Acknowledgement

Special Acknowledgement to
Phullara Kole
For her outstanding assistance in editing this compendium

Preface

The crop plants cater not only to our basic F5 (food, feed, fiber, fuel, and furniture) needs but also provide a number of nutraceuticals with potential nutritional, safety, and therapeutic attributes. Many crop plants provide an array of minerals, for example, Ca, Mg, K, Na, P, Cr, Cu, Fe, Mn, Mo, Ni, Se, and Zn; vitamins, for example, A, B-series, C, E and K; and antioxidant-rich bioactive phytochemicals, including Carotenoids, Phytosterols, Limonoids, Polyphenols, Glucosinolates, phytoestrogen, Terpenoids, Fibers, Polysachharides, and Saponins. Increasing incidences of chronic diseases such as cancer, diabetes and HIV, and malnutrition necessitate global attention to health and nutrition security with equal emphasis on food security. Stupendous amount of researches on biochemical, physiological, and genetic mechanisms underlying the biosynthesis of the health and nutrition related nutraceuticals and precise breeding strategies for augmentation of their content and amelioration of their quality in crop plants are underway all over the world under all commodity categories of crops including cereals and millets, oilseeds, grain legumes, fruits and nuts, and vegetables. This major review work entitled, "Compendium of Crop Genome Designing for Nutraceuticals," comprises five sections dedicated to these five commodity groups and presents enumeration on the concepts, strategies, tools, and techniques of nutraceutomics. These sections include 50 chapters devoted to even number of major crop plants. These chapters present deliberations on the biochemistry and medicinal properties of the nutraceuticals contained; genetic variation of their contents; classical genetics of and breeding for their quantitative and qualitative improvement; tissue culture and genetic engineering for augmentation of productivity and quality; and sources of genes underlying their biosynthesis. They also include comprehensive enumeration on genetic mapping of the genes and QTLs controlling the contents and profile of the nutraceuticals and molecular breeding for their further improvement through marker assisted selection and backcross breeding tools. Prospects of post-genomic precise and targeted breeding strategies including genome-wide association mapping, genomic selection, allele mining and genome editing are also discussed. This compendium would fill the gap in academia, and research and development wings of the private sector industries and will also facilitate understanding of the policy making agencies and people in the socio-economic domain, and benefit students, teachers, scientists, policy makers and sponsoring agencies involved in an array of subjects relevant to

crop sciences, specifically genetics, genomics, tissue culture, genetic engineering, molecular breeding, genomics-assisted breeding, gene editing, bioinformatics, biochemistry, physiology, pathology, entomology, pharmacognosy, and IPR.

I express my thanks to the authors of the chapters of this compendium for their useful contributions and sincere cooperation. I am also grateful to the staff of the publisher for their assistance since inception till completion of editing this compendium.

About the Editor

Prof. Chittaranjan Kole is an internationally renowned academician with a spectacular professional career of about 40 years!. His pioneering scientific contributions, specifically in the fields of plant genomics and biotechnology, have been globally appreciated. Prof. Kole has developed a number of original concepts and strategies, which have contributed enormously to science and benefited the national as well as global society. His scholarly publications include 150-plus research articles and over 180 books with globally-reputed publishers. Prof. Kole's academic contributions have been profusely appreciated by seven Nobel Laureates including Profs. Norman E. Borlaug, Arthur Kornberg, Werner Arber, Phillip A. Sharp, Günter Blobel, Leland H. Hartwell, and Roger D. Kornberg. His scientific achievements have been honored with several awards, fellowships and recognitions including the "Outstanding Crop Scientist Award" conferred by the International Crop Science Society in recognition of his "life-time and original contributions in the field of crop science."

Prof. Kole worked as a researcher, faculty member and administrator in a large number of premier institutions and universities in India and abroad. In India, he worked across all academic positions from an Assistant Professor to Vice Chancellor in three premier universities including Orissa University of Agriculture and Technology, Sam Higginbottom University of Agriculture, Technology and Sciences, and Bidhan Chandra Krishi Viswavidyalaya. He also worked in Indo-Russian Center for Biotechnology as its First

Project Coordinator. In abroad, he worked in the USSR Academy of Sciences, erstwhile USSR, as a Post-Doctorate Scholar; University of Wisconsin, USA as an Overseas Research Associate; The Pennsylvania State University, USA, and Clemson University, USA, as a Visiting Professor; and Institute of Nutraceutical Research at Clemson University as Director of Research.

Prof. Kole is recognized as a visionary science leader in the global arena. He is the Founding President of three international organizations including the Genome India International, International Climate Resilient Crop Genomics Consortium, and International Phytomedomics and Nutriomics Consortium. In recognition of his international leadership quality, the Food and Agriculture Organization invited Prof. Kole to act as the Leader of the Climate Change theme for the FAO International Symposium on "The Role of Agricultural Biotechnologies in Sustainable Food Systems and Nutrition" in 2016. He organized and chaired many prestigious international workshops, chaired several technical sessions; and delivered innumerable invited plenary lectures and keynote addresses in many international scientific meetings.

Prof. M. S. Swaminathan, World Food Prize Laureate, once wrote to Prof. Kole that "You are a role model for all of us." while Nobel Laureate in Chemistry Prof. Roger D. Kornberg wrote to the Honorable Prime Minister of India about Prof. Kole that "your country will be increasingly benefitted by utilizing his comprehensive knowledge and visionary ideas on science, education and agriculture." Above all, Nobel Laureate in Peace, Dr. Norman E. Borlaug, the Father of Green Revolution, wrote to Prof. Kole that "May all Ph.D.s, future scientists and students that are devoted to agriculture get an inspiration as it refers to your work."

Abstract

Rice is a staple food for more than half of the world's population and is grown in more than 100 countries in varied water regimes and ecological systems. In recent years, the perspective of rice has changed from staple food to its potential to be used as a functional food. Industrialization brought changes in lifestyle, leading to the consumption of milled rice, leaving aside the rice bran. Brown rice is a good source of energy, fats, vitamins, and minerals, and the colored rice grains have higher mineral content, antioxidants, and bioactive compounds; the polished rice is a poor source of nutrients. Challenges like climate change with elevated CO_2, and drought and heat stress are also reducing the nutritional quality of rice. Enhancing the nutritive value of rice grain and promoting as a nutraceutical functional food could address nutrition security. Breeding interventions and the application of next-generation technologies can hasten the development of nutritive rice varieties with desired levels of the mineral, vitamin, and bioactive compounds and glycemic index. Landraces and wild species are the potential genetic donors aiding in the generation of the breeding material with the increased functionality of rice grain. The availability of enormous rice germplasm gives scope to identify new nutraceuticals and develop nutraceutical-rich varieties. Genomic regions and genes associated with nutritive function in grain are being identified by deploying sequencing, resequencing, genome-wide association, and biparental mapping. CRISPR-based genome editing appears to be the most potent tools for developing rice varieties with high grain nutrient levels.

1 Introduction

1.1 Rice: A Staple Food Across the World

Rice is a major cereal crop and a staple food for half of the world's population (Fukagawa and Ziska 2019). Globally, rice is cultivated in more than 100 countries, spanning an area of approximately 163 million hectares (FAO 2021). Rice has two cultivated species, *Oryza sativa,* which is predominant worldwide, and *Oryza*

glaberrima, limited to a few parts of Western Africa (Khush 1997). Within *O. sativa*, two major subspecies have been identified: *indica*, cultivated in tropical Asia, and *japonica*, primarily found in Southern China, South East Asia, Indonesia, and outside Asia (Londo et al. 2006). Later, five distinct groups were made in *O. sativa* corresponding to *indica*, *aus*, *aromatic*, temperate *japonica,* and tropical *japonica* (Garris et al. 2005).

Rice is cultivated worldwide in varied water regimes, ecology systems, and soil types. Nearly three-quarters world's rice is produced from irrigated lowland systems with two to three crops per year (De Datta 1981). Around 20% of global rice production is from the rainfed lowland system, which is predominant in Southeast Asia and Africa. The upland condition accounts for approximately 4% of the world's rice production. Deepwater, semi-deep water, and floating kinds of rice are cultivated in specific geographical regions in some South Asian countries (Khush 1987).

