding plants show difference in morphology, then use them for selfing to develop new lines. White curding plants should be rejected in

every generation. In purple broccoli, the recurrent selection was carried out in exotic segregating material and Delhi Purple Broccoli-1 line was selected, which was identified as Pusa Purple Broccoli-1 for cultivation during winter months in Delhi region. It is rich in health beneficial glucosinolates + anthocyanin (30.31 ± 0.68 mg/100 g fw). The Pusa Purple Broccoli-1 is a short-duration (75–85 days) variety suitable for taking early crop in purple broccoli. It will expand harvesting period of purple broccoli (December–January) since presently available variety Palam Vichitra is available during February–March months in plains. Unlike Palam Vichitra, DPB-1 has subtropical flowering habit, so seed production is possible in North Indian plains during winter season (IARI, 2020). The seeds produced in North Indian plains can be used for raising the crop and microgreens.

Backcross Breeding

It is useful to transfer *Pr* locus in a desirable background. For this, *Pr* locus itself acts as marker (due to variation in intensity of purple color of curd among homozygous and heterozygous varieties). Hence, backcrossing need to be carried out up to BC_2 or BC_3 generation followed by selfing/sibbing of horticulturally important individuals, having intermediate purple curding color trait, to derive homozygous lines for *Pr* locus. This may be done in later stages if the background/recurrent genotypes are from different group. It is a semidominant gene and its transfer is not like recessive or dominant gene. So, selfing of backcross population is required to isolate suitable lines.

Hybridization Method

In purple cauliflower, a new open-pollinated variety Pusa Purple Cauliflower-1 was developed through hybridization method using a cross between Pusa Snoball Kt-25 x Graffitti. It forms marketable curds during January–March months (IARI, 2020). A similar line of work is being undertaken by the authors for development of anthocyanin-rich purple cauliflower in early maturing Indian cauliflower.

Hybrid Selection

The *Pr* locus has incomplete dominance; hence, to attain intense colored curds, it is essential to have both parents in homozygous state for the *Pr* locus to get desired color in curds. The steps in breeding of purple color hybrids in cauliflower are shown in Fig. 19. Pusa Red Cabbage Hybrid-1 of cabbage was developed using red cabbage CMS lines and red cabbage fertile line as pollen parent (IARI, 2020). A CMS-based red cabbage hybrid has purple-green outer leaves and head is completely purple, very compact, and round. It matures in 70–75 days after transplanting. Average head weight is 1.2 kg and yield is 47.0 t/ha. The varieties developed in vegetable Brassicas for anthocyanin content are given in Table 1.

4.3.5 Breeding for Glucosinolates

Breeders of *Brassica* have sought to enhance the nutritional profiles of their plants by increasing the concentration of GSL, which includes glucoraphanin, glucoiberin, glucoerucin, and the indolic compound glucobrassicin. The development of broccoli

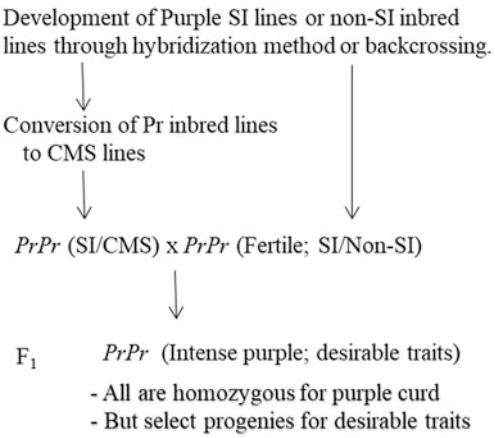

Fig. 19 Steps in development of purple color hybrid in cauliflower

with a higher glucoraphanin concentration as a result of extensive epidemiological data linking the therapeutic effects of broccoli to the bioactivity of sulforaphane, the ITC obtained from glucoraphanin, serves as an example of traditional breeding in vegetable *Brassica* crops. This development occurred as a result of extensive epidemiological data linking the nutritional benefits of broccoli to the biological processes of sulforaphane, which was produced from glucoraphanin (Riso et al. 2014). Sulforaphane may have anticarcinogenic characteristics, which are beneficial to human health, as shown by a variety of in vitro and animal studies (Mithen et al. 2000; Juge et al. 2007). In the 1990s, researchers from the UK evaluated nine distinct wild species of *B. oleracea* and discovered that *Brassica villosa* species had the greatest amounts of glucoraphanin out of all the species. According to Faulkner et al. (1998), hybrids produced by mating broccoli inbred lines with this wild cousin species had higher levels of glucoraphanin and were better able to stimulate phase 2 enzymes than broccoli inbred lines. This was found to be the case even though broccoli inbred lines had higher levels of glucoraphanin. Later on, Mithen (2003) made the discovery that the long-term introgression of two *B. villosa* L. chromosomal regions into broccoli led to an increase in the amount of ITC that was produced by the plant. One region of the B. villosa genome positioned on LG 5 increased 3C GSLs, while other regions placed on LG 9 and 2 elevated GSLs emanating from methionine. Because nitrile synthesis is inhibited in these genotypes, not only do they have higher GSL levels, but they also have a greater capacity for converting GSL into ITC. The *MYB28* allele, which was introgression from the *B. villosa* region, was shown to be highly expressed in hybrids with high levels of glucoraphanin. The amount of glucoraphanin found in these hybrids is about two to three times higher than that seen in conventional hybrids. One of the early uses of these results was the granting of a patent in the USA for broccoli sprouts that were created using genotypes that were rich in GSL (Fahey et al. 1997). Beneforté® broccoli is the brand name given to glucoraphanin-packed broccoli hybrids that are grown commercially in the Netherlands and the USA. A human intervention study

made use of the experimental hybrid HG1, which was a high-glucoraphanin F_1 hybrid originating from the UK initiative.

Some types of *Brassica* plants have benefited from additional breeding and selection methods carried out by GSL. For instance, a strategy of boosting marrow stem kale with a low indole GSL level that used a full-sib family selection approach proved successful (Bradshaw and Wilson 2012). In contrast, plant breeding use divergent mass selection to establish populations of individuals with genetically identical ancestry and outstanding GSL attributes. This is accomplished via the breeding of Brassicas. According to Stowe and Marquis (2011), this kind of choice on a speedily *B. rapa* variety can impact the cumulative GSL of the leaves. The Misión Biológica de Galicia (MBG-CSIC) selected for both high and low amounts of glucoiberin, sinigrin, and glucobrassicin, in the leaf tissue of turnips leaves (*Brassica rapa*). These selection programs were also used on the kale's ancestral population (Stowe and Marquis 2011).

5 Genetic Diversity Analysis

Brassica vegetables were originated from a common ancestor *B. oleacea* var. *sylvestris*. During evolution major and minor mutations as human selection for adaptive and economic traits resulted in diverse botanical varieties in *B. oleracea,* namely var. *caitata* (cabbage), var. *acephala* (kale), var. *botrytis* (cauliflower), var. *gemmifera* (brussels sprouts), and var. *italica* (broccoli). These botanical varieties have different plant parts as edible portion, hence differ in composition of quality constituents. *Brassica* species also have great extent of diversity in phytochemicals and metabolites (Branca et al. 2018). They found a wide range of carotenoids, total anthocyaninascorbic acid, glucosinolate concentration, and polyphenols, some of which might be employed as phytoconstituents indicators for accountability. Wild *Brassica* species contain higher levels of glucosinolates than the *B. rapa* subsp. *oleifera*, *B. oleracea* and *B. rapa* (Fig. 20). They also reported inter- and intraspecies variation in *Brassica* species for total and individual glucosinolates such as sinigrin, gluconapin, glocobrasicanapin, progoitrin, glucoiberin, glucoraphanin, and glucobrassicin. They reported only glucoiberin (100% of total GSLs) in *B. rupestris* and predominantly progoitrin (86% of total GSLs) in Pop. 1 (Sadinia) of *B. insularis*. In wild *B. oleracea*, gluconapin (79%) was the predominant GSL followed by glucobrassicin (18%) and progoitrin (3%), while in the case of cultivated *B. oleracea*, predominant GSLs in *B. o.* var. *capitata* were glucobrassicin (65%), sinigrin (25%), and I-methoxyghrcobrassicin (15%). Glucobrassicin (57%) was also highest GSL in *B. o.* var. *botrytis,* while in *B. o.* var. *italica*, glucoraphanin (48%) was major GSL followed by glucobrassicanapin (39%). The GSLs profiles of cauliflower does not matche with its probable ancestor *B. cretica*, which had gluconapin (86–97% of total GSLs) as the predominant GSL, indicating for major changes in the GSL pathway genes during evolution process. The study of GSLs in 51 species of Cruciferae from Middle Eastern region detected 30 compounds with three unknowns of limited occurrence. They found *p*-hydroxybenzylglucosinolate in six species, 4-methylsulfinyl-3-butenyl, 3-methoxycarbonylpropyl,

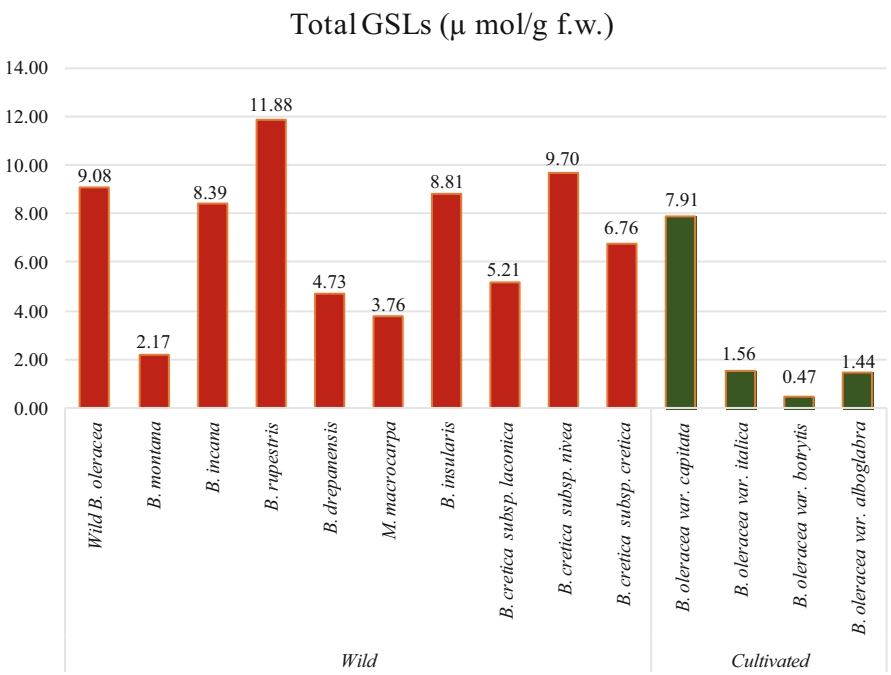

Fig. 20 Total glucosinolates content in cultivated and wild vegetable *Brassica*

and *p*-rhamnopyranosyloxybenzyl in *Sinapis aucheri, Erysimum*, and *Thlaspi perfoliatum*, respectively. They concluded that the distribution of GSLs is very useful at the species and genus levels but may provide only minimal support to the tribal alliance of certain genera. It supports the removal of *Sinapis aucheri* from the genus, the recognition of *Fibigia clypeata* and *F. macrocarpa* as distinct species, and the alliance of *Ochthodium* with *Euclidium* and *Arabis* with *Drabopsis.*

Glucosinolates component variability is associated to the A, B, and C genomes of three ancient vegetable *Brassica* species having diploid genetic chromosomes. These genomes are from species of vegetable *Brassica*.

- *B. nigra (BB, 2n = 16)* has glucosinolates with 3C side chains, which are the result of a single elongation process.
- The glucosinolates in *B. oleracea* (CC, 2n = 18) have either 3C or 4C side chains.
- The glucosinolates in *B. rapa* (AA, 2n = 20) have either 4C or 5C side chains.
- *Digenomic species B. carinata* (BBCC, 2n = 34), *B. juncea* (AABB, 2n = 36), and *B. napus* (AACC, 2n = 38) possess following glucosinolate composition that consists of the profiles of two elementary species.
  - Glucoiberin: white cabbage, red cabbage, cauliflower, and kale
  - Sinigrin: *B. oleracea* (cabbage, kale, brussels sprouts, cauliflower, and knol khol), *B. juncea*, and *B. carinata*
  - Glucoerucin: *Eruca sativa*

- Glucoraphanin: *B. oleracea* (broccoli, cauliflower, and kohlrabi) and *Eruca sativa*
- Gluconapin: *B. rapa* (bok choy and turnip) and *B. oleracea* (broccoli)
- Progoitrin: *B. rapa* (turnip and pak choi) and *B. oleracea* (brussels sprouts, cauliflower, and broccoli)
- Dehydroerucin: radish (80% of all glucosinolates)
- Glucobrassicanapin: *B. rapa* vegetables

Assefa et al. (2019) analyzed intact glucosinolate in the leaves of 50 germplasm collections and commercial cultivars of *B. rapa*, *B. juncea*, and *B. oleracea* from six countries grown under uniform cultural conditions. They reported total GSLs content in the range of 36.80–2383.12 μmol/kg DW with predominance of aliphatic GSLs (23.0–98.9%). Gluconapin and glucobrassicanapin contributed the greatest proportion.

6 Molecular Mapping of HR Genes and QTLs

6.1 Carotenoids

6.1.1 Marker-Assisted Breeding of *Or* Gene

The *Or* gene is a semidominant gene and it is almost impossible to differentiate between white and orange individuals as well as homozygous orange and heterozygous orange individuals because these all produce normal seedlings and show similar vegetative growth pattern. However, in later phases some visible morphological differences occur because of the impact of homozygous orange gene such as enhanced petiole length, small curds, and delayed flowering in case of homozygous orange (Crisp et al. 1975). To differentiate white (*oror*) and orange (*OrOr/Oror*) individuals, Li and Garvin (2003) identified ten amplified fragment length polymorphism (AFLP) markers using bulked segregant analysis. They converted four AFLPs most close to the target *Or* gene into restriction fragment length polymorphism (RFLPs). Mapping of these RFLPs could find close linkage between two markers and the target *Or* locus. Of these, one marker was at 0.5 cM from the *Or* locus while another RFLP was on another side of the locus at a distance of 1.6 cM. Subsequently, they converted two close flanking RFLPs into SCAR (sequence-characterized amplified region markers). It has been discovered that the SCAR markers (SA4, SA7, and SA9) are associated to the *Or* region. SA4 marker was found to be gene-specific marker for foreground selection. These markers are useful for large-scale screening of *Or* genotype in segregating population from the white individuals.

A single-locus recessive mutation called the *Or* in Chinese cabbage results in an accumulation of carotenoids in the plant's head leaves, giving them an orange coloration (Zhang et al. 2008). Microspore culture was used to develop a doubled haploid population from an F1 cross between the lines "91–112" and "T12–19" (white head leaves × orange head leaves), which revealed the SCAR markers connected to the *Or* gene. In Chinese cabbage, the Or gene is responsible for producing orange head leaves. Three RAPD markers, P67M54-172, OPAX18-656,

and OPB01-845, were effectively converted into the SCAR markers SCOR 127, SCOR204, and CSR 845. These three SCAR markers were used in a genetic analysis to map to the same linkage group as the *Or* gene with a LOD score of 6.0, implying that the *Or* gene should be found on A genome linkage group R9. They were also combined with two previously identified SSR markers, Ni4D09 and BRMS-51 (on linkage group R9). Furthermore, accuracy values of 92%, 90%, and 89.1% were found when 110 distinct inbred breeding lines of Chinese cabbage were examined using these three SCAR markers. This shows that these markers might be used for marker-assisted testing in the selection of beta-carotene-rich genotypes.

6.2 Anthocyanins

Ken et al. (2010) identified five RAPD markers around the locus for purple pigmentation in *Brassica rapa*. With the use of two SSR markers, one CAPS marker, and four RAPD markers, a preliminary linkage map of the pigmentation locus was constructed. A 0.84-kb segment of the RAPD marker OPU10 was amplified, cloned, sequenced, and then turned into a CAPS marker (OPU10C). On the partial linkage map and in linkage group R07 of the previously published reference map of *B. rapa*, this CAPS marker was mapped 4 cM distant from the pigmentation locus. Zhang et al. (2016) discovered a mustard (Anm) anthocyanin locus on *B. rapa* chromosome A02. The amplified bits were sequenced and aligned, and they revealed that purple Chinese cabbage contains purple mustard components on chromosome A02. Five genes were expressed at higher levels in purple Chinese cabbage than in nonpurple Chinese cabbage, according to the expression patterns of 12 anthocyanin-related genes on A02. Liu et al. (2021) found two QTLs linked with broccoli anthocyanin production on chromosomes 7 (*BoPur7.1*) and 9 (*BoPur9.1*). They then performed high-resolution mapping of *BoPur9* and discovered that the key anthocyanin biosynthesis QTL region is 73 kb in size and comprises 14 genes. AT5G07990 (gene encoding flavonoid 3′ hydroxylase), a putative gene for *BoPur9.1*, had a considerable degree of similarity with *Bo9g174880, Bo9g174890*, and *Bo9g174900.* The expression of BoF3'H was much higher in BT 126 than in SN60. Chiu et al. (2010) mapped the *Pr* locus in purple cauliflower at 0.3 cM resolution, including *BoMYB2, BoMYB3, BoMYB4,* and the *Pr-D* locus. Among these markers, *BoMYB2* has been shown to be located inside the *Pr-D* locus. The expression of anthocyanin regulatory and biosynthetic genes was shown in eight marketed cultivars (Yuan et al. 2009). They discovered that all kinds of red cabbage have a similar mechanism for controlling anthocyanin production. Except for CHI, all other structural genes, including *CHS, F3H, F3'H, DFR, LDOX,* and *GST*, were constitutively upregulated in red types, which coincided with an increase in the transcript levels of a *bHLH gene, BoTT8,* and a *MYB* transcription factor, *BoMYB2*.

6.3 Glucosinolates

The process of glucosinolate synthesis in *Arabidopsis* and *Brassica* is well established, as previously said, particularly as a consequence of investigations

carried out over the past ten years. It has been clear since the 1970s that glucosinolates are important for both human and animal nutrition. In the 1990s, preliminary efforts were made to identify the region of the genome that was responsible for GSL formation. One of these approaches included searching at quantitative trait loci (QTLs). In the last few decades, several researches have tried to identify QTLs related to GSL inheritance due to the accessibility of molecular markers.

Breeders may choose certain genotypes by predicting the parental alleles at the QTLs from the genotype at marker loci connected to those QTLs (Uzunova et al. 1995). Finding QTLs is also the first step in finding and cloning the genes responsible for the desired traits. The accessibility of the genetic data of the major *Brassica* crops, similar to *Brassica* species, and understanding of the genes that govern GSL formation in *Arabidopsis* have facilitated the search for possible loci for GSL synthesis in *Brassica* crops. QTL analysis has been regularly used in *Brassica* crop breeding to increase GSL content. Numerous studies on QTLs have been conducted on the vegetable forms of *B. rapa*, such as Chinese cabbage, pak choi, turnips, turnip tops, and cima di rapa. Lou et al. (2008) identified QTLs for GSL amounts and deposition in *B. rapa* young leaves in two inbred populations comprised of Kairiyou Hakata, pak choi, a Japanese turnip, and yellow sarson cultivars. Aliphatic GSL concentration was regulated by 16 QTLs, indolic GSL concentration by 3, and aromatic GSL concentration by 3 QTLs. To find candidate genes, metabolomics have often been utilized in conjunction with genomic, transcriptomic, and other platforms. Del Carpio et al. (2014) examined the profile of GSLs and the transcript quantity of genes associated with GSL synthesis in the leaves of plants from a breeding population generated from a combination of a pak choi and yellow sarson plant. In genomic areas on linkage groups A03 and A09, significant microsatellite quantitative trait loci (mQTLs) were generally co-localized. The results of the 94 probes were analyzed, and 42 of them indicated at least one eQTL. These findings depict 25 candidate genes. Both cis- and trans-eQTL were present in the majority of hotspots in the genomic areas at A09 and A03 for these genes, with the majority of genes exhibiting trans-eQTL effects at the locations of *MYB28* in A09 and *MYB29* and *UGT74B1* in A03. Nuclear magnetic resonance (NMR) was used by Bagheri et al. (2013) to investigate the genetic variation for a variety of secondary metabolites in *B. rapa*. Six GSL QTLs were assigned to the loci A10, A9, A5, and A3, with two QTLs in A3 and two QTLs in A5 presumably co-locating. The progoitrin QTL and the MYB29/MYB28 map sites were detected on A3 at 95 cM. Recently, efforts have been made to cultivate *B. oleracea* plants with high glucoraphanin contents. In a broccoli mapping population, Brown et al. (2015) found 14 QTLs for both general and particular GSLs. While *GSL-PRO* and *GSL-ELONG* have been linked to specific loci in *C05* and *GSL03*, respectively, *GSL-ALK* has been proposed as the gene responsible for GSL12 variation in C09. Sotelo et al. (2014) identified 18 metabolic QTLs for total and individual GSL content in leaves, flower buds, and seeds, in a inbred population generated from an intercross of broccoli and Chinese kale inbred lines. It was believed that the GSL-OH, GSL-PRO, and GSL-ALK genes were responsible for the QTL-3, QTL-5.1, and QTL-9.2, modifications, respectively. The indolic GSL pathway genes ATR1, CYP81F2,

CYP79B3, and CYP79B2 were among the candidates for QTLs QTL-8.1, QTL-2.1, QTL-7.4, and QTL-1.2, respectively.

6.4 QTL Analysis for Quality Traits in *Brassica* Vegetables

There has been an increase in consumer demand for nutrient- and biochemically dense foods that have a positive effect on human health during the past decade. Brassicaceae plants include crucial natural physiologically active compounds, such as enzymes, pigments, vitamins, and particular secondary metabolites, with antioxidant, cardioprotective, anticarcinogenic, and anti-inflammatory properties and immune-boosting properties (El-Mogy et al. 2019; Artemyeva et al. 2014). Biparental quantitative trait locus (QTL) linkage mapping is an efficient method for finding genetic regions that co-segregate in the trait of interest within the research population. Mapping quantitative trait loci (QTL) has shown to be a useful technique for analyzing complex traits controlled by several genes (Salvi and Tuberosa 2005). Thousands of quantitative trait loci (QTL) that control multiple health-promoting characteristics have been identified in varied species by linkage mapping techniques (map-based QTL), and dozens of important genes have been cloned by fine mapping of QTL in several crop species (Bernardo 2008). In populations of doubled haploid lines of *Brassica rapa*, Egorova et al. (2021) discovered a correlation between molecular markers and chromosomes and the amount of dry matter and physiologically active compounds such as sugars, carotenoids, anthocyanins, ascorbic acid, and chlorophylls a and b. They identified 102 quantitative trait loci (QTLs) that regulate the expression of biochemical quality parameters under both short- and long-daylight circumstances. In addition, they discovered that the majority of loci controlling all of the investigated biochemical parameters were located in the fifth, sixth, seventh, and ninth linkage groups, which were consistent with field and controlled environmental data. The outcomes of prior analyses of the most crucial biochemical quality criteria in Brassicaceae have been presented. Artemyeva et al. (2014) identified quantitative trait loci (QTLs) for five nutritional quality markers, namely beta-carotene, ascorbic acid, total protein, and chlorophylls a and b, using two mapping populations of *Brassica rapa* doubled haploid lines. QTLs, their effects, the fraction of phenotypic variability impacted by each QTL, and molecular markers genetically related with each QTL were discovered for each characteristic investigated. Significantly, Jan et al. (2016) identified a significant variation in the cumulative seed protein content of several *Brassica rapa* ecotypes, which has significance for agricultural development and effective utilization. Ullah et al. (2017) examined the heritability, genetic variation, and association of several biochemical characteristics in advanced populations of *Brassica rapa*. They discovered substantial differences in glucosinolate, oil content, protein content, oleic acid, linolenic acid, and other biochemical indicators. Zhao et al. (2007) mapped the *B. rapa* QTL for phytate and phosphate levels in seeds and leaves. Lou et al. (2008) found the QTL for the glucosinolate aggregation trait, which influences the nutritional value of *B. rapa* and is a vital plant defense mechanism. The location of QTLs

linked with the amount of sugars, amino acids, organic acids, aromatic compounds, and glucosinolates in seedlings was found using QTL analysis of metabolites (Bagheri et al. 2013).

Leaf heads of cabbage (*Brassica oleracea*) and Chinese cabbage (*B. rapa*) are vital sources of minerals, crude fiber, and vitamins in the human diet. Yu et al. (2013b) conducted QTL mapping on 150 RILs derived from the combinations of heading and nonheading Chinese cabbage in order to investigate the genetic component of leafy head in Chinese cabbage (*B. rapa*). The parental genome resequencing identified more than one million SNPs. Genotyping RILs with high-quality SNPs provided a high-quality genetic map with 2209 markers and 18 QTLs (LOD of more than three and phenotypic effect [R2] of more than 5% for six head features, from which three candidate genes were identified). Gao et al. (2022) analyzed 16 important agronomic characteristics in 240 F_2 individuals derived from two separate inbred lines of Chinese cabbage, ZHB and G291. A genetic map of 105 intragenic simple sequence repeat (ISSR) markers dispersed over ten linkage groups (LGs) spanning over 2034.1 cM in length was constructed having an average interlocus distance of 21.75 cM. His team discovered 48 QTLs on the studied LGs for the assessed major agronomic parameters, with LOD values varying from 2.51–12.49, which accounted from 3.41 and 26.66% of the morphological characters.Several quantitative trait loci (QTLs) for anthocyanin accumulation in Chinese cabbage have been found (Guo et al. 2015). In an F_3 population, genes regulating basic hereditary traits, such as seed color, seed erucic acid content, and the presence of leaf hairs, have also been identified (Teutonico and Osborn 1994). Bagheri et al. (2013) revealed QTLs influencing seedling metabolite and seed tocopherol concentrations in a RILs generation of *Brassica rapa* obtained from L58 (with a higher level of glucosinolates and phenylpropanoids) and R-o-18 (having high sucrose, glucose, and glutamate levels). The QTLs that were linked with seed tocopherol concentrations (a-, ß-, d-, α/β, and total tocopherol) were identified on chromosomes A10, A9, A6, and A3, and they accounted for 11–35% of the variance that was significant. The region on A3 is located near to the *BrVTE1* gene, which codes for tocopherol cyclase. NMR spectroscopy reveals that seedlings contain organic/amino acid, sugar/glucosinolate, and aromatic compounds. The majority of identified chemicals have their QTL locations established. In contrast to prior investigations, specific loci for glucosinolate amounts have been identified. Five to seven QTLs with additive and/or epistatic effects have been discovered in a doubled haploid (DH) population of *B. napus* for tocopherol, total tocopherol, and their ratio (Marwede et al. 2005). In another DH population of *B. napus* and its rebuilt F2 progeny, 50 QTLs and related markers for tocopherol composition and content were identified (Wang et al. 2012b). In two recombinant inbred line (RIL) populations of the *Brassica* reference plant species *Arabidopsis thaliana*, 14 QTLs affecting seed tocopherol content and composition have been found. Using mutational analysis and genomic-based methodologies, several researches have discovered and cloned the genes of the tocopherol synthesis pathways in *A. thaliana* (Bagheri et al. 2013).

Numerous secondary plant metabolites in the plant metabolome may have a nutritional effect. Glucosinolates are sulfur-containing plant compounds that have anticancerous properties. They encompass more than one hundred plant secondary

metabolites, the majority of which are found in the Brassicaceae family. Glucosinolates are of particular interest because of their anticarcinogenic properties (Hayes et al. 2008). In two doubled haploid (DH) populations of *B. rapa*, leaf aliphatic glucosinolate QTL mapping identified 16 loci regulating aliphatic glucosinolate concentration (Lou et al. 2008). According to comparative genomic studies, 102 putative glucosinolate-producing genes in *B. rapa* are orthologs of 52 associated genes in *A. thaliana* (Wang et al. 2011). Five consensus areas align to chromosomes C1, A9, A2, C3, and A8 in the genome of *Brassica napus* Darmor-bzh. In addition, 24 orthologs of functional key genes for biosynthesis of fatty acids were detected.

7 Marker-Assisted Breeding for HR Traits in *Brassica* Vegetables

7.1 Carotenoids

Kalia and his colleagues showed a marker-assisted breeding technique for the efficient introgression of the *Or* gene in Indian cauliflower for the purpose of beta-carotene biofortification (Fig. 21). Repetitive backcrossing and screening of advanced items employing accessible foreground markers were utilized in this approach. They employed background markers to quickly retrieve the genome of

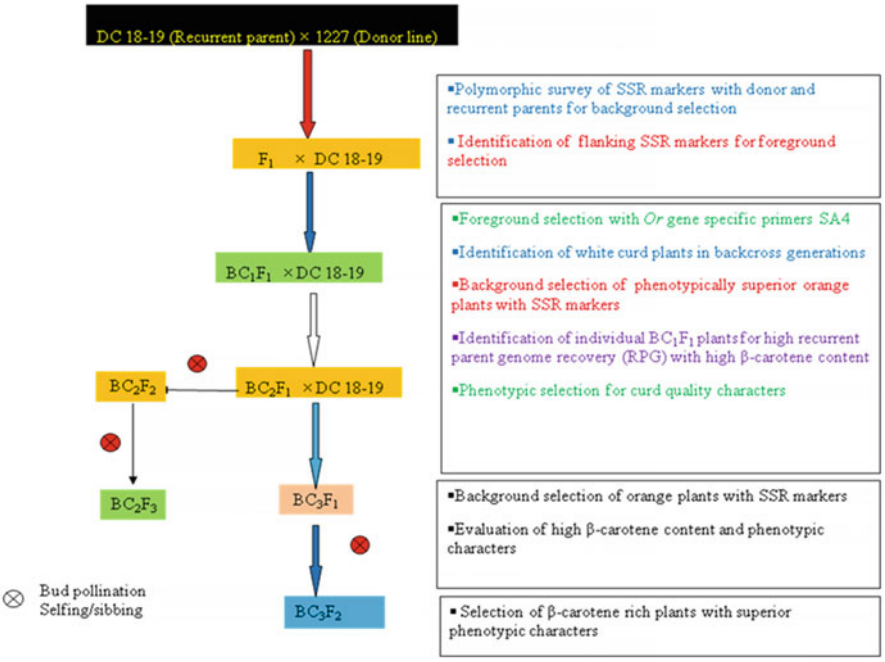

Fig. 21 Marker-assisted breeding of *Or* gene in Indian cauliflower. (Source: Muthukumar 2016)

the 'DC-18-19' recipient genotype. Kalia et al. (2020) used PCR to confirm the AFLP-based SCAR marker SA4 in *Or*-introgressed lines of Indian cauliflower. They also reported the creation of a functional SSR marker that allows the selection of *Or* gene carrier plants at the seedling stage. Furthermore, 400 SSR markers encompassing nine chromosomes were employed for polymorphism survey and background selection. On this basis, 35 polymorphic markers were discovered and employed for background selection in selected BC2 plants in order to extract the parent genome.

7.2 Anthocyanin

In purple cauliflower, Chiu et al. (2010) found a high-resolution genetic mapping of the *Pr* was done having *BoMYB2, BoMYB3, BoMYB4,* and the *Pr-D* locus at 0.3 cM. Of these markers, BoMYB2 is shown to be located within the *Pr-D* locus.

8 Map-Based Cloning of HR Genes/QTLs in *Brassica* Vegetables

Li and Garvin (2003) sought to isolate *Or* using a map-based cloning technique, utilizing the cauliflower *Or* mutant as a model, in order to elucidate the molecular mechanism through which the *Or* gene controls carotenoid accumulation. They used a flanking marker technique in which they used two previously identified, locus-specific, SCAR markers for the study of 1632 F_2 individuals to create a high-resolution genetic linkage map of the *Or* locus area (Li et al. 2003). They defined the *Or* locus to a 50-kb BAC clone, which corresponds to a genetic interval of 0.3 cM, utilizing positional cloning using BAC clones.

GSL-ALK was cloned and tested in two recombinant inbred line populations of *B. oleracea*. Table 2 depicts the evolutionary variety in glucosinolates. Giamoustaris and Mithen (1996) proposed a model in which 3-methylthiopropyl GSL is sequentially transitioned to 3-methylsulfinylpropyl and finally to 2-propenyl GSL by the action of dominant alleles at two distinct loci in a backcross inbred population (BILs) generated from a cross between two *B. oleracea* relatives viz. GSL-ALK and GSL-OXID. These two loci were assigned to the same LG as the *B. napus* LG 19 loci, which were validated using RFLP mapping in *Arabidopsis* but also wild *Brassica* species. On the basis of these results and previous research on *Arabidopsis*, four key biosynthetic loci were proposed: GSL-AOP, ELONG, OH, and OX. All four of these loci are prefixed. *Brassica* includes glucosinolates with three, four, and five carbons, but *Arabidopsis* includes glucosinolates that have as many as eight carbons. Secondary metabolites identified in broccoli include carotenoids, glucosinolates/sulforaphane, flavonoids, and phenolic acids. Multiple loci/genes have been found that influence the accumulation of these compounds in broccoli. Broccoli may be investigated using *Arabidopsis* genetic models of secondary metabolite synthesis (Frerigmann and Gigolashvili 2014). Some broccoli genes,

including *cytochrome P450 83A1 (CYP83A1), cytochrome P450 79F1 (CYP79F1), sulfotransferase UDP-glucosyltransferase 74B1 (UGT74B1), 18 (ST5b),* and *flavin-containing monooxygenase GS-OX1 (FMOGS),* are isolated directly using homologous cloning (Rahim et al. 2019). Furthermore, genetic mapping was carried out in order to discover genetic loci that impact the variability of secondary metabolites. Sotelo et al. (2014) used genotyping to identify 82 considerable QTLs for specific and quantitative glucosinolate production in leaves, seeds, and flower buds, with QTL9.2 (proposed candidate as GSL-ALK) being one of the important in glucosinolate differences and implying epistatic interrelations with other loci (Sotelo et al. 2014). Using a broccoli mapping population, Brown et al. (2015) developed a genetic linkage map, discovered 14 QTLs associated with indolic, aliphatic, or aromatic glucosinolate storage in florets, and showed that a locus GSL12 on C09 is responsible for almost 40% of progoitrin phenotypic diversity. Li et al. (2021b) used a DH population to do genetic mapping for sulforaphane metabolism in broccoli florets; they revealed 18 QTLs for sulforaphane synthesis in broccoli flower heads, six of which were found in several environments. Brown et al. (2015) utilized a known function population to construct a functional genomic map and an SNP array to detect three quantitative trait loci (QTLs) involved in carotenoid variation in broccoli heads (Brown et al. 2014). In at least two studies, Gardner et al. (2016) utilized a QTL analysis saturated with SNP markers on an Illumina 60 K array to identify 23 loci for overall phenolic content and its constituents in the population, which Brown et al. (2014) studied in high-density single nucleotide polymorphism (SNP) array mapping in Brassica oleracea for identification of QTL associated with carotenoid variation in broccoli florets. In the BolTBDH mapping population, a total of 33 QTLs that influence the amount of phenolic compounds found in seeds, leaves, and floral buds were discovered (Francisco et al. 2016; Gao et al. 2014; Lee et al. 2017). Additionally, broccoli seeds, sprouts, and by-products were subjected to transcriptome analyses to discover genes with expression levels associated to glucosinolate synthesis.

9 Genomics-Assisted Breeding for HR Traits in Vegetable Brassicas

Using association mapping, linkage disequilibrium (LD) mapping, and genome-wide association study (GWAS) is useful for elucidating the molecular genetic foundation underpinning natural phenotypic variation. Through this several causal allele(s)/loci that had not been found in QTL mapping populations were identified. This potential technique represents a significant advancement in genetic research and has clearly shown to be a beneficial tool in the discovery of candidate genes. Association mapping is increasingly being employed in wild populations of Brassicaceae with high genetic variation to identify DNA-based markers linked to essential health-promoting features.

Using 60 K SNP array in the *Brassica*, Qu et al. (2017) performed a genome-wide association investigation of fatty acid content in 520 different genetic oilseed

germplasms. Using the PCA + K model in TASSEL 5.2.1, the researchers analyzed 62 genetic loci that were associated significantly with the substance of seven fatty acids, in as well as five consensus regions that pertained to the C1, C3, A9, A8, and A2, chromosomes of the *Brassica napus* Darmor-bzh genome, respectively. The researchers then discovered various orthologs of functional candidate genes involved in lipogenesis, excluding BnaA.FAE1 and BnaC.FAE1 on the A8 and C3 homologous genome blocks, which are recognized to have significant functions in the fatty acid biosynthetic pathways, as well as promising orthologs of these genes (*KCS17, CER4, LPAT4, FAB1, LACS9, KCR1, TT16,* and *ACBP5*).

One of the most essential features of oil crops is seed oil content, which acts quantitatively (Zhao et al. 2005; Delourme et al. 2006). Linkage mapping of several populations revealed that many QTLs regulate oil content in rapeseed (*Brassica napus*) (Qiu et al. 2006). However, the number of parents utilized in prior genetic linkage mapping of QTL represents a relatively tiny part of rapeseed germplasm, and it is unknown how often the QTL may be discovered again in practical breeding (Mackay et al. 2009). By using association analysis or association mapping, QTL may be found in a way that is independent of linkage mapping populations. Zou et al. (2010a) investigated the efficiency of association mapping for seed oil content in new-type *B. napus* lines and a collection of traditional B. napus varieties from various countries. The new-type *B. napus* has relatively rich genetic diversity, although it has a greater amount of linkage disequilibrium than the classic *B. napus*. Similarly, in the population of new-type *B. napus*, there was a higher diversity in oil content and a greater number of related markers. Meanwhile, more than half of the genetic loci to which the linked markers belonged were found earlier in linkage mapping research, demonstrating the effectiveness of association mapping in *B. napus*.

10 Recent Concepts and Strategies Evolved in *Brassica* Vegetables

10.1 Genome Editing

The technology of gene editing provides essential technological foundations for plant functional gene research and agricultural genetic modification. In recent years, CRISPR/Cas9-mediated gene editing has emerged as a promising experimental technique for crop genomic sequence editing, and a number of different crops have widely used it (Tao et al. 2021). Murovec et al. (2018) developed a method for genome editing in a variety of *Brassica* species, such as *Brassica napus*, *Brassica oleracea*, and *Brassica rapa*. They identified the vernalization-determinant phytoene desaturase gene (PDS) and FRIGIDA (FRI) gene, which are both engaged in the carotenoid production pathway and are located at separate locations. Erucic acid (EA), which is known to have adverse health consequences, is one of the fatty acids that affect the edibility and processing qualities of vegetable oils. Low erucic acid (LEA) has been a *B. napus* selection characteristic for years. The enzyme fatty acid elongase 1 (FAE1) is required for the synthesis of EA. *B. napus* possesses two

functionally identical copies of FAE1 on chromosomes A08 and C03. Liu et al. (2022) used CRISPR/Cas9 to produce targeted mutations on these two homologous copies of BnaFAE1 in three *B. napus* accessions with high EA (>30%) and oil (>50%) levels. The EA content of the mutant BnaC03 was reduced by more than 10%. FAE1 (c03), while the combined mutation of *BnaA08.FAE1* and *BnaC03.FAE1* (a08c03), resulted in almost no EA and a variable rise in oleic acid content in three BnaFAE1-edited accessions.

CRISPR-Cas9 genome editing of *FAD2* has created rapeseed seeds with low linoleic acid and high oleic acid (Huang et al. 2020), providing a unique strategy for generating high oleic acid content oil crops. In addition, Ozseyhan et al. discovered that utilizing CRISPR technology to delete FAE1 might significantly reduce VLCFAs (Okuzaki et al. 2018).

Zhai et al. (2020) employed CRISPR/Cas9 and guide RNA to activate basic helix-loop-helix transcription factors (bHLH-TF) in a yellow-seeded *B. napus*. *BnaC09.TT8b* and *BnaA09.TT8* are transparent tests. The double mutant's enhanced seed oil level, greater protein content, and changed fatty acid (FA) composition were likely due to its thinner seed shell. Naturally occurring LOF mutations in these genes produce a phenotype characterized by yellow seeds in *B. juncea* and *B. rapa* (Li et al. 2012a, 2012b). The principal technique by which crops store phosphorus is phytic acid, which is antinutritional as it chelates minerals and limits their absorption. This is because phytases were unable to hydrolyze it into myo-inositol and free inorganic phosphate (Padmaja et al. 2014). Sashidhar et al. (2020) significantly enhanced the quality of canola meal by inactivating 15 paralogs of the canola ITPK gene family using the CRISPRCas9 technology. Karunarathna et al. (2020) used *Agrobacterium tumefaciens* with CRISPR/Cas9 reagents to improve seed oil content by changing of hypocotyl segments of WOSR cv. RS306 (and hence oil per acre) and chemical mutagenesis. Seed oil content was raised without impacting seed germination or vigor by introducing LOF mutations to the *Bnasfar5* (10%) and *Bnasfar4* (9.7–14.5%) genes late in the seed maturation phase.

Canola oil is mostly made up of free fatty acids, such as monounsaturated oleic acid and a 2:1 ratio of polyunsaturated linoleic and linolenic acid (Hu et al. 2006). Because of their improved shelf life and thermal stability, vegetable oils with a greater oleic acid content (C18:1) are appealing. In plants, the FAT ACID DESATURATION 2 (FAD2) gene encodes stearoyl-acyl carrier protein desaturase, which converts stearic acid (C18:0) to oleic acid (C18:1). Okuzaki et al. (2018) designed a *CRISPR/Cas9* vector that preferentially targeted BnaFAD2a in both the A and C genomes. While the amount of C18 polyunsaturated fatty acids decreased drastically, the amount of oleic acid generated by homozygous mutant plants increased substantially.

Huang et al. (2020) recently attempted to change all three active BnaFAD2 gene targets and found that although the oleic acid content of homozygous BnaA05.fad2a mutant crops rose considerably (6–16%), the C18 polyunsaturated fatty acid content declined dramatically. He et al. (2022) intended to modify a glucosinolate transporter gene with no genetic variations in order to create a cultivar with reduced seed glucosinolate for quality and resistance breeding of polyploid *Brassica napus* canola, the world's second-largest source of edible protein and oil meal.

10.2 Nanotechnology

Nanotechnology has proven several benefits in agricultural sciences (Prasad et al. 2014). Nanoparticles increase plant yield by interacting directly or indirectly with plants through the soil. They promote plant development by controlling nutrient transport or regulating the amount of micronutrients, and they give phytopathogen resistance (Kriti et al. 2020). It has been demonstrated that metal nanoparticles such as Ag, Au, TiO_2, ZnO, and iron enhance plant growth. As zinc is an important element involved in several metabolic processes, zinc oxide nanoparticles (ZnO NPs) have been utilized extensively (Hafeez et al. 2013). Numerous experts have researched the effect of ZnO NPs on a variety of agricultural plants, and their findings indicate that ZnO NPs promote plant development. There have been very few papers discussing the application of nanotechnology to boost health-promoting compounds in Brassicas. Mazumder et al. (2020) employed an alpha amylase enzyme to create and characterize zinc oxide nanoparticles (ZnO NPs), and then evaluated the nanoparticles' positive influence on the growth and development of *Brassica juncea*. According to *in silico* research, the amino acids lysine, glutamine, and tyrosine contained in the alpha amylase enzyme play a crucial role in the transformation of zinc acetate dihydrate to ZnO nanoparticles. *Brassica juncea*'s biochemical parameters and oxidative enzymes were compared with those of ZnO NPs-treated plants. According to the findings, nanoparticles might serve as an alternative to conventional, dangerous chemical fertilizers. Sohail et al. (2019) analyzed the effect of green synthetic NPs on two distinct cultivars of *Brassica napus*. When B. napus was treated to ZnNPs at concentrations of 5, 15, and 25 mg l-1, root and shoot length considerably increased. Utilizing nanoparticles dramatically enhanced plant germination and the production of secondary metabolites and antioxidant enzymes. ZnNPs enhanced the levels of chlorophyll, superoxide dismutase, and total flavonoid content (TFC), as well as antioxidant enzymes, while lowering the levels of total phenolic content.

Nanoparticle-mediated gene delivery has lately gained popularity; it appears to be superior to conventional biomolecular techniques since it improves the efficiency of transformation in several plant species for both transient and stable genetic changes. Nanotechnology technological advances have enabled us to transcend the limitations of conventional biomolecule delivery methods, and nanoparticles (NPs) appear potential for the species-independent passive transport of proteins, RNA, and DNA (Cunningham et al. 2018).

The amalgamation of nanotechnology into the process of generating genetically modified organisms (GMOs) is a powerful method that includes the employment of nanoparticles (NPs), the formation of an involved nanioparticle in the deal with biomodifier molecules (the CRISPR/Cas system), and the transportation of biomodifiers into plant cells (Abd-Elsalam 2020; Demirer et al. 2021). However, no reports have been published on nanoparticle-mediated biomolecule delivery for the enhancement of health-promoting substances in Brassicas, despite the fact that the incorporation of nanotechnology into existing molecular technologies could provide a forum for overcoming obstacles to the production of genetically modified plants and biotransformation in this field (Cunningham et al. 2018; Gad et al. 2020).

11 Genetic Engineering for HR Traits in *Brassica* Vegetables

The *Or* gene is a unique carotenoid gene mutation that generates a high concentration of β-carotene in orange cauliflower's edible curd. The *Or* gene promotes the accumulation of carotenoids in weakly pigmented or nonpigmented tissues, such as curd and pith. The *Or* gene has a negligible influence on leaf carotenoids, floral petal pigmentation, and chromoplast appearance. The *Or* gene transformants are capable of causing carotenoids accumulation by inducing the formation of large carotenoids sequestering sheets as a carotenoids deposition sink.

In recent years, biosynthesis/regulation-related genes have been altered to increase broccoli's anticancer glucosinolate/sulforaphane concentration (Kim et al. 2020). Upregulation of *BoMYB29* in the AG1012 (DH line) triggered the aliphatic glucosinolate pathway and increased the synthesis of glucoraphanin pathway, according to Zuluaga et al. (2019). Despite the absence of transgenic broccoli plants, this study provides a benchmark for increasing glucosinolate levels in broccoli (Li et al. 2019b). Despite research suggesting the significance of *BroMYB28* in glucoraphanin synthesis (Cao et al. 2021), its role in broccoli was not verified until 2019 (Kim et al. 2020). Broccoli accumulates glucoraphanin due to the transitory overexpression of *BroMYB28* by *Agrobacterium*. Recombinant broccoli was engineered by upregulating myrosinase, MAM1, and FMOGS-OX2, either alone or in combination. Genetic recombination increased sulforaphane content of individual myrosinase, MAM1, and FMOGS-OX2 by 3.7, 1.7–3.4, and 1.6–2.7 folds above wild-type plants, respectively, while the triple transgene increased it by 1.86–5.5-folds.

Numerous *Arabidopsis* and *Brassica* genes with comparable roles have been cloned and characterized, and the GSL synthesis pathway is well established. Genetic engineering is now being used to change the GSL content of cruciferous crops by concentrating on various phases of GSL production and degradation. Transgenic techniques that allow the overexpression or silencing of a single gene or a large quantity of genes enable for the rapid and precise manipulation of metabolic activities to obtain certain plant traits. The insertion of transgenes by genetic modification is a novel method for modifying the amount and type of GSLs. Liu et al. (2012) created glucoraphanin-rich B. napus seeds by inhibiting the *GSL-ALK* gene via RNA interference. Effective transfer of *Arabidopsis* genes is responsible for the generation of aliphatic and indolic GSLs into Chinese cabbage lines (Zang et al. 2008a, b). Overexpression of these genes led to the development of transgenic strains that accumulate indolyl (glucobrassicin and 4-methoxyglucobrassicin) and aliphatic (gluconapin and glucobrassicanapin) GSLs. Various strategies targeting biosynthetic or regulatory genes in the GSL biosynthesis pathway may be utilized to engineer GSL metabolism in plants. It appears that transcription factor regulation is more successful than genes encoding particular enzymes in governing metabolic pathways in plants. In *Arabidopsis*, around 20 genes with possible regulatory involvement in GSL metabolism have been discovered in recent years. In the near future, more research will provide the knowledge essential to simplify the complicated GSL biosynthesis in plants. Moreover, genetic modification has permitted the production of GSLs in

non-*Brassica* plants, such as *Nicotiana benthamiana* (Geu Flores et al. 2009), paving the path for GSL-enriched diets in other vegetable products, such as cancer-preventative commodities. Due to the success of breeding programs in reducing GSL levels in *B. napus* by conventional breeding and the rejection of genetically manipulated (GM) crops in certain oilseed rape–growing zones, the commercial sector is less inclined to explore GSL reduction through gene transformation. Likewise, consumers may dislike genetically modified broccoli with a high GSL content. Modern, guided genetic engineering is speedier, simpler, and more predictable than conventional breeding. The creation of a molecular key based on the genomic sequences of *Brassica* plants and *Arabidopsis* would speed up the marker-assisted discovery of target GSLs, therefore boosting the number of desirable GSLs in edible Brassicas.

12 Role of Bioinformatics as a Tool

Similar to other biological disciplines, nutrition science may gain a great deal from bioinformatics resources. If nutrition researchers, particularly those in the area of nutrigenomics, add bioinformatics abilities to their toolkits, they stand to gain a great deal from the many new opportunities that have emerged since the decoding of the human genome. Numerous bioinformatics techniques have the potential to significantly advance food science. For instance, bioinformatics sequence similarity algorithms have been used to find sweet and sour taste receptors in animals. Similarly, bioinformatics technology might be utilized to link diverse flavor components for the development of new goods based on customer preferences (Liu et al. 2008). There are several molecular marker techniques for detecting microbes that cause deterioration and illness. In addition, the Food and Drug Administration has developed a microarray-based tool for the molecular characterization of food-borne illnesses (Fang et al. 2010). In addition, bioinformatics tools may be utilized not only to determine the allergenicity and cross-reactivity of dietary proteins (Jenkins et al. 2005), but also to identify bioactive peptides (Walther and Sieber 2011). AllerMatch (Fiers et al. 2004), the Informal FARRP Allergen database, and SDAP (Mari et al. 2006) provide data on food allergens, while the protein sequences from UniProtKB, SwissProt, and TreMBL may be used to identify bioactive peptides. In addition to these bioinformatics tools, there are other databases with specialized neutrigenomics applications, such as Food DB, EuroFIR-BASIS, and the Foodomics database. FooDB (http://foodb.ca) is a comprehensive database on the chemistry and biology of food components. The EuroFIR-BASIS database, which is available at https://www.eurofir.org, combines biological activity and dietary composition for pharmacological activities in plant-based diets. FoodWiki database is a repository for consensus-based food and nutritional information, whereas Foodomics database is a repository for food molecular profiles (Kumar and Chordia 2017). Currently, it is obvious that advancements in "omics" approaches have not only led to the accumulation of massive datasets, but have also stimulated the creation of bioinformatics tools for analyzing these datasets. It is imperative that researchers in the nutrition

sciences utilize these analytical tools to mine information relevant to genomics, epigenomics, transcriptomics, proteomics, and metabolomics, as well as to investigate and decipher the composition of food, its microconstituents, nutritive value, and the chemistry and biology of food components.

12.1 Gene and Genome Databases

The genetics of *B. oleracea* have been researched throughout the last ten years. The entire genome of cabbage line 02-12 was made public by Liu et al. (2014). The whole genome of the cabbage double haploid mutant TO1000 was published by Parkin et al. (2014). Next technologies of genomic sequences were used in the construction of these two genomes. Third-generation sequencing technology was used in subsequent studies to finish the genomic construction and produce high-quality, rich genomes of variably shaped cabbage lines (D134, OX-heart, and JZS) (Belser et al. 2018), broccoli (HDEM) (Lv et al. 2020; Cai et al. 2020), and cauliflower (D134, OX-heart, and JZS) (Sun et al. 2019; Guo et al. 2021). The *Brassica* database was created by Cheng et al. (2011), and it is an online repository for extensive genomic and genetic data on important *Brassica* plants. *Brassica rapa* was the first genome to be sequenced in its entirety, and those results were used to create BRAD (Chiifu-401-42). It contains the complete *B. rapa* genome sequence, which was constructed from BAC clone sequences, and Illumina GA II short reads as well as predicted genes and related annotations, transposable elements (TE), noncoding RNAs, *B. rapa* genes orthologous to those in *A. thaliana*, linkage maps, and genetic markers. Unlike BLAST and Gbrowse, BRAD's search and data mining capabilities are far more robust, allowing users to do things like browse across annotation sets, look for nonsyntenic or syntenic orthologs, and explore the regions around a certain region. A user may contribute almost any kind of information to BRAD, including a gene ID from *B. rapa* or *A. thaliana*, a geographic location, or a genetic marker. There are three public databases that provide access to *B. oleracea* genome sequence data: Brassica.info (http://www.brassica.info/resource/databases.php), the AAFC Comparative Genome Viewer (http://brassica.agr.gc.ca/navigation/viewer f.asp), and the *Brassica* Genome Gateway (http://brassica.bbsrc.ac.uk/). These databases include some *B. oleracea* genomic data, such as cloned genes, ESTs, and QTLs. Bolbase (http://ocri-genomics.org/bolbase), a web-based database containing genomic sequences information and genome-wide relevant data, was designed to facilitate the access, search, modeling, and understanding of the *B. oleracea* exome sequencing, annotation, configuration, and evolvement. This collection facilitates study on gene function, comparative genomics, and the evolution of highly associated Brassicaceae species, as well as modern breeding developments within the *Brassica* genus. In addition to 45,758 predicted genes, 13,382 transposable elements, and 3,581 noncoding RNAs, there are nine completely constructed chromosomes and 1,848 scaffolds. Information regarding comparative genomics includes syntenic regions between *B. oleracea*, *Brassica rapa*, and *Arabidopsis thaliana*, synonymous (Ks) and nonsynonymous (Ka)

substitution rates between orthologous gene pairs, gene families, or clusters, and variations in the number, classification, and distribution of mobile genetic elements. Bolbase's search and data mining capabilities include a text search, a local BLAST browser, and a customized GBrowse tool that can be employed to retrieve tags of genome elements, locate related sequences, and show syntenic areas across species. Users may access comprehensive genetic data and conduct comparative genomics research using an interface that is extremely apparent.

12.2 Targeted Databases of Genome, Transcriptome, and Proteome in Brassicas

In addition to sequence analysis and assembling of DNA, research on *B. oleracea* proteomics, transcriptomics, and metabolomics has revealed patterns of gene expression (Wei et al. 2021), metabolite abundance (Parkin et al. 2014; Liu et al. 2014), and protein (Zhao et al. 2020) in a broad range of genotypes. The genomic analysis for just two *B. oleracea* species is insufficient, even if the BRAD V3.0 database has genomic data for a range of vegetable *Brassica* species (Chen et al. 2022). In response to this need, Wang et al. (2022) developed the *B. oleracea* Genome Database (BoGDB), which is the first omic database and a user-friendly platform for doing research on *B. oleracea*. This database includes data on the organism's genome, transcriptome, and metabolome. In order to get the most out of multiomics data, the BoGDB database incorporates a wide variety of useful genomic modules, such as "Gene Search," "Heatmap," "Genome Browser," "Genome," "Tools," "Metabolic," and "Variation." This lays the groundwork for crop genomic, genetic, and molecular design breeding experiments using *B. oleracea*, and it does so in an approachable manner.

13 Social, Political, and Regulatory Concerns

Regulation is essential for guiding the economic growth of any nation because it grants rights on tangible or corporeal property, intangible or incorporeal properties such as intellectual property (IP), exploitation of natural resources, etc. in the form of controlling human or societal behavior with the force of law by means of certain rules or defined norms. To increase productivity and growth, every nation needs improved regulation, primarily to alleviate corporate regulation, to promote job creation, to lower barriers to international commerce and investment, and to bolster investment by implementing a number of financial sector reforms. In order to enhance the uniformity and quality of the regulatory environment, the regulatory framework must be streamlined by addressing specific regulatory challenges across nations and also inside the country, particularly between federal, state, and municipal governments. Throughout the years, as a result of shifting political and societal landscapes, a number of regulations have been revised in conjunction with the development of new technologies to alleviate the difficulties in managing global

regulatory compliances and to meet challenges in compliance and enforcement through a set of transparent, consistent, and nondiscriminatory rules in order to create dynamic and competitive situations.

13.1 Genesis

In 1944, during World War II, the United Nations designated a comprehensive trade barrier that sharply divided nations and wreaked havoc on business and the economy. Thus, a conference known as the Bretten Woods Monetary Conference was convened with 44 member nations to form the World Bank, IMF (International Monetary Fund), and ITO (International Trade Organization). GATT was founded in 1947 with the purpose of regulating trade as part of a wider plan for the post-World War II economy's recovery via the removal of trade subsidies, quantitative constraints, and tariff barriers. The GATT was a contract, not a corporation. The history of the GATT may be divided into three major phases. The first round, which ran from 1947–1950 and was known as the Torquay Round, was largely concerned with deciding which goods would be included by the agreement and freezing present tariff levels. The second phase, which ran three cycles from 1959–1979, focused on reducing tariffs. Only the Uruguay Round, which ran from 1986–1994, comprised the third phase, which substantially enlarged the agreement to encompass more sectors, such as intellectual property, services, capital, and agriculture. The WTO resulted from these negotiations. In 1995, the GATT was superseded by the WTO. India is one of the founding countries to join the World Trade Organization, which was founded by the Marrakesh Agreement, in compliance with the TRIPS agreement.

- Patents must be issued in all "fields of technology," but various exceptions for the public interest may be established (Art. 27.2 and 27.3).
- Article 27 of the TRIPS Agreement outlines the innovations that nations must make accessible for patenting and those that they may prohibit from patenting.
- Patentable inventions may be both goods and processes, and they should normally span all fields of technology.

13.2 Patent and IPR Issues

Intellectual property rights (IPR) are legal rights granted to the inventors or producers for a limited time to prevent others from replicating, producing, utilizing, or selling a protected substance, process, ideas, or innovations. Under Indian law, there are a variety of intellectual properties (IPs), including the Indian Patent Act of 1970, the India Copy Right Act of 1957, the Trade Marks Act of 1999, the Designs Act of 2000, the Geographical Indications of Goods (Registration and Protection) Act of 1999, the semiconductor Integrated Circuits Layout Design Act of 2000, and the Protection of Original Works Act of 1999. The Protection of Plant Varieties and Farmers' Rights Act (PPVFRA) of 2001 is the most recent intellectual property

legislation in India. The Indian Copy Right Act, which was passed in 1957, is the country's oldest IP law.

A patent is a 20-year monopoly that the government provides to an inventor over his or her creation from the date of filing. Patents protect both new and improved versions of existing concepts. An inventor may get a patent for his/her invention, as may anybody he/she assigns the patent to. The inventor or his assignee may get a patent by filing an application to the patent office in accordance with the nation's Patent Act requirements. Only original, obscure, and industrially applicable innovations are eligible for patent protection (utility).

- Novelty (newness): It must possess a characteristic that is not present in the corpus of prior work in the relevant technological domain.
- Nonobviousness (innovative step): It must indicate an imaginative step that a person with an ordinary comprehension of the technical field could not infer.
- Utility (industrial applicability): The invention must be advantageous and applicable to industry.

Section 3 (j) of the Indian Patent Act did not allow for the patenting of agricultural and horticultural production systems. Since 2005, India has been required to comply with the TRIPS Agreement in order to make its domestic laws compliant with TRIPS. In the past, India had no laws to conserve plant types or genetic resources, as there was no need. After India signed TRIPS, Article 27 (3) (b) of TRIPS mandated that member countries guarantee protection for plant types. UPOV places restrictions on the rights of farmers. In light of its socioeconomic circumstances, India established a *sui generis* strategy, combining the rights of breeders, farmers, and researchers and adding FRs to its Act. To improve the efficiency of the *sui generis* system, the PPVFRA was adopted in 2001. Its rules were created in 2003, and the Authority was founded in 2005, not only to offer intellectual property protection for plant types, but also to protect the interests of farmers.

13.3 Access, Benefit Sharing, and Disclosure of Genetic Resources (ABS)

The genetic resources (GRs) and other biological resources are key components of the system of intellectual property (IP). These resources may be obtained from plants, microorganisms, animals, or any other source holding functional units of heredity. Genetic resources derived from humans are excluded from this group. In research and development, the utilization of genetic resources is essential to the creation of a large diversity of commodities and services for the benefit of humanity. Access to GRs is necessary for these activities in order to utilize GRs based on an equal and fair distribution of benefits between users and providers. The Nagoya protocol specifies the GRs in accordance with Article 15(7) of the Convention on Biological Diversity, which states that access and benefit-sharing objectives must be met with regard to genetic resources with greater legal certainty and transparency for

both providers and users of genetic resources. In certain instances, in addition to GRs, indigenous and local community (ILC) traditional knowledge related with GRs is also incorporated. Depending on the aim of usage (research and knowledge) or the product output, the type of the benefit sharing may be monetary or nonmonetary (sharing royalties from a commercial product). In order to secure the equitable and fair exchange of genetic resources (GRs) and their advantages, the provider of access and benefit sharing (ABS) must get prior informed consent (PIC) from a user before signing of mutually agreed terms (MAT).

13.4 Traditional Knowledge

Traditional knowledge (TK) refers to the skills, discoveries, and practices that indigenous and local communities (ILC) have acquired over centuries of experience in respect to GRs. These cultural heritages are comprised of information that has been passed down through the centuries and altered to meet the needs of the local community. Traditional knowledge is important for determining the human benefits of GRs derived from plants, animals, or microorganisms. Information on the beneficial features of these GRs is used in both research and the marketing of items used for a range of essential reasons, including food, medicine, and agricultural practices, among others. In order to protect biodiversity and utilize it in a sustainable way, the Convention on Biological Diversity (CBD) incorporated rules for the use and preservation of indigeneous technical or conventional knowledge. There are three primary safeguarding measures for traditional knowledge. The first emphasizes the significance of maintaining traditional knowledge as a type of cultural heritage. The second section examines the safeguarding of traditional knowledge as a collective human right. Thirdly, the WTO and WIPO investigate the application of existing or new special measures to safeguard traditional knowledge. The result is the "Biodiversity Act of 2002."

13.5 Farmer Rights (FRs)

Both the Convention on Biological Diversity (1992) and the International Treaty on Plant Genetic Resources for Food and Agriculture (2001) lay a strong focus in Article 9 of their separate conventions on the role of rural and indigenous societies in preserving and developing biodiversity. The most sophisticated law of India is the only one that gives farmers a wide variety of rights, including the capacity to register their own kinds. The rights that farmers have under the PPVFR Act of 2001 are described here.

13.5.1 Seed Rights of Farmers

Farmers still have the same rights to their agricultural goods as they did before to the Act's implementation, including the freedom to keep, use, sow, resow, trade, share,

and sell any seeds of kinds covered by the Act. Farmers do, however, have the right to sell unbranded seed of a variety that is covered by this Act.

13.5.2 Farmers' Rights to Register Traditional Varieties

Farmers have the right to register any new varieties they independently developed as well as any old kinds they generated or protected. It costs nothing for farmers to register their varieties.

13.5.3 Farmers' Rights to Reward and Recognition

The Act includes provisions to reward and recognize individual farmers, agricultural communities, and tribal groups for their accomplishments to the conservation of agricultural plant diversity and the enhancement of plant genetic resources (PGR) via the Plant Genome Savior Award.

13.5.4 Farmers' Rights for Benefit Sharing

Under the Act, farmers or tribal groups that supplied the kinds utilized as parents are entitled to an equal share of the benefits from the new variety. When their variety is utilized as a parent, farmers have the option to make claims for benefit sharing. The Act mandates that the registered seed be marketed with a statement on varietal agronomic performance and commercial features. Farmers have the right to get compensation for losses caused by the registered variety.

13.5.5 Farmers' Rights to Get Compensation for Losses Suffered

The PBR holder is required to provide restitution to impacted farmers in the event that farmers are unable to deliver the promised performance.

13.5.6 Farmers' Rights to Reimbursement for Covert Use of Traditional Varieties

When submitting a registration application, applicants are obliged to identify the traditional varieties that were utilized as parents to produce the new variety. In the case that the applicant conceals information about the community's use of traditional varieties or knowledge and if this is done, a third party may file claims for compensation, which the Authority will then decide to provide. Farmers have the right to purchase seeds from registered varieties at a fair price.

13.5.7 Farmers' Rights for the Seeds of Registered Variety

Farmers are permitted to acquire seeds from recognized varieties. If this condition is not met, the breeder's exclusive ownership of the variety is suspended under the compulsory licensing regulation, and the breeder is compelled to grant a licence to a competent legal organization for the production, distribution, and sale of the variety's seeds.

13.5.8 Farmers' Rights to Receive Free Services

Farmers are exempt from all fees, including those associated with the registration of varieties, conducting DUS tests on varieties, renewing registration, fees associated

with any applications, fees associated with legal proceedings, etc., in consideration of their limited financial resources and to facilitate their access to the Act's benefits.

13.5.9 Farmers' Rights to Be Protected Against Innocent Infringement

Legal precedent dictates that inadvertent lawbreaking is not regarded a valid defense. However, there are protections in place to avoid the violation of the rights of innocent persons. Act violations committed by farmers cannot be tried in court.

13.6 Treaties and Conventions

13.6.1 Convention on Biological Diversity (CBD)

It is a 1992 UNCED international agreement that took effect on December 29, 1993. Its key goals are the maintenance of biological variability (biodiversity), the sustainable use of resources, and the equitable and fair sharing of the value gained from the use of genetic traditional knowledge and resources.

13.6.2 The Nagoya Protocol on Access and Benefit Sharing

It is a supplement to the Convention on Biological Diversity (CBD) from 1992. It was approved in Nagoya, Japan, in 2010 and entered into force on October 12, 2014; India is a signatory. This protocol includes genetic resource access, profit sharing, and compliance processes as member responsibilities.

13.6.3 International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA)

It is an all-encompassing accord consistent with the CBD. The treaty was adopted during the 2001 FAO meeting and entered into force on June 29, 2004. The pact tackles conservation, utilization, international cooperation, technical aid, and the rights of farmers. It also establishes regulations for access and benefit sharing for selected ex situ and in situ crops (35 food crops and 29 forage species) while protecting property rights.

13.6.4 The WTO's Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPs)

The World Trade Organization (WTO) is responsible for enforcing the TRIPS International Agreement, which establishes the fundamental standards for various forms of intellectual property (IP) protection. The Uruguay round of the General Agreement on Tariffs and Trade (GATT) concluded in 1994; this was the final round of negotiations. It stipulates that member nations protect plant species through effective sui generis (standalone) regimes, patents, or a combination of the two. The majority of countries have laws that adhere to the UPOV Convention and meet this requirement. The UPOV Council rejected a law protecting the rights of Indian plant breeders because it violated the conditions of the treaty.

13.6.5 The International Union for the Protection of New Varieties of Plants (UPOV)

It is a multinational organization headquartered in Geneva, Switzerland. It was developed by the International Convention for the Protection of New Varieties of Plants with the objective to optimize plant breeding efforts by offering a paradigm for assuring protection for plant breeder's rights under UPOV.

13.7 Participatory Plant Breeding (PPB)

Participatory breeding is a collective method of plant genetic improvement used by farmers to enhance crops and create new plant varieties in collaboration with scientists, consumers, and other stakeholders with breeding objectives based on their particular region, environment, culture, and need, among other factors. Promising lines are chosen, varieties are generated, and evaluated and novel procedures are used for further multiplication, assessment, seed production, and distribution to farmers using the local germplasm or GRs. The goal of participatory breeding is to guarantee that farmers have access to genetic lines so they may get varieties that meet their needs for quality and livelihood usage. This strategy promotes genetic diversity. In order to effectively employ farmers' varieties (traditional varieties/landraces/wild relatives) and GRs to generate superior cultivars, participatory breeding programs are being developed. Farmers are also offered a compensation and support system for their contribution to the global genetic pool.

14 Future Perspectives

Throughout the course of the past several decades, there has been a consistent rise in the degree of knowledge about the significance of glucosinolates, both in terms of their involvement in the process of plant self-defense and in terms of their importance for human and animal nutrition. As a direct consequence of this discovery, a significant amount of research into the genetic underpinnings of glucosinolate production has been carried out. However, the QTL analysis showed that there are additional genetic traits in *Brassica* crops that need further investigation. These characteristics include: The most important genes in these plants have been thoroughly studied. Other facets, such as the method in which glucosinolate genes and systems interact with environmental stressors, are examples of areas that are examples of topics that are obtaining an increasing relevance in current society. In light of the fact that other species of the Brassicaceae that are not in the genus *Brassica* are recognized as being good sources of beneficial chemicals, it is feasible to include them into one's diet as a result of the data provided here. These animals each have a unique glucosinolate pattern, which is distinguishable from the others. Investigating the genetics behind these traits will provide exciting insights that might be used in the breeding of other Brassicaceae species. Breeding efforts are now integrating a complete understanding of the genetics of glucosinolates with the mechanism by

which they are inherited in order to change the levels of these useful metabolites. This is being done in an attempt to modify the levels of these helpful metabolites. This process will be sped up as a consequence of the sequencing of the primary *Brassica* crops and the commonalities that now exist between those crops and *Arabidopsis*.

Abstract

Carrot is an economically important vegetable crop worldwide. Its storage root, the consumed organ, varies broadly within the carrot germplasm, exhibiting different colors due to the accumulation of anthocyanin and carotenoid pigments, as well as extensive variation for phytochemicals composition and consumer-quality traits. Anthocyanins and other phenolics, carotenoids, polyacetylenes, and terpenes represent the major carrot nutraceutical classes. In recent years, the use of next-generation sequencing technologies has facilitated the application of "multi-omics" approaches, in combination with transgenics and classical genetic tools, for studying the genetics underlying the accumulation of these phytochemicals in the carrot root. In purple carrot, such approaches allowed the identification and mapping of simply inherited and quantitative trait loci (QTLs) conditioning anthocyanin pigmentation in different tissues and genetic backgrounds, and the discovery of key genes conditioning anthocyanin biosynthesis, glycosylation, and acylation. Glycosylation and acylation influence the chemical stability and bioavailability of anthocyanins, and therefore their potential use as food colorants or nutraceutical agents, respectively. Similarly, important advances were made for two major loci conditioning carotenoids accumulation in white, yellow, and orange roots, namely *Y* and Y_2. With the sequencing of the carrot genome, a candidate for the *Y* gene involved in photosystem development and carotenoid storage was described, whereas fine mapping of Y_2 drastically reduced the genomic region of interest to 650-kb, but a clear candidate was not identified. Another gene, *Or*, which regulates chromoplasts development, was associated with carotenoids presence in the carrot root. Besides these nonstructural genes, progress towards understanding the role of several carotenoid biosynthetic genes has been made. The genetics of carrot polyacetylenes is also becoming increasingly understood. Candidate fatty acid desaturase 2 (FAD2) genes with specific desaturase and/or acetylenase activities have been identified by QTLs analysis and proposed as catalyzers of different steps in the polyacetylene pathway, and their genomic organization was described. Similarly, gene members of the large

carrot terpene synthase family were catalogued, partially associated with QTLs for characteristic carrot root monoterpenes like sabinene, and functionally characterized in vitro. This chapter reviews and discusses recent advances in genetics and genomics of the main carrot nutraceuticals.

TPC	Total phenolics content

1 General Introduction

The carrot (*Daucus carota* L.) germplasm displays broad genetic and phenotypic variation for many agronomic, compositional, and consumer-quality traits. Its storage root, the main consumed organ, can exhibit different colors due to the accumulation of different combinations of anthocyanin and carotenoid pigments, resulting in anthocyanin-rich purple or black carrots, orange carrots with high levels of β-carotene and α-carotene, both provitamin A carotenoids (PACs), lycopene-rich red carrots, yellow carrots that predominantly accumulate xanthophylls, and white-rooted carrots with nearly undetectable levels of the previous pigments. Each of these pigments has particular physicochemical properties, bioactivities, and health-beneficial effects. Among the latter, strong antioxidant, anti-inflammatory, anticancer, immunomodulatory, cardioprotective, and neuroprotective effects, among others, have been reported for some of these pigments. In addition, carrots of all root colors accumulate varying types and concentrations of other non-anthocyanin phenolics, polyacetylenes (with predominance of the C_{17}-compounds falcarinol, falcarindiol, and falcarindiol-3-acetate), and terpenes. While major carrot phenolics (e.g., chlorogenic acid) are

recognized antioxidant agents, some polyacetylenes, particularly C_{17}-falcarins, have been reported to exert strong anti-inflammatory and anticancer effects against various cancer types. However, in high concentrations, some polyacetylenes can be toxic for human health and may confer unpleasant bitter-off taste to carrots. Terpenoids from carrot essential oils exhibit antimicrobial, antioxidant, and anticancer activities. Together, anthocyanins and other phenolics, carotenoids, polyacetylenes, and terpenes represent the major nutraceutical type classes present in the carrot root.