Worldwide paddy production was around 0.8 billion tons in 2019, with an 8% contribution to global crop production (FAO 2021). China, India, and Indonesia are major rice-producing countries, accounting for 50% of rice production (www.fao.org). Other Asian countries like Bangladesh, Vietnam, Myanmar, Thailand, the Philippines, Japan, Pakistan, Cambodia, the Republic of Korea, Nepal, and Sri Lanka contribute to the remaining world's total rice production. Brazil, the United States, Egypt, Madagascar, and Nigeria produce around 5% of global rice production (Muthayya et al. 2014).

Nearly 490 million tons were reported to be global rice consumption in 2019. Daily rice consumption is also the highest in Bangladesh, the Lao People's Democratic Republic, Cambodia, Vietnam, Myanmar, Thailand, Indonesia, and the Philippines among the Asian countries. Significant rice consumption is also indicated in South America, Latin America, the Caribbean, and Oceania, with China and India accounting for ~50% of the world's rice consumption. Interestingly, only 60% of the consumption in Africa is covered by local rice production, with the remaining rice being imported (www.africarice.org). Rice is reported to be the source of 20% of the world's dietary energy, supplying more than 70% of calories in some Asian countries (GRiSP 2013).

Rice production has significantly increased, more than doubling after the advent of the Green Revolution from yield levels of less than 2 t/ha during the 1950s. The development and broad adoption of semi-dwarf rice varieties responsive to increased inputs of fertilizers, irrigation, pesticides, and other resources considerably enhanced rice yield (Dalrymple 1986; Hedden 2003). Rice production was reported to be increased by 130% between the 1960s and 2000s (Muthayya et al. 2014). The next level of yield enhancement was made possible with the exploitation of heterosis by developing hybrid rice during the 1970s in China and other countries (Cheng et al. 2007a).

1.2 Growing Importance of Rice in the Face of Chronic Diseases and Malnutrition

Rice is the staple diet of more than 3.5 billion people (Xu et al. 2021a), mainly in Asian and African countries populated by people with poor purchasing power and access to nutritious food. The world's population is projected to be 8.5 billion in

2030, 9.7 billion in 2050, and 10.9 billion in 2100 (United Nations Department of Economic and Social Affairs 2019). Most of the population growth is expected in Southern Asia and Africa, which are already excessively dependent on rice. Thus, rice has become a crucial commodity in global food security, and around a 70% increase in food production is needed to meet the food demand in 2050 (FAO 2017). The anticipated increase in rice production could be possible from India, China, Vietnam, and Thailand as per projections by the OECD-FAO Agricultural Outlook, global rice production (OECD-FAO 2021).

In addition to being targeted for the enhancement of its production for the future, rice is also being aimed for its nutraceutical quality improvement. People who subsist on polished rice are vulnerable to vitamin and mineral deficiencies. Increasing the nutritive value of rice grain can address nutrition security and food security, especially in countries where rice is the major source of calories/energy. More than 32% of women worldwide and 36.6% in Asia are reportedly anemic (FAO 2019; https://globalnutritionreport.org/reports/global-nutrition-report-2018/). The Global Nutrient Database of availability of macro- and micronutrients in 195 countries from 1980 to 2013 revealed higher consumption of carbohydrates in South Asia against the world's consumption. It has also reported the poor availability of macro- and micronutrients per day per person in South Asia, viz., 47 g fat (world: 72 g), 56 g protein (world: 71 g), 362 μg vitamin A (world: 705 μg), 19 g iron (Fe) (world: 18 mg), and 8 mg zinc (Zn) (world: 10 mg) (https://nutrition.healthdata.org/global-nutrient-database). Half of the world's malnourished children reside in three countries of South Asia, viz., Bangladesh, India, and Pakistan (World Bank 2009). Concerning the Global Nutrient Database, the values of availability of energy (2500 to <2500 kcal), saturated fat (150 to <250 kcal), and protein (200 < 250 kcal) were much lesser in most of the Asian countries than the recommended levels (Schmidhuber et al. 2018). The Comprehensive National Nutritional Survey (CNNS) of India was conducted during 2016–2018 on 38,060 preschool children (aged 0–4 years), 38,355 school-age children (aged 5–9 years), and 35,830 adolescents (aged 10–19 years). It revealed that in children aged 0–4 years 35% were stunted and 17% wasted; in 5- to 9-year-olds, 22% were stunted and 6% were severely stunted, and 35% were underweight, with 10% severely underweight. Nearly one-quarter of children aged 5–9 years (23%) and adolescents aged 10–19 years (24%) were underweight. Anemia was most severe (>50%) among the children (<2 years), 41% of preschoolers, 24% of school-age children, and 28% of adolescents. A higher incidence of anemia was observed in female adolescents (40%) compared to boys (18%). Prevalence of Fe deficiency was also seen in preschoolers (32%), female adolescents (31%), school-age children (17%), and male adolescents (12%). Nearly 17–19% of children and 32% of adolescents were Zn deficient. Among vitamins, deficiency of vitamin A was ~16–22%, vitamin D was 14–24%, vitamin B_{12} was 14–17% in children and 31% in adolescents, and deficiency of folate was also seen in 23–28% among children and 37% of adolescents.

The enhanced rice yield levels are also vulnerable to the significant decline in grain micronutrient content reported in cereal varieties developed over the last few

decades. The decline could be due to the selective breeding of cultivars with higher yields but lesser micronutrient density because of the dilution effect (Marles 2017; McDonald et al. 2008). Though the production of nutrient-rich nonstaples such as vegetables, pulses, fruits, and animal products has also increased, their affordability is less than staple cereals for people with low purchasing power.

Climate change poses a serious challenge to improving the nutritive status of cereals, including rice, thereby threatening global nutritional security. Excess soil moisture/drought/heat and elevated CO_2 could lead to a reduction in nutritional quality in terms of protein, micronutrients, and vitamins in wheat and rice (Soares et al. 2019; Soba et al. 2019; Zhu et al. 2018) and also decrease the concentration of protein in grains of many crops species (Smith and Myers 2018), thereby directly affecting human nutrition (Toreti et al. 2019). As per the study, elevated CO_2 could lead to deficiencies of Zn for 175 million people, protein for 122 million, and Fe for 1.4 billion women of childbearing age and young children (Smith and Myers 2019).

Staple cereals have become major food source during the lockdown period of the COVID-19 pandemic in several Asian countries because of their affordability by low-income groups and ready availability, unlike perishable food items (Bairagi et al. 2022; Neeraja et al. 2022). Despite the disproportionate hikes in noncereal food prices, cereals like rice and wheat prices were stable during and after COVID-19 lockdown (Rathod et al. 2022). Any incremental improvement in the nutritional status of staple cereals would directly impact addressing the nutrient/micronutrient malnutrition of the world. Appropriate agricultural interventions help enrich micronutrient density and encourage dietary diversity could be ideal and long-term sustainable strategies (Bouis et al. 2019). Biofortification could be a suitable agricultural intervention to enrich micronutrient density in commonly consumed cereals such as rice, wheat, and other cereals. Biofortification refers to the genetic enhancement of crucial food crops with enhanced nutrients through agronomy, breeding, and biotechnology strategies (Bouis and Saltzman 2017).

Biofortification is different from fortification, wherein nutrients are externally added to the food items. Since global rice production is concentrated in a few Asian countries, fortification of rice for local consumption and export is proposed to be a strategy to address vitamin and mineral deficiency (Muthayya et al. 2014). Biofortification can be integral to achieving the third Sustainable Development Goal (SDG), focusing on good health and well-being.

1.3 Development of Biofortified Rice Varieties: Limitations of Conventional Breeding and Rationale for Next-Generation Breeding

The development of high-yielding cereals during the Green Revolution era helped many countries in Asia and globally to address food security. However, it led to excessive dependence on cereals as a food source, the rise of micronutrient malnutrition, or hidden hunger, which has been observed globally (Bouis et al. 2019). The initiatives of the Consultative Group on International Agricultural Research

(CGIAR) during the late 1990s and early 2000s led to the HarvestPlus Challenge Program across the world aiming to develop biofortified staple food crops through conventional plant breeding (Sanjeeva Rao et al. 2020).

Crop improvement requires genetic variability within and between the species, and this variability can be assessed by screening with different molecular or genetic markers, which are specific DNA sequences with known locations on chromosomes. They are classified into two categories: classical (morphological, cytological, and biochemical markers) and DNA markers. DNA markers help in the precise characterization of germplasm, construction of linkage maps, and DNA fingerprinting of crop varieties that ultimately result in marker-assisted crop improvement. Several DNA marker systems like restriction fragment length polymorphism (RFLP), random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), microsatellites or simple sequence repeat (SSR), single-nucleotide polymorphisms (SNP), etc., have been developed. The high-throughput sequencing platforms further enhanced provide thousands of SNPs. They help us to identify genomic region/s or gene/s that control a trait like Zn, Fe, vitamin A, or any nutraceutical. It is followed by reconfirming the gene–trait relationship and their usage options to develop better rice varieties. Transgenic strategies were also applied to develop biofortified grains of rice, especially targeting vitamin A deficiency since 1992 (Yu et al. 2022a). With nutritional quality becoming a primary global breeding target in rice improvement programs across ecologies, marker-assisted selection (MAS) for the significant quantitative trait loci (QTLs) would expedite the development of rice biofortified varieties through marker-assisted breeding (Neeraja et al. 2017). QTL mapping provides opportunities to identify the genomic region (s) associated with the targeted traits by combining genome information with phenotyping. Subsequently, identified genomic region(s)/QTLs/genes could be deployed in the breeding programs through MAS (Collard and Mackill 2008). In marker-assisted backcross breeding (MABB), DNA markers associated with desirable traits are used to select a plant for inclusion in a breeding program. In stage 1, the donor parent having the trait of interest is crossed with the recipient, followed by a screening population with markers to identify the progeny having the trait of interest, which is backcrossed once or repeatedly with the recipient to retain the essential features of the recipient parent (Collard and Mackill 2008). The second stage entails choosing backcross progeny containing the targeted gene using closely spaced flanking markers to reduce linkage drag. The last step is the selection of backcross progeny with background markers (Islam et al. 2017). Hence, a better line with only the donor parent's targeted gene and the recipient parent's remaining genome is obtained (Hasan et al. 2015). In the last few years, either all or the contrasting lines of the trait along with the parents are being subjected to genotype by sequencing (GBS). However, among the several thousands of SNP, a few thousand that are available in both parents are being utilized for the identification of candidate genes that may dilute the purpose of identifying the genomic regions of the donor parent. Genome-wide association mapping is an excellent approach to characterizing the phenotypic and molecular diversity to identify marker–trait associations (Huang et al. 2010). Genomic selection (GS) is another potential strategy

deploying genome-wide markers and phenotypes of phenotypic traits that have been proposed as a recent breeding strategy, especially for the improvement of quantitative traits (Meuwissen et al. 2001). The GS could be useful for developing biofortified varieties in rice as there are major common QTLs/genomic regions associated with nutrients that can be used globally. Among several strategies/approaches toward supporting the development of rice biofortified genotypes, CRISPR-based genome editing appears to be the most promising owing to its targeted gene editing (Kumar et al. 2022). The polymorphic sequence information of genes associated with nutrient-related genes is helpful to check the prudence of the identified SNP through clustered regularly interspaced short palindromic repeats, and CRISPR-associated proteins9 (CRISPR/Cas 9) technology.

2 Nutritional Composition of the Rice Grain

The nutritional composition of rice has been well documented and reviewed, covering both improved varieties and landraces. Rice is the primary source of carbohydrates for regions of the world, consuming it as a staple diet. Mature rice grains are generally harvested with about 20% moisture and dried to 14% moisture for safe storage. The complete grain consists of an outer husk/hull layer (25%), germ and bran layers (10%), and a large endosperm (65%). The resultant product is called brown rice when the husk/hull is removed from the complete, mature grain. Brown rice (100 g) possesses protein (7.3 g), crude fat (2.2 g), carbohydrate (71.1 g), dietary fiber (4 g), and crude ash (1.4 g) with 384 kcal. It has vitamins and mineral content in 100 g in the form of thiamine (0.29 mg), riboflavin (0.04 mg), niacin (4 mg), vitamin E (0.8 mg), Fe (3 mg), and Zn (2 mg) (Souci et al. 1986; Eggum 1969, 1977, 1979). Therefore, brown rice is a good source of energy, fat, mono- and polysaturated fats, carbohydrates, protein, fiber, B complex vitamins, calcium, Fe, and Zn. The B-complex vitamins like thiamin, riboflavin, and niacin promote youthful energy and nourishment to the skin and blood vessels (Lloyd et al. 2000). Vitamin E (especially tocopherols and tocotrienols), selenium, manganese, magnesium, potassium, and manganese are lost during milling and polishing (Lloyd et al. 2000; Lee et al. 2019). This is partly reduced in brown rice with or without polishing. Though brown rice is relatively healthier, polished rice is the preferred form for consumption because of its palatability, cooking ease, and longer shelf life. It is the most preferred form of rice provided through the public distribution system. Populations that subsist on polished rice are vulnerable to vitamin and mineral deficiencies. Various levels of polishing of brown rice give white rice, and bran is a by-product of the brown rice polishing process. However, bran has yet to be fully exploited for its enormous economic and nutraceutical values. Researchers have investigated the anticancer activities of tocopherols (Kline et al. 2004), tocotrienols (Lloyd et al. 2000), and the ability of oryzanols to reduce cholesterol absorption (Lloyd et al. 2000). It was also found that tocotrienol in rice bran can prevent or reverse blood clots and lesions that may lead to strokes or thrombosis (Frei and Becker 2004). In addition, the bran of

red and purple rice is rich in anthocyanins and tannins, which possess antioxidant and anti-inflammatory properties.

Several landraces have been reported to be rich in various nutrient contents in rice such as Zn, Fe, and other minerals, along with bioactive components (Bollinedi et al. 2022; Berni et al. 2018). Recently colored or pigmented rice grains are receiving significant attention because of their higher mineral content, antioxidants, phenolics, and anthocyanins (Raghuvanshi et al. 2017; Shao et al. 2018; Mbanjo et al. 2020). The color of the rice grain is attributed to the accumulation of secondary metabolites like carotenoids and flavonoids (Lap et al. 2021). The health benefits of colored rice grains are well demonstrated through several research studies on rice. Black rice with enhanced anthocyanins is shown to have nutraceutical properties (Butelli et al. 2008; Zhang 2021). The therapeutic properties of colored rice grains, with different local names, in traditional treatments in India and the Philippines have also been widely reported (Ahuja et al. 2007; Umadevi et al. 2012; Hemamalini et al. 2018). However, the existing rice varieties do not provide sufficient micronutrients for optimal health. In this regard, breeding specific nutrients for different market segments is critical. Collaborative DA-PhilRice-IRRI's Heirloom rice project promoted the Cordillera Autonomous Region (CAR) and Arakan Valley Complex (AVC) landraces, especially those that were pink to purple colored rice possessing higher anti-oxidants, and got them premium prices in the market by way of genetic purification, phenotypic characterization, and deeper understanding of their nutritional values (http://cure.irri.org/stories-archive/heirloom-rice-recovering-a-vanishing-treasure). The role of tocopherol and anthocyanin from red and purple-colored rices in cleaving the reactive oxygen species (Ghasemzadeh et al. 2018; Suwannakul et al. 2015) and antioxidation capacity in reducing the inflammatory response (Petroni et al. 2017) has been reported. The enhanced content of γ-oryzanolin-colored rice grains compared to normal rice (Chakuton et al. 2012) and the role of phytosterols in the inhibition of the absorption of cholesterol were also reported (Jesch and Carr 2017). Among the carotenoids in rice, lutein and zeaxanthin are predominant, along with low concentrations of carotenes, lycopene, and β-carotene (Melini and Acquistucci 2017). Red rice grains were reported to consist of relatively higher total tocopherol and tocotrienol than polished red rice grains (Gunaratne et al. 2013; Irakli et al. 2016). Interesting divergence of phenolic acids is seen in different colored rices such as red and black and also in brown and polished grains of rice (Zhang et al. 2015; Shao et al. 2018). Differential content of flavanones was reported in colored and white rice grains (Park et al. 2016; Poulev et al. 2019). Pro-anthocyanidins and catechins are indicated to be predominant in red rice, and anthocyanins in black and purple rice grains (Pereira-Caro et al. 2013; Kim et al. 2014; Zhang et al. 2015). High levels of genetic variation were observed for color differences based on the differential quantity and composition of bioactive compounds (Baek et al. 2015). Differential accumulation of color in grains is regulated by several regulatory proteins and enzymes involved in flavonoid and carotenoid biosynthesis. *MYB* and *bHLH* gene family members are the major regulators of these pathways (Lap et al. 2021).