For each of these carrot phytochemical groups, important advances have been made with regards to characterizing their chemical diversity at various levels, ranging from intra-plant, organ- and tissue-specific compositional variations, to variation across carrot genetic backgrounds in large germplasm collections, to evaluating changes in compounds content and profile under abiotic and biotic stimuli/stressors. In addition, physicochemical, bioactive, and health-related attributes of some of these carrot compounds have been studied and described. Breeding has also been important for some of these traits, mainly associated with pigment content and flavor, resulting – for example – in the development of high PAC carrots with virtually no bitter-off taste, and released cultivars with other root colors.

In recent years, the sequencing of the carrot genome and the improvement in throughputness, cost per sequence read, and availability of next-generation sequencing (NGS) technologies have facilitated the application of "multi-omics" approaches, in combination with transgenics and classical genetic tools, for studying the genetic regulation underlying the accumulation of these phytochemicals in the carrot root. Although progress in understanding the genetic basis of these traits has advanced at varying speeds for the different carrot nutraceuticals, perhaps being most accelerated for anthocyanins and carotenoids, such approaches have allowed significant advances for all the compound types. As a result, in just a few years, it was possible to identify and genetically map simply inherited and QTLs conditioning the type, content, and composition of these phytochemicals across different plant tissues and genetic backgrounds, as well as discovering and functionally characterizing candidate regulatory and structural genes for these traits. This chapter reviewed and discussed recent advances in diversity, health properties, genetics, and genomics of the main carrot nutraceuticals.

2 Anthocyanins

2.1 Introduction

Anthocyanins are water-soluble pigments that confer blue, purple, and red color to several organs and tissues in many plants. In the plant, they serve multiple functions including the attraction of pollinators, and attenuation of biotic and abiotic stresses such as insect and phytopathogen attacks, salinity, drought, low temperatures, exposure to ultraviolet light, heavy metal toxicity, and mechanical wounding, among others (Shirley 1996). Because of their widespread occurrence in many plant foods, predominantly found in higher concentrations in fruits and vegetables, these pigments represent important components of the human diet. Anthocyanin consumption has been linked

to various health benefits, including reduced risk of cardiovascular disease, prevention or delay of cognitive decline and neurodegenerative-related disorders, improved regulation of glycemia, prevention of some autoimmune diseases, and decreased risk of some cancer types (reviewed by He and Giusti 2010). These health benefits are largely attributed to the proven antioxidant and anti-inflammatory properties of these pigments, as it is currently thought that chronic inflammation and oxidative stress represent major components in the etiology of chronic diseases (He and Giusti 2010).

Chemically, anthocyanins belong to the flavonoid subclass of phenolic compounds, and they are produced via the phenylpropanoid pathway, a late branch of the shikimate pathway (Herrmann and Weaver 1999) (Fig. 1). Their structure consists of a central molecule called "anthocyanidin" to which different sugars and organic acids can be attached. Although several anthocyanidins have been described, only six of them are widely found in nature, namely cyanidin, petunidin, pelargonidin, malvidin, delphinidin, and peonidin (Andersen and Jordheim 2006). When anthocyanidins are bound to sugars, the form most commonly found in nature, they are called "anthocyanins." A fairly large list of simple sugars may glycosylate anthocyanidins to form anthocyanins. In addition, the sugars bound to the anthocyanidins are often acylated by different aromatic or aliphatic organic acids. As result, a huge molecular diversity spectrum has been reported in the plant kingdom for these pigments as consequence of the many different combinations found among anthocyanidins, sugars, and organic acids (Andersen and Jordheim 2006). The extent to which these pigments are bound to sugars, a process called "glycosylation," and to organic acids, termed "acylation," strongly influences anthocyanin physicochemical and biological properties (reviewed by Prior and Wu 2006). For instance, glycosylation increases water solubility and chemical stability, whereas acylation of the glycoside residues has been found to confer protection against degradation and significantly increase the chemical stability of these pigments (Mazza et al. 2004). The latter was recently shown in a study by Perez et al. (2022) using carrot anthocyanins, demonstrating the acylated anthocyanins (AA) were significantly less prone to degradation than their non-acylated (NAA) counterparts under higher temperature and pH conditions. Because of their greater chemical stability, AA are preferred over NAA for their potential use as natural food colorants. In contrast, carrot NAA have been shown to be significantly more bioavailable than AA (Kurilich et al. 2005; Charron et al. 2009), and this may be relevant when breeding for increased functional value in anthocyanin-rich crops, as bioavailability is a major factor conditioning the potential of a dietary agent to provide health benefits.

The biosynthetic pathways and genetic regulation of anthocyanins have been studied in extensive detail in several model species – e.g., Arabidopsis, snapdragon (*Antirrhinum majus*), petunia (*Petunia hybrida*), and maize (*Zea mays*) – generally revealing that both structural and regulatory genes participate, yet finding broad variations regarding the key genes that control this process among species (Holton and Cornish 1995). In the last decades, important advances have been made concerning the composition, distribution, physicochemical properties, bioactivities, and – most intensively in recent years – the genetic regulation of anthocyanin pigmentation in carrot. Thus, the following sections concern these aspects of carrot anthocyanin pigmentation and their relevance for breeding and genetic research.

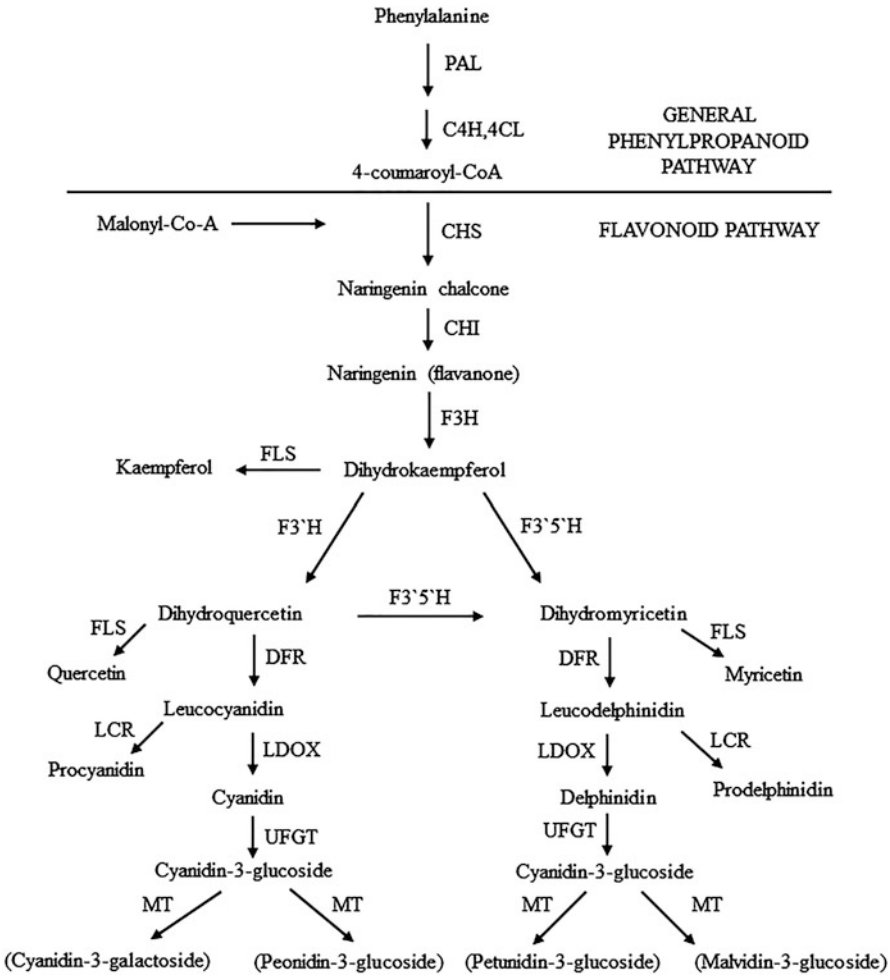

Fig. 1 Schematic representation of the anthocyanin biosynthesis pathway. *PAL* phenylalanine ammonia-lyase, *C4H* cinnamate 4-hydroxylase, *4CL* 4-coumarate CoA ligase, *CHS* chalcone synthase, *CHI* chalcone isomerase, *F3H* flavanone 3-hydroxylase, *FLS* flavonol synthase, *F3′H* flavonoid 3′- hydroxylase, *F3′5′H* flavonoid 3′,5′-hydroxylase, *DFR* dihydroflavonol 4-reductase, *LDOX* leucoanthocyanidin dioxygenase, *UFGT* UDP-glucose-flavonoid 3-*O*-glucosyl-transferase, and *MT* methyltransferase (Reproduced from Cavagnaro and Iorizzo (2019))

2.2 Chemical Diversity of Carrot Anthocyanins and Relevance as Nutraceuticals and Food Colorants

2.2.1 Diversity for Anthocyanin Content and Composition in the Purple Carrot Germplasm

Extensive genetic variation exists among purple carrot genetic stocks for anthocyanin pigmentation across different tissues of the taproot, and tissues and organs of

the aerial plant part (Cavagnaro et al. 2019). Root pigmentation phenotypes across root tissues vary broadly, from dark purple or black fully pigmented roots (i.e., all tissues accumulate anthocyanins in large quantities) to anthocyanin accumulation restricted to the outermost epidermal cell layers, and include intermediate phenotypes exhibiting different intensities and patterns of purple pigmentation in the epidermis, outer phloem (or "cortex"), inner phloem, and xylem tissues. In some particular backgrounds, the color of the root surface is not uniform purple, and anthocyanin pigmentation in this phenotype was estimated visually as a percentage of the root surface (Cavagnaro et al. 2014). As result of these different pigmentation patterns, root total anthocyanin concentration varies broadly across genetic stocks. A first study by Kammerer et al. (2004) reported a range of 45–17,400 mg/kg dry weight (dw) in a collection of 15 purple carrot accessions [in fresh weight (fw), these estimates are equivalent to ~0.5–191 mg/100 g fw, considering 11% of root dry matter]. Later, Montilla et al. (2011) found a range of 1.5–17.7 mg/100 g fresh weight (fw) in 4 commercial cultivars, whereas Algarra et al. (2014) found a range of 93.4–126.4 mg/100 g fw in 2 Spanish cultivars, and Bannoud et al. (2018) 1–229 mg/100 g fw in 26 accessions from diverse geographical origins. Interestingly, there is a strong positive association between the intensity of the purple color (estimated visually) across root tissues and the total anthocyanin concentration, with accessions with dark fully pigmented roots generally presenting the greatest concentration and accessions with pale purple color in the outer phloem and periderm tissues typically exhibiting very low pigment levels. Such association between pigment levels and visual color intensity may be useful for rapidly and inexpensively estimating pigment levels across genetic stocks in purple carrot breeding programs. Also, total anthocyanin content is significantly and positively correlated with TPC, with correlation values (r) ranging from 0.85 (Bannoud et al. 2018) to 0.99 (Leja et al. 2013), suggesting that anthocyanins account for a large proportion of the phenolic compounds present in purple carrots.

The main carrot anthocyanins are cyanidin derivatives (Kammerer et al. 2004; Montilla et al. 2011; Algarra et al. 2014; Bannoud et al. 2018), although pelargonidin, petunidin, and peonidin have been found in trace amounts in some genetic backgrounds (Kammerer et al. 2004; Montilla et al. 2011; Algarra et al. 2014). Among the cyaniding glycosides, two NAA and three AA are commonly found in purple carrots (Table 1). The percentage of AA relative to the total

Table 1 Carrot cyanidin glycosides with approximate HPLC retention times and molecular masses

Compound	Abbreviation	RT	MW
Cy-3-(2″-xylose-6-glucose-galactoside)	Cy3XGG	14.0	743
Cy-3-(2″-xylose-galactoside)	Cy3XG	15.1	581
Cy-3-(2″-xylose-6″-sinapoyl-glucose-galactoside)	Cy3XSGG	15.4	949
Cy-3-(2″-xylose-6″-feruloyl-glucose-galactoside	Cy3XFGG	16.0	919
Cy-3-(2″-xylose-6″-(4-coumuroyl)glucose-galactoside)	Cy3XCGG	16.4	889

RT is retention time (min) for the chromatographic procedure described by Kurilich et al. (2005). MW is molecular weight

anthocyanin content found across accessions in different studies ranged from 25% to 99% (Kammerer et al. 2004; Netzel et al. 2007; Montilla et al. 2011; Algarra et al. 2014, Cavagnaro et al. 2014), although in most commercial cultivars AA generally predominate over NAA. In absolute values, carrot roots may have up to ~155 mg/100 g fw of AA (Kammerer et al. 2004).

Purple carrots vary in anthocyanin composition and relative content (%) of individual pigments. In general, cyanidin glycosides acylated with ferulic acid (Cy3XFGG) predominate in most accessions, followed by glycosides of the same anthocyanidin acylated with sinapic (Cy3XSGG) and coumaric acid (Cy3XCGG). Evaluation of anthocyanin composition in 15 purple carrots revealed that 13 accessions had Cy3XFGG as the most abundant pigment, representing its concentration 42.5–83.8% of the total anthocyanin content, whereas Cy3XSGG predominated in the other 2 accessions (Kammerer et al. 2004). Another study that examined four purple-rooted cultivars found Cy3XFGG as the major pigment in three accessions and Cy3XSGG in the remaining one (Montilla et al. 2011). Coincidently, Bannoud et al. (2019) characterized pigment composition in a carrot F_2 mapping population segregating for purple pigmentation in different root tissues, reporting Cy3XFGG and Cy3XSGG (in that order) as the predominant anthocyanins in both the phloem and xylem. Non-acylated glycosides were in general less abundant, with Cy3XG usually predominating over Cy3XGG (Kammerer et al. 2004; Montilla et al. 2011, Bannoud et al. 2019).

2.2.2 Acylated Anthocyanins for the Food Colorant Industry and Non-acylated Anthocyanins for Increased Nutritional Functionality

A major disadvantage of natural colorants relative to synthetic dyes is, generally, that the formers are more susceptible to degradation. In contrast, synthetic dyes tend to be chemically more stable and maintain their color across a broad range of food conservation conditions, tolerating greater variations in, for example, temperature, acidity, oxygen concentration, and light intensity. Despite their generally higher chemical stability, in the last decades, a number of potential health risks have been associated with the consumption of synthetic food dyes, including behavioral and neurological disorders (McCann et al. 2007), higher incidence of allergies (Koutsogeorgopoulou et al. 1998), and potential carcinogenesis (Dees et al. 1997). Such health-related concerns have raised the interest in finding alternative sources of natural colorants for the food industry.

A very recent study by Perez et al. (2022) investigated the chemical stability of anthocyanins from purple carrots as compared to that of a synthetic food dye (E131) and a commercial food colorant from grape, under a range of temperature and pH conditions. It was found that carrot anthocyanin extracts had greater thermal stability – with regards to color intensity, color space parameters, and concentration of anthocyanins – than anthocyanins from the grape extract and the synthetic dye. The higher stability of the carrot colorants was attributed to their richness in AA. Also, carrot anthocyanins, in general, were more stable at low pH and temperature conditions (i.e., 4 °C, pH = 2.5), whereas under less favorable conditions

(25–40 °C, pH = 7.0), the rate of decay was substantially and significantly different among the individual anthocyanins, with all AA being less affected than the NAA. In particular, anthocyanins acylated with feruloyl (Cy3XFGG) and coumaroyl glycosides (Cy3XCGG) were the most stable carrot pigments. Altogether, these data strongly suggest that carrots with high levels of AA and, in particular, Cy3XFGG and Cy3XCGG, would be most suitable as sources of colorants for the food industry.

Based on these previous data, and from the perspective of developing suitable plant materials for the production of food colorants, three objectives appear as highly relevant: (i) increasing total anthocyanin concentration in the root; (ii) increasing the AA:NAA ratio as much as possible, ideally to the extent that AA account for nearly all of the root anthocyanins; and (iii) shift the AA composition towards a predominance of Cy3XFGGand Cy3XCGG (the most chemically stable AAs) over Cy3XSGG (the least stable AA). A comprehensive review on the potential of carrot anthocyanins as food colorants was recently published by Iorizzo et al. (2020). From another point of view, carrots rich in NAA would be ideal for increasing anthocyanin bioavailability (Kurilich et al. 2005; Charron et al. 2009) and – therefore – nutritional value in, for instance, fresh-consumption carrots, although genotypes with predominance of NAA are not frequent in the carrot germplasm. Considering these two breeding goal (i.e., food colorant production and fresh-consumption carrots with high pigment bioavailability), it is advisable to devote efforts towards characterizing anthocyanin profiles in larger purple carrot germplasm collections, to identify suitable genotypes for either purpose, and to advance research on the genetic regulation of these pigments.

2.2.3 Nutraceutical Properties of Carrot Anthocyanins

Several studies have addressed nutritional aspects of purple carrot anthocyanins. In a clinical feeding trial conducted by Kurilich et al. (2005), fresh and cooked carrots rich in anthocyanins were consumed by human subjects, and the recovery rate of anthocyanin pigments in the blood and urine was estimated. It was found that the recovery of NAA was 8–14 times higher than recovery of AA, whereas the consumption of cooked carrots increased further the recovery rate of NAA but not their acylated counterparts. In this study, whole carrots were use and, therefore, it was not possible to separate the effect of the anthocyanin molecular structure from that of the root matrix on pigment bioavailability. Thus, in a following study by Charron et al. (2009) purple carrot juice, instead of whole carrots, was used in order circumvent matrix effects, revealing recovery rates of NAA nearly fourfold higher than those of AA. Given that anthocyanins were consumed as a carrot juice, without the root matrix, the higher bioavailability found in NAA is mainly attributable to their molecular structure, rather than to possible interactions with the food matrix. In line with these results, Netzel et al. (2007) reported that after consumption of an anthocyanin rich carrot extract by human subjects, the urine recovery of NAA was eightfold higher than that of AA.

Sun et al. (2009) analyzed carrot antioxidant capacity (AOC), using ABTS and DPPH-based procedures, in seven carrot cultivars with different root color, finding that purple carrots had the greatest AOC, with values 3.6- to 28-fold higher than the

AOC in other root colors. The high AOC of purple-rooted carrots was associated with their high concentration of anthocyanins and other phenolics but not with carotenoids levels. The latter contributed minimally to the overall AOC of purple carrots, representing less than 3% of the total AOC. In agreement with results from Sun et al., Leja et al. (2013) reported that purple carrots (two genotypes) were the plant materials with greatest AOC in a collection of 35 carrot cultivars with different root color, noting also that the average TPC content in purple-rooted carrots was ~ninefold greater than in cultivars of other root colors, suggesting that TPC levels may explain the observed variation in AOC. Coincidently, AOC analysis in two purple-rooted and one orange carrot revealed significantly greater AOC in purple carrots, with AOC being directly correlated with root anthocyanin level.

Narayan et al. (1999) reported potent antioxidant activity of purple carrot anthocyanins, as indicated by their ability to inhibit enzymatic and nonenzymatic lipid peroxidation in vitro, in a dose-dependent manner. Furthermore, under this system, carrot anthocyanins exhibited stronger AOC than the classical food antioxidant preservatives "butylated hydroxyanisole" (BHA) (food additive E320) and "butylated hydroxytoluene" (BHT). In addition, carrot anthocyanins were found to confer protection against oxidative stress in human colon mucosa cells, reducing oxidative DNA damage in ~20% relative to untreated (control) cells. Interestingly, this study used the fraction of the purple carrot extract that passed through a simulated gastrointestinal tract (including the stomach, small intestine, and colon), suggesting that even after partial degradation by digestion, carrot anthocyanins exerted significant antioxidant effects in the colon. In full agreement with these data, anthocyanin-rich phenolic extracts from purple carrots exhibited strong AOC in a colon carcinoma (Caco-2) cell line, by means of direct radical scavenging and reduction of H_2O_2-induced inflammation markers, such as interleukins (IL)-1β, IL-6, IL-8, and tumor necrosis factor (TNF)-α (Zhang et al. 2016). In addition, the carrot anthocyanin extracts increased the activity of endogenous antioxidant enzymes and glutathione concentration.

In addition to the antioxidant and anti-inflammatory effects, these carrot pigments may confer protection against some cancer types. The use in vitro of carrot extracts rich in anthocyanins on human cancer cell lines (promyelocytic leukemia HL-60 and colorectal adenocarcinoma HT-29) revealed significant and dose-dependent antiproliferative effects in both types of cancer cells (Netzel et al. 2007). Jing et al. (2008) examined the antiproliferative effects of various anthocyanin-rich extracts obtained from different fruits and vegetables (purple carrot, bilberry, purple corn, chokeberry, grape, elderberry, and radish) varying in the chemical structure of their anthocyanins on a cell line of human colorectal adenocarcinoma (HT29), reporting that all anthocyanin extracts significantly inhibited HT29 growth, although with varying antiproliferative potencies: purple corn > chokeberry and bilberry > purple carrot and grape > radish and elderberry. Interestingly, monoglycosylated NAA exerted the strongest antiproliferative effects, whereas triglycosylated AA had the least effect. Another study by Sevimli-Gur et al. (2013) expanded the anticancer *in vitro* evaluation of purple carrot extracts to various cancer cell lines from human (MCF-7, SK-BR-3, and MDA-MB-231 for breast cancer; HT-29 for colon cancer;

and PC-3 for prostate cancer) and mouse (Neuro 2A for neuroblastoma), reporting potent and dose-dependent cytotoxic effects on all of these cancer lines, with the strongest antiproliferative effects found in brain neuroblastoma. Considering that the study also found very little cytotoxicity by the carrot extract in a normal – not cancerous – cell line (VERO, from African green monkey kidney), the authors concluded that purple carrot extracts may have greatest potential as a dietary treatment for brain cancer, avoiding negative side effects in normal cells.

2.3 Genetics and Genes Controlling Carrot Anthocyanin Pigmentation

2.3.1 Inheritance and Mapping of Simply Inherited Traits

A first inheritance study by Simon (1996) described a major effect locus, termed P_1, controlling the presence or absence of purple color in the taproot of carrot, being purple dominant over non-purple, by analyzing segregation ratios in different populations derived from crosses between purple and non-purple rooted carrots. Purple pigmentation was also scored in aerial plant parts of the same segregating populations, leading to the discovery of another simply inherited dominant locus, P_2, which conditioned pigmentation in the nodes, and it was estimated that both loci were genetically linked at a distance of ~36 cM. In two subsequent studies by Vivek and Simon (1999) and Yildiz et al. (2013), P_1 was mapped to carrot chromosome 3 in F_2 mapping populations derived from crosses that used "B7262" as the purple root progenitor. B7262 is a Turkish carrot with anthocyanin accumulation only in the outer phloem of the root, being the inner phloem and xylem orange. A later study by Cavagnaro et al. (2014) identified and mapped another simply inherited dominant locus, called P_3, controlling anthocyanin accumulation in the taproot and in leaf petioles in the genetic backgrounds of P9547 (from Turkey) and PI652188 (from China), both exhibiting purple color in the taproot and petioles. P_3 mapped to Chr. 3 but it was positionally unrelated to P_1, distanced from the latter at >30 cM, as indicated from results of comparative map analysis using common markers across the three segregating populations were the two traits had been mapped (Cavagnaro et al. 2014). Figure 2b presents root phenotypes of the purple-rooted progenitors and derivative segregating populations used to map these and other simply inherited and QTLs conditioning root and petiole anthocyanin pigmentation.

More recently, Iorizzo et al. (2019) analyzed segregation for anthocyanin pigmentation in the root and petioles in an F_2 mapping population derived from BP85682, a Syrian carrot with purple root and petioles, and in advanced progenies (F_3 and F_5 families) of the populations used earlier by Cavagnaro et al. (2014). Phenotypic segregations for root and petiole anthocyanin pigmentation co-segregated in the F_2, and both traits exhibited a 3:1 ratio (purple:non-purple), suggesting that a single major-effect locus conditions both traits. Comparative linkage mapping using markers in common across this population and other populations with known pedigree revealed that this anthocyanin-conditioning locus in the Syrian BP85682 background corresponds to P_3. Thus, the phenotypic

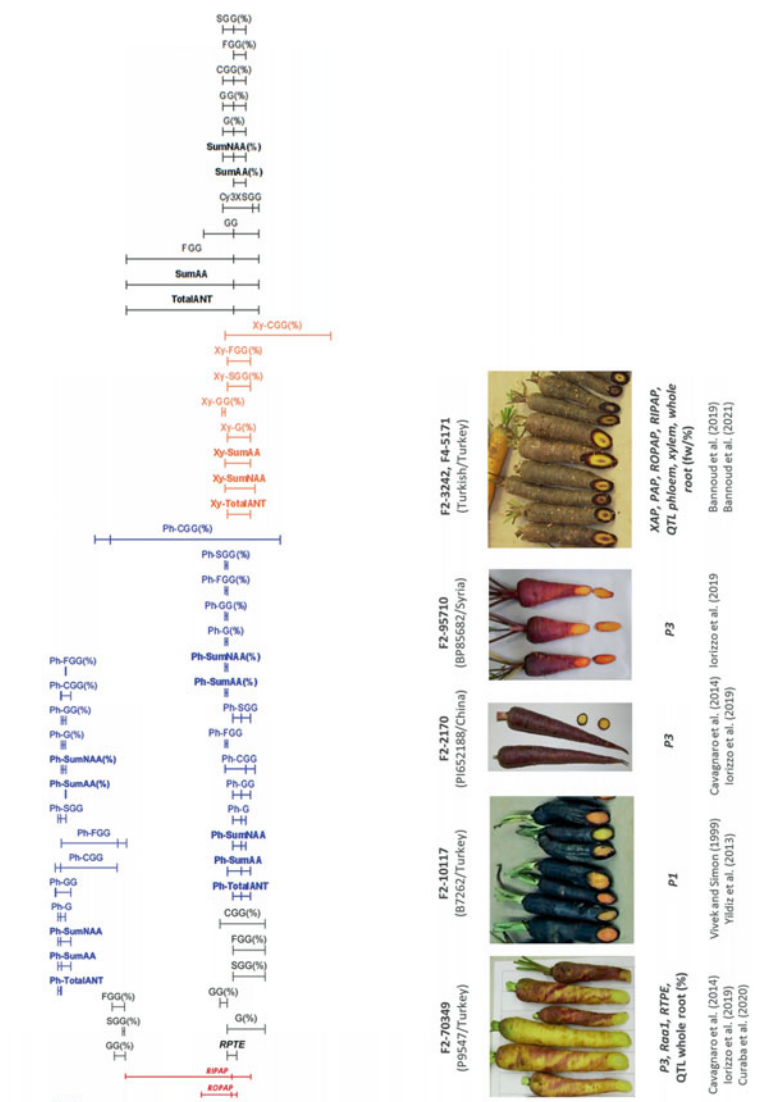

Fig. 2 Genomic locations of anthocyanin QTLs in chromosome 3 and phenotypes mapped in carrot with respective references. (**a**) Representative QTLs and simply inherited traits conditioning the presence and concentration of anthocyanins mapped onto carrot chromosome 3, displaying the physical position of genes associated with anthocyanin biosynthesis. Transcription factors are indicated in purple; anthocyanin biosynthetic structural genes in black; anthocyanin acyltransferases, glucosyltransferases, and methyltransferases in green; and genes involved in anthocyanins cellular transport in orange. The genes were labeled

locus P_3 conditions root and petiole anthocyanin pigmentation in all of the purple carrot materials evaluated to date, except for the Turkish carrot B7262, in which P_1 controls root but not petiole pigmentation.

Bannoud et al. (2019) investigated tissue-specific anthocyanin pigmentation in the carrot root and leaves, using F_2 and F_3 populations segregating for purple color in the root phloem and xylem tissues, and in the leaf petiole. They described and mapped two simply inherited loci controlling the presence/absence of pigmentation in the root xylem and leaf petioles, with purple color being dominant over non-purple in both tissues. These loci, called *XAP* and *PAP*, for "xylem anthocyanin pigmentation" and "petiole anthocyanin pigmentation," respectively, were mapped in the same chromosome region of P_3 (Fig. 2a). In this genetic background, purple phloem pigmentation segregated consistently with a two-gene model, dominant for purple over non-purple, with its main effects co-localizing with the P_1 and P_3 regions. In a recent follow-up study concerning tissue-specific pigmentation in the root outer phloem (also called "cortex") and inner phloem tissues, Bannoud et al. (2021) genetically mapped purple pigmentation in both the outer and inner phloem tissues. The mapping of these simply inherited phenotypic traits, called *ROPAP* and *RIPAP*, for "root outer-phloem and root inner-phloem anthocyanin pigmentation," respectively, revealed colocalization of *ROPAP* with the P_1 and P_3 regions, whereas *RIPAP* co-localized with P_3 only (Fig. 2a). Noteworthy, the populations used by Bannoud et al. had the unprecedented characteristic that P_1 and P_3 as well as pigmentation in the root phloem and xylem, and in leaf petioles all segregated in the same mapping population (3242). Together, the studies of Bannoud et al. (2019, 2021) provide information on the tissue-specificity of P_1 and P_3, and reinforce previous findings by Cavagnaro et al. (2014) and Iorizzo et al. (2019) suggesting that, in some genetic backgrounds, P_3 controls root and petiole anthocyanin pigmentation, while in other backgrounds (e.g., B7262), P_1 controls pigmentation exclusively in the root outer phloem (Yildiz et al. 2013).

Fig. 2 (continued) by their abbreviated names followed by the DCAR or LOC number, in parenthesis. The physical position of each gene in the chromosomes is expressed in terms of nucleotide coordinates from the carrot genome assembly and indicated by the ruler on the left. Major-effect phenotypic traits are denoted in red, italic, and bold fonts. QTLs conditioning absolute (i.e., expressed on a fresh weight basis) or relative pigment concentration (i.e., % of the total anthocyanin content) in the whole root (in black), as well as in the root phloem (in blue) or xylem tissues (in orange), are presented. QTLs for total or combined anthocyanin pigments (e.g., sum of acylated anthocyanins) are indicated in bold. QTLs bars indicate the 1.5 LOD interval (nt) and the position of the maximum LOD value. QTLs are labelled by their pigment abbreviations G = Cy3XG; GG = Cy3XGG; CGG = Cy3XCGG; FGG = Cy3XFGG; SGG = Cy3XSGG; Total ANT = total anthocyanins; Sum AA = sum of acylated anthocyanins (i.e., CGG + FGG + SGG); Sum NAA = sum of non-acylated anthocyanins (i.e., G + GG) preceded by the type of root tissue (Ph = phloem, Xy = xylem), in the case of tissue-specific QTLs, and followed by "(%)" to indicate QTLs expressed as relative concentration. (**b**) Main characteristics of the segregating populations and purple-root sources used for mapping anthocyanin traits (Modified from Bannoud et al. (2019, 2021) and Iorizzo et al. (2020))

Besides the phenotypic loci described above conditioning the accumulation of anthocyanins in different tissues of the root and the aerial part of the plant, a major-effect trait locus controlling the proportion (%) of AA (relative to the total anthocyanin content) was discovered and mapped to Chr. 3, located between the P_1 and P_3 loci, at a distance of 17.9 cM from the latter (Cavagnaro et al. 2014) (Fig. 2a). This locus was termed *Raa1*, for "root anthocyanin acylation" (Cavagnaro et al. 2014). More recently, Curaba et al. (2020) performed fine mapping of *Raa1* in F_3 populations derived from the 70,349 family used by Cavagnaro et al. (2014) and an F_2 family obtained by crossing a 70,349-F_3 plant homozygous recessive at the *Raa1* locus with a homozygous dominant plant of Chinese origin known as "Ping Ding." Overall, the phenotyping and genotyping of a total of 926 plants allowed narrowing down the *Raa1*-containing genomic region, which was used for identifying candidate genes for *Raa1* (described in Sect. 2.3.3).

2.3.2 QTL Mapping

A first study concerning carrot anthocyanin QTLs was published by Cavagnaro et al. (2014) and reported on the genetic mapping of QTLs for individual and total root anthocyanins using an F_2 population derived from the Turkish purple-root progenitor P9547 (Fig. 2b). Fifteen significant QTLs conditioning total root anthocyanin levels, referred to as *RTPE* (for "root total pigment estimate"), and relative content of four cyanidin glycosides were identified and genetically mapped to five chromosomes. The QTLs with largest phenotypic effects (26.6–73.3% explanatory power) co-localized in two regions of Chr. 3. Five of these major-effect QTLs co-localized with P_3, and included a QTL for *RTPE* with 50% phenotypic effect, and four major QTL for concentration of three acylated pigments and one NAA (Fig. 2a). These results confirmed that the P_3 region controls anthocyanin accumulation in the carrot root and petioles in the P9547 genetic background (Cavagnaro et al. 2014). In a more recent study, fine mapping was performed in the P_3 region using a larger mapping population of the same genetic background as used earlier by Cavagnaro et al., detecting the same 5 major-effect QTLs for *RTPE* and four root cyanidin glycosides. Because of the larger population used, a better map resolution was obtained for this region, with overlapping QTLs for *RTPE*, Cy3XG, Cy3XSGG, and Cy3XFGG within a 3 cM region.

Bannoud et al. (2019) used two biparental populations (3242 and 5171) to map QTLs for concentration of individual and combined (i.e., AA, NAA, and total) anthocyanins, and relative percentages of individual and combined anthocyanins, in the root phloem and xylem. In the 3242 population, which was the most informative population with regards to the number of tissue-specific segregating traits, 41 and 8 QTLs for phloem and xylem anthocyanins, respectively, with QTLs explanatory power ranging from 1.3% to 53.4% were mapped across four carrot chromosomes (chromosomes 3, 4, 6, and 7). Thirty of the QTLs for phloem anthocyanins, including those with greatest phenotypic effect, and all of the QTLs for xylem anthocyanins co-localized to two region of Chr. 3, corresponding to the P_1 and P_3 regions previously described and mapped (Fig. 2a). While the QTL for phloem anthocyanins mapped to both of these regions, all the xylem QTLs mapped

to the P_3 region only, co-localizing with other phloem QTLs and the simply inherited traits *XAP*, *PAP*, *ROPAP*, and *RIPAP* conditioning presence/absence of pigmentation in the root xylem and phloem, and in leaf petioles. Altogether, these data strongly suggest that the P_3 region controls anthocyanin pigmentation (i.e., presence/absence of purple color) and concentration in the root phloem and xylem, and in leaf petioles, whereas P_1 conditions only phloem pigmentation and anthocyanin concentration, particularly in the outer phloem or cortex (Fig. 2a). The QTLs mapped in other chromosomes had relatively low explanatory weight, suggesting little phenotypic effect and/or interactions with major loci of Chr.3, as was revealed by Bannoud et al. (2019).

This chapter focused on the most important simply inherited phenotypic traits and QTLs with strongest effects conditioning anthocyanin pigmentation in carrot, as well as on the genes underlying these traits. These correspond to the P_1, P_3/RTPE, and *Raa1* regions in chromosome 3 controlling the presence, concentration, and acylation of these pigments. Additional and detailed information concerning all of the anthocyanin-related QTLs mapped to date across different chromosomes and carrot genetic backgrounds can be found in a recent review by Iorizzo et al. (2020).

2.3.3 Candidate Genes Conditioning Anthocyanin Biosynthesis, Acylation, Glycosylation, and Transport

By means of linkage analysis, Yildiz et al. (2013) attempted to identify candidate genes for P_1, mapping regulatory (*DcMYB3, DcMYB5,* and *DcEFR1*) and structural biosynthetic genes (*UFGT*, *PAL3, LDOX2*, *F3H*, and *FLS1*) of the anthocyanin pathway in the same population used for mapping the phenotypic trait. However, the map position of these genes did not coincide with P_1, indicating that none of them is a likely candidate for P_1. Later, Xu et al. (2014) compared gene expression of 13 anthocyanin structural genes in purple and non-purple roots of nice cultivars, finding upregulation in anthocyanin-containing roots for 9 of these genes, being their expression levels correlated with total root anthocyanin contents. The correlated expression of these anthocyanin genes with root pigment levels suggests a coordinated transcriptional regulation and their involvement in anthocyanin biosynthesis. However, no candidates for P_1, P_3, or *Raa1* – the phenotypic traits described prior to their study – could be identified.

A glycosyltransferase gene, termed *DcUCGalT1*, was isolated and cloned from the root of a purple carrot (Xu et al. 2016). The cloned gene encodes a galactosyltransferase that catalyzes the glycosylation of cyanidin with galactose. The enzyme has high affinity for galactosylation of cyanidin, but not for other anthocyanidins and flavonoid substrates, as indicated by its much lower galactosyltransferase activity for pelargonidin, peonidin, quercetin, and kaempferol observed in a heterologous expression system of *E. coli*. It was also found that the enzyme encoded by *DcUCGalT1* catalyzes exclusively the transfer of UDP-galactose to cyanidin, but it was unable to use other glycosyl donors like UDP-glucose or UDP-xylose, suggesting that *DcUCGalT1* is highly specific for galactosylation of cyanidin. Gene expression analysis of *DcUCGalT1* in nine purple and non-purple rooted cultivars revealed significantly greater expression in all purple roots compared to

non-purple ones, and the expression level was correlated with pigment content in the taproot. Together, these data indicate that *DcUCGalT1* is involved in cyanidin galactosylation. A BLAST search of *DcUCGalT1* in the carrot genome assembly showed greatest sequence homology with DCAR_009912 which is located in Chr. 3 at a position (12,350,188-12,351,646) unrelated to P_1, P_3, *Raa1*, *RTPE*, and the other tissue-specific phenotypic loci positionally associated with P_1 and P_3, suggesting that *DcUCGalT1* is not a major gene controlling anthocyanin pigmentation in the carrot root or petioles.

Following a similar approach as used for the *DcUCGalT1* gene, Xu et al. (2017) isolated and described an R2R3-type MYB transcription factor, designated *DcMYB6*, from purple carrot roots. The expression pattern of *DcMYB6* in purple and non-purple carrots was correlated with anthocyanin content in the roots. *Arabidopsis thaliana* plants genetically transformed with *DcMYB6* under a strong promoter showed anthocyanin pigmentation in various plant parts, including reproductive organs, paralleled with increased transcription of structural anthocyanin genes. These results suggest that *DcMYB6* upregulated the expression of Arabidopsis structural anthocyanin genes and may – presumably – play a similar role in the carrot root. In a subsequent study by Kodama et al. (2018), the transcriptomes of purple versus non-purple tissues from carrot roots and calli were compared by mean of RNA-Seq analysis and searched for differentially expressed members of the MYB, bHLH, and WD40 transcription factor families. They found a total of 104 differentially expressed TF genes, of which 32 had expression levels significantly correlated with root anthocyanin content. Additional analyses in other genetic stocks and root developmental times revealed that 11 of the 32 genes were consistently up- or downregulated in purple-rooted carrots, and included 6 MYBs, 4 bHLH, and 1 WD40 TF. Only one of these genes is located in Chr. 3, with the remaining ones being located throughout seven other chromosomes (and therefore are disqualified as potential candidates of the phenotypic traits in Chr. 3P_1, P_3/*RTPE*, and *Raa1*). The gene in Chr. 3 is a MYB TF (LOC108213488), which the authors referred to as *DcMYB6*, the same MYB gene described earlier by Xu et al. (2017). However, a closer analysis of the position of this gene in the carrot genome sequence revealed that the gene annotated as LOC108213488 is not *DcMYB6* but*DcMYB7*, another MYB TF described later as a potential candidate of P_3 by Iorizzo et al. (2019) and Xu et al. (2019).

Along with the sequencing and publication of the carrot genome, a list of 97 annotated structural biosynthetic flavonoid genes, including genes involved in anthocyanidin/anthocyanin biosynthesis and modification (e.g., glycosyltransferases and methyltransferases) was reported by Iorizzo et al. (2016). Besides facilitating this first large-scale catalogue of predicted structural genes involved in carrot flavonoid/anthocyanin biosynthesis, the availability of an annotated carrot genome sequence was instrumental for the discovery of key genes conditioning some of the phenotypic traits previously described and mapped. Among the first studies to take advantage of such an unprecedented genomic tool were those of Iorizzo et al. (2019), Xu et al. (2019), and Bannoud et al. (2019); the first two aiming at identifying candidate genes for P_3, while the latter investigated candidates for tissue-specific pigmentation in the root phloem and xylem.

Iorizzo et al. (2019) performed high-resolution mapping in the P_3/*RTPE* region of Chr. 3 using five mapping populations of different genetic backgrounds, including a larger-size population of the 70,349 F_2 used to first map these traits by Cavagnaro et al. (2014), for a total of 1669 plants phenotyped (421 individuals were phenotyped for *RTPE*, by HPLC analysis, and 1248 for P_3, by visual phenotyping of root color) and genotyped using different molecular marker types. The inclusion of common sequence-based SNP markers across the different maps allowed their comparative analysis to further delimit the region of interest, as well as anchoring such region of interest to the carrot genome assembly. Thus, by this approach, it was able to obtain a higher resolution of this map region, restricting the confidence interval of the *RTPE* QTL to a 2.6 cM region, whereas the closest flanking markers of P_3 delimited a 0.3–0.8 cM map region. A close examination of the linkage blocks harboring *RTPE* and P_3 in the different maps allowed further narrowing down the position of P_3 to a 494 kb region flanked by SNP markers K2590 and K0363 (Fig. 3). In this region, 8 anthocyanin-related transcription factor (TF) genes (6 MYB and 2 bHLH) were identified, whereas no structural anthocyanin biosynthetic genes were found. By means of gene prediction, orthologous, and phylogenetic analyses using MYB and bHLH TFs from other species with known functions, allowed the identification of six MYBs that had high sequence homology with MYBs involved anthocyanin biosynthesis, which were considered potential candidates for P_3/*RTPE.* The identified MYB TFs positionally associated with P_3/*RTPE* were designated as *DcMYB6*-*DcMYB11*, and they belong to the R2-R3-MYB family (Table 2). Noteworthy, *DcMYB6* corresponds to the MYB gene previously described by Xu et al. (2017). In the same study, the transcriptomes of purple versus non-purple roots and petioles were compared by means of RNA-Seq analysis, followed by validation of the candidate genes by RT-qPCR analysis. Of all six MYB TFs identified in the P_3 region, *DcMYB7* was the only gene consistently upregulated in all of the anthocyanin-containing tissues (as compared to non-purple tissues), suggesting that this MYB controls anthocyanin pigmentation in both the carrot root and petioles. *DcMYB11* was consistently upregulated in purple petioles (relative to green petioles) but not in purple roots, suggesting that it may co-regulate petiole pigmentation along with *DcMYB7*. Together, these results strongly point at *DcMYB7* as the main candidate for P_3 and a key gene conditioning root and petiole pigmentation, while *DcMYB11* specifically (co)regulates petiole pigmentation. These results by Iorizzo et al. (2019) suggest that, for the purple carrot lines used in their study, *DcMYB6* described earlier by Xu et al. (2017) does not play a major role in regulating anthocyanin biosynthesis in neither the taproot nor in the leaf petioles. Table 2 presents the MYB transcription factors associated with carrot anthocyanin pigmentation described to date, including their chromosome positions and gene IDs. The six anthocyanin-related MYB TFs found by Iorizzo et al. (2019) in the P_3 region are arranged in a small cluster of genes within a ~166 Kb region of Chr. 3 (Fig. 3b). A number of studies concerning genome wide analysis of R2-R3-MYB family members have revealed that MYB TFs are commonly found in gene clusters in the genomes of many plants species. Interestingly, it has been proposed that the expansion of MYB gene-families and their organization into gene clusters is mainly driven

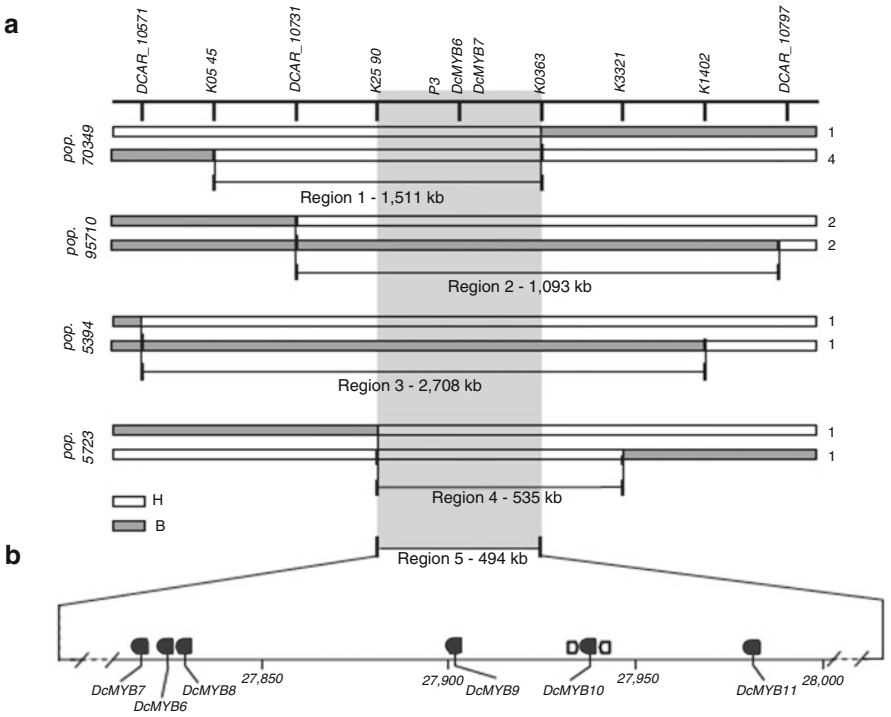

Fig. 3 Scheme of the fine mapping approach and identification of candidate genes in the P_3/*RTPE* region of chromosome 3 associated with anthocyanin pigmentation in the carrot root and petioles. (**a**) haplotypes delimiting the genomic regions controlling the *RTPE* QTL in population 70,349 (region 1), and the P_3 locus in populations 95,710, 5394 and 5723 (regions 2–4). White bars indicate the heterozygous haplotypes (*Aa*) and gray bars indicate the homozygous recessive haplotypes (*aa*). Region 5 represents the genomic sequence delimited by the nearest markers flanking *RTPE* and the P_3 locus across regions 1–4. The number of plants with recombinant genotypes is indicated by on the right of each bar. (**b**) Schematic representation of carrot chromosome 3 containing regions 1–5 and the six anthocyanin related MYBs (*DcMYB6-DcMYB11*) denoted in black boxes (Modified from Iorizzo et al. (2019))

by the occurrence of tandem and segmental duplications (Feller et al. 2011). Thus, it is possible that tandem and segmental duplications could have also influenced the genome organization of the carrot R2-R3-MYB gene family.

Xu et al. (2019) functionally characterized*DcMYB6* and *DcMYB7*, both candidates of P_3, by upregulating and shutting down their expression in carrot using a transgenic approach. It was found that overexpression of *DcMYB7*, but not *DcMYB6*, in the orange-rooted carrot cultivar 'Kurodagosun' led to the accumulation of large amounts of anthocyanin in the root and other tissues of this cultivar. Conversely, knockout of *DcMYB7* in the solid purple-rooted cultivar 'Deep Purple', obtained by gene-editing using the CRISPR-Cas9 system, resulted in carrots with yellow roots. These results confirm the role of *DcMYB7* as a major regulator of anthocyanin pigmentation in carrot root, as well as the main candidate of P_3. Their study also

[a]*DcMYB6* was first described by Xu et al. (2017) and later incorporated manually into the carrot genome assembly [i.e., this gene was not included in the published genome assembly (Iorizzo et al. 2016)] with the coordinates above (Iorizzo et al. 2019)

[b]In the study of Bannoud et al. (2021), these MYBs were referenced with a generic name (i.e., "MYB" followed by their DCAR number); here we propose *DcMYB27* and *DcMYB28* to designate DCAR_026095 and DCAR_026095, respectively

demonstrated that *DcMYB7* could interact with – and activate the expression of – *DcbHLH3* (a homolog of the anthocyanin related *bHLH3* from *Malus domestica*) and structural genes of the anthocyanin biosynthetic pathway, and could also activate the expression of a putative glycosyltransferase (*DcUCGXT1*) and an acyltransferase (*DcSAT1*) genes identified in the same study (by orthologous analysis with related genes from other species). Together, these results provide strong evidence on the role of *DcMYB7* as a transcriptional activator of other regulatory and structural anthocyanin genes, including genes involved in pigment decoration (i.e., glycosylation and acylation). Interestingly, in non-purple carrots, the promoter of *DcMYB7* was interrupted either by *DcMYB8*, a nonfunctional tandem duplication of *DcMYB7*, or by two transposons, leading to the transcriptional inactivation of *DcMYB7*, thereby resulting in no anthocyanin synthesis and accumulation in their roots.

In the P_1 region, another MYB transcription factor, initially identified by Bannoud et al. (2019) and termed *DcMYB12*, was recently renamed as *DcMYB113* and functionally characterized by Xu et al. (2020). *DcMYB113* is an R2R3-MYB TF that controls anthocyanin pigmentation in the root of the carrot cultivar 'Purple Haze' and related genetic backgrounds [e.g., in B7262 (Bannoud et al. 2021)]. The function of *DcMYB113* is root- and tissue-specific, conditioning pigmentation only in the root periderm and outer phloem (also known as "cortex"). Also, as mentioned above, it is genotype-dependent, as indicated by the fact that this gene was not expressed in the roots of genetic backgrounds exhibiting anthocyanin pigmentation in both roots and petioles, including the commercial cultivars Deep Purple, Cosmic Purple, and Pusa Asita, and the inbred line P9547 (Xu et al. 2020; Bannoud et al. 2021). The root-specific activity of this gene was verified by genetic transformation of the orange carrot cultivar 'Kurodagosun' with *DcMYB113* fused to its own promoter and – in an independent transformation event – under the action of the CaMV 35S promoter. Transgenic 'Kurodagosun' plants carrying *DcMYB113* driven by the CaMV 35S promoter had solid purple roots and petioles, while the transgenic 'Kurodagosun' expressing *DcMYB113* with its own promoter had purple root and

green petioles, suggesting that root-specific expression of *DcMYB113* was determined by its promoter (Xu et al. 2020). As found previously for *DcMYB7*, it was also reported that *DcMYB113* could transcriptionally activate the expression of *DcbHLH3* and a number of structural anthocyanin biosynthetic genes, as well as two genes involved in pigment glycosylation (*DcUCGXT1*) and acylation (*DcSAT1*). Together, results from this study indicate that *DcMYB113* is the most likely candidate for P_1 and provide insights into its role in regulating anthocyanin biosynthesis and modification in the carrot root phloem.

Recently, a candidate gene for the *Raa1* locus, conditioning the relative content (%) of AA in the root, was identified and characterized by Curaba et al. (2020). By means of fine mapping in populations segregating for high AA versus low AA (individuals with more than 60% of the NAA Cy3XGG were scored as "low AA" and those with less than 22% of Cy3XGG were scored as "high AA"), followed by linkage blocks analysis, a genomic region of 576 kb harboring *Raa1* was identified and further searched for candidate genes. In this region, three predicted "Serine Carboxypeptidase-Like" (SCPL) genes, designated as *DcSCPL1-DcSCPL3*, were identified and analyzed at various levels. Phylogenetic analysis clustered the three carrot SCPLs with anthocyanin-related acyltransferase SCPL genes from other species, suggesting a similar role in carrot. Comparative transcriptome analysis indicated that only *DcSCPL1* was always expressed in association with anthocyanin pigmentation in the root and was co-expressed with *DcMYB7*. Structural (gene sequence) and expression analyses of *DcSCPL1* in roots with high AA and low AA revealed an insertion causing an abnormal splicing of the third exon during mRNA editing, likely resulting in the production of a nonfunctional acyltransferase and explaining the reduced acylation phenotype in the "low AA" plants. Together, results from this study strongly suggest that *DcSCPL1* is a major regulator of anthocyanin acylation in the carrot root and the main candidate of *Raa1*. Furthermore, the 700 bp-insertion found in the recessive allele of *DcSCPL1* was used to design flanking primers to develop a codominant PCR-based marker for aiding in the selection of plants with high or low AA in carrot breeding programs. It must be noted that the *DcSAT1* and *DcSCPL1* acyltransferase genes described independently by Xu et al. (2019, 2020) and Curaba et al. (2020), respectively, correspond to the same gene, with locus ID LOC108214129.

A few studies have addressed the genetics underlying tissue-specific pigmentation in the carrot root, using linkage mapping and comparative transcriptomic approaches in purple and non-purple root tissues. In addition to mapping QTLs for phloem and xylem anthocyanins, Bannoud et al. (2019) searched for candidate genes controlling pigmentation in the phloem, reporting that *DcMYB7* conditions both presence/absence and concentration of anthocyanins, while two cytochrome CYP450 genes with putative flavone synthase activity may negatively influence pigment content in this tissue. In a similar follow-up study concerning pigmentation in the outer phloem (*ROPAP*) and inner phloem (*RIPAP*), *DcMYB7* and *DcMYB113* appear as the main candidates for *ROPAP*, depending on the genetic background analyzed, while only *DcMYB7* conditions *RIPAP* (Bannoud et al. 2021). A MADS-box gene (DCAR_010757) located in the P_3 region was consistently upregulated in

association with purple pigmentation in the outer phloem (as compared to the non-purple inner phloem) in the two genetic backgrounds analyzed (3242 and B7262), as well as with *RIPAP* in P9547. However, this MADS-box was not phylogenetically related to MADS-box genes from other species known to be involved in anthocyanin biosynthesis and, therefore, its role in carrot anthocyanin biosynthesis is still inconclusive. Considering that the most striking differences in purple pigmentation between carrot cultivars are between the root xylem and phloem, comparative transcriptome analysis in these tissues may uncover major genes influencing their pigmentation. Such comparative analysis was conducted by Meng et al. (2020), finding 10 MYBs (Table 2) and 14 bHLHs, including *DcbHLH3*, differentially expressed between these two tissues. Interestingly, four of these MYBs, including two that were predicted as MYB1R1-like TFs (*DcMYB1R1-1* and *DcMYB1R1-2*), were downregulated in both purple phloem and purple xylem tissues, suggesting that they may act as transcriptional repressors of anthocyanin structural genes, thereby negatively regulating anthocyanin biosynthesis. Their role in carrot anthocyanin pigmentation deserves further investigation, as MYB transcriptional repressors of anthocyanin biosynthetic genes have been reported in several plant species, including the ornamental *Mimulus lewisii* and grapevine.

The regulation of anthocyanin metabolism ends with their transport into the vacuole, a process which can involve glutathione S-transferases (GSTs) (reviewed by Sylvestre-Gonon et al. 2019), and members of the "multidrug and toxic compound extrusion" (MATE) (Gomez et al. 2009) and "ABC-C transporter" gene families (Behrens et al. 2019). *DcGST1* (DCAR_003401), which co-localized with a minor-effect QTL on Chr. 1 conditioning total root anthocyanins, was reported to be upregulated in two solid purple cultivars compared to orange-rooted ones, and its upregulation correlated with increased vacuolar anthocyanin accumulation in purple carrots (Meng et al. 2020). Very recently, Bannoud et al. (2021) evaluated the expression of *DcGST1*, *DcMATE1* (DCAR-031151), and a carrot ABC Transporter gene (DCAR-010639) located in the P_3 region of Chr. 3, in purple versus non-purple root phloem tissues in two unrelated genetic backgrounds, B7262 (controlled by *DcMYB113*) and 3242 (controlled by *DcMYB7*), reporting significant upregulation of *DcGST1*and *DcMATE1* – but not of ABC Transporter – in all the purple tissues. Both of the upregulated genes were co-expressed with *DcMYB113* (in B7262) and *DcMYB7* (in 3242). Interestingly, according to Xu et al. (2020), *DcMYB113* was also co-expressed with *DcMATE1* in purple tissues of the cultivar 'Purple Haze'. Altogether, results from these three studies strongly suggest that *DcMYB113* and *DcMYB7* transcriptionally activate *DcGST1*and *DcMATE1* in their respective genetic backgrounds. Such regulatory role of MTB TFs on anthocyanin transporter genes has been reported in other plant species (Zhang et al. 2014).

2.4 Perspectives and Implications for Breeding

In recent years, candidate genes for the main phenotypic traits (P_1, P_3/*RTPE*, and *Raa1*) and QTLs conditioning anthocyanin biosynthesis, glycosylation, and

acylation across different carrot tissues and genetic backgrounds, as well as genes involved in cellular transport and vacuolar accumulation of these pigments, have been discovered and functionally characterized, and their causal mutations described and – for one of these genes (*DcSCPL1*) – used for the development of a molecular marker to aid in marker-assisted breeding (MAB). These advances are encouraging for breeding programs aiming at improving anthocyanin content and pigment profile for different end purposes, such as fresh consumption carrots with increased content of bioavailable NAA and – consequently – greater nutritional value; or carrots with high concentration of chemically stable AA suitable for the food colorant industry; and/or introgressing such pigment profiles into carrot genetic backgrounds with other desirable agronomic and consumer-quality traits. Also, the fact that these pigments have a role, in the plant, of ameliorating abiotic stresses (Shirley 1996), suggest that increasing general anthocyanin levels may result in more resilient carrot cultivars, of relevance in the current climate change context. Moreover, not only total anthocyanin content but also pigment profile, particularly with regards to AA:NAA ratios, may be relevant for this purpose, as it has been shown in other crops, such as red grapes, that exposure to high temperature results in reduced total anthocyanin content but increased proportion of AA, mediated by an upregulation of acyltransferases, suggesting that pigment acylation may be a mechanism for attenuating high temperature-stress consequences by reducing anthocyanin degradation (de Rosas et al. 2022).

To pursue these goals more rapidly and effectively, it would be ideal for breeding programs to combine well-stablished classic breeding strategies with molecular tools that allow tagging gene variants associated with specific pigment phenotypes. An example of such type of molecular tool is the codominant PCR-based marker targeting the *DcSCPL1* gene which allows differentiation of "low acylation" and "high acylation" alleles, which could be very useful for assisting early selection of plants with high or low proportion of AA. However, such MAB strategy would require developing additional markers for other key genes conditioning anthocyanin concentration and accumulation in different purple carrot backgrounds (e.g., *DcMYB7* and *DcMYB113*), and evaluating their usefulness for predicting pigment phenotypes across diverse carrot germplasm. Considering that the efficacy of molecular markers for predicting a phenotype relies on how tightly linked they are to the mutation that effects the phenotype, among other factors, marker development should ideally target the causal mutation of these genes, as was done with the *DcSCPL1* gene.

Alternatively, transgenic approaches represent technologically effective strategies for developing carrots with high anthocyanin content and specific pigment profiles. For example, increased anthocyanin concentration could be achieved by transforming carrots with *DcMYB7* under a strong constitutive promoter (CaMV 35S), whereas manipulating pigment profiles for high or low ratios of AA/NAA may be done using a similar strategy for upregulating *DcSCPL1* or generating a *DcSCPL1*-knockout by editing this acyltransferase gene, respectively. These and other transgenic approaches have been experimentally successfully applied to carrot for a number of traits (reviewed by Baranski and Lukasiewicz 2019), including

anthocyanin pigmentation (Xu et al. 2019, 2020). However, consumer's perceptions of transgenic crops vary widely across geographical regions and may represent an important barrier for a general wide acceptance of carrot cultivars developed by these methods. However, it can be speculated that food colorants derived from transgenic carrots may be accepted with less resistance than transgenic carrots for fresh consumption, especially considering the (publically perceived?) negative health effects associated with the consumption of some synthetic colorants.

3 Other Non-anthocyanin Phenolics

3.1 Introduction and Biosynthesis

As described for anthocyanins, phenolic compounds are secondary metabolites composed of an aromatic ring bearing one or more hydroxyl groups, and they exert similar functions in the plant as described for their colored-relatives anthocyanins, conferring protection against biotic and abiotic stresses (e.g., drought, salinity, ultraviolet radiation, extreme temperatures, phytopathogenic and predator attacks, etc.) and contributing to the organoleptic properties of plant foods (reviewed by Balasundram et al. 2006). Phenolic compounds can be subclassified as phenolic acids, flavonoids, tannins, lignans, stilbenoids, and curcuminoids. Carrot roots accumulate mainly phenolic acids, among which HCAs large predominate, being chlorogenic acid the major carrot HCA (Sharma et al. 2012). These phenolic acids are formed from the phenylpropanoid pathway, a late branch of the shikimic acid pathway. Figure 4 illustrates the core part of the pathway leading to HCAs and chlorogenic acid synthesis. HCAs are produced from phenylalanine through a series of reactions catalyzed by several enzymes, the first one being phenylalanine ammonia lyase (PAL), which converts phenylalanine to cinnamic acid. Cinnamic acid is then converted to coumaric acid by "cinnamate 4-hydroxylase" (C4H), and then to 4-coumaroyl CoA by "4-coumarate: CoA ligase" (4CL). 4-coumaric acid and 4-coumaroyl CoA represent important branch points in the phenylpropanoid pathway from which other subclasses of phenylpropanoids can be produced, such as coumarins, lignins, flavonoids, and hydroxybenzoic acids (another type of phenolic acids). 4-coumaroyl CoA is then converted to 4-caffeoyl quinic acid, known as chlorogenic acid, by a series of reactions catalyzed by the enzymes "hydroxycinnamoyl-CoA shikimate/quinate hydroxycinnamoyl transferase" (HCT), "hydroxycinnamoyl CoA quinate hydroxycinnamoyl transferase" (HQT), and "4-coumarate-3-hydroxylase" (C3H) (Fig. 4).

3.2 Chemical Diversity and Distribution

Total phenolics content (TPC) in the carrot root varies broadly across accessions and root color phenotypes, as measured spectrophotometrically (Singleton et al. 1999; Fukumoto and Mazza 2000), with estimated ranges in different germplasm collections of 19.8–342.2 mg/100 g fw (Leja et al. 2013), ~25.9–426 mg/100 g fw

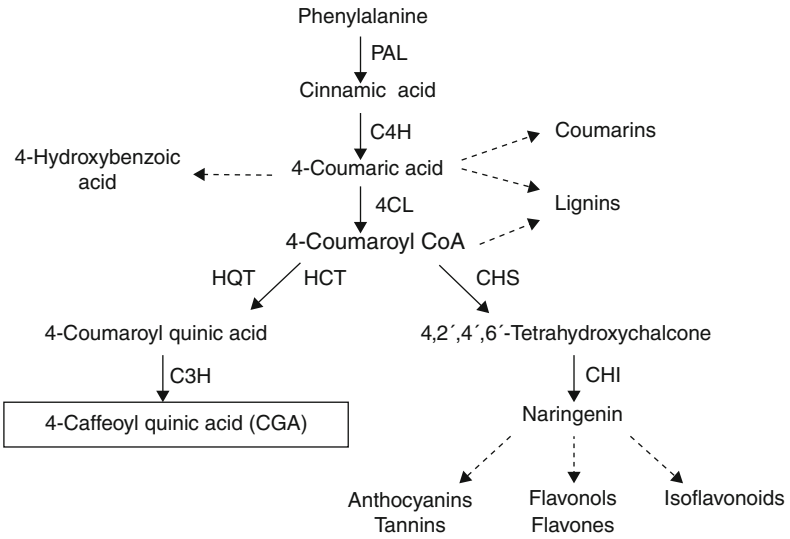

Fig. 4 Simplified phenylpropanoid biosynthetic pathway leading to the production of chlorogenic acid. Abbreviations used: *PAL* phenylalanine ammonia-lyase, *C4H* Cinnamate 4-hydroxylase, *4CL* 4-coumarate: CoA ligase, *HCT* hydroxycinnamoyl-CoA shikimate/quinate hydroxycinnamoyl transferase, *HQT* hydroxycinnamoyl CoA quinate hydroxycinnamoyl transferase, *C3H* 4-coumarate3-hydroxylase, *CHS* chalcone synthase, *CHI* chalcone isomerase, *CGA* chlorogenic acid (4-caffeoylquinic acid) (Reproduced from Bartley et al. (2016))

(considering a dry matter content of 11% for expressing values on a fresh weight basis) (Sun et al. 2009), and 8.7–74.6 mg/100 g fw (Alasalvar et al. 2001). Because anthocyanins account for a large proportion of the TPC in purple carrots, the latter had much higher TPC than other root colors, with overall TPC means for purple carrots being 9 times (Leja et al. 2013) and 13 times higher than mean TPC in other carrot colors (Sun et al. 2009). In non-purple carrots, TPC levels varied little among the different root colors, with reported overall ranges of means – for white, yellow, orange, and red carrot cultivars – of 18–31, 24.2–40.4, and 18.3–25.9 mg/100 g fw, with mean differences among these root colors being statistically insignificant or marginally significant (Sun et al. 2009; Leja et al. 2013). By means of HPLC analysis, it was possible to precisely quantify non-anthocyanin TPC in purple and non-purple carrot cultivars, revealing significantly greater mean values in purple carrot (74.6 mg/100 g fw) than in orange (16.2 mg/100 g fw), yellow (7.7 mg/100 g fw), and white (8.7 mg/100 g fw) carrots (Alasalvar et al. 2001). Similar results were obtained in another HPLC-based study of phenolic composition in 10 carrot cultivars with different root colors grown across two locations and 3 years, reporting greater non-anthocyanin TPC in purple carrots (with a range of ~28.6–101.2 mg/100 g fw) than red (~ 0.07–6.41 mg/100 g/fw), orange (~ 0.09–3.41 mg/100 g fw), yellow (~ 0–0.93 mg/100 g fw), and white carrots (~ 0–0.77 mg/100 g fw) (for comparison purposes, values were converted on a basis of fw, considering 11% of dry matter for all the cultivars) (Kramer et al. 2012).

In the HPLC-based studies, non-anthocyanin TPC in different root color cultivars varied in the following rank order: purple > red > orange > yellow ≈ white (Alasalvar et al. 2001; Kramer et al. 2012). Altogether, data from these studies indicate that purple carrots generally have not only greater TPC but also greater total concentration of colorless phenolics than carrots of other colors.

Among the non-anthocyanin phenolics, HCAs and derivatives largely predominate in all the root color phenotypes (Kramer et al. 2012), including typical orange carrots where HCAs accounted for 73.7–99.7% of the root TPC (Zhang and Hamauzu 2004). With a few exceptions, in most of the cultivars analyzed to date, chlorogenic acid (5-*O*-transcaffeoylquinic acid) is the predominant HCA and – more generally – the predominant phenolic compound found in carrot roots. According to Kramer et al. (2012), this compound was detected in highest quantities in purple carrots, accounting for 54.1–79.7% of the total non-anthocyanin phenolics, while it showed broader ranges of variation in the other root colors, representing 5.1–64.9%, 13.2–68.2%, and 0–68.7% in red, orange, and yellow carrots, respectively, as varying across different growing locations and years. White carrots were the exception, with chlorogenic acid accounting for only 0.1–12.1% of the total phenolics, with vanillic acid derivatives being the predominant phenolics found in their roots, representing 10.4–83.6% of the TPC. Also, in one of the yellow cultivars evaluated (Yellowstone), ferulic acid and vanillic acid derivatives predominated over chlorogenic acid (Kramer et al. 2012). According to Alasalvar et al. (2001), chlorogenic acid represented 51–72% of the non-anthocyanin TPC in carrots of different root color (purple, orange, yellow, and white), whereas Zhang and Hamauzu (2004) reported that this compound accounted for 42–62% of the TPC in two orange-rooted cultivars. Besides the generally predominant chlorogenic acid, other phenolic acids that can be found in sufficient quantities in some carrot genetic backgrounds are derivatives of ferulic, vanillic, and caffeic acids (Alasalvar et al. 2001; Kramer et al. 2012).

In orange carrots, the concentration of phenolics varies across root tissues in the following order: periderm > phloem > xylem. According to Zhang and Hamauzu (2004), the root periderm only accounts for 11% of the carrot fresh weight, yet it provides 54.1% of the TPC in the root, whereas the phloem and xylem tissues provide 39.5% and 6.4% of the root TPC, respectively. Coincidently, chlorogenic acid levels and AOC in these three tissues followed the same relative ranking (i.e., periderm > phloem > xylem), with the periderm providing 67.4–80.1% of the total AOC and 66.5–88.2% of the total chlorogenic acid content, the phloem 7.5–9.6% and 10.7–29.6%, and the xylem 3.2–7.5% and 1.1–4.0%, for these two variables, respectively. These data illustrate the tissue-specific distribution of phenolic compounds in the carrot root and strongly suggest that chlorogenic acid is the major phenolic and antioxidant agent in orange carrots.

In line with the proposed role of phenolics in conferring protection to the plant against biotic and abiotic stresses, carrot TPC, chlorogenic acid, and AOC have been shown to concomitantly increase in response to numerous postharvest stimuli/stresses, including ultraviolet light radiation and wounding (Surjadinata et al. 2017), UVC light and hyperoxia (Formica-Oliveira et al. 2016), storage in modified

atmosphere (Pace et al. 2020), and water loss and wounding (Becerra-Moreno et al. 2015). In the field crop, nitrogen fertilization, boron deficiency, the cultivation system (organic vs. conventional), and the growing location and year can also influence carrot phenolic levels and AOC (Søltoft et al. 2010; Kramer et al. 2012; Singh et al. 2012).

3.3 Carrot Phenolics and Human Health

The consumption of polyphenols-rich plant foods has been associated with various health benefits, including maintenance of normal blood glucose and cholesterol levels, prevention or delayed onset of cognitive decline, and decreased risk of cardiovascular disease, diabetes, neurodegenerative disorders, and some cancer types (reviewed by Soto-Vaca et al. 2012). These general health-enhancing effects have been attributed – to a considerable extent – to the antioxidant and anti-inflammatory properties of phenolic compounds. Based on data concerning the relative impact on health of different phenolic subclasses, mainly with regard to their antioxidant, anti-inflammatory, and antiproliferative effects, the average dietary intake of polyphenols was estimated to be 1058 mg per day for males and 780 mg for females, with half of these composed of HCAs, 20–25% of flavonoids, and 1% anthocyanins (Stevenson and Hurst 2007).

A number of health-related studies, conducted in vitro and in vivo, have used purple carrot extracts as sources of anthocyanins and other phenolics, evidencing significant and substantial antioxidant, anti-inflammatory, and antiproliferative effects (described in Sect. 2.2.3). In germplasm evaluations including carrots of diverse geographical origins, root color, and genetic structure, significant and strong positive correlations have been found between TPC and AOC (evaluated by different methods), with reported correlation coefficient (r) values of 0.98–0.99 (for all root colors included) and 0.64–0.82 (considering only non-purple carrots) (Leja et al. 2013), 0.99 (includes all root colors) (Sun et al. 2009), 0.98–0.99 (includes only orange carrots) (Zhang and Hamauzu 2004), 0.62–0.93 (includes only orange carrots) (Surjadinata and Cisneros-Zevallos 2017), and 0.92 (only orange carrots) (Alegria et al. 2016). Similarly, significant positive and strong correlations between chlorogenic acid content and AOC were found, with estimated r values of 0.91 (Sun et al. 2009) and 0.89 (Alegria et al. 2016). Altogether, these data, and the fact that chlorogenic acid is the major carrot phenolic compound, strongly suggest that phenolics in general, and chlorogenic acid in particular, are largely responsible for carrot antioxidant properties.

Bioavailability is a relevant aspect for phenolic compounds being able to exert their health benefit effects in the organism. Generally, there is limited absorption despite the epidemiological studies showing significant health benefits associated with polyphenolic consumption. According to Soto-Vaca et al. (2012), the absorption of phenolic compounds in humans is a multifactorial, complex, and highly variable phenomenon, influenced by the type of phenolic compound, its molecular structure, the accompanying food matrix, interactions with other macromolecules and minerals (e.g., forming iron-chelating complexes), the processing by the

microbiome and resulting profile of phenolic metabolites, among many other factors. Because phenolics are generally considered to have poor bioavailability, there is considerable amount of literature – and ongoing studies – on these factors affecting the absorption of phenolic compounds (reviewed by Soto-Vaca et al. 2012).

3.4 Genetics of Carrot Phenolics

Compared to other nutraceutical classes, very little is known about the genetic regulation of non-anthocyanin carrot phenolics. Thus, very few studies have investigated possible genes involved in carrot HCAs and chlorogenic acid synthesis. A first work by Becerra-Moreno et al. (2015) examined the effect of water stress and wounding, applied alone or combined, on the expression of structural genes of the early shikimic acid pathway and later phenylpropanoid pathway, estimated by RT-qPCR analysis, along with the accumulation of related phenolic metabolites. Their findings indicate that both pathways are activated by these stresses applied alone, being wounding a stronger activator than water stress, while both stresses combined acted synergistically and showed the strongest pathway activation. Water stress favored the lignification process, while wounding led to the preferential accumulation of shikimic acid, phenolic compounds, and lignin. The increase in these phenolic compounds due to both types of stresses combined was accompanied by upregulation of PAL, C4H, 4CL, "caffeoyl-CoA3-O-methyl transferase" (CCoAOMT), "cinnamoyl-CoA reductase" (CCR), and "cinnamyl alcohol dehydrogenase" (CAD) genes involved in the phenylpropanoid pathway, whereas three upregulated genes of the early shikimic pathway were found, namely "3-deoxy-D-arabino heptulosonate 7-phosphate synthase" (DAHP synthase), 5-enolpyrovylshikimate 3-phosphate synthase (EPSP synthase), and chorismate mutase-prephenate dehydratase (CMPD).

Another study by Bartley et al. (2016) analyzed the expression of 12 structural genes (4 PAL, 2 CHS, and 1 each of C4H, 4Cl, HCT, HQT, C3H, and CHI) and 7 transcription factors (4 MYBs and 1 each of HY5, ERF, and UVR8) described or predicted earlier as being involved in phenylpropanoid synthesis in carrot and other species, in carrot root slices irradiated and not irradiated with UV-B light followed by incubation at 15 °C and 45% relative humidity for 6 days. Increases in gene expression – varying in intensity, duration of the peak maximum, and time of onset from the application of the UV treatment – after UV radiation were reported for all the structural genes except CHI, and most of the regulatory genes analyzed [except for ERF, which was not induced, and one of the MYB TF (termed *DcPcMYB1*) showing very little induction by UV] relative to their UV-untreated counterparts. These increases in gene expression by the UV treatment were paralleled with increases in the content of chlorogenic, caffeic, ferulic, and coumaric acids, compared to the content in untreated samples. These results suggest that most of the structural and regulatory genes evaluated in their study are involved in the UVB-induced synthesis of carrot HCAs.

While these two studies revealed genes involved in postharvest stress-induced synthesis of phenolic compounds, additional comparative studies using genetic

backgrounds varying in phenolic concentration and/or profile are necessary to identify genes influencing carrot phenolic levels under non-stressed field-cultivation conditions. Furthermore, in order to identify hierarchical genes controlling root phenolic content and profile, such studies should be combined with, or preceded by, linkage or association mapping approaches to localize the genomic region of the trait locus or QTLs conditioning such compositional variations, to then search for candidate genes – in the region of interest – using comparative gene expression analyses in contrasting phenotypes. This approach has been successfully used for identifying key genes controlling the type and content of other carrot nutraceuticals, namely anthocyanins and carotenoids (discussed in Sects. 2 and 6, respectively).

4 Polyacetylenes

4.1 Introduction

Polyacetylenes are a large and diverse chemical class of bisacetylenic oxylipins derived from fatty acids, characterized by the presence of at least two, usually conjugated, triple carbon-carbon bonds. Polyacetylenes are widely distributed in the plant kingdom, but they are also present in fungi, lichens, moss, marine algae, and invertebrates. The majority of the more than 2000 known polyacetylenes have been isolated from higher plants and notably from the botanically related plant families Apiaceae, Araliaceae, and Asteraceae (Dawid et al. 2015). The predominant structural types of polyacetylenes are different between Apiaceae and Asteraceae. In the Apiaceae and the closely related Araliaceae family, C_{17}-polyacetylenes with a variable number of additional double bonds and hydroxyl functions are dominating, while Asteraceae family members accumulate structurally diverse polyacetylenes. The most common C_{17}-polyacetylenes are falcarinol (FaOH) and falcarindiol (FaDOH). They occur in the edible and nonedible parts of vegetables and herbs of the Apiaceae family including carrots, parsnip, fennel, celery, and parsley. Falcarinol-type polyacetylenes, also called as falcarins (Santos et al. 2022), are less common in other food species, although falcarinol, falcarindiol, and related C_{14}- and C_{15}-polyacetylenes have been described for Solanaceae species like tomatoes and aubergines, where they are known to function as phytoalexins (Christensen 2011). Excessive amounts of falcarinol-type polyacetylenes have often been reported to contribute to the undesirable bitter off-taste of carrots and their products such as juice or puree. Quantitative chemical analyses combined with sensory perception tests indicate that falcarindiol is highly correlated with bitterness, whereas falcarinol is not (Czepa and Hofmann 2004). Apart from that, several in vitro studies have confirmed that falcarinol is among the most cytotoxic polyacetylenes in Apiaceae vegetables and, according to the current state of knowledge, has a higher bioactivity than falcarindiol (Christensen 2020).

The accumulation of falcarins in external plant tissue layers such as the root periderm is also in accordance with their assumed roles in plant defense, either as protective agents present constitutively in plant tissues or induced in response to

pathogen attack. For instance, in carrots, falcarindiol could inhibit the growth of the fungal leaf blight pathogen *Alternaria dauci* during in vitro tests, and the polyacetylene levels increased in response to *A. dauci* infection (Lecomte et al. 2012). However, compared with the knowledge available for polyacetylene effects on human health, there is still much to be learned about the role of these compounds in plant defense. With regard to putative effects of polyacetylenes on human health, falcarins have demonstrated numerous interesting bioactivities including antimicrobial as well as anti-inflammatory, antiplatelet-aggregatory, neuritogenic, and serotonergic effects. In addition, the cytotoxicity of falcarin-type polyacetylenes on human cancer cells and their proposed anticancer effects indicate that these compounds may contribute to the nutraceutical effects of carrots (Christensen 2011).

Despite their interesting biological functions, the genetic basis of the structural diversity and function of falcarins is widely unknown. A better understanding of the genetics of falcarin production in carrot roots might support breeding of carrot cultivars with tailored polyacetylenes levels for food production or nutraceuticals. The following sections summarize the knowledge on the distribution of falcarins in carrots, their bioactivity, biosynthesis, genetics, and genomics. A perspective is given for future carrot breeding programs aimed at elevating the levels of these specific polyacetylenes in specific carrot cultivars with high human health potential.

4.2 Diversity, Quantification, and Distribution

Among the more than 1400 polyacetylenes known to date in higher plants, a subset of 14 structurally related bisacetylenic oxylipins has been identified in *Daucus carota.* The first polyacetylenes isolated from carrots were falcarinol, falcarindiol, and falcarindiol-3-acetate. Besides these quantitatively predominating polyacetylenes which are typically C_{17} compounds with conjugated triple bonds, nine additional C_{17} falcarins were identified in *D. carota* by Schmiech et al. (2009), and Busta et al. (2018) recently identified two additional carrot polyacetylenes, falcarintriol-8-acetate and falcarintriol-9-acetate. A subset of five falcarin-type polyacetylenes present in carrot in noteworthy concentrations is shown in Fig. 5. A joining molecular characteristic of falcarin structures is their conjugated carbon–carbon triple bond system. Using this feature as a reference point to compare diverse falcarin structures by atom-to-atom correspondence analysis, a falcarin structural similarity network was constructed for 80 representative falcarins from the four families Apiaceae, Asteraceae, Araliaceae, and Solanaceae (Santos et al. 2022). This network suggests that falcarin metabolism may have diverged in these lineages and might support future efforts to elucidate falcarin biosynthesis in specific taxa.

Quantification of falcarinol-type polyacetylenes in tissues of carrots and other plants is generally based on chromatographic methods such as several HPLC and GC-MS methods. For the isolation of falcarins from plant extracts a combination of column chromatography (CC) and preparative and semi-preparative high-performance liquid chromatography (HPLC) have been used for the isolation of relative large amounts of these polyacetylenes, allowing the analysis of their bioactivity, for

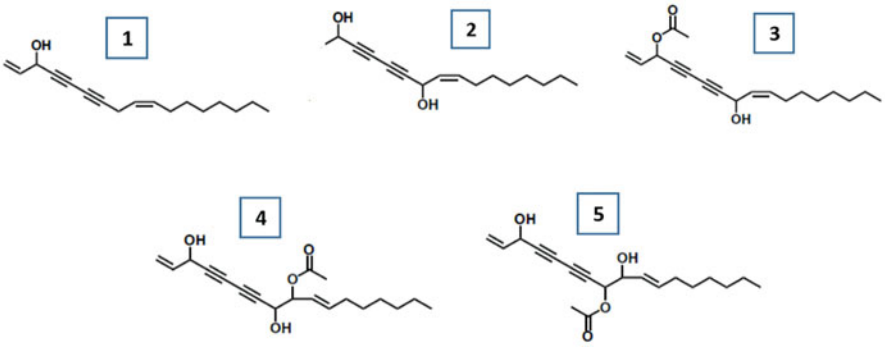

Fig. 5 Chemical structures of falcarin-type polyacetylenes present in carrot roots and leaves: (**1**) falcarinol, (**2**) falcarindiol, (**3**) falcarindiol-3-acetate, (**4**) falcarintriol-9-acetate, and (**5**) falcarintriol-8-acetate (Modified from Santos et al. (2022))

example, in preclinical studies. Modified qualitative and quantitative chromatographic methods have been described for falcarins, including analytical HPLC combined with UV-detection (Zidorn et al. 2005), HPLC with diode array detection (HPLC/DAD) (Christensen and Kreutzmann 2007), and capillary gas chromatographic techniques (GC–FID and/or GC–MS) (Czepa and Hofmann 2004). An alternative method based on plasma samples by liquid chromatography combined with mass spectrometry (LC–MS/MS) was used for the quantification of falcarinol and related polyacetylenes (Christensen and Brandt 2006). The nondestructive FT-Raman spectroscopic approach has been reported to differentiate the main falcarin compounds occurring in different tissues of a single plant (Krähmer et al. 2016).

In many reports, it has been shown that the concentration of falcarin-type polyacetylenes depends on factors such as genotype, developmental stage, cultivation, postharvest storage, and processing (for review, see Dawid et al. 2015). However, considering the numerous factors that influence the falcarin levels and the circumstances under which falcarin concentrations were obtained in the different studies, partly using different analytical methods, the falcarin levels published in different carrot papers are difficult to compare. Moreover, falcarin accumulation patterns in the carrot plant may be influenced by several abiotic and biotic stress factors. For instance, it has been shown that water stress due to drought or waterlogging may influence the major falcarin contents (Lund and White 1990), but previously it was reported that the genotypic effect (i.e., cultivar) appeared to have a stronger impact under these stress conditions (Schmid et al. 2021). The accumulation of falcarins can vary strongly among carrot cultivars, and major differences were found between cultivated orange carrots and differently colored carrots such as white, yellow, and purple cultivars (Czepa and Hofmann 2004; Schulz-Witte 2011). Recently, two main polyacetylenes, falcarinol and falcarindiol, were quantified by HPLC/DAD in different taproot tissues of seven carrot cultivars with purple, yellow, and orange taproot colors. Periderm tissue of the two purple cultivars, 'Deep Purple' and 'Anthonina', accumulated on average 580 or 720μg/g

dry weight (DW) falcarinol, respectively, but in the three orange cultivars significantly lower falcarinol levels ranging from 50 to 240μg/g DW were found. With regard to falcarindiol in root periderm, the purple cultivar 'Deep Purple' showed the highest concentration of 1230μg/g DW, whereas the levels of the orange cultivars were in the range of 450–650μg/g DW (Dunemann and Böttcher 2021).

The falcarin distribution in the carrot plant can vary considerably among the different plant organs and even within the different root segments. The most abundant falcarin in cultivated carrots is falcarindiol, and the highest total falcarin levels are generally found in the root periderm (Czepa and Hofmann 2004). Busta et al. (2018) analyzed tissue-specific accumulation of the five falcarins shown in Fig. 5 in the orange cultivar 'Danvers' and measured the highest total falcarin level in the periderm tissue, with falcarindiol as the dominating compound. In the purple cultivars 'Anthonina' and 'Deep Purple', the levels of falcarinol and falcarindiol were also significantly increased compared with phloem, xylem, and leaf tissue samples (Dunemann and Böttcher 2021). Detailed analysis of the spatial distribution of falcarins from the top to the bottom as well as from the outer phloem to the inner xylem of carrot roots indicate specific accumulation pattern dependent of the falcarin compound (Schmiech 2010). Results from in situ Raman spectroscopy experiments have indicated that polyacetylenes are located in vascular bundles in the young secondary phloem as well as in pericycle oil channels located close to the periderm layer. Moreover, analysis of the falcarin distribution in roots of some carrot wild relatives, for instance, *D. carota* ssp. *commutatus*, showed that the whole phloem tissue was enriched for falcarins with a maximum concentration near the pericyclic parenchyma (Baranska et al. 2005). Two novel falcarins detected previously in carrot cultivar 'Danvers' reached concentrations in the leaf, petiole, and root xylem, which are in the same magnitude as the levels of falcarinol, falcarindiol, and falcarindiol-3-acetate, with the difference that these novel falcarins appear to be accumulated preferably in the aboveground plant parts (Busta et al. 2018).

In the rare studies focused on polyacetylene accumulation in carrot wild relatives, it was shown that *Daucus* species and subspecies can contain often much higher falcarin contents than cultivated carrots (Schulz-Witte 2011). The concentration of falcarinol and falcarindiol in some wild *D. carota* accessions and other wild carrot (sub-) species, such as *D. c. maximus, D. c. maritimus,* or *D. c. halophilus* can be up to 10 or even 20 times higher in comparison to cultivated forms of carrots. Moreover, comparative quantification of falcarinol, falcarindiol, and falcarindiol-3-acetate in more than 100 accessions of wild carrot relatives revealed a large variation for falcarin content, indicating the enormous genotypic variability for this natural substance in the genus *Daucus.*

Falcarins such as falcarinol and falcarindiol can also be produced in vitro in large amounts by carrot hairy root cultures obtained after genetic transformation with the soil bacterium *Rhizobium rhizogenes.* HPLC/DAD quantification of falcarins in freeze-dried hairy root samples derived from different carrot cultivars revealed concentrations of these compounds that are considerably higher than reported to date for carrot root periderm tissue. The average falcarinol contents of the hairy roots varied from 1200 to 3000 μg/g DW, and the concentrations of falcarindiol were in the same magnitude (Dunemann and Böttcher 2021).

4.3 Bioactivity and Relevance for Human Health

Bioactive C_{17}-falcarins were first described for traditional medicinal plants such as ginseng (*Panax ginseng*, Araliaceae), the wild carrot Queen Anne's lace (*Daucus carota* subsp. *carota*, Apiaceae), and the understory native shrub Devil's Club (*Oplopanax horridus*, Araliaceae), all members of the closely related Apiaceae and Araliaceae families. Later it was found that the edible members of the Apiaceae family such as carrot, parsnip, celery, fennel, and parsley also contained falcarin-type polyacetylenes, and it was assumed that the content of these compounds, and falcarinol in particular, might be responsible for the beneficial effects of carrot consumption (Christensen and Brandt 2006). On the other hand, these phytochemicals might have some unwanted toxic side effects in plant foods. Some polyacetylenes, such as falcarinol, are powerful skin sensitizers and known to be neurotoxic in high concentrations, but at nontoxic concentrations, they may function as highly bioactive compounds with potential health-promoting properties. The number of reports about biological and pharmacological activities of polyacetylenes and in particular the contribution to health benefits associated with C_{17}-falcarins is increasing. In a recent review article, the cytotoxic, anti-inflammatory, and anticancer effects of C_{17}-falcarins and other acetylenic oxylipins from terrestrial plants including Apiaceae species are comprehensively described, and their possible mechanisms of action and structural requirements for optimal cytotoxicity are presented in detail (Christensen 2020).

With regard to anticancer actions of polyacetylenes in in vitro studies, both falcarinol and falcarindiol have been shown to have toxicity against a large variety of cancer cells including gastric, skin, intestine, colorectal, lymphoma, leukemia, breast, and lung, but their cytotoxic potential depends on the cell lines (Christensen 2020). Overall, from several in vitro studies it has been concluded that falcarinol is generally more cytotoxic than falcarindiol in many different cell types (Warner 2019). Furthermore, falcarinol and falcarindiol may have a synergistic inhibitory effect on cell proliferation. In the study of Purup et al. (2009), it was demonstrated that the cytotoxicity of lipophilic extracts from different carrot cultivars depended on the amounts of falcarinol, falcarindiol, and falcarindiol-3-acetate in the extracts. It was shown that falcarinol can reduce cell proliferation of Caco-2 cells at 2.5 μg/mL but maintains healthy cells at the same concentration. This was the case up to 10μg/mL at which concentration it significantly reduced proliferation of both cell types. Moreover, it was shown that the cytotoxic effect of falcarinol on Caco-2 cells was enhanced synergistically when combined with falcarindiol in different ratios. Falcarindiol was less potent in this experiment but reduced Caco-2 proliferation up to 20 μg/mL with no effect on healthy cells (Purup et al. 2009). Falcarinol was reported to have high cytotoxic activity to leukemia (L-1210), mouse fibroblast-derived tumor cells (L-929), mouse melanoma (B-16), and human gastric adenocarcinoma (MK-1) cells, showing the lowest ED_{50} values in the MK-1 cancer cells (Christensen 2011). Falcarindiol and its derivative falcarindiol-3-acetate isolated from carrots were able to induce apoptosis in different leukemia cell lines (CCRF-CEM, Jurkat, and MOLT-3). Falcarinol only caused induction of apoptosis

in CCRF-CEM cell lines but was the most cytotoxic substance on leukemia cells (Zaini et al. 2012). Falcarin-type polyacetylenes have also been shown to bind covalently to cysteine in enzymes such as mitochondrial aldehyde dehydrogenases (ALDHs) in cancer cells leading to a reduction of activity (Heydenreuter et al. 2015). Reduction of the activity of ALDHs may lead to oxidative stress and endoplasmic reticulum (ER) stress causing cell injuries, cell cycle arrest, and apoptosis, and thus could be one of the mechanisms of action that could explain the cytotoxicity of falcarins (Christensen 2020). Falcarins may also play a role in cancer chemotherapy. For instance, it has been demonstrated that falcarins function as inhibitors of the breast cancer resistance protein BCRP/ABCG2, which is an efflux transporter involved in breast cancer chemotherapy resistance (Tan et al. 2014). Bioactive C_{17}-polyacetylenes may also inhibit the formation of pro-inflammatory cytokines and inflammatory enzymes such as COXs and LOXs indicating that inhibition of these inflammatory-promoting substances might be an important mechanism of cancer prevention (Christensen 2020).

While there is strong evidence that polyacetylenes may have anticancer effects in vitro, much less information is available about the mechanisms and effects in vivo. A small number of investigations with rodents have been conducted with the aim to study both the effect of carrots and isolated falcarins as dietary supplements in feeding studies. However, little is known about their effects in vivo in humans. Rat feeding experiments with purified falcarinol and falcarindiol suggest preventing effects of these polyacetylenes on the development of colorectal cancer (CRC). Both falcarins can have an inhibitory effect on certain inflammatory markers in neoplastic lesions, and it has been proposed that falcarins may act as selective COX-2 inhibitors in relation to CRC prophylactics (Kobaek-Larsen et al. 2019). A large prospective cohort study in a Danish population of 57,053 individuals examining the risk of being diagnosed with CRC indicated a CRC-preventive effect of carrot intake. Self-reported intake of 2–4 raw carrots per week (>32 g/day) was associated with a 17% decrease in risk of CRC (Deding et al. 2020). These results and the results from the rat feeding experiments suggest a CRC-preventive effect of carrot falcarins.

Epidemiological studies have also shown that carrot intake is inversely associated with cardiovascular heart disease (CHD). In a prospective study, a 25 g/day increase in the intake of carrots was associated with a 32% lower risk of 10-year incidence of CHD (Oude Griep et al. 2011). One way the polyacetylenes could be affecting CHD risk is through modulation of platelet activity in the blood. Antiplatelet aggregatory abilities of polyacetylenes are most likely due to their anti-inflammatory activity in relation to COXs, LOXs, and other enzymes (Warner 2019). Furthermore, falcarins may also have impact on type 2 diabetes. Falcarinol and falcarindiol from carrots may function as ligands for nuclear receptors such as peroxisome-proliferator-activated receptors (PPARs), suggesting their usage as partial PPAR agonists with possible antidiabetic properties (El-Houri et al. 2015). Falcarinol was also identified as an inverse agonist of the cannabinoid receptor *CB1*. Acting by selectively alkylating the anandamide binding sites, falcarinol can increase the expression of chemokines in the skin involved in the induction of allergic reactions (Leonti et al. 2010). In addition, GABA receptors are exquisitely sensitive to polyacetylenic

oxylipins. In comparison to the activity of falcarindiol, falcarinol has a higher affinity for GABA receptors and a substantially different profile of pharmacological actions. Taken together, falcarin-type polyacetylenes are highly bioactive natural products that may be used in the prevention and treatment of cancers but likely possess additional positive properties with regard to human health and well-being. The health-promoting effects of carrot falcarins should be evaluated and confirmed in further preclinical and clinical studies in future.

4.4 Biosynthesis, Genetics, and Genomics

Compared with the extensive research concerning the analytical and biochemical identification and characterization of plant falcarin-type polyacetylenes, and the relatively large number of studies about their bioactivity, by far less is known about the biosynthesis, genetics, and genomics of falcarins. Major advances have only recently been made toward understanding their biosynthesis (reviewed by Santos et al. 2022), and carrots are among the species, where most knowledge exists. In carrots and other plants, falcarin biosynthesis starts from unsaturated fatty acids such as oleic acid and linoleic acid. Results of several metabolic studies have pointed out that a diverse pathway from linolenic acid to "unusual" fatty acids, such as crepenynic and dehydrocrepenynic acid, is the major route for the biosynthesis of falcarins (Minto and Blacklock 2008). A proposed model for falcarin biosynthesis is shown in Fig. 6.

The enzyme primarily responsible for the synthesis of linoleic acid from oleic acid is a Δ12-fatty acid desaturase. Numerous divergent forms of FATTY ACID DESATURASE 2 (FAD2) enzymes with diversified functionalities in fatty acid modification are also known to have diversified functionalities in fatty acid modification, such as hydroxylation, epoxidation, and the formation of acetylenic bonds and conjugated double bonds (Minto and Blacklock 2008). Some functionally divergent FAD2 enzymes are multifunctional, such as the bifunctional hydroxylase/desaturase from *Lesquerella fendleri.* FAD2 enzymes that introduce a triple bond within a fatty acid are designated as acetylenases. The first FAD2 acetylenase gene cloned was termed *Crep1* and derived from *Crepis alpina,* a herbaceous species from the Compositae family. *Crep1* encodes a functional acetylenase and its activity leads to the accumulation of the acetylenic fatty acid crepenynic acid in *C. alpina* seeds (Minto and Blacklock 2008). The genomes of other plant families like Apiaceae, Araliaceae, and Asteraceae also harbor FAD2 acetylenase genes, although only a few members of these families accumulate acetylenic fatty acids in their seeds, a fact that raises questions about the role of these divergent FAD2s in the plant.

The FAD2 gene family has been extensively studied in plants at the molecular and biochemical levels. Since cloning of the first plant FAD2 gene in *Arabidopsis thaliana* (Okuley et al. 1994), additional FAD2 genes from other species have been described and functionally characterized, including members with acetylenase activity. Although only a single FAD2 gene was found in Arabidopsis, in most other

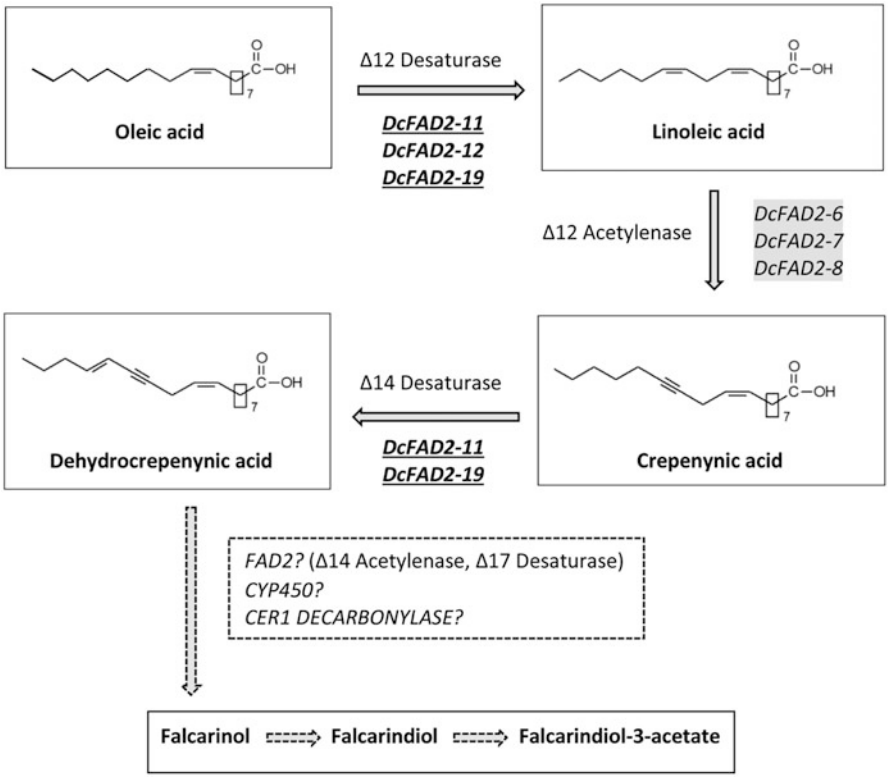

Fig. 6 Proposed biosynthetic steps of production of falcarin-type polyacetylenes in carrots. Carrot FAD2 genes functionally characterized by Busta et al. (2018) are shown at their presumed positions. FAD2 desaturase genes are in bold letters, and FAD2 acetylenase genes are shaded in gray. Bifunctional FAD2 desaturase genes are underlined. FAD2 gene designation was according to Table 4 (Adapted from Cavagnaro (2019) and Santos et al. (2022))

plant species, multiple FAD2 homologues have been reported. For example, seven FAD2 gene family members were identified in soybean, and nine each in cotton and tomato (Lee et al. 2020). Species with the largest known number of FAD2s are all family members of the Asteraceae, Apiaceae, and Araliaceae. The carrot genome contains at least 30 FAD2 genes (Dunemann et al. 2022). In sunflower (*Helianthus annuus*, Asteraceae), about the same number of FAD2 genes is present, and for ginseng (*Panax ginseng*, Araliaceae), over 50 FAD2 gene copies have been reported recently (Santos et al. 2022). A major contribution for the inventory and putative function of carrot FAD2 genes was made by the work of Busta et al. (2018), which identified 24 carrot FAD2s. To identify which of these genes participate in falcarin biosynthesis, six FAD2 genes were selected for functional analysis by screening of published, tissue-specific carrot transcriptomic data sets for co-expression of genes that are highly expressed in root periderm. These candidate genes were heterologously expressed, individually and in combination, in yeast and *A. thaliana*,

resulting in the identification of one canonical FAD2 that converts oleic to linoleic acid and three divergent FAD2-like acetylenases that convert linoleic into crepenynic acid (Busta et al. 2018). In addition, two bifunctional FAD2s with Δ12 and Δ14 desaturase activity were found (DCAR_013547, DCAR_019786) that are involved in two biosynthetic steps, the conversion of oleic acid into linoleic acid and the conversion of crepenynic into dehydrocrepenynic acid. Three of the characterized FAD2s are located in a tandem array of six FAD2genes, two of which encode FAD2 acetylenases and one encoding a bifunctional Δ12/Δ14 desaturase, in a small region (29.30–29.35 Mbp) of carrot chromosome 4 (Busta et al. 2018). Tandemly arrayed FAD2 genes, which might represent biosynthetic gene clusters, were previously described also in tomato, lettuce, and sunflower and might have been originated from local tandem duplications, as suggested from phylogenomic and microsyntenic analyses (Busta et al. 2018). The largest carrot FAD2 cluster in the carrot genome, consisting of nine FAD2s, is located on chromosome 8, spanning the genomic region 20.87–21.54 Mbp (Dunemann et al. 2022). This gene cluster also contains the newly discovered FAD2 genes *DcFAD2-25* to *DcFAD2-28*. The seven new carrot FAD2 genes identified recently after a reannotation of the whole carrot genome sequence extend the total number of *Daucus* FAD2s to 31. The total list of known carrot FAD2s and a proposed renaming are shown in Table 3. The newly predicted FAD2 genes *DcFAD2-29*, *DcFAD2-30*, and *DcFAD2-31* are located as unclustered genes on chromosomes 1, 3, and 4. A phylogenetic analysis of the carrot FAD2s (Fig. 7) showed that *DcFAD2-25*, *DcFAD2-26*, *DcFAD2-27*, and *DcFAD2-28* are located in a common clade containing ten known *Daucus* FAD2s which have been classified as divergent FAD2s. This clade contains also the genes *DcFAD2-6* (DCAR_017011), *DcFAD2-7* (DCAR_013552), and *DcFAD2-8* (DCAR_013548) which were functionally characterized by Busta et al. (2018) as Δ12-acetylenases. These three genes are also highly similar (amino acid identity >95%) to the parsley gene *PcELI12,* which was identified as a pathogen-inducible FAD2 acetylenase gene (Cahoon et al. 2003).

Table 3 List of 31 *Daucus carota* FAD2 gene models sorted by their physical position on the assembled 9 carrot chromosomes according to the whole-genome sequence (Iorizzo et al. 2016) and the carrot FAD2 inventory published by Busta et al. (2018) and Dunemann et al. (2022)

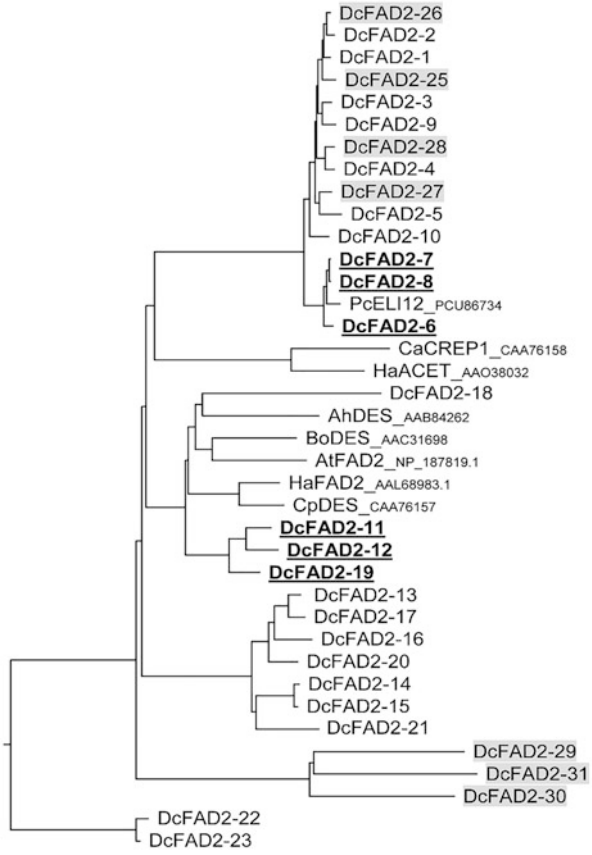

Fig. 7 Similarity of *Daucus* FAD2s shown by a phylogenetic tree (ClustalW) of deduced FAD2 protein sequences from *D. carota* (Busta et al. 2018, Dunemann et al. 2022) and some other putative FAD2 acetylenases and desaturases (Pc *Petroselinum crispum*; Ca *Crepis alpina*; Ha *Helianthus annuus;* At *Arabidopsis thaliana*; Bo *Borago officinalis*; Cp *Crepis palaestina*; Ah *Arachis hypogaea*). Carrot FAD2s newly identified by Dunemann et al. (2022) are shaded in gray. Carrot FAD2 genes with known function are indicated in bold/underlined (Busta et al. 2018)

The biochemical formation of falcarindiol from its presumed precursor falcarinol in later steps of the falcarin pathway was largely unknown until now. It is hypothesized that plants having the enzymatic machinery necessary for cuticular waxes should also be able to perform decarbonylation and in-chain hydroxylation of fatty acids required for falcarin biosynthesis (Santos et al. 2022). However, the substrates and mechanisms for these processes are unclear. Recently a pathogen-induced biosynthetic gene cluster was discovered in tomato and shown to be putatively involved in falcarindiol production (Jeon et al. 2020). The four genes of this cluster were consistently and strongly co-expressed, three of which were FAD2 acetylenases or desaturases, with the remaining one being a CER1 decarbonylase homologue. In *Arabidopsis thaliana*, CER1 (ECERIFERUM1) and CER3 (ECERIFERUM3) gene products catalyze fatty acid decarboxylation in the alkane biosynthetic pathway and play a major role in wax production (Aarts et al. 1995). Although the study of Jeon et al. (2020) implicates a possible role for CER1 in falcarindiol production, a functional proof for a possible involvement of CER1 in the decarbonylation of falcarin precursors has, to date, not been described.

Compared with the outcome from research on identification and functional characterization of genes putatively involved in biosynthesis of falcarin-type polyacetylenes, relatively less is known about the genetic control of falcarin contents in carrots. However, in carrot breeding programs aiming at reducing bitter taste (e.g., for baby food or juice and puree production), or – conversely – increasing pathogen resistance and/or enhanced health benefits, more information about the inheritance of falcarin accumulation is needed. Especially the availability of molecular markers linked to QTLs, or usage of functional markers developed directly from candidate TPS genes, would strongly support such breeding strategies. First QTLs for carrot falcarins were identified by using a segregating F_2 family and indicated that levels of falcarin compounds are heritable traits (Le Clerc et al. 2019). In the carrot population used in this study over a 2-years period for QTL identification of three major falcarins, a relatively low environmental influence on the falcarin contents was found, and broad-sense heritability, for example, falcarindiol, was estimated to be 0.88. A transgressive segregation pattern was also observed in this study. Several QTLs could be mapped for falcarindiol and falcarindiol-3-acetate in carrot roots, and some of these QTLs were also associated with QTLs for bitterness and resistance to the fungal leaf blight pathogen *Alternaria dauci* (Le Clerc et al. 2019). In another biparental carrot F_2 progeny derived from a cross of a cultivated breeding line and the wild relative *D. carota* subsp. *commutatus*, large phenotypic variability was obvious for the contents of falcarinol and falcarindiol (Dunemann et al. 2022). The observed frequency distributions in this F_2 family indicated a polygenic inheritance, which is expected considering the assumed complex biosynthetic pathway of falcarin production. Nevertheless, the large phenotypic variation, ranging from individuals with no measurable falcarins to plants with very high contents of 1000 μg/g DW (dry weight) falcarinol or even 3000 μg/g DW falcarindiol, suggests the action of major regulatory or structural genes. However, significant falcarin QTLs were identified on six of the nine carrot chromosomes, which is a sign for the complexity of the genetic control of falcarin production in carrot roots. Common QTLs with high LOD scores were identified for both falcarinol and falcarindiol on carrot chromosomes 4 and 9, indicating a major involvement of these two genomic regions in polyacetylene biosynthesis (Dunemann et al. 2022).

The six-gene FAD2 cluster associated with QTLs on chromosome 4 contains the two genes, *DcFAD2-7* and *DcFAD2-8*, which have been functionally characterized as Δ12-fatty acid acetylenases, and *DcFAD2-19*, described as a bifunctional desaturase (Busta et al. 2018). The genetic association of three CER1 candidate genes with the strongest QTLs on chromosome 9 might be a further indication that these genes might also play a role in falcarin production. However, a functional proof that CER1 genes contribute to the production of falcarin-type polyacetylenes is still missing and remains to be biochemically established.

4.5 Implications for Breeding

Falcarin-type polyacetylenes are among the phytochemicals that may contribute to bitter taste of fresh carrots or carrot products, being an undesirable trait that can

cause consumer rejection. Therefore, carrot breeding generally aims at low bitterness. Bitterness is a very complex trait, because not only polyacetylenes but also a variety of other chemically different potential bitter compounds, such as volatile mono- and sesquiterpenes, phenylpropanoids, and isocoumarins, may be involved in this quality trait. Recently, Schmid et al. (2021) analyzed and listed more than ten known bitter off-taste compounds present in carrot roots including the major falcarins, falcarinol and falcarindiol. Nevertheless, the falcarins appear to be a lead substance for bitter taste. In the study of Le Clerc et al. (2019), total falcarin content was closely related to bitterness, and the highest quantities of this compound accumulated in the most bitter genotypes, whereas the lowest amounts were measured in the least bitter genotypes. It is likely that lowering falcarin levels in carrots occurred in the past during the domestication process and breeding of cultivated orange carrot forms with the desired low bitterness. However, carrot cultivars with relatively high falcarin contents, such as the purple-rooted cultivar 'Anthonina' are still available in the seed market. This dark-purple cultivar also contained the highest contents of other putative health-relevant phytochemicals such as special phenylpropanoids and flavonols, when compared with white, yellow, orange, and red cultivars (Leja et al. 2013). As shown in a carrot biodiversity study, 'Anthonina' is closely related to carrot landraces originating from continental Asia (Baranski et al. 2012). Therefore, this cultivar is a good example that early domesticated purple carrots might be used directly as nutraceuticals or, alternatively, for the large-scale production of pharmaceutically relevant falcarins to be used, for instance, as food supplements. On the other hand, some modern purple F_1 hybrid cultivars, such as 'Deep Purple', might also be suited. Considering the proposed health-promoting effects of falcarins, specific carrot chemotypes with high but acceptable amounts of bioactive falcarins may be developed in future by molecular breeding using gene-specific functional markers or, to reach the goal faster, by application of genome editing techniques such as CRISPR/Cas. For both approaches, it will be necessary to first reveal the most important genes that control the decisive steps in the biosynthesis of falcarins.

5 Terpenes

5.1 Introduction

Terpenes are the largest and most structurally diverse class of plant natural products, comprising tens of thousands different substances. They can be classified into the subclasses monoterpenes (C_{10}), sesquiterpenes (C_{15}), diterpenes (C_{20}), and triterpenes (C_{30}), according to the number of isoprenoid structures. In plants, low-molecular-weight terpenes produced by terpene synthases (TPS) contribute to multiple ecologically and economically important traits. Low-molecular-weight terpenes are involved in plant-to-plant communication and plant protection against abiotic and biotic stresses. They play an important role in plant defense against insect, fungal, and bacterial pathogens, which has been demonstrated in numerous studies

(Yoshitomi et al. 2016; Chen et al. 2018; Shaltiel-Harpaz et al. 2021). A typical characteristic of mono- and sesquiterpenes is their volatility, and therefore they contribute to the typical flavor and aroma of many plant species including carrot. The typical flavor of carrots is determined by a complex blend of mono- and sesquiterpenes, representing up to more than 90% of the total volatile compounds. In a few studies, the correlation between volatile terpenes and carrot sensory attributes has been investigated (Alasalvar et al. 2001; Fukuda et al. 2013). Because carrots contain a huge amount of different terpene compounds, it is difficult to relate single terpene compounds to specific aroma notes and positive or negative sensory perception by humans. Using a GC olfactometry (GC-O) approach, an association between the carrot aroma and flavor and several isolated terpenes could be established (Kjeldsen et al. 2003). On the other side, terpenes are often involved in harsh or bitter flavor notes, and these off-flavor characteristics were shown to increase with terpene contents in different carrot genotypes. The combination of chemical analyses with sensorial approaches has predicted the monoterpenes sabinene, α-terpinolene, and β-pinene as candidates for bitterness in carrots (Le Clerc et al. 2019). Terpenes are present abundantly in essential plant oils of many plants, and they are also important components of resins and floral scents. Although there is general acceptance that volatile terpenes play a role as bioactive substances which might have an impact on human physiology and health, the current knowledge about putative health effects of terpenes present in carrots is restricted. Furthermore, the existing knowledge is rarely based on studies with terpenes isolated directly from *D. carota* but is generally founded on terpenoid compounds present in considerable quantities in other plant species such as, for instance, *Cannabis sativa* or the tea tree *Melaleuca alternifolia.*

A better understanding of the genetic and molecular bases of the TPS enzymes involved in terpene biosynthesis will be needed for future breeding strategies aimed at the improvement of quality traits, such as aroma and taste, but might be also relevant for phytopathological aspects, for example, resistance against fungi or insects. In addition, the development of specific carrot chemotypes to be used for pharmaceutical applications might be feasible. In the following sections, we briefly describe the analysis, the spectrum of volatile terpenes in carrot roots and seeds, and their putative bioactivity with regard to human health. We further review the current knowledge about TPS enzymes and genes involved in terpene biosynthesis in carrot.

5.2 Diversity, Quantification, and Distribution

The most common analytical method for determining volatile terpenes is headspace solid-phase microextraction gas chromatography (HS-SPME-GC). This method was used in several investigations on carrot roots, leaves, and seeds, either coupled with flame-ionization-detection (FID) or with mass-spectrometry (MS). As a sensitive sampling method, headspace (HS) sampling of terpenes emitted by carrot tissues has been proved successful to achieve a complete qualitative and quantitative volatile organic compound (VOC) analysis. Particularly, solid-phase micro-extraction

(SPME), which is a popular and simple HS sampling technique requiring no or little preparation of the samples, was mostly used in the past for the analysis of carrot VOCs, including terpenes. For example, using HS-SPME-GC-FID and MS, Ulrich et al. (2015) analyzed the diversity of terpene volatile patterns of carrot roots and leaves, and the same method was used to examine the terpene profiles in a large collection of carrot cultivars (Keilwagen et al. 2017). Since a full multi-compound quantitation using the SPME technique is impossible in complex organic matrices like homogenates of carrot leaves and roots, semiquantitative data are usually reported, for instance, as relative concentrations. Auto-HS-SPME-GC-MS was used for terpene analysis of differently colored carrot roots and carrot seed oil (Yahyaa et al. 2015, 2016). Headspace sorptive extraction (HSSE), a technique similar to SPME, was applied in carrots to link special volatile terpene profiles with sensory attributes (Fukuda et al. 2013). This technique uses a twister stir bar coated with polydimethylsiloxane (PDMS) to adsorb VOCs in the headspace of diced carrot tissue prior to thermal desorption and GC-MS analysis (Ibdah et al. 2019). For determination of absolute amounts of terpenes by the headspace sampling method, a precise calibration using authentic standards is required. An alternative is to use ground plant tissue for extraction with an organic solvent such as hexane and to use the extracts for GC-FID or GC-MS with the appropriate internal standards (Ibdah et al. 2019).

Detailed chemical analysis of the volatile terpene pattern in carrot leaves and roots revealed differences in total amounts and proportions of individual compounds, suggesting large tissue-dependent differences in terpene biosynthesis (Habegger and Schnitzler 2000). In contrast to carrot roots, the terpene profiles of leaves have rarely been studied. Conversely to results of Hampel et al. (2005), reporting no correlation between leaf and root terpenes, Ulrich et al. (2015) showed strong correlations for some compounds present in leaves and roots. Another investigation based on different carrot root tissues revealed that the biosynthesis of terpenes is mainly localized in the phloem (Hampel et al. 2005). Higher concentration of terpenoids in the root phloem than in the xylem has been explained by the observation that oil ducts, a possible site of volatile terpenoid biosynthesis, are found only in the phloem. Nevertheless, in the root xylem, biosynthesis of terpenes was also detectable, even in the absence of oil ducts in this tissue (Hampel et al. 2005).

The existing knowledge about volatile terpene patterns in carrot roots is mainly based on research aimed at the identification of compounds involved in flavor, aroma, and taste. The majority of the terpenes identified from roots are mono- and sesquiterpenes (Fig. 8). Although a comparatively large number of publications is available for VOCs in carrots, no accordance exists about typical carrot volatile profiles. The lack of agreement in finding typical patterns of major terpenes related to flavor and taste was documented by Ulrich et al. (2015), who examined about ten publications dealing with carrot terpenes. Out of the more than 120 compounds described in the literature, about 80 VOCs are single entries and were identified only in a single study. In 11 studies, the following 5 terpenes were identified: sabinene, limonene, terpinolene, β-caryophyllene, and α-humulene. In addition, other frequently mentioned volatiles were α-pinene, β-pinene, γ-terpinene, and p-cymene

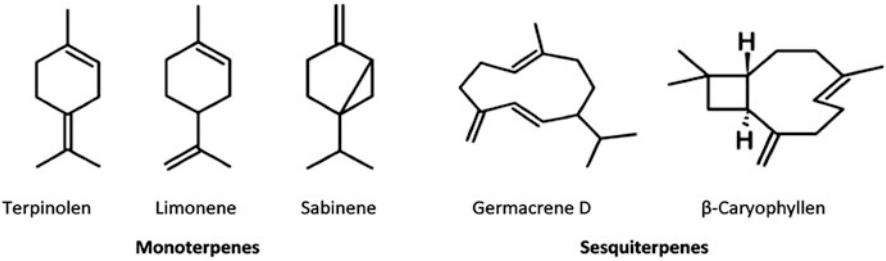

Fig. 8 Chemical structures of typical mono- and sesquiterpenes present in carrot roots, leaves, and seeds

(Ulrich et al. 2015). The monoterpenes α-terpinolene and α-pinene were found as the main terpenes in extracts from 11 differently colored carrot cultivars, and among the totally identified 16 monoterpenes, the monoterpenes α-pinene, β-pinene, β-myrcene, d-limonene, γ-terpinene, α-terpinolene, and p-cymene constituted more than 60% of total VOCs identified (Güler et al. 2015). A compilation of predominant mono- and sesquiterpenes identified by different researchers in fresh roots of differently colored carrots was shown by Ibdah et al. (2019). In the study of Keilwagen et al. (2017), 85 *D. carota* accessions representing the worldwide gene pool of cultivated carrots were analyzed for the qualitative and semiquantitative composition of VOCs in both roots and leaves. Totally, 31 VOCs, mostly monoterpenes and sesquiterpenes, were identified in roots or leaves, and some of them were present in both organs. In leaves, the most abundant compounds were β-myrcene, β-caryophyllene, and limonene, whereas terpinolene, β-caryophyllene, and bornyl acetate dominated the VOC patterns of roots. The majority of the root VOCs were monoterpenes, whereas only four sesquiterpenoids were present in the roots, namely β-caryophyllene, β-farnesene, β-bisabolene, and caryophyllene oxide. Five of the compounds (sabinene, β-caryophyllene, ocimene, α-pinene, and terpinen-4-ol) showed correlations between leaves and roots, which was in accordance with earlier results for sabinene and β-caryophyllene (Ulrich et al. 2015; Keilwagen et al. 2017). Twenty-three of these substances were also present in a biparental carrot F_2 mapping population consisting of 320 individuals (Dunemann et al. 2019). In the work of Koutouan et al. (2018), targeted analyses of terpene volatiles in carrot leaves identified compounds potentially linked to resistance to the leaf fungus *Alternaria dauci.* In total, 30 terpenes, 15 monoterpenes, and 15 sesquiterpenes were quantified over several environments and years. In all genotypes, the main monoterpenes were β-myrcene, sabinene, α-pinene, and limonene, and the main sesquiterpenes were caryophyllene and germacrene. Seven terpenes differentiated resistant genotypes from the susceptible H1 genotype. Compared with carrot cultivars, very little information is available about terpene distribution and their amounts in wild *Daucus* relatives. A rare example is the study of Reduron et al. (2019), in which seedling root extracts of wild populations of *D. carota* from Corsica (France) were chemically analyzed and separated by their individual VOC profiles. For instance, the *D. c.* ssp. *commutatus* population 786, adapted to stony soils and a dry and hot habitat, showed

very high contents of limonene and sabinene in roots, and γ-himalachene in leaves, indicating an eco-subspeciation process and adaptation to specific environmental conditions (Reduron et al. 2019).

The cultivated carrot is mainly used as a root vegetable, while its seed oil is sometimes employed as a flavoring agent in food products, in the cosmetics industry, and aroma therapy. Therefore, a number of investigations have focused on the identification and quantification of VOCs from essential oils of carrot seeds. Since wild carrots have been used as a medicinal plant since ancient times, the majority of analyses was performed in carrot wild relatives and local natural carrot populations. Aćimović et al. (2016) analyzed the essential oil from seeds of wild (*D. carota* ssp. *carota*) and cultivated carrots (*D. carota* ssp. *sativus*) collected in northern Serbia and reported that the oil derived from wild-grown carrots contained mainly sabinene and *α*-pinene, followed by β-bisabolene, β-pinene, and *trans*-caryophyllene as further dominant compounds. The major constituents of essential oil from seeds of the cultivated carrots were carotol, sabinene, and *α*-pinene. Sabinene and *α*-pinene, together with myrcene, p-cymene, and limonene, were also the major compounds among 70 terpenoid VOCs identified in nine carrot cultivars (Flamini et al. 2014). In another study based on seeds of wild growing *D. carota* ssp. *carota in* Lithuania, the oils from all samples were of the sabinene chemotype. The other major constituents were α-pinene, terpinen-4-ol, γ-terpinene, and limonene (Mockute and Nivinskiene 2004). In the work of Sieniawska et al. (2016), the chemical composition of commercially available (Moroccan and French) and hydrodistilled (Polish) wild carrot seed essential oils from *D. carota* ssp. *carota* was analyzed, and the sesquiterpene alcohol carotol was found to be the main constituent in three seed oils. Pinene, sabinene, myrcene, limonene, geranyl acetate, bisabolene, caryophyllene oxide, and daucol were identified as other main compounds. Profiling the terpene metabolome in carrot seeds of wild carrot accessions from Israel revealed significant differences in volatile composition among the accessions. In most, but not all the accessions, the monoterpene α-pinene was the most abundant volatile, followed by limonene (Yahyaa et al. 2016). As discussed by these authors, there are many factors, such as genotypic differences, stage of development, environment, and geographical origin that can considerably influence the volatile composition pattern of *D. carota* seed oil. It is therefore not surprising that values obtained in the different studies are inconsistent to some extent.

5.3 Bioactivity and Relevance for Human Health

Despite the large diversity of terpenoid volatiles in carrot roots and their high relevance for flavor and taste, their biological effects have been particularly associated with the essential oils of the carrot seed and their compounds, which seem to be primarily terpenes. Essential oil of *D. carota* ssp. *carota* from Portugal, enriched for geranyl acetate, α-pinene, and other terpenes showed antibacterial and antifungal activity against several Gram-positive and Gram-negative bacteria, yeasts, dermatophytes, and *Aspergillus* strains. In addition, this seed oil was also able to inhibit germ

tube formation and preformed biofilms of *Candida albicans* (Alves-Silva et al. 2016). Essential oil derived from *D. carota* ssp. *halophilus* has displayed antifungal properties against several human pathogenic fungi (Tavares et al. 2008), while the oil from *D. carota* ssp. *maritimus* has been shown to have potential antibacterial effects (Jabrane et al. 2009). Antimicrobial and antioxidant activities of carrot seed oil were also reported by Jasicka-Misiak et al. (2014). Vasudevan et al. (2006) described antinociceptive and anti-inflammatory properties of wild carrot seed extracts, and Shebaby et al. (2013) demonstrated antioxidant and anticancer effects. Hydrodistilled yellow and red carrot oils derived from seeds of *D. carota* ssp. *sativus* (yellow carrot) and D. c. *ssp. boissieri* (red carrot) were able to suppress 5-LOX and prostaglandin E2 production indicating excellent anti-inflammatory activities (Khalil et al. 2015). The cytotoxicity of both essential oils was evaluated on two human cancer cell lines, namely HepG-2 (liver hepatocellular carcinoma cells) and MCF-7 (breast adenocarcinoma cells), after 72 h incubation. The highest cytotoxic activity was observed against HepG-2 cells with IC_{50} values in the range of 163–172 μg/ml for both oils (Khalil et al. 2015). The observed cytotoxic activity of the two oils may be caused by carotol, which is the major component in both yellow and red carrot oils. Carotol was also among the main compounds in three carrot seed oils of different origin, amounting 19–33% of the sum of compounds (Sieniawska et al. 2016). Cytotoxicity tests based on green monkey kidney (VERO) and human pharynx squamous cell carcinoma (FaDu) cell lines treated with isolated carotol indicated nonselective moderate cytotoxicity on both cell lines, but apparently this substance was not solely responsible for the cytotoxic effects of the seed oils (Sieniawska et al. 2016). In another study, carotol was reported to inhibit the growth of myeloid leukemia cancer cell lines (Radoslaw 2012). The bioactivity of essential oil from wild carrot seeds is also probably due to its high contents of the monoterpenes sabinene and α-pinene. For instance, both terpenes are major components of pharmaceuticals which are used to treat the protozoan *Trypanosoma brucei* causing the African sleeping sickness disease.

Other reports about the wide spectrum of bioactive effects of carrot terpenes are available from studies with other plant species containing the same terpene compounds. For example, the monoterpene limonene, comprising up to >90% of orange peel oil, and other monoterpenes have shown chemopreventive activity against rat mammary, lung and forestomach cancers (Crowell 1999). The sesqiterpene β-caryophyllene (BCP) was shown to increase the cytotoxic activity of paclitaxel in various cancer cell lines (Legault and Pichette 2007), with the largest observed effect on DLD-1 cells treated with paclitaxel plus 10 μg/mL BCP. Application of geraniol has been shown to sensitize cancer cells to the conventional chemotherapeutic agent 5-fluorouracil (5-FU), and it supported an increased uptake of the drug (Carnesecchi et al. 2004). The monoterpene terpinen-4-ol is known as the main component of the oil of tea tree (*Melaleuca alternifolia*), which has pharmaceutical importance due to its known antibacterial and anticancer effects (Lee et al. 2020). The sesquiterpene BCP is not only one of the major terpenoids in carrots but also known as a major plant volatile present in large amounts in the essential oils of many different spice and food plants. BCP is a major component (up to 35%) in the

essential oil of *Cannabis sativa* and has been identified as a functional non-psychoactive *CB2* receptor ligand in foodstuff and as a macrocyclic anti-inflammatory cannabinoid (Gertsch et al. 2008). BCP selectively binds to the cannabinoid receptor *CB2* and functions as a *CB2* agonist. Among numerous cannabinoids, BCP has received attention in the past few years due to its therapeutic potential by mediating anti-inflammatory and immunomodulatory properties. The various pharmacological properties and the therapeutic potential of BCP are comprehensively summarized by Jha et al. (2021). Only recently, it has been hypothesized that BCP could be a promising therapeutic agent to target the triad of infection, immunity, and inflammation in COVID-19 (Jha et al. 2021). Evidence from a preclinical study also suggests that a BCP-*CB2* interaction might be involved in anxiety and depression disorders of mice, and that *CB2* receptors may provide alternative therapeutic targets for the treatment of anxiety and depression (Bahi et al. 2014). The monoterpenes β-pinene and linalool can directly hit the central nervous system and have an enhanced activity after inhaling (Guzmán-Gutiérrez et al. 2014). Another interesting finding is that β-pinene can interact with dopaminergic D1 receptors, which is a mechanism used by many antidepressant drugs (Cox-Georgian et al. 2019).

5.4 Biosynthesis, Genetics, and Genomics

Terpenoids represent the largest class of natural substances produced by land plants. Many of these secondary metabolites are highly specialized and often involved in interactions with the environment. Thus, continued innovation of terpenoid biosynthesis has played an important role in the adaptation of land plants during evolution and diversification. The large diversity of terpenes is formed by members of terpene synthase (TPS) family from few substrates by similar carbocation-based reaction mechanisms (Tholl 2006). Terpenoids derive from the isomeric 5-carbon building blocks isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP). Two independent pathways in plants, the methylerythritol phosphate (MEP) pathway operating in plastids and the mevalonate (MVA) pathway operating in the cytosol/peroxisomes, lead to the synthesis of both IPP and DMAPP. Geranyl pyrophosphate (GPP) or geranylgeranyl pyrophosphate (GGPP) formed in the MEP pathway, and farnesyl pyrophosphate (FPP) formed in the MVA pathway are the substrates for terpene synthases, which catalyze the production of mono- or diterpenes from GPP or GGPP, respectively, or sesquiterpenes from FPP. Many volatile terpenes are formed directly by TPS enzymes, and various other enzyme classes are involved in modification of the primary terpene skeletons. These other enzymes belonging for a major part to the classes of dehydrogenases, methyl- and glycosyltransferases, and cytochrome P450 hydroxylases, can increase the volatility of terpenes and modify their olfactory features (Pateraki et al. 2015).

In plants, the classification of the TPS gene family comprises eight subfamilies, known as TPS-a to TPS-h, based on their protein sequences and functional characteristics (Chen et al. 2011). The subfamilies TPS-a, TPS-b, and TPS-g are only

present in angiosperms and, among these, the TPS-a subfamily includes mainly sesquiterpene and diterpene synthases, whereas members of the TPS-b subfamily are responsible for the production of monoterpenes or isoprenes. Members of the smaller TPS-g subfamily are predominantly monoterpene synthases. The TPS-d subfamily is only found in the gymnosperms, whereas TPS-h is specific to the spikemoss *Selaginella moellendorffii*. The TPS-c subfamily is, presumably, the ancestral clade, and it includes several copalyl diphosphate synthase genes. The TPS-f clade derived from the TPS-e subfamily, and they are, therefore, often combined and referred to as the TPS-e/f subfamily, which harbors ent-kaurene synthase genes and other diterpene, monoterpene, and sesquiterpene synthase genes (Chen et al. 2011).

Analysis of sequenced plant genomes have revealed varying TPS gene family sizes among species, ranging from 30 to more than 100 members, which presumably evolved – as for many other gene families – by duplication followed by functional divergence. For example, the genomes of *A. thaliana*, rice, and grapevine contain 32, 34, and 69 full length TPS, respectively (Chen et al. 2011). More than 100 putative TPS genes were identified each in the representative *Eucalyptus* species *E. grandis* and *E. globulus* (Külheim et al. 2015). TPS gene families have also been studied and described extensively in several other plant species such as tomato (Falara et al. 2011) and *Vitis vinifera* (Martin et al. 2010).

Using the first published carrot whole-genome assembly, Iorizzo et al. (2016) performed a preliminary characterization of the carrot TPS family and predicted 36 potentially functional TPS genes. Using the same version of the carrot genome, Keilwagen et al. (2017) conducted a genome-wide identification of carrot TPS genes by applying a newly developed homology-based gene prediction software called GeMoMa. In total, the carrot TPS inventory actually consists of 65 predicted full-length TPS gene models. The predicted carrot TPS genes were assigned, with one exception (TPS-d) to all angiosperm TPS subfamilies, TPS-a to TPS-g. Subfamily TPS-b (monoterpene synthases) was identified as the largest subfamily in the carrot genome with a total of 32 putatively functional genes. Subfamily TPS-a (sesquiterpene synthases) was found to be the second largest subfamily with 22 genes. The huge number of TPS-a and TPS-b genes correspond with the dominance of mono- and sesquiterpenes present in the large panel of carrot genotypes (Keilwagen et al. 2017). Results from this study revealed that carrot is among the species with high or very high number of TPS genes, suggesting broad potential for further functional diversification and specialization of terpene metabolism. Analyzing the carrot genome sequence, most of the TPS genes are found in gene clusters, dispersed throughout all of the chromosomes (Keilwagen et al. 2017). Especially the TPS gene clusters on chromosomes 1, 3, 4, and 9 might be results of multiple gene duplications (Fig. 9). The whole known inventory of *Daucus* TPS genes together with existing information about their putative function is shown in Table 4. A maximum-likelihood phylogenetic tree including all predicted TPS genes in *D. carota* was presented by Ibdah et al. (2019).

In contrast to the high impact of mono- and sesquiterpenes for the total volatile profile and, therefore, for taste and flavor of carrots, only a few research papers had

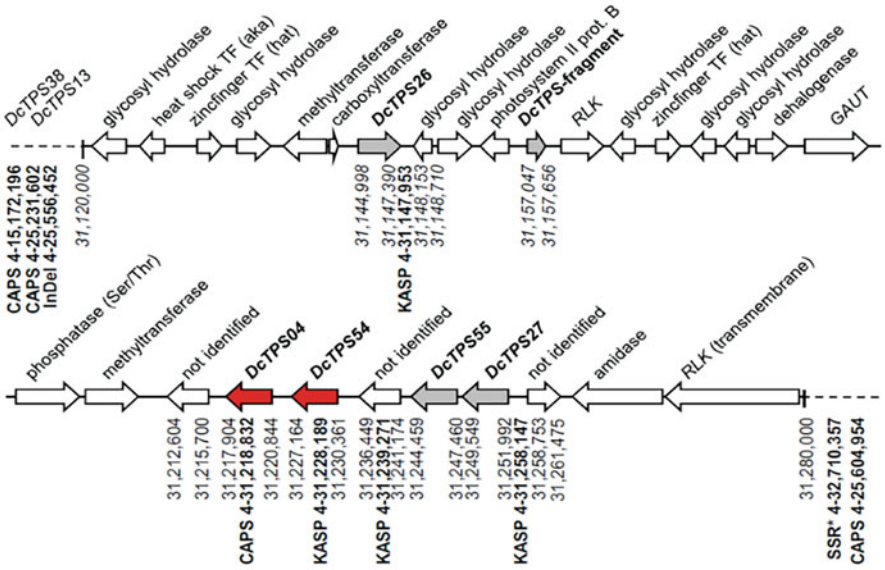

Fig. 9 Schematic representation of the physical location of the TPS gene cluster on chromosome 4 of the carrot genome (Reproduced from Reichardt et al. 2020)

focused on functional characterization of carrot TPS genes. A *DcTPS1* recombinant protein synthesized in a heterologous expression system in *E. coli* produced mainly the sesquiterpenes β-caryophyllene and α-humulene, while recombinant *DcTPS2* functioned in *E. coli* as a monoterpene synthase with geraniol as the main product (Yahyaa et al. 2015). *DcTPS2* is a gene encoding a monoterpene synthase of the TPS-b subfamily and produced also β-myrcene, which is among the carrot terpenes with strongest influence on carrot aroma. The function of *DcTPS2* as a geraniol synthase was confirmed by analysis of a very similar gene cloned from a wild carrot accession, which contained geraniol as the predominant terpene in seeds (Yahyaa et al. 2016). Based on QTLs mapping results and the genetic dissection of a five-TPS gene cluster on chromosome 4 with molecular markers, Reichardt et al. (2020) selected *DcTPS04* and *DcTPS54* for further functional analyses. In vitro enzyme assays in *E. coli* showed that *DcTPS54* encodes a single-product enzyme catalyzing the production of the monoterpene sabinene, whereas *DcTPS04* was found to be a multiple-product terpene synthase producing α-terpineol as a major product and four other products, namely sabinene, myrcene, β-pinene, and β-limonene. These results were confirmed by Muchlinski et al. (2020), who functionally characterized 19 carrot TPS genes in the double-haploid orange carrot genotype DH1 and compared spatial expression profiles and in vitro products of their recombinant proteins with the volatile terpene composition of DH1 and the respective terpene profiles from four genotypes with different root colors. As TPS enzymes involved in the production of major compounds of carrot flavor, *DcTPS07* and *DcTPS11* (germacrene D), *DcTPS30* (γ-terpinene), and *DcTPS03* (α-terpinolene) were biochemically identified

Table 4 List of 64 *Daucus carota* TPS gene models sorted by their physical position on the assembled 9 carrot chromosomes according to the whole-genome sequence (Iorizzo et al. 2016) and the carrot TPS inventory published by Keilwagen et al. (2017). For functionally characterized TPSs, only the main product is named together with the reference publication: (1) Yahyaa et al. (2015), (2) Reichardt et al. (2020), and (3) Muchlinski et al. (2020)

(Table 4). No functional characterization of isolated TPS genes *in planta* has been published yet but would be highly desirable in order to analyze TPS genes putatively involved in plant pathogen defense mechanisms. Overexpression of isolated TPS genes in carrot hairy root cultures in vitro might be a possible way to produce large amounts of pharmaceutically relevant terpenes in future.

Compared with the knowledge about carrot terpene profiling, the TPS genes involved, and their putative functions, less was known about the inheritance of carrot terpenes until the studies of Keilwagen et al. (2017) and Le Clerc et al. (2019). However, for targeted breeding, for example, to enhance specific aroma notes or, vice versa, to avoid unwanted terpene profiles leading to bitter taste, it will be necessary to define the most important TPS and other genes from the MEP and MVA pathways involved in the production of major terpenes in carrot roots. Using a combinatorial approach of terpene metabolite profiling, SNP analysis through

genotyping-by-sequencing (GBS), and a subsequent genome-wide association study (GWAS) in a panel of 85 carrot cultivars, Keilwagen et al. (2017) detected 30 QTLs for 15 terpenoid volatiles. Genetic association analysis identified 21 significant QTLs in roots, and 9 QTLs were detected in leaves. Root QTLs were mostly detected for the monoterpenes sabinene, ocimene, β-pinene, borneol and bornyl acetate, and most QTLs were located on carrot chromosomes 4, 5, 7, and 9. Three genomic regions were detected after GWAS, which contained terpene QTLs either associated with a single TPS candidate gene (*DcTPS03* for bornyl acetate and *DcTPS29 for* γ-terpinene) or with the cluster of five mono-TPS genes with high sequence homology on chromosome 4 (*DcTPS04*, *DcTPS26*, *DcTPS27*, *DcTPS54*, and *DcTPS55*) which were associated with QTLs for sabinene and terpinen-4-ol. Analysis of this TPS cluster by QTL mapping in a biparental carrot F_2 population confirmed the results found by GWAS for sabinene and terpinen-4-ol and identified additional QTLs for the monoterpenes α-thujene, α-terpinene, γ-terpinene, and 4-carene in the same genomic region of chromosome 4 (Reichardt et al. 2020). Another previous QTL study, which focused on bitterness trait variation and resistance to *Alternaria dauci* in a segregating carrot F_2 population, identified 71 QTLs for 25 terpenes (Le Clerc et al. 2019). These QTLs were placed mainly on chromosomes 3, 4, and 9, and eight terpenes were the same as in the work of Keilwagen et al. (2017). However, only the QTLs for sabinene on chromosome 4 appeared to be the same in both studies indicating the importance of this genomic region for monoterpene metabolism.

5.5 Implications for Breeding

Marker-assisted breeding (MAS) based on molecular markers linked to QTLs for volatile terpenes might be utilized in carrot breeding programs. Determination of the functional allelic diversity of TPS genes present in *Daucus* germplasm can help to select putative crossing parents. The molecular KASP marker developed by Reichardt et al. (2020) is a first example for such approach (Fig. 9). This allele-specific marker developed from the sequence of the gene *DcTPS54* can discriminate carrot F_2 individuals as well as cultivar genotypes with high or low sabinene content (Reichardt et al. 2020). Sabinene is likely one of the predominant and most important terpenes in carrots, since this substance may be involved in carrot flavor and taste, but was also described to be responsible for bitterness and fungal resistance (Le Clerc et al. 2019). Such correlations between wanted (aroma and resistance) and unwanted (bitterness) traits might lead to conflicts when molecular breeding would ignore such relationships. Therefore, for molecular breeding of high-quality carrot cultivars fulfilling all demands of growers and consumers, specific molecular markers for single terpenoid volatiles would be probably not helpful without a concomitant sensorial perception analysis. Nonetheless, carrot appears as a very promising target crop for breeding programs aiming at the development of specific chemotypes possessing enhanced levels of economically important terpenes for industrial or pharmaceutical exploitations. Special new carrot varieties containing

large amounts of bioactive terpenes but, if necessary, with compromised taste may also be considered as nutraceuticals.

6 Carotenoids

6.1 Introduction

Carotenoids comprise a family of 40-carbon isoprenoids that includes non-oxygenated carotenes as well as oxygenated xanthophylls, among other compounds. They are found in a variety of organisms, including plants, animals, and microbes. Plant carotenoids aid in the absorption of light during photosynthesis and provide protection against photooxidative stress. As accessory pigments, they are essential to development and growth (Lu and Li 2008). In addition, plant growth, flavor, and mycorrhizal connections need carotenoid pathway byproducts (Della Penna and Pogson 2006; Cazzonelli and Pogson 2010). Moreover, carotenoids enhance the plants' non-photosynthetic parts by attracting animals and insects that help pollinate and disperse seeds. It is essential for animals, including humans, to get carotenoids from their diets since with very few exceptions – mammals cannot synthesize carotenoids on their own. These pigments are present in a diverse range of food plants, including carrots, and are the primary precursors of vitamin A, required for immune system function, sight, maturation, and reproduction. In addition, specific carotenoids, such as lycopene and lutein, have been found to reduce the risk of some types of cancers, osteoarthritis, neurodegenerative disorders, and cardiovascular disease (Tanumihardjo 2012).

When it comes to the number and composition of carotenoids in a plant, there is a wide range of variation among tissues and organs within a plant, which also vary during the plant's growth, and across different accessions within a species. Since carotenoids are attractive to animals, their bright colors may have attracted humans' interest as they were domesticated. Multiple regulatory mechanisms are involved in controlling metabolite transport across pathways and cells involved in carotenoid accumulation via biosynthesis (Sun et al. 2018), degradation (Yuan et al. 2015), and sequestration, many of which are characterized by alterations in photomorphogenesis and plastid growth in certain cases (Lu and Li 2008). The recent advances in carrot genomics provided opportunities to expand knowledge about the genetic mechanism controlling carotenoid accumulation in carrot.

Carotenoids are present in very small quantities in the unpigmented roots of wild carrots (*Daucus carota* subsp. *carota*), also called Queen Anne's Lace (QAL), and in white-rooted cultivated carrots, whereas they are present – in varying concentrations – in the majority of the cultivated colored carrots. The primary carotenoid pigments in carrot roots are yellow, orange, and red, and the main compounds that account for such colors are lutein, α- and β-carotene, and lycopene, respectively (Arscott and Tanumihardjo 2010). Yellow carrots predominantly accumulate lutein, zeaxanthin, and α- and β-carotene in small levels (Alasalvar et al. 2001; Arscott and Tanumihardjo 2010), whereas orange carrots typically accumulate large quantities of α- and

β-carotene, and trace amounts of phytoene, lutein, and ζ-carotene. Red carrots accumulate primarily lycopene and often include small amount of α- and β-carotene, as well as lutein (Arscott and Tanumihardjo 2010). Carrot is among the main dietary sources of PACs in many regions of the world, with particular relevance in the USA, where it ranks first in the relative contribution of PACs to the general population's diet. When compared to other dietary sources of PCAs, orange carrots are distinct in that α-carotene can account for a much higher percentage of the total carotenoids content, representing 13–40% of total carotenoids, with higher percentages observed in carrot roots with higher total carotenoid content (Simon and Wolff 1987; Santos and Simon 2006). According to a previous study, carrots can provide 67% of the α-carotene required by the average American diet.

The total carotenoid concentration of dark orange cultivars can exceed 500 ppm on a fresh weight (fw) basis. According to Simon et al. (1989), dark orange cultivars may have a total carotenoid content as high as 500 ppm of fw, and this potential to accumulate carotenoids is associated with the formation of carotenoid structures and crystals in root chromoplasts (Maass et al. 2009; Sun et al. 2018).

Interestingly, there was no report of orange carrots until the seventeenth century. Indeed, when it was first domesticated, about 1100 years ago in Central Asia, carrots had purple or yellow roots (reviewed by Simon 2000). The first orange-rooted carrots were reported in Southern Europe in the sixteenth century and the first red carrot was reported in Asia in the seventeenth century. Since their selection, orange-rooted carrots became – and still are – the predominant market type worldwide. However, red, yellow, and purple carrots still have a relatively large market in some parts of Asia.

6.2 Role of Carrot Carotenoids in Human Nutrition

Orange carrots are rich in carotenes, which predominantly include α- and β-carotene, as well as smaller and varying amounts of γ- and ζ-carotenes, β-zeacarotene, and lycopene, with total carotene content varying from 63 to 548 ppm across different orange-rooted cultivars (Simon and Wolff 1987; Simon 2000). One of the most important functions of carotenoids in the human diet is the role of α-carotene, β-carotene, and cryptoxanthin as precursors of vitamin A. α-carotene and β-carotene account for 13–40% and 45–50% of the total PACs present in orange carrots (Simon and Wolff 1987; Simon 2000). After ingestion, PACs can be cleaved in the intestine or liver, yielding retinaldehyde (retinal) which can then be reduced to retinol, vitamin A (reviewed by Krinsky 1998, and Semba 1998). Vitamin A plays an essential role in human vision and immune function, including apoptosis, keratinization, and B-lymphocyte function (Semba 1998). Vitamin A deficiency can cause a variety of symptoms such as night blindness, xerophthalmia, and increased susceptibility to infections and cancer (Semba 1998). In addition to its ability to produce vitamin A, β-carotene also possesses strong antioxidant activity in humans (Krinsky 1998).

Red-rooted carrots are particularly rich in lycopene, another carotenoid frequently found in the human diet. Lycopene is not a PAC. However, because of the high

number of conjugated double bonds, lycopene has higher antioxidant activity than other carotenoids with fewer double bonds. Several studies have reported an inverse relationship between serum levels of lycopene and risk for several types of cancer, especially prostate cancer, suggesting that lycopene possess anticancer effects (reviewed by Rao and Agarwal 2000). Red carrots are widely consumed in some regions of the world, such as India, where they are preferred over orange carrots.