The starch of rice grain's endosperm is also gaining importance with its critical role in the glycemic index (GI; Butardo and Sreenivasulu 2016). GI is a measure of

glucose release and uptake upon digestion, leading to increased blood glucose content. It is a clinical measure of the tendency of food or drinks containing 50 g of available carbohydrates to influence the blood glucose release and response upon intake relative to the same amount of glucose standard (Jenkins et al. 1981). Rice genotypes show intermediate (>55–69) to high GI (≥70), with a few genotypes with low GI (≤55) (Fitzgerald et al. 2011; Atkinson et al. 2008). Recently, the Indian rice varieties, Improved Samba Mahsuri (Sundaram et al. 2018) and RNR15048 (Prasanthi et al. 2019), have been reported to have a low GI (~51). Polished rice has a higher glycemic load and may impact glucose homeostasis. Genetic manipulation of GI traits was reported to be associated with yield penalty and undesirable cooking and textural properties (Jukanti et al. 2020).

Rice being a staple food, various sections of society – research and development, extension agencies, seed producers, farmers, paddy buyers, rice sellers, and consumers – are associated. Hence, NIN collected samples from 107 selected districts across the country and analyzed a series of compounds in all the samples (Longvah et al. 2017).

The market rice has around 9.3% moisture content. Starch is around 75% and is the dominant component of brown and polished grains, followed by 4.3–20.2% of protein (Chattopadhyay et al. 2011; Santos et al. 2013), 2.4–3.9% of lipids (Juliano 1977), and 0.5–2.0% of other compounds.

2.1 Starch

Starch contains both amylose and amylopectin that assemble to form crystalline large (irregular to cubical), medium or small (spherical or ellipsoidal) granules (Burrell 2003; Reddy and Bhotmange 2013). It comprises 70% amorphous regions of amylose and branching points of amylopectin and 30% crystalline, which contains outer chains of amylopectin (Reddy and Bhotmange 2013). Amylose is a linear or unbranched molecule with α-D-(1-4) linkages between two successive glucose residues. Rice is categorized into waxy (0%), very low (1–9%), low (10–19%), intermediate (20–25%), and high (>25%) amylose (Juliano, 1971). Amylopectin is branched with α-D-(1-4) and α-D-(1-6) glycosidic bonds within the branches and branching points, respectively. The amylopectin proportion decreases with the increase in amylose content.

Sugars are transported from the phloem of the seed coat to the maternal tissue, to the embryonic apoplast, and finally to the endosperm due to the osmotic gradient between the leaf and the growing seed. In the cytoplasm, ADP-glucose pyrophosphorylase (AGPase) activates glucose to ADP-glucose, which enters into the amyloplasts where granule-bound starch synthase I (GBSSI) uses ADP-glucose to synthesize amylose chains. In japonica rice, this enzyme (Wx^b) is less efficient due to a transversion (G to T) mutation in the first intron. Three categories of enzymes coordinate amylopectin synthesis. Soluble starch synthases (SSI, SSIIa, and SSIIIa) elongate (add glucose), and starch branching enzymes (BEI, BEIIa, and BEIIb) create branching points. Debranching enzymes (isomerase and pullulanase)

will enhance the granule compactness by removing some branching points. Involvement of multiple enzymes may accumulate similar amounts of starch; however, they can vary in chain length, branching density, compactness, etc.

Regarding the medicinal/physiological properties and functions of starch concerning human health, in the gastrointestinal tract or gut, starch digestion in the mouth is negligible since the food is generally swallowed into the stomach. Pancreatic juice contains multiple enzymes. The α-amylase and maltase digest starch into maltose and glucose, respectively. SGLT1 and GLUT2 are hexose transporters in Caco-2 cells. GLUT2, a facilitated transporter, is on the apical side and gathers to the membrane at a high glucose concentration. It is the main transporter of glucose (Kamiloglu et al. 2015) into the blood, leading to its increase above normal level (140 mg/100 ml).

In response, insulin hormone is secreted into blood from pancreatic β-cells. Insulin decreases the blood glucose to a normal level by either converting the extra glucose to glycogen in the liver and muscles or into fats and other molecules. During fasting or between the two meals, glucose can decrease by <80 mg/100 ml of blood. In response, glucagon hormone is secreted from pancreatic α-cells and is responsible for glucose release from glycogen and for making glucose from fats and other molecules. Type 1 DM is due to the absence or lower levels of insulin. Insulin is secreted in type 2 DM; however, it cannot show its effect.

Rice varieties were classified into low (GI $\leq$ 55), medium (GI 56–69), and high (GI $\geq$ 70) glycemic index. Lalat and Sampada recorded low GI and gave high, medium, and low glycemic load (GL) for 100, 50, and 25 g raw rice per meal, respectively (Table 1). Therefore, GI and available carbohydrate values must be considered before deciding the approximate amount of low GI rice per meal to maintain safe blood glucose levels following routine day-to-day activities (Sanjeeva Rao et al. 2022).

$$\mathrm{GI} = (\mathrm{iAUCtest\ food}/\mathrm{iAUCreference\ food}) \times 100$$

$$\mathrm{GL} = (\mathrm{GI} \times \text{available carbohydrate in the given amount of food})/100\ (\mathrm{J\ et\ al.\ 1997})$$

The rate of glucose release is more from amylopectin than from amylose, which need more time for digestion, and its consumption may help diabetic patients. Total starch, resistant starch (RS), amylose, and amylopectin contents vary among the rice

Table 1 Available carbohydrate, in vivo GI and GL in rice varieties

S. No	Variety	Available carbohydrate in 100 g rice	GI	GL for 100 g raw rice	GL for 50 g raw rice	GL for 25 g raw rice
1	Sampada	75.28	51.17	38.52	19.26	9.63
2	Lalat	75.84	53.17	40.32	20.16	10.08
4	Savitri	76.52	68.85	52.68	26.34	13.17
5	Jaya	78.53	75.58	59.35	29.68	14.84

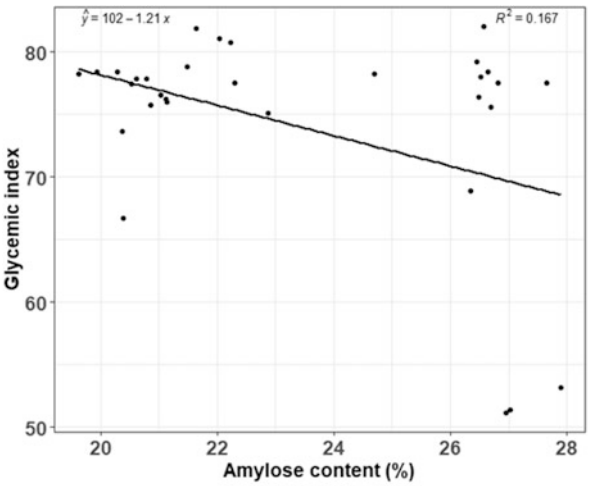

Fig. 1 Relationship between GI and amylose content

varieties and hybrids. Rice varieties released through AICRIP are of intermediate to high amylose. The in vivo glycemic index decreased with the increase in amylose content (Fig. 1). However, varieties with similar amylose content also varied in glycemic index. Amylose content varied from 25.25 to 33.70% for Samba Mahsuri across the locations. Glycemic index can vary with variation in amylose content, particularly varieties with low marginal GI can become medium GI and vice versa. This minor variation may not significantly affect blood glucose.

2.1.1 Resistant Starch (RS)

It was first identified and described as a small fraction of starch that does not hydrolyze to the D-glucose (Englyst and Cummings 1985) within 120 min in the small intestine (Ratnayake and Jackson 2008) and enters the large intestine (Englyst et al. 1992) where it is fermented by microflora (Nugent 2005) leading to flatulence. RS is linear and low molecular weight (1.2 × 105 Da) derived from the retrograded amylose fraction (Tharanathan 2002). In rice, RS range from 0.5 to 2.5%. RS content can vary among humans for the same rice variety due to variations in gastrointestinal functioning, like enzyme concentrations, the viscosity of the gastric fluid, and the food matrix itself. This is the chief reason for the dissimilarity between in vivo and in vitro results.