Yellow carrots are rich in xanthophylls, predominantly lutein and in less amount zeaxanthin. Compared to orange-rooted forms, yellow carrots generally have lower concentration of total carotenoids and β-carotene (Sun et al. 2009). The xanthophyll pigments present in yellow carrots provide protection against cataracts and age-related macular degeneration (Tanumihardjo 2012). These pigments accumulate in both the lens and the macula of the human eye, where they are thought to play a role quenching reactive oxygen species generated by high exposure to ultraviolet light. In addition, it has been indicated that increased intake of lutein may also prevent early atherosclerosis.

White carrots have trace amounts of carotenoids, if any. Because of their extremely low carotenoid content, they lack the carotenoid-related health enhancing properties of the other root color phenotypes. However, the do provide fiber and other nutrients found as well in other colored carrots.

6.3 Biosynthesis of Carrot Carotenoids

Carotenoids are produced in two separate pathways in the plastids and the cytosol. In plastids, the 2-C-methyl D-erythritol-4-phosphorate (MEP) pathway converts pyruvate and glyceraldehyde 3-phosphate to Isopentenyl diphosphate (IPP), and in the cytosol, the mevalonic acid (MVA) pathway converts acetyl-CoA to IPP and geranylgeranyl diphosphate (GGPP). GGPPs are then transformed into phytoene, which is the first step in the carotenoid pathway. Figure 10 presents the MEP and MVA pathways with the respective carrot genes, loci, and enzymes. It is mostly through the MEP route that the majority of carotenoid precursors are made (reviewed by Rodriguez-Concepcion and Stange 2013). There are 44 isoprenoid and 24 carotenoid biosynthesis genes in carrot. Each gene contains various paralogues involved in a variety of modifications, indicating that distinct paralogues evolved specialized functions in different plant taxa, tissue types, developmental stages, environmental conditions, and/or pathways (Rodriguez-Concepcion and Stange 2013; Iorizzo et al. 2016; Simpson et al. 2016). Most of the carotenoid biosynthetic genes are functional in all of the color phenotypes of carrot storage roots, including white-rooted cultivated (Wang et al. 2014; Perrin et al. 2016, 2017a) and wild carrots (Just et al. 2007; Clotault et al. 2008; Bowman et al. 2014; Ma et al. 2017). This is indicative that pathway metabolites serve as precursors for key substances needed for general plant growth and development, such as the hormones abscisic acid and strigolactones.

In carrots with orange, yellow, and red roots, carotenoid concentration increase during root development (Clotault et al. 2008; Fuentes et al. 2012; Perrin et al. 2016; Wang et al. 2014). While the expression of genes increase during root development, it

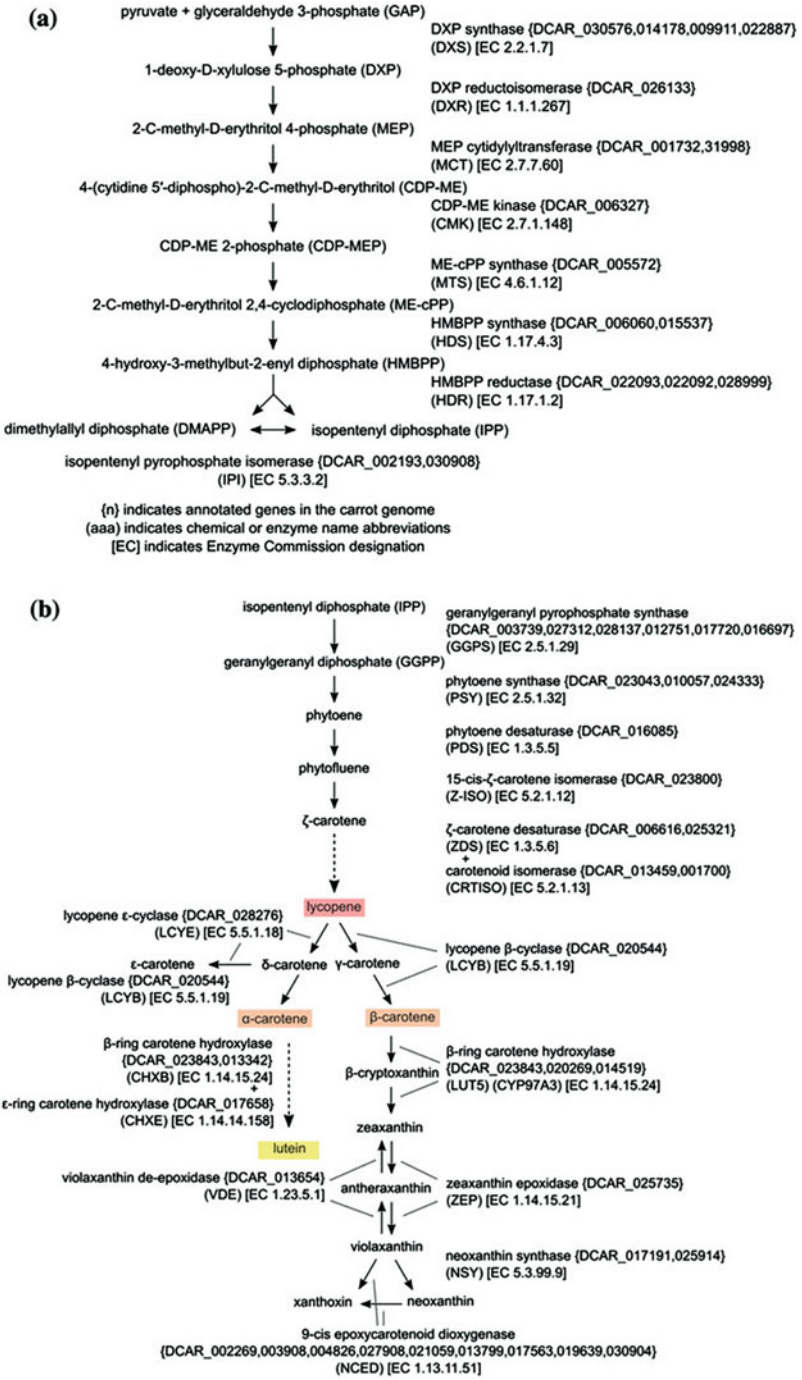

Fig. 10 MEP (2-C-methyl D-erythritol-4-phosphorate) (**a**) and carotenoid (**b**) pathways. Enzyme names, carrot locus tags (in curly brackets), abbreviations (in parentheses), and Enzyme Commission numbers (in square brackets) are included (Reproduced from Simon et al. 2019)

has often been observed that such increase in gene expression is not proportional to – i.e., it is several folds less than – the increase in pigment content (Clotault et al. 2008; Stange et al. 2008; Fuentes et al. 2012; Bowman et al. 2014; Wang et al. 2014; Ma et al. 2017). Greater expression levels of *Lycopene ß-cyclase 1* (*DcLcyb1*) were found in leaves and roots of mature plants than in those organs in immature plants (Moreno et al. 2013). *DcLcyb1* overexpression in transgenic carrots led to increased carotenoid content and increased expression of other carotenoid genes – namely *DcPsy1, DcPsy2, and DcLcyb2* – in leaves and roots. These results suggest that *DcLcyb1* does not possess an organ specific function and modulate carotenoid gene expression and accumulation in carrot leaves and roots.

Transgenic approach has been used by Arango et al. (2014) to study the role of carotene hydroxylase in the metabolism and accumulation of carotenoids in carrot root and leaves. When *CYP97A3* was overexpressed in transgenic orange carrots, the leaves had levels of α-carotene that were about the same as those of untransformed wild carrots. Furthermore, levels of carotenoids were significantly reduced in orange transformed carrots, as was *PSY* protein expression, despite the fact that *PSY* was not expressed in these carrots. This indicated that there is a mechanism that regulates carotenoid metabolism. Indeed, exposure of storage roots to light has a significant impact on the amount of carrot carotenoids and gene expression (Stange et al. 2008; Fuentes et al. 2012).

As with the carotenoid content and the levels of most of the genes involved in the process, the carrot root's shape altered when it was exposed to light in the research. As a consequence of inadequate light and temperature conditions, the carotenoid content of both roots and leaves is decreased (Perrin et al. 2016). The transcriptional control of all of the carotenoid genes in the leaves, as well as the zeaxanthin epoxidase (*ZEP*) and phytoene desaturase (*PDS*) genes in the roots, was held responsible for the observed reduction in AOC. Changes in carotenoid transcript levels, on the other hand, could not explain changes in carotenoid content in contexts with both *Alternaria dauci* infection and water scarcity (Perrin et al. 2017b). This shows that there are other regulatory mechanisms that are not involved in the pathway's functioning.

Due to the wide range of carotenoid content and color intensity found in different carrot genetic stocks and cultivars, many studies have looked at how the expression of carotenoid genes varies in carrots of different colors (Clotault et al. 2008). The enormous and diversified changes in carotenoid composition throughout a wide range of storage root colors are not matched by qualitative differences in gene expression in the pathway, although there are certain similarities in gene expression that are paralleled by carotenoid accumulation patterns (Bowman et al. 2014). White and orange carrots have different levels of two to four times more *PSY1* and *PSY2* genes than white carrots. This is what happened in studies that compared the levels of these two genes in white and orange carrots (Wang et al. 2014). Clotault et al. (2008) reported that yellow carrots have a higher concentration of genes that produce lycopene and ζ-carotene desaturase than orange or white carrots. According to the findings of Ma et al. (2017), yellow cultivars exhibited more genes that produce xanthophyll than orange cultivars. During the period of plant growth in a controlled environment, the expression of carotenoid genes modulates in a way that is comparable to the method in which carotenoid accumulation changes in phloem tissue.

Among genes that encode enzymes are involved in the MEP and MVA pathways, 1-deoxy-d-xylulose-5-phosphate (DXP) synthase 1 (*DXS1*) was the only one to be upregulated in a way that is consistent with the amount of carotenoid present in carrot root (Iorizzo et al. 2016). *DXS* has been identified to be a regulator of isoprenoid biosynthesis in a number of Arabidopsis experiments. According to Simpson et al. (2016), *DXS* is the rate-limiting enzyme in the synthesis of carotenoid pigments in transgenic carrots. In addition, the study found that *PSY* transcript was upregulated in the *DXS* regulatory cascade, which confirms *PSY*'s important role in carotenoid metabolism (Lu and Li 2008; Yuan et al. 2015; Sun et al. 2018). The results that the *PSY* transcript was upregulated in assessments of orange and white carrot roots are likewise consistent with these findings (Bowman et al. 2014). Many studies have also looked at how carotenoid gene sequences change over a wide range of root colors. Carotenoid genes have different nucleotides in carrots from different parts of the world, suggesting that root color was highly relevant in the domestication of carrots. Variation for gene sequence and expression levels were found for seven carotenoid alleles in 46 carrots with different root colors from across the world (Clotault et al. 2012). They found that there was a lot of variation in how much selection was put on genes like *PDS* and *IPP* isomerase (*IPI*), which are at the beginning of the process. The carotene isomerase (*CRTISO*), *LCYB1*, and *LCYE* genes, which are closer to lycopene in the pathway, were also found to be selected for. The sequence variation for *LCYB1* was different between color groups, suggesting that it was selected during domestication. However, there was not a pattern of sequence variation that pointed to candidate genes in the carotenoid pathway that could account for color variation.

Jourdan et al. (2015) examined 17 carotenoid genes in 67 carrot cultivars from across the globe and concluded that there were linkages between α-carotene content and the plastid terminal oxidase (*PTOX*) and *CRTISO* polymorphisms, as well as links between total carotenoid content and the *ZEP*, *PDS*, and *CRTISO* polymorphisms. Genetic linkage between individuals who have the *Y* and Y_2 genes on the same chromosome as *ZEP* and *PDS* may have occurred, which may have contributed them in their connection with one another (Just et al. 2007).

6.4 Carrot Carotenoids Genetics and Genomics

In the late 1960s and early 1980s, Gabelman and his students discovered multiple genes that influence carrot root color. Segregation analysis in populations derived from intercrosses of carrots with different root color revealed that a single dominant gene conditions white root color over yellow, whereas F_2, F_3, and backcross populations from white × orange intercrosses exhibited white and orange-rooted plants consistent with a 2–3 gene patterns of inheritance (Imam and Gabelman 1968; Laferriere and Gabelman 1968). The yellow root color was shown to be more strongly influenced by a monogenic inheritance pattern than the orange root color in this study. One or two additional dominant genes, Y_1 and Y_2, were identified by Kust (1970) as governing white coloration over yellow, as reported by Laferriere and

Gabelman (1968). *O* and *IO*, two genes that enhance orange phloem color, were also discovered by Kust (1970), and further characterized by Buishand and Gabelman (1979), who analyzed segregation of orange color in phloem and xylem tissues in derivatives of orange × white crosses. When the dominant alleles were present in the cross, the carotenoid contents in the offspring of "white × yellow" and "yellow × orange" crosses decreased.

Additionally, Umiel and Gabelman (1972) determined that orange root color predominated over "red white × orange" and "white × yellow" crosses. Two simply inherited loci, *A* and *L*, that influence the accumulation of lycopene and α-carotene were identified by segregation analysis in F_2 and backcross populations derived from intercrosses between red and orange rooted carrots (Umiel and Gabelman 1972). Buishand and Gabelman (1980) found three key genes segregating in progenies from red × yellow crosses: Y_2, which inhibits the synthesis of carotene; *L*, which promotes the synthesis of lycopene; and A_1, which has a phenotypic impact comparable to either *O* or *IO* described by Kust (1970).

Gabelman and colleagues uncovered a number of critical genetic elements influencing root color. Because there were no intercrosses to test for allelism or chromosomal complementation, the only way to distinguish between alleles was to look at the phenotypic traits alone. On the basis of accounts of their characteristics, researchers have emphasized on the *L*, *O*, and *IO* genes.

As previously reported by Arango et al. (2014), the activity of the carotene hydroxylase gene *CYP97A3* in orange carrot roots is reduced, resulting in a higher concentration of α-carotene and higher ratio of α-carotene/β-carotene. This indicates that the "A_1" phenotypic locus described earlier by Buishand and Gabelman (1980) and reported to be essential for α-carotene synthesis in orange carrots, has been identified. A frameshift mutation in the *CYP97A3* gene, which is found only in orange carrot roots, was reported as the causal mutation leading to reduced expression of *CYP97A3* and – thereby – increased accumulation of α-carotene (Arango et al. 2014). This reveals the genetic and molecular foundation for orange carrots' high α-carotene content.

Goldman and Breitbach (1996) described an orange carrot mutant, characterized by "reduce pigment" in the root, caused by the recessive gene "*rp*." This gene reduces the concentration of α- and β-carotene in storage roots by more than 90%, while raising the concentration of phytoene (Koch and Goldman 2005). A distinguishing green color is developed by the sixth leaf in the development of *rprp* plants, which are initially chlorotic and even white. The *rp* mutation results in a decrease in plant vigor, which is rare among genes that regulate carotenoid color in carrots. The carotenoid pathway is thought to be suppressed in the *rp* mutant (Goldman and Breitbach 1996); however, this hypothesis has yet to be tested. Because of its uniqueness, further characterization of *rp* might provide new insights into the metabolism of carrot carotenoids.

In three orange × yellow crosses, Simon (1996) used carotenoid mapping populations to examine the relationship between Y_2 and genes that govern sugar and anthocyanin accumulation. He found that Y_2 had a monogenic inheritance pattern. Because the observed phenotype most closely correlated with Buishand and

Gabelman's (1979) phenotypic descriptions of this trait, the gene was designated as Y_2. An AFLP fragment genetically linked to Y_2 was converted into a PCR-based marker to help in the phenotyping of carotenoid accumulation genes in breeding programs (Bradeen and Simon 1998). AFLPs were initially used to map the Y_2 gene, which conditions yellow versus orange root color and carotene concentration (Vivek and Simon 1999). Santos and Simon (2002) employed AFLP markers to map QTLs for carotenoids concentration (assessed by HPLC analysis) in two mapping populations. Significant QTLs were identified for several carotenoid products, including phytoene, lycopene, β-carotene, and α-carotene. Eleven QTLs for concentration of α- and β-carotene were detected and they were associated with orange root color.

Carotenoid accumulation genes were formerly thought to be metabolic pathway structural genes, like in other crops. It is possible that the genes conditioning carotenoid-related coloring of carrot roots are not structural biosynthetic genes but rather control carotenoid accumulation (Santos et al. 2005). A single major QTL for β-carotene, total carotene, and lycopene content was identified in the F_2 population of P50006 and HCM A.C. using sequence related amplified polymorphism (SRAP) markers, and this QTL accounted for ~12.8–14.6% of the total phenotypic variation for the three pigment traits. The genetic variability of these three QTLs was attributed to additive genetic variance rather than additive genetic variation. Furthermore, a pair of epistatic QTLs for β-carotene and lycopene accumulation was shown to account for 15.1% and 6.5% of the total phenotypic variance, respectively. The SRAP markers tightly linked to these QTLs might be employed in carrot breeding to select for high carotenoids and lycopene content via QTLs pyramiding or selection for high carotenoids and lycopene content through selection.

Santos and Simon (2006) also estimated broad-sense heritability values for individual carotenoids and cumulative carotenoid concentration in the two populations. A segregating pattern was revealed in the progeny of a hybrid between a wild, white-rooted carrot, known as QAL, and a dark orange cultivated carrot, known as B493, in which the *Y* and Y_2 genes were segregating, as well as quantitative loci that contributed to variation in total carotenoid concentration.

In the same study of Santos and Simon (2006), progenies from another cross between the orange-rooted Brasilia and the dark orange HCM were examined. Although the genotypes of the progenies were all recessive for the *Y* and Y_2 loci (yyy_2y_2), the progenies were quantitatively segregating for carotene content, in approximately fivefold difference between the two parents. The total heritability of carotenoid content in the 'B493 × QAL' population ranged from 0.89 to 0.98, while it ranged from 0.38 to 0.45 in the 'Brasilia × HCM' background, demonstrating that the *Y* and Y_2 genes had a significant influence on descendants in the B494 × QAL population. Carotenoid concentrations in the same orange carrot genetic stocks may vary up to twofolds in different environments, according to Simon and Wolff (1987) and Perrin et al. (2016), explaining why the 'Brasilia × HCM' population had lower heritability than the other HCM populations. It was hypothesized that the genes encoding the carotenoid biosynthesis enzymes could be linked to the carotenoid color genes, hence Just et al. (2007, 2009) identified and mapped 22 probable carotenoid enzyme genes in carrot. The population used in this research was generated from a cross between a wild

white-rooted carrot known as QAL and a cultivated carrot known as B493, which has a dark orange root. This population segregated for orange, yellow, and white root colors, with ratios consistent with a two-gene model. Bradeen and Simon (1998) genetically mapped the Y_2 gene on linkage group 5 and *Y* on linkage group 2. *ZEP* and *ZDS* were found to be positionally associated with the Y_1 and Y_2 genes, respectively. The Y_1 gene was shown to be associated with ε-ring carotene hydroxylase (*CHXE*), 9-cis-epoxycarotenoid dioxygenase 2 (*NCED2*), and phytoene desaturase (PDS). Due to the lack of close relationships, they were designated positional candidates (Just et al. 2009). After sequencing the carrot genome (Iorizzo et al. 2016), a *Y* gene candidate was found. Fine mapping in this study revealed a 75-kb region of chromosome 5 responsible for both the orange and pale orange (YYy_2y_2) root color segregating as a monogenic trait in the B493 × QAL cross population, as well as the yellow (yyY_2Y_2) and white (YYY_2Y_2) root color segregating in an unrelated population. In this study, the light orange phenotype (yyy_2y_2) has not previously been connected to aYYy_2y_2 genotype, since earlier phenotyping had not been able to differentiate it from orange (yyy_2y_2). The identification of a potential *Y* locus gene was made using differential expression analysis and nucleotide polymorphisms (*DCAR_032551*) (Iorizzo et al. 2016). It was observed that this gene co-expressed with *DXS1* and *LCYE*, two genes engaged in the isoprenoid pathway, in non-photosynthetic root tissue, along with a slew of other genes involved in photosynthetic induced changes and functioning, plastid biosynthesis, and chlorophyll metabolism. Arabidopsis has a pseudo-etiolated morphology and interacts with genes that control light response and photomorphogenesis, including the *Y* gene potential homolog pseudo-etiolation in light (Ichikawa et al. 2006). *DXS1* is involved in the production of carotenoid precursors in photosynthetic metabolism and is activated by light (Stange et al. 2008; Fuentes et al. 2012). *DXS1* overexpression and carotenoid synthesis may be facilitated by a recessive allele (*yy*) in etiolated roots, according to a study by Iorizzo et al. (2016). Orange carrot roots exposed to light have been shown to undergo morphological changes that might be explained by this hypothesis, which is currently being tested out (Stange Klein and Rodriguez-Concepcion 2015).

The Y_2 and *Y* genes were shown to be segregating in the 'B493 × QAL'-derived population (Just et al. 2009). By combining molecular mapping with transcriptome analysis, it was feasible to determine the location of the gene Y_2 in a population that was homozygous recessive for *Y* (*yy*) but segregated for root color associated with the Y_2 region (Ellison et al. 2017). Many carotenoid-related genes were found to be differentially expressed between orange and yellow roots at 40 and 80 days following planting. A total of 6 genes were discovered in the 650-kb region, including *PSY1, PSY3*, geranylgeranyl diphosphate synthase 1 (*GPPS1*), neoxanthin synthase 1 (*NSY1*), carotenoid cleavage dioxygenase 1 (*CCD1*), *LUTEIN DEFICIENT 5 (LUT5)*, and two cytochrome genes. In this study, it was observed that DXP reductoisomerase (DXR) was the only MEP or carotenoid pathway gene expressed present in that region, despite the fact that it did not express differently in orange versus yellow carrots. Among the 17 genes that changed between 40 and 80 days were detected in the fine-mapped region, only 4 were found in the fine-mapped region. A recessive phenotype was anticipated for just one of the four, the "protein

dehydration-induced 19" homolog 5 *(Di19)* (DCAR 026175) gene, which showed lower expression in orange roots than yellow roots. *AtDi19-7*, a member of the Arabidopsis *Di19* gene family, has been associated with light signaling responses, and other abiotic stimuli, including abscisic acid (Milla et al. 2006). Variations in the expression of *Di19* during photomorphogenesis may have an impact on the synchronized synthesis of chlorophyll and carotenoids throughout this process. In order to confirm the Y_2 candidate, more testing is needed since the 650-kb region reported by Ellison et al. (2017) contains several candidate genes.

Another gene that impacts carotenoid accumulation in carrot roots and includes the whole spectrum of carotenoid colors was identified in a recent association research that included data from 154 wild and 520 cultivated carrots from geographically diverse worldwide growing regions (Ellison et al. 2018). This carrot collection was analyzed using genotyping by sequencing (GBS) to look for evidence of domestication. The study discovered a connection between high levels of carotene and the existence of the *Or* gene in a 143-kb genomic region of chromosome 3, which lacked any MEP or carotenoid genes. *Or* is essential for chromoplast formation, which acts as a sink for carotenoids in several plants species, including Arabidopsis, cauliflower, and sweet potato (Lu and Li 2008; Yuan et al. 2015; Sun et al. 2018), and a similar role for *Or* in carrot root has been hypothesized (Lu and Li 2008; Yuan et al. 2015; Sun et al. 2018). Cultivated carrots from Central Asia, which is the principal source of carrot diversification (Iorizzo et al. 2013), had higher expression levels of the *Or* gene than cultivated carrots from Europe. While the wild-type allele for *Or* (*Orw*) causes yellow root color, recessive genotypes present light orange root, and the storage roots of $OrcOrcyyy_2y_2$ plants are yellow in color, while the wild-type allele for *Or* (*Orw*) causes yellow color. *Orc* allele polymorphism may have had a role in carrot domestication in Central Asia prior to the *Or* gene being fixed for use in European carrots. Scientists are currently investigating the relationship between *Or* allele-specific gene expression and phenotypes.

6.5 Genetic Engineering for Enhancing Carotenoids Levels in Carrot

Increased carotenoid production and accumulation were achieved by introducing the phytoene synthase (*PSY*) gene from *Erwinia herbicola* into the carrot plant and combining it to a plastid transit peptide, which targets the enzyme that targets chromoplasts (Hauptmann et al. 1997). Its expression enhanced phytoene biosynthesis in orange carrot root, which resulted in ~twofold increase in β-carotene concentration. When the *crt*B gene under the control of a yam root-specific promoter was genetically engineered into wild carrot, the color of the transformed roots shifted from white to brilliant yellow, indicating that the gene was successfully expressed. A high concentration of carotene intermediates, such as phytoene, phytofluene, and ζ-carotene and lycopene, which accompanied β-carotene in significantly lower proportions than in normal orange root, were responsible for the different root colors, whereas α-carotene was not detected in this sample. In this way, upregulation of *PSY* in resulted in higher

carotenoid concentrations in carrot roots and enhanced carotenoid storage in chromoplasts in the crystalline form, similar to what occurs in orange carrots, despite the fact that the carotenoids composition was different (Maass et al. 2009).

The carrot homologue of the carotene hydroxylase gene from Arabidopsis*CYP97A3* was found to be expressed in orange carrot roots as well as in other plants. However, while the Arabidopsis gene (*AtCYP97A3*) is fully functional, the carrot *DcCYP97A3* present in orange-rooted cultivars is only partially functional or nonfunctional, due to an 8-nucleotide frameshift insertion that generated a premature stop codon, resulting in the production of a truncated hydroxylase protein (Arango et al. 2014). As a result, the conversion of α-carotene to lutein is inhibited, therefore α-carotene content and the α/β carotene ratio are increased (Fig. 1). The overexpression of *AtCYP97A3* in transgenic orange carrots resulted in a reduction in the quantity of α-carotene present in the carotenoid composition. It was also noticed that carotene hydroxylase overexpression was associated with a reduction in total carotenoids, which was due to a lower *PSY* protein level, despite no changes observed in *PSY* gene expression. It was hypothesized that carotene hydroxylase overexpression may negatively affect *PSY* protein translation (Arango et al. 2014).

Similarly, the significance of precursors in carotenoid biosynthesis was investigated by introducing – via transgenics – the Arabidopsis deoxyxylulose 5-phosphate synthase (*DXS*) and reductoisomerase (*DXR*) genes from the MEP pathway in carrot. The overexpression of *DXS* increased *PSY* transcript levels and, as result, increased carotenoid quantities by an average of twofold, but the overexpression of *DXR* had no significant impact (Simpson et al. 2016).

The effect of the algal *Haematococcus pluvialis* β-carotene ketolase (*bkt*) on carrot carotenoids production was investigated. In the presence of this enzyme, β-carotene is converted to ketocarotenoids such as canthaxanthin and astaxanthin, which have great antioxidant effects and are useful nutraceuticals in the human diet, as well as feed additives for pale fish, salmon, and trout cultures. It was necessary to fuse the bkt gene to the ribulose bisphosphate carboxylase-oxygenase (RuBisCO) signal peptide in order to assure that the enzyme would function in plastids. Leaf and root levels of carrot β-carotene hydroxylases were upregulated in comparison to other tissues. The accumulation in carrot roots of ketocarotenoids, primarily astaxanthin, adonirubin, and canthaxanthin, up to concentrations of 2400μg/g dry weight, was seen in conjunction with a decline in carotenes (Jayaraj and Punja 2008). The growth of plants having high concentrations of ketocarotenoids was improved when they were subjected to intense UV-B irradiation, and the leaves were less damaged when H_2O_2 or methyl viologen stress was administered to them. As a result of the significant antioxidant and free radical scavenging activity of ketocarotenoids, it was inferred that the cells were protected from oxidative stress (Jayaraj and Punja 2007).

6.6 Perspectives on Carrot Carotenoids

Carrot roots may store a variety of carotenoids via divergent pathways. The study of carotenoid production and accumulation in carrot storage roots employs a

multidisciplinary approach that includes genetics, gene expression, and metabolic interactions. There are three primary root colors associated with the accumulation of carotenoids in this organ: yellow, orange, and red. Each color represents a very simple set of metabolic activities that are linked to variations in genetic differences for the genes involved, expression levels, and carotenoid accumulation throughout periods of development. However, when looking at the link between root color and carotenoid content, it has been difficult to figure out how the carotenoid pathway may account for the variations observed in carotenoid composition in orange, yellow, and red carrots. The color of carotenoid pigments is affected by variations in the way they are synthesized, as well as by changes in photomorphogenesis and plastid development. We know relatively little about the regulatory genes involved in the non-carotenoid biosynthesis pathway, discovered by means of carrot genome sequencing and other multi-omics approaches, and we hope to learn more in the future.

Metabolomics and Cytoplasmic Genomics of *Allium*

Mostafa Abdelrahman, Rawan Rabie, Magdi El-sayed, and Masayoshi Shigyo

Contents

Abstract

Allium is the biggest genus of petaloid monocotyledons, with more than 750 species widely distributed in a range of climatic conditions worldwide, especially in the Northern Hemisphere. *Allium* comprises commercially significant food crops, including onions, garlic, leeks, and chives, as well as species with medicinal

qualities. Bulb onions rank second only after tomatoes in terms of global production, which indicates the importance of *Allium* crops and the need for developing new *Allium* crop varieties with beneficial agronomical traits. Recently, there has been considerable interest in investigating the genetic resources of *Allim* crops and their wild relatives for improving *Allium* breeding and possible future genetic manipulation. This chapter provides a comprehensive review of major *Allium* crops and their wild relatives from scientific and horticultural perspectives. This chapter broadly covers the unique resources for *Allium* genetics and breeding, including the recent development of cytoplasmic male sterility, inbred lines, and wild species. We also discuss and summarize the recent developments in *Allium* genome sequencing, including novel tools for large genome sequencing, the chloroplast genome, mitochondrial genomes, and the nuclear genome. Furthermore, we provide a brief overview of the linkage, cytogenetic, and physical mapping in various Allium crops. Finally, we provide a special focus on *Allium* metabolome and transcriptome analysis as important approaches for understanding *Allium* stress responses. Our book chapter provides recent developments in *Allium* genomics and metabolome dynamics, which open the possibility of developing novel *Allium* crop cultivars with enhanced nutritional value and stress tolerance under current climatic conditions.

1 Introduction

Onions (*A. cepa* L. Common onion group), shallots (*A. cepa* L. Aggregatum group), garlic (*A. sativum* L.), Japanese bunching onion (*A. fistulosum* L.), and leeks (*A. ampeloprasum* L. Leek group) are all in the same genus *Allium* that have been cultivated globally as important spices, condiments, and vegetables (Abdelrahman et al. 2016). The genus *Allium* comprises ~1000 species (Govaerts et al. 2005–2020), of which onions, shallots, and leeks are widely cultivated, and displayed remarkable diversity in their morphological and physiological properties, particularly in life form (Abdelrahman et al. 2017a, b, c). *Allium* is propagated commonly through the Northern Hemisphere from the boreal region to the dry subtropics. A region with high density of species diversity started from the Mediterranean Basin to Central Asia, in addition to a second smaller centre of species diversity which is located in North America (Fritsch et al. 2010; Abdelrahman et al. 2017a, b, c) (Fig. 1).

Additionally, *Allium* species show significant variation in a number of cytogenetic traits, including ploidy level (ranging from 2× to 16×), genome size, and chromosomal numbers ($x = 7$, 8, and 9). Specifically, the largest genomes have been found in Alliums, ranging from 18.1 picograms (pg) in *A. triquetrum* L. to 31.5 pg in *A. ursinum* L. (Bennett et al. 2000; Peška et al. 2019). For instance, the haploid

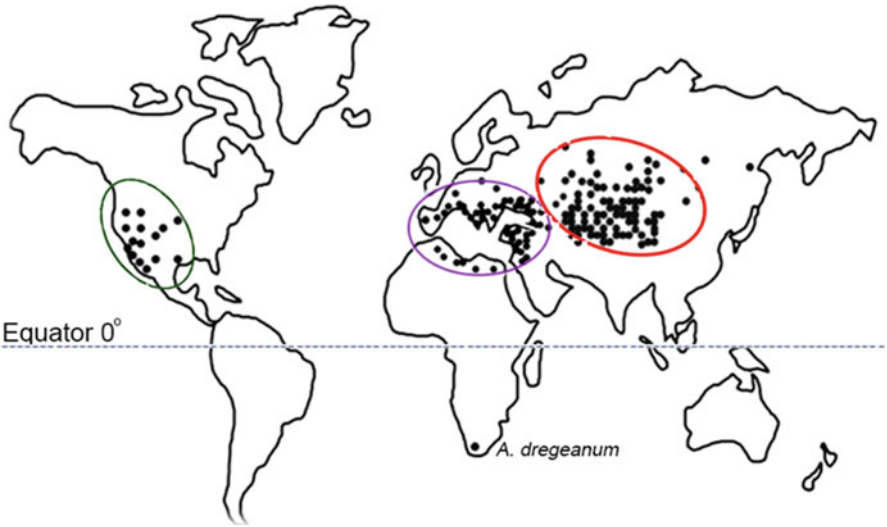

Fig. 1 *Allium* distribution in the northern and southern hemisphere. The red and purple circles indict the center for high *Allium* diversity from Central Asia to the Mediterranean Basin

genome size of the bulb onion was calculated to be about 16,400 Mega bases (Mb)/1C, making it the largest among all cultivated diploid crops. This size is 120 times larger than *Arabidopsis* (ca. 125 Mb) and 5 times larger than the human genome, which is only about 3000 Mb (Ricroch et al. 2005). At least 95% of the onion genome is made up of repetitive sequences (Vitte et al. 2013), which are typically associated with large genome sizes (Kelly and Leitch 2011). As a result, mapping and genomic-assisted breeding in Alliums are behind that of other crops like tomato (*Solanum lycopersicum*), wheat (*Triticum aestivum*), and rice (*Oryza sativa*), making the entire genome sequencing of bulb onions a considerable problem. With the development of next-generation sequencing (NGS) technology, DNA sequencing of many plant species, including *Allium*, grew faster and more efficient with higher throughputs and greater genome coverage (Abdelrahman et al. 2017a, b, c; Abdelrahman 2020; Valliyodan et al. 2017). With the use of these NGS technologies, the first waves of crop genome sequencing, gene expression atlases, and a better knowledge of the signalling networks underlying plant responses to biotic and abiotic stresses were all made possible (Rothberg et al. 2011; Abdelrahman et al. 2019). In this chapter, we report the first trail of the genome assembly of doubled haploid (DH) *A. cepa*. Additionally, the presentation of the *Allium* genome organization, which includes the nuclear, mitochondrial, and chloroplast genomes are given. This chapter also addressed how the genetic resources of the *Allium* species, such as DHs, alien chromosomal addition lines, and cytoplasmic substitution lines, have been employed in various genetic research to comprehend the discrepancy between *Allium*'s phenotype and genotype traits. This chapter's contents will be a useful tool for studying onion breeding genetic resources, which are valuable for onion breeding and research.

2 Unique Resources for Genetics and Breeding in *Allium*

Since Peffley et al. (1985) published their pioneering research, monosomic addition lines (MALs) have been useful genetic resources for studying important agronomic traits in cultivated Alliums and assigning linkage groups to physical chromosomes. For example, in a backcross population (BC_2) of amphidiploid hybrids between *A. fistulosum* (FF) and shallot (*A. cepa* Aggregatum group, AA), a full set of *A. fistulosum* and *A. cepa* MALs ($2n = 2x + 1 = 17$, genomes + chromosomes FF +1A-FF+8A) was identified (Shigyo et al. 1996). To confirm the integrity of the chromosomal constitutions, the MALs were subjected to genomic in situ hybridization (GISH) as described by Shigyo et al. (1996). Following that, 48 shallot chromosome-specific molecular markers were developed in conjunction with qualitative data for morphological identifications (Shigyo et al. 1997a, b). All of these morphological characteristics appear to be related to the genetic effects of the shallot additional chromosome(s) on the A. fistulosum integral diploid background. The reddish-brown sheaths of FF+5A indicated that this line had a high flavonoid and anthocyanin content (Shigyo et al. 1997b). Evidently, integrated metabolome and transcriptome assessment of the entire set of MALs provides additional evidence that shallot chromosome 5A harbored many candidate genes associated in flavonoid biosynthesis (Abdelrahman et al. 2019). When compared to other MALs, FF+5A exhibited high expression of many downstream and upstream flavonoid and anthocyanin-related genes, which was coherent with the accumulation of several flavonoids and anthocyanin-related compounds. Similarly, saponin transcriptome and phytochemical screening in MALs revealed that FF+2A accumulated Alliospiroside, a saponin with powerful antifungal activity against Fusarium pathogens and an useful attribute for disease resistance (Abdelrahman et al. 2017a, b, c). Furthermore, Yaguchi et al. (2013) also investigated antioxidant capacity and polyphenol concentration in MALs, discovering that the FF+2A and FF+6A lines had the greatest polyphenol concentration and antioxidant capacity. As a result, the additional chromosomes 2A and 6A contain anonymous genes associated with polyphenol production increased expression. Shigyo and co-workers carried out such approaches in six interspecific-combinations, *A. cepa – A. fistulosum* (Hang et al. 2004; Yaguchi et al. 2008), *A. cepa – A. roylei* Stearn (Vu et al. 2012), *A. fistulosum– A. roylei* (Ariyanti et al. 2015), *A. fistulosum – A. galanthum* Kar. et Kir. (Tashiro et al. 2000), *A. fistulosum – A. oschaninii* O. Fedtsch. (Tashiro et al. 2000), and *A.fistulosum – A. vavilovii* M. Pop. et Vved. (Tashiro et al. 2000) together with further approaches for disomic additions (Shigyo et al. 2003; Yaguchi et al. 2008) and multiple alien chromosome additions (Masuzaki et al. 2007), some of which are relevant to elucidating a specific epistatic regulation related to secondary metabolite biosynthesis (Masuzaki et al. 2006).

2.1 Cytoplasmic Male Sterility (CMS)

CMS is a maternally inherited trait that prevents the formation of viable pollens while leaving female gametes unaffected, allowing them to serve as seed parents in hybrid

seed production (Yamashita et al. 2007). In contrast, a single nuclear locus renowned as *Ms* is known to revive CMS male fertility in onions. In a recent study by Yu and Kim (2020), inheritance patterns in segregating populations implied that the *Ms* and *Ms2* loci were both engaged in fertility restoration in onions. The *Ms2* locus was found at the end of chromosome 2 at a distance of 70cM from the *Ms* locus (Yu and Kim 2020). Although it is unknown whether the causal genes for *Ms* and *Ms2* loci are paralogs, transcription levels of *orf725*, a CMS-associated gene in onions, were significantly down-regulated in male-fertile individuals of segregating populations, suggesting that the causal gene for *Ms2* may be able to restore male fertility by suppressing transcription of *orf725* or degrading transcripts (Yu and Kim 2020).

Allium galanthum (G) cytoplasm induces CMS in bulb onion (Havey 2002), Japanese bunching onion (Yamashita et al. 1999a, b, 2002, 2005; Yamashita and Tashiro 2004), and shallot (Yamashita et al. 1999). In shallot, the G cytoplasm was introduced through continuous backcrossing to shallot the recurrent parent, to obtain interspecific F_1 hybrids (Yamashita et al. 1999). *A. roylei* (R) originated CMS lines, were identified in the BC_2 progenies of a single amphidiploid (possessing Rcytoplasm) between *A. roylei* (female parent) and *A. cepa*. Breeding onion F_1 hybrid varieties takes 10–12 years to establish the A (malesterile line), B (male-sterile maintainer), and C (restorer) lines (Shigyo and Kik 2008), while alloplasmic lines possessing either GorR cytoplasm saves breeders' time and nullifies the need for B line. Moreover, since the CMS system is conditioned by the incompatibility between the wild species' cytoplasm and the *A. cepa* nucleus, any onion population acts as a male sterility maintainer. Unfortunately, no G or R CMS onion lines have been used in actual onion F_1 seed production. It should be noted, however, that compared to the S-type cytoplasmic male sterility, there are concerns about nectar production, a preferred factor by flower-visiting insects, and/or interaction of pollen production with the environment. Further research on the ecology and physiology of cytoplasm in wild species is needed.

2.2 Inbred Lines

The traditional breeding of onion inbred lines is long and difficult because of its biennial life span, inbreeding depression, and high heterozygosity. Thus, DH lines provide several advantages, including complete homozygosity, reduced DNA methylation, and elimination of deleterious alleles compared with inbred lines (Bohanec 2002) and consequently exhibit vigorous vegetative growth, morphological uniformity (Hyde et al. 2012; Khan et al. 2020). Single- and two-step protocols have been used to generate gynogenic haploids in onion. The former involves culturing whole flower buds, ovaries, or ovules to the embryo, or plantlet stage (Bohanec and Jakše 1999; Bohanec 2002). Whereas the latter includes preculture of flower buds on basal media with or without plant growth regulators. Then, isolation of ovary or ovule and subsequent subculturing on regeneration media with growth regulators (Michalik et al. 2000; Martinez et al. 2000). DH lines may be induced in vitro by culturing haploid cells from the male (androgenesis) or female (gynogenesis) gametophytes. However, the efficiency of androgenic generation DHs is limited in some *Allium*

cepa genotypes due to defective pollen or anthers, or/and the production of albinos during culture. Gynogenesis has been the most commonly used method for producing haploids in *A. schoenoprasum* L. (Keller 1990), leek (Kaska et al. 2013; Alan et al. 2016), *A. altaicum* (Keller 1990), *A. giganteum* (Susek et al. 2002), shallot (Sulistyaningsih et al. 2006), *A. fistulosum* (Ibrahim et al. 2016), *A. tuncelianum* (Yarali and Yanmaz 2016), and others.

DH lines offer very promising tools to understand the gap between phenotype and genotype, and DH chromosomal doubling can shorten the time, offer homozygous pure lines, and provide valuable materials for genomic analysis. For example, comparative metabolome analysis of shallot and bulb onion DHs (DHA, and DHC, respectively) and F_1 hybrid revealed genotype-specific metabolites for each. DHA accumulated several stress-related metabolites, which is consistent with the biotic and abiotic stress shallot tolerance compared with bulb onion (Abdelrahman et al. 2015). Similarly, Khosa et al. (2016) developed transcriptome data from reproductive and vegetative organs of onion DH line 'CUDH 2107' to identify tissue-specific expressed genes involved in pollen fertility.

The Cornell onion breeding program compared 20 DH lines with commercial hybrids and open-pollinated cultivars (OP) developed from the same source germplasm over 2 years, under field conditions (Hyde et al. 2012). Results indicated a similar vegetative vigor of both DH and OPs, with minimal inbreeding depression. A comparison between two sets of hybrids produced using male DH lines and two different commercial females showed increased vegetative growth vigor of DH lines and their derived hybrids probably due to elimination of deleterious lethal genes during gynogenesis, an additional benefit for onion breeding strategies (Hyde et al. 2012).

DH lines lack allelic exchanges within a locus, thus genetic effects are controlled by single alleles or interactions between *loci*, thus facilitating detection of quantitative trait loci (QTL) (Duangjit et al. 2014). Hence, onion DH lines from the four Spanish cultivars, including highly pungent landrace 'BGHZ1354', sweet cultivar 'Fuentes de Ebro', and 'Recas' and 'Rita,' two commercial Valenciana-type varieties (Fayos et al. 2015) served for the development of linkage maps. More comprehensive research and improved DH in vitro gynogenesis production methods are needed and would be useful to produce DH in onion and other *Allium* species.

2.3 Wild Species

Wild relatives have great potential to expand the supply of usable genetic variation and useful traits, thus are important for introgression breeding (Hao et al. 2020). *Allium roylei* (RR, $2n = 16$) possess several desired traits, including resistance to Botrytis leaf blight and downy mildew (Abdelrahman et al. 2014). Similarly, *Alliumfistulosum* (AF) exhibits several important agronomical traits for onion improvement (Matsuse et al. 2022), thus great attention has been given to the introgression of *A. fistulosum*genes to *A. cepa*. However, the interspecific hybrid is largely sterile, and heteromorphic bivalents are present (Emsweller and Jones 1935; Albini and Jones 1990). In addition, the backcross (BC_1) of the interspecific hybrid

with *A. cepa* usually yields a small progeny, due to nucleo-cytoplasmic incompatibility (van der Valk et al. 1991). Using *A. roylei* as a bridging species helps to circumvent these problems. Hence, *A. cepa* (CC) × *A. roylei* (CR), *A. cepa* × *A. fistulosum* (CF), and *A. fistulosum* × *A. roylei* (FR) (Khrustaleva and Kik 1998) were bridge-crossed with (CC × FR) where *A. Cepa* served as the female parent and *A. roylei* as a male parent (Khrustaleva and Kik 1998). Thereafter, genome organization of the interspecific hybrids and trihybrid population were analyzed using multicolor GISH (Khrustaleva and Kik 1998).

In a follow-up study, trihybrid genotypes from the CC × RF population where only one homolog of a chromosome pair underwent interspecific recombination, were used for GISH analysis of chromosomes 5 and 8 recombinants. Visualization of recombination points and the physical positions of recombination were integrated into amplified fragment length polymorphism (AFLP) linkage maps of both chromosomes, thus concluding that in *Allium,* recombinations predominantly occur in the proximal half of chromosome arms. Of the *Pst*I/*Mse*I markers, 57.9% are located near the centromeric region, thus suggesting genes' presence in this region (Khrustaleva et al. 2005).

Investigations of trihybrid 'CC × RF' population for root traits inheritance revealed quantitative trait loci (QTLs) for the rooting system, implying that breeding for an enhanced rooting system in onion is feasible (De Melo 2003). Analyzes of trihybrid 'CC × CF' population for the genetic background for response to arbuscular mycorrhizal fungus *Glomus intraradices* revealed that the amalgamation of three genomes increases the genetic variation for plant development and the mycorrhizal reaction (Galván Vivero et al. 2011). On linkage group 9, one QTL for the number of stem-borne roots of mycorrhizal plants was discovered, which was connected with *A. fistulosum* alleles. This QTL co-segregated with QTLs for mycorrhizal and nonmycorrhizal plant average performance and total dry weight. Another QTL for Fusarium basal rot (FBR) resistance from *A. roylei* was identified on a distal region of chromosome 2, and one QTL from *A. fistulosum*was identified on the long arm of chromosome 8 (Galván Vivero 2009). These QTLs showed an additive effect and together accounted for 31 and 40% of the total variation for FBR incidence and severity at harvest; and 31 and 29% after storage, respectively.

3 Genomes

Plant cells have three genomes, mitochondrial, plastid, and nuclear. The number of genome copies per organelle depends on the cell type, the age of tissue, and species. Hence, each *Arabidopsis thaliana* (L.) Heynh cell has two copies of the nuclear genome (gDNA) (Lutz et al. 2011). The number of mitochondria and plastid DNAs (mtDNA, and ptDNA, respectively), however, vary with cell types. *Arabidopsis*root cells have ~400 mtDNA (Kato et al. 2008), whereas maize anther cells have a 20 to 40-fold higher number of mtDNA (Warmke and Lee 1978). In *Arabidopsis* and sugar beet, the copy number of ptDNAs remains at ~1700 per a single gDNA molecule, and the ratio of ptDNA to gDNA remains constant even as the ploidy level of the cell changes (Lutz et al. 2011).

3.1 Chloroplast Genome

The chloroplast (cp), which evolved from photosynthetic bacteria, is the primary organelle responsible for carbon fixation and photosynthesis in green plants (Cho et al. 2015). Most angiosperms have maternally inherited cps genomes and genetic information (Song et al. 2017). The evolutionary conserved genome architecture and gene content assisted in the creation of genetic markers for DNA barcoding, molecular identification, phylogenetic classification, and genetic resource and breeding screening. (Hu et al. 2016). The *Allium* cp whole-genome DNA sequencing initiation (von Kohn et al. 2013) resulted in cpgenomes sequencing of *A. obliquum* L., *A. prattii* C. H. Wright, *A. victorialis* L. Sp. Pl. 1: 295. 1753, *A. cepa*, and *A. sativum* (http://www.ncbi.nlm.nih.gov/genome/organelle/). Recently, the cp genomes of *A. tuberosum* Rottl. ex Spreng., *A. fistulosum*, *A. sativum,* and *A. cepa* have been sequenced using NGS technologies (Huo et al. 2019), and comparisons with cp genomes of *A. cepa* CMS-T and CMS-S, *A. victorialis, A. obliquum*, and *A. prattii* revealed that the length of cp DNAs ranged from 152 (*A. obliquum*) to 154 kb (*A. prattii*) and that the genomic structure and gene organization are well conserved (Huo et al. 2019).

The *Allium* cp genome contained large and small single-copy regions (LSC and SSC, respectively) separated by large inverted repeats (IRs) (Fig. 2). The nine cp genomes had typically quadripartite structures, with two IRs (ranged from 26,370 to 26,564 bp) splitted by the LSC (81,588 to 83,392 bp) and SSC (17,853 to 18,066 bp) regions (Huo et al. 2019) (Fig. 2).

Furthermore, all Allium cp genomes had a similar gene arrangement and content, with 140–141 genes in the IR regions, including 8 rRNA genes, 5–10 pseudogenes, 37–38 tRNA genes, and 88–89 protein-coding genes (Huo et al. 2019) (Fig. 2). The GC copy number of nine complete cp genomes was very similar in each region, including the entire cp genome, LSC, IR, SSC, coding sequences (CDSs), rRNA, tRNA, and pseudogene. The highest was observed in rRNA (>55%) and the lowest in SSC (>29%). The numbers and distributions of 3 repeat types in the 9 *Allium* cp genomes, including 394 repeats with 131 tandem repeats, 154 dispersed repeats, and 109 palindromic were similar and conserved. The number of simple sequence repeats (SSRs) varies between the nine *Allium* genomes, ranging from 73 in *A. tuberosum* to 96 in *A. cepa*. CMS-N and CMS-T (Huo et al. 2019). In the phylogentic analysis of the genus *Allium*, nine accessions were separated into two sister clusters. The first cluster comprised *A. prattii* and *A. victorialis*; the second cluster comprised seven entrees, in which *A. cepa* CMS-T and CMS-N were grouped in a sister branch and then clustered with *A. fistulosum*, *A. obliquum*, *A. cepa* CMS-S, *A. sativum*, and *A. tuberosum* (Huo et al. 2019).

3.2 Mitochondrial Genome

Scheffler (2008) stipulates that the plant mitochondrial genome harbors important information, such as mode of gene expression, organizational diversity, evolution, and nuclear-cytoplasmic interactions. Collectively these make the mitochondrial

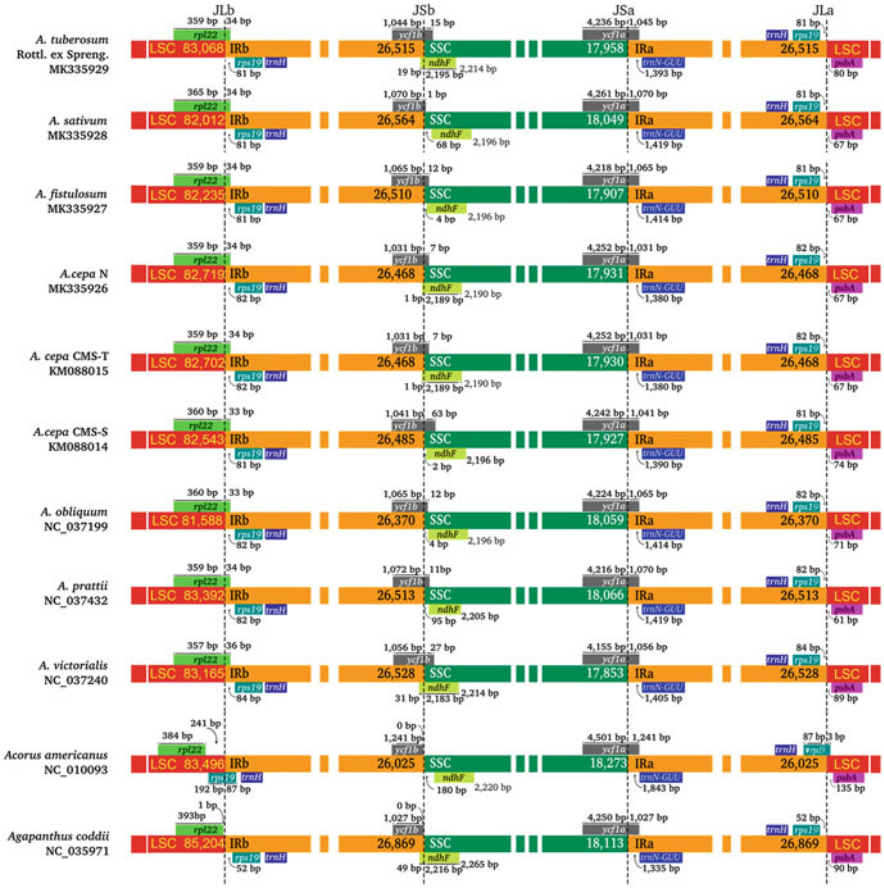

Fig. 2 Comparison of the large single copy (LSC), inverted repeat (IR), and small single-copy (SSC) boundary regions among the nine chloroplast genomes of different *Allium* species. The numbers indicate the distances from the end of the gene to the boundary sites. (This figure is adopted from Huo et al. 2019 after modification)

genome one of the most interesting genomes to molecular biologists and plant genetics. Plant mitochondrial genomes typically have many long and short repeated sequences and intra- and intermolecular recombination may create various DNA molecules in this organelle, and recombination may create a novel gene that causes CMS (Tsujimura et al. 2019). The complete onion mitochondrial genome sequence was reported for a CMS-S inbred line (Kim et al. 2016), of which ~10% consisted of repetitive sequences with short repeats of <100 base pairs. Additionally, the gene encoding cytochrome c biogenesis protein ($ccmF_N$) was split into two genes (Kim et al. 2016), as recorded in 30 other *Allium* species [REF]. In a follow-up study, comparative analysis of mitochondrial genome sequences of two recently diverged cytoplasms CMS-S and CMS-T-like resulted in the identification of *orf725*, a

chimeric gene consisting of *cox1* with other sequences, as the casual gene responsible for CMS in onions (Kim et al. 2018). In addition, CMS-T-like cytoplasm has recently diverged from the normal cytoplasm by the introduction of *orf725* (Kim et al. 2018). More recently, NGS sequencing of the mitochondrial genome of the bulb onion variety 'Momiji-3' possessing CMS-S-type cytoplasm revealed that the three circles as a result of recombination. In addition, mitochondrial genome structure was visualized using pulsed-field gel electrophoresis (Tsujimura et al. 2019). Further, mapping the transcript data to mitochondrial genome indicated that a new functional gene was absent from the 'Momiji-3' mitochondrial genome f and confirmed *orf725* candidacy gene for CMS. Recently, Hui et al. (2020) published the complete sequence of the onion's yellow stripe mutant mitochondrial genome. Compared with normal onions, 556 single nucleotide polymorphisms (SNPs), 279 small indel numbers were detected, out of which 14 SNPs and two small indels in the exon region affected the translation protein. It should be noted, however, that studies on purified *Allium* mitochondrial DNA have not yet been performed thus the number of differences between onion genotypes remains unclear.

3.3 Nuclear Genome

A study of *Allium* gDNA in 42 indicated that 4C nuclear DNA contents ranged between 41.19 and 142.78 pg, irrespective of the basic chromosome number, ploidy, or taxonomic group (Labani and Elkington 1987). Similarly, there was no correlation between the proportion of the C-banded region in the karyotype and the increase in DNA nuclear content. For example, *A. ursinum* L. has the largest DNA content of 71.39pg/4C DNA/genome but showed the lowest proportions of C-banded chromosomal region in the genus, while *Allium* species with moderate DNA amounts (21.11–42.45 pg)/4C DNA/genome showed the highest proportions of C-banded chromosomal region (Vosa 1976; Al-Sheikh Hussain 1977).

In general, DNA amounts in *Allium* species showed high divergence. For instance, the DNA values (2C) in triploid *A. carinatum* L. vary between 32 $\pm$ 67 and 50 $\pm$ 28 pg (Nagl and Fusenig 1979; Labani and Elkington 1987) and in leek between 24 $\pm$ 1 and 60 $\pm$ 58 pg (Ranjekar et al. 1978; Labani and Elkington 1987). Such contradictory data highlighted a need for clarification about the reliability of the nuclear DNA values published in the *Allium* genus.

Baranyi and Greilhuber (1999) reported that the 2C DNA values of the investigated *Allium* species were normally distributed, and only 29 of the 60 2C values published deviate less than 10% from the above results thus highlighting a need for improving a general agreement in the standardization and preparative procedures of cytophotometric genome size determination in *Allium* species.

The nuclear DNAs of two onion bacterial artificial chromosomes (BACs) were measured in order to study the existence and distribution of repetitive sequences as well as to assess gene densities (Jakše et al. 2008). The full sequences from two BACs were AT-rich (64.8%) and demonstrated lengthy tracts of degenerated retroviral elements and transposons, which were similar to those found in bigger plant

genomes. An estimated mean density of one gene per 168 kb was obtained from 499,997 bp of onion nuclear DNA, which is among the smallest reported to date. In comparison to random shotgun reads, methyl filtration reduced the frequency of anonymous sequences from 82% to 55% while increasing nonorganellar protein hits from 4% to 42%. (Jakše et al. 2008). Ricroch et al. (2005) evaluated the genome size of 30 *Allium* species including major vegetable crops and their wild allies. The 2C DNA value of gDNA was measured and compared with data derived from the angiosperms (http://www.rbgkew.org.uk). Overall, genome size (1C DNA) values varied from 7 pg in *A. altyncolicum* to, 31.5 pg in *A. ursinum*, showing 3.3-fold variation and a coefficient of variation of 27.4%. The GC content, evaluated in 24 accessions representing 23 *Allium* species, displayed values ranging from 38.5% in leek to 41.2% in *A. cernuum*, with a median value of 39.9% (Ricroch et al. 2005). Using different molecular markers, the comparison of molecular phylogenies led Fritsch and Friesen (2002) to propose a new idea for the classification of *Allium*, with 67 sections and 14 subgenera. A variation in cytogenetic characters such as nuclear DNA amount and chromosome numbers, when compared to the classification of the genus *Allium*, does not reveal clear discontinuities between the taxonomic groups (Ohri et al. 1998); but the variation mirrors the great diversity observed in morphology, life form, ecology, and breeding systems (Hanelt 1990).

4 Linkage, Cytogenetic, and Physical Mapping

The initial efforts have been succeeded by the construction of an *Allium* species genetic map using restriction fragment length polymorphism (RFLP) markers of the intraspecific onion cross 'BYG15-23 × AC43' (King et al. 1998). This map was subsequently extended with the SNP, and SSR markers, and homologs of transposable elements derived from the sequencing of expressed sequence tag (EST) in onion (Kuhl et al. 2004; Martin et al. 2005). These markers enabled partial map constructions in other intraspecific onion crosses to develop the map-based genetic analyses of various traits, including fertility restoration and bulb color development (Gokce et al. 2002; McCallum et al. 2006; Khar et al. 2008). More recently, another genetic map based on *A. fistulosum* genomic SSR markers and onion EST-derived SNP and SSR markers, providing further insight into comparative studies between the genomes of the two crops (Tsukazaki et al. 2010). The key resource that enabled alignment of *Allium* genetic maps to physical chromosomes and facilitated comparison between species was the complete set of *A. fistulosum-A. cepa* monosomic addition lines developed by Shigyo et al. (1996). These were initially applied to anchor AFLP-based maps in the interspecific *A. cepa*×*A. roylei* cross (van Heusden et al. 2000) and subsequently to anchor the 'BYG15-23 x AC43' map (Martin et al. 2005) and anchor SSR-based maps in *A. fistulosum* (Tsukazaki et al. 2008) to physical chromosomes and more recently to assign many more onion EST-derived anchor markers used in *A. fistulosum* maps (Tsukazaki et al. 2010). Further, a large number of molecular and phenotypic markers associated with many candidate genes coding for valuable economic traits, have also been assigned to A. *cepa* chromosomes (Martin et al. 2005; Masuzaki et al. 2006;

Yaguchi et al. 2008), providing an important guide for functional and QTL studies. Recently, RobustDb, a generic online genomics database that presented information mainly for garlic maps led to the development of marker data (Bhasi et al. 2010). Likewise, the VegMarks database (http://vegmarks.nivot.affrc.go.jp/) contained detailed information regarding *A. fistulosum* markers. A total of 107 markers comprising three *A. fistulosum* genomic SSRs, 31 SNP markers, and the 73 additional onion EST-SSRs derived from onion ESTs were evaluated in the population previously used to construct an AFLP-based linkage map (McCallum et al. 2012). Additionally, an interspecific *A. cepa* × *A. roylei* map was augmented with additional genetic markers to increase correspondences among *Allium* maps. Then, 11 linkage groups spanning one Morgan were formed using LOD 5 cutoff. Using the monosomic addition set, the anchor *loci* were assigned and mapped in the interspecific cross with the consequent additional landmarks for aligning genetic linkage maps in *A. cepa* and *A. fistulosum*. The AlliumMap database (http://alliumgenetics.org.) contains 512 correspondences between markers in various *Allium* maps (McCallum et al. 2012). This database represents an integrated point to access details of the genetic markers and sequence resources employed across multiple studies in cultivated *Allium* to resolve common questions of crop evolution and economic trait regulation across these major *Allium* crops. The genotyping-by-sequencing (GBS) provides a high degree of complexity reduction followed by synchronized SNP discovery and genotyping for species with complex genomes (Jo et al. 2017). GBS analysis conducted on F_2('NW-001' X 'NW-002') population, provided 1,851,428 SNPs. After filtering, 10,091 high-fidelity SNP markers that satisfied the criteria of segregation ratio were used to construct an onion genetic map (eight linkage groups) and spanned a genetic length of 1383 centiMorgans (cM) with an average marker interval of 8.08 cM. The newly developed linkage map will be valuable tools for the genetic mapping of important agronomic traits and marker-assisted selection in onion breeding programs worldwide. Likewise, the F_2[doubled haploid (DH) 'H6' (red bulb) and the inbred line 'SP3B' (yellow bulb)] population was used to construct another SNP-based genetic linkage map to identify the QTLs associated with the total anthocyanin content of onion bulbs using GBS analysis (Choi et al. 2020). Hence, an onion genetic map with eight linkage groups consisting of 319 GBS-based SNP loci and 34 high-resolution melting markers was constructed (Choi et al. 2020). Based on this linkage map, two QTLs, *qAC4.1* and *qAC4.2*, for anthocyanin content and one major QTL, *qAS7.1*, for anthocyanin synthesis were identified. This major QTL located on chromosome 7 with a phenotypic variation of 87.61% can be putatively identified as *dihydroflavonol 4-reductase* (*DFR*) gene responsible for bulb coloring in onion. Recently, an ultra-high-density linkage map of transcriptome-based unigene markers was assigned on *A. cepa* chromosomes using RNA sequence data from 96 lines of the F_2 mapping population (a doubled haploid shallot 'DHA' × a doubled haploid onion 'DHC') (Fujito et al. 2021). SNPs with at least four reads on 25,462 unigenes were anchored on eight *A. cepa* chromosomes. In total, multiple SNPs were identified on 22,184 unigenes and a single SNP site on 3278. The chromosome marker information was made public via the web database *Allium* TDB (http://alliumtdb.kazusa.or.jp/), which is valuable in genome sequencing and useful for validation of the original genetic map in *Allium.* In

a recent study, an ultrasensitive dual-color Tyr-FISH technique was developed to construct a reliable and easy method for in situ mappings of short unique DNA sequences on onion chromosomes (Kudryavtseva et al. 2021), which allows more accurate determination for physical distances between markers and can be applied for the faster integration of genetic and cytogenetic maps. For instance, Tyr-FISH was applied to physically locate molecular markers tightly linked to the nuclear male-fertility (Ms) restoration locus on onion (Khrustaleva et al. 2016). Relatively short genomic amplicons and a cDNA clone were successfully visualized on chromosome 2 near the centromere, a region of low recombination, which partially explained the identified molecular markers tightly linked to the Ms. locus in different segregating progenies (Khrustaleva et al. 2016). Likewise, Tyr-FISH mapping on *A. cepa* chromosomes was performed using EST-clones API20 and API66, previously mapped in the linkage groups corresponding to *A. cepa* chromosomes1 and 5, respectively (Romanov et al. 2014). Results indicated that API66 possesses insert with high homology to the sucrose transportase gene, and API20 – to the light harvesting-like protein 3 encoding gene (Romanov et al. 2014). In addition, Tyr-FISH analysis of EST-clone API66 revealed 25 hybridization sites on the mitotic metaphase chromosomes of *A. cepa*, and the signals were dispersed along all chromosomes (Romanov et al. 2014). It is worth noting that the sucrose transportase gene belongs to a large superfamily of genes in plants, which explained multiple sites of API66 hybridization (Romanov et al. 2014). Future research involves the creation of more molecular cytogenetic markers based on mapping chromosome-specific repeats and genes/markers can be further applied in onion breeding and genome assembly at the chromosome level. Expansion of FISH applications in plants with the development of new technologies as oligo-FISH mapping, CAS-FISH for living cells, RNA-FISH for measuring gene transcription, and a haplotype-specific FISH for crossing over visualization will be gold stand method for mapping physical chromosomes and detection their organization.

5 Novel Analysis Methods for Large Genome Size

Irrespective of ploidy, genome sizes refer to the amount of DNA enclosed in a haploid genome set expressed in terms of the number of base pairs (1 kb = 1000 bp), megabases (1 Mb = 1,000,000 bp), the DNA mass in picograms (1 pg = 10^{-12} g = 1000 Mb of DNA), or as C-value ('C' stands for constant referring to the fact that the genome size is constant from cell to cell in a given organism), equals to the mass of DNA in Pg) in a haploid set of chromosomes (Maloy and Hughes 2013), regardless of ploidy level which means one-third or one-fourth of the total mass of DNA in the cell (Maloy and Hughes 2013).

The genome size depends on differences in the rates at which insertions and deletions (indels) occur, transposon activity, segmental duplications, and the efficiency of natural selection in eliminating or promoting such changes (Sung et al. 2016). Large genomes have higher mutational liability, even in noncoding areas,

thus, a large fraction of noncoding regions is likely to evolve neutrally concerning indels (Mueller 2015).

Bulb onion has a large haploid genome size of 16,400 Mb and unique telomeric sequences with the lowest GC content (32%) among angiosperms (Abdelrahman et al. 2020a, b; Shigyo et al. 2018), yet it is the largest of all diploid crops (Brenchley et al. 2012; Marcussen et al. 2014). Enormous genome-size differences exist among closely related *Allium* species. For example, bulb onion has 28% more nuclear DNA than *A. fistulosum* and 7% more than garlic nuclear DNA.

The bulb onion genomic fragments cloned into BACs demonstrated that most sequences were similar to retro-element and transposons, indicating that the onion genome exhibited low gene densities and high frequencies of repetitive DNA as major components of large chromosomes (Suzuki et al. 2001). The C_oT reannealing kinetics indicated that about 40% of the onion genome is highly repetitive ($>1000\times$ copies) and 40% has 100–1000 copies (Stack and Comings 1979). Overall, at least 95% of the *A. cepa* genome consists of repetitive sequences, most of which are dispersed repeats (Shibata and Hizume 2002). Due to the size of the genome and its repetitive nature, developing an onion reference genome assembly is challenging.

Although the accessibility of the structural genomic resources in *Allium* species is limited, using next-generation sequencing (NGS; e.g., Roche, Illumina, and ABI Solid platforms) technologies and large computational abilities, sequencing, assembly, and annotation of large genomes has become feasible. The advantages of third-generation sequencing (TGS) technologies such as Pacific Biosciences over short-read sequencing as Illumina's HiSeq, NovaSeq, NextSeq, MiSeq instruments, and Ion Torrent sequencers (Thermo Fisher Scientific) include greater read lengths, thus facilitating the assembly of large and complex genomes such as onion (Abdelrahman et al. 2018a, b), i.e., reads of up to 600 bases (Goodwin et al. 2016), and >10 kb (Rothberg et al. 2011), respectively. Consequently, improved *de novo* assembly, mapping certainty, transcript isoform identification, and detection of structural variants become feasible (Depledge et al. 2019). Concomitantly, the ever-diminishing computational power costs and the growing availability of on-demand cloud-based computing steadily increase assembly and annotation efficiency. Hence, large-scale and cost-effective sequencing, assembly, and annotation of onion DNA are becoming feasible (Abdelrahman et al. 2020a, b).

The three key approaches to large genome sequencing like the onion genome include the shot-gun sequencing, where DNA is fragmented into short reads, which are then sequenced. Since a large proportion of onion reads are repeated sequences, shot-gun sequencing is unsuitable for its large and complex genome. Suzuki et al. (2001) were the first to Sanger sequence large genomic fragments cloned into BACs. Two entire BAC clones, and the random ends of genomic fragments cloned into BACs, yielded 298 kb of random-end sequences and 202 kb from the entire BAC clones (Jakše et al. 2008), with AT content of 35.7%, which is close to the estimate of 32% by Kirk et al. (1970). Additionally, only 5% of these random genomic sequences showed significant similarities to nonorganellar proteins, 25% were highly similar to transposons or retrotransposons, and 70% showed no significant hits to the databases and were primarily degenerated retroelements (Jakše et al.

2008). Additional sequence survey of onion random genomic sequences was conducted using DNA isolated from DH line 15,197. The DNA was trimmed, and random fragments were sequenced using Sanger and 454 technologies, generating 6590 reads, among them, 82% had no significant hits in the databases, 4% matched nuclear-encoded proteins, and 14% matched transposons (Jakše et al. 2008).

The second approach efficiently samples expressed regions. Sequencing random cDNAs thus revealed the collection of genes (the transcriptome) expressed in any given tissue, at a specific developmental stage, or after treatment (Abdelrahman et al. 2017a, b, c, 2020a, b). However, the normalization of the cDNA reduces the frequencies of highly expressed genes and increases the number of sequencing reads from rarer transcripts (Abdelrahman et al. 2017a, b, c).

A free access web-based tool named *Allium* TDB (http://alliumtdb.kazusa.or.jp/) contains several transcriptional data of *Allium* species. Likewise, the transcriptome sequencing on vegetative and reproductive tissues of homozygous DH CUDH2107 was used to develop a multi-organ reference transcriptome catalogue (Khosa et al. 2016). In general, the 271,665 contigs of transcripts were generated using the Trinity pipeline. This dataset was analyzed for gene ontology (GO), and the bulb onion transcripts were grouped into 95 functional groups, and among which Binding Domains the most abundant GO term followed by Carbohydrate-Binding (Khosa et al. 2016).

The third approach involves enrichment for lower-copy regions by removing repetitive DNAs, and reduced representation sequencing involves selection against methylated DNA (Rabinowicz et al. 1999). In bulb onion, the sequencing of these fragments is an efficient approach to enrich genic regions in its enormous genome. Hence, the complete onion DH 15197 sequencing of methyl-filtered DNA fragments revealed that among the 2712 methyl-filtered fragments, 3% matched transposons, 55% were anonymous, and 42% were similar to nonorganellar proteins (Jakše et al. 2008).

The first insight into the genome sequencing of *A. cepa* is now ongoing through the SEQUON project (http://www.oniongenome.net) using Illumina HiSeq 2500, intending to sequence the onion nuclear DNA and provide de novo genome assembly and ab initio annotation thus applied to the doubled haploid onion line DHCU066619, for a whole-genome shotgun sequencing of an onion genome (Finkers et al. 2021). Initially, Illumina HiSeq 2500 sequencing of 3 small libraries yielded 769 Gb sequence data, whose analyses provided an estimated genome size of ~13.6 Gb. Secondly, the MaSurCa based assembly resulted in 10.8 Gb in 6.2 M contigs with a contig N50 of 2.7Kb. This assembly was further scaffolded using 18.1 M PacBio RS II reads. Finally, the hybrid Illumina/PacBio assembly was further improved using Dovetail Chicago and subsequent HiRise scaffolding, thus indicating no misassemblies in the Illumina/PacBio hybrid contigs. The combination of these 3 technologies resulted in an assembly of 14.9 Gb in 92.9 K scaffolds with a scaffold N50 size of 436Kb. With an estimated genome size of 164 Gb/1C. To further organize genome assembly, three intraspecific genetic linkage maps (Duangjit et al. 2013; Fujito et al. 2021; Choi et al. 2020) and two interspecific genetic linkage maps (Scholten et al. 2016) were used to anchor scaffolds into pseudomolecules using AllMaps (Tang et al. 2015). A final assembly of 14.9 Gb with an N50 of 461 Kb. out of which, only 2.2 Gb (~6.7%) was ordered into

8 pseudomolecules using 5 different genetic linkage maps (Finkers et al. 2021), whereas the remaining of the genome is presented in 89.8 K scaffolds. Additionally, 72.4% of the genome was successfully identified as repetitive sequences consisting mainly of retrotransposons. The ab initio gene prediction indicated 540,925 putative gene models, which is far more than expected, possibly due to the presence of pseudogenes. Of these models, 86,073 showed similarity to UNIPROT published proteins. No gene-rich regions were found, and most genes were uniformly distributed across the genome (Finkers et al. 2021). The analysis of synteny with garlic showed collinearity but also major rearrangements between both species. This assembly is the first high-quality genome sequence available for the study of onion and will be a valuable resource for further research.