2.2 Protein

Proteins are distributed both in the aleurone layer and endosperm. They are classified into albumins (16–18 bands with 10–200 kDa), globulins (9 bands with 10–150 kDa), glutelins (12–21 bands with 22–33 kDa), and prolamins (5 bands

Table 2 Protein (%) categories and total protein content in polished grain

Variety	Albumin	Globulin	Prolamin	Glutelin	Total protein
Vibhava	0.54 ± 0.15	0.072 ± 0.03	0.72 ± 0.89	0.54 ± 0.05	4.95 ± 0.37
Ravi	0.38 ± 0.06	0.051 ± 0.006	0.36 ± 0.01	0.45 ± 0.19	6.09 ± 0.74
BPT 5204	0.14 ± 0.07	0.025 ± 0.004	0.81 ± 0.37	0.61 ± 0.40	6.52 ± 0.07
Sampada	0.12 ± 0.03	0.023 ± 0.002	0.28 ± 0.01	0.36 ± 0.17	5.25 ± 0.23
Rasi	0.03 ± 0.003	0.033 ± 0.002	0.82 ± 0.37	0.16 ± 0.09	5.48 ± 0.312

Table 3 In silico amino acid composition of protein sequences

Protein	Number of amino acids	Proportion of EAA %
Albumin	823	51.27
Globulin	155	44.82
Prolamin	237.0	41.5
Glutelin	499.56	43.32

with 10–16 kDa) and their availability (Table 2) varied among the varieties. More number of amino acids were observed in albumins (Table 3), while the proportion of essential amino acid (EAA) was the highest in albumins (Wen and Luthe 1985; Ogawa et al. 1987; Chrastil and Zarins 1992; Umadevi et al. 2019).

In four rices (three inbred varieties – Aghoni Bora, Swarna, and Samba Mashuri, – and one hybrid – DRRH3), among the nonessential amino acids (NEAA), glutamic acid was the highest and cysteine was the least. Of the EAA, leucine and arginine were the highest while the least available amino acids varied among the samples (Fig. 2).

Almost all the rice protein is digestible and less immunogenic. Hence, it is fed to infants. Protein digestion starts in the stomach where pepsin breaks proteins into peptides. In the small intestine, chymotrypsin and trypsin further hydrolyze peptides to oligopeptides that are hydrolyzed into amino acids by exopeptidases. Proteins as such cannot be absorbed in the gut and are the only sources of amino acids (protein synthesis in humans) that are absorbed into the blood.

Ten of the 20 standard amino acids are EAA since they cannot be synthesized in the body (Table 4) and must be supplied through food. Glutamic and aspartic acids provide an amino group for the synthesis of NEAA. However, histidine and arginine are essential for growing children and pregnant women. Cysteine and tyrosine are synthesized from methionine and phenylalanine, respectively.

Protein turnover is the amount of protein synthesized and degraded per day. It is around 2% in humans and can increase during pregnancy. About 75% of the amino acids released during degradation are reutilized, while the remaining are lost as urea. The intake and output of protein is equal in nitrogen equilibrium. The intake is less while output is higher and vice versa in the negative (leads to kwashiorkor, especially in children) and positive nitrogen balance, respectively.

In India, so far, three high-protein (>10%) varieties – CR Dhan 310, CR Dhan 411, and CR Dhan 311 in milled rice – were released through the AICRIP biofortification trial and one BRRI Dhan 84 (9.7%) was released in Bangladesh.

The average daily requirement of nitrogen is 0.83 g/kg body weight, and the average body weight is 65 kg for India, thus, 51.46–53.95 g protein (72 g for pregnant or breastfeeding women) is required. These high-protein varieties can

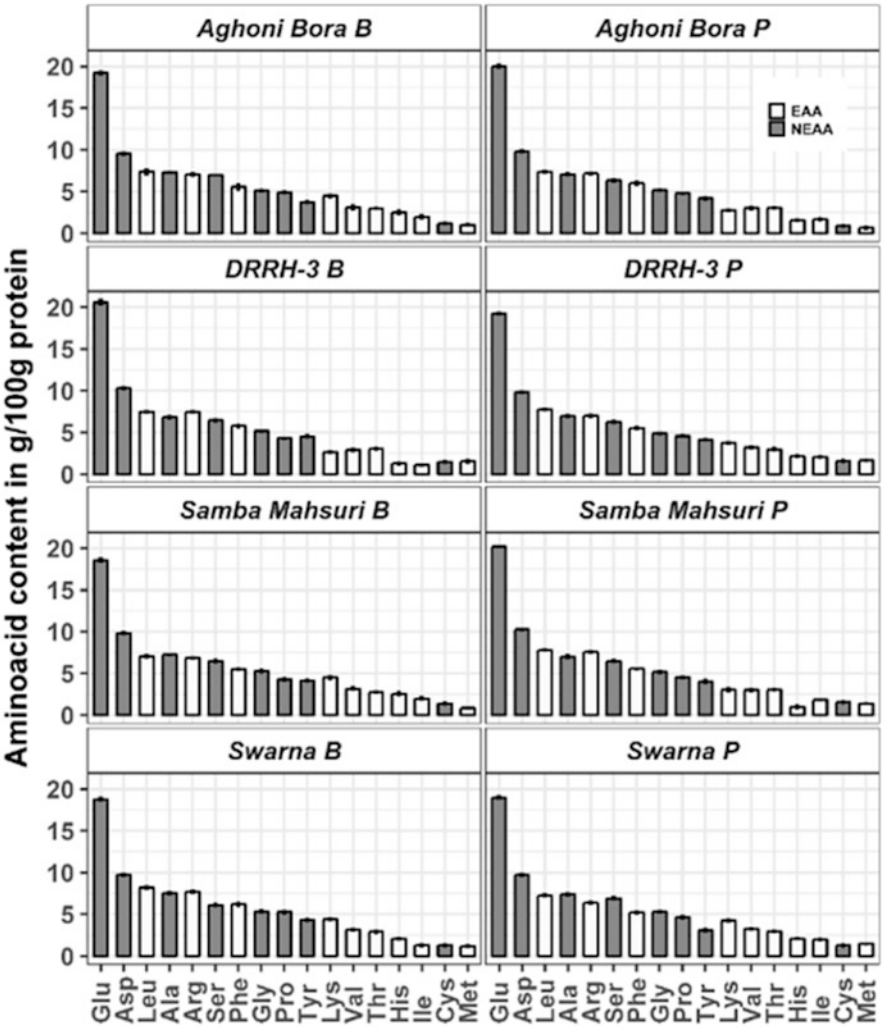

Fig. 2 Amino acids (17) in brown (B) and polished (P) rice (unpublished data)

provide around 24–30 g of protein from 220 g of rice. As nitrogen fertilizer application decreases in the future, germplasm screening must be intensified to identify donors and promising markers to enhance protein.

2.3 Lipids

Lipids are present in the aleurone layer (marginally higher) and endosperm. Bran is a by-product while milling brown rice. Lipids extracted from bran are called bran oil, containing triglycerides, free fatty (bulky side chains) acids, and oryzanol. Rice contains

Table 4 EAA (g/100 g) in raw rice (Longvah et al. 2017) and their role in human

Amino acid	Brown	Milled	Role
Methionine (M)	2.39 ± 0.26	2.60 ± 0.34	Increases the antioxidant levels (glutathione). Reduce blood cholesterol level
Arginine (R)	7.69 ± 0.37	7.72 ± 0.55	Precursor for nitric oxide, ornithine, polyamines, agmatine, proline, glutamate, creatine, and urea. Optimal growth and development of infants
Threonine (T)	3.38 ± 0.25	3.28 ± 0.27	Prevents fatty buildup in liver
Tryptophan (W)	1.00 ± 0.17	1.27 ± 0.14	Prevents fatty buildup in liver. Precursor of neurotransmitter serotonin (calming effect)
Valine (V)	6.72 ± 0.36	6.06 ± 0.02	Influences brain to uptake of tryptophan, phenylalanine, and tyrosine
Isoleucine (I)	4.08 ± 0.51	4.29 ± 0.23	Formation of hemoglobin. Prevents muscle wasting in debilitated individuals
Leucine (L)	8.40 ± 0.55	8.09 ± 0.40	Promotes healing of skin and broken bones. Reduces protein breakdown in the muscles
Phenylalanine (F)	5.50 ± 0.49	5.36 ± 0.43	Production of collagen. Precursor of tyrosine. Enhances learning, memory, mood, and alertness
Histidine (H)	2.36 ± 0.18	2.45 ± 0.30	Production of RBC (anti-anemic) and WBC
Lysine (K)	3.63 ± 0.29	3.70 ± 0.39	Inhibits viruses – herpes simplex virus. Lysine and vitamin C together form L-carnitine that enables muscle tissue to use oxygen more efficiently and delay muscle fatigue

higher levels of C16 and C18 fatty acids. Notably, the latter was at the highest level of the two essential fatty acids, linolenic and linoleic acids. Eventually, the proportion of unsaturated or polyunsaturated fatty acids (PUFA) is higher (Table 5).