Similarly, garlic chromosome-level reference genomes and annotations by combining SMRT sequencing with PacBio Sequel Nanopore, 10x Genomics, Illumina HiSeq paired-end, and high-throughput chromosome conformation capture (Hi-C) sequencing resulted in a genome of 16.24 Gb (contig N50 length = 194 kb, scaffold N50 length = 725 kb (Sun et al. 2020). Then, 252.5-Gb of long reads obtained from Nanopore sequencing were mapped to the assembly. Thereafter, the Hi-C technology was applied to assemble a chromosome-level genome. A total of 6.34 billion reads from four Hi-C libraries were used, and approximately 87.5% of the assembled sequences were mapped to 8 pseudomolecules with a super-scaffold N50 length of 1.69 Gb (Sun et al. 2020). The final assembly covered 96.1% of the garlic genome (approximately 16.9 Gb), as estimated by the k-mer analysis. In addition, a total of 38 alliinase genes were expressed in various tissues, out of which, 4 tandem duplicated genes (*Asa5G05557.1*, *Asa5G05559.1*, *Asa5G05560.*1, and *Asa5G05561.1*) produced highly abundant transcripts in bulb tissues (Sun et al. 2020). In addition, their expression levels increased during bulb growth and expansion, suggesting that these four genes exhibited functional redundancy and may be responsible for the biosynthesis of allicin at a high concentration in garlic bulbs (Sun et al. 2020).

6 Metabolomic and Transcriptomic Landscapes of *Allium* Crops in Response to Environmental Stress

Because of the high yield losses in principle crops caused by global warming in addition to the rapidly increasing consumption of food, there is an urgent need to boost food security (Abiala et al. 2018; Zhang et al. 2019). Nevertheless, there have been few studies that address the Allium metabolome and transcriptome profiling in the context of environmental stress, so the Allium international community may need to make more efforts in this area. Transcriptome analysis of commercial brown onion cv. 'Orlando' inner and outer scales in response to heat stress revealed that oxidation and lipid metabolism pathways, in addition to cell-wall adjustment, were abundantly expressed in the onion outer scale under heat stress (Galsurker et al. 2018). However, defense response-related genes, such as those gene that encodes antioxidant activities, heat shock proteins, or even the manufacturing of osmoprotectant metabolites, were highly stimulated in the inner scale. (Galsurker et al. 2018). These transcriptomic data

led to the creation of a conceptual framework that proposes sequential processes for the advancement of desiccation and browning on the outer scale versus processes associated with defense response and high temperature tolerance in the inner scales (Galsurker et al. 2018). Transcriptome sequencing of cold-tolerant and cold-sensitive onion genotypes under freezing and cold conditions revealed that freezing and cold stresses significantly induced numerous genes in tolerant lines compared to susceptible genotypes (Han et al. 2016). Among these transcript, genes-encoding hypothetical proteins, heat shock proteins (HSPs), zinc finger (ZIP) proteins, and CBL-interacting protein kinase (CIPK) , as well as a subset of transcription factors (TFs), especially TFs that function as activators including dehydration-responsive element (DRE)-binding (DREB), CBL, MYB, bZIP, zinc finger of *Arabidopsis thaliana* (ZAT), HSPs, and basic helix-loop-helix (bHLH) were radically changed during freezing and cold stress conditions (Han et al. 2016). Likewise, a genome-wide transcriptome profiling analysis of garlic under cold stress revealed that enzyme-encoding genes, which knowingly enriched in the "proteasome" pathway such as γ-glutamyltranspeptidase-, δ-aminolevulinic acid dehydratase-, and alliinase-encoding genes are conceivably implicated in garlic discoloration under low temperature stress (Li et al. 2018). These stress-responsive genes could be to blame for garlic discoloration caused by low temperatures (Li et al. 2018). Because environmental stress impacts plant growth, identifying stress biomarkers is an important prerequisite for breeding stress-tolerant crops. In this respect, shallots are recognized as an important genetic resource for the breeding of common onions due to their high versatility to subtropical and tropical climates (Abdelrahman et al. 2015). The bulb onion double haploid, shallot double haploid, and its F1 hybrid were checked using LC-QqQ-MS. There were 113 targeted metabolites found in total, and the principal component analysis and volcano plot analysis clearly revealed genotype-specific metabolites that can be used as metabolic markers of environmental tolerance (Abdelrahman et al. 2015). Likewise, incorporated transcriptome and metabolome analysis of *A. fistulosum* with extra shallot chromosome 5A disclosed an accumulation of many flavonoids that are important in abiotic and biotic stress tolerance (Abdelrahman et al. 2019). The increase in flavonoid pool in A. fistulosum with extra chromosome 5A from shallot was also coherent with the increased expression of many upstream and downstream flavonoid biosynthesis and regulatory genes (Abdelrahman et al. 2019). The above study proved that shallot can be used as a genetic resource to enhance onion stress tolerance. Similarly, Zhang et al. (2018) used transcriptome analysis of two contrasting dark-red and white onion cultivars to discover that both *flavonoid 3′,5′-hydroxylase* (*F3′,5′H*) and *dihydroflavonol 4-reductase* (*DFR*) genes play important roles in the biosynthesis of dark-red bulbs, and that flavonol synthase (*FLS*) and *DFR gene* expression levels could respond to prevent blue coloration. In addition, the positive variation in the F3′,5′H/F3′H ratio also affects onion bulb color diversity (Zhang et al. 2018). The metabolic characteristics in the bulbs of eight Indonesian shallot landraces and seven short-day and three long-day bulb onion cultivars have been identified using LC-Q-TOF-MS/MS in order to generate new genetic materials for the development of a novel bulb onion cultivar derived from intraspecific hybrids with beneficial agronomic traits from shallots (Abdelrahman et al. 2020a, b). The results showed that free and

conjugated amino acids, flavonoids (particularly metabolites containing flavonol aglycone), anthocyanins, and organic acids were among the top metabolite factors that were largely correlated with shallot landraces when compared to bulb onion cultivars (Abdelrahman et al. 2020a, b). Furthermore, the measurement of 21 amino acids using traditional HPLC analysis revealed that shallots had elevated concentrations than bulb onions (Abdelrahman et al. 2020a, b). The current study found that shallots reprogrammed their metabolism to accumulate more amino acids and flavonoids as an adaptation to incredibly hot tropical environments.

7 Prospects

Omics' techniques such as transcriptomics, proteomics, metagenomics, metabolomics, and genomics have the potential to provide new avenues of research as well as advancement for Allium crops with restricted genome sequence knowledge. NGS systems have lately been regularly used to reveal markers such as SSRs and SNPs in numerous bulb onion populations. For example, a high-throughput genotyping method, such as diversity arrays (DArTseq), was used to analyze population dynamics in a large garlic population with 417 accessions. (Egea et al. 2017). Likewise, SNPs were discovered using the double digest restriction site-associated DNA sequencing (ddRAD-seq) method in inbred lines of Korean short-day onion, allowing for structure analyses and genetic relationship studies (Lee et al. 2018). Even though genomic resources in Allium species have been limited to date, the latest rapid advancement of NGS technology has rendered whole-genome sequencing much easier than previously. The genome sequencing of *A. cepa* is now ongoing through the SEQUON project (http://www.oniongenome.net) by using Illumina HiSeq 2500 sequencer. More recently, HiFi reads [a type of data produced using the circular consensus sequencing (CCS) mode on one of the PacBio Sequel Systems], provide base-level resolution with >99.9% single-molecule read accuracy. HiFi reads can accurately detect all types of variants, from single nucleotide to structural variants, with high precision and recall and phase haplotypes, even in hard-to-sequence regions of complex genomes such as onion.

Transcriptome sequencing is an efficient approach to generate sequence information from expressed regions of the genome and has been widely used in the Alliums. Several workers use RNA-seq for studying organ development, marker discovery, male sterility, flavonoid biosynthesis, the abiotic stress response in different *Allium* species (Abdelrahman et al. 2015; Abdelrahman et al. 2019). In context, *Allium*TDB (http://alliumtdb.kazusa.or.jp/) contains many useful transcript libraries of root, stem, bulb, and leaves for various *Allium* species. Similarly, a draft reference transcript for onion, using long-read sequencing technology will help in whole-genome sequencing in Alliums (Sohn et al. 2016). A transcriptome catalogue for homozygous double haploid line 'CUDH2107' for understanding the genetic and molecular basis of various traits was developed (Khosa et al. 2016).

After the establishment of omics platforms, plant metabolism research has transitioned from the study of individual gene functions to metabolic system research.

Mass spectrometry (MS) is a major instrument that has high sensitivity and broad metabolite detection capabilities, thus facilitated the detection of hundreds of metabolites having diverse bioactivities in the alliaceous crops (Abdelrahman et al. 2020a, b, 2021a, b). In the future, the individual bio-resource-specific metabolic patterns can be used for molecular breeding of *Allium* crops while the broad metabolic profiles of *Allium* bio-resources can be used for integrated omics approaches. The integration of metabolomics and transcriptomics will provide insight into the molecular mechanism of *Allium* metabolite biosynthesis.

Image techniques such as GISH and FISH using fluorescent imaging systems are important approaches for *Allium* breeding and genetic studies, thus further developments in *Allium* imaging analysis are needed. Recently, the selection of fusarium basel rot-resistant onion was carried out using digital image analysis to quantify symptom development in the basal plate of dormant bulbs (Mandal and Cramer 2021). Analysis with confocal microscopy identified bright blue-green autofluorescence from *Fusarium oxysporum*-infected tissue, effectively differentiating diseased from healthy tissue. Visual scoring of the fusarium basel rot symptom was combined by stereo fluorescence microscopic images, captured using a green fluorescence protein dual filter to quantify accurately fusarium basel rot severity in the basal plate tissue (Mandal and Cramer 2021). The new developed method could be used for developing resistant cultivars for onion breeding programs in the near future.

Targeted genome-editing technologies, especially clustered regularly interspaced short palindromic repeats (CRISPR)/(CRISPR)-associated protein 9 (Cas9), have great potential to aid in the breeding of crops that can produce high yields under biotic/abiotic stress (Abdelrahman et al. 2018a, b). This is due to their high accuracy and low risk of off-target effects, compared with conventional methods. The use of the CRISPR/Cas9 system is commonly used for targeted mutagenesis in crop plants, including gene knockouts, modifications, and the activation and repression of target genes. However, there are no reports regarding genome editing in onion probably due to the complex genome structure with many repetitive sequences, affecting the efficacy of the CRISPR/Cas9 system. Genomic selection (GS) is being increasingly applied in plant breeding programs to enhance the genetic gain of economically important traits. For example, the GS scheme was proposed to prevent inbreeding depression in onions by avoiding the co-selection of closely related plants and combining the shortening of generation time (Sekine and Yabe 2020). Ten years of breeding programs to evaluate the efficiency of different selection schemes in onion, including general phenotypic selection, self-crossing phenotypic selection, general genomic selection, and inbreeding avoiding genomic selection were compared (Sekine and Yabe 2020). General GS with shortening of generation time yielded the highest genetic gains among the selection schemes, however, inbreeding depression increased rapidly in later years. The proposed GS combining shortening of generation time with updating of the prediction model was superior to the others in later years, as it yielded relatively high genetic gain while maintaining significantly low levels of inbreeding. These results suggested that GS can be beneficial in onion breeding, and an optimal scheme should be selected depending on the selection period.

8 Conclusion

In conclusion, the study of metabolome and cytoplasmic genomics of *Allium* holds significant promise in advancing our understanding of this plant genus. By analyzing the metabolites present in the cytoplasm and investigating the genetic information within the organelles, researchers can gain valuable insights into the biochemical pathways and genetic mechanisms that underlie various traits and processes in *Allium* species. This knowledge could have broad implications for agriculture, medicine, and biotechnology, potentially leading to improved crop yields, novel pharmaceutical compounds, and more sustainable farming practices. However, further research and collaboration are needed to fully unravel the complex interplay between metabolome and cytoplasmic genomics in *Allium* and unlock its full potential for practical applications.

Eggplant (*Solanum melongena* L.) Nutritional and Health Promoting Phytochemicals

Partha Saha, Jugpreet Singh, N. Bhanushree, S. M. Harisha, Bhoopal Singh Tomar, and Bala Rathinasabapathi

Contents

Abstract

Eggplant is one of the most important Solanaceous vegetable crops which has been cultivated in different continents of the world. The greatest diversity of landraces and cultivars is found in India, China, and several countries in the Southeast Asian region. Eggplant has various culinary and medicinal uses and a great phytochemical diversity defines these uses. Phenolic compounds in eggplant are excellent antioxidants. While numerous studies on eggplant anthocyanins showed their value as antioxidative and radical-scavenging compounds, more studies on potential medicinal properties are needed. Multiple studies on the identification and mapping of genes/QTLs for the contents of chlorogenic acid, solasonine, and solamargine indicate the possibility of breeding lines

specifically improved for these phytochemicals. Metabolomics, where high-throughput identification and quantification of metabolites are done using mass spectral methods, are increasingly applied to study crop plants. Eggplant metabolites have been profiled and attempts have been made to link metabolite profiles to fruit morphology and nutrition, drought stress, nutrient use efficiency, response to pathogens, and other desirable traits. This crop has emerged as a model system for improving health benefiting traits with additional yield components. Different nuclear genomes of the eggplant have been sequenced within the last decade. With the availability of high-quality chromosome scale genomes, it is now feasible to characterize the genomic diversity and evolutionary footprints of eggplant. The information of genome sequencing is very useful to assist breeding programs to develop new varieties via marker-based selection. In this chapter we have discussed the importance of eggplants, bioactive compounds present and their role, biosynthetic pathways and progress in genome sequencing and metabolomics. We have suggested effective strategies to improve the quality of eggplant cultivars of the future.

Anthocyanins · Chlorogenic acid · Crop breeding · Fruit quality · Nasunin · Solanum alkaloids · *Solanum melongena*

1 Introduction

Eggplant (*Solanum melongena* L.) is an important vegetable crop widely grown in many parts of the world for its immature fruit. More than 90% of production is in Asia and top producing countries are China, India, Egypt, Turkey, and Iran (Solberg et al. 2022). Eggplant and its wild relatives are grouped in the Leptostemonum clade of the Solanaceae (Weese and Bohs 2010; Särkinen et al. 2013) along with "spiny" Solanums. This crop is known as eggplant (US, Canada, Australia), brinjal (Indian subcontinent, Singapore, Malaysia, South Africa), aubergine (UK, Ireland), and Guinea squash (Southern US). The fruit of the eggplant contains numerous edible soft seeds that are bitter because of their alkaloid content. It is a rich source of vitamins, minerals, fibers, and other phytochemicals (Chlorogenic acid) which have medicinal properties (Saha et al. 2016).

Solanum melongena is native of "Indo-Chinese Center" (Taher et al. 2017) and is cultivated worldwide primarily in the tropical and subtropical regions and in temperate zone especially in the summer months or in greenhouses as off-season crop. Eggplant is known to have originated from the progenitor species *Solanum incanum* and *Solanum insanum* which have a wide distribution in India, Africa, the Middle East, and Southeast Asia (Aubriot et al. 2018; Ranil et al. 2017). A recent compilation indicated more than 19,000 accessions in various seed banks (Solberg et al. 2022). Figure 1 illustrates the species dispersal from Africa to Asia during eggplant domestication (Weese and Bohs 2010). Some of the variations in fruit shape, size, and color are shown in Fig. 2.

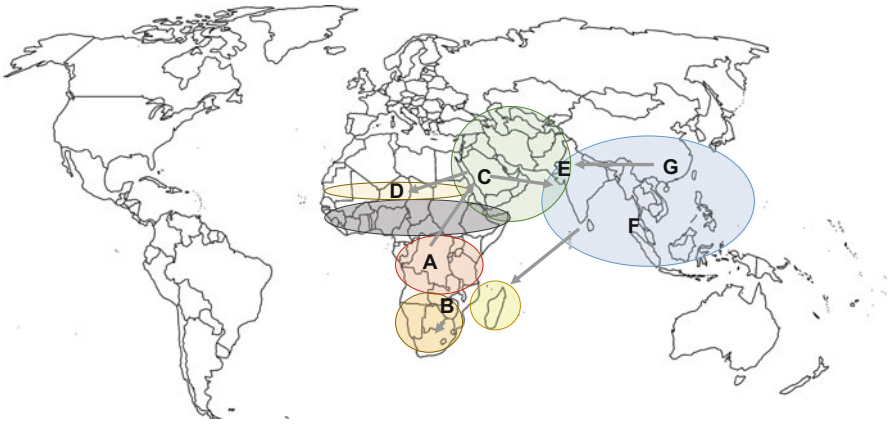

Fig. 1 Biogeography of *Solanum melongena* and related species. (Diagram adapted from Weese and Bohs (2010) and Aubriot et al. (2018)). *S. incanum* types are naturally present in regions marked A–D in eastern Africa and the Middle East and *S. melongena* types are distributed in regions marked E–H (India, China, Thailand, Korea, Vietnam, and Japan). Arrows indicate suggested directions of migration according to Weese and Bohs (2010) and Aubriot et al. (2018)

Fig. 2 Some of the variations in relative fruit size, shape, and color of immature fruit of eggplant. (Photo by B. Rathinasabapathi)

The greatest diversity of landraces and cultivars is found mainly in India, China, and countries in the Southeast Asian region. The secondary centers for this crop are in the Middle East and the Mediterranean region (Frary et al. 2007). Eggplant has been thought to be domesticated several times in Asia from *Solanum incanum*, in which human selection played a significant role. The primary traits involved in domestication process are selection for increased fruit size, decrease in prickliness, and fruit bitterness as compared to the wild progenitor species (Daunay and Hazra 2012; Meyer et al. 2012). The wild relatives *S. incanum* and another species recognized as *S. insanum* or *S. melongena insanum* have the phenotype of large spiny leaves and small, hard-textured green fruit. Species of *Solanum* that are used as

major or minor vegetables are shown in Table 1. Species of *Solanum* that are useful as sources of disease and pest resistance in eggplant breeding are shown in Table 2. A taxonomic key to the species of the eggplant clade is available in Knapp et al. (2013).

Table 1 *Solanum* species used as vegetables, their common names, distribution, and edible parts

Species	Common name	Distribution	Edible part(s)
S. aethiopicum	Molk tomato Golden apple	Tropical Africa	Leaves and immature fruit
S. americanum	Glossy nightshade	Central Eastern USA	Leaves and green fruit
S. gilo	Gilo, Jilo	Western Africa, Brazil	Fruit, shoot
S. hirsutissimum	Lulita	Central and South America	Mature fruit
S. incanum	Sodom apple	West Africa, India	Immature fruit
S. indicum	Indian nightshade	Southeast Asia	Fruit, leaves
S. integrifolium	Scarlet eggplant	Warm temperate, Subtropical Asia	Fruit
S. lycopersicum	Tomato	American Tropics	Fruit
S. macrocarpon	African eggplant	Subtropical and tropical regions, West and Central Africa	Fruit, leaves
S. melanocerasum	Garden Huckleberry, Wonderberry, Black nightshade	Warm temperate regions, Subtropical America and West Africa	Mature fruit
S. melongena	Eggplant, brinjal, aubergine	Warm temperate, Subtropical and tropical regions	Immature fruit
S. muricatum	Pepino, melon pear	Subtropical and tropical America	Mature fruit
S. quitoense	Naranjillo, lulo	Subtropical and tropical America	Mature fruit
S. sessiliflorum	Cocona	Northern South America	Mature fruit
S. torvum	Turkey berry	South American tropics	Immature fruit
S. tuberosum	Potato	Central and South America	Tuber

Table 2 Wild *Solanum* species as sources of resistance to pests and diseases (Swarup 1995)

Species	Source of resistance
S. melongena var. *insanum, S. integrifolium*	Bacterial wilt
S. incanum, S. indicum, S. integrifolium	Fusarium wilt
S. indicum, S. aculeatissimum	Verticillium wilt
S. xanthocarpum, S. nigrum, S. sisymbrifolium	Fruit rot
S. torvum, S. mammosum, S. khasianum	Spotted beetle
S. sisymbrifolium, S. aethiopicum	Root knot nematode
S. viarum, S. incanum, S. gilo	Little leaf

2 Eggplant as a Source of Food, Nutrition, and Health Promoting Compounds

Eggplant has various culinary and medicinal uses. Here, we summarize a variety of culinary uses for immature fruit of eggplant from different areas of the world. Eggplant is mainly used to prepare *Baingan ka Bhartha* or *Gojju*, stir fries and soups in India, *Yu Xiang Qiezi* and *Di San Xian* stir fries in the Chinese cuisine, *nasu dengaku* of Japan, *ratatouille* of the French cuisine, *moussaka* and *melitzanosalata* of the Greek, *baba ghanoush* of the Middle East, *nigvzianibadrijani* in the Caucasus and the *melanzaneallaparmigiana* of the Italian cuisine. Two species namely, *S. aethiopicum* and *S. macrocarpon* are commonly grown for the consumption of cooked leaves in Africa. Eggplant is a "low-calorie vegetable" due to its low energy density. But the presence of vitamins, minerals, proteins, fiber, and phenolic compounds in the fruit proves its beneficial value to human health (Frary et al. 2007). The nutritive value of eggplant is presented in Table 3. A comparative study on tomato, pepper, and eggplant showed that eggplant had greater levels of mineral nutrients potassium, magnesium, and copper, total sugars, and the antioxidant chlorogenic acid compared to pepper and tomato (Rosa-Martínez et al. 2021).

Besides, as a source of food, eggplant is used in traditional medicine to treat asthma, bronchitis, cholera and dysuria, skin-related problems, and in lowering blood cholesterol levels (Rotino et al. 2014; Meyer et al. 2014). Studies in rats suggested that eggplant could reduce the absorption of dietary cholesterol (Kritchevsky et al. 1975). However, small scale clinical trials on the potential of dietary eggplants in reducing serum lipid levels have shown either no or transitory effects only (Guimaraes et al. 2000; Praca et al. 2004). Donmez et al. (2020) showed hemorrhoid healing activity for the extracts of eggplant calyx in an animal model. Additional controlled clinical studies are needed to test efficacy and modes of action.

As other Solanaceous crops tomato, potato, and pepper, eggplant also contains glycoalkaloids such as solasonine and solamargine, which are known to have beneficial biological and anticancer properties (Cham 2012). However, these alkaloids at excess levels exert potential toxic effects (Chami et al. 2003) and impart bitterness to fruits making them unpalatable (Frary et al. 2007). But the cultivated varieties of *S. melongena* have levels of alkaloids which are acceptable for human consumption, unless the plants have been subjected to stress conditions. Figure 3 depicts structures of major health promoting phytochemicals in eggplant.

Several studies have documented that the *Solanum* alkaloid solamargine induces apoptosis of cancer cells. Via multiple signaling pathways, solamargine sensitizes the cells to certain cancer drugs, and hence may have promising applications for cancer therapy (Kalalinia and Karimi-Sani 2017). Solamargine has also been reported to have anti-inflammatory effects against UVB-induced skin hyperpigmentation (Zhao et al. 2022).

Phenolic compounds in eggplant are excellent antioxidants and there is high genetic variation for this trait (Nandi et al. 2021; Plazas et al. 2013a, b). In addition to their antioxidant potential eggplant extracts were shown to inhibit alpha-glucosidase and angiotensin converting enzyme, target enzymes for therapies for

Table 3 Nutritional profile of raw eggplant (per 100 g fresh weight). Values from the USDA "Food Data Central" (Haytowitz et al. 2019) are compared to mean and standard error values from a study that examined ten eggplant varieties grown under same horticultural conditions (Rosa-Martínez et al. 2021)

Composition	Raw	Mean and standard error for ten varieties

type 2 diabetes and hypertension respectively (Kwon et al. 2008). Among the wild accessions, *Solanum insanum* has significantly higher phenolic content than *Solanum xanthocarpum* and *Solanum khasianum*. The wild accessions are rich sources of total phenolics (Kaur et al. 2014; Kaushik et al. 2020; Nandi et al. 2021).

Early research in eggplant breeding focused on the improvement of horticultural characteristics such as fruit yield, fruit size, color, and shape (Kashyap et al. 2003; Frary et al. 2007), low prickliness, and adaptation to climatic conditions (Daunay et al. 2001). A few studies focused on the resistance to biotic stresses (Rotino et al. 2014). Within the last few years, however, there is an increased research interest on

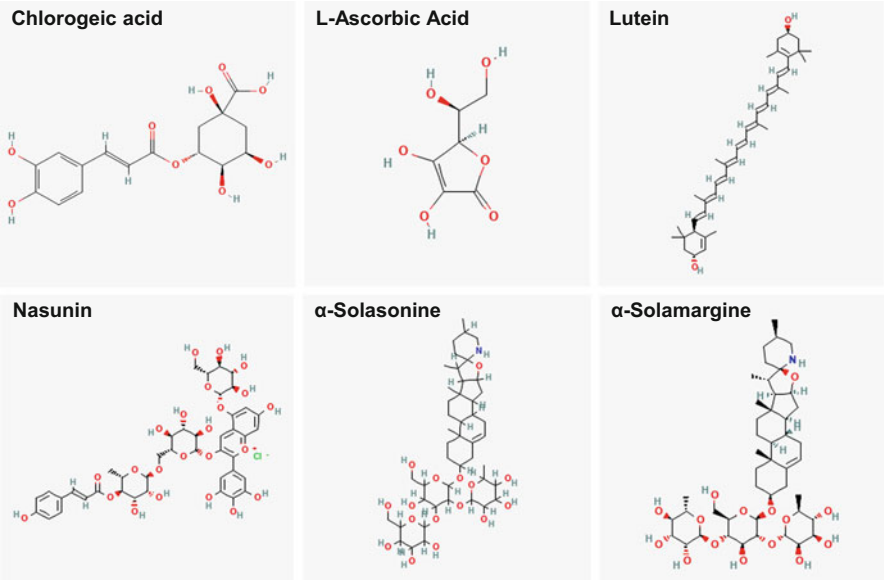

Fig. 3 Health promoting phytochemicals in eggplant. Representative compounds from the organic acids, phenolic compounds, carotenoids, anthocyanins and glycoalkaloids are shown. Note that other forms of these compounds and related compounds with bioactivity are also known but not depicted. Structures are from PubChem database

organoleptic and nutritional properties, bioactive metabolites, and postharvest traits of eggplant fruit. A few of these studies also highlight genetic and genomic perspectives (Prohens et al. 2007, 2013; Gajewski et al. 2009; Plazas et al. 2013a, b; Zhang et al. 2016; Docimo et al. 2016b; Scalzo et al. 2016; Mangino et al. 2022).

Eggplant is a nutritionally valuable vegetable as a good a source of vitamins and minerals (Grubben et al. 1977, Table 3). It also contains several classes of health-promoting metabolites including anthocyanins (delphinidin glycosides) and chlorogenic acid (Stommel and Whitaker 2003; Mennella et al. 2010) with nutraceutical and antioxidant properties (Cao et al. 1996; Kwon et al. 2008; Akanitapichat et al. 2010). An eggplant variety 'Pusa Hara Baingan 1' developed from ICAR-IARI, New Delhi has fruit with high antioxidant activity (3.41 CUPRAC μ mol trolox /g, 3.07 FRAP μ mol trolox /g) (Kumar et al. 2020). The bioactive compounds and health promoting properties of eggplant is presented in Table 4. Eggplant also contains certain anti-nutritional compounds, like toxic saponins and steroidal glycoalkaloids (SGA), which form the basis for the bitter taste of the flesh (Aubert et al. 1989a, b; Sánchez-Mata et al. 2010). The accumulation of these metabolites in the fruit and the total amount of all these metabolites appear to be influenced by genetic and developmental factors (Mennella et al. 2012). There is genetic variability for phytochemical accumulation traits among different eggplant varieties and environmental stress affects these traits (Plazas et al. 2013a, b).

Multiple studies focused on the genetic basis for fruit quality traits in eggplant. Quantitative trait loci (QTLs) affecting the content of health promoting or

Tannins	Enhance glucose uptake and inhibit adipogenesis. Inhibition of LDL-cholesterol oxidation	Kumari and Jain (2012)
Hydroxycinnamic acids	Free radical-scavenging properties, protection from side effects of chemotherapy	El-Seedi et al. (2012)

antinutritional compounds are known. These studies have also identified QTLs for various other fruit quality traits (Shetty et al. 2011; Gramazio et al. 2014). QTLs associated to fruit content of sugars, organic acids, dry matter and total soluble solids, chlorogenic acid, the steroidal glycoalkaloid solamargine, pigments delphinidin-3-

rutinoside (D3R), and delphinidin-3-(p-coumaroylrutinoside)-5-glucoside (nasunin) are useful resources to breed cultivars improved for specific phytochemical profiles. Very recently, the HPLC analysis identified cyanidin-3-*O*-glucoside, delphinidin-3-*O*-glucoside and delphinidin-3-rutinoside anthocyanins in brinjal lines and the highest delphinidin-3-*O*-glucoside was found in purple fruited variety Pusa Upkar, delphinidin 3-rutinoside in purple fruited line BR-40-7 (Harisha et al. 2023).

3 Major Bioactive Nutraceutical Compounds Present in Eggplant

3.1 Polyphenolics

Among all the studied Solanaceous crops, eggplant is a rich source of total phenolic acids, which are nutritionally important bioactive constituents (Helmja et al. 2007). The most prevalent group of phenolic compounds present in eggplant are the conjugates of hydroxycinnamic acid (HCA) and their concentration ranges from 4240 to 9610 mg/kg. HCA conjugates are synthesized by converting phenylalanine to cinnamic acid by the enzyme phenylalanine ammonia-lyase (PAL). Among HCA conjugates, chlorogenic acid (5-*O*-caffeoyl-quinic acid; CGA) an ester of HCA, contributes to 70% to over 95% of the total phenolic content (Whitaker and Stommel 2003; Plazas et al. 2013a; Niño-Medina et al. 2017). Quinic acid has four stereocenters namely carbons 1, 3, 4, and 5, and each one of these positions can be substituted by caffeic acid giving rise to 15 possible combinations. While CGA is the major hydroxycinnamic acid conjugate in eggplant, its 3-*O*, 4-*O*, 5-*O*-cis isomers, and 3,5- and 4,5-dicaffeoylquinic acid isomers have also been identified (Whitaker and Stommel 2003). Chemistry, synthesis, analytical challenges and bioactivity of caffeoylquinic acids in plants have recently been reviewed by Magania et al. (2021).

Growing interest in breeding for high CGA is mainly due to its beneficial properties including antioxidant (Chen et al. 2009; Zhao et al. 2012), anti-inflammatory (Morishita and Ohnishi 2001; dos Santos et al. 2006; Jin et al. 2006; Sheu et al. 2009; Sato et al. 2011), anticarcinogenic, antimicrobial (Almeida et al. 2006), anti-obesity (Cho et al. 2010), antipyretic, neuro-protective and analgesic properties (Cho et al. 2010; Plazas et al. 2013a; dos Santos et al. 2006). As a source, eggplant contributes substantially to CGA intake and there exists a significant variability among eggplant lines studied as compared to other sources of fruits and vegetables (Chumyam et al. 2013; Kaur et al. 2014; Prohens et al. 2013; Okmen et al. 2009; Chioti et al. 2022). The biochemical pathway and range of CGA content in different eggplant lines in comparison to other sources are shown in Fig. 4 and Table 5, respectively.

Fruit CGA content of eggplant fruit is influenced by both genetics and environmental factors including the fruit developmental stage, season, and storage conditions (Plazas et al. 2013a). The crop grown in the summer season showed a trend of decrease phenolic compounds compared to spring-grown crop suggesting negative influence of high temperatures on phenolic content. This information will help in monitoring the suitable time of harvest (García-Salas et al. 2014). In some of the

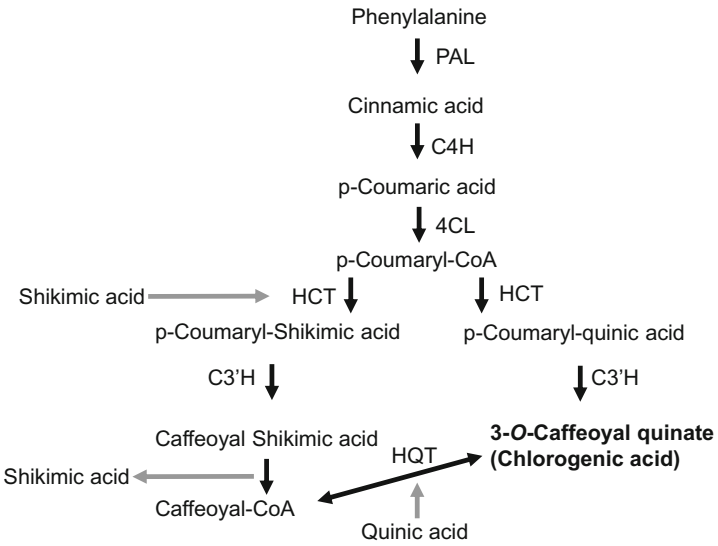

Fig. 4 Biosynthetic pathway of chlorogenic acid in eggplant. Enzyme catalyzed steps are shown with an arrow and the names of the enzymes are shown in three-letter abbreviations of enzyme names listed in Table. (Adapted from Plazas et al. (2013a))

Table 5 Chlorogenic acid contents of eggplant compared with other major vegetables (as summarized by Plazas et al. 2013a)

Plant source	CGA (g kg^{-1} dw)	References
Eggplant	4.9–21.6	Stommel and Whitaker (2003)
	4.2–9.5	Whitaker and Stommel (2003)

Artichoke	1.1–1.8	Lutz et al. (2011)

studies it was also noticed that organically grown eggplants had greater levels of total phenolics than conventionally produced eggplants (Raigon et al. 2010), but the contrary report also exists in which conventional and organic cultivation of the American variety 'Blackbell' had comparable levels of phenolic contents (Luthria et al. 2010). As compared to other derivatives of phenolic compounds CGA is quite stable at high temperatures, therefore boiling eggplant boosts its bioavailability when compared to uncooked eggplant (Lo Scalzo et al. 2010).

3.1.1 Genetic Sources of Phenolic Compounds

Generally, wild relatives had higher content of total phenolics with broader range of variation in them as compared to cultivated eggplant (Kaushik et al. 2017). The results of screening of the eggplant germplasm for the sources of high CGA content indicate that wild species *S. incanum* can contribute significantly for improving the CGA content in eggplant. Other species, like *S. sodomaeum* L. (*S. linneanum* Hepper & Jaeger) also showed a higher CGA content than that of *S. melongena* (Mennella et al. 2010). Therefore, utilization of wild relatives, such as *S. incanum*, in breeding of eggplant varieties will be of great interest. Along with the wild species the landraces also represent another useful source of variation. Introgressive breeding and selection for desired profiles of phenolic compounds along with other horticulturally relevant traits should be useful in this regard.

3.1.2 Breeding Strategies for Increased CGA

The strategies proposed for breeding of high CGA content exploit naturally available variation to selection among accessions, selection from intraspecific variation, development of hybrids and inbred lines or introgression of the high CGA trait from wild species into cultivated background. It is also necessary to have good horticultural and commercial characteristics along with the improved concentrations of CGA in new cultivars (Daunay 2008). Molecular markers for traits associated with high CGA content will be useful for developing new and improved cultivars in a resource-efficient manner. In case of conventional breeding methods, utilization of intraspecific variation and selection among the accessions or varieties resulted in the identification of lines with increased content of CGA (Stommel and Whitaker 2003; Whitaker and Stommel 2003; Hanson et al. 2006; Prohens et al. 2007; Raigón et al. 2008; Okmen et al. 2009; Mennella et al. 2012). An alternative and very successful method of breeding for high CGA is to develop hybrids along with commercial traits by using the lines having parents with high CGA content. The developed hybrids can be further used to select and develop inbred lines with higher content in CGA as suggested by the researchers (Prohens et al. 2007: Raigón et al. 2008). Prohens et al. (2013) improved the phenolic acid content in commercial eggplant lines by developing interspecific *S. melongena* and *S. incanum* backcross generation (BC1) progenies to introgress the alleles of *S. incanum* involved in CGA biosynthesis in the genetic background of *S. melongena*. *S. incanum* was found fully fertile with *S. melongena*. The individuals having high content in CGA in the first backcross generation was found and selected. The gene action studies from the population suggested the presence of additive genetic effects explaining CGA variation. Therefore, it is necessary to have the alleles of *S. incanum* in homozygous state to obtain lines with stable and high levels of CGA in the fruit.

The identification and mapping of genes involved in the CGA synthesis pathway was carried out by Gramazio et al. (2014). The authors were successful in amplifying the candidate genes encoding enzymes of CGA synthetic pathway and the identified genomic regions were syntenic with the tomato genome (Wu et al. 2009). Table 6 lists the candidate genes and their linkage group locations in the eggplant genome as reported by Gramazio et al. (2014).

Table 6 Candidate genes encoding enzymes of chlorogenic acid (CGA) biosynthesis and their chromosomal locations

S. No	Candidate genes coding for biosynthetic enzymes	Linkage group
1	*PAL* (phenylalanine ammonia-lyase)	9
2	*C4H* (cinnamic acid 4-hydroxylase),	6
3	*4CL* (4-coumaroyl: CoA-ligase)	3
4	*C3H* (p-coumarate 3-hydroxylase),	1
5	*HQT* (hydroxycinnamoyl CoA quinate hydroxycinnamoyltransferase),	7
6	*HCT* (hydroxycinnamoyl-coAshikimate/quinatehydroxycinnamoyltransferase)	3

Gene transfer technologies are well developed in eggplant and have been used to improve several traits (Acciarri et al. 2000; Donzella et al. 2000; Pal et al. 2009). Kaushik et al. (2020) obtained transgenic plants overexpressing the central enzyme hydroxycinnamoyl CoA-quinate transferase (*SmHQT*), which catalyzes the reaction to the chlorogenic acid synthesis. Using agro infiltration technique the gene construct having *SmHQT* gene was transformed into the eggplant and was further validated by HPLC analysis of transgenic tissue for CGA. The results of the study confirmed the increase in CGA content by twofold in the transformed plants. When the general public's acceptance of genetically modified crops (Raybould and Poppy 2012) improve and national policies toward genetically modified crops become favorable, nutritionally enhanced transgenic eggplant cultivars will become more widely useful.

3.1.3 Effect of CGA Content on Fruit Flesh Browning

When an eggplant fruit is cut, the phenolic compound CGA present in eggplant fruits acts as the substrate for polyphenol oxidases which catalyze the oxidation of phenols to quinones. Quinones reacting non-enzymatically with O_2 and other molecules cause tissue browning (Ramírez and Virador 2002; Prohens et al. 2007; Plazas et al. 2013b; Mishra et al. 2013; Prohens et al. 2013; Docimo et al. 2016a).

The polyphenol oxidase reaction is a major drawback for increasing the CGA content in fruit (Prohens et al. 2007, 2013; Plazas et al. 2013b; Mishra et al. 2013) because browning reduces the visual quality of the fruit both for the fresh market and for the processing industry (Mishra et al. 2013). In order to reduce this potential side effect, it has been emphasized for indirect selection for lower content of total phenolic compounds in fruit flesh. Also, variation for PPO activity was observed between the different groups of the germplasm. The primary gene pool species consisting of cultivated eggplant and hybrids display significantly lower PPO specific activities than those of the wild species of the secondary and tertiary gene pools (Kaushik et al. 2017). Eggplant's wild relatives had higher PPO activity than the cultivated species (Shetty et al. 2011), suggesting enhanced defense in the wild species. In several crops, PPO activity was shown to have a positive correlation with browning traits, which indicates that by selecting for low PPO activity, it is possible to develop materials with reduced browning (Di Guardo et al. 2013; Nayak et al. 2015;

Urbany et al. 2011). In eggplant, the correlation between fruit flesh phenolic concentration, and particularly CGA content, and fruit flesh browning has been found to be moderate (Prohens et al. 2007; Plazas et al. 2013a; Docimo et al. 2016a). Other physiological or cell anatomical factors related to flesh browning were suggested (Docimo et al. 2016a; Mishra et al. 2013; Prohens et al. 2007). Prohens et al. (2007) found a moderate relationship ($r = 0.389$) between the total phenolic content and fruit flesh browning among the cultivated eggplants. This study suggests that there is a possibility to select varieties with high content in phenolics but with low or moderate fruit flesh browning traits. In the later studies by Prohens et al. (2013), fruit flesh browning and total content of hydroxycinnamic conjugates (CGA) has been correlated in interspecific progenies between *S. melongena* and *S. incanum.* The genetic and QTL mapping studies carried out by Gramazio et al. (2014) led to identification and mapping of five genes that encode PPO enzymes in eggplant. All the five genes *PPO1, PPO2, PPO3, PPO4*, and *PPO5* were mapped on the linkage group 8 and were found to be syntenic with the tomato genome (Wu et al. 2009). Presence of all the five genes on same linkage group suggest that *PPO* genes form a cluster in eggplant genome (Newman et al. 1993; Thipyapong et al. 2007; Tran et al. 2012) and it was also confirmed that the genes involved in CGA synthetic pathway were not linked to the *PPO* gene cluster.

3.2 Anthocyanins

Anthocyanins are the most abundant class of water-soluble pigments in plants (Mazza 2007). They are mainly responsible for red, purple, and blue colors in fruits, vegetables, flowers, and grains. Derivatives of six anthocyanidins, namely pelargonidin, cyanidin, delphinidin, peonidin, petunidin, and malvidin are widespread in plants (Kong et al. 2003). Among the above mentioned anthocyanidins, delphinidin glycosides [i.e., delphinidin-3-rutinoside (D3R) and delphinidin-3-(p-coumaroylrutinoside)-5-glucoside (nasunin)] were found more abundantly in eggplant than any other groups (Toppino et al. 2016). Multiple studies have identified several delphinidin derivatives in eggplant accessions and they have been reviewed by Niño-Medina et al. (2017).

Anthocyanins are found to have significant biological functions in plants as insect pollinator attractants, seed dissemination agents and protector of plants against various biotic and abiotic stresses (Chalker-Scott 1999; Ahmed et al. 2014). They were found to have photo protective activity, by absorbing excess visible and UV light and scavenging free radicals thus protecting the photosynthetic apparatus (Guo et al. 2008). Anthocyanin extracts have been shown to have antioxidative and radical-scavenging activities (Astadi et al. 2009), and serve as chemoprotective agents. Anthocyanins also have anti-diabetic characteristics, such as decreasing cholesterol (DeFuria et al. 2009), and increasing insulin secretion (Matsui et al. 2004). There are lines of evidence that a balanced diet rich in anthocyanin-rich foods can significantly reduce the chance of developing various chronic illnesses, including cancer (He and Giusti 2010). While certain health-promoting effects of

anthocyanins could be due to their high antioxidant activities, specific anthocyanins can modulate signaling pathways in mammalian cells, which could explain some of their specific beneficial effects (Salehi et al. 2020).

Light and temperature are the main environmental factors regulating the anthocyanin biosynthetic pathway. In general, high light intensity increases anthocyanin production in many plant species (Maier and Hoecker 2015). In one study addition of UV-A irradiation improved anthocyanin pigmentation of eggplants when grown in a greenhouse with low UV transmittance (Matsumaru et al. 1971). It is well known that low temperature stress induced anthocyanin accumulation in plants of the Solanaceae (Løvdal et al. 2010; Jiang et al. 2016). It has been proposed that the promotion of anthocyanin accumulation by low temperature and light might be through the same or overlapping mechanism (Jaakola 2013; Xu et al. 2015), as induction of anthocyanin biosynthesis at low temperature needed light.

3.2.1 Biosynthetic Pathway of Anthocyanin

Malonyl-CoA and 4-Coumaroyl-CoAarethe precursors for the flavonoid biosynthetic pathway in plants. Chalcone synthase (*CHS*) catalyzes the first committed step. The anthocyanin biosynthesis process is a conserved network which is well studied in crop plants. Figure 5 illustrates the steps leading to delphinidin, the most abundant anthocyanin in the eggplant.

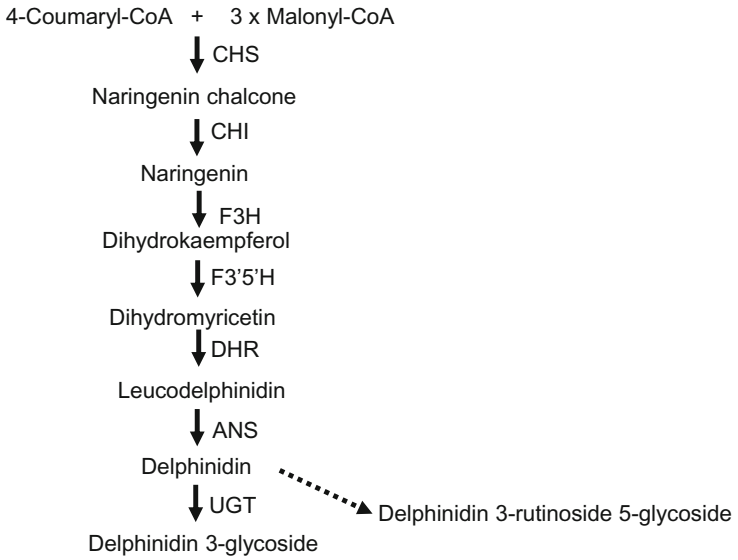

Fig. 5 Key steps in the biosynthesis of anthocyanin nasunin (delphinidin 3-rutinoside-5-glucoside) based on *KEGG* pathway database's anthocyanin biosynthesis. Steps with dotted arrows denote uncharacterized steps, but beginning to be understood (Florio et al. 2021). Enzyme name abbreviations are *CHS* chalcone synthase, *CHI* chalcone isomerase, *F3H* hydroxylase, *F3′,5′H* hydroxylase, *DHR* dihydromyricetin reductase, *ANS* anthocyanin synthase, *UGT* glycosyltransferase

The early biosynthetic genes (*EBGs*) are known to involve in genetic regulation of anthocyanin biosynthesis. The EBGs namely – *CHS*, *CHI*, and *F3H* are the common flavonoid biosynthetic pathway genes which are involved in the synthesis of all flavonoids and late biosynthetic genes (*LBGs*) namely – *F3′H, F3′ 5′H, DFR, ANS*, and *UFGT* are required for the biosynthesis of specific classes of flavonoids, including anthocyanins. In eggplant, *EBGs* (*SmCHS, SmCHI,* and *SmF3H*) were reported to respond to low temperature and light earlier than LBGs (*SmF3′ 5H, SmDFR*, and *SmANS*) (Jiang et al. 2016).

Positive correlations between expression levels of LBGs and anthocyanin content have been recorded in many Solanaceous vegetables (Borovsky et al. 2004; André et al. 2009; Povero et al. 2011; Aza-Gonzalez et al. 2013). *MYB-bHLH-WD40* (*MBW*) complex regulates the structural genes of the anthocyanin biosynthetic pathway. This complex consists of MYB, basic helix-loop-helix (*bHLH*) and *WD40* repeat family proteins. A study combining transcriptomic and proteomic analyses on light-induced anthocyanin biosynthesis in eggplant (Li et al. 2017) identified multiple genes and gene products critical in the accumulation of anthocyanins. It should be noted that although much is known about the pathway, phytochemistry of various forms of delphinidin derivatives in eggplant and the enzymatic steps leading to them are poorly known.

3.2.2 Breeding for Anthocyanin Content in Eggplant

In recent days, consumers prefer anthocyanin-rich food products, and such products are marketed for their health promoting potentials (Pojer et al. 2013). The correlation study between the antioxidant activity and total anthocyanin concentration in different eggplant types was carried out by Nisha et al. (2009). The extracts from small sized purple-color fruit showed greater antioxidant activities with maximum concentration of anthocyanin (0.756 mg/100 g) than that of other samples, such as long green (0.0475 mg/100 g), purple colored moderate size (0.525 mg/100 g) and purple colored big size (0.553 mg/100 g). Similar study was carried out by Dhruve et al. (2014) to screen the available eggplant genotypes and to quantify the amount of anthocyanin present. In those studies, AB-07-02 was found to have maximum anthocyanin content in peel of about 474.85 mg/100 g and in the genotypes GBL-1 and GP-White anthocyanin content was not detected. Screening of 26 different colored eggplant genotypes by Koley et al. (2019) reported that the total anthocyanins (in monomeric form) in the purple genotype varied from 27.63 to 359.28 μg C3G/100 g FW, whereas in green and white-colored genotypes anthocyanin was not detected.

It is important to know the inheritance pattern and nature of gene action for selection of breeding methods to improve a particular trait. A study was conducted to decipher the inheritance pattern for anthocyanin using the F_2 and backcross population from a cross of 'Pusa Safed Baingan 1' and 'Pusa Uttam' implying dominant epistasis (Bhanushree et al. 2019). Efforts have been made to develop purple fruited varieties in India. Few dark purple fruited varity Pusa Oishiki, Pusa Vaibhav, Pusa Unnat (F1) rich in anthocyanin were developed very recently (Saha et al. 2021, 2022, 2023). Barchi et al. (2012) identified QTLs determining anthocyanin

pigmentation in different plant parts of eggplant by conducting the experiment in two different locations. This study looked for marker associations to the following phenotypes: adaxial leaf lamina anthocyanin (*adlan*), stem anthocyanin (*stean*), abaxial leaf lamina anthocyanin (*ablan*), calyx anthocyanin (*calan*), corolla color (*corcol*), leaf venation anthocyanin (*lvean*), and fruit peduncle anthocyanin (*pedan*). The list of QTLs detected is shown in Table 7. This study revealed that QTLs located in five different chromosomes control anthocyanin accumulation in this population. Later, QTL studies by Toppino et al. (2016) identified the QTLs affecting fruit color traits and nasunin. Two QTLs for fruit color traits were mapped on chromosome 5, explaining 56.3% and 69.9% of the phenotypic variance in two different locations respectively. One QTL was detected on the same chromosome (chromosome number 5) explaining 28% and 28.4% of the variance in two different locations.

In a different study eggplant was genetically engineered by introducing *SmMYB1* gene encoding a *R2R3 MYB* transcription factor involved in regulating anthocyanin biosynthesis in the peel of eggplant into a non-anthocyanin-accumulating cultivar (*Solanum aethiopicum* group Gilo) via *Agrobacterium*-mediated transformation (Zhang et al. 2016). The transgenic plants had high concentrations of anthocyanin

Table 7 QTLs detected in the mapping population by Barchi et al. (2012), their chromosomal location (Chrom), log of odds ratio score (LOD) for detection of the QTL, percent contribution to phenotypic variance (PVE), and additive (A) and dominant variance (B) contributions

Trait code	QTL	Chrom	Position (cM)	LOD	PVE	A	D

in leaves, petals, stamens, and fruit peels under normal growth conditions, especially in fruit flesh. Later studies of qRT-PCR analysis revealed that transformed plants showed significantly high up-regulation of anthocyanin structural genes than the non-transformed plants. Additionally, they had a greater tolerance to freezing stress and better recovery under rewarming conditions, suggesting that anthocyanin synthetic and regulatory circuits are potential targets to improve eggplants for stress tolerance. Recently, the proof for *R2R3-MYB* transcription factor *SmMYB75* promotes anthocyanin biosynthesis in eggplant was supported by the study of Shi et al. (2021). Overexpression of *SmMYB75* in the eggplant cultivar '116' showed increased accumulation of anthocyanins, which resulted in a change in the color of the calli from green to purple. The Yeast one-hybrid (*Y1H*) and dual-luciferase (*Dual-LUC*) assays showed that *SmMYB75* could bind to the promoter of *SmCHS* and activate its expression for anthocyanin synthesis. *SmMYB75* was suggested to modulate the anthocyanin's accumulation by combinatorically interacting with a basic helix-loop-helix (*bHLH*) factor. A study analyzing a multiparental population identified two *MYB113* genes on chromosomes 1 and 10 to be involved in anthocyanin accumulation in the fruit (Mangino et al. 2022).

3.3 Glycoalkaloids

Glycoalkaloids are biologically active secondary metabolites, which are chemically defined by the presence of their nitrogenous steroidal aglycone and glycoside residues located at the C-3 position (Zhao et al. 2020; Al Sinani and Eltayeb 2017). The crops of the Solanaceae family are the warehouse of steroidal glycoalkaloids (SGA) which are present in all tissues of eggplant (Sawai et al. 2014) and are better characterized in tomato and potato (Friedman 2002, 2006; Kozukue et al. 2008). The first discovery of SGA is from the species *Solanum nigrum* in 1820. The higher concentration of *Solanum* glycoalkaloids in fruits have a significant impact on the organoleptic properties of flesh by imparting a characteristic bitter taste and off flavor (Aubert et al. 1989a, b; Sánchez-Mata et al. 2010). Eggplant is a source of two main glycoalkaloids namely, water-soluble triglycosides solasonine (SN) and solamargine (SM), which are in general referred to as α-compounds (Trivedi and Pundarikakshudu 2007). The chemical structures of solasonine and solamargine of eggplant are represented in Fig. 3.

The glycoalkaloid accumulation is modulated by several environmental factors during plant growth, harvesting, and post-harvest treatment including light exposure, temperature, altitude, soil type, soil moisture, drought, and soil fertility. Wounding increased glycoalkaloid contents (Sinden et al. 1984; Zhao et al. 2020). Solamargine and solasonine are known to play important roles in plant abiotic and defense stress resistance, assisting plant-environment interactions against a variety of pathogens and predators (Zhao et al. 2020; Al Sinani and Eltayeb 2017). They were also found to have allelopathic effects to suppress seedling growth in crop fields (Vaananen 2007). However, depending on the dose, they can also be used as drugs due to their various biological activities with potential therapeutic potentials (Lee et al. 2007;

Tiossi et al. 2012). But the higher concentration of these glycoalkaloids were known to cause toxic effects on target organisms leading to cell-membrane disruption, acetylcholinesterase inhibition, liver damage, heart damage, teratogenicity, and embryotoxicity (Al Sinani and Eltayeb 2017). Various methods have been employed for analyzing glycoalkaloids in foods and plant materials, of which high performance liquid chromatography (HPLC), high performance thin-layer chromatography (HPTLC), gas chromatography (GC), and mass spectrometric methods and rarely immunoassays are routinely used (Kuronen et al. 1999; Kreft et al. 2000; Dinan et al. 2001; Trivedi and Pundarikakshudu 2007; Vaananen 2007; Eanes et al. 2008).

3.3.1 Biosynthesis Pathway

Cholesterol is a key intermediate for biosynthesis of glycoalkaloids which is obtained as intermediate of acetyl-CoA pathway. SGA biosynthesis begins with the cytosolic mevalonate pathway and a multi-step pathway for the production of cycloartenol, cholesterol, and core SGA, culminating in the synthesis and glycosylation of the steroidal alkaloid aglycone (Zhao et al. 2020). The aglycones are glycosylated through the action of a series of glycosyl transferases (Wang et al. 2017) to form the final products α-solasonine and α-solamargine (Wang et al. 2017) (Fig. 6). The biosynthesis is regulated by a group of genes clustered together in *Solanum* species and the modulation of these genes changes the biosynthesis in the plant (Wang et al. 2017). The site of synthesis of glycoalkaloids has been extensively studied in tomato. The storage of glycoalkaloids occurs in the soluble phase of the cytoplasm and/or in the vacuoles. The alkaloids are not transported throughout the plant system, but they tend to remain confined to the site of synthesis. It is also known that the isopentenyl pyrophosphate (IPP) acts as an intermediate in the biosynthetic pathways of chlorophyll, carotenoid, and glycoalkaloid; therefore, the biosynthesis of each of these three compounds influence that of the others (Zhao et al. 2020). The presence of a gene encoding dioxygenase involved in the

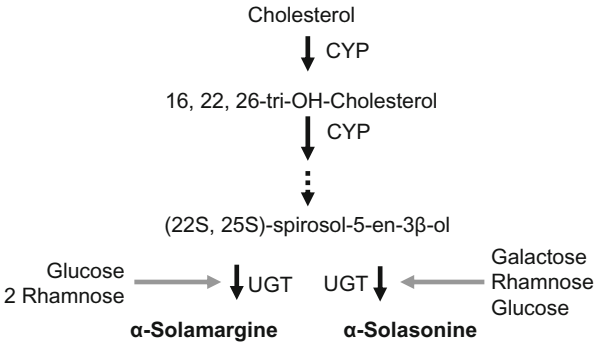

Fig. 6 Suggested biosynthetic pathway for solasonine and solamargine in eggplant. (Adapted from Akiyama et al. (2021)). Enzyme abbreviations are shown in three letters near the arrows: *CYP1* cytochrome *P450* monooxygenase involved in cholesterol hydroxylation, *CYP2* cytochrome *P450* monooxygenase involved in oxygenation, *UGT* uridine diphosphate-dependent glycosyltransferase

conversion of spirosolane alkaloids to solanidane-type alkaloids in eggplant suggest that leaves of eggplant could contain solanidane alkaloids also but have not been tested for its role (Akiyama et al. 2021).

3.3.2 Breeding for Glycoalkaloid Content

Reduction in glycoalkaloid content has been an important breeding objective for crop improvement in eggplant. In certain populations of eggplants studied, the long-fruited cultivars contained a higher concentration of reducing sugars, phenolics, and dry matter than round-fruited types. The range of glycoalkaloid contents in the Indian commercial cultivars varied from 0.37 to 4.83 mg/100 g fresh weight, whereas increase in concentration to 20 mg/100 g fresh weight results in bitter taste and off flavor (Dhruve et al. 2014). The range of glycoalkaloid content in the study of Dhruve et al. (2014) varied from 0.128 to 0.191% with the lowest concentration found in the cultivar 'Doli-5' and significantly higher concentration in 'GOB-1' cultivar. The studies of Sanga et al. (2019) reported the cultivar 'G-3' was found to have the highest concentration of solasodine with the value of 28.25 mg/100 g, whereas lowest concentration of solasodine was in the cultivar 'G-5' (8.78 mg/100 g). Other studies (Lelario et al. 2019) confirmed the phytochemical diversity for alkaloid content in eggplant varieties and others have shown such variation in different species of *Solanum* (Amadi et al. 2013; Eze and Kanu 2014; Chinedu et al. 2011). A significant negative association ($r = -0.588$) was observed between ascorbic acid content and glycoalkaloid content. And glycoalkaloid content had a positive correlation with fruit weight ($r = 0.381$) and fruit volume ($r = 0.399$) (Sanga et al. 2019).

The identification and mapping of genes/QTLs for the contents of solasonine, and solamargine were carried out by Toppino et al. (2016) using an F_2 intraspecific mapping population of 156 individuals ("305E40" × "67/3."). The QTL analysis revealed the presence of one major QTL, *SME06.ML* on chromosome number 6 having the LOD value of 5.02 and PVE of 13.9. The genetic transformation studies paved the path to understand the effects of photosynthetic pigment accumulation on glycoalkaloid biosynthesis in eggplant. Since both chlorophyll and carotenoid biosynthesis pathways share intermediate metabolites with glycoalkaloid synthesis and are regulated by light, it was hypothesized that changes in one pathway could affect the others. Therefore, the study was carried out to silence three key genes involved in carotenoid biosynthesis (PDS) and chlorophyll biosynthesis (*ChlI* and *ChlH*) using TRV-mediated VIGS to block the biosynthesis of respective metabolites. The transformed plants were quantified for carotenoid and chlorophyll levels using liquid chromatography-mass spectrometry. The results revealed a significant reduction in glycoalkaloid production in transformed plants along with the other metabolites in the silenced lines suggesting the crosstalk of both the SGA and chlorophyll biosynthesis. This finding of Toppino et al. (2016) suggests strategies to reduce the levels of endogenous antinutritional compounds in crops. Later, Barchi et al. (2019) studied the evolution of glycoalkaloid biosynthesis in solanaceous crops. In eggplant most core genes for steroidal glycoalkaloid (SGA) biosynthesis genes form two metabolic gene clusters, on chromosome 7 and chromosome 12, while the one on chromosome

12, contains genes named *GLYCOALKALOID METABOLISM 4* and *12* (*GAME4* and *GAME12*).

4 Metabolomics to Identify Novel Eggplant Phenotypes

Metabolomics, where high-throughput identification and quantification of metabolites are done using mass spectral methods, are increasingly applied to study crop plants. Eggplant metabolites have been profiled and attempts have been made to link metabolic profiles to fruit morphology and nutrition, drought stress, nutrient use efficiency, response to pathogens, and other desirable traits (Mauceri et al. 2022; Chen et al. 2021; Hanifah et al. 2018; Mibei et al. 2017).

Hanifah et al. (2018) analyzed eggplant fruit from 21 accessions using untargeted metabolomics with gas chromatography and mass spectrometry in tandem (GC-MS) and liquid chromatography with mass spectrometry (LC-MS) methods. Untargeted metabolomics identified 207 and 51 putative metabolites from GC-MS and LC-MS analysis, respectively, and they belonged to terpenoids, alkaloids, flavonoids, and fatty acid pathways. Two metabolite clusters were identified from GC-MS analysis that further discriminated the 21 eggplant accessions into two respective groups. For example, linoleic acid, palmitic acid, alpha-tocopherol (vitamin E), and neophytadiene metabolites from GS-MS were present across most of the eggplant accessions. Similarly, 2, 5-Bis (N-hexylmethylsilyl) thiophene, 2-(Methylthiomethyl)-3-phenyl-2-propenal, and Boscalid metabolites from LC-MS were present across more than three eggplant accessions. These metabolites represent terpenes and alkaloid pathways. Interestingly, most of the metabolites detected from both GC-MS and LC-MS analysis were accession-specific (Hanifah et al. 2018), suggesting a unique metabolic landscape from fruits of diverse eggplant accessions. Some of these accession-specific metabolites represented the steroids, flavonoids, alkanes, terpenoids, saturated and unsaturated fatty acid pathways. In addition to known metabolites, the LC-MS also detected previously unknown metabolites in a sub-set of eggplant accessions. Furthermore, different fruit characteristics also showed significant correlations with specific metabolic profiles in the 21 eggplant accessions (Hanifah et al. 2018). These fruit traits represented curvature (*CVT*), spininess of calyx (*SCL*), anthocyanin coloration under calyx (*IUC*), depth of indentation of pistil scar (*DPS*), and fruit patches (*PTC*), density of stripes (*DST*), and ribs (*RBS*). For instance, G55 eggplant accession had strong fruit CVT and showed high correlation with 1,2,4-nonadecanetriol. Similarly, PTC trait correlated with farnesyl acetone, and lariciresinol, and clionasterol metabolites, while SCL trait had high correlations with ethyl 9-heptadecenoate and 1-tetradecanoyl-glycero-3-phosphoserine metabolites in different eggplant accessions.

Studies also demonstrated the use of metabolomics to understand the effect of biotic and abiotic stresses in eggplant. For example, eggplant genotypes with high ('AM222') and low ('305E40') nitrogen utilization efficiency (NUE) were characterized for primary and secondary metabolites under nitrogen starvation, and short- and lone-term nitrogen-limiting resupply conditions using GC-MS and

UPLC-qTOF-MS approaches (Mauceri et al. 2022). A differential metabolite analysis revealed several pathways associated with differential NUE in eggplant. For instance, glycine and glyA transcript accumulation in high NUE genotype appears useful for acclimation to the N-limiting stress conditions. An abundance of sucrose and starch pathway metabolites were associated with improved NUE. Similarly, higher levels of L-aspartate and L-asparagine in high NUE genotypes were also identified at short-term low-nitrogen treatment, whereas granule-bound starch synthase and endoglucanase were downregulated under long-term nitrogen stress (Mauceri et al. 2022). These results delineate specific metabolic pathways to target for improving NUE in eggplant. In a similar way, GC-MS was applied to analyze the biochemical changes related to drought stress in African eggplant accessions (Mibei et al. 2017). Nineteen eggplant accessions were analyzed for metabolite changes under regular and water limiting conditions. Drought stress broadly affected the metabolic landscape of eggplant genotypes by changes in sugar, amino acid, and organic acid pathways. The levels of sucrose, fructose, trehalose, xylose, and mannose sugars were positively correlated with the drought stress (Mibei et al. 2017). Likewise, the concentrations of proline, glutamate, citrate, isocitrate, malate, and fumarate were relatively abundant in drought conditions. In contrast, the levels of glucose, myo-inositol, glycine, alanine, quinic acid, aspartate, and malate were less abundant under water-limiting conditions (Mibei et al. 2017). The metabolic changes were defined by genotype, growth stages, and water stress conditions, hence suggesting the complexity of drought stress responses in eggplant.

Recently, a metabolome and volatilome analysis has been conducted to elucidate the biochemical responses of eggplant and tomato against infestation from *Tuta absoluta*, a destructive pest of Solanaceae crops (Chen et al. 2021). A total of 141 volatiles and 797 metabolites were identified that consisted of alcohols, aldehydes, amines, ketones, and terpenes (Chen et al. 2021). The terpene metabolites were differentially enriched in eggplants than tomato. Interestingly, several compounds were either unique in eggplant or were present in lower quantity in tomato in both control and *T. absoluta* infested samples. The study identified about 35 differentially regulated compounds associated with evoked *T. absoluta* response, hence were considered to regulate the pest behavior (Chen et al. 2021). Overall, the differentially accumulated compounds might determine the eggplant resistance against *T. absoluta* infestation, which helps to develop integrated pest control measures for sustainable eggplant production.

5 Eggplant Genomes and Resequencing

Different nuclear genomes of the eggplant have been sequenced within last decade. First draft genome sequence "SME_r2.5.1" of the common eggplant (*Solanum melongena* L.) cultivar 'Nakate-Shinkuro' was assembled using the Roche 454 GS FLX Titanium and Illumina HiSeq 2000 technologies (Hirakawa et al. 2014). It had a total length of 833.1 megabase (Mb) from 33,873 assembled scaffolds. These scaffolds covered about 74% of the predicted 1.12 gigabase (Gb) genome size (Hirakawa

et al. 2014). Annotation of "SME_r2.5.1" genome revealed a total of 85,446 coding sequences, which represented about 48% transposable elements, 2% pseudogenes, and 0.7% short length genes. The repeat sequences constituted about 70% (586.8 Mbs) of the draft genome assembly and mainly represented Gypsy class retrotransposons (Hirakawa et al. 2014). Out of remaining 42,035 genes, 91.6% and 8.4% were designated as "intrinsic" genes having start and stop codons, and partial genes without start and/or stop codons, respectively. A comparative genomic analysis of predicted eggplant genes against other solanaceous plant genomes revealed about 4018 genes exclusive to eggplant genome. In addition, a total of 16,573 orthologous gene pairs were identified between eggplant and tomato that were spread across 56 conserved syntenic blocks. These observations indicated a considerable level of synteny between these two solanaceous crop species.

Due to highly fragmented nature of "SME_r2.5.1" genome, recent efforts from the Eggplant Genome Project (http://www.eggplantgenome.org) led to a chromosome scale fully anchored eggplant genome by integrating single molecule optical mapping and Illumina sequencing approaches (Barchi et al. 2019). This genome assembly from an inbred eggplant line '67/3' consisted of 0.92 Gb ungapped and 1.22 Gb gapped sequences across 469 scaffolds – a significant improvement from the previously available draft genome (Hirakawa et al. 2014). The hybrid scaffolds were anchored to 12 chromosomes using a genetic map of 5964 markers, and the resulting anchored pseudomolecules represented 1.14 Gb gapped and 0.82 Gb ungapped sequences (Barchi et al. 2019). The '67/3' genome had low residual heterozygosity (0.027%) and high (73%) transposable element sequences. It had a total of 34,916 predicted protein-coding genes (Barchi et al. 2019), which were comparable to other Solanaceae genomes (Barchi et al. 2019). A Benchmarking Universal Single-Copy Orthologs (*BUSCO*) score was 96.9%, indicating a near complete gene annotation of the '67/3' eggplant genome. An ortholog analysis with the new eggplant gene models indicated that 667 gene families were specific to eggplant – with a significant enrichment of "pentatricopeptide repeat-containing protein" family than found in tomato, potato, pepper, and Arabidopsis. A survey of single-locus simple sequence repeats (SSRs) identified about 125 SSRs/1 Mbs of '67/3' genome space.

More recently, another chromosome-scale genome of 'GUIQIE-1' eggplant cultivar has been assembled by combining the long read PacBio and Hi-C sequencing approaches (Li et al. 2020). The total length of 'GUIQIE-1' genome is 1155.8 Mb (N50 = 93.9 Mb), out of which, repetitive sequences were 70.1% of the total assembly. Genome annotation identified a total of 35,018 protein-coding genes – a little higher than the annotated genes in the '67/3' eggplant genome. The number of eggplant-specific gene families ($n = 646$) were almost similar between 'GUIQIE-1' and '67/3' genomes. An additional orthologous gene family analysis indicated an expansion in disease resistance genes for bacterial spot resistance in eggplant and pepper than in tomato and potato (Li et al. 2020). Overall, the fully anchored and high-quality genome assemblies from '67/3' and 'GUIQIE-1' accessions provide important resources for genetic improvement and functional genomics studies in eggplant and related species.

With the availability of high-quality chromosome scale genomes, it is now feasible to characterize the genomic diversity and evolutionary footprints of eggplant and its wild relatives. Until now, the genomes of a small set of seven *S. melongena* and one wild *S. incanum* accession has been re-sequenced at 19.8 × depth (Gramazio et al. 2019). Alignments of these eight re-sequenced genomes against '67/3' reference genome identified about nine million single nucleotide polymorphisms (SNPs) and 700,000 Insertion/Deletions (Indels). The wild *S. incanum* accession represented most of this variation. The variants in the *S. melongena* accessions ranged from 0.8 to 1.3 million (Gramazio et al. 2019), indicating a narrow genetic diversity in cultivated eggplant. In addition, about 98% of the variants were present in intergenic and intronic regions. The moderate effect protein-coding (codon insertion/deletion, codon substitution) SNPs ranged from 0.61% to 0.78%, while the large effect SNPs (loss of function mutations or protein truncation) ranged from 0.05% to 0.09% (Gramazio et al. 2019). This analysis provides a preliminary overview of genetic variation and its use for eggplant genetic improvement. Genome sequence resources should allow us to develop and utilize DNA markers for key traits of importance in eggplant that are connected to health promoting metabolites and methods to select desirable plants. Exploration of genomic and phytochemical diversity in the eggplant will also lead to future synthetic biology strategies to overproduce specific phytochemicals of value.

Abstract

Known for its high nutritional value and ability to thrive in the most adverse conditions, amaranth grain is considered a superfood by many. Amaranth is gluten-free and rich in protein, especially lysine, an essential amino acid very scarce in other plants. The antioxidant properties of amaranth may improve the nutritional status and health of consumers. In fact, as an antioxidant, anti-inflammatory, and anticancer agent, amaranth has been pharmacologically reported to be highly effective against chronic inflammation. Other benefits of amaranth include lowering cholesterol and preventing cardiovascular disease. Even amaranth antinutrients, such as phenolic compounds, have antioxidant properties. Amaranth can be used for the biofortification of staple food by simply adding amaranth compounds to flour or bakery products. A more complex approach involves creating transgenic plants with higher nutritional profiles. Amaranth biofortification may also increase yield and resistance to multiple diseases. Despite these unique characteristics, amaranth is considered an underutilized grain, with greater potential to overcome hunger and diseases. One of the limitations of amaranth cultivation is the lack of high-yielding varieties. Therefore, we provide in this chapter a broad overview of amaranth grain cultivation and the current state of the art of genetic breeding of this crop. We highlight plant breeding using molecular markers and genetic diversity assessment. In addition, we describe the development of transgenic plants that have been enhanced by amaranth genes as well as new and promising gene editing techniques for amaranth, such as CRISPR and nanotechnology. Furthermore, we highlight the main germplasm and genomic databases for amaranth, as well as bioinformatic tools for assessing and analyzing the data. Altogether, this information may aid the rational design for nutritional quality and yields in *Amaranthus* and other plants, by using amaranth as a role model for nutritional improvement design.

Amaranthus · Gene editing · Biofortification · Bioinformatics · Genetic diversity · Nutrition · Malnutrition · Food security

1 Introduction

1.1 Agricultural Importance of Amaranth

Amaranth is an ancient grain, with the first archeological register dated from 4000 BC in South America, more specifically in Mexico (Jimoh et al. 2018). Amaranth is mainly cultivated in South America (yielding 4600–7200 kg/ha), Africa (50–2500 kg/ha), and Europe (1200–6700 kg/ha) (D'Amico and Schoenlechner 2017). Amaranth

is widely grown in Africa (Ma et al. 2021), and it has been domesticated in the Americas (Stetter et al. 2016). There are three *Amaranthus* species cultivated for grain production: *Amaranthus caudatus*, *Amaranthus cruentus*, and *Amaranthus hypochondriacus* (Jimoh et al. 2018; Stetter et al. 2016).

Amaranth is a flowering plant belonging to the Amaranthaceae family and *Amaranthus* genus and includes more than 60 species (Sauer 1957; Tabio-García et al. 2021). Amaranth is considered a superfood, rich in many macro- and micronutrients necessary for humans (Jimoh et al. 2018). Besides, amaranth can grow in harsh environmental conditions, making the species very suitable for agriculture in a vast geographic range (Jimoh et al. 2018). Amaranth presents resistance to water deficit, saline soils, and acid/alkaline stresses (Tabio-García et al. 2021). Amaranth's resistance to drought and increased photosynthesis effectiveness are due to the C_4 photosynthetic pathway (Jimoh et al. 2018). C_4 plants can use CO_2 and water more efficiently, lowering photorespiration, compared to C_3 plants, like many cereals (Jimoh et al. 2018). Therefore, amaranth tolerates heat and drought, which are typical of arid and semiarid regions (Jimoh et al. 2018). Besides being resistant to abiotic stresses, amaranth is also resistant to biotic stresses (Packard et al. 2021).

Due to amaranth's resistance to several stresses, ability to thrive in a vast range of environments, and great nutritional value, this vegetable is suitable to supply high-quality foods in countries affected by hunger, such as in South Africa (Emmanuel and Babalola 2021; Ma et al. 2021). Even though amaranth has been cultivated in South Africa and many other regions, this crop has been underutilized (Emmanuel and Babalola 2021; Ma et al. 2021) due to the lack of improved, high-yielding varieties, as we will further discuss.

1.2 Amaranth Is a Rich Source of Nutrients

The three main macronutrients for the human diet are protein, carbohydrates, and fat (Holesh et al. 2022). Amaranth has high levels of the majority of the nutrients required for a balanced diet, exceeding many staple crops, such as barley, corn, rice, maize, and wheat (Adhikary et al. 2020; Joshi et al. 2018). Amaranth presents high-quality essential nutrients, such as protein, lipids, carbohydrates, vitamins, and minerals (Table 1).

Protein intake is a very important part of the human diet, providing the essential amino acids (EAA) that the human body needs, but does not synthesize itself (Floret et al. 2021; Lopez and Mohiuddin 2021). The proteins are the major effector of the cells, participating in signaling cascades, gene expression regulation, and several enzymatic reactions (Floret et al. 2021). Besides, amino acids are the building blocks for enzymes, antibodies, hormones, muscle, and many other cellular processes (Lopez and Mohiuddin 2021).

One way to determine the nutritional value of a food item is by measuring the protein content, on which if some essential amino acid is missing, it can be defined as the "limiting amino acid" (Jimoh et al. 2018). By definition, a complete protein source contains all the essential amino acids (Lopez and Mohiuddin 2021). This

Table 1 Nutrient composition from amaranth grains

Nutrient	Nutrient Type	Value per 100 g	Unit
	Water	11.29	g
	Energy	371	kcal
Protein	Total protein	13.56	g
	Glutamic acid	2.26	g
	Glycine	1.64	g

Adapted from Jimoh et al. (2018)

notion holds particular significance when examining vegetarian diets since the most complete protein sources are usually derived from animals (Jimoh et al. 2018; Lopez and Mohiuddin 2021). On the other hand, plant-based foods are usually considered incomplete sources of proteins, for which they may lack some essential amino acid or the limiting amino acid is present in a very low concentration that it does not meet the requirements for human nutrition (Lopez and Mohiuddin 2021). Consequently, it is very important to find good sources of vegetables and cereals for a well-balanced vegetarian-based diet. Plant-based food promotes many benefits to human health, because they are a healthy source of macronutrients and dietary minerals, reducing calorie density and cholesterol consumption (Ivanova et al. 2021). The amaranth symbolizes a nearly complete source of protein for humans. For instance, amaranth grains are abundant in protein (15% of the content) and have nearly all the essential amino acids required for human nutrition (Adhikary et al. 2020)**.** Amaranth is especially rich in lysine, which is a limiting amino acid in other grains (Gebreil et al. 2020; Sisti et al. 2019). Amaranth's only limiting amino acid is leucine, which can be easily obtained by combining amaranth with other food sources (Adhikary et al. 2020). Besides its nutritional value, amaranth proteins also have antioxidant capacity (Coelho et al. 2018), and it has been considered a good source of antihypertensive peptides (Nardo et al. 2020).

On the other hand, carbohydrates have been considered a "great villain" of a healthy nutrition. However, carbohydrates are a great source of energy and, therefore, a fundamental component of the human diet (Holesh et al. 2022). Carbohydrates are categorized based on both the composition of sugars present in their structures and the specific types of sugars they contain (Holesh et al. 2022). Regarding the sugar content, they are classified into: monosaccharides (single sugar molecules), disaccharides (two sugars molecules), oligosaccharides and polysaccharides (more than two sugar molecules linked in long chains, with polysaccharides being the longest) (Holesh et al. 2022). Regarding the sugar type, they are classified as simple (one or two types of sugars), complex (three or more types of sugars), starches (complex carbohydrates rich in glucose) and fiber (non-digestible complex carbohydrates) (Holesh et al. 2022). Plants are one of the richest sources of all types of carbohydrates, with starches and fiber being very specific to these organisms (Holesh et al. 2022). A healthy and balanced diet should favor complex carbohydrates (such as whole grains) and dietary fiber, which are low in glycemic index and calories. These features are important for preventing diabetes, obesity, and inflammatory-mediated diseases (Ivanova et al. 2021). A highlight should be given

to the maintenance of the gut microbiota, which is related to many aspects of human health, such as immunity and energy metabolism (Holesh et al. 2022; Valdes et al. 2018). The consumption of low-digestible carbohydrates (LDC), present in processed foods, can be very detrimental to the gut health (Hollie et al. 2009). The LDC tends to accumulate in the large intestine, serving as substrates for pathogenic bacteria fermentation leading to the dysregulation of the gut microbiome and many other health issues (Hollie et al. 2009). Therefore, the intake of natural or unprocessed food is the best choice for a healthier gut. For instance, amaranth is a great source of healthy carbohydrates. Amaranth is rich in starch, ranging from 47% to 72% of the grains, depending on the species (Coelho et al. 2018; Nardo et al. 2020). Amaranth starch is mainly formed of amylopectin, and the unusual characteristics of the starch granules, such as small size, low resistance, and granular structure, make amaranth's grains very unique (Coelho et al. 2018). Amaranth is also rich in insoluble fiber, such as lignin and cellulose, which contributes to lowering cholesterol and to preserving gut health (Coelho et al. 2018).

Additionally, amaranth is a great source of unsaturated fatty acids, tocopherols, squalene, phytosterols, and polyphenols (Jimoh et al. 2018; Sisti et al. 2019). For instance, amaranth oil has a reasonable amount of squalene, when compared with other vegetable oils, such as olive oil (Coelho et al. 2018; Jimoh et al. 2018). Squalene is a precursor of all steroids in animals and plants (Coelho et al. 2018) and has many health properties, such as anticancer, antioxidant, and anti-inflammatory (Jimoh et al. 2018; Joshi et al. 2018). Squalene from fish oils (especially shark liver oil) has been consumed in high amounts (Kim and Karadeniz 2012). However, due to the regulations on the consumption of animal products, amaranth oil could be a great alternative source for squalene to fish oil (Ibrahim et al. 2020; Jimoh et al. 2018). Amaranth is also rich in tocopherols which are important precursor molecules for vitamin E (Ryan et al. 2007).

Aside from the macronutrients, amaranth is also rich in micronutrients, such as vitamins and minerals (Jimoh et al. 2018). Worldwide, human diets are deficient in vitamins and minerals, especially magnesium (Jimoh et al. 2018). Children and pregnant women are most affected by it, resulting in many diseases (Jimoh et al. 2018). Some of the micronutrients found in amaranth leafy vegetables and/or grain are phosphorus, iron, calcium, potassium, and vitamin A, B, C, and E (Table 1) (Jimoh et al. 2018). Therefore, amaranth is a very promising plant that can be used by humans to replenish their food needs, as well as promoting their health (Jimoh et al. 2018). Amaranth is a very promising vegetable for human consumption because of its unique nutritional and medicinal properties, as well as its ability to grow in non-abiotic and biotic soil conditions throughout the world (Gebreil et al. 2020; Jimoh et al. 2018).

1.3 Amaranth and Nutrigenomics

Food choices affect our body on many levels, including the molecular one. Nutrigenomics is the science that integrates how food constituents affect the

genomics, transcriptomics, proteomics, and metabolomics of an individual (Berná et al. 2014). Diseases occur when environmental conditions act on a predisposed genome. These external factors can be related to healthy or unhealthy lifestyles (Berná et al. 2014). This means that what we eat may interfere with gene expression and downstream signal transduction and ultimately prevent or increase the risk of diseases (Berná et al. 2014).

There is a lack of information on how amaranth-specific nutrients work at the genomic level. Besides, even though some diseases appear to have a genetic predisposition component, sometimes the pathogenesis of the disease is not very well comprehended, for instance, diabetes mellitus (DM) (Berná et al. 2014). Ultimately, it is well known that many disorders, such as obesity, cardiovascular diseases, and cancer, might be related to an interaction of predisposing genes with an imbalanced diet (Berná et al. 2014) and oxidative stress (Berná et al. 2014). Amaranth is rich in antioxidant compounds that play an important role as scavengers of the free reactive oxygen species (ROS) (Coelho et al. 2018), preventing further damage to molecules such as DNA, protein, and lipids, among others. Antioxidant molecules may as well have a role in epigenetics and nutrigenomics (Berná et al. 2014).

In order to develop personalized diets, we need to understand how epigenetics, microRNA, and others affect the expression of genes related to disease (Berná et al. 2014). A healthy diet, based on individual genomic profiles, will maximize gut microbiota health and minimize inflammation and disease susceptibility (Berná et al. 2014).

1.4 Amaranth's Importance to Prevent Diseases and Malnutrition

Plant-based food sources are a great way to combat both starvation and obesity, which pose great threats to food security.

Hunger affects the lives of billions of people worldwide, especially in Africa, and it is a great concern for all nations (Emmanuel and Babalola 2021; Webb 2021). The UN World Food Program (WFP) raised the concern that COVID-19 pandemics would accelerate and amplify the lack of food, as a result of the lockdowns to control the virus spreading (Webb 2021). The COVID-19 pandemic has increased the economic and social damage, leading to more than 70 million people to extreme poverty by the end of the year of 2020 (Webb 2021). The increased food prices amplified the consumption of lower quality food and, therefore, have increased malnutrition (Webb 2021). The COVID-19 pandemic has worsened the food crisis, but, even before that, it was estimated that almost 39% of the world population subsisted on a suboptimal diet because a healthy diet could not be afforded (Webb 2021). It is well known that simple solutions may have a great impact to improve the human diet, such as adding iodine to table salt, which prevents iodine deficiency disorders (that range from hypothyroidism to infant mortality) (Eastman and Zimmermann 2000). Likewise, introducing amaranth vegetable and/or grain as a great source of macronutrients, micronutrients, and bioactive compounds will supply requirements for a balanced diet and improve the medical conditions of consumers.

For instance, amaranth can be used for dietary fortification, improving the nutritional value of processed food (Jimoh et al. 2018). Amaranth flour could be used as a replacement for corn flour in the preparation of many bakery products, such as crackers, cookies, tortillas, and bread, increasing the nutritional value of these processed foods (Gebreil et al. 2020; Jimoh et al. 2018). Besides, amaranth flour is gluten-free, which is very important with the growth of gluten sensitivity and celiac disease (Gebreil et al. 2020; Jimoh et al. 2018). Amaranth can also be used to make pastes, sauces, dressings, and a very large variety of processed food (Jimoh et al. 2018). The high consumption of cheap processed food has been associated with overweight/obesity in both developed and developing countries (Żukiewicz-Sobczak et al. 2014). It is estimated that obesity levels and, consequently, several associated diseases are tending to increase (Żukiewicz-Sobczak et al. 2014). These diseases are more than ever in the spotlight, due to the COVID-19 pandemic (Sattar et al. 2020). People with comorbidities are more vulnerable to the acute respiratory syndrome caused by COVID-19 and also are at the greatest risk for severe illness and even death (Ivanova et al. 2021; Sattar et al. 2020). A recent study has suggested that amaranth might be important in preventing diseases, such as the COVID-19 (Datta 2021).

Amaranth compounds, from proteins to lipids and bioproducts, are potent antioxidants (Adhikary et al. 2020). Since inflammation is a major factor in many chronic diseases, a diet rich anti-inflammatory antioxidants is very important (Ivanova et al. 2021).

Amaranth compounds contribute to lowering cholesterol and consequently diminishing the chances of cardiovascular diseases (Jimoh et al. 2018; Sarker et al. 2020). For instance, amaranth fiber and protein consumption affects cholesterol metabolism and prevents hypercholesterolemia (Sisti et al. 2019). Amaranth is also a great source of vitamin E that, likewise squalene, can contribute to lower cholesterol. Vitamin E also has antioxidant, anticancer, and cardio-protectant properties, besides preventing Alzheimer's (Ryan et al. 2007). Amaranth is also rich in phytosterol, which is a plant sterol. Plant-based diets may lower cholesterol levels and reduce the risk of cardiovascular disease because they reduce sterol absorption by the digestive system (Ryan et al. 2007). Amaranth also has antihypertensive peptides (Nardo et al. 2020).

Amaranth is rich in unsaturated fatty acids, such as omega-3 and omega-6 (Soriano-García et al. 2018). Amaranth lipid portion, such as squalene, has antioxidant, autoinflammatory, and anticancer properties (Soriano-García et al. 2018). Besides the aforementioned medical properties, amaranth natural antioxidants may also have a role in the prevention of cataracts and retinopathies, arthritis, atherosclerosis, and even neurodegenerative diseases (Sarker et al. 2020). The bioactive compounds of the lipid fraction may additionally have antidiarrheal and antidepressant effects as well (Coelho et al. 2018).

Great attention has been given to the *Amaranthus* component betalain, which is responsible for amaranth red color (betacyanin) (Adhikary et al. 2019) (Fig. 1) and can be used as a natural colorant for food (Coelho et al. 2018). Betalains have antioxidant, anticancer, antibacterial, and antimalarial properties (Packard et al. 2021). The betalain from amaranth is therefore a potential natural coloring agent with interesting health benefits for the food industry (Tabio-García et al. 2021). Consumers who want a

Fig. 1 *A. tricolor* "Red Leaf"

healthier lifestyle and are concerned about synthetic colorants' detrimental effects have been attracted to these features (Tabio-García et al. 2021).

There are many nutrients in amaranth, but some compounds, such as non-digestible glucosides, can reduce its ability to be digested and utilized (Jimoh et al. 2018). However, it is possible to improve the bioavailability of nutrients in the edible parts of plants through biofortification (Malik and Maqbool 2020). In the next section, we will discuss bioavailability and biofortification in more detail.

1.5 Bioavailability of Amaranth Nutrients

Bioavailability is the nutrient portion that is utilized by the human body (Jimoh et al. 2018). The fact that amaranth contains a diversity of compounds does not mean all of them are absorbed by the body. For instance, the bioavailability of amaranth proteins can be reduced by the presence of antinutrient compounds, such as phytic acid, nitrate, oxalates, and tannins (Coelho et al. 2018; Jimoh et al. 2018). So far, these compounds have not been associated with toxic effects on human nutrition (Coelho et al. 2018). Therefore, amaranth grain should be properly processed before

ingestion, to increase bioavailability (Coelho et al. 2018; Jimoh et al. 2018). Another trending field is using encapsulation to improve bioavailability of amaranth bioactive compounds (Coelho et al. 2018).

1.6 Amaranth Biofortification

Micronutrients, such as iron, zinc, iodine, and vitamins, are crucial for human health, and their lack in malnourished populations can lead to many disorders and diseases (Malik and Maqbool 2020). In countries with a limited choice of diets, biofortification holds the promise of providing a single source of complete nutrition (Malik and Maqbool 2020). Some health conditions affected by malnourishment are highlighted in Table 2. Pregnant women and children are particularly vulnerable to these conditions (Malik and Maqbool 2020).

Biofortification can be obtained through agricultural practices, traditional breeding, or genetic editing (Malik and Maqbool 2020). Staple cereals, vegetables, beans, and fruits have been biofortified using these approaches (Garg et al. 2018). Different from simply adding nutritional value to staple foods, biofortification attempts alterations in the plant phenotype (Malik and Maqbool 2020). Besides creating grains with enhanced nutritional value, the biofortified plants also may become less susceptible to biotic and abiotic stresses (Malik and Maqbool 2020).

So far, our agricultural practices have not been focused on increasing nutrient quality but, instead, maximizing yield, which can decrease the nutritional quality of the grains (Garg et al. 2018). Agricultural practices that can favor crops' biofortification involve fertilization, seed treatment and nurseries, and certified seeds (Ochieng et al. 2019).

1.6.1 Genetic Approaches for Amaranth Biofortification

There is a great effort from the scientific community to produce plants with an improved protein profile, including limiting amino acids (Wenefrida et al. 2013).

Table 2 Micronutrient deficiency and health conditions

Deficiency in micronutrients	Health condition
Iron	Anemia
Zinc	Night blindness, dermatitis, loss of appetite, impaired immune system
Iodine	Pregnancy related issues (affects the neurodevelopment of fetus), affects growth and cognitive functions in children
Vitamin A	Blindness, pregnancy and breastfeeding related issues, impaired immune system
Vitamin B	Skin inflammation, impaired immune system, fatigue, and depression
Vitamin C	Dermatologic issues, joint pain, and impaired immune system
Vitamin E	Nerve and muscle damages, impaired immune system, hemolytic anemia, ophthalmological disorders

Source: Malik and Maqbool (2020)

Several methods can be used with this purpose, such as genetic breeding and genetic engineering, genomics, and selection assisted by markers (Wenefrida et al. 2013).

Biofortification through genetic breeding is possible when genetic diversity is available for a given species (Garg et al. 2018). Genetic diversity is represented in the germplasm databases, which are a collection of genetic resources for a given organism. Amaranth includes up to more than 11,000 accessions among 8 gene banks (Joshi et al. 2018). However, it seems that amaranth genetic diversity has been poorly used in breeding programs (Joshi et al. 2018).

Finally, genomic editing is one of the most promising approaches to improving amaranth nutritional value. The increased amount of genetic data generated by sequencing, such as amaranth reference genome (Lightfoot et al. 2017) and other genomic and transcriptomic data (Clouse et al. 2016; Délano-Frier et al. 2011; Sunil et al. 2014), is increasing the potential to edit amaranth genome.

Using gene edition, amaranth macronutrients, such as protein, have been targeted (Garg et al. 2018). The amaranth lysine pathway, for example, is an attractive biofortification target. According to Sunil et al. (2014), amaranth contains more lysine and threonine than major cereals such as rice and wheat, and some plants don't even produce lysine or threonine (Wenefrida et al. 2013).

Using amaranth genes, many crops have been biofortified. To modify rice grains, which lack lysine and threonine, synthetic genes combining endogenous rice sequences with lysine and threonine coding sequences were inserted under the promoter 35S to produce these amino acids in large quantities (Jiang et al. 2016). However, there are limitations to the production of transgenic biofortified plants (Jiang et al. 2016). Still, Jiang et al. (2016) research opened venues for producing transgenic plants with synthetic genes with enhanced lysine and threonine content. In order to produce plants biofortified with lysine and threonine, we must understand their biosynthetic pathway. In this regard, the draft of *Amaranthus hypochondriacus* genome and transcriptome was obtained in 2014 (Sunil et al. 2014), with particular attention given to the annotation of the genes involved in lysine biosynthesis. Amaranth genes such as albumin genes (AmA1) have also been used to change the protein content in plants, such as wheat (*Triticum aestivum* L.) (Garg et al. 2018). The amino acids that increased in content were methionine, cysteine, and tyrosine, besides lysine (Garg et al. 2018; Tamás et al. 2009). In addition, transgenic potatoes were also improved in amino acid content using the same albumin gene (AmA1) from amaranth (Chakraborty et al. 2010; Garg et al. 2018). A further result of this biofortification was an increase in potato photosynthetic activity and yield, proving the importance of biofortification with the AmA1 albumin gene from amaranth (Chakraborty et al. 2010).

It appears that amaranth genes have been used more to biofortify plants than to alter the amaranth itself. It is likely that the most recent gene editing strategies will increase the possibility of improving amaranth traits in the near future.

1.7 Biochemical Pathways of Amaranth Compounds

Understanding the genes and proteins underlying a biosynthetic pathway is crucial to improving plant breeding programs using gene editing.

This chapter will focus on two amaranth compound biosynthetic pathways, which may be of great interest for the food and health industries: lysine biosynthesis and betalain biosynthesis.

The lysine biosynthetic pathway in plants shares a common route with the amino acids threonine, isoleucine, and methionine: the aspartate pathway, where L-aspartate is the precursor of these amino acids (Sunil et al. 2014). Two main enzymes regulate the lysine biosynthetic pathway: the aspartate kinase (AK; EC 2.7.2.4) and the dihydrodipicolinate synthase (DHDPS; EC 4.3.3.7) (Sunil et al. 2014). As stated by Sunil et al. (2014), the high-lysine content in *Amaranthus* is due to the presence of only one ortholog of aspartate kinase 1 (AK1) gene and high expression of the dihydrodipicolinate synthase (DHDPS) gene in seeds.

The lysine biosynthetic pathway in amaranth is not very clear yet. Sunil et al. (2014) published a draft of *A. hypochondriacus* genome and found several isoenzymes AK and DHDPS, among other five important enzymes of the aspartate biosynthetic pathway in plants, such as aspartate semialdehyde dehydrogenase (ASD; EC 1.2.1.11), dihydrodipicolinate reductase (DHDPR; EC 1.17.1.8), diaminopimelate aminotransferase (DAPAT; EC 2.6.1.83), diaminopimelate epimerase (DAPE; EC 5.1.1.7), and diaminopimelate decarboxylase (DAPDC; EC 4.1.1.20). The gene expression profile of the AK and DHDPS revealed a correlation with the high-lysine content in amaranth (Sunil et al. 2014). The study of amaranth lysine biosynthesis as a model for understanding plant lysine biosynthesis is of great importance in order to produce high-lysine content plants.

Regarding betalains, these molecules are composed of at least one heterocyclic ring containing a nitrogen atom and are derived from betalamic acid [4-(2-oxoethylidene)-1,2,3,4- tetrahydropyridine-2, 6-dicarboxylic acid] (Böhm and Rink 1988; Packard et al. 2021). The betalain biosynthetic pathway is controlled by several factors and conditions, and it was very well discussed by Packard et al. (2021). In summary, betalamic acid condensates with *cyclo*-DOPA, forms betacyanin, and, when it condensates with amino acids or amines, forms betaxanthin (Böhm and Rink 1988; Packard et al. 2021). L-tyrosine is the main precursor of betalains, being first converted to L-DOPA and subsequently to cyclo-DOPA by several enzymes of this biosynthetic pathway (Böhm and Rink 1988; Packard et al. 2021).

The betalain biosynthetic pathway has been carefully reviewed by Packard et al. (2021), and it is a reliable source of information to guide gene editing or gene expression of betalain-related genes. It is interesting to notice that betalains are not very well represented among many plant edible species; therefore, they are less consumed than other antioxidant pigments (Grützner et al. 2021). Grützner et al. (2021) suggested that incorporating betalain biosynthetic genes in a varied range of transgenic species, such as tomatoes, could increase betalain consumption. Moreover, many other transgenic plants producing betalain have been obtained through heterologous expression (Packard et al. 2021). Therefore, these techniques can be exploited to scale up betalain production commercially (Packard et al. 2021).

Since many plants lack the amino acid lysine, and the betalain pigment is restricted to the order of Caryophyllales, amaranth is an excellent role model for

understanding the biosynthesis of these two compounds, which present many desirable effects for human nutrition and health.

2 Genetic Resources of Amaranth

2.1 Brief on Genetic Diversity Analysis of Amaranth

Amaranth and its wild relatives harbor considerable phenotypic plasticity and genetic variability (Gerrano et al. 2017) which contribute to their adaptability to a variety of soil and agroclimatic conditions (Dharajiya et al. 2021). Therefore, amaranth has excellent potential for breeding and variety development. In this respect, the characterization of genetic diversity of amaranths is fundamental for the development of germplasm widely diverse to be efficiently used in genetic breeding programs (Dharajiya et al. 2021; Thapa et al. 2021). As previously described, amaranth grain has high potential from cultivation in the field to the production of value-added products, including nutritional and health benefits (D'Amico and Schoenlechner 2017).

The amaranth genus has gained attention as a promising food crop, mainly owing to its tolerance to stressful conditions (Pulvento et al. 2021) besides its great nutritional and functional benefits (Coelho et al. 2018; D'Amico and Schoenlechner 2017). Moreover, in view of the wide geographic distribution and genetic diversity, cultivated and weedy amaranths emerged as appealing models to be explored in improving yield and nutraceutical value (Soriano-García et al. 2018).

Efforts have been made to maintain amaranth's diversity in germplasm banks worldwide (Das 2016; Joshi et al. 2018). Examples of germplasm banks include the US National Plant Germplasm System, with more than 3000 accessions of amaranth from 40 countries (Joshi et al. 2021; Trucco and Tranel 2011). Various morphological and molecular markers have been used for the study of genetic diversity and evolutionary relationships in selected species of the genus *Amaranthus*. We will further discuss the use of molecular markers in the characterization of the amaranth germplasm.

2.1.1 Genetic Diversity Analysis of Amaranth Assisted by Morphological Traits

An approach adequately used to assess genetic diversity is through a combination of morphological, biochemical, and molecular data within amaranth genus (Govindaraj et al. 2015). Morphological descriptors (i.e., color of leaf, flower, stem, and panicle; leaf and panicle shape; plant habit; etc.) have been used to assess amaranth's diversity (Gerrano et al. 2017; Thapa and Blair 2018). Such characteristics are useful to obtain basic information on existing morphological variability from cultivated species and their wild relatives, which can be incorporated into pre-breeding programs (Showemimo et al. 2021). Examples include the selection of parental materials based on the existence of genetic variation. Gerrano et al. (2017) used morphological traits of *Amaranthus* species, aiming to identify the best parents for

the traits of interest that could be used in the *Amaranthus* breeding program. This study revealed a wide genetic diversity among the species evaluated, helping with the selection of target accessions for the amaranth breeding program in South Africa (Gerrano et al. 2017). Thapa and Blair (2018) observed a wide diversity in phenotypic traits among amaranth species when studying 293 cultivated grain amaranths and their wild relatives. According to the authors, field assessment of major morphological traits can be successful in amaranth grain with implications for breeding varieties (Thapa and Blair 2018). In another study (Showemimo et al. 2021), 12 amaranth grain accessions exhibited high phenotypic and genetic variability for all the traits measured (particularly the desired leaf traits and grain yield traits). Phenotypic variances were slightly higher than the genotypic variance for all the traits measured, revealing little influence of the environment, suggesting that the accession variability is considered useful for amaranth selection and improvement (Showemimo et al. 2021).

Morphological characters also have been useful in understanding the evolutionary relationship of *Amaranthus* species. In India, a study revealed an evolutionary relationship of six amaranth species (*A. blitum*, *A. blitoides*, *A. deflexus*, *A. dubius*, *A. polygonoides*, and *A. retroflexus*) from different states (Kamble and Gaikwad 2021). However, the insufficient distinctive morphological characters for *Amaranthus* species have hampered the use of morphological markers alone (Govindaraj et al. 2015; Thapa and Blair 2018). For this purpose, molecular markers have been widely considered to assess *Amaranthus* genetic diversity in complementing morphological information (Oduwaye et al. 2019).

2.1.2 Genetic Diversity Analysis of Amaranth Assisted by Molecular Markers

Germplasm characterization based on molecular markers has gained importance due to the speed and quality of information of genetic diversity data created. The use of improved marker systems may aid in the better characterization of the vegetal germplasm, rather than using only the morphological trait system (Dar et al. 2019). For this purpose, molecular markers have been employed in germplasm characterization, phylogenetic analysis, and genetic diversity of the major crop species (Dar et al. 2019). Markers such as amplified fragment length polymorphism (AFLP), random amplified polymorphic DNA (RAPD), microsatellites or simple sequence repeats (SSRs), inter-simple sequence repeat (ISSR), and single nucleotide polymorphisms (SNPs) have been efficiently used to evaluate the variability of germplasm accessions in amaranth (Thapa and Blair 2018).

For instance, AFLP was applied by Chandi and collaborators (2013), to assess genetic diversity in Palmer amaranth populations (from North Carolina and Georgia) and to characterize diversity among states, populations, gender, and even response to glyphosate. These results are important, for example, to optimize weed management in breeding programs of amaranth populations (Chandi et al. 2013).

The RAPD marker has also been used to assess genetic diversity and in the selection of potential parents for characters of interest in plant breeding programs. For instance, the genetic diversity within 29-grain amaranth accessions in Southwest

Nigeria was accessed using 27 phenotypic characters (10 morphological and 17 nutritional) and RAPD marker (Akin-Idowu et al. 2016). The level of polymorphism obtained with RAPD primers (81%) broadly indicates the degree of heterogeneity observed in this amaranth germplasm (Akin-Idowu et al. 2016). The RAPD marker has also contributed to the understanding of the origin and evolution of cultivated amaranth and wild species. In this sense, seven amaranth species from different phytogeographic regions were evaluated by RAPD which was sufficient to promote a level of (intra- and interspecific) informative characters (Kumar Pandey et al. 2019).

Furthermore, the availability of high-throughput sequencing technologies has facilitated the fast discovery of thousands of microsatellite regions, which may further facilitate understanding evolutionary relationships, genetic diversity, and genomic texture of *Amaranthus* species (Tiwari et al. 2021).

Due to their multiallelic nature, codominant inheritance, and wide distribution throughout the plant's and animals' genome, including organellar genomes (mtSSR and cpSSR) (Gupta et al. 2021), microsatellites have gained considerable importance in plant genetic diversity studies, population genetics, and evolutionary studies. They have also been used in fundamental research such as genome analysis, gene mapping, and marker-assisted selection, among others (Gupta et al. 2021).

Using *A. hypochondriacus* genome, Tiwari et al. (2021) identified and characterized a set of SSRs, which facilitated the identification of 97 alleles among 10 *Amaranthus* species (*A. hypochondriacus*, *A. caudatus*, *A. retroflexus*, *A. cruentus*, *A. tricolor*, *A. lividus*, *A. hybridus*, *A. viridis*, *A. edulis*, and *A. dubius*), revealing relationships among amaranth spp. that could be useful in species identification, DNA fingerprinting, and QTL/gene identification (Tiwari et al. 2021).

Amaranthus genetic diversity has also been accessed by chloroplast sequences**.** Full-length chloroplast sequences for four *Amaranthus* species (*A. hypochondriacus*, *A. cruentus*, *A. caudatus*, and *A. hybridus*) were assembled by Chaney et al. (2016) revealing polymorphic microsatellite and informative SNP (*single nucleotide polymorphism*) markers, with application in amaranth phylogenetic and genetic diversity studies. A chloroplast matK marker (maturase K gene) was used to identify leafy amaranth species from Vietnam (Nguyen et al. 2019). Twenty-one SSR markers were developed for *A. tricolor* 'Biam', which successfully amplified single alleles in 294 Vietnamese and overseas accessions (Nguyen et al. 2019). According to the authors, there was a positive relationship between geographic distance and genetic differentiation among most of the overseas groups and the Vietnamese collection (Nguyen et al. 2019). In another study, Hong et al. (2019) also related a close relationship among the chloroplast genomes of *Amaranthus hybridus*, *A. hypochondriacus*, and *A. caudatus*. This relationship was reassured by the complete chloroplast genome of *A. hybridus* sequencing (Bai et al. 2021), which revealed a close relationship between *A. hypochondriacus* and *A. caudatus*. These studies are fundamental to promoting a better understanding of the phylogeny and evolution of the genus *Amaranthus*.

2.1.3 The Evolutionary Relationship of Amaranth

Molecular markers have also made great contributions to the elucidation of the origin and evolution of amaranth. The evolutionary relationship among *A. caudatus*,

A. hybridus, and *A. quitensis* was determined by Stetter et al. (2016). In this study, 119 accessions of the 3 species from the Andean region were genotyped using genotyping by sequencing (GBS) with phenotypic variation in 2 domestication-related traits: seed size and seed color (Stetter et al. 2016). As a result, 9485 SNPs were obtained, and a strong genetic differentiation of the cultivated *A. caudatus* from the relatives *A. hybridus* and *A. quitensis* was observed (Stetter et al. 2016). Given its utility in detecting large numbers of SNPs, the GBS technology was applied to study the diversity and population structure of the grain amaranth, compared to an outgroup of *Amaranthus* species (Wu and Blair 2017). This analysis revealed a high variation within amaranth grain species and their close relatives (Wu and Blair 2017).

Thapa et al. (2021) studied the diversity and relationship among collections of amaranth (accessions of all three cultivated grain amaranth species and their wild relatives). The authors suggested that two Mesoamerican species (*A. cruentus* and *A. hypochondriacus*) were intercrossed and distantly related to the South American species (*A. caudatus* and the weedy relative *A. quitensis*), which persisted in a wild-cultivated hybrid state (Thapa et al. 2021).

The knowledge and characterization of genetic diversity, within amaranth's populations, as well as germplasm conservation, are essential steps for developing new varieties/cultivars with desired agronomic traits, and it is useful for exploring its nutritional and medicinal properties. Collectively, molecular markers have been an excellent approach for various purposes, including genetic studies, breeding efforts, and marker-assisted selection of amaranth.

3 Molecular Mapping of Genes/QTLs Underlying Nutritional Traits in Amaranth

DNA markers have been a useful tool not only for assessing intraspecific variation but also for the subsequent characterization and identification of quantitative trait loci (QTLs) for agronomic and nutritional quality in amaranth genotypes (Akin-Idowu et al. 2016). Marker-assisted breeding employs the linkage between known QTLs and genetic markers to select individuals. SNP markers have therefore been effective when used in marker-assisted selection (MAS), especially when linked to target QTLs (Stetter et al. 2016).

When it comes to complex traits, effective breeding methods are needed to identify and exploit previously unexplained trait variation caused by a large number of small-effect QTLs, as well as methods that utilize genomic selection (GS) information (Varshney et al. 2021). As high-throughput sequencing technologies have improved, crop breeding programs have become more precise and efficient due to the discovery and mapping of genome-wide allelic variation (Varshney et al. 2021). For instance, genome-wide surveys on comprehensive diversity panels and reference genomes have facilitated phenotypic associations. The DArTSeq technology (based on GBS methods) was used by Jamalluddin et al. (2022) to determine the genetic relationships and population structure between 188 amaranth accessions from 18 agronomically important vegetable, grain, and weedy species. Out of the

74,303 SNP markers identified, 63,821 could be physically mapped to the *A. hypochondriacus* genome (Jamalluddin et al. 2022). This marker allowed a genome-wide association study (GWAS) analysis for ten morphological traits and, hence, provided useful information on genetic diversity and its correlation with agronomic traits in amaranth (Jamalluddin et al. 2022).

In addition, a universal SNP dataset across *Amaranthus* species was produced using double-digest restriction site-associated DNA (ddRAD-Seq) sequencing, allowing access to genetic diversity across the major species of the World Vegetable Center (with over 1000 *Amaranthus* accessions) (Lin et al. 2022). Candidate loci that regulate days to flowering were revealed by an interspecific genome-wide association study (GWAS) (Lin et al. 2022). This study showed that genotypic data is useful for species demarcation in the genus *Amaranthus* and that interspecific GWAS can detect quantitative trait loci (QTLs) across species (Lin et al. 2022). Recently, *A. tricolor* accessions (preserved by the World Veg and USDA gene banks) were also evaluated using genome-wide SNPs developed by ddRAD-Seq (Hoshikawa et al. 2023). The 440 accessions contained 10,509 SNPs, with 5638 without missing data (Hoshikawa et al. 2023). With these results, a core collection is now available that represents a wide diversity of amaranth germplasm. This collection will help researchers find important agronomic gene loci to improve genetic breeding, thus improving the economics of amaranth (Hoshikawa et al. 2023).

In addition, Ma et al. (2021) assembled the genome of *A. cruentus* at the chromosome level using short-read, long-read, and phased sequencing technologies. The goal of this study was to identify the genomic features related to the high levels of micronutrients and proteins in these species leaves (Ma et al. 2021). In this study, gene colocations for the key enzymes that synthesize betalain were found across the Amaranthaceae family (Ma et al. 2021). Furthermore, 22 possible biosynthetic gene clusters were identified in *A. cruentus* genome (10 of which are conserved in *A. hypochondriacus*) that may facilitate the elucidation of other metabolic biosynthetic pathways present in this plant species (Ma et al. 2021). This will benefit amaranth breeding programs.

As in cultivated species, the genome sequencing of wild and weedy species would be advantageous for various large-scale genotyping applications, including germplasm characterization, cultivar identification, and QTL discovery (Joshi et al. 2018). In contrast to major crops (including model plants), amaranth weeds have not been adequately explored, and genomic tools can be efficiently applied in the identification and characterization of genes related to genetic traits that make weeds so resilient when compared with crops in identical niches. Thus, weed species of agronomic importance, such as *A. rudis* (common waterhemp), *A. palmeri* (palmer pigweed), and *A. hybridus* (smooth pigweed), are also potential candidates for genomics studies (Trucco and Tranel 2011).

The QTL regions for different traits of amaranth have been identified (Lightfoot et al. 2017; Maughan et al. 2011). Recently, Stetter and collaborators (2020) showed strong evidence that the grain amaranth was domesticated three times and that the white seed color was independently selected in each grain species. Furthermore, the authors identified a MYB-like transcription factor (TF) gene within a QTL region

showing to be a potential regulator of seed coat color variation of amaranth grain (Stetter et al. 2020).

TFs have also been related in different amaranth studies as the most promising gene family involved in response to biotic and abiotic stresses (Palmeros-Suárez et al. 2021). Therefore, TFs are important candidates to increasing plant resistance to stresses through genetic engineering (Palmeros-Suárez et al. 2021).

Genetic mapping is an important resource to gain further insight into the underlying genes for traits of economic importance. Thus, the knowledge of genetic diversity in amaranth breeding programs is essential, especially in the identification of the best parents to a generation of segregating population with genetic variability for introgression of desired traits in the development of high-yielding varieties of amaranth (Dharajiya et al. 2021). The use of genomic prediction could largely accelerate the genetic gain for nutritional traits and holds great potential for biofortification breeding in grain amaranth (Joshi et al. 2018).

4 Limitations of Conventional Breeding and Genetic Resources of Amaranth

A little number of amaranth cultivars with enhanced agricultural traits have been released so far (Schafleitner et al. 2022). The most successful amaranth variety implemented in the USA has been the Plainsman (Baltensperger et al. 1992), which is an improvement of *A. hypochondriacus* genotype, where the trait earliness was introduced (Joshi et al. 2018). However, there is still so much room for improvement of amaranth cultivars, especially if the "wild" genes from native species, which represents a diverse genetic resource, were more explored (Joshi et al. 2018).

One of the challenges to the amaranth breeding program is the nature of amaranth flowers, which are numerous and self-pollinating, making the crossing processes difficult (Stetter et al. 2016). Stetter et al. (2016) evaluated different crossing methods within three amaranth grain species, where the highest success rate was obtained with the hand emasculation method (74%). It has been suggested that amaranth heterotic breeding across the grain cultivars could also be a good strategy for advanced breeding in amaranth (Joshi et al. 2018). Additionally, mutation breeding has shown great results in increasing the polygenic variability of four cultivars of amaranth (Joshi et al. 2018). Lysine content, among other traits, has been increased in amaranth species through mutational approaches (Joshi et al. 2018).

Other traits that have been targeted for amaranth genetic breeding are plant height reduction, increased seed size, and adaptation to the mechanical harvesting (Joshi et al. 2018; Schafleitner et al. 2022; Stetter et al. 2016). Besides, improving the taste and nutritional quality of the leaves, rapid growth, and resistance to biotic and abiotic stresses are important targets to plant breeding programs (Schafleitner et al. 2022). Even though amaranth is very resistant to abiotic and biotic stresses, this trait should be kept in breeding pools to improve amaranth's abundance and distribution (Joshi et al. 2018). The knowledge of the genetic diversity of

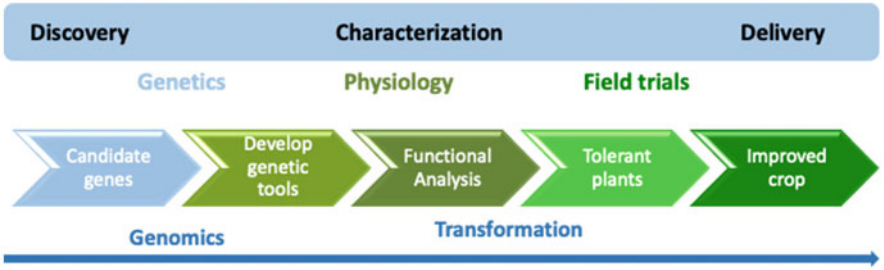

Fig. 2 Improved crop design flowchart

Amaranthus species will provide information for creating superior cultivars in plant breeding programs (Joshi et al. 2018).

Amaranth genetic traits and the current state of genetic breeding have been carefully reviewed by Joshi et al. (2018). Genetic resources, genotyping, and genomics are the core information to create superior genotypes through traditional breeding programs, genetic engineering, and genome editing (Fig. 2) (Joshi et al. 2018). This will lead to an increased use of amaranth as a main agricultural crop. The use of minor crops will increase agrobiodiversity and, therefore, favor food global security (Joshi et al. 2018).

Although genomic prediction can accelerate the selection of grain with increased nutritional value, very few studies have been performed with *Amaranthus* so far (Joshi et al. 2018) as previously discussed. The available strategies for amaranth gene editing will be discussed in the next section.

5 Strategies for Amaranth Gene Editing

Gene editing is a great strategy for precise genome modifications in plants (Wada et al. 2020). The most advanced technologies for gene editing are zinc finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and clustered regularly interspaced short palindromic repeat (CRISPR)-associated protein 9 (CRISPR/Cas9) (Liang et al. 2014; Wada et al. 2020). CRISPR has many advantages when compared with ZFNs and TALENs, because it is simpler, while these other techniques require more complex constructs (Bortesi and Fischer 2015; Joshi et al. 2018; Liang et al. 2014). CRISPR allows using multiple targets for genetic improvement and therefore can aid in the creation of new crop varieties in an unprecedented way, by inducing double-strand breaks (DSBs) in DNA (Wolter et al. 2019). CRISPR is a powerful tool for genome editing and is generating exciting new possibilities to increase the genetic diversity of amaranth (Joshi et al. 2018). However, none of these genome editing techniques have been used with amaranth so far (Joshi et al. 2018), even though many other studies using reverse genetics have been published for this plant (Packard et al. 2021).

Amaranth is a great candidate for gene editing since it has a vast repository of genomic data (Clouse et al. 2016; Délano-Frier et al. 2011; Lightfoot et al. 2017; Sunil et al. 2014), and protocols for regeneration using tissue culture are well-established for this plant (Adhikary et al. 2019; Joshi et al. 2018). In fact, the technology VIGS (virus-induced gene silencing) has been successfully used to study genes of betalain biosynthesis in amaranth (Adhikary et al. 2019). Adhikary et al. (2019) work established an efficient genetic transformation protocol that can be used for the improvement of genes involved with amaranth's nutritional and medicinal properties, besides the yield (Joshi et al. 2018). That being said, it is very important to invest in the development of protocols for using the most varied gene editing techniques in amaranth.

Another potential technology for amaranth genome editing is the nanotechnology-based genome editing system (Ahmar et al. 2021). This technology claims to be even more efficient, safe, and simpler than CRISPR (Ahmar et al. 2021). It is also possible that CRISPR/Cas9 nanotechnology coupled systems represent the most advanced technology available in gene editing (Naik et al. 2022). These techniques have not been employed in amaranth so far but could speed up the creation of improved varieties at a lower cost, by overcoming the challenges of traditional breeding methods (Ahmar et al. 2021). In conclusion, the production of varieties with high nutritional value and yields, and many times also resistant to biotic and/or abiotic stresses, would be an incredible mark for food safety and in the combat of malnourishment worldwide.

6 Brief Account on the Role of Bioinformatics as a Tool

For some years, biology and computer science were very connected. Therefore, a new field has emerged named bioinformatics, which is the science of managing, mining, integrating, and interpreting information from biological data from different levels of an organism.

Given the complexity and exponential growth of biological data from omics projects, computational storage and analysis techniques have become increasingly demanded, to solve three main problems: efficient storage, information's management, and extraction of relevant information from the data (Quintans et al. 2022). The last problem is one of the main challenges of computational biology and bioinformatics, which requires the development of tools/databases capable of transforming all this heterogeneous data into biological knowledge (Greene et al. 2014). These bioinformatic databases and tools go beyond a description of the data, by delivering new biological insights. It is almost impossible to carry out research in bioinformatics without using a database and bioinformatic tools to process and explore the vast collection of available data, both public and private.

In this context, in this sections, we will describe databases of genes, genomes, gene expression, proteins, genome comparison tools, and the integration of other different types of data from plants of the amaranth genus that allow increasing knowledge about the system biology of these plants, providing nutritive and weed

resistance biotechnological advances. Furthermore, the amaranth genome study will underpin the research of this orphan crop and accelerate the development of improved varieties.

6.1 Amaranth Genome Sequencing

To date, a few amaranth genomes have been published, such as *A. hypochondriacus* (Clouse et al. 2016; Sunil et al. 2014) and *A. cruentus* (Clouse et al. 2016; Ma et al. 2021) of grain species and *A. tuberculatus*, *A. hybridus*, and *A. palmeri* (Montgomery et al. 2020) of weed species. Table 3 summarizes the genomic information of amaranth, such as haploid chromosome number, total genome length (Mb), and the GC content.

A. hypochondriacus genome was sequenced in 2014 (Sunil et al. 2014) representing the first C4 dicot genome and the first grain species from Caryophyllales. *A. hypochondriacus* is an interesting species for its C4 metabolism, being capable of tolerating many adverse conditions, such as drought, and still producing highly nutritious seeds (NCBI Resource Coordinators 2016; Sunil et al. 2014). *A. hypochondriacus* genome encodes at least 24,829 proteins (Sunil et al. 2014). However, only 112 gene results are displayed after a search at NCBI, when the query "*Amaranthus hypochondriacus*" is used in the "Gene" category (NCBI Resource Coordinators 2016, Access 24 June, 2022). Likewise, a high-quality draft of *A. hypochondriacus L.* genome (N_{50} of 371 kb) was obtained by Clouse et al. (2016) using whole-genome sequencing (WGS) and transcriptome sequencing (TS). The assembled genome presented 377 Mb, being rich in repetitive sequences (48% of the sequences), including many retrotransposons (Clouse et al. 2016). In this study 23,059 protein-coding genes were identified (Clouse et al. 2016) corroborating with Sunil et al. (2014). Clouse et al. (2016) also acknowledged that *A. hybridus* is the progenitor species of the grain amaranth.

Table 3 Summary of information about the genomes of *Amaranthus* species: haploid chromosome, total length (Mb) of genome, and GC content

	Amaranthus hypochondriacus (Sunil et al. 2014)	*Amaranthus hypochondriacus* (Clouse et al. 2016)	*Amaranthus tuberculatus* (submitted by the University of Illinois)	*Amaranthus palmeri* (submitted by Clemson University)	*Amaranthus cruentus* (Ma et al. 2021)
Haploid chromosomes	16	16	16	17	17
Total length (Mb)	417.46	377	572.9	395.293	370.914
GC%	34.5087	34.7	35	33.45	33.0875

Source: (CABI 2022; Clouse et al. 2016; Ma et al. 2021; Montgomery et al. 2020; Sunil et al. 2014)

Furthermore, a genome draft of three *Amaranthus* weed species of agricultural importance was published in 2020: *A. tuberculatus*, *A. hybridus*, and *A. palmeri* (Montgomery et al. 2020). Montegomery and collaborators (2020) obtained the most contiguous draft assemblies for these amaranth weeds, including the very first genome assembled for *A. hybridus*, by combining several sequencing approaches, such as long-read sequencing and chromatin mapping (Montgomery et al. 2020). The study of the weed's genome will aid in a better understanding of herbicide's resistance evolution, which is essential for weed's management (Montgomery et al. 2020).

In 2021, another amaranth grain species, *A. cruentus,* had its genome sequenced (Ma et al. 2021). *A. cruentus* genome (370.914 Mb and 33.0875% of GC content) was sequenced using short-read, long-read, and phased sequencing technologies by the University of York (Ma et al. 2021). However, *A. cruentus* lacks details regarding the genome annotation, and also, there is no gene associated with this species in NCBI (Ma et al. 2021; NCBI Resource Coordinators 2016).

Currently, the NCBI holds 1109 plant genomes and 476,498 plant genes, of which 518 are from *Amaranthus* species (NCBI Resource Coordinators 2016, Access 31 March, 2022). There are four species of *Amaranthus* with their whole genomes sequenced and available at the NCBI, namely, *A. hypochondriacus*, *A. tuberculatus*, *A. palmeri*, and *A. cruentus* (NCBI Resource Coordinators 2016, Access 31 March, 2022).

The amaranth genome sequencing supplies a reference genome for transcriptomic and proteomic studies, besides being valuable for evolutionary insights of *Amaranthus* genus, the Caryophyllales order, and, ultimately, angiosperms in general (Sunil et al. 2014; Adhikari et al. 2021). This knowledge will be useful for the rational design of amaranth crops, with increased productivity and quality traits (Ma et al. 2021).

6.2 Amaranth Sequences Among the Gene and Genome Databases

Genomic databases are DNA sequence repositories from many different species of plants and animals. The National Center for Biotechnology Information (NCBI), for instance, is one of the most important biological databases and stores genes from different organisms in domains of life (NCBI Resource Coordinators 2016).

There are many types of databases according to the biological data, such as genomic databases (DNA sequences), transcriptomic databases (RNA sequences), proteomic databases (protein sequences), and structure databases (mainly protein structures). There are also more specific databases, such as Metabolic and Signaling Pathways, Diseases Databases, Gene Expression Databases, Plant Databases, and Taxonomic Databases. Each of them includes a specificity, and some can integrate a variety of database functions (Quintans et al. 2022). These databases offer information on the sequences and can be created for specific organisms, such as animals and plants. For instance, the AmaranthGDB (Gonçalves-Dias and Stetter 2021) is a genetics and genomic database specific to the genus *Amaranthus*.

6.2.1 AmaranthGDB

AmaranthGDB is a database with genetic and genomic information on amaranth and tools to accelerate amaranth research (Gonçalves-Dias and Stetter 2021). One of the available tools is the PopAmaranth, which is a genetic browser that combines amaranth genomic data and genome-wide population (Gonçalves-Dias and Stetter 2021). The information is easily retrieved and may be used to identify target genes by the researcher (Gonçalves-Dias and Stetter 2021). Regarding improving the nutritional value of amaranth, some genetic features have been pinpointed as putative targets, such as genes that participate in the synthesis of phytic acid (which is an antinutrient), gene families of ion transporters, and biosynthetic gene clusters within amaranth line (Gonçalves-Dias and Stetter 2021).

6.2.2 Amaranth and Gene Expression Databases

The genomic projects have been adding expressive data to the current databases, as we previously discussed. Although genomic data are important, the identification of genes linked to important agronomic traits requires gene function analysis, which is why Gene Expression Databases, such as Gene Expression Omnibus (GEO), are essential (Edgar et al. 2002). However, GEO, which is a nonspecific database, does not hold any data from amaranth species (Edgar et al. 2002; Accessed 12 April, 2022).

There are plant-specific gene expression databases: DRASTIC (Button et al. 2006), PLANEX (Yim et al. 2013), and PLEXdb (Dash et al. 2012); however, no data is available for the *Amaranthus* genus. These databases hold data of genes regulated in response to abiotic and biotic stresses, as well genes important to the phytopathogens (Dash et al. 2012; Yim et al. 2013).

Although there is no data on amaranth in the gene expression databases, some authors have carried out research on the subject. Délano-Frier et al. (2011) were pioneers in attempting to increase the limited transcriptomic information on amaranth, a highly nutritious and stress-tolerant crop. Briefly, they performed large-scale transcriptome analysis from different tissues (leaves and stems) of *A. hypochondriacus,* in response to several biotic (herbivory and bacterial infection) and abiotic stresses (water and salt stresses), using 454 pyrosequencing (Délano-Frier et al. 2011). The comparative transcriptome analyses returned 8260 homologous sequences between *A. tuberculatus* and *A. hypochondriacus* transcriptomes, and 1971 DEG were identified in response to at least 1 of the treatments applied (Délano-Frier et al. 2011). This study greatly contributed to underpin the multiple stress resistance in plants, a desired trait for plant biotechnology (Délano-Frier et al. 2011).

The lack of expression data on amaranth in the main databases reinforces the need of increasing functional gene analysis research of this crop, with transcriptomic experiments, such as RNA-seq, with different tissues and conditions. The increasing amount of data is not the only limiting factor to improve the knowledge on amaranth gene expression: the data integration is likewise important, facilitating research. This knowledge will be useful to reveal genes and mechanisms related to agronomic traits of interest, such as increased nutritional value and resistant varieties.

6.2.3 Amaranth and Protein Databases

In addition, transcriptomic information, proteomic data, and metabolomic data are crucial for understanding how plants function. The information necessary to create new amaranth varieties with desirable nutritional traits is directly related to functional omics data. Therefore, the UniProt (Universal Protein Resource) (The UniProt Consortium 2018) is the main curated database of annotated protein sequences. There are 2090 protein records on UniProt related to *Amaranthus* genus, in which only 23 were curated, and are now available on Swiss-Prot (The UniProt Consortium 2018; Accessed 5 April, 2022). Rodríguez et al. reviewed the amaranth potential bioactive proteins from the UniProt database with potential to prevent chronic diseases (Montoya-Rodríguez et al. 2015).

In addition, protein 3D structures are very important to design food of high nutrition and benefits for health. The Protein Data Bank (PDB) archive is the only repository for protein (Altschul et al. 1997). A quick search in PDB using the term "viridiplantae" returns 7165 structures (Altschul et al. 1997, Accessed 24 June, 2022). Of those, 17 protein structures seem to be related to the *Amaranthus* genus (when the term "*Amaranthus*" was searched) (Altschul et al. 1997, Accessed 24 June, 2022). However, five of the retrieved matches were from heterologous expression systems, mainly *Zea mays* (Altschul et al. 1997, Accessed 24 June, 2022). Another option to increase amaranth 3D structures and function is using protein modeling tools, molecular dynamics, and molecular docking (Rasheed et al. 2020). Although bioinformatics is a growing science, only 9% of the structures from RSCB PDB (Research Collaboratory for Structural Bioinformatics Protein Data Bank) are from plants (Rasheed et al. 2020). Rasheed et al. (2020) claimed that the elucidation of seed storage protein structure and function is crucial to plant applications in the food industry. However, few studies regarding the structure of storage proteins have been performed. Therefore, amaranth structure prediction using bioinformatics might lead to the prediction of targets for enhancing the nutritional value of this plant (Rasheed et al. 2020).

Increasing proteomics research is of great importance to elucidate proteins with economic importance for this plant. For instance, the effect of an *A. cruentus* peptidome fraction on enzymes involved in the cholesterol biosynthesis was studied by Soares et al. (2015). This study showed that very small peptides (under 3 kDa) from amaranth might be involved in the hypocholesterolemic effect of this grain (Soares et al. 2015). These results show the importance of proteomics and peptidome's studies of amaranth to identify bioactive peptides with importance to health and nutrition.

In conclusion, with the arising data from HT NGS (high-throughput next-generation sequencing), several specific databases for genomic, transcriptomic, and proteomic data have been created, as we previously stated. However, the data is scattered across the platforms in many different formats, making it difficult to mine innovative knowledge. Integrative bioinformatics attempts to solve this problem by unifying this biological data (Quintans et al. 2022).

6.3 Amaranth and Comparative Genomics

Another powerful resource to analyze data from next-generation sequencing (NGS) is the Comparative Genome Databases (GGD) such as CoGe (Lyons and Freeling 2008) and Phytozome (Goodstein et al. 2012), which we will further discuss.

6.3.1 CoGe

The CoGe (Comparative Genomics research) holds data from 21,016 organisms and 56,091 genomes, where 23 genomes are from 4 species of the *Amaranthus* genus: *A. hybridus*, *A. hypochondriacus*, *A. palmeri*, and *A. tuberculatus* (Lyons and Freeling 2008; Accessed in June 24, 2022). The tools available for the comparative genome analyses at CoGe are CoGeBlast (Lyons et al. 2008), which performs an alignment of a query sequence with other genomes; SynMap (Haug-Baltzell et al. 2017), which identifies syntenic regions between genomic sequences from two organisms and creates a dotplot; SynMap3D, which plots the results from synteny analyses, from up to three genomes, in 3D (Haug-Baltzell et al. 2017); the SynFind tool, which identifies syntenic regions in whichever set of genomes; and GEvo, which is a genomic evolutionary tool analysis. Additionally, genomic features can be analyzed and visualized with tools such as FeatView and LoadExp+ (Grover et al. 2017; Lyons and Freeling 2008).

For instance, SynMap4.2 (Haug-Baltzell et al. 2017) has been used to infer synteny analysis between *A. hypochondriacus*, *B. vulgaris* (Ref Beet-1.1), and *Arabidopsis thaliana* (genome assembly TAIR10) revealing insights about amaranth evolution, such as the events of polyploidization, and a high correlation with other members of Amaranthaceae family (*B. vulgaris*) (Clouse et al. 2016; Lightfoot et al. 2017). Montgomery and collaborators (2020) also inferred evolution events (such as genomic duplication and translocation) among amaranth genomes by the comparison of *Amaranthus tuberculatus*, *Amaranthus hybridus*, and *Amaranthus palmeri* with *Amaranthus hypochondriacus*, using Sinmap2 (Haug-Baltzell et al. 2017). Besides, the genetic mapping performed in this study was used to authenticate the quality of the scaffolds and revealed a need to use different methods in order to obtain a higher quality genomic assembly for *A. tuberculatus* (Montgomery et al. 2020). Regarding the genomic composition, Sunil et al. (2014) used the SinMaP to compare amaranth genome with other plants, such as *S. lycopersicum*, *V. vinifera*, and *A. thaliana*, and found that *A. hypochondriacus* A-T (66%) content is very comparable within the studied plants, revealing common genomic features.

Transcriptomic comparative analyses are also possible using CoGe tools (Grover et al. 2017). For instance, the tools available are tRNAView, which searches for tRNAs in genomes or a given genomic sequence; the MatrixView which creates a dotPlot between two genomes and may be used to analyze genomic duplications (Nguyen et al. 2019); QuotaAlign, which analyzes and screens for whole syntenic blocks, based on expected coverage; GenomeMap, which is a visual map of the distribution of genomic features in the genome; GenomeView, which is a CoGe's

interactive genome browser (also known as EPIC-CoGe); and CodeOn, which is a tool for generating an amino acid usage table binned by the C-G content of each CDS (Grover et al. 2017). Regarding amaranth comparative transcriptome analysis, using SynMap (Haug-Baltzell et al. 2017), Sunil et al. (2014) have found that amaranth transcriptome is also rich in A-T content, which is also very comparable to other plant transcriptomes. The degree of synteny among genomes can also be used to infer the nutritional quality of plants, by revealing genomic features of interest (Ma et al. 2021).

6.3.2 Phytozome

There are databases and tools for comparing genes and genomes specific to plants, such as the Phytozome (Goodstein et al. 2012). Phytozome includes several genomic sequences from selected algae to land plants, allowing the researcher to infer their evolutionary stories from a molecular level (Goodstein et al. 2012).

Phytozome v13 (Goodstein et al. 2012) holds 274 assembled and annotated genomes, where only the *A. hypochondriacusv2.1* genome is available for the *Amaranthus* genus, with an estimated size of 466 Mb (Clouse et al. 2016; Lightfoot et al. 2017). This database is very useful to easily retrieve gene sequences from *A. hypochondriacus* that will support research with this plant. Beyond the dataset, Phytozome provides several tools to analyze and compare amaranth genome with others species, such as BLAST (a search tool based on sequence similarity) (Altschul et al. 1997), JBrowse (a web-tool for genome visualization and analysis) (Buels et al. 2016), and PhytoMine, which is an interface to visualize data from Phytozome.

7 Conclusion and Prospects

This work presented the recent advancement in amaranth research focusing on the genetic resources that can be leveraged to improve the crop. After decades of neglect, the crop was redomesticated and brought to the attention of farmers and researchers. Despite its exceptional nutritional quality, medicinal and industrial uses, climate resiliency, and ability to thrive in a broad range of climatic zones, the crop is still underutilized. Since the pioneering work of Jonathan Sauer in the 1950s, there has been slow progression in the development of taxonomic, biological, and molecular information on the crop. In recent years, reference genome and transcriptome information are developed, and several genes related to biotic and abiotic stresses, growth, and development were identified. Reverse genetics tools such as VIGs were developed for amaranths; however, there is still a lack of functional genomics work; therefore, numerous putative genes with potentially important agricultural traits are not functionally validated. Molecular breeding efforts especially utilizing multi-omics approaches are lacking. Most of the genomics and transcriptomics work involve domesticated species; there is also a need for high-quality "omics" information comparing wild-type, cultivated, and weedy amaranths; DNA fingerprints from the comparative studies aid not only in the discovery of genes and QTLs that are agronomically useful but also in high-throughput genotyping and understanding of

the complexity that exists in the *Amaranthus* genus. Taken together, all this omics information helps in the molecular improvement of the crop, which can add nutritional value to the agricultural systems for our future generations.

1 Introduction

Among the cucurbits, cucumber (*Cucumis sativus* L.) is A valuable vegetable crop cultivated for its immature fruits and is one of the oldest cultivated vegetable crops. It has been known in history for over 5,000 years and probably originated in India (Whitaker & Davis 1962). Cucumber was domesticated about 3000 years ago; total cultivated area under cucumber and gherkins is 26,500 ha with 168,000 tones production and 7.5 t/ha productivity in India (FAOSTAT 2018). It is considered as an important salad crop grown both in north and lower as well as higher hills in India (Pandey & Kujur 2022) (Fig. 1).

A lot of diversity exists with respect to shape, size, and color of the fruits which contains 0.4% protein, 2.5% carbohydrates, 1.5 mg iron, and 2 mg of vitamin C per 100 g of fresh weight (Pandey et al. 2018). Fruits are good for people suffering from constipation, jaundice, and indigestion. The quality of cucumber depends on its total soluble solids, fruit firmness, desired fruit size, and other phytochemicals like antioxidant capacity, phenols, and vitamin C content.

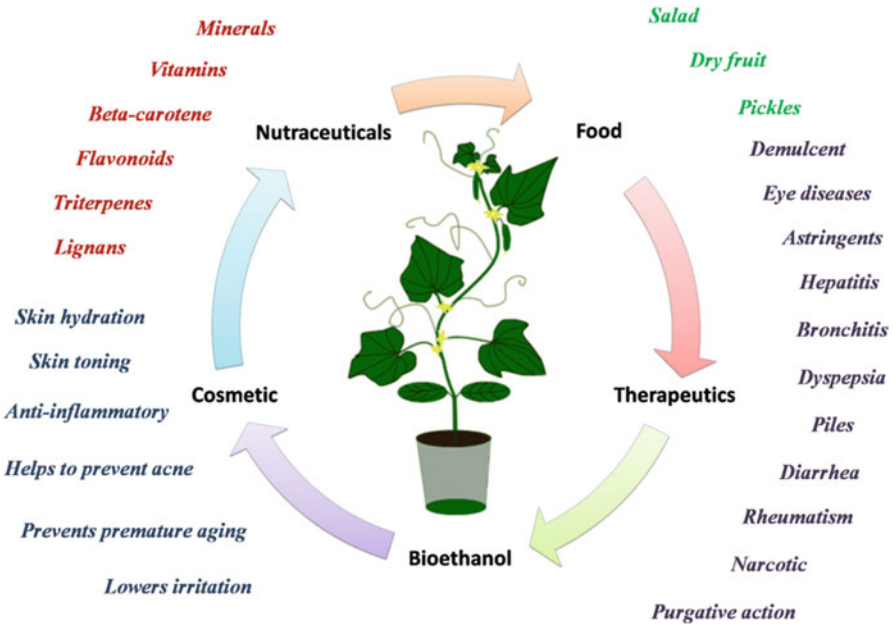

Fig. 1 Diverse sectors and uses of cucumber

2 Cucumber for Culinary Purposes

Most of the human diseases like cancer, inflammation, heart-related disease, diabetes, and autoimmune diseases as well as neurodegenerative diseases which affect neurotransmitter levels resulting various mental disorders are resultant of oxidative stress or disturbance in the cellular redox balance. The cell proliferation is promoted with more oxidizing conditions. Diet plays a crucial role including various phytochemicals maintaining human health. Cucumber is rich in water content and very low in calories. Cucumber is considered as vegetable crop rich in phytochemicals and polyphenolics. Major groups of dietary antioxidants-phytochemicals found in cucumber are vitamin C (ascorbic acid), folic acid, phenolic compounds (phenolic acids such as cinnamic acid and polyphenols such as flavonoids), and Phytocassane D; Cucurbitacin E; Cucurbitacin I; Nomilin; terpenes such as Limonin; and isoprenoids (vitamin E tocopherols and carotenoids). The exocarp of cucumber is also a rich source of different minerals such as calcium, magnesium, iron, potassium, phosphorus, sodium, manganese, zinc, and sulfur. These amino acids are also found in cucumber in their higher to lover concentrations as glutamine, oxoproline, alanine, glycine, citrulline, leucine, isoleucine, valine, tyrosine, serine, glutamic acid, gaba, aspartic acid, proline, phenylalanine, threonine, histidine, ornithine, lysine, methionine, 4-aminobutyric acid, beta-alanine, and homoserine (Zhao et al. 2016). The seeds of cucumber also contain

considerable quantity of minerals having mainly magnesium (8.5%), calcium (2.0%), manganese (66.3 ppm), sodium (79.4 ppm), and iron (21.4 ppm) with small quantity of zinc (11.7 ppm), copper (3.3 ppm), and potassium (5.1%) (Abiodun and Adeleke 2010). Cucumber is well known for its anticarcinogenic, antioxidant, antielastase, antihyaluronidase, hypolipidemic, antihyperglycemic, anti-inflammatory, diuretic, antimicrobial, amylolytic, and analgesic properties. With strong nutty flavor, cucumber seeds are used as dry fruit as well as to extract oil. Seed kernel of *C. sativus* contains proteins like globulins, albumins, and glyoxysomal enzymes in peroxisomes such as isocitrate lyase, malate synthase, citrate synthase, malate dehydrogenase, crotonase, and catalase (Köller et al. 1979).

Tender and fresh fruits of cucumber are consumed as salads and desserts and as cooked vegetables known as slicers, were as it is also preferred as preserved in form of pickles from cultivars know as picklers. The whitish to greenish mesocarp of cultivated cucumber has been of culinary importance for consumer preference worldwide. Diverse types of cucumber are commercially grown worldwide, together with American food processing and fresh market industries, Oriental trellis (burpless) varieties, European gherkin and glasshouse variety, the Mideast Beit Alpha type, and the German Schalgurken (Staub et al. 2008).

Tender fruits of particular small-fruited cultivars known as 'gherkin' are most excellently used pickled in vinegar. Cucumber fruits are also preserved in high concentration of salt. Cucumber in Korea as Oi sobagi kimchi and oiji as pickled, whereas in Egypt, brine soaking is common, known as torshi khiar. In many Asian countries, the seed kernels are dehusked and used in confectionary. The oil extracted from cucumber seeds is used for salad dressing in French cooking (Lim 2012).

3 Cosmetic Properties

As ayurvedic and conventional remedy, cucumber is used for various skin-related problems, including inflammation under the eyes and sunburn, and is assumed to have cooling, curative, comforting, emollient, lenitive, anti-itching effect on irritated skin, and extended cosmetic effects (Sotiroudis et al. 2010). Cucumber fruits are extensively used as skin-cleansing agent and are an integral part of various skin-whitening- and -softening-related cosmetic formulations. In addition, the cucumber fruit juice is utilized for a number of cosmetic formulations (Grieve 1998; Chiej 1984).

4 Nutraceuticals and Therapeutic Properties

Due to the presence of numerous active constituents distributed throughout the plant parts, including vitamins, minerals, amino acids, phytosterols, phenolic acids, fatty acids, and curcurbitacin, cucumber exhibits a variety of pharmacological properties. Cucumber fruit that have an orange-colored endocarp or mesocarp have high β-carotene content. Carotenoids play vital roles in human nutrition as potent precursor for various vitamins for biosynthetic pathways.

4.1 Antioxidant Activity

The cucumber fruit and seeds contain various antioxidants and secondary metabolites such as terpenoids, flavonoids, cardiac glycoside, tannins, phenols, and abundance of carbohydrates. The sturdy antioxidant activity and phytochemical analysis of ethanolic seeds extracts of cucumber have been performed by various workers (Begum et al. 2018). Methanolic extracts of cucumber pulp have also been reported to show powerful antioxidant activity through DPPH assay owing to its high amount of phenolics (Sotiroudis et al. 2010). Agarwal et al. (2012) reported good antioxidant activity in the aqueous solvent extracts from peel of the cucumber based on phospho molybdenum assay and established that this activity is due to the polyphenols content. In another study, cucumber fruit extract was tested for its ability to scavenge free radicals and functions as an analgesic. The extract was tested for analgesic effects at doses of 250 and 500 mg/kg and *in vitro* antioxidant investigations at 250 and 500 g/ml, respectively. Ascorbic acid and BHA (butylated hydroxyl anisole) were tested for their ability to scavenge free radicals, whereas diclofenac sodium (50 mg/kg) was used to examine their analgesic effects. The greatest antioxidant and analgesic effects of the cucumber fruit extract were observed at 500 g/ml and 500 mg/kg, respectively. According to early phytochemical screening, the extract contains flavonoids and tannins, which may be the cause of the analgesic and free radical-scavenging properties (Kumar et al. 2010).

4.2 Antimicrobial Activity

Three antimicrobial sphingolipids, first (2S,3S,4R,10E)-2-[(2′R)-2-hydroxy-tetracosanoyl amino]-1,3,4-octadecanetriol-10-ene, second 1-O-β-D-glucopyranosyl, and third soyacerebroside-I, have been identified in crude methanolic homogenate of cucumber stems. Cucumber extract exhibited antifungal and antibacterial activity against microorganisms, including four fungal and three bacterial species (Tang et al. 2010). Antimicrobial activity in the ethanolic extracts of seeds of cucumber has also been reported against *Staphylococcus aureus*, *Salmonella typhi, Acremonium, Verticellium, Pythium,* and *Tricoderma* spp. using disc diffusion assay (Begum et al. 2018). Antimicrobial activity against six Gram negative and Gram positive bacterial strains have been reported along with three human-pathogen fungi (*Candida albicans, C. tropicalis,* and *C. glabrata*) in methanolic and dichloromethane extracts of the fleshy pericarp and the exocarp of cucumber fruit (Sotiroudis et al. 2010).

4.3 Wound-Healing Activity

The aqueous extract cream formulation containing soft white paraffin as base in 2.5%, 5%, and 10% w/w of cucumber fruit have been reported for its ameliorative effects on 300 mm wide and 2 mm deep wounds in rats (Patil et al. 2011). Significant

Table 1 Nutraceutical compounds in different plant parts of cucumber and their use

Parts of plant	Therapeutic and medicinal uses	Reference
Fruit	Astringents, bronchitis, hepatitis, dyspepsia, diarrhea, piles, cough hoarseness of voice, asthma, and eye diseases	Mallik et al. (2013), Sahu and Sahu (2015)
Seed oil	Skin care properties like soothing, moisturizing, and protection from UV rays	Abiodun and Adeleke (2010)
Kernel of fruit	Rheumatism, narcotic, and purgative action	Campbell (2008), Mallik et al. (2013)
Pericarp of fruit	Dropsy, dysenteric-diarrhea, piles, and leprosy	Gopalakrishnan et al. (2014), Sahu and Sahu (2015)
Gum of bark	Demulcent, purgative	Arya et al. (2012), Mallik et al. (2013), Sahu and Sahu (2015)

decrease of $P < 0.05$, $P < 0.001$, and $P < 0.001$ was observed for wound area, epithelization period, and scar width, respectively. The faster wound contraction compared with control samples indicated that cucumber's wound-healing abilities are attributable to its antioxidant and scavenging properties due to various flavanoids and secondary metabolites. Phytofabrication has been achieved and found significantly wound healing potential in rat model. The ointment was obtained by encapsulated metallic silver-encapsulated bioactive molecules in metallic silver nanoparticles using callus (*CAgNPs*) and leaf extracts (*LEAgNPs*) of cucumber (Venkatachalam et al. 2015) (Table 1).