The growing fatty acid gains 2 carbons (acetyl CoA) during each condensation cycle, and it grows up to C16 in the cytoplasm. Further elongation as well as unsaturation (introduction of double bonds) occurs in the endoplasmic reticulum.

Oryzanol was first isolated by Kaneko and Tsuchiya (1955). It is a mixture of sterol esters of ferulic acid. It contains cycloartenol, β-sitosterol, 24-methylene-cycloartanol, cyclobranol (cycloartenol), and campesterol (4-desmethysterols) (Rogers et al. 1993), and composition varies among varieties.

Regarding the medicinal/physiological properties and functions of lipids of rice concerning human health, triacylglycerols are emulsified by bile juice into micelles. Pancreatic lipase digests them into free fatty acids and glycerol, which enter into intestinal cells where they are resynthesized into triacylglycerols and packaged with cholesterol and specific proteins to form chylomicrons.

Chylomicrons enter into the lymph and, through blood, reach various tissues to supply fatty acids and glycerol. The remnant chylomicrons reach the liver and are converted into very low-density (VLDL), low-density (LDL), or high-density (HDL) lipoproteins based on the availability of lipids.

Table 5 Fatty acids in raw rice samples collected across the country (Longvah et al. 2017)

S. No	Compound (mg/100 g)	Systemic name	Brown	Milled
1	Myristic	Tetradecanoic acid	30.42 ± 3.15	13.19 ± 3.00
2	Palmitic	Hexadecenoic acid	273 ± 14.9	143 ± 28.0
3	Stearic	Octadecanoic acid	33.01 ± 4.34	14.50 ± 3.27
4	Arachidic	Eicosanoic acid	3.09 ± 0.21	1.46 ± 0.40
5	Behenic	Doeicosanoic acid	1.98 ± 0.21	1.98 ± 1.49
6	Lignoceric	Tetraeicosanoic acid	2.49 ± 0.38	1.14 ± 0.35
7	Palmitoleic	*cis*-9-Hexadecenoic	2.77 ± 0.46	1.49 ± 0.47
8	Oleic	cis-9-Octadecenoic	197 ± 15.4	109 ± 21.2
9	Eicosenoic	icos-11-enoic acid	1.89 ± 0.25	1.54 ± 0.44
10	Nervonic	Tetracos-15-enoic acid	0.89 ± 0.22	0.75 ± 0.36
11	Linoleic	all-cis-9,12-Octadecadienoic	490 ± 33.2	234 ± 45.8
12	α-Linolenic	all-cis-9,12-Octadecadienoic	16.10 ± 0.92	9.51 ± 1.09
13	Total saturated fatty acids (SFA)		346 ± 20.3	184 ± 8.9
14	Total mono-unsaturated fatty acids		203 ± 15.7	117 ± 6.6
15	Total PUFA		506 ± 33.6	253 ± 13.2

In the liver, PUFA is converted into ketone bodies. While SFA is converted into LDL (Beynen and Katan 1985) and acetyl CoA, which is converted into cholesterol, this quantity is different from the one absorbed from the intestine where γ-oryzanol in food can inhibit cholesterol absorption. Rice contains more linolenic acid and will reduce LDL and simultaneously increase the HDL (Cicero and Gaddi 2001).

Linolenic acid, the precursor of eicosanoids (C20) and docosahexaenoic acid (DHA; ω3, 22:6), is converted into eicosanoic acid (C20) that in turn form prostaglandins and thromboxanes (hormones) and into leukotrienes and lipoxins. Prostaglandins deal with inflammation and regulate blood coagulation and reproduction. Leukotrienes help in muscle contraction and chemotactic properties and are slow reactive substances of anaphylaxis (SRSA). DHA is required for brain and retina development. Thus, except for essential fatty acids, human metabolism is capable of synthesizing all other lipids from protein or carbohydrates.

2.4 Other Compounds

Rice also contains vitamins (Table 6), minerals, phytosterols, organic acids, etc. Some are more in the aleurone layer (Fe), and others are more in the endosperm. Highly pigmented brown rice is in red, purple, or black color (Table 7), and the various concentrations of cyanidin-3-O-glucoside equivalent (CGE) and catechin acid equivalent (CAE) are responsible for the variation in the color (Goufo and Trindade 2014). Generally, pigments (flavonoids) are glycosylated (aglycone), methylated or acylated forms of anthocyanidin ("Anthos" means flower, and "kyanos" is blue). Pigmented rice contains carotenoids, 159 and 16.87 μg/100 g in brown and milled rice, respectively.

Table 6 Water-soluble vitamins in raw rice (Longvah et al. 2017) and their role in human

S. No	Compound (mg/100 g)			Functions	Deficiency symptom
		Brown	Milled		
1	Thiamine (B1)	0.27 ± 0.023	0.05 ± 0.019	Coenzyme in pyruvate, α-ketoglutarate, dehydrogenases, and transketolase; nerve conduction	Beri-beri central nervous system lesions
2	Riboflavin (B2)	0.06 ± 0.011	0.05 ± 0.006	Coenzyme in redox reactions. Prosthetic group of flavoproteins	Lesions of corner of mouth, lips, tongue; seborrheic dermatitis
3	Niacin (B3)	3.40 ± 0.12	1.69 ± 0.13	Coenzyme in redox reactions. Formation of NAD and NADP	Pellagra
4	Pantothenic acid (B5)	0.61 ± 0.04	0.57 ± 0.05	Functional part of CoA and ACP in fatty acid metabolism	Huntington's disease (HD)
5	Total pyridoxine (B6)	0.37 ± 0.035	0.12 ± 0.012	Coenzyme in transamination, decarboxylation, glycogen phosphorylase, and steroid hormone action	Disorders of amino acid metabolism, convulsions
6	Biotin (B7) (μg)	1.38 ± 0.21	0.60 ± 0.12	Coenzyme in carboxylation, gluconeogenesis, and fatty acid synthesis	Impaired fat and carbohydrate metabolism, dermatitis
7	Total folates (B9) (μg)	11.51 ± 1.69	9.32 ± 1.93	Coenzyme in one carbon transfer	Megaloblastic anemia

Table 7 Composition of colored rice

Pericarp color	Anthocyanin (mg/100 g)	Proanthocyanidin (mg/100 g)
Black	1884	78
Purple	2874	525.4
Red	8.78	716.6
Brown	3.09	4.34

Phenylalanine is converted into 4-coumaroyl CoA to chalcone (committed step) in the presence of ATP, CoA, and three molecules of malonyl CoA (Fig. 3). Chalcone is converted into naringenin, which is oxidized to dihydrokaempferol. It, in turn, is hydroxylated at position 3 or 5 to dihydroflavonols, which are reduced to