5 Genome Structure and Fruit Quality-Related Genes in Cucumber

Cucumis hystrix Chakr. is a wild species native to Asia whose fruits possess a flavor typical of cultivated cucumber (Chen et al. 1994). Although the literature indicates that *C. hystrix* is $2n = 2x = 14$ (Dane 1991), no definitive cytogenetic analysis has been made of this species, and its taxonomic placement has been based entirely on morphological characteristics (Kirkbride 1993). Isozyme analysis of *C. hystrix*, *C. sativus,* and *C. melo* led to the theory that a triangular phylogenetic relationship exists among these species (Chen et al. 1995).

Cucumis, a genus of twining, tendril-bearing plants in the family Cucurbitaceae, can be divided into two designated subgenera as *Cucumis* ($2n = 2x = 14$ and 24) and *Melo* ($2n = 2x = 24$) forming five number of cross-sterile species groups (Jeffrey, 1980). Furthermore, the subgenus *Cucumis* has been separated as Sino-Himalayan species, including *C. sativus* ($2n = 2x = 14$) and *C. hystrix* Chakr. ($2n = 2x = 24$). *C. sativus* is the most commercially utilized group including var. *sativus*, the cultivated cucumber, and the wild, naturally occurring var. *hardwickii* (R.) Alef. (Kirkbride 1993).

6 Biosynthesis of Phytochemicals in Cucumber

Cucurbitacins, the bitter triterpenoid compounds found in cucurbits, are toxic to most of the organisms but are able to attract specialized insects. The expression of cucrbitacin depends on a Mendelian gene known as "*Bi.*" The enzyme oxidosqualene cyclase (OSC) catalyzes the biosynthesis of responsible triterpene carbon skeleton in fruits and plants. An oxidosqualene cyclase (OSC) gene in squash (*Cucurbita pepo* L.) known as cucurbitadienol synthase (CPQ) is the first enzyme of the biosynthetic pathway of cucurbitacin (Shibuya et al. 2004).

Four oxidosqualene cyclase genes have been previously identified responsible for cucurbitacin synthesis; the ortholog of CPQ, *Csa008595,* has been recognized in cucumber which resides in a genetic interval that defines the *Bi* gene. It was also deduced that *Csa008595* constitutes a cluster of genes, which include one acyltransferase-encoding gene (*Csa008594*) and two cytochrome P450–encoding genes (*Csa008596* and *Csa008597*) (Huang et al. 2009). Authors have also reported that abovementioned three genes (*Csa008594*, *Csa008595,* and *Csa008597*) are expressed simultaneously strongly in cucumber leaf tissue in a similar fashion to that of the operon like gene cluster involved in thalianol biosynthesis in Arabidopsis (Field and Osbourn 2008). This gene set may consequently catalyze the stepwise formation of cucurbitacin in cucumber. Cucumber is considered as model system for studying sex expression in plants. Ethylene promotes the femaleness and is thought as the sex hormone of the cucumber (Rudich et al. 1972). Huang et al. (2009) also reported 137 genes in cucumber related to ethylene biosynthetic and signaling pathways. A crucial regulating enzyme in the ethylene biosynthesis pathway is 1-aminocyclopropane-1-carboxylate synthase (ACS), which is encoded by the melon gene *Cm-ACS7* (Boualem et al. 2008) and its cucumber ortholog *Cs-ACS2*, respectively (Boualem et al. 2008). Both the genes are essential for the development of the female flower and the suppression of male organ development. The *Cm-ACS7* and *Cs-ACS2* transcripts exclusively accumulate in the pistil and ovule, according to in situ mRNA hybridization assays, while its Arabidopsis ortholog, *AT4G26200*, is only expressed in the roots (Yamagami et al. 2003). These results suggest that the acquisition of novel cis regions of the ACS genes may have contributed to the evolution of unisexual flowers in cucurbits. A 454 pyrosequencing analysis of 359,105 expressed sequence tag (EST) sequences from near-isogenic unisexual and bisexual flower buds revealed that six auxin-related genes and three short-chain dehydrogenase or reductase genes are more highly expressed in unisexual flowers (Huang et al. 2009).

7 Transcriptional Control of Bitterness in Cucumber

Regulation of bitterness has been well studied in cucumber. Two transcription factors, responsible for bitterness in fruits and leaves, have been identified by Shang et al. (2014). The bitterness-related loci, which have already been reported, have Bitter (*Bi*) and Bitter fruit (*Bt*) genes that regulated bitterness basically due to

Cucurbitacin C (CuC) in cucumber and related plants. Cucumber genome variation map has been drawn by use of association analysis. An oxidosqualen cyclase gene (*Csa6G088690*) was identified known as cucumber *Bi* gene. To elucidate further, researchers made an ethylmethane sulfonate (EMS)-based mutation-induced library and screened for nonbitter leaves in large number of plants. On sequencing two mutant plants, a single nucleotide polymorphism (SNP) in gene *Csa5G156220* was obtained, which encodes a transcription factor expressed exclusively in leaves. This gene was renamed as Bitter leaf (*Bl*), and that actually regulated the expression of *Bi* gene. A total of 11 variants in homolog of *Bl* (*Csa5G157230*) were found associated with extreme bitterness via local association analysis. The cosegregation with *Bt* gene was observed in F_2 population suggesting that it should be *Bt* gene. It was well established by several workers that the expression of *Bi* gene is regulated by *Bt* gene. A total nine genes have been identified downstream of *Bl* and *Bt* for the biosynthetic pathway for CuC via RNA-interference system.

8 Cucumber Genome-Wide Delineation

Cucumber genome (Huang et al. 2009), melon genome (Garcia-Mas et al. 2012), and multiple other Cucurbitacae genomes (Guo et al. 2020; Kim et al. 2016) have been analyzed and published that elucidated various aspects of genome architecture and functions. The sequence information have opened the doors for various genome-wide expression analysis and identification of gene families and functional characterization at genome scale. As cucumber was the first released genome among cucurbits, all the focus for identification and characterization of gene families was on cucumber. Most of the transcription factors with structural and functional genes were well-described by various studies in cucumber; their transcriptional expression has been instigated under adverse climatic conditions like high salinity, high and low temperatures, hormonal disturbances, etc. in different tissues (roots, leaves, stems, flower buds, and fruits) at different developmental stages. The novel bioinformatic methods are minimizing sequencing errors offering a good-quality genome contiguity on manyfold less costs. The even resequencing of many crops is being done with magnifying exploration of the genome. Simple sequence repeats (SSRs) or microsatellites and other functional markers from cucumber, melon, watermelon, bitter gourd, and spine gourd have been identified (Blanca et al. 2011; Cavagnaro et al. 2010; Zhu et al. 2016; Shukla et al. 2015; Ameen et al. 2022). Other important genomic regions like long intergenic noncoding RNA (lincRNA) have also been identified in cucumber that are at least 200 nucleotide long intergenic transcripts (Hao et al. 2015). Intergenic transcripts encode linc RNAs associated predominantly with the euchromatic or gene-rich regions of the genome with ability to transcription termination and initiation mainly targeting miRNAs. The gene regulation and transcription factor gene activities are together governed by these regulatory repeats. These unique properties compel researchers for identification and characterization of these microsatellites and small RNAs in cucumber and other plant species (Fig. 2).

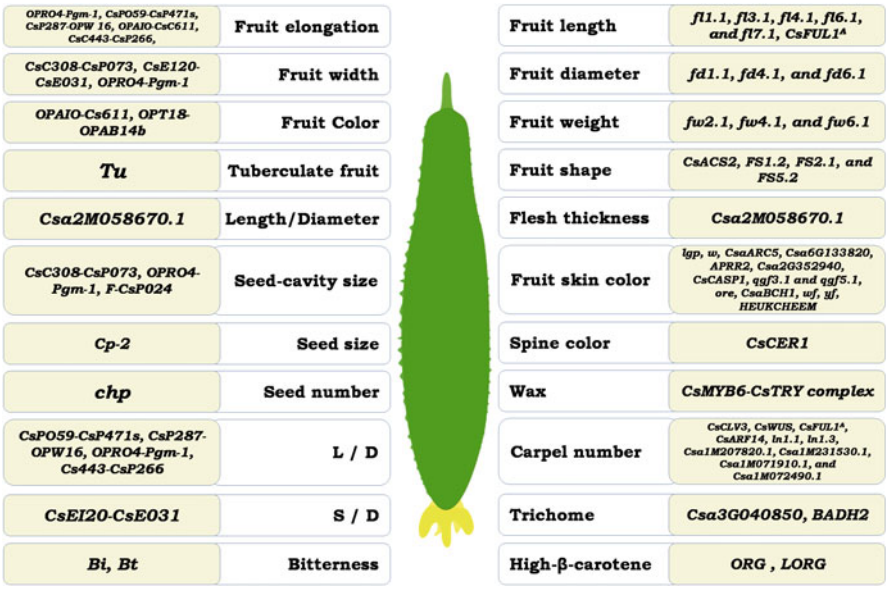

Fig. 2 Some important quality-related traits and responsible genes

9 Transcriptome Analysis in Cucumber

The speedy advancement of high-throughput sequencing tools and genome assembly pipelines has made huge gene annotation information, which offers a prospect for functional studies of genes that are associated to vital traits. RNA-seq technology has made it easy to study various complex traits related to plant growth and development. The technique allows exploring and integrating various gene expression studies and novel gene identification studies. Sex determination, a complex process with many metabolic pathways (e.g., ethylene biosynthesis and other hormone-signaling pathways), is being studied in cucumber since long. These are confirming engagements of strong regulatory processes like ion homeostasis, cell wall synthesis, cytoskeleton modifications, ubiquitination, lipid and sugar metabolism, and gene expression mediated by transcription factors for sex differentiation. Comprehensive analysis of mRNA-Sequence data also enables to identify key genes influenced under various stresses in cucumber. With the aid of high-throughput technologies, it became easy to simultaneously discover and estimate abundance of RNA-Seq data. The novel technology has helped to search new genes as well as to study the transcriptomes. The RNA-Seq can be achieved with the help of algorithms that are not bound to use old annotations and are responsible for alternative transcription and splicing (Trapnell et al. 2010). Prior to this RNA-Seq technology, the experiments were mostly dependent on microarray platform with a limited number of genes plotted on the microarray slides/chips. The major limitation to the

microarray technology is its inability to identify novel transcripts desired for the development of functional molecular marker.

The new technologies like next-generation sequencing (NGS) have ramped the genomics, transcriptomics, and proteomics studies in cucurbits. The availability of cucumber genome has accelerated the molecular studies. The genetic data along with clustered regularly interspaced short palindromic repeats/CRISPR-associated protein 9 (CRISPR/Cas9)-based new genome editing techniques are flourishing. Simultaneously the advancement of breeding technologies and sequence-based marker system with genomic and bioinformatics-based tools are also contributing to genetic improvement of cucumber and related cucurbits. This extensive research will lead to better knowledge about cucumber genomics, and scientists will be able to change various traits according to the consumer needs.

The sequence data exploration studies of two cucumber lines PI 308915 (compact vining) and PI 249561 (regular vining) resulted in a total of 200 genes expressed differently, and the SNPs and SSRs among two isogenic lines were also obtained. The protein coding genes were studied by comparison with different types of tissues (leaf, root, stem, female flower, male flower, tendril, ovary, expanded ovary under fertilization, expanded ovary unfertilized, and base part of tendril). The results were compared with previously available protein-coding gene set (Li et al. 2011; Huang et al. 2009). In the study, 8700 genes were found to be structural modifications, where 5300 genes were identified showing similarity with cucumber genome (Li et al. 2011).

As per results of *de novo* transcriptome analysis, SSRs, single nucleotide variants (SNVs) and singly nucleotide molecular markers were useful for vegetable improvement. The construction of genetic map helps to conduct genetic studies of cucumber and related family of plants.

10 Mapping of Fruit Quality-Related Quantitative Trait Loci (QTLs)

The quantitative trait loci (QTLs) control a number of agronomic traits. When one or more sequence-based DNA markers are used in conjunction with an appropriate experimental method and statistical analysis, a quantitative trait locus (QTL) can be described as any region of the genome that is linked to the persistent variation for a trait phenotype in a pertinent reference population. It is determined by analyzing the associated molecular markers for these clusters of sequences governing QTLs for specific traits, helps breeders in genetic studies and Marker Assisted Selection. The ideal populations for QTL mapping are recombinant inbred lines (RILs), near-isogenic lines (NILs), or any segregating wide cross population. RILs and NILs are almost homozygous and have less environmental influences, which increase the accuracy of QTL detection. It is then possible to clone the gene underlying the QTL and use the detected markers in molecular breeding programs.

Similar to a Mendelian hereditary characteristic, the QTLs controlling horticultural traits can be introduced into desirable parents by molecular marker assisted selection

(MAS). Using the F_3 population (GY14 x PI 432860), Wenzel et al. (1995) determined the QTLs for fruit length, fruit diameter, seed cavity size, and color. They noticed that several QTLs overlapped with fruit length and diameter as well as seed cavity size and fruit diameter. It was suggested that QTL overlapping is due to phenotypic positive correlation between fruit diameter and seed cavity size and negative correlation between fruit length and diameter. The QTLs for sex expression, the number of lateral branches, fruit weight, fruit length, and fruit diameter were examined by Serquen et al. (1997). Fruit diameter was discovered to be close to the QTLs for fruit weight, while QTLs underlying lateral branching and fruit diameter were shown to be in the same chromosomal area. Four QTLs (LOD > 3) for sex expression, four for multiple lateral branching, two for earliness, and two for fruit length were also detected. OP-AJ2-F (sex expression), de-OP-L18-2 and BC-403-OP-W7-2 (multiple lateral branching), BC-551-II and II-BC592 (fruit weight), and II-BC592, de-OP-L18-2, and BC551-II were the flanking markers linked to the QTLs (fruit length and diameter). Fazio et al. (2003) developed and studied 171 RILs using the phenotypes having unique alleles for gynoecious (F), determinate (de), standard-sized leaf, the monoecious, indeterminate, and little-leaf (ll) and found additional QTLs for multiple lateral branches, fruit form, and sex expression in addition to confirming the findings of Serquen et al. (1997). In cucurbits, MAS has been successfully demonstrated for phenotypic screening of the *Fom-2* gene (*Fusarium* wilt disease resistance in melon)-associated markers and for multiple lateral branching (*MLB*) in cucumber (Wang et al. 2000; Burger et al. 2003; Fazio et al. 2003). The color of fruits is dependent on concentration and composition of some pigments, mainly flavonoids (especially anthocyanins and chalcones), carotenoids, and chlorophylls. Melon rinds contain a number of colors, e.g., green, orange, white, variegated, and yellow, and are striped too. It is well known that pigments like β-carotene accumulate to contribute orange color (Ma et al. 2022).

11 Metabolic Pathway Studies for Quality Traits in Cucumber

Metabolites are the final products of cell biological regulation process, and metabolomic analysis enables us investigate the relationship between biological processes and plant characteristic. The content of anthocyanins and flavonoids has crucial effect on fruit color and taste. The metabolome data combining with transcriptome profiling discovered genes involved in anthocyanins and flavonols synthesis, thus searching for useful information to illustrate phenomenon of different colors in cucumber fruits (Table 2).

12 Conclusion and Future Perspectives

The diversity in cucumber is mostly found due to simple genetic factors in association with various environmental factors constituting fruit quality, such as bitterness, fruit shape, skin color, spine color, presence or absence of warts and spines, and fruit firmness. Fruit firmness is a crucial factor that is influenced by the

Table 2 Volatile compounds found in cucumber

Functional group	Photochemical
Alkaloids	Hordenine; Piperidine; Isohemiphloin; Betaine; Trigonelline; and Aminophylline
Anthocyanins	Peonidin O-hexoside; Rosinidin O-hexoside; Peonidin; Cyanidin O-syringic acid; Cyanidin O-acetylhexoside; Malvidin 3-O-galactoside; Malvidin 3-O-glucoside (Oenin); Pelargonidin; and Malvidin 3,5-diglucoside (Malvin)
Carbohydrates	D(−)-Threose; Ribulose-5-phosphate; Glucosamine; 2-Deoxyribose 1-phosphate; D(+)-Melezitose O-rhamnoside; Glucarate O-Phosphoric acid; Trehalose 6-phosphate; D-(+)-Sucrose; D(+)-Melezitose; Gluconic acid; D-(+)-Glucono-1,5-lactone; (+)-Glucose; DL-Arabinose; L-Gulonic-γ-lactone; N-Acetyl-D-glucosamine; D-Glucose 6-phosphate; D-Sedoheptuiose 7-phosphate; D-Fructose 6-phosphate; and D-glucoronic acid
Coumarins	N-sinapoyl hydroxycoumarin; O-Feruloyl 4-hydroxylcoumarin; 7-hydroxycoumarin-beta-rhamnoside; Scopoletin (7-Hydroxy-5-methoxycoumarin); 4-Hydroxycoumarin; Esculetin (6,7-dihydroxycoumarin); 6-Methoxy-7,8-DihydroxyCoumarin; Psoralen; and Daphnetin
Flavone	Selgin 5-O-hexoside; Chrysoeriol 5-O-hexoside; Tricin 5-O-acetylglucoside; Selgin O-malonylhexoside; Tricetin O-malonylhexoside; Spinacetin; Syringetin 5-O-hexoside; Luteolin O-sinapoylhexoside; Chrysoeriol O-sinapoylhexoside; Chrysoeriol O-hexosyl-O-rutinoside; Chrysoeriol 7-O-rutinoside; Chrysoeriol O-hexosyl-O-pentoside; Syringetin 7-O-hexoside; Chrysoeriol O-malonylhexoside; Tricin 5-O-hexosyl-O-hexoside; Tricin 7-O-hexosyl-O-hexoside; Tricin O-malonylhexoside; Tricin 7-O-feruloylhexoside; Tricin 7-O-hexoside; Tricin O-sinapoylhexoside; Tricin; Acetyl-eriodictyol O-hexoside; Acacetin O-acetyl hexoside; Chrysoeriol O-hexosyl-O-hexosyl-O-Glucuronic acid; Chrysoeriol O-acetylhexoside; Apigenin 7-O-glucoside (Cosmosiin); Chrysoeriol 7-O-hexoside; Tricin O-sinapic acid; Tricin O-saccharic acid; Tricin 5-O-hexoside; Tricin 5-O-rutinoside; Tricin di-O-hexoside; Tricin O-glucuronic acid; Luteolin; Apigenin 7-O-neohesperidoside (Rhoifolin); Chrysoeriol; Apigenin 7-rutinoside (Isorhoifolin); Baicalein (5,6,7-Trihydroxyflavone); Nobiletin; Tangeretin; Luteolin 7-O-glucoside (Cynaroside); Tricetin; and Butin
Flavanone	Naringenin O-malonylhexoside; Eriodictyol O-malonylhexoside; Hesperetin O-malonylhexoside; Hesperetin 7-O-neohesperidoside (Neohesperidin); Naringenin 7-O-neohesperidoside (Naringin); Naringenin 7-O-glucoside (Prunin); Naringenin; Xanthohumol; Hesperetin 5-O-glucoside; 7-O-Methyleriodictyol; Hesperetin; Hesperetin 7-rutinoside (Hesperidin); Naringenin chalcone; Isosakuranetin-7-neohesperidoside (Poncirin); Afzelechin (3,5,7,4′-Tetrahydroxyflavan); and Homoeriodictyol

[a]Table adopted from Wang et al. (2020)

firmness of the flesh and the seed cavity (endocarp). Various genetic and metabolic datasets for cucumbers are now accessible for cucurbit breeding and biological study. Cucumber serves as a model plant for the cucurbit family because of the strong collinearity between it and the majority of other cucurbits. The cucumber's genome has just undergone an upgrade, making it possible to use this knowledge for focused breeding efforts. The metabolic profile identified the metabolic intermediates as well as potential dietary and nondietary components. Alkaloids, tannins, flavonoids, steroids, phlobatannins, and saponins are just a few of the physiologically active, nonnutritive phytochemicals that are present in both cucumber fruits and seeds at the same time. Knowledge of the mechanisms

underlying sex determination can speed up the process of obtaining desired fruit quality and will help breeders meet other objectives like producing cucumbers with a high and steady yield.

https://doi.org/10.1007/978-981-19-4169-6_58

Abstract

Sweetpotato, *Ipomoea batatas* ($2n = 6x = 90$), is a polyploid, outcrossing species considered a staple food in many developing countries due to its starch-rich storage roots. In addition to energy, roots or leaves can provide minerals (such as Fe and Zn), and vitamins (such as A and C). β-carotene- or anthocyanin-rich varieties and their respective orange and purple fleshed roots have attracted great attention given the increased nutraceutical properties they present. Originally from Latina America, several studies have been conducted to assess germplasm diversity around the world using both morphological and molecular descriptors. Similarly, there have been some attempts to describe genetic architecture of traits of interest such as dry matter content and resistance to sweetpotato virus disease and nematodes. However, only recently, major developments in molecular tools have allowed the genetic mapping of major quantitative trait loci and genome-wide-based characterization of population structure. Releasing new varieties that show high yield under challenging environments combined with resistance to pests and diseases plus nutritious characteristics is a long-lasting process. Recent advances such as the availability of diploid, wild relative genomes, and their associated bioinformatics tools have facilitated functional studies. Likewise, the ability of detecting single nucleotide polymorphisms and measuring the allele

dosage have facilitated genetic studies in sweetpotato and have paved the way to the implementation of genomics-assisted breeding.

1 Introduction

Sweetpotato [*Ipomoea batatas* (L.) Lam.] belongs to the Convolvulaceae or morning glory family of the genus *Ipomoea*, where it is the only economically important species. It is an autohexaploid with 90 somatic chromosomes ($2n = 6x = 90$), with a large genome size of about ~4.4 Gb (Yang et al. 2017), and complex inheritance pattern. According to Food and Agriculture Organization of the United Nations, its estimated global production of 90 million metric tons in 2020 is led by Asia and sub-Saharan Africa (SSA), accounting for most of the global sweetpotato production with 83% production in Asia and 14.6% in Africa. In SSA, the crop is a major starch staple and a source of calories, fiber, vitamins, and mineral requirements for humans and domestic animals (Low et al. 2017). In fact, the various parts of sweetpotato crop have been reported to contain phenolics, dietary fiber, and mineral nutrients. Sweetpotato leaves have been reported to contain more polyphenols compounds and at least 15 anthocyanins compared to other commercial vegetables such as spinach, cabbage, and lettuce (Nguyen et al. 2021). Its roots are enriched with secondary metabolites of immense nutritional value and high sensory versatility in terms of taste, texture, and flesh color (white, cream, yellow, orange, and purple).

Orange-fleshed sweetpotato (OFSP) is a very nutritious food, as it is a very good source of β-carotene, iron, potassium, vitamin C, fiber, and protein (Low et al. 2017). Sweet OFSP clones with low dry matter (<20%) are the preferred types in the USA and Europe, whereas the less sweet, white or cream fleshed clones are the preferred types in much of SSA. Due to their reduced vitamin A content, these types are not as nutritious as the OFSP types. Therefore, the breeding product profile of most SSA sweetpotato breeding programs are tailored toward development of higher dry matter and less sweet OFSP, to address the ever-growing challenge of vitamin A deficiency needs of the population to prevent malnutrition and enhance nutrition and food security. The purple-fleshed sweetpotato (PFSP) varieties are anthocyanin rich with an attractive color with more than 20 known anthocyanins in different varieties (Wang et al. 2018) which are the specialty type in Asia.

Carotenoid biosynthesis and degradation and/or plastid sink strength processes occur naturally in sweetpotato and can be readily selected in breeding populations. Nonetheless, the genetic improvement of sweetpotato for consumer preferred quality traits such as storage root dry matter, starch, sugar, and β-carotene contents has been

difficult. This could be attributed to the complex polyploid genome of sweetpotato, negatively correlated traits, and its outcrossing nature resulting in very challenging breeding (Cervantes-Flores et al. 2011; Truong et al. 2018). There is always a constant need to explore different mechanisms that are most often governed by many genes. In the case of OFSP, the negative starch/β-carotene correlation and the yet undefined textural characteristics have limited the actual adoption of improved OFSP varieties. Therefore, comprehensive analysis of the genetic architecture of the negative association between starch and β-carotene could aid in advances of breaking this linkage as an important objective of breeding programs targeting sweetpotato for food and nutritional security.

2 Description of Nutritional Constituents

2.1 Detailed Chemical Composition

Sweetpotato storage roots contain carbohydrates, proteins, minerals, and vitamins. The major constituents of sweetpotato storage roots are carbohydrates in which the principal component is starch (Woolfe 1992). In addition to starch, the storage roots of sweetpotato provide free sugars such as fructose, glucose, and sucrose in raw and cooked as well as maltose that is usually contained in cooked storage roots (Kitahara et al. 2017; Truong et al. 2018). Other carbohydrates include pectin, hemicellulose, and cellulose, which have been reported to affect the textural properties of storage roots (Woolfe 1992). The vitamin component consists of vitamins C, K, E, and several B vitamins (Truong et al. 2018). The OFSP varieties contain β-carotene which is converted into vitamin A in the body. Research has shown that the darker the orange color in the root flesh, the more β-carotene is present (Low et al. 2017). Sweetpotato root mineral composition includes potassium, phosphorus, and other minerals. Detailed mineral and vitamin composition per 100 g of fresh weight can be found in Table 1.

Storage roots of sweetpotato vary widely in nutrient composition depending on cultivar, growing conditions, maturity, and storage (Truong et al. 2018). Also, different varieties of sweetpotato show variations of chemical composition influenced by dry matter content and storage root flesh color. OFSP varieties, for example, usually have low dry matter content (18–25%), high β-carotene level, and sweetness due to relatively high sugar content. OFSP varieties with low dry matter content (~20%) are the major types of varieties produced in the USA (Cervantes-Flores et al. 2011). These varieties are usually sweet with high sugar (15–20% relative to dry matter – DM) and low starch (45–55% DM) contents. A number of studies have reported negative correlations between starch and dry matter content. In most parts of SSA, the preferred types are cream- or white-fleshed varieties with high dry matter content (28–30%) that have relatively low sweetness (Cervantes-Flores et al. 2011), low sugar (10–20% DM), and high starch (50–80% DM) contents. PFSP varieties, on the other hand, contain high anthocyanin content (Truong et al. 2018). Variability in sugar content is influenced by the conversion of starch into sugars during curing and postharvest storage (Truong et al. 2018). The storage roots of

sweetpotato contain reasonable amounts of protein (~5% DM). In addition, the storage roots also contain α- and β-amylases with β-amylase being the most abundant (Amankwaah 2019).

Variations in chemical composition have also been reported to exist in raw storage roots and cooked ones. Heating sweetpotato storage roots to a temperature of 75 °C retains a relatively high percentage of endogenous amylases required for starch conversion and free sugar formation in the cooked product. It has been observed that increasing temperature and heating time generally reduces β-amylase activity and enhances maltose formation, thereby increasing sweetness (Amankwaah 2019). Major changes were observed in starch content composition in raw storage roots after baking, which demonstrates the fact that starch is hydrolyzed in raw sweetpotatoes to sugars. The major product obtained after starch hydrolysis in cooked products is maltose. Amankwaah (2019) observed that production of maltose caused a big difference in total sugars between raw and baked treatments.

2.2 Chemical Type, Structure, and Biochemical Pathways of Production

The starch contained in storage roots of sweetpotato consists of linear or slightly branched amylose and highly branched amylopectin. The amylose content of sweetpotato starch is approximately 20–30% while its amylopectin is 70–80%. The

size of starch granules is variety-based and determined by starch content, chemical properties, and amylopectin/amylase ratio as well as supramolecular structures (Noda et al. 2009). Starch granule distribution is an important characteristic and vital factor for the quality of final products derived from sweetpotato. Several factors affect the formation of different granules including growth and agronomic management as well as gene expression mechanisms, especially those associated with starch biosynthesis. In sweetpotato, starch biosynthesis is a complex and highly regulated process that requires coordinated activities of multiple enzymes including AGPase, starch synthase (SS), starch branching enzyme (SBE), and starch debranching enzyme (DBE). The structure and properties of starch are controlled by starch biosynthetic enzymes and regulators, such as granule-bound starch synthase I (GBSSI) is the key enzyme in the biosynthesis of amylose. On the other hand, soluble SS, SBEs I and II, and DBE act in concert to produce amylopectin (Kitahara et al. 2017).

Carotenoid pigments are widespread in nature. These molecules in plants play significant roles in light harvesting of photosynthetic reaction centers. Furthermore, in conjunction with chlorophyll in the chloroplast, cells are protected from excessive light by absorbing blue-green wavelengths (Kang et al. 2017). Different carotenoid types are contained in the storage roots of sweetpotato including β-carotene, β-crypthoxanthin, zeaxanthin, violaxan thin, and other unknown carotenoids. However, β-carotene is a major component in yellow- and orange-fleshed sweetpotato (Kang et al. 2017).

The carotenoids metabolic pathway and the function of the biosynthetic enzymes involved have been well-studied in higher plants. They are synthesized by the 2-C-methyl-D-erythritol 4-phosphate/1-deoxy-D-xylose 5-phosphate pathway (MEP/DOXP pathway) of isoprenoid biosynthesis. From isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP), two molecules of geranylgeranyl diphosphate (GGPP) are produced by geranylgeranyl pyrophosphate synthase (GGPS). Through the condensation of two GGPP molecules and phytoene, the first C40 carotenoid is formed, a reaction catalyzed by phytoene synthase (PSY). Phytoene is then processed by a series of enzymes including phytoene desaturase (PDS) and ξ-carotene desaturase (ZDS) to yield lycopene. Lycopene is further processed by two carotenoid biosynthetic pathways, the α-branch pathway (from α-carotene to lutein) and the β-branch pathway, and both play distinct roles in photo-protection (Kang et al. 2017). Subsequently, α-carotene and β-carotene are modified by hydroxylation, epoxidation, or isomerization to express a variety of structural features. Lutein is then synthesized in the α-branch pathway by α-carotene ε-ling hydroxylase (CHY-ε). On the other hand, in the β-branch pathway, hydroxylation by β-hydroxylase (CHY-β) converts β-carotene to zeaxanthin, and then zeaxanthin epoxidase (ZEP) mediates the formation of violaxanthin. Violaxanthin is converted to neoxanthin by neoxanthin synthase (NXS) (Kang et al. 2017).

2.3 Medicinal Properties and Functions in Relation to Human Health

A wide variety of roots and tubers plays a major role in human diet, animal feed, and industrial raw materials. Sweetpotato is now being promoted as a “superfood” for

good health globally since it is a rich source of carbohydrates, minerals, and vitamins (Low et al. 2017). Sweetpotato is recognized as a secondary staple food, and it is known to play significant role in the diet of humans in many underdeveloped countries (Neela and Fanta 2019). Sweetpotato has been reported to be different from other staple food crops as it has balanced nutritional composition in addition to adaptability in wider topography, good productivity in short durations, and ability to grow on marginal soils. Awareness of the high nutritional value of sweetpotato is driving increasing consumer demand for the crop among health-conscious consumers globally (Grüneberg et al. 2015). In many developed countries, sweetpotato has been reevaluated as a health-promoting food, because of its high content of nutrients in balanced and functional components, such as anthocyanins, carotenoids, and phenolic compounds, which have antioxidant properties.

In addition to nutrients, sweetpotato roots are regarded as functional food and provide physiological benefits. They contain phytochemical compounds that include carotenoids, tocopherols, phenolic compounds, tannins, flavonoids, saponins, and anthocyanins, which differ among varieties based on the storage root flesh color (Woolfe 1992). Either single or synergistically, these bioactive phytochemicals provide the human body with antioxidant, cardioprotective, antidiabetic, hepatoprotective, neuroprotective, anti-inflammatory, antimicrobial, and bowel-regulation properties (Panda and Sonkamble 2012). Storage roots, when consumed containing these bioactive chemicals, result in boosting of the immune systems to fight diseases and subsequent promotion of a healthy life and longevity. Furthermore, these bioactive phytochemicals serve as potential sources of antioxidants that can scavenge free radicals and reduce or inhibit cellular damages. Additionally, reduction in oxidation stress results in disease prevention and better health (Anbuselvi and Muthumani 2014).

Significant improvement in human health can be achieved when biofortified crops such as sweetpotato are consumed regularly. In fact, OFSP varieties are rich in provitamin A carotenoids, mainly in the form of β-carotene (Neela and Fanta 2019). They have potential to prevent vitamin A deficiency and are good for consumption by children and pregnant women. Research on nutraceutical properties of PFSP varieties indicated that the extracted anthocyanins showed strong radical scavenging activity, antimutagenic activity, and significant reduction in high blood pressure and liver injury in rats (Truong et al. 2018).

2.4 Cultural Methods of Nutraceutical Improvement

The process of increasing vitamins and minerals in a crop attributed to plant breeding, transgenic techniques, or agronomic practices is termed biofortification. It is a feasible and cost-effective mean of delivering micronutrients to populations that may have limited access to diverse diets and other micronutrient interventions (Bouis and Saltzman 2017). Increasing nutrition levels in staple crops to target levels, required for improving human nutrition without compromising yield or farmer-preferred agronomic traits, could be achieved through conventional plant breeding. It involves screening germplasm for available genetic diversity, prebreeding parental genotypes, developing and testing micronutrient dense germplasm, selecting, and advancing

generations for product development. Genotypes with desirable levels of micronutrients are tested in several locations across target environments to evaluate their genotype-by-environment interaction and stability (Bouis and Saltzman 2017). Many countries in SSA including Uganda, Malawi, Ghana, Mozambique, Kenya, and Ethiopia have recently embarked on biofortification programs. These efforts have contributed to release new orange-, yellow-, and cream-fleshed sweetpotato varieties with emphasis on the former (OFSP), due to its provitamin A content.

To ensure all year-round availability of storage roots of sweetpotato in temperate regions, where production is limited to summer season, roots are cured and stored after harvesting. Careful handling and packing is also necessary to ensure long-term storage. Roots are immediately cured at ~30 °C at relative humidity of 85–90% after harvesting with proper ventilation for 4–7 days. This process facilitates the healing of bruises and wounds that occur during harvesting. Cured roots are then stored at 13–15 °C at 85–95% relative humidity making storage roots available for marketing up to 12 months (Truong et al. 2018).

2.5 The Need for Biotechnology

Biotechnological tools are needed to complement conventional breeding approaches especially for traits whose conventional breeding efforts have not produced the desired results. This assertion is highly manifested in breeding for diseases and pest resistance as well as development of varieties for different end users regarding domestic, commercial, and industrial purposes. Sweetpotato is a polyploid, outcrossing species with high levels of heterozygosity and numerous mating incompatibilities, making its breeding a complex endeavor.

Since the beginning of sweetpotato breeding efforts in 1930, there have been significant improvements in fungal, bacterial, and nematode resistance, β-carotene and anthocyanin levels, yields, storage ability, root size, and starch characteristics. Considerable work continues on insect and virus resistance, processing qualities, and finding regionally adapted cultivars which match consumer preferences (Truong et al. 2018). A significant need still exists for genomic research focused on understanding the inheritance of economically important traits to develop more efficient breeding strategies to facilitate crop improvement. In 2014, the Genomic Tools for Sweetpotato Improvement (GT4SP) project, funded by the Bill & Melinda Gates Foundation (BMGF), addressed this issue and enabled substantial progress in understanding the inheritance of traits of economic importance. These traits include root knot nematode resistance, storage root α- and β-amylases activity, storage root flesh color, and dry matter, starch, and β-carotene contents.

Weevil resistance remains a challenge, and it is still unclear if conventional breeding can result in 100% weevil-resistant varieties, despite many years of work to date focused on breeding for resistance to *Cylas* and *Euscepes* weevils. Several approaches have been suggested to achieve virus and weevil resistance including transgenic approaches, because of the limited progress observed with conventional breeding (Grüneberg et al. 2015). Breeding for weevil resistance requires a

better understanding of the insect's biology and its interaction with plants and environments.

Breeding for desired quality attributes in sweetpotato is challenging because traits of economic importance are often correlated, either positively or negatively. Identifying haplotypes which control traits of economic importance will help in facilitating selection both at the phenotypic and molecular levels. Mapping complex traits is by far the most expensive but also an important approach to identifying functional variants. Some of the quantitative trait loci (QTL) discovered for traits of economic importance were hypothesized to be associated with important candidate genes in sweetpotato which could be targeted in improving cell wall structure, texture, and flavor aside nutritional quality attributes. These could be achieved through the use of biotechnological approaches.

3 Genetic Resources and Sources of Health-Related Genes

3.1 Origin of Sweetpotato and Its Available Germplasms

Ipomoea batatas, the scientific name for the cultivated sweetpotatoes, is a member of the *Ipomoea* genus and Convolvulaceae family. There are more than 600 species described as belonging to the *Ipomoea* genus. Due to the large size of this genus, sweetpotato and its close relatives were gathered in 14 taxa series Batatas. *Ipomoea batatas* is a self-incompatible allogamous species, and its genome is classified as a hexaploid ($2n = 6x = 90$), although earlier studies have revealed the presence of tetraploids ($2n = 4x = 60$) (Austin 1988). Thus, sweetpotato is a polyploid species, and its genetic nature makes genetics and segregation ratios rather complicated.

Since 1985, the International Potato Center (CIP) has conducted breeding studies and developed new sweetpotato varieties. A cooperation between CIP and the International Board for Plant Genetic Resources (IBPGR) was initially established through the collection of extensive amounts of germplasm, focusing on cultivars of sweetpotato and wild *Ipomoea* species throughout Latin America, the region with the most diversity. The collections from the Asian Vegetable Research and Development Center (AVRDC) and International Institute of Tropical Agriculture (IITA) would have been centralized at CIP, which currently houses over 3520 accessions in total. The number of genetic resource collections around the world has expanded, particularly at the national levels, even though a current compilation of germplasm collections is not yet accessible.

The Plant Genetic Resources Conservation Unit (PGRCU), belonging to the United States Department of Agriculture – Agricultural Research Service (USDA-ARS), located in Griffin, Georgia, is responsible for maintaining the US sweetpotato germplasm collection. This genebank contains sweetpotato clonal propagules that are kept as in vitro cultures in addition to maintaining a broad collection of *Ipomoea* species. Hexaploid *I. batatas* clones have been collected over a long period of time, frequently in cooperation with numerous national and international programs and

organizations. The genetic bases for continuous research and advancement in sweetpotato breeding have been provided by this collection.

Based on an analysis of morphological characters of sweet potato and wild *Ipomoea* species, the center of origin of *I. batatas* is thought to lie somewhere between the Yucatan Peninsula in Mexico and the mouth of the Orinoco River in Venezuela (Austin 1988). The highest diversity in Mesoamerica recently revealed by molecular markers indicates that Mesoamerica is an important center of diversity and probably a center of origin, due to the wealth of wild relatives of sweet potato (Huang and Sun 2000). The sweetpotato was brought to Western Europe from the Caribbean after the first voyage of Columbus in 1492. In the sixteenth century, Portuguese explorers took the sweet potato to Africa, India, Southeast Asia, and the East Indies, where it was directly transmitted. The plant was carried by Spanish trading galleons from Mexico to the Philippines. Recent studies assessing genetic diversity using AFLP suggested that prehistoric introductions into Oceania may have originated from the Mesoamerican sweet potato through natural dispersal (Rossel et al. 2001).

Multiple origins have been hypothesized from two separate autopolyploidization events from an ancestral farmed sweetpotato that shares *I. trifida*. According to a recent study (Muñoz-Rodríguez et al. 2018), *I. trifida* was the only progenitor of cultivated sweetpotato, being originated from autopolyploid events. Other studies have suggested that the $B_1B_1B_2B_2B_2B_2$ genome of sweetpotato, which was formed by crossing a tetraploid and a diploid followed by whole genome duplication, has an allo-autohexaploid origin (Yang et al. 2017). The same study claimed that the tetraploid progenitor of cultivated sweetpotato was unknown but assumed the diploid progenitor to be *I. trifida*. According to a newly created genetic map, strict allo-autohexaploid nature cannot exist because no preferential pairing has been observed and haplotypes have shown hexasomic inheritance in an F_1 population (Mollinari et al. 2020).

3.2 Gene Pools and Wild Relatives

It is challenging to genetically improve sweetpotato by conventional plant breeding because of its polyploid nature, genetic complexity, high level of variability in terms of flower production, and incompatibility. The creation of more genomic resources would improve the development of efficient and effective marker-assisted breeding techniques and aid efforts to unravel the genetic causes of phenotypic diversity.

There are 12 species in the *Ipomoea* section *Batatas* whose chromosomes numbers are multiples of 15. The only known hexaploid species in the genus is *I. batatas*, which has sizeable storage roots. All other species into this section are diploid or tetraploid (Austin 1988). The diploid *I. trifida* seems to be the closest wild relative of the cultivated sweetpotato, according to several molecular genetic investigations. In relation to the origin of cultivated sweetpotato, two hypotheses have been provided. Between the Yucatan peninsula and the Orinoco basin, according to Austin's reports from 1988, a natural hybridization between *I. trifida* and *I. triloba* could have produced the ancestors of the sweetpotato. Kobayashi (1983), on the other hand,

hypothesized that *I. trifida* constitutes an autopolyploid complex with ploidy levels ranging from diploid to hexaploid and that domesticated sweetpotato was originated from this group.

It has been suggested that the domesticated sweetpotato, *I. batatas* (6×), is a product of interspecific hybridization between *I. trifida* (2×, 4×, 6×), *I. littoralis* (2×), and *I. leucantha* (2×) (Austin 1988). *I. trifida* and *I. tabascana* have been suggested as the species most closely related to the tetraploid crop (4×). The presumed closest related taxa to sweetpotato are placed in the secondary gene pool in accordance with the gene pool concept of Harlan and de Wet (1971), and because of ploidy incompatibility with the cultivated species: wild forms of *I. batatas* (4×), *I. trifida*, *I. littoralis*, and *I. tabascana* (Jarret and Austin 1994). *I. cordatotriloba*, *I. cynanchifolia*, *I. grandifolia*, *I. lacunosa*, *I. leucantha*, *I. ramosissima*, *I. splendorsylvae*, *I. tenuissima*, *I. tiliacea*, and I. *triloba* are among the species categorized as tertiary wild relatives (Jarret and Austin 1994).

Three novel interspecific hybrids were created by crossing *I. batatas* (L.) Lam. with *I. hederacea* Jacq, *I. batatas* (L.) Lam. with *I. muricata* (L.) Jacq, and *I. batatas* (L.) Lam. with *I. lonchophylla* J. M. Black, as an example of an improved hybridization technique. The storage roots of the first two hybrids were normal, a notable improvement over those of the interspecific *Ipomoea* hybrids that are currently in existence. These three novel interspecific hybrids were genetically compared to three hybrids naturally occurring, namely, diploid, tetraploid, and hexaploid species of the *Ipomoea* section Batatas, using amplified fragment length polymorphism (AFLP) markers. These three novel interspecific hybrids can be used as a bridge to transfer foreign genes from wild species to domesticated species, according to cluster analysis of AFLP bands, which revealed that new interspecific hybrids were closely related to domesticated sweetpotato (Cao et al. 2014). However, due to variances in ploidy levels and inability of wild species to develop storage roots, wild material cannot yet be efficiently used. Further research is needed on certain features and heterosis effects that do not exist in farmed sweetpotato to use wild relatives practically.

4 Classical and Molecular Genetics and Breeding

4.1 Genetics of Health-Related Genes and Breeding Objectives

Classical genetics and conventional breeding principles have enabled the study and improvement of sweetpotato traits which would otherwise not have been possible. Conventional breeding of sweetpotato was initiated in the USA in the early 1900s, relying mainly on plant introductions from the tropics and favorable mutations. With the introduction of sweetpotato flowering under long day conditions, a major breakthrough was realized, which led to the transition from mutation-based breeding to the true seed sexual production-based breeding. A procedure for sweetpotato breeding, based on recurrent selection methods for improvement of maize and other crop species considers the use of polycross and recurrent selection as an effective

way to combine favorable alleles from parental genotypes. This procedure was especially important in sweetpotato for long-term improvement of traits with low heritability.

Population improvement and product development have slowly been performed in sweetpotato due to the complex nature of the crop combined with the constantly changing consumption patterns and environmental conditions. Genotypes that thrive under drought and saline conditions, for example, may be good parents. However, due to the low heritability of drought tolerance and lack of efficient selection strategies, production of drought-tolerant sweetpotato cultivars has been difficult. Although conventional breeding has empowered the improvement of qualities and traits in other crops, this has remained difficult in sweetpotato. Some issues involving sweetpotato conventional breeding can be attributed to male sterility, hexaploid nature, and self-incompatibility.

The breeding objectives of most sweetpotato programs include high yield, tolerance to local biotic and abiotic stresses, and nutritional quality, including traits such as starch, dry matter, and β-carotene contents, as well as amylases, iron, and zinc contents. Specific biotic stresses are dependent on the region where the breeding program is located. Abiotic constraints include low levels and unpredictable rainfall patterns, drought, and low soil fertility. In SSA, the sweetpotato virus disease (SPVD), which is a combination of two different viruses, namely, sweetpotato feathery mottle virus (SPFMBV) and sweetpotato chlorotic stunt virus (SPCSV), is the most common viral stress. *Alternaria* blight, which is a fungal infection, and sweetpotato weevils are both common especially in the eastern parts of Africa. These are the core breeding objectives in those regions.

Increasing emphasis is being focused on "hidden hunger," which is a result of micronutrient deficiencies and not necessarily a low intake of calories. Vitamin A and iron deficiencies affect 50% and 60% of children in SSA, respectively (Mwanga et al. 2021). These are the major causes of anemia and micronutrient deficiency globally. Conventional breeding of sweetpotato has been challenging in this sense. Mass selection has been primarily employed to select resistant clones to advance to the next generation. To do this, a large population of sweetpotato genotypes is assembled and screened for selection of parents and clones for the next breeding cycle.

Phenotyping large populations is challenging and hinders quick progress in terms of selection. A very useful tool for the analysis of health-related traits in sweetpotato is near-infrared spectroscopy (NIRS). It is a nondestructive technique that does not require the use of chemical reagents and has the advantage of being able to screen for numerous constituents with a single scan. Wavelength bands between 780 and 2500 nm penetrate the sample, and light is absorbed selectively according to the sample's molecular composition. Other modern high-throughput phenotyping tools can help with increasing heritabilities and providing higher selection accuracies.

4.2 Molecular Genetics and Inheritance Studies

A large potential exists in the application of DNA-based markers for the improvement of crops. In sweetpotato, the technologies are relatively new and have only

recently initiated to have practical applications into its breeding programs. Previously, most of the studies used dominant gel-based markers, which are relatively easy to score, or microsatellite markers, that have low abundance in the genome (Yada et al. 2017) and only capture limited genetic information. Recently, advances in next-generation sequencing methods and bioinformatics resources have enabled a large number of single nucleotide polymorphism (SNP) markers to be developed and utilized in sweetpotato (Shirasawa et al. 2017; Wadl et al. 2018). SNPs are the most abundant DNA polymorphisms in the genome and can therefore be more readily utilized in a cost-effective genotyping platform. Because they are spread throughout the genome, the genetic information that they capture is massive.

Genetic markers linked to QTL that have been effectively utilized for cultivar development include the QTL for several major crops where the favorable allele presented a large and consistent effect easily measured and fixed by standard breeding procedures. This is more difficult in sweetpotato because of ploidy, high heterozygosity, and high degree of deleterious mutations which are difficult to flush out in asexually propagated species. Maintaining heterozygosity is therefore paramount to keep these mutations at bay, the downside of this being that a typical backcrossing breeding scheme to incorporate a single gene is difficult to achieve.

Few molecular approaches have been exploited in breeding for sweetpotato traits. For SPVD, two recessive genes, *spfm1* and *spcsv1*, were identified for sweetpotato SPFMV and SPCSV from a biparental cross between 'Tanzania' and 'Bikilamaliya' (Mwanga et al. 2002). They used AFLP and random amplified polymorphic DNA (RAPD) markers to map these QTL. In the advent of high throughput next-generation genotyping, it is now possible to identify and utilize SNP markers for genetic studies in sweetpotato. One of the major advantages of SNPs in polyploids is the increased informativeness at a given segregating locus. The development of modern genotyping protocols (Davey et al. 2011), like genotyping-by-sequencing or restriction-site-associated DNA (RAD)-seq, and their optimizations for highly heterozygous and hexaploid sweetpotato, together with a complete reference genome of *I. trifida*, have enabled the evaluation of SNP markers throughout the genome of hexaploid sweetpotato.

Using the previously developed full-sib populations derived from the crosses 'New Kawogo' × 'Beauregard' (NKB), 'Beauregard' × 'Tanzania' (BT), and their reciprocals (TB), together with the new genomic tools developed under the GT4SP and SweetGAINS projects, the core resources needed to bring sweetpotato into the genomics era have been obtained. The new breeding tools include the following: (i) two fully sequenced and annotated diploid lines (*I. trifida* and *I. triloba*) used as reference genomes for cultivated sweetpotato; (ii) a sequencing-based genotyping platform for highly heterozygous hexaploid sweetpotato, *GBSpoly*, with supporting bioinformatics tools (Kuster et al. 2021); (iii) three high-density genetic linkage maps of hexaploid sweetpotato – BT, TB, and NKB; (iv) dosage-dependent SNP calling, phasing, and linkage mapping algorithms for autopolyploids; (v) statistical methods for QTL analysis and linkage mapping in polyploids, implemented in both R packages *QTLpoly* (Da Silva Pereira et al. 2020) and *MAPpoly* (Mollinari et al. 2020), respectively; and (vi) a breeding program database, named *Sweetpotato Base* (Morales et al. 2022).

5 Genetic Diversity Analysis

5.1 Phenotype-Based Diversity Analysis

Diversity can be measured in a variety of ways and helps populations adapt to shifting surroundings. Morphological or molecular markers have been utilized in a number of studies to analyze natural, landrace, or breeding populations of sweetpotato. For instance, a study was reported using morphological characteristics and electrophoretic banding patterns of total proteins and esterase to characterize 1939 Peruvian collections out of 5000 sweetpotato accessions available at the CIP (Huamán et al. 1999). Vargas et al. (2018) evaluated 95 accessions and two commercial cultivars morphologically, and distances were estimated by means of multicategory variables, the data being consequently clustered by the Tocher method. The descriptors that contributed more than 60% of diversity involved the following: leaf size, general leaf profile, immature leaf color, petiole pigmentation, predominant branch color, branch secondary color, stem length, cortical thickness, predominant periderm color, and periderm color intensity.

A phenotypic analysis using morphological and chemical assessments was performed based on 16 factors to complete the study. Italian accessions were found to be extremely close to South American germplasm based on the molecular findings; however, they were subclustered into two groupings. Furthermore, based on similar physical traits and molecular fingerprints, the population's genetic structure analysis revealed that one of the two Italian genotype groups may have descended from South American accessions. Overall, the genetic markers and agronomic parameters used in combination were successful in distinguishing or clumping the sweetpotato genotypes in accordance with their geographic origin or phenotypic descriptors. Breeders and farmers might both use this knowledge to find and safeguard commercial types (Palumbo et al. 2019).

5.2 Molecular Marker-Based Assessment Diversity

According to recent studies on diversity assessment using molecular markers, the largest diversity of sweetpotato was identified in Central America, which supported the idea that this region is the principal center of variability and most likely the sweetpotato's origin (Huang and Sun 2000; Zhang et al. 2000). This origin and its relationships with other species have been studied using different molecular techniques, such as restriction fragment length polymorphism (RFLP), RAPD, microsatellites or simple sequence repeat (SSR), AFLP, and other systems including SNP. Below, we will present some studies on genetic diversity in sweetpotato based on a series of such techniques.

5.2.1 Randomly Amplified Polymorphic DNA (RAPD)

Among eight *Ipomoea* species from section Batatas and 26 accessions of sweetpotato from Peru, Philippines, and the USA, 15 RAPD primers were employed

in this study. The South Pacific and Peruvian sweetpotato lines were readily distinguished in the hexaploid *I. batatas* by a total of 56 polymorphic bands. The species that are most closely related to the farmed hexaploid *I. batatas* are *I. tabascana* and *I. trifida*. These results confirm the value of RAPD markers in assessing sweetpotato genetic diversity and identifying taxonomic and evolutionary links in *Ipomoea* (Jarret and Austin 1994).

5.2.2 Inter-Simple Sequence Repeat (ISSR)

Using ISSR markers, Zhang et al. (2014) evaluated 240 sweetpotato accessions from different germplasms in China. The mean genetic similarity coefficient, Nei's gene diversity, and shared allele distance were each 0.73, 0.32, and 0.27, respectively. Based on the results of Neighbor-Joining (NJ) clustering analysis and STRUCTURE, the 240 accessions could be classified into six subgroups and five subpopulations, and clear genetic links between the tested accessions were found. The marker-based NJ clustering and population structure of the examined sweetpotato germplasm revealed no clear assignment pattern corresponding to flesh color or geographical ecotype. Between white and orange-fleshed sweetpotato accessions, AMOVA found a slight but significant difference. Sweetpotato accessions from the Southern summer-autumn sweetpotato region, the Yellow River Basin spring and summer sweetpotato region, and the Yangtze River Basin summer sweetpotato region all showed small but noticeable differences.

5.2.3 Amplified Fragment Length Polymorphism (AFLP)

Using AFLP markers, 69 cultivars of sweetpotato from four different regions of Latin America were fingerprinted from CIP germplasm (Zhang et al. 2000). The diversity distribution was revealed by mean similarity, multidimensional scaling (MDS), and AMOVA. Central America has the largest genetic variety, whereas Peru-Ecuador had the lowest. These findings are in line with the theory that Peru-Ecuador should be regarded as a secondary center of diversity, with Central America serving as the primary center of diversity and most likely the origin of the sweetpotato.

Bruckner (2004) used AFLP markers to assess the genetic diversity of 75 sweetpotato accessions from CIP, Lima, Peru, and PGRCU, Griffin, USA. AMOVA and main coordinate analysis were applied to the data of 183 polymorphic bands in order to draw the conclusion that the collection had many clusters. Using ten different primer combinations, AFLP analysis of 75 sweetpotato accessions produced 202 distinct polymorphic bands, which allowed for the separation of those accessions. The AFLP analysis results showed that the genetic diversity among the germplasm accessions was relatively modest and that there were few genetic distances between regions.

5.2.4 Simple Sequence Repeat (SSR)

In order to assess the genetic diversity among 112 cultivars in Burkina Faso and to create a core collection, 30 morphological characters and 30 SSR markers were used. While 28 SSR markers were helpful in differentiating the 112 accessions and

identifying 5 duplicates, eight morphological characters were able to distinguish the accessions and identify 11 duplicates. When comparing the results of the two methods, it was found that the phenotypic data produced a high diversity coefficient of 0.73 while the SSR markers produced a moderate diversity coefficient of 0.49. The outcomes demonstrate no relationship between the two methods. Utilizing SSR-based data, a core collection was created, and eight discriminative phenotypic characteristics will be utilized to identify cultivars (Koussao et al. 2014).

Using ten SSR primers, the genetic diversity of 40 sweetpotato accessions from ICAR-CTCRI and CIP was examined. For each SSR and accession, the existence of bands was assessed, and the data were then analyzed using principal coordinate analysis. The sweetpotato cultivars were divided into seven primary clusters using the polymorphic SSR loci, which revealed different relationships among them. Jaccard similarity coefficients between 0.5 and 1.0 in cluster analysis indicated considerable genetic diversity. AMOVA was used to analyze the data, which revealed that the majority of the diversity (82.17%) was found among populations and among the *I. batatas* within the populations (17.83%) (Nair et al. 2017).

Rahman et al. (2023) studied the genetic diversity of 20 sweet potato germplasms originating from Bangladesh, CIP, Philippines, Taiwan, and Malaysia with 20 SSR markers for germplasm characterization and utilization. A total of 64 alleles were generated using the 20 primers from the 20 samples, with locus IBS97 having the highest number of alleles (5), whereas locus IbU33 had the fewest alleles (2). The alleles varied in size from 105 (IbU31) to 213 base pairs (IBS34). The Polymorphism Information Content (PIC) values for the loci IbL46 and IBS97 varied from 0.445 to 0.730. IBS97 has the highest number of effective alleles (3.704), compared to an average of 2.520. The average Shannon's diversity index (H) was 1.003, ranging from 0.673 in IbU3 to 1.432 in IBS97. The value of gene flow (Nm) varied between 0.000 and 0.005, with an average of 0.003, whereas genetic differentiation (Fst-values) ranged between 0.901 and 1.000. Total 20 genotypes were classified into two groups in the UPGMA dendrogram, classified as group "A" with 16 genotypes and the remaining classified as group "B" with 4 genotypes. As a result, SSR markers could be successfully evaluated for the genetic relationships among the sweet potato accessions used and generated a high level of polymorphism.

Liu et al. (2023) studied the genetic diversity of 617 sweetpotato accessions from China using 30 SSR primers. Based on the population structure analysis, these accessions were grouped into three groups, Group 1, Group 2, and Group 3, containing 228, 136, and 253 accessions, respectively. The results were obtained via phylogenic analysis and principal coordinate analysis (PCoA). Of the three groups, Group 2 showed the highest level of genetic diversity and were mainly distributed in low-latitude regions. The accessions from South China exhibited the highest level of genetic diversity, which assists the hypothesis that Fujian and Guangdong were the earliest regions where sweetpotato was brought to China. Analysis of molecular variance (AMOVA) showed that there were significant genetic differences between different groups.

5.2.5 Start Codon Targeted (SCoT) Polymorphisms

Using ten SCoT primers, 40 sweetpotato accessions obtained from ICAR-CTCRI and CIP had their SCoT polymorphisms examined. There were created 128 bands in all, 75 of which were polymorphic among the accessions. With a product size range of 200 bp to 2 kb and a polymorphism of 56.5%, the primer SCoT 11 produced the greatest number of bands (25), whereas the primer SCoT 21 produced the fewest bands (7). The genotypes of the sweetpotato lines employing the SCoT marker were grouped into three major clusters as a result of the hierarchical cluster analysis. Nearly all of the ICAR-CTCRI released varieties fell into cluster I, while the CIP high-carotene clones were divided into clusters II and III. These findings suggested that the SCoT marker system is useful for identifying polymorphism and separating variability among sweetpotato lines (Nair et al. 2016).

5.2.6 SNP

Using a genotyping-by-sequencing (GBS) protocol optimized for highly heterozygous and polyploid species, GBSpoly, Wadl et al. (2018) reported the diversity study of 417 USDA sweetpotato accessions coming from eight broad geographical regions (Africa, Australia, Caribbean, Central America, Far East, North America, Pacific Islands, and South America). The accessions were divided into four genetic groups by population structure using Bayesian clustering analysis (STRUCTURE) with 32,784 polymorphic SNPs. Indicating a significant degree of mixed ancestry, the population structure analysis was supported by a neighbor-joining cladogram and principal components analysis based on a pairwise genetic distance matrix of the accessions. Based on the origin of accessions, pairwise Fst values between major geographic areas ranged from 0.017 (Far East – Pacific Islands) to 0.110 (Australia – South America).

Feng et al. (2018) identified the diversity and relationship of different polyploid types in sweet potato and *I. trifida* using Restriction-site Associated DNA sequencing (RAD-seq). A total of 38,605 RAD tags containing 832,204 SNPs were identified. These tags were annotated with five public databases, and approximately 11,519 tags were mapped to functional genes in different pathways. Based on the SNP genotype, the results of phylogenetic analysis confirmed that cultivated sweet potato is closely related to wild species, *I. trifida*.

Using 662 parents from the International Potato Center (CIP) global breeding program covering Peru, Uganda, Mozambique, and Ghana, a low-density, very informative set of SNP markers has been developed to be used for routine quality assurance and control (QA/QC) (Gemenet et al. 2020b). Segregation of the selected 30 SNPs was evaluated in a recombinant breeding population using 282 offspring of the selected parents. Genotypes were reproduced in vitro, in a screen house, and in the field, and it was confirmed that the selected SNP set identified relatively similar similarities as a dense SNP set of 10,159 markers. The study also allowed us to assess the global breeding population structure of CIP and the impact of some of the most devastating stressors, such as sweet potato virus disease, on the management of genetic variation. These results provide insight into the future implementation of genomic selection in sweet potato.

5.3 Relationship with Geographical Distribution

To represent both domesticated gene pools, *I. batatas* (329 landraces) was sampled across its distributional range from Mexico to Peru by nuclear and chloroplast microsatellite markers. Both markers maintained the presence of two geographically restricted genepools, corresponding to accessions from the Peru–Ecuador region of South America (Southern genepool) and accessions from the Caribbean and Central America region (Northern genepool). According to the tripartite hypothesis of sweet potato introduction into Oceania (Oceania corresponds here to the entire insular region between Asia and the Americas, including Polynesia, Micronesia, and Melanesia), the three lines introduced different genepools into different areas. The distributional ranges of *I. trifida* (40 accessions) and *I. triloba* (15 accessions) were sampled. It has been hypothesized that one accession of *I. tabascana* is a cross between *I. batatas* and *I. trifida* (McDonald and Austin 1990).

Further research strongly suggested that *I. batatas* may comprise actual wild populations with lower ploidy levels in addition to the hexaploid cultigen, from which cultivated forms would have been domesticated. In addition, recent research suggests that the domestication of the sweetpotato may have had two separate origins. Cultivated landraces have two distinct geographically clustered chloroplast lineages, with the other two landraces being found in northwestern South America. These differentiation patterns were supported by nuclear microsatellite markers (Roullier et al. 2011).

Six geographical regions and a total of 23 countries that produce sweetpotato were used to analyze the genetic links among 74 sweetpotato accessions using a total of 71 polymorphic RAPD molecular markers. The genotypes from Central or the Caribbean and South America formed two distinct clusters, according to MDS approach. East African variations stood out from other traditional kinds from South America and Oceania due to their distinctive traits from other traditional varieties. These findings lend support to the proposed theory on the genesis and spread of the sweetpotato and showed that the main source of diversity likely contains two different gene pools. It is suggested that, rather than variants from South America, the spread of the sweetpotato from its origin may have mostly involved types from Central America or the Caribbean. There is evidence that new gene pools may be developing in Africa and Asia as a result of hybridization and environmental adaption (Gichuki et al. 2003).

According to Khoury et al. (2015), the richest areas for sweetpotato's closest wild relatives are Mesoamerica and the extreme Southeastern United States, which stretch from the Central United States to Argentina. The adaptation of designated species to temperature, precipitation, and edaphic features varies among them and in comparison to the crop, and the majority of species have also exhibited significant intraspecific variation. Because 79% of the species were deemed high priority for crop genetic resources and in ex situ conservation systems, breeders and researchers' access to these species was insufficient. Additional taxonomic study, characterization, and evaluation of germplasm, as well as developing methods to get over

obstacles to introgression with wild species, are required in order to mobilize the genetic resources for improved conservation of sweetpotato's wild relatives.

6 Molecular Mapping of Health-Related Genes and QTLs

6.1 Molecular Markers: Types, Evolution of Molecular Markers

Individuals within a species will present variations at the DNA level among themselves. These genetic variations are the source for the development of molecular markers, which provide genetic information at specific loci for individuals within a population. As such, molecular markers are employed in plant breeding for germplasm characterization, gene introgression tracking, genetic variability assessment, genetic and QTL mapping, and cultivar protection. In diploids, molecular markers application is straightforward, but for polyploids there are quite a few hurdles for their usage. The major hurdle is the large number of genotypic classes. Thus, most markers can only be scored as dominant (single-dose markers), and allele dosage or multiallelic information is lost. Although several advances have been attained in the polyploid statistics field, molecular and statistical methods still have a gap among them to efficiently estimate genotypic classes. As a hexaploid species, the application of molecular markers in sweetpotato breeding is still hindered by such difficulties.

The introduction of molecular markers in sweetpotato genetic studies started in the early 1990s. Jarret et al. (1992) used RFLP markers to study the phylogenetic relationships among 13 *Ipomoea* species with different ploidy levels. The marker analysis showed that the diploid *I. trifida* and wild tetraploids are phylogenetic close to *I. batatas*. RAPD markers were the first ones used to study genetic linkage in sweetpotato (Thompson et al. 1997). Gichuki et al. (2003) fingerprinted 74 sweetpotato varieties with RAPD markers to infer the relationship among genotypes from different geographic sources. South American and Central American varieties formed two separate clusters, probably indicating two centers of diversity. Additionally, the results suggested that new gene pools might have been evolving in Africa and Asia due to hybridization and local environments adaptation.

The first sweetpotato genetic map with considerable coverage was constructed using AFLP markers (Kriegner et al. 2003). Rossel et al. (2001) employed AFLP markers to investigate the dispersal of sweetpotato to Oceania by comparing the relationships among samples from Peru, Ecuador, Mexico, Philippines, and eight Oceania countries. The results showed the occurrence of gene flow between Mexico and Oceania, and little relationship with Peru-Ecuador genotypes. Sweetpotato genetic diversity was also greater in Oceania, and the authors hypothesized a nonhuman dispersal from Mesoamerica to Oceania. AFLP markers were also used in disease resistance studies.

SSRs, also called microsatellites, are highly polymorphic and are scattered throughout the genome. Only in diploids, though, they can be analyzed as codominant markers. The first SSRs for sweetpotato were developed in 1994 (Jarret and Bowen 1994), and since then the development and usage of these markers in

sweetpotato only increased (Zhang et al. 2001; Roullier et al. 2011; Roullier et al. 2013; Yada et al. 2017). Zhang et al. (2001), using SSR markers, observed a distinct geographical pattern within sweetpotato Latin America gene pool. The authors proposed that Mesoamerica is the primary center of diversity and probable center of origin, while Peru-Ecuador region would be the secondary center of diversity. SSR markers also indicated the existence of two domesticated sweetpotato gene pools, including the Northern and Southern genotypes, which suggests two domestication events (Roullier et al. 2011). In addition, these markers also showed that sweetpotato most probably has an autopolyploid origin, sharing an ancestor with *I. trifida*. Considering the high genetic diversity present in sweetpotato, the species seem to not have suffered a severe bottleneck during domestication (Roullier et al. 2013). Associations of SSR loci with desirable sweetpotato agronomic characteristics were also identified (Yada et al. 2017).

In polyploids, SNPs can have multiple doses of a nucleotide allele. Being a hexaploid, sweetpotato can have up to seven different genotypic classes: six copies of the reference nucleotide (*AAAAAA*), one to five copies of the alternative nucleotide (*AAAAAa*, *AAAAaa*, *AAAaaa*, *AAaaaa*, and *Aaaaaa*), and six copies of the alternative nucleotide (*aaaaaa*). Inferring allele dosage from next-generation sequencing data is now possible in sweetpotato (Mollinari et al. 2020) by the usage of software such as SuperMASSA (Serang et al. 2012).

6.2 Genetic Linkage Maps

In general, the construction of genetic linkage maps is performed to generate a representation of the genome and to provide an appropriate structure for QTL mapping. This construction is dependent on the genetic structure and size of the population and the genome complexity. In sweetpotato, genetic linkage maps are constructed using F_1 segregating populations derived from biparental crosses between highly heterozygous individuals. It occurs because this crop has self-incompatibility and does not generate inbred or homozygous lines, which are explored in many of the experimental crosses used for mapping in plants.

In this sense, several F_1-based genetic linkage maps have been published for sweetpotato to date. The first one was proposed by Ukoskit and Thompson (1997), who used 196 RAPD markers for constructing two low-density genetic linkage maps based on 76 F_1 progenies. Two maps were obtained separately for each parent ('Vardaman' and 'Regal') using 25 and 20 single-dose (simplex) markers segregating in a 1:1 ratio, following the two-way pseudo-testcross approach. The final maps were obtained incorporating the double-dose (duplex) and triple-dose (triplex) markers, increasing the total number of polymorphisms to 48 ('Vardaman') and 46 ('Regal'). With the nonsimplex markers, authors identified homologous groups in both maps, improving the informativeness.

More recently, Shirasawa et al. (2017) developed a high-density genetic linkage map based on 142 progenies derived from self-pollination of the 'Xushu 18' cultivar. A total of 94,361 SNP markers were identified after filtering for coverage depth

(≥10) and missing data (<0.25), of which 36,590 (38,8%) were double-simplex (expected segregation of 1:2:1). However, because the number of reads was insufficient to distinguish two genotypic classes (*AAAAAa* and *AAAAaa*), the authors coded the data as dominant loci, with an expected segregation of 3:1. After filtering to Mendelian segregation, the genetic linkage map was constructed using 28,087 (29,8%) SNPs, which generated 96 LGs (90 + six small extra groups) and covered a total distance of 33,020.4 centiMorgan (cM). On average, each LG presented a length of 344 cM and 293 SNPs.

Although all referenced genetic maps have contributed to represent the sweetpotato genome and confirmed its hexasomic segregation, they were limited on its characterization. Most of them used the two-way pseudotestcross approach to construct one map for each parent, which was proposed for diploid species. Moreover, this strategy does not allow the construction of an integrated map containing multiple markers with different segregation types, which should improve the genetic characterization. In addition, most of maps were built using a two-point approach, which does not consider multiple markers simultaneously to the map construction.

In this sense, Mollinari et al. (2020) proposed the first integrated multilocus genetic map to simultaneously estimate recombination fractions and linkage phases for a complex polyploid. The method was applied for a sweetpotato F_1 progeny consisting of 315 individuals, which was originated from a cross between the 'Beauregard' and 'Tanzania' cultivars. An ultradense genetic map consisting of 30,684 SNP markers (~2046 SNPs per LG) was built, covering 2708.3 cM (180.6 cM per LG; 11.3 SNPs/cM) and containing the complete hexaploid haplotypes for the mapping population. This comprehensive map showed that most of the meiotic configurations (73.3%) were bivalents and clearly evidenced a hexasomic-bivalent inheritance in sweetpotato, which should promote stability to the allelic transmission along the generations.

6.3 QTL Mapping

Traits selected by breeding programs are usually quantitative and strongly influenced by environment. Generally, breeders need to evaluate a lot of candidate genotypes in multiple locations and years to select the best ones, which takes a long time and lots of resources. One way to accelerate this process is to use DNA-based markers (i.e., without environmental influence) genetically associated with quantitative traits to perform selection, based on the marker-assisted selection (MAS). Different approaches can be used to identify markers associated with traits. Here, we will present the QTL mapping, focusing on the studies developed for sweetpotato.

QTL mapping, i.e., association between the genotype (DNA-based markers) and the phenotype (trait expression), can be performed using different statistical methods such as single marker analysis (SMA) and interval mapping (IM) based models (Lander and Botstein 1989). Except for SMA, all these methods use a genetic linkage map to search for QTL, considering that mapping population is diploid and originated from inbred parents. Although sweetpotato is an autohexaploid and

outcrossing species, these methods were applied in previous studies of the crop. Currently, QTL mapping can be specifically performed for a complex autopolyploid and outcrossing species (Da Silva Pereira et al. 2020), and we will discuss the application of this approach in sweetpotato. First, we will briefly describe the previous studies.

For the first mapping QTL in sweetpotato, SMA detected nine markers/QTL associated with root-knot nematodes (RKN) resistance, being seven QTL for one parent ('Tanzania') and two QTL for the other parent ('Beauregard'). For 'Tanzania', four QTL showed positive additive effects on RKN resistance and explained approximately 21% of the phenotypic variation. For 'Beauregard', the two QTL had positive additive effects on RKN resistance and explained 6% of the phenotypic variation (Cervantes-Flores et al. 2008b). Authors have also used IM and composite interval mapping (CIM) on previous genetic maps (Cervantes-Flores et al. 2008a) and confirmed the same results of SMA.

QTL mapping has also been done for quality traits in this crop. Cervantes-Flores et al. (2011), who were first to map QTL in this context, used CIM in two previous genetic linkage maps (Cervantes-Flores et al. 2008a) to identify 13 (15–24%), 12 (17–30%), and 8 (17–35%) QTL for dry matter, starch, and β-carotene, respectively. The same traits were investigated by Yada et al. (2017), who used another mapping population (Yada et al. 2015) and SMA to detect four, six, and eight SSR markers associated with dry matter, starch, and β-carotene. These markers, which could directly be associated with traits or in linkage disequilibrium with QTL, explained overall 15.8, 32.3, and 37.8% of the phenotypic variation, respectively.

Although all these studies were important and made progress, they were limited to map QTL in sweetpotato, due to its genetic complexity. Recently, Da Silva Pereira et al. (2020) proposed a comprehensive QTL mapping for sweetpotato using an extension of MIM for a complex autopolyploid. Considering a previous integrated linkage map (Mollinari et al. 2020), the authors detected a total of 13 QTL for eight yield-related traits, with the number of QTL per trait ranging from one to four. These QTL explained up to 55% of the variation, being that both parents ('Beauregard' and 'Tanzania') contributed with alleles to increasing the trait means in the mapping population.

Using the same mapping population of Mollinari et al. (2020) and Da Silva Pereira et al. (2020), Gemenet et al. (2020a) identified two major QTL related to starch, β-carotene, and their respective correlated traits, dry matter and flesh color. The authors used the extension of MIM proposed by Da Silva Pereira et al. (2020), which enabled to evidence that both QTL presented a pleiotropic effect to reducing starch and increasing β-carotene in genotypes carrying a haplotype from the 'Beauregard' parent.

Mwanga et al. (2021) and Oloka et al. (2021) also used the extension of MIM for autopolyploids (Da Silva Pereira et al. 2020) to detect QTL in sweetpotato. The former mapped a total of six QTL (two per trait) for β-carotene and other important traits such as iron (Fe) and zinc (Zn) contents, and the QTL explained 65.8%, 51.0%, and 23.5% of the phenotypic variation, respectively. The latter identified one major QTL (58.3% of the phenotypic variation) for RKN resistance, which would be a putative candidate to perform MAS for this important disease.

In summary, QTL mapping has been used in different populations (backgrounds) and for many traits in sweetpotato to date. Great progress has been achieved, particularly with the recent studies which used molecular markers and statistical methods specifically developed for an autopolyploid and outcrossing species. Next steps in QTL mapping should remain in the extension of the methods to account for multiple traits or environments simultaneously, enabling the investigation of pleiotropic effects and linkage as well as the interaction between QTL and environments. Certainly, the future results of these approaches will be helpful to improve our understanding regarding genetic architecture of the traits, providing valuable information for MAS into sweetpotato breeding.

6.4 Association Mapping

Association mapping is a powerful approach to identifying QTL that requires a large number of polymorphisms and overcomes the need for biparental populations. Diversity panels are used instead, allowing for the exploitation of historical recombinant events, relying on linkage disequilibrium (i.e., nonrandom associations at different loci) to find associations between markers and traits. It identifies alleles controlling complex traits and presents higher resolution than linkage analysis, but its effectiveness depends on marker density, sample size, population structure, and relatedness.

There are two main approaches of association mapping: genome-wide association studies (GWAS) and candidate gene analysis. The selection of approach depends on the availability of markers. While candidate gene association uses markers previously chosen based on their locations and on previous QTL studies, GWAS test associations across the entire genome, using individuals that are densely genotyped. Association mapping has been successfully used in major diploid crop species, where the availability of genomic tools and resources is large. However, in autopolyploid species, such as sweetpotato, genomic analysis has been challenging for a long time, mainly due to the complex genomes. Autopolyploid species do not resemble the meiotic chromosome behavior of diploids (Yamamoto et al. 2020), so allele dosage information is required to effectively map complex traits using all the allelic information of the genotypes and population.

The first attempts in polyploids were based on AFLP or SSR markers, which are used as dominant markers, and scored according to the presence or absence of bands. Advances in DNA sequencing via next-generation sequencing technology have enabled the usage of SNP, the most abundant markers in the genome. In autopolyploids, allele dose estimation for array- and mass spectrometry-based SNP data dates back to 2012 (Serang et al. 2012).

In autopolyploids, GWAS has evolved from using diploid models, where marker data are "diploidized," to models accounting for allele dosage. GWASpoly (Rosyara et al. 2016) is the first R package designed for GWAS with SNP in autopolyploids using the classic Q + K method, which takes into account both population structure (Q) and cryptic relatedness (K). GWASpoly can conduct single marker association

tests using different models of gene action. The modified Q + K model was evaluated and validated in GWASpoly using simulated data and a tetraploid potato diversity panel with nulliplex (*aaaa*), simplex (*Aaaa*), duplex (*AAaa*), triplex (*AAAa*), and quadriplex (*AAAA*) states.

In sweetpotato, a study aimed to determine whether the genetic mapping of polyploids could be possible when there is no accurate allele dose information. The applicability of the low-coverage NGS was confirmed using real data from autohexaploid sweetpotato. The authors performed an association study using an analogous approach to the "general" option presented in GWASpoly, but not including the kinship matrix. Three peaks on homologous group 6 were detected, with simplex dominant phenotypic inheritance mode, where all heterozygotes were equivalent to one of the homozygotes.

An association study using 46,788 SNPs was performed to map resistance to southern root-knot nematode (SRKN; *Meloidogyne incognita*) race SP2 in hexaploid sweetpotato using multiple-dose markers. One peak was found on chromosome 7 and another on chromosome 3, both loci presenting a simplex state. DNA markers were developed to screen for nematode resistance using the SNPs present on the peaks. The accuracy of selecting SRKN-SP2-resistant plants using the two markers was approximately 70% (Obata et al. 2022).

7 Marker-Assisted Breeding for Health-Related Traits

7.1 Germplasm Characterization

Germplasm characterization of varieties and breeding populations has been essential for crop improvement, and diversity has long been seen as vital for rational management and use of crops. A crucial step in breeding for improved nutrient content is the characterization of quality steps. Genetic diversity analysis is key for deciphering the extent of genetic variation available between and within germplasm collections.

Molecular markers are used in complementarity with phenotypic markers when trait expression is environmentally unstable. The most predominant marker system used in the past few decades were the SSR markers or microsatellites. These markers are highly polymorphic, and codominant, and can easily be detected on high-resolution gels. Marker systems keep on evolving, and those based on genomic SNPs have gained center stage in germplasm characterization, due to their amenability for high-throughput sequencing and detection.

7.2 Limitations and Prospects of Marker-Assisted Breeding

MAS is an approach that identifies and selects genotypes based on markers rather than phenotypes per se. MAS can improve the selection efficiency since it (i) can be performed early on seedlings, (ii) is not affected by environmental conditions, (iii) can identify recessive alleles controlling the trait of interest, (iv) can perform gene

pyramiding, and (v) allows selecting for traits with low heritability. However, the use of MAS in routine breeding programs presents some limitations, including (i) the cost: MAS is more expensive than conventional breeding. Even though markers are cheap, the initial cost can be high; (ii) the degree of linkage between the marker and the target gene: recombination between the marker and the target gene may occur as far as the marker is from the gene; (iii) markers are, sometimes, population-specific; and (iv) QTLs have distinct effect in different genetic backgrounds: QTL effects are not always consistent across environments, and the magnitude of their effects depends upon QTL by environment interaction.

Marker-assisted backcrossing breeding (MABCB) is considered an applicable form of MAS. It is an effective approach to introgress major genes from a donor parent into the elite and improved variety, while recovering the recurrent parent genome through multiple backcross generations, minimizing linkage drag. The MABCB involves the usage of markers to select for target loci, minimizing the segment containing the loci of interest and accelerating recovery of the recurrent parent during backcrossings by using markers. Selection strategies for MABCB for a gene in diploids find three generations of backcrossings to be sufficient to recover a high proportion of the recurrent parent, saving two to four backcross generations in the transfer of a single locus. Such an approach, however, is hardly applicable to sweetpotato breeding due to its strong inbreeding depression and self-incompatibility, as well as the polyploid and complex nature of its genome.

7.3 GWAS and Genomic Selection (GS)

GWAS and genomic selection (GS) are effective approaches to investigating marker-trait associations. Both approaches are based on genome-wide markers. GWAS use genotypic and phenotypic information from diversity panels to estimate marker effects across the genome. The analysis is based on linkage disequilibrium and can identify novel QTL and genes for the trait of interest.

Instead of identifying specific associations, GS uses all genome-wide markers simultaneously to predict the performance of individual candidates for selection. The idea is that QTLs will be in linkage disequilibrium with some markers because the marker information is dense enough to do so. The selection is based on genomic estimated breeding values (GEBVs) obtained from a predictive model that integrates genotypic and phenotypic data of a training population. The selection of superior individuals based on GEBVs leads to a shorter breeding cycle since it is not necessary to wait for late progeny generations to phenotype the traits of interest. It promotes acceleration of process and reduction of costs, enabling to effectively deliver increased genetic gain per unit time and cost.

Breeders of polyploids and clonally propagated species such as sweetpotato have additional questions regarding the usage of GS models in their breeding programs. The first one is related to the inclusion or not of nonadditive (dominance and epistasis) genetic effects in the models. Modeling nonadditive genetic effects in sweetpotato, whether diploidized or with dosage information, it was found that the

models without nonadditive effects were comparatively better in prediction accuracy than the models including nonadditive effects (Gemenet et al. 2020c). A second question was whether the dosage information significantly improves accuracy. The authors stated the relative importance of considering dosage is dependent on trait architecture. The general rule is that the more complex the trait, the more important dosage information is.

The GS strategy using low-depth sequencing data applied by the blueberry breeding program at the University of Florida may be helpful for a range of other polyploid species. Their approach simplified the allele dosage information in auto-polyploids and resulted in similar prediction accuracies compared with more refined scenarios (Ferrão et al. 2021). The authors stated the inclusion of allele dose information on GS models might improve the accuracy of the GEBVs by considering the additive effect of dose and the potential dominance effects.

A combined GS plus de novo GWAS model was proposed to combine the results of GWAS using the GS training population in rice (Spindel et al. 2016). Briefly, the model uses the results of the GWAS as part of the GS model, with no need for extra datasets. The authors stated the significant SNPs identified from the GWAS would be relevant to the population under selection and that the method is more suitable for traits with one or more medium-large QTL segregating in the population. Since statistical models have evolved for autopolyploids, GS plus de novo GWAS could also be applied to sweetpotato breeding programs.

8 Genomics-Aided Breeding for Health-Related Traits

8.1 Health-Related Functional Genomics Resources

Access to large-scale gene expression profiling datasets from a wide range of species has revealed genes controlling certain health traits and those in response to abiotic and biotic stresses. For sweetpotato, a reference genome sequence from its wild *I. trifida* has recently been made available (Wu et al. 2018), enabling more genomic resources deployment to address sweetpotato genome complexity (Wadl et al. 2018; Wu et al. 2018; Da Silva Pereira et al. 2020). This has aided the understanding of genetic architecture and control of β-carotene and starch in sweetpotato as well as unraveling genes in sweetpotato carotenogenesis (Gemenet et al. 2020a) and those responding to abiotic stress such as drought (Lau et al. 2018). So far, a few studies have reported genes responding to health-related (HR) traits such as carotenoids and starch (Wu et al. 2018; Gemenet et al. 2020a; Mwanga et al. 2021).

Insights into genes involved in regulation of the pathways for carotenoid and starch/carbohydrate metabolic pathways are well characterized in many crops, but still generally lacking in sweetpotato. Besides, until recently (Gemenet et al. 2020a), the molecular mechanisms driving the association between starch and carotenoids metabolic pathways in sweetpotato were studied independent of each other.

Genome redundancy exhibited by *Brassica* species provides a model to study the evolutionary fate of multicopy genes and the effects of polyploidy in economically

important crops. Significant work has been done unraveling the mode of action of phytoene synthase (PSY), as the catalyst of the first committed reaction of the carotenoid biosynthetic pathway and the main bottleneck in the carotenoid pathway (Cazzonelli and Pogson 2010). In *Arabidopsis thaliana*, a single *PSY* gene (*AtPSY*) is responsible for regulating phytoene synthesis in all tissues. However, in most plant species, the *PSY* gene family seems to be composed of two or three homologous genes. For example, carrots (Just et al. 2007) have two PSY encoding genes while in other crops, such as maize and tomato (Fraser et al. 1999), three *PSY* homologs have been reported. The three *PSY* copies in grasses have subfunctionalized and provided a fine tine control of carotenogenesis in response to various developmental and external cues (Li et al. 2009).

While some isoforms participate in the biosynthesis of carotenoids in chloroplast-containing photosynthetic tissues, others participate in the production of carotenoids in nonphotosynthetic tissues of the fruit (tomato *PSY1*), seed endosperm (maize *PSY1*), or the root (tomato, maize, and rice *PSY3*). The *Arabidopsis PSY* gene is expressed in virtually all tissues, including both photosynthetic and non-photosynthetic (Rodríguez-Villalón et al. 2009), and shows high rates of coexpression with the rest of the genes involved in the carotenoid pathway and in the supply of their isoprenoid precursors (Meier et al. 2011). The Orange protein regulates carotenoid accumulation by posttranscriptionally regulating PSY, promoting the formation of carotenoid-sequestering structures, and also preventing carotenoid degradation. The Orange protein contributes to homeostasis regulation, improving plant tolerance to abiotic stress (Park et al. 2016).

Orange flesh color in sweetpotato has been correlated with high β-carotene content. Logical control points/loci for the accumulation of β-carotene in OFSP were identified by Wu et al. (2018), providing targets for MAS of OFSP varieties. Three SNPs in gene homologs encode key carotenoid biosynthetic enzymes, including PSY (*itf03g05110*), phytoene desaturase (PDS; *itf11g08190*), and ζ-carotene isomerase (Z-ISO; *itf04g12320*), in a set of sweetpotato parents composed of orange- and white-fleshed accessions. Upregulation of the *PSY* SNPs in orange-fleshed 'Beauregard' storage roots compared to other toot types suggested their involvement in conferring the orange flesh in 'Beauregard' storage roots. Furthermore, gene expression profiling of root development in 'Beauregard' showed biased expression of the "orange" alleles of the SNPs in *PSY* at late (at 40 and/or 50 days after transplanting) development stage of the storage roots, proposing expression-based increment of carotenoid accumulation. However, one SNP associated with orange flesh in *PDS* showed a weak but significant biased expression of the "orange" allele, at an early stage of storage root development (20 DAT), and a not significant in later stage of storage roots development (50 DAT). This showed the importance of the expression of specific PDS alleles before storage root initiation in the development of orange flesh.

QTL and differential gene expression analyses of β-carotene and starch loci, in a biparental population, may perhaps be one of the most comprehensive studies where the two traits have been studied together unraveling the genetic basis for the negative association between β-carotene and starch (Gemenet et al. 2020a). The study

contained 315 F_1 genotypes generated from an OFSP cultivar, 'Beauregard', and a white fleshed cultivar, 'Tanzania'. Enabled by the availability of a sweetpotato reference genome (Wu et al. 2018) and new linkage and QTL mapping methods for polyploids (Mollinari et al. 2020; Da Silva Pereira et al. 2020), four correlated traits, namely, dry matter, starch, β-carotene, and flesh color, were placed on QTLs based on an integrated genetic map of the 15 LGs of sweetpotato (Gemenet et al. 2020a). Variation for the traits in the mapping population was explained by a major QTL colocalized on LG3 and LG12. At LG12 QTL, both parents contributed with major alleles presenting similar allelic effects on the traits; however, the OFSP parent, 'Beauregard', contributed the major allelic effect to traits at the LG3 QTL.

Dry matter, starch, β-carotene, and flesh color are traits affected by the same haplotypes which act in completely opposite directions, i.e., same haplotypes participating in decreasing the means for dry matter and starch were also responsible for increasing the means for β-carotene and flesh color. This explains the observed negative association between starch and β-carotene in sweetpotato, a phenomenon also seen in cassava (Rabbi et al. 2017). Given that the two parents are contrasting for these traits, it appears that interaction of alleles in QTL on LG12 with those QTL on LG3 determines the accumulation or lack of accumulation of β-carotene in the storage roots of sweetpotato. Furthermore, the rate-limiting gene in the carotenoid biosynthesis, *PSY* gene (*itf03g05110*), was reported to sit in between the two colocalized QTL peaks at LG3, one at 2,994,719 bp (for β-carotene and flesh color) and the other at 3,185,578 bp (for dry matter and starch). Moreover, gene expression profiling datasets from developing roots showed carotenoid accumulation in both storage and fibrous roots in 'Beauregard' but not 'Tanzania'.

Similar expression levels of the starch gene *sucrose synthase* were found (*SuSY*; *itf03g05100*) during the early days of root development (10–20 days) for both parents but persist only in 'Tanzania' after 50 DAT. 'Beauregard' has a maturity period of 60 DAT while 'Tanzania' matures in 150 days. Moreover, *PSY* gene and *SuSY* genes are located within a reach of 12.2 kb with no intervening genes (Gemenet et al. 2020a). *Orange* (*Or*) gene homolog (*itf12g24270*) was found near (5.7 kb) the QTL peak associated with β-carotene on LG12. The *Or* gene has been reported to act on and regulate *PSY* allowing modification of amyloplasts into chromoplasts in several species including OFSP cultivars (Park et al. 2015). Together, this analysis identified logical control points for the accumulation of β-carotene in sweetpotato and loci that provide targets for MAS.

Starch is the most important carbohydrate in storage root in sweetpotato accounting for about 75% of human caloric intake. The composition, size, and shape of starch granules contributes to sweetpotato eating quality (Kitahara et al. 2017). Starch is primarily synthesized and accumulated as starch grains (SGs) in amyloplasts, which are also modified to store carotenoids in starchy organs such as seeds of wheat, rice, barley, and maize, as well as potato tubers, sweetpotato, and cassava roots. A mutually exclusive relationship exists between carotenoid accumulation and starch granule development in tobacco floral nectaries and carrot roots, suggesting that enhanced carotenogenesis serves as a developmental signal that directs the transition from amyloplasts to chromoplasts (Kim et al. 2010). However, storage of carotenoids in modified amyloplasts results in carbon competition for both starch

biosynthesis and carotenoid biosynthesis, which leads to the negative association reported in several crops including sweetpotato (Yada et al. 2017; Gemenet et al. 2020a).

8.2 Other Functional Genomics Resources

Expression profiling has become a valuable tool to investigate how an organism responds to environmental changes and can define both tolerant and sensitive responses. Profiles of plant response to environmental extremes are expected to lead to useful regulators in biotechnological approaches to improve stress tolerance and new tools for studying regulatory genetic circuitry. Alterations in the plant transcriptome may lead to further insights into effect of abiotic stress to plant physiology. De novo transcriptome studies have been carried out for hexaploid sweetpotato under abiotic stresses such as drought and salt (Lau et al. 2018; Arisha et al. 2020b; Zhou et al. 2022), and heat (Arisha et al. 2020a) in different *Ipomoea* species.

Even though sweetpotato tolerates abiotic stress, both drought salinity and heat stress still affect its productivity. Transcriptome studies have led to the discovery of key genes, gene networks, and transcription factors involved in single or regulatory roles in multiple abiotic stress responses in sweetpotato. While some genes respond to multiples stressors, others are stress specific. For instance, aquaporins (Arisha et al. 2020a) and Late embryogenesis proteins (LEAs), including late embryogenesis abundant protein and dehydrin, which are considered as a part of stress-protecting protein families in sweetpotato, can facilitate water uptake especially during drought. LEAs were highly upregulated in the water stress experiments (Lau et al. 2018). These proteins play a protective role under osmotic stress conditions, and homeostasis of proteins and nucleic acids.

Several stress-inducible genes have been identified in sweetpotato through transcriptomics, but their function within the molecular mechanisms for stress response and tolerance still needs to be deciphered. For example, the production of the phytohormone abscisic acid (ABA) causes stomatal closure, induces the expression of stress-responsive genes (Lau et al. 2018; Arisha et al. 2020b; Zhou et al. 2022), and plays a key responsive element binding factors (ABFs)-regulatory role in multiple abiotic stresses responses (Wang et al. 2019). Expression of *IbABF4* was induced by ABA and several environmental stresses including drought, salt, and heat shock (Wang et al. 2019). However, how they work is unknown. Further research trials tailoring cultivars for abiotic tolerance and enhanced yield by overexpression of the genes in sweetpotato should be increased all over the globe with the premier goal of more crops.

8.3 Gene Editing and Transgenics

The need to edit genomes keeps on evolving in many crops with sweetpotato not being an exception. Genome sequences have been developed for several crops, and

their availability and advances in genome editing approaches have made way to breed for almost any given desirable trait (Jaganathan et al. 2018). Examples of genome editing technologies include zinc finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and clustered regularly interspaced palindromic repeats (CRISPR/Cas9). CRISPR/Cas9-mediated genome editing is a powerful technology that facilitates the genetic modification of a number of species. In plant breeding of crops with valuable traits such as antioxidant-rich purple tomatoes, omega-3 fatty acid-enriched oil crop, starch altered potato, and high yielding rice, CRISPR/Cas9 system has been successfully used (Jaganathan et al. 2018). Previous studies have demonstrated that CRISPR/Cas9 technology is an effective tool for the improvement of starch qualities in sweetpotato and breeding polyploid root crops (Wang et al. 2019).

Some of the opportunities for applying nanotechnology in sweetpotato improvement lie in the areas of genetic improvement (Mukhopadhyay 2014) such as delivery of genes and drug molecules to specific sites at the cellular level in plants and animals. In addition, nanoarray-based technologies for gene expression in plants, to overcome stress and development of sensors and protocols for its application in precision farming, are prospective tools that could be considered for the improvement of sweetpotato crop. Furthermore, management of natural resources and early detection of pathogens and contaminants in food products also present good opportunities for improvement (Mukhopadhyay 2014).

Efforts were made to change the two starch components amylose and amylopectin. Amylose-free genotypes were generated using a transgenic approach (Kimura et al. 2001). Through gene stacking means, transgenic sweetpotato plants that produce both carotenoid and anthocyanin in the same storage root were developed by overexpressing the *IbOr* gene, involved in accumulation of carotenoids, or the *IbMYBI* gene, a transcription factor involved in the biosynthesis of anthocyanin (Kang et al. 2017). Using the CRISPR/Cas9 technology, altering the amylose/amylopectin ratio through selective knockout of *IbGBSSI* or *IbSBEII* was demonstrated (Wang et al. 2019).

9 Role of Bioinformatics as a Tool

9.1 Gene and Genome Databases

In the past decades, completion of the *Arabidopsis* and rice genome sequences and the continuing sequencing of other economically important nonmodel crop plants have been carried out. These efforts have provided an unprecedented amount of genome sequence data for large-scale genomics studies and analyses. For example, discovery and identification of novel genes, comparative genomics, and functional genomics can now be performed.

The ease of access and organization of the data primarily determines the efficient utilization of these large data sets in databases. Several plant databases have been set up to maintain various data types including genomic sequence, annotation, analyses

expressed transcript assemblies and analyses, and gene expression profiles from microarray studies. Several plant genomic databases have been developed. However, while some are inclusive, others are relational species-specific databases containing substantial amounts of data from one species such as tje *Arabidopsis* Initiative Resource (TAIR: http://www.arabidopsis.org/) database for the model plant *Arabidopsis thaliana*.

Increased genome projects have enabled the creation of databases with various related species. One example is the Solanaceae Genomics Network database (SGN; http://solgenomics.net/), comprising the reference genomes of tomato, potato, pepper, and *Solanum pennelli*; the draft genomes of *Solanum pimpinellifolium*, *Nicotiana benthamiana*, and *N. tabaccum*; and the genomes of two inbred lines of *Solanum lycopersicum*. The Sweetpotato Genomics Resource (SGR; http://sweetpotato.uga.edu) was recently developed to host the genome sequences and RNA-seq gene expression data of *I. trifida* and *I. triloba,* wild ancestors of the cultivated hexaploid sweetpotato. The Sweetpotato Genomics Resource serves as a reference for genetic improvement of the cultivated hexaploid sweetpotato (*I. batatas*) (Wu et al. 2018). Moreover, the *Ipomoea* Genome Hub is an integrated web-based database for *Ipomoea* species and hosts the haplotype-resolved genome sequence of hexaploid *I. batatas* (cv. Taizhong6) (Yang et al. 2017). Despite the efforts, the genome assembly is still incomplete and contains a considerable amount of redundancy and misassemblies, including erroneous assembly of haplotypes and therefore not of much use as a reference for genome-enabled breeding.

9.2 Comparative Genome Databases

The genome consists of a unique gene list controlling the specific phenotype and its interaction with the environment; however, this changes during evolution. New genes can arise when evolution tinkers with old ones but can also be caused by the natural selection. Variations, caused by natural selection, are encoded in an organism's genome, and provide clues to their genetic divergence from a common ancestor. The inference of variations between species based on gene inventories compositions opens the door to the rich branch of comparative genomics. The current innovations and speedy progress in sequencing technologies have substantially improved whole genome data providing scientists with a large dataset for orthologous-sequence comparisons.

Several databases have been developed and enabled comparative analysis of various sequenced plant genomes. The National Center for Biotechnology Information (NCBI) genome database provides a large suite of online resources for biological information and data, including the genebank nucleic acid sequence database and the PubMed database of citations and abstracts published in life science journals, giving access to genomic information for science advancement (Sayers et al. 2010). NCBI uses an integrated database retrieval system website termed Entrez, reaching a diverse set of databases that together contain billions of records. Entrez acts as the analysis and retrieval resources for the data in GenBank and other biological data

fields (Sayers et al. 2010). The NCBI Assembly database (www.ncbi.nlm.nih.gov/assembly/) gives stable access and data tracking for genome assembly data and may accommodate a range of assembly structures, including sets of an unordered contig or scaffold sequences depending on the database model. NCBI serves as a valuable genomics resource for model crops; however, it is not the case for sweetpotato (Table 2). The limited availability of sweetpotato genomic resources is further demonstrated by its absence in other integrative databases like the Phytozome (https://phytozome-next.jgi.doe.gov/), a comparative hub for plant genome and gene family data and analysis, and Ensembl Plants (http://plants.ensembl.org/).

The new generation of comparative genomics offers a powerful aid to identify biologically active regions of a genome based on the observation that sequences that hold key functions are frequently conserved between cross-species sequences, and thus can be distinguished from nonfunctional surrounding sequences. Therefore, comparative genomics is seen in this sense, as equivalent to evolutionary genomics. Orthology gene search using comparative genomics data reveals gene expansions and contractions that a species has undergone during evolution and can advance our understanding of the process of adaptation. A good illustration is found in the lineage-specific expansion of genes encoding sporamin proteins in both *I. trifida* and *I. triloba*. Sporamin (Kunitz-type trypsin inhibitor – KTI) is analogous to patatin in potato and a key storage protein in sweetpotato storage roots; the latter plays an important role in storage, defense, and development (The Potato Genome Sequencing Consortium 2011).

Comparative analysis offers an unprecedented understanding of gene duplications, new gene functions, and the impact of gene duplication on genome evolution. Through comparative analyses, whole genome triplicate events (WGT) were found to have

Table 2 Comparisons of genomic resources available in the NCBI database for sweetpotato compared to other common crops

Species	Assembly	Genome	Genes	Nucleotides	SRA	BioSample	Bioproject
Ipomoea batatas	3	1	14,097	464,681	5418	4761	156
Triticum aestivum	48	1	183,127	2,973,037	115,887	58,710	1424
Zea mays	85	16	74,430	5,320,607	130,769	104,306	5302
Oryza sativa	105	1	57,069	2,933,812	118,091	120,019	7054
Sorghum bicolor	15	1	46,948	1,365,256	31,267	26,293	5785
Solanum lycopersicum	17	1	57,119	938,027	26,706	25,248	1228
Solanum tuberosum	28	1	73,099	538,023	15,802	15,222	455
Saccharum officinarum	12	9	29,637	534,355	1509	1243	162
Manihot esculenta	9	1	34,354	358,460	8756	26,632	130

occurred in an ancient ancestor of the *Ipomoea* lineage specifically after the divergence with Solanaceae. Enrichment of WGT genes ontologies were suggestive of regulatory functions. For instance, two genes associated with storage root development, sweetpotato knotted-like homeobox genes, *IBKN2* (orthologous to *itf01g32840*) and *IBKN3* (*itf01g32840*), were duplicated in the ancestral *Ipomoea* WGT event (Wu et al. 2018). These genes also had higher expression level in 'Beauregard' storage roots compared with fibrous roots and were upregulated during the development of storage roots suggesting that the WGT contributed to additional gene copies that function in storage root development (Wu et al. 2018). Moreover, the strategy for comparative genomics between plants and distantly related relatives has been used to identify functional genes among different plants species and also helps researchers study genes annotation in newly sequenced plant species.

Access to the data is provided through a genome browser incorporating many specialist interfaces for different data types, and through a variety of additional methods for programmatic access and data mining. Bioinformatics tools used to compare the genome sequences, and the RNAs, proteins, and gene annotations from different organisms, are constantly evolving to deal with the exponential production of sequenced genomes driven by advances in sequencing technology, and therefore becoming more comprehensive and user-friendly.

9.3 Gene Expression Databases

Gene expression data from transcriptome experiments (microarray and RNA-seq datasets) have been archived in public repositories such as NCBI Gene Expression Omnibus (GEO; https://www.ncbi.nlm.nih.gov/geo/) and the EBI ArrayExpress (AE; https://www.ebi.ac.uk/arrayexpress/). Furthermore, the DNA DataBank of Japan (DDBJ) recently started a repository called the Genomic Expression Archive (GEA: https://www.ddbj.nig.ac.jp/gea/). These databases are useful resources for the functional interpretation of genes but have been separately maintained and may lack RNA-seq data, while the original sequence data are available in the Sequence Read Archive (SRA). Millions of RNA sequence sequences have been generated by sweetpotato experiments involving different abiotic and biotic conditions (Lau et al. 2018; Wu et al. 2018; Gemenet et al. 2020a; Arisha et al. 2020b), developmental stages (Gemenet et al. 2020a), and health traits such as β-carotenoid (Wu et al. 2018; Gemenet et al. 2020a), anthocyanin (Xiong et al. 2022), and starch (Qin et al. 2021) which are all available at the NCBI SRA. Several known stress-responsive transcription factors (TFs) in *Arabidopsis* and rice have been used to correctly predict stress-responsive TFs in other plant species, including sweetpotato (Zheng et al. 2016).

9.4 Other "Omics" Databases

Plant proteome research is an exciting and essential frontier of integrative biology. Proteome analysis in different plant systems has been carried out using various tissue

samples such as leaves, root, flower, and fruits, among others. Analysis of the proteome component of an organism offers structural, functional, and network scale insights; however, most existing databases focus on DNA/RNA data or specific gene families, with less emphasis on protein structure, function, and variability. Furthermore, high-throughput mass spectrometric techniques augment understanding of proteins and their expression patterns under various conditions. The Protein DataBase, PPDB, is a whole Plant Proteome DataBase dedicated for *Arabidopsis thaliana* and maize (*Z. mays*). Supplemented with plastid and mitochondrial genomes, protein-encoding gene models in *Arabidopsis*, maize, and rice, as assembled, respectively, in http://www.arabidopsis.org/, http://www.maizesequence.org/index.html, and http://rice.plantbiology.msu.edu/, are uploaded in PPDB and are linked to each other via a BLAST alignment (Sun et al. 2009). Thus, every predicted protein in both species can be searched for experimental and other information (even if not experimentally identified). The PPDB stores experimental data from in-house proteome and mass spectrometry analysis, curated information about protein function, protein properties, and subcellular localization. Importantly, proteins are particularly curated for possible (intra) plastid location and their plastid function. Protein accessions identified in published *Arabidopsis* (and other Brassicacea) proteomics papers are cross-referenced to rapidly determine previous experimental identification by mass spectrometry.

Protein-protein interactions (PPIs) play key roles in diverse biological processes, and therefore it is necessary to understand the interaction details of plant PPIs. Experimentally validated or predicted PPI data have thus become increasingly available in diverse plant species. Protein interaction details can be annotated at various levels by integrating bioinformatics algorithms, and then compiled into user-friendly databases. PlaPPISite (http://zzdlab.com/plappisite/index.php) is a comprehensive, high-coverage, and interaction details-oriented database for 13 plant interactomes (Yang et al. 2020). The source species of interolog templates, GO annotations, subcellular localizations, and gene expression similarities are provided to facilitate the reliability assessment of predicted PPIs.

The Plant Metabolic Network (PMN) constitutes the PlantCyc, a database containing biochemical pathway and their catalytic enzymes, compounds, and genes from various plant species (Hawkins et al. 2021). A greater number of pathway diagrams in PlantCyc were manually extracted from the plant literature but are either supported by experimental evidence or are based on expert hypotheses. Enzymes and genes are experimentally verified and assigned to pathways with evidence codes to provide information about data quality.

The stage for genomics, transcriptomics, and proteomics, coupled with bioinformatics and biostatistics, are gaining momentum. However, they are still, for the most part, assessed individually with distinct approaches generating monothematic rather than integrated knowledge. In addition, despite a fast-growing number of available plant genomes, available computational resources are poorly integrated and provide only limited access to the underlying data. The PlantsDB gives a good example of a platform that is inclusive of integrative and comparative plant genome research (Spannagl et al. 2007). PlantsDB is constituted from genome databases for

Arabidopsis, Medicago, lotus, rice, maize, and tomato, and it might be leveraged to help sweetpotato research in its data integration process.

10 Final Considerations and Prospects

Sweetpotato cultivation and consumption can distinctively be partitioned based on flesh color. In SSA, selective breeding has been conducted over the years for high dry matter (>25%) in varieties that have white, cream, and yellow flesh colors with higher starch content and have mealy firm texture after cooking. The OFSP varieties with high β-carotene level, but low dry matter content (18–25%), are commercially popular in the USA. They are sweet and have a moist texture after cooking. Overall, in comparison with other tuber crops, tropical sweetpotato varieties comprise higher contents of carbohydrates, various minerals, and more protein estimates than other vegetables. The protein content of sweetpotato is low (~2%), but still higher than cassava and plantain, for example.

Efforts to biofortify sweetpotato have focused on increasing β-carotene content and improving organoleptic qualities of commonly consumed varieties. Continuous efforts have been made to improve the nutritional value of landrace sweetpotato varieties through biofortification, leading to improved carotenoid content. These improvements have been successful through the adoption of advanced breeding techniques, which involve the screening of large number of genotypes for nutritional quality, agronomic traits, yield traits etc., in order to select progenies with the best traits for further breeding (Yada et al. 2017; Gemenet et al. 2020a). Replacement of white-fleshed sweetpotato with OFSP varieties has benefited ~50 million children below 6 years of age at risk of vitamin A deficiency (Low et al. 2017). Furthermore, OFSP clones are being selected for other health traits such as Fe and Zn. Several studies have reported a common set of genetic loci controlling β-carotene, Fe, and Zn contents and highly correlated levels providing a basis to improve more than one trait concurrently (Mwanga et al. 2021).

Purple sweetpotato have attractive purple-red color, high anthocyanin content, high total phenol content, and high antioxidant activity (Steed and Truong 2008). The anthocyanin content in purple sweetpotato is similar to those of anthocyanin temperate fruits, such as blueberries, blackberries, cranberries, and grapes. Moreover, purple sweetpotato is a low-cost source of natural anthocyanin pigments. The PFSP anthocyanins contain various chemical structures mainly cyanidins and peonidins in the form of monoacylation and deacetylation. These acylated forms give advantages to heat and light stability as well as antioxidant activity (Mu et al. 2021), which is an advantage as natural pigments in food additives. Besides, the PFSP varieties have high dry matter content even up to 38.96% compared to the OFSP and a negative correlation between anthocyanin level and water content (Steed and Truong 2008).

Marker-assisted breeding allows assessment of young plants at the seedling stage for multiple traits of interest, greatly reducing costs associated with growing the plants to maturity. This approach is especially valuable for sweetpotato, where the expense of

long-term field evaluation is a major limiting factor in breeding efforts. It is not feasible to conduct backcrossing breeding to introgress simple or oligogenic traits. Furthermore, genomic data provide a foundation to elucidate genetic relationships among parental lines and potentially identify new sources of genetic variation associated with environmental tolerance, pest and disease resistance, and other high-value traits. GS may also facilitate the assessment of hardiness, resistance to emerging diseases and insect pests, and changing consumer preferences. Less expensive genome sequencing, innovative methods for the construction of nucleic acid libraries, improved mapping methodologies, and advanced computational approaches make genomics-based breeding an attractive and powerful option for the improvement of sweetpotato.

Although sweetpotato is a globally important crop, investment in genomic resources to unravel its full genetic potential has been inadequate. In real-world plant breeding, it is a major challenge to pyramid polygenic traits and integrate them with the quest of obtaining high yield and end-user preference simultaneously. In order to dissect the mechanism of inheritance, phenotypic assessment needs to be correlated with a large number of molecular markers spread across genomes using linkage maps or high-density SNP markers across the genome. Transgenic and genome editing also show potential in tackling such HR traits (Okwuonu et al. 2022). Changes to the conventional breeding schemes, such as accelerated breeding schemes (Andrade et al. 2017) and participatory breeding (Gibson et al. 2011) can help with the quick turnaround time for both release and adoption of new healthier sweetpotato varieties.

Designing *Dioscorea* Genomes for Improved Nutritional and Pharmaceutical Properties

Ranjana Bhattacharjee

Contents

Abstract

Dioscorea species, commonly known as "Yams," belong to family *Dioscoreaceae* consisting of about 600 species distributed from Africa, Asia, the Caribbean's South America, and the South Pacific islands. The tuber of this genus is well known for their organoleptic properties, making them the most widely used food for carbohydrate, dietary supplements, and famine food. West Africa represents the region where yams are mostly consumed because of their underground and/or aerial tubers representing valuable sources of proteins, fats, and vitamins for millions of people. In addition to their nutritional properties, yams are the potential source of several bioactive compounds used in the treatment of many diseases, thus providing an opportunity for their use in pharmaceutical industries. However, the pharmaceutical properties of these bioactive compounds in yams need to be well researched and validated. Yams are known for the presence of secondary metabolites such as steroid saponin, allantoin, quinones, cyanidins, phenolics, and nitrogen-containing compounds as well as diosgenin representing different

properties including antioxidant, hypoglycemic, hypolipidemic, antimicrobial, inflammatory, antiproliferative, androgenic, estrogenic, and contraceptive properties. This chapter summarizes the available information on nutritional and pharmaceutical properties of yams through published manuscripts and provides recommendations for future research directions for better utilization of yam tubers in human health and nutrition.

Keywords

Dioscorea · Yams · Traditional use · Nutritional properties · Pharmacological properties

1 Introduction

In the times of climate change and concerns about healthy diets across almost all the countries in the world, there is a need to develop sustainable food systems. The issues around food and nutritional security are of paramount importance today, and it has become necessary to diversify the present-day agricultural system as well as the food basket in this context. Root and tuber (RT) crops play a very important role after cereals in providing high calorific and superior carbohydrate contents as an alternate food source. Among these root and tuber crops, yams are well-known for providing both food and medicines to millions of people in the world, specifically in the tropical and subtropical regions in Africa, Asia, Latin America, the Caribbean, and the South Pacific islands. Yams represent the fourth most important root and tuber crop after potatoes, cassava, and sweet potatoes, contributing about 10% of total world's production of RT crops (Viruel et al. 2016) and second in West Africa after cassava (Lev and Shriver 1998). According to FAOSTAT 2021, the world's yam production was 75.14 million tonnes with West Africa, contributing up to 94% of production (71.22 million tonnes). In West Africa, three countries majorly contribute towards yam production, namely, Nigeria with 70.9% (50.4 million tonnes), Ghana with 11.7% (8.3 million tonnes), and Cote d'Ivoire with 11.0% (7.8 million tonnes) (FAOSTAT 2022) (Table 1). Yam production is growing at a rate of 4.07% in the world; however, this increase can be attributed to the increase in the area under yam cultivation (FAOSTAT 2022), as well as its recognition as food, income, and nutritional security crop. Additionally, yams play a very important role in the sociocultural environment of millions of people in West Africa (Obidiegwu and Akpabio 2017).

Yams (*Dioscorea* spp.) belong to the family Dioscoreaceae and subfamily Dioscoreoideae within the order Dioscoreales (Alexander and Coursey 1969), and the genus consists of about 600 species spread globally (Amanze et al. 2011). Majority of these species are known for their food, medicinal, and economic values, and play an important role as famine food or food system of millions of small and marginal rural families and forest-dwelling communities (Ngo Ngwe et al. 2015). The roots, tubers, and rhizomes of yams have been used as food and medicine since

Table 1 Production and area harvested for the first ten countries in the world for yams (FAOSTAT 2022)

Country	Area harvested (million Ha)	Production (million tonnes)
Nigeria	5.9	50.4
Ghana	0.45	8.3
Cote d'Ivoire	1.4	7.8
Benin	0.25	3.2
Togo	0.10	0.89
Cameroon	0.05	0.61
Central African Republic	0.06	0.48
Chad	0.05	0.46
Colombia	0.33	0.41
Papua New Guinea	0.21	0.37
Guinea	0.37	0.03
Africa	8.54	73.5
West Africa	8.2	71.2
World	8.7	75.1

prehistoric times by indigenous people (Singh 1960). Among all *Dioscorea* spp., only ten have been domesticated and are widely cultivated across Africa, Asia, and Latin America for food and income security (Scarcelli et al. 2017). The potential of yam as food can be attributed to its high levels of carbohydrates contributing about 200 dietary calories per person per day, while providing other nutritional components such as proteins, lipids, vitamins, and minerals (Lásztity et al. 1998). In addition, the pharmacological qualities of yams have also been reported due to the presence of bioactive compounds such as flavonoids, phenols, saponins, tannins, and alkaloids (Okwu and Ndu 2006), leading to antioxidant, immunomodulatory, estrogenic, angiotensin I-converting enzyme inhibiting, carbonic anhydrase and trypsin inhibiting, chitinase, anti-insect, anti-dust mite, lectin, and antiproliferative activities (Zhang et al. 2019). These compounds present in yams are believed to treat medicinal conditions such as inflammatory and cardiovascular diseases, aging disorders, menopause, cancers, and osteoporosis. With about 600 cultivated and wild species available in the genus *Dioscorea*, this crop has a great potential to provide starch and energy, as well as additional secondary bioactive compounds for the nutritional and medicinal needs of humans, mainly in rural and marginal areas. The high nutritional and pharmaceutical properties of this genus suggest that there is a need for conservation of all the species; however, currently the international yam collection maintained at the Genetic Resources Center, International Institute of Tropical Agriculture (IITA) represents only eight *Dioscorea* spp. One of the major challenges with conservation of such a large number of species is the widespread nature of this crop across the world and involvement of plant protection as well as exchange of genetic resources across borders. In addition, there is a need for more well-controlled research to validate the food, nutritional, and pharmacological value of different *Dioscorea* spp. spread across the world. This chapter summarizes the information

currently available on nutritional and pharmacological properties of different *Dioscorea* spp. while providing recommendations for research needs to generate appropriate and specific data on the importance of this crop.

2 Phytochemical Properties of Yams

Over the past several years, researchers across the world have evaluated and reported the phytochemical and nutritional qualities of different *Dioscorea* spp. It is obvious that the phytochemical abundance and associated nutritional qualities vary from one species to another and from one variety to another within each species, as well as the environmental conditions and agricultural practices under which the plants grow (Wu et al. 2015; Bekele and Bekele 2018) (Fig. 1). The most commonly available secondary metabolites in yams are saponins, and according to Ou-Yang et al. (2018),

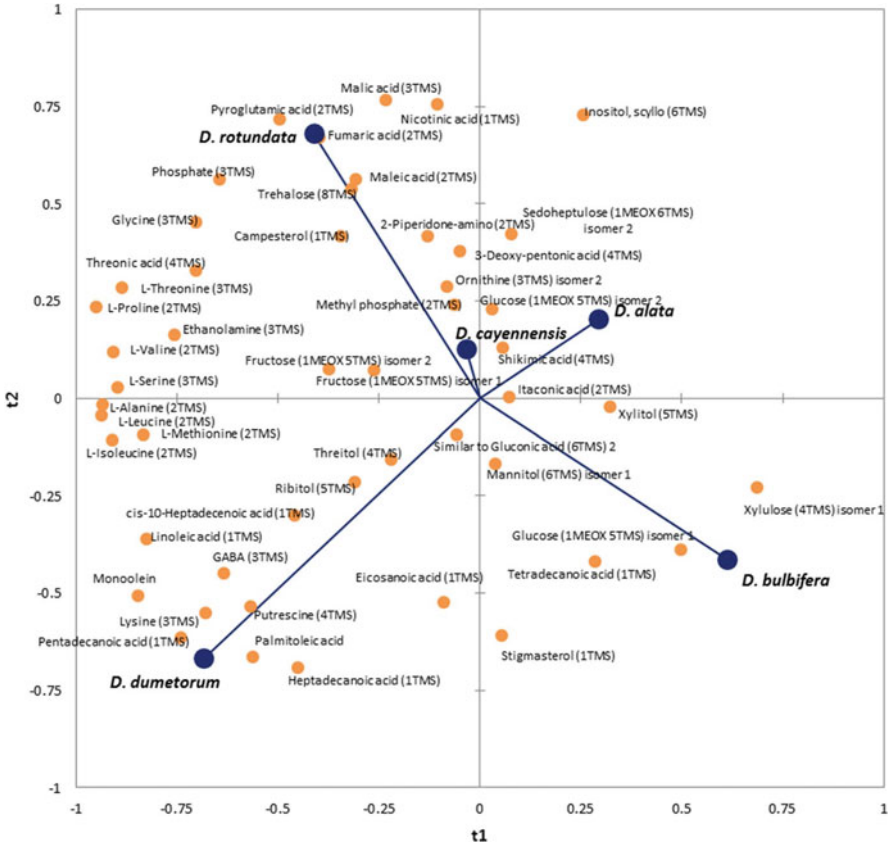

Fig. 1 The list of secondary metabolites present in different cultivated *Dioscorea* species (Price et al. 2017)

more than 100 steroidal saponins (such as stigmastanol, furostanol, spirostanol, cholestanol, ergostanol, and pregnanol glycosides) were isolated from various *Dioscorea* species. Additional compounds such as clerodane diterpenes, phenolics, cyanidins, quinones, diarylheptanoids, and nitrogen-containing compounds were also quantified (Ou-Yang et al. 2018). Similarly, Sautour et al. (2006) revealed over 50 saponins in 13 *Dioscorea* spp. including *D. cayenensis*, *D. bulbifera*, *D. colletti*, *D. futschauensis*, *D. deltoidea*, *D. panthaica*, *D. nipponica*, *D. pseudojaponica*, *D. parviflora*, *D. spongiosa*, *D. polygonoides*, *D. zingiberensis*, and *D. villosa*. Diosgenin (3-β-hydroxy-5-spirostene) is a primary saponin found in several plants, including *Dioscorea* species, and has several medicinal properties, such as hypolipidemic, antioxidant, anti-inflammatory, hypoglycemic, and antiproliferative activities (Jesus et al. 2016). The presence of diosgenin has been reported in several species of yams, making yams as one of the main raw materials in the pharmaceutical industry for production of anti-inflammatory, androgenic, estrogenic, and contraceptive steroidal drugs, used in the prevention/treatment of several diseases (Balandrin et al. 1985).

Although diosgenin has been reported in several yam species, its content varies from one species to another. Among all species, *D. barbasco* (Mexican wild yam) and *D. zingiberensis* (Chinese yam) are reported to consist high quantities of diosgenin (Yi et al. 2014; Kaimal and Kemper 1999), making both China and Mexico as world's highest (67%) diosgenin producers (Xiang et al. 2010). The presence of diosgenin has also been reported in *D. alata* (Jesus et al. 2016).

3 Nutritional Properties of Yams

Yams are considered to represent various dietary nutrients compared to other tuber crops, consisting of essential components such as starch, proteins, lipids, vitamins, minerals, and others (Arinathan et al. 2009; Mohan and Kalidass 2010) (Fig. 2). Among the researched *Dioscorea* spp., *D. alata* was reported to have high starch content (up to 84.3%) (Wanasundera and Ravindran 1994). Similarly, Afoakwa et al. (2013) evaluated the starch composition of seven cultivated yam species (*D. cayenensis*, *D. rotundata*, *D. alata*, *D. bulbifera*, *D. esculenta*, *D. prahensilis*, and *D. dumetorum*) and reported starch quantity ranging between 63.2% and 65.7%. In addition, yams contain dietary fiber which not only plays a vital role in the digestive system but also promotes physiological activities such as reduction in blood sugar and cholesterol levels, trapping of toxic substances, and increasing growth of microbial flora in the gut (Dhingra et al. 2012; Satija and Hu 2012; Slavin 2013; Sánchez-Zapata et al. 2015). Several dietary fibers such as hemicelluloses, cellulose, lignin, and pectins have been reported in yam (Abara et al. 2011; Shajeela et al. 2011).

Protein is one of the major nutritional components required for growth and development. In general, root and tuber crops consist of low proteins in comparison to legumes and cereals; however, among RT crops, yam represents higher dietary protein, although there is a wide variation in the protein content among different yam species (Chandrasekara and Josheph Kumar 2016). The essential amino acids present in yam tubers are phenylalanine and threonine (FAO 2022), while a recent

study on eight *Dioscorea* species reported the presence of aspartic acid and glutamic acid (Doss et al. 2019). Similarly, yams are known to contain essential minerals such as potassium which is higher than other RT crops such as cassava, potatoes, and sweet potatoes as well as cereals (maize, rice, and wheat) (Neela and Fanta 2019). Yams are also good source of other minerals such as calcium (Ezeocha et al. 2014), magnesium (Shajeela et al. 2011), iron (Otegbayo et al. 2018), manganese, zinc, and copper (Soto et al. 2014; Shajeela et al. 2011). There are reports that *Dioscorea* species consists of higher dietary fiber compared to potatoes, cassava, and sweet potatoes (Shanthakumari et al. 2008; Baah et al. 2009). The sugar and starch content of yams are reported to be less than potatoes and cassava (Baah et al. 2009; Afoakwa et al. 2013; Otegbayo et al. 2018), which is related to the presence of high dietary fiber, thus making it a suitable starchy crop for nutrition. Therefore, yams are reported to contribute 12% energy food after cassava (20%) (Otegbayo et al. 2018). The yam tubers are also rich in vitamin C (Udensi et al. 2008) and carotenoid content (Bhattacharjee et al. 2011).

4 Pharmacological Properties of Yams

There are not very many studies that explored the pharmacological properties of yams, although abundant information and traditional knowledge on the medicinal values of yams are prevalent in the tropical countries. Almost all *Dioscorea*

species contains high amounts of secondary metabolites that help in modulating metabolic processes in humans and animals, thus exhibiting beneficial health effects such as anti-oxidative, antihypertensive, anti-inflammatory, and anti-diabetic activities as well as inhibition of receptor activities and triggering enzyme activities (Correia et al. 2012; Price et al. 2017) (Table 2). A wide range of other compounds with medicinal properties as well as anti-nutritional properties are also present in yams such as phenolics, flavonoids, allantoin, dioscin, dioscorin, diosgenin, polyphenols, tannins, oxalate, saponin, and alkaloids have also been reported in yams by various researchers (Padhan et al. 2020; Price et al. 2016; Wadkar et al. 2014; Chiu et al. 2013; Mohan and Kalidass 2010; Shajeela et al. 2011; Kwon et al. 2015).

Saponins are glycosidic compounds with triterpenoid and steroidal properties, of which steroidal saponins are mainly present in different *Dioscorea* spp. (Escobar-Sánchez et al. 2016). Steroidal saponins can be further classified based on biological activities as spirostane, stigmastane, furostane, cholestane, ergostane, and pregnane families (Ali et al. 2013). Predominantly yams contain spirostane steroidal saponin known as diosgenin (Raju and Rao 2012; Cai et al. 2020), a precursor for the synthesis of steroidal drugs such as cortisone (Shah and Lele 2012), estrogen, and progesterone by the pharmaceutical companies (Balandrin et al. 1985; Cheng et al. 2015). In addition, diosgenin is used in the synthesis of hormonal drugs, including sex hormone, prevention of inflammation and malignant transformation, and regulation of T-cell immune responses as anticancer, neuro- and cardiovascular, as well as skin protection (Escobar-Sánchez et al. 2016; Raju and Rao 2012; Chen et al. 2015; Jesus et al. 2016; Tada et al. 2009). About 15 Dioscorea species are used as source of diosgenin with an estimated market value of USD 500 million (Price et al. 2017). However, its content varies considerably among different species and within each species, which may be attributed to the environmental conditions such as cultivation methods and storage conditions (Huai et al. 1989). In addition to diosgenin, several other steroidal saponins with pharmacological properties such as cytotoxic and antifungal properties have been reported in many *Dioscorea* species (Sautour et al. 2006).

Additionally, yams contain other bioactive compounds such as water-soluble polysaccharides and dioscorin (Myoda et al. 2006; Harijono et al. 2013). Dioscorin is the main storage protein of yam tubers classified as dioscorin A and dioscorin B that accounts for 90% of extractable water-soluble proteins (Hou et al. 2000; Conlan et al. 1995; Rachman 2011). Dioscorin acts as trypsin inhibitor, carbonic anhydrase, and antioxidant (Hou et al. 2001; Liu et al. 2007), and inhibits the activities of angiotensin-converting enzymes, thus controlling hypertension (Hsu et al. 2002) and activation of innate and adaptive immune system (Fu et al. 2006). There is also presence of alkaloids in yams, which are utilized in the pharmaceutical industry for their therapeutic activities including antimicrobial, antihypertensive, anticancer, anti-inflammatory, and several others. However, alkaloids also contribute to unwanted qualities such as bitterness and toxic substances causing nausea, dizziness, vomiting, and even trigger fatal paralysis (Banaag et al. 1997). In yams, the major alkaloid is dioscorine, a toxic molecule related to bitter taste and production of poisons (Broadbent and Schnieden 1958).

Table 2 Medicinal or pharmacological properties of few *Dioscorea* species (Obidiegwu et al. 2020)

Species name	Plant extract	Medicinal properties
D. alata	Tuber/bulb	Cure piles, gonorrhea, and leprosy; anti-inflammatory, purgative, diuretic, and antirheumatic properties; prevent cancer, reduce blood sugar, and diabetes
	Tuber	Antihelminthic properties
	Leaf	Fever
D. bartletti	Rhizome	Stagnation of blood and anemia
D. belophylla	Tuber	Treatment of fever, dysentery, headache, and malaria
D. bulbifera	Tuber	Treatment of dementia; treatment of diabetes, leprosy, tumors, microbial infections, and pig cysticercosis; antispasmodic, analgesic, aphrodisiac, diuretic, and rejuvenative tonic; effects on liver and heart; reduces carbuncles, lung abscesses, breast lumps, goiter, and abdominal pain; and oral contraceptive
	Raw tuber	Consumed as an appetizer, rheumatism, and aphrodisiac
	Aerial bulb	Oxidative stress-induced pathological disorders
D. belophylla	Tuber	Lowers blood cholesterol and reduces heart attack
D. cayenensis	Tuber	Antidiarrheal
D. collettii	Rhizome	Cervical carcinoma, urinary bladder carcinoma, and renal tumor
D. deltoidea	Tuber	Digestive disorders, sore throat, diarrhea, abdominal pains, wounds, burns, anemia, antirheumatic and treatment of ophthalmic conditions, birth control, and oral contraceptive
D. dumetorum	Tuber	Treatment of diabetes; control hyperlipidemia, hypercholesterolemia, and hyperketonemia; jaundice treatment
D. esculenta	Tuber	Inflammations, nervous disorders, respiratory infections, dysentery, and pain relief
D. hamiltonii	Tuber	Stomach ache and appetizer; management of diarrhea
D. hirtiflora	Tuber	Gonorrhea treatment
D. hispida	Leaf/root/ tuber	Treatment of mole, insect bites, and insomnia
	Tuber	Treatment of vomiting, indigestion, and serves as a purgative when consumed fresh; treatment of wounds and injuries; and ophthalmic ointment
D. japonica	Rhizome	Diarrhea and dysentery due to spleen deficiency, fatigue, wasting and thirsting, seminal emission, vaginal discharge and frequent urination, inflammation, asthma, rheumatoid arthritis, coughing, and wheezing
D. membranacea	Rhizome	Cancer
D. nipponica	Rhizome	Dissipation of lumps and goiter, clears heat, relieves toxicity, cools the blood, stops bleeding and coughing, calms sneezing, poisonous snake bites, bleeding due to blood heat and whooping cough, antirheumatic, analgesic, aids blood circulation, anti-diuretic, and aids digestion

(continued)

Table 2 (continued)

Species name	Plant extract	Medicinal properties
D. oppositifolia	Rhizomes/ tuber	Relief of menopausal syndromes and rejuvenation of early mothers
D. panthaica	Rhizome	Gastric diseases, bone injuries, rheumatic arthritis, and cardiovascular diseases
D. pentaphylla	Leaf/vine	Treatment of paralysis
	Tuber/flower/ young shoot	Rheumatism
	Tuber	Pain relief and reduce swelling, stomach disorders
D. polystachya	Rhizome	Consumptive cough and dysentery, aid for digestion and gastric motility, and for restraining nocturnal emissions
D. septemloba	Rhizome	Rheumatism, urethra, and renal infection
D. sylvatica	Tuber	Decoction used to treat cuts, wounds, and sores
D. trinervia	Tuber	Chronic diarrhea, asthma, and diabetes
D. villosa	Rhizome	Rheumatism, menstrual complaints, and perimenopausal symptoms
D. zingiberensis	Rhizome	Cough, anthrax, rheumatic heart disease, rheum, arthritis, tumefaction, and sprain

Water-soluble polysaccharides from yams are reported to reduce blood glucose (Fan et al. 2015) and cholesterol levels especially the LDL cholesterol (Harijono et al. 2013) while improving the immune system. The presence of flavonoids has also been reported in several species of yams (Padhan et al. 2020), which is known to exhibit antioxidant, antidiabetic, anti-inflammatory, antimicrobial, antidepressant, and antihypertensive properties (Sangeetha et al. 2016). The presence of active constituents in yams such as allantoin and dioscin is responsible for α-amylase and α-glucosidase activity providing antidiabetic, antioxidant, and anti-dyslipidemic properties (Niu et al. 2010). The presence of tannins in yams gives the bitter taste and is reported to treat diseases such as leukorrhea, rhinorrhea, healing of wound, and diarrhea (Eleazu et al. 2013).

In addition to medicinal properties, yam starch is being used extensively by the pharmaceutical industry for tablet and capsule formulation as well as thickening agent compared to potato starch (Zuluaga et al. 2007). Yam starch is also used as a binder in tablet formulations that contain both soluble and insoluble organic substances (Nasipuri 1979).

5 Anti-nutritional Properties of Yams

The presence of anti-nutritional factors influences the bioavailability of dietary nutrients such as proteins, minerals, and vitamins. Yam tubers are acrid in nature representing several anti-nutritional properties associated with skin irritation and inflammation of throat after consumption (Kumar et al. 2017). The presence of some bioactive compounds such as phenolic acids (Zhao et al. 2019), tannins, phytates,

and oxalates have been reported in different species of yams, which are referred to as anti-nutritional because of their toxic properties and bitterness associated with them (Poornima and Ravishankar Rai 2009). Similarly, the presence of trypsin inhibitors in yams (wild yam tubers have higher content than cultivated yams) inhibits the enzymatic activities of trypsin and chymotrypsin in the digestive tract, thus impairing protein digestion (Bhandari and Kawabata 2006; Padhan et al. 2020). Yams are identified as possible source of phenols and phenolic acids which are responsible for browning of tuber flesh when exposed to air. The presence of phenol and phenolic acids can decrease the digestibility of proteins, carbohydrates, and minerals (Padhan et al. 2018). Similarly, yam tubers are known to contain higher amount of phytates compared to other tuber crops which has a negative impact on the bioavailability of dietary minerals such as zinc, iron, calcium, copper, and magnesium (Polycarp et al. 2012; Padhan et al. 2018). Additionally, phytates also form insoluble complexes with other food components such as proteins, lipids, and carbohydrates, and inhibits the utilization of these nutrients (Kumar et al. 2010; Singh and Krikorian 1982). The presence of oxalates as insoluble calcium oxalate or soluble oxalate or combination of both have been reported in yams (Otegbayo et al. 2018), which may bind to minerals especially calcium, magnesium, and iron, resulting in their unavailability. Other effects could be linked with yam mucilage containing calcium oxalate that can cause severe skin irritation and throat inflammation (Noonan et al. 1999). It is reported that most of the anti-nutritional properties of yams are removed through washing, boiling, and processing (Otegbayo et al. 2018; Akin-Idowu et al. 2008).

6 Application of Multi-omics Tools for Nutritional and Pharmacological Properties of Yams

The genus *Dioscorea* with 600 species and several varieties within each species (at least for 10 cultivated species) provides a wide genetic diversity along with indigenous knowledge to explore the possibilities of application of modern omics tools for its improvement. Modern genomics tools, such as molecular markers linked to genes controlling traits such as nutritional traits, offer a golden opportunity to improve yam production (Mignouna et al. 2003) and application of in vitro micropropagation (Borges et al. 2004; Mantell et al. 1978; Ondo Ovono et al. 2007) and cleaning of viral disease (Wang et al. 2008; Ita et al. 2020), genetic transformation (Nyaboga et al. 2014), developing low cost, high throughput, scalable disease diagnostic tools (Filloux et al. 2018), and use of gene editing for trait improvement. However, the information on application of different omics technologies, including genomics, proteomics, etc., for yam improvement is limited (Sharma and Deswal 2016). Additionally, the yam breeding programs globally only target few cultivated *Dioscorea* species, mainly focusing on two species such as *D. rotundata* and *D. alata*. These programs target majorly traits, including tuber yield, resistance/tolerance to diseases, and quality-related traits, which may vary from one country to another (Mignouna et al. 2007). However, over the years, additional tuber

characteristics targeted to consumer preferences (tuber size and shape), higher dry matter, tuber flesh color, tuber flesh oxidation, and starch properties are being routinely measured for wider acceptance of newly developed varieties (De Koeyer et al. 2017; Darkwa et al. 2020). Some high-level traits requiring robust phenotyping such as resistance genes to viruses, anthracnose and nematodes, shrub-like or dwarf plant architecture, tuber bulking, tolerance to drought and heat, long shelf life of fresh tubers or processed food products, and culinary attributes suited to consumer needs for fresh and processed yam are not currently included in the breeding programs for developing new varieties.

Recently, there has been some progress on application of advanced molecular or omics tools to several species of *Dioscorea*. Currently based on short-reads, long-reads, and chromosome conformation sequencing, good-quality reference genomes have been released for four Dioscorea species such as *D. rotundata* (Tamiru et al. 2017), *D. alata* (Bredeson et al. 2022), *D. dumetorum* (Siadjeu et al. 2020), and *D. zingiberensis* (Cheng et al. 2021). This has enabled to develop high-quality linkage maps and identification of quantitative trait loci (QTLs) for several agronomic and quality traits such as sex determination systems (Tamiru et al. 2017; Cormier et al. 2019; Sugihara et al. 2020), anthracnose disease, tuber oxidative browning, tuber starch content (Bredeson et al. 2022), and postharvest hardening (Siadjeu et al. 2020). Similarly, Nakayasu et al. (2015) have performed comparative transcriptome analysis of high saponin-containing yams such as *D. esculenta* and *D. cayenensis*, and a low saponin-containing species, *D. alata*, to understand the biosynthesis of steroidal saponins. They identified the β-glucosidase (DeF26G1) gene for higher accumulation of saponins in *D. esculenta*. Wu et al. (2015) carried out transcriptome analysis of *D. alata* tubers (purple-flesh and white-flesh variety) and identified a total of 125,123 unigenes from cDNA libraries, out of which 61 unigenes encoded for various well-known enzymes in the flavonoid biosynthesis pathway. These genes were flavanone 3-hydroxylase (F3H), chalcone isomerase (CHS), dihydroflavonol 4-reductase (DFR), leucoanthocyanidin dioxygenase (LDOX), flavonoid 3′-monooxygenase (F3′H), and flavonol 3-O-glucosyl-transferase (UF3GT), which were more abundant in the purple-flesh variety than white flesh variety. The first report of genome-wide characterization was reported in *D. zingiberensis* by Zhou et al. (2018) and identified 4935 genes, 81 tRNAs, 661 miRNAs, and 69 rRNAs from them. Price et al. (2016) revealed 151 secondary metabolites from the polar extracts of the leaves of 19 *Dioscorea* species, including cultivated and wild species, using gas chromatography-mass spectrometry. This study provided insights about the presence of essential compounds such as shikimic acid (precursor utilized in the manufacture of the antiviral drug oseltamivir) in some species. Similarly, Price et al. (2017) carried out metabolite profiling of 49 accessions across 5 cultivated *Dioscorea* spp. (*D. alata*, *D. bulbifera*, *D. cayenensis*, *D. dumetorum*, and *D. rotundata*) and revealed about 200 bioactive compounds which can be used for chemo-typing of yams and integration with other omics studies for yam improvement. Again, Price et al. (2018) investigated the carotenoid profiling of the above accessions to determine the β-carotene content and provitamin A activity across species. This study clearly elucidated the lack of correlation

between yellow tuber flesh color and provitamin A content in yam as opposed to other crops like cassava. This study also profiled other isoprenoids, such as tocopherols and quinones as well as identified elite genotypes with high provitamin A content, and tentatively identified C25-epoxy-apocarotenoid persicaxanthin, which may influence tuber dormancy. Lebot et al. (2019) used high-performance thin-layer chromatography (HP-TLC) method for rapid quantification of individual sugars, allantoin, phenolic acids, catechins, and saponins in yam tuber flours. This technique was further used for rapid quantification of compounds related to tuber flour quality of eight *Dioscorea* species.

7 Genetic Engineering and Gene Editing in Yams

Genetic engineering and gene editing have emerged as important methodologies to improve crops including yam. The use of conventional breeding for improvement of several traits in yams is difficult, and application of transgenic methods provides an alternative and complimentary tool. Quain et al. (2011) developed a transient transformation for *D. rotundata* using agrobacterium, but this did not yield any transgenic plants. *Agrobacterium*-mediated gene delivery system is the most preferred method due to its ease of accessibility and ability to transfer low copies of DNA fragments carrying the desirable genes at higher efficiencies with minimal cost (Gelvin 2003; Shibata and Liu 2000). Nyaboga et al. (2014) developed an efficient and reproducible protocol for *Agrobacterium*-mediated transformation of *D. rotundata* which generated stable transgenic plants. This laid the foundation for successful implementation of genetic engineering and gene editing in yams, and the Genome-Enabled Platforms for Yam Project was launched in 2016 in collaboration between scientists at IITA and Iowa State University (https://www.nsf.gov/awardsearch/showA ward?AWD_ID = 1,543,888). Additionally, a genome-editing tool for yam using phytoene desaturase (a key enzyme in the β-carotene biosynthesis pathway, which converts the colorless phytoene to colored carotenoids) as a marker has been developed (Tripathi 2018; Syombua et al. 2021). Similarly, Feng et al. (2018) successfully applied clustered regularly interspaced short palindromic repeats/CRISPR-associated protein 9 (CRISPR/Cas9)-mediated targeted mutagenesis in *D. zingiberensis* using *Agrobacterium*-mediated transformation and aimed at the farnesyl pyrophosphate synthase gene (*Dzfps*) (an essential gene involved in the synthesis of secondary metabolites). They detected five types of mutations among the transformed plants and discovered that the transcript levels of *Dzfps* and the content of squalene in isolated mutants were drastically decreased. They concluded that CRISPR/Cas9 provided a rapid and efficient approach for targeted genome modification in *D. zingiberensis* which can be adopted to other *Dioscorea* species with slight modifications. The browning in yams due to the presence of polyphenol oxidase (PPO) is responsible for changes in the flavor, texture, and color, thus reducing the commercial value (Jia et al. 2015). The CRISPR/Cas system can be applied to generate heritable and stable mutations on the yam *PPO* loci without affecting other crop attributes. This technology for nutrition improvement has been

already proven through knockout of *PPO* gene in potatoes, mushrooms, and apples (Halterman et al. 2016; Nishitani et al. 2016; Waltz 2016) to create non-browning varieties. Similarly, raw yellow yam naturally has significantly low levels of beta carotene and thiamine compared to yellow cassava (Adepoju et al. 2018; Price et al. 2018), and the CRISPR/Cas approach could be applied to improve the nutritional potential of yam by redirecting the biosynthetic pathways to generate higher quantities of beneficial compounds and less anti-nutritional compounds (Sabzehzari et al. 2020). Lycopene cyclization during carotenoid biosynthesis involves two genes: *lycopene epsilon-cyclase* (*LCYE*) gene, which diverts the pathway towards biosynthesis of ε-carotenoids, and lycopene beta cyclase (LCYB), which catalyzes the formation of β-rings (Richaud et al. 2018). Thus, mutations on the yam *LCYE* gene could accumulate the flux of biosynthetic precursors towards the β branch and hence increase the β-carotene contents. Carotenoid biosynthetic pathway of banana has been manipulated by Kaur et al. (2020) using CRISPR/Cas9 to knock out the *LCYE* gene and obtained up to sixfold increase in the β-carotene contents. The thiamine content of yam could also be enhanced by CRISPR/Cas-based overexpression of the genes involved in the biosynthetic pathway, primarily *thi1*, *thi4*, and *thiC*. This has been already tested in Arabidopsis that led to simultaneous overexpression of *thi1*/*thi4* and *thiC* in the seed and leaf thiamine contents (Dong et al. 2015). Genome editing protocol can therefore be successfully incorporated in the yam breeding programs for targeted traits such as resistance to yam mosaic virus and anthracnose diseases, herbicide tolerance, and nematode resistance as well as quality traits in consultation with the breeders. It is, however, necessary to consider the ethical and regulatory implications related to genetically modified and gene-edited crops. The major challenge with CRISPR/Cas9 technology is that it may recognize sequences with up to five mismatched bases suggesting high rates of off-target effects (Roy et al. 2018). Some approaches such as DNA-RNA chimeric guides, Cpf1, a single RNA endonuclease that employs a T-rich PAM on the 5′ side of the guide, and specific point mutations have been developed to mitigate this limitation (Kleinstiver et al. 2016; Zetsche et al. 2016).

8 Conclusions and Recommendations

All the species (cultivated as well as wild) of *Dioscorea* genus make a significant contribution as a tuber crop to the diets of more than 300 million people living in the tropical countries. They are considered as an important source of energy food during famine. Despite their importance as a food source, yams contain several bioactive compounds including diosgenin which is useful for the treatment of various ailments and disorders as well as production of steroidal drugs. However, many of the pharmacological potential of yams needs to be validated through detailed investigations of about 600 cultivated and wild *Dioscorea* species occurring around the world. This will require a multidisciplinary and holistic approach including the involvement of indigenous natives who knows the properties of such a wide diversity of *Dioscorea* species, health specialists, and pharmacological experts

followed by conservation and sustainable use of the species diversity. Although several medicinal properties of yams such as hypolipidemic, hypoglycemic, antioxidant, anti-inflammatory, antimicrobial, antiproliferative, androgenic, estrogenic, and contraceptive have been reported, majority of these active constituents, however, have not been characterized. Similarly, the properties of all the secondary metabolites (alkaloids, saponin, flavonoids, tannins, and phenols) from different *Dioscorea* should be validated through standardized procedures to define the actual biological potentials of each species. It is essential to include clinical trials to understand the pharmacological properties of yams including the bioavailability of different bioactive compounds. Overall, this chapter suggests that the species of *Dioscorea* genus cannot be ignored and should be prioritized as a good alternative source of bioactive compounds that can prevent or alleviate both functional and infectious disease burden on pharmaceutical industries, which is a big challenge in developing countries. The lack of enough information on clinical trials with safety, toxicity, and efficacy on the use of yams in human health is a gap, and this will require concerted efforts among the researchers and donors to recognize yams as a valuable crop in the international market for its food, nutritional, medicinal, and pharmacological properties.

Although transgenics and modern genomic technologies have been applied in the last decade to complement classical breeding efforts in improving most crops, including vegetatively propagated crops, such research efforts, however, have been limited in yams. This slow progress can be attributed to the limitation of resources for yam research, lack of good genomic information, and genetic resources for yam. The recent sequencing of various yam genomes coupled with modern breeding tools offers unprecedented opportunities to accelerate yam biology research for accelerated genomics-assisted breeding. The genome editing technologies, in particular, offer possibilities for improving the yam nutritional composition, enhancing tolerance to abiotic stresses, and metabolic engineering of products applicable to pharmaceutical, biofuel, and agricultural industries. Majority of the traits in yams are controlled by minor genes with cumulative effect, and conventional QTL mapping and genome-wide association studies (GWAS) proves laborious and may not be validated. Therefore, the CRISPR/Cas technology coupled with the recent reference sequencing information of different *Dioscorea* species and pedigree analysis could facilitate rapid and efficient genetic characterization in yam.

Yams represent several inherent biological constraints, making it very arduous and lengthy endeavor for application of modern technologies, and significant milestones have been achieved in its improvement recently. A wide array of genomic resources, including markers for genetic studies, techniques for ploidy determination, and QTLs for several traits are currently available. Prospect for discovering additional molecular markers linked to genes and QTLs of additional target traits including nutritional and medicinal relevance, and applying marker-assisted selection in yam breeding is high due to reduction in sequencing cost and availability of reference genomes of four *Dioscorea* species. Recent advances and application of different "omics" tools such as genomics, transcriptomics, metabolomics, and phenomics will substantially increase the identification of functional gene (s) affecting important traits.