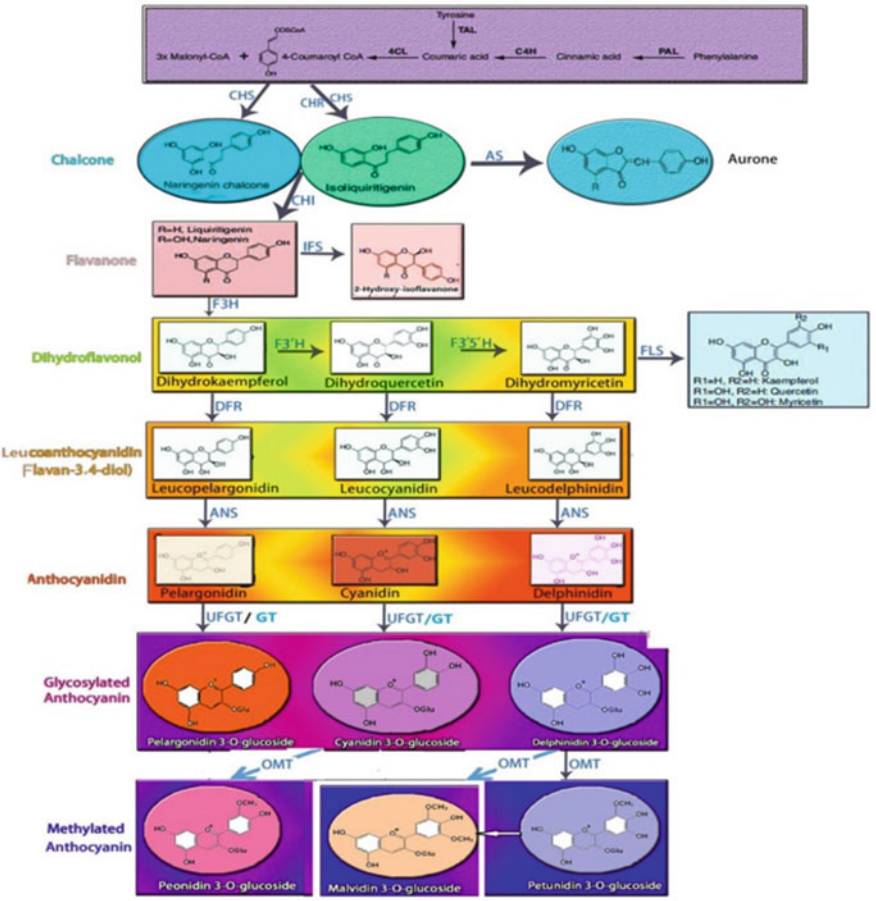

Fig. 3 Anthocyanin biosynthetic pathway (Mackon et al. 2021)

leucoanthocyanidin by NADPH and dihydroflavonol 4-reductase (DFR), which is another critical enzyme. The leucoanthocyanidin is oxidized to anthocyanidin and sequentially glycosylated and methylated to form anthocyanins (Mackon et al. 2021).

The chalcones are isomerized to flavanones and converted into flavones by flavone synthases (FS I and II). FSII is a group of cytochrome P450 enzymes (CYP93G1) that desaturate naringenin to apigenin (Fig. 4), which is hydroxylated to luteolin followed by esterification to form chrysoeriaol, hydroxylation to form selgin, and final esterification to form tricin (Lam et al. 2015).

Regarding the medicinal/physiological properties and functions of other compounds of rice concerning human health, the Ayurvedic treatise indicates the prevalence of medicinal rice varieties in India (Das and Qudhia 2001). Both Njavara and Jyothi are red rice; however, only Njavara is considered to have medicinal properties (circulatory, respiratory, and digestive systems). Antioxidant contents and capacities of pigmented rice were much higher than white rice (Pramai and Jiamyangyuen

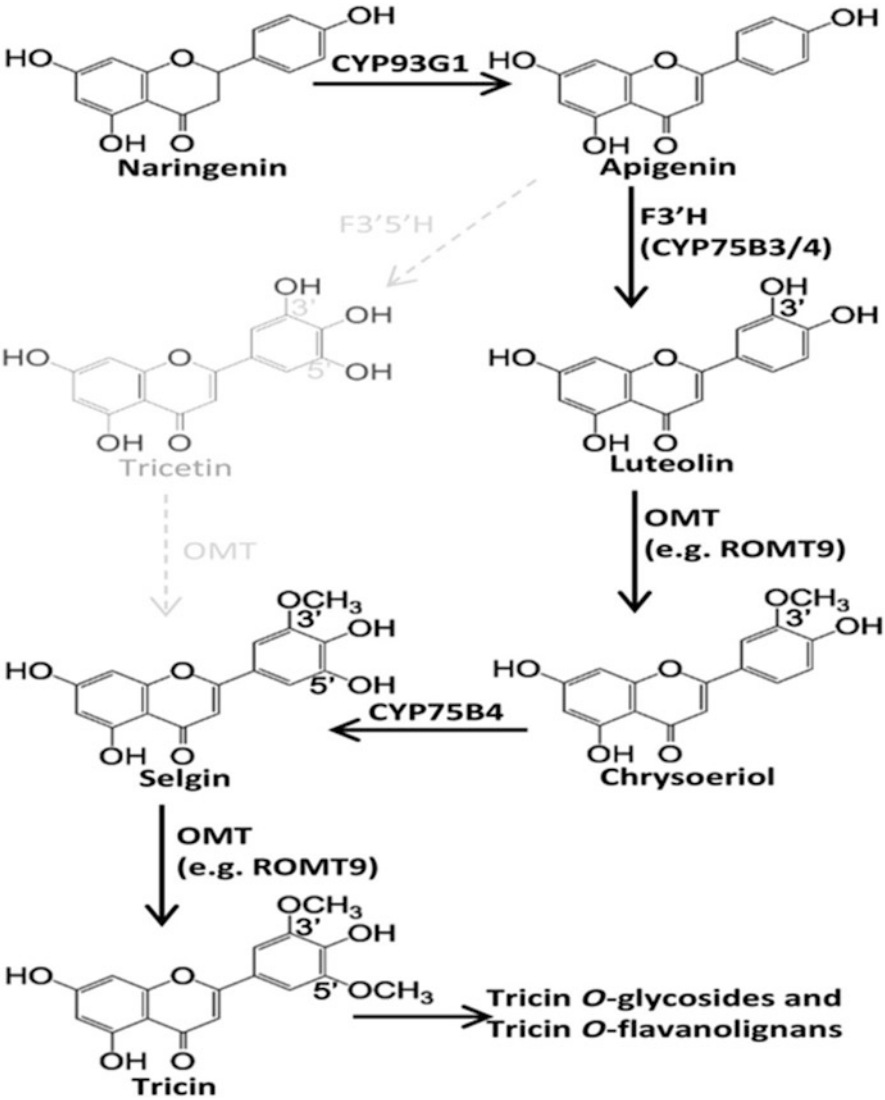

Fig. 4 Tricin biosynthesis pathway (Lam et al. 2015)

2016). Njavarakizhi is prepared by cooking Njavara rice in milk, with herbs, like *Sidarectusa* and *Alpinia galanga,* for the treatment of paralysis, arthritis, and neurological problems (Das and Qudhia 2001). Antioxidant, antiarthritic, antidiabetic, and antigastritis (peptic ulcers) activities were observed in Kavuni rice (Valarmathi et al. 2015). Karungkavuni is useful to cure elephantiasis and contains antioxidant, hypercholesteremic, hepatoprotective, anti-inflammatory, cancer-preventive, and antimicrobial compounds (Kalaivani et al. 2018).

In black rice (Longjin), cyanidin-3,5-diglucoside is the major compound (Hou et al. 2013). Ethanol extract of black rice bran (EEBRB) contains 3.28 ± 0.34 mg/

100 g of anthocyanin content, which can regenerate pancreatic β-cells (Wahyuni et al. 2016), particularly cyanidin-3-glucoside (Tantipaiboonwong et al. 2017) which competes with glucose (having glucose moiety) to get absorbed through GLUT2 (Kroon et al. 2004) and inhibits glucose absorption (Kamiloglu et al. 2015).

Despite the effector compound yet to be identified, extracts of black or red rice can inhibit the multiplication of breast cancer cells (Ghasemzadeh et al. 2018) by inhibiting cytochrome P450 or scavenging free radicals (Insuan et al. 2017). Similarly, purple rice extract was effective against hepatocarcinogenesis (Suwannakul et al. 2015). Tricin has been noted to have antioxidant, anticancer, anti-inflammatory, and cardiovascular properties (Lam et al. 2015). It inhibits cyclooxygenase I, which leads to the reduction of prostaglandin E_2 (PGE_2) and the inhibition of colorectal cancer cells.

The vitamin E tocotrienols (0.08 mg/100 g) and tocopherols (1.09 mg/100 g) in nonpigmented rice (Longvah et al. 2017) are lesser than in pigmented rice (Irakli et al. 2016). The antioxidant activity of oryzanol is due to ferulic acid moiety. It inhibits cholesterol oxidation and lipid peroxidation in retinal homogenates under oxidative stress (Hiramitsu and Armstrong 1991) and can kill leukemia cells (Parrado et al. 2006). The scavenger receptor class B type I (SR-BI) on enterocytes, CD36 membrane protein at the border of duodenum and jejunum, and NPC1-like transporter 1 (NPC1L1) is a major sterol transporter in the intestine that help in the uptake of carotenoids, fat-soluble vitamins, long chain fatty acids, etc. (Reboul 2019).

The ecological and climatic conditions were reported to influence the anthocyanin and bran oil content. Anthocyanin content was higher in two genotypes in the lowland and others in the highland. Similarly, antioxidant capacity was fourfold higher in lowland and other in highland (Rerkasem et al. 2015). Rice experiences high temperature during the grain filling stage of the dry season. In the AICRIP trial, high-temperature conditions (4–5 °C higher than the control) were created, covering the treatment with a polythene sheet. In eight entries, bran oil content ranged from 10.5–12.5 and 5.8–13.0 g/100 g bran in control and high-temperature stress, respectively. The octanoic acid peak was higher while the palmitoleic acid peak was smaller under treatment in susceptible.

2.5 Iron (Fe) and Zinc (Zn)

Around 3.1% and 0.9% of 3177 germplasm showed Zn content ≥35 and ≥40 mg/kg, respectively (Sanjeeva Rao et al. 2020). As the maximum Zn content in germplasm is four- to fivefold higher than the cultivars, high Zn varieties (24 mg/kg) were released (Table 8).

For Fe, diversity in germplasm itself is narrow, and moreover, 70% is lost during milling. Hence, biotechnological tools were used to release 1 (the Philippines), 1 (Latin America), and 3 (Bangladesh) varieties having high Fe of 7–10 mg/kg in polished and 13–31 in brown rice.

Table 8 List of high Zn (mg/kg) biofortified rice varieties released

S. No	Country	Name of varieties	Zn	Sl. no.	Country	Name of varieties	Zn
1	India	DRR Dhan 45	22.3	13	Bangladesh	Binadhan 20	26.5
2		Chhattisgarh Zn Rice 1	22–24	14		BRRI Dhan 62	19.6
3		DRR Dhan 48	20.91	15		BRRI Dhan 64	25
4		DRR Dhan 49	26.13	16		BRRI Dhan 74	24.2
5		Surabhi	22.84	17		BRRI Dhan 84	27.6
6		GR-15	21.58	18		BU Aromatic Hybrid Dhan-1	21.8
7		Surabhi	22.84	19		BU Aromatic Dhan-2	22
8		Zno Rice-MS	27.4	20	Indonesia	INPARI 47 Nutri Zn	29.54
9		Chhattisgarh Zn Rice-2	22–24	22		INPARI IR Nutri Zn	26
10		DRR Dhan 63	24	23	LAC	CENTA A-Nutremas	22.86
11		CR Dhan 315	24.9	24		CIAT BIO-44 +Zn	25
12	Philippines	NSICRc460	19.6			Fedearroz BIO Zn 035	26

The recommended dietary allowance (RDA) of Fe and Zn for the human population (25–50 years of age) are 10–15 and 12–15 mg, respectively. In India, the average daily intake of rice is 220 g, and polished rice having 45.5–68.2 mg/kg Fe and 54.5–68.2 mg/kg Zn can only meet the RDA without considering the bioavailability (Sanjeeva Rao et al. 2014).

As the maximum Zn in brown rice is 45 mg/kg, it may not be possible to get varieties >50 mg/kg through conventional breeding coupled with Zn-deficient soils. Strategies are to be chalked out to test rice's actual genetic potential with sufficient Zn experimental fields. If the grain Zn content is still <50 mg/kg, then biotechnological intervention is required.

The highest amount of Zn (50 mg/kg) and Fe (14.7 mg/kg) contents were achieved by NASFer-274 transgenic event having rice nicotianamine synthase (OsNAS2) and soybean ferritin (SferH-1) genes into IR64 controlled by glutelin promoter (Trijatmiko et al. 2016). On crossing this with three popular varieties, the Zn and Fe contents in F2 bulked milled rice ranged from 33–45 mg/kg and 6–11 mg/kg, respectively. As IR64 is also a popular variety in India, this transgenic event may be utilized through MABB to further enhance Fe and Zn contents in the biofortified high Zn varieties.

Soils (micronutrient source) are 30% and 20% deficient in Fe and Zn, respectively. In the AICRIP Biofortification trial, Zn content in high Zn variety Fe and Zn varied from 2.65–7.05 mg/kg and 13–27.85 mg/kg across 17 locations, respectively. Of the seven rice varieties cultivated in low N, N50, and N100, minor variations were noted for grain Fe content except Vandhana (Fig. 5). But grain Zn content was

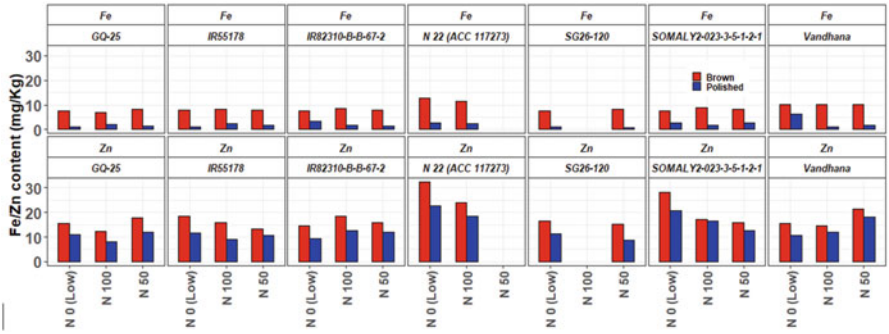

Fig. 5 Fe and Zn content in rice grain at varied soil N

more in Somaly2-023-3-5-1-2-1 and N22 under low N. Purple rice noted higher Zn (33–35 mg/kg) in lowland over highland, and the difference between altitudes ranged from 16 to 50% among the ten genotypes.

Postharvest processing, like parboiling, increases head rice recovery during milling and nutrient content in the endosperm. As most nutraceuticals are heat or acid-sensitive, enzymatic treatment is the best (Parrado et al. 2006), where bran is treated with an endoprotease mixture that hydrolyzes lipase completely to stop rancidity (unpleasant odor) and enhances oryzanol (3.4 times). Alternately, brown rice is packaged in smaller quantities in the presence of nitrogen. The absence of oxygen can avoid rancidity and enhance the shelf-life. However, this will hold well till the packet is opened. Industrial chemical fortification of broken rice powders with Fe and Zn is followed by conversion into rice pellets through an extruder, mixed with field-grown rice, and released into markets.

3 Marker-Assisted Breeding for Health-Related Traits

For achieving food and nutritional security, increasing the production of nutrient-rich rice is challenging. As conventional breeding is time consuming and very dependent on environmental conditions, marker-assisted breeding (MAS) is one of potential modern molecular tools for nutrient improvement of crops. It aids in value addition of varieties by incorporating gene responsible for enhanced micronutrient. By availing technologies like DNA markers, genetic engineering, etc., it helps us to detect the allelic variation in genes underlying the traits. Information on nutritional traits such as grain protein, vitamins, minerals, glycemic index value, and phenolic and flavonoid compounds has been reported (Mahender et al. 2016). Several quantitative trait loci (QTLs) for nutrient traits, amino acids, fat content, low phytate content, etc., have been mapped in rice in different mapping populations (Thangadurai et al. 2020; Raza et al. 2019). Research studies involving wild species, landraces, and mutants in backcrossing breeding programs by applying MAS resulted in the identification of promising lines with high Zn, Fe, high protein, and low phytate content.

3.1 Germplasm Characterization

The importance of genetic resources is widely recognized. There is rich variability in rice genetic resources related to nutritional and health-related traits. Due to a lack of availability of information and limited production, these resources could only reach some of the population. The information on all genetic resources of rice enriched with nutritional and health-promoting traits could be used to develop functional food and drugs to prevent and treat several human disorders, metabolic diseases, oxidative stress-related pathogenesis, and carcinogenesis. Many nutraceuticals are available in rice, and huge germplasm is yet to be screened, which may contain a higher concentration of the known or novel nutraceuticals. Hence, the requirement of biotechnology intervention can be nutraceutical dependent. In other words, a significant amount of research was conducted on Fe, Zn, and golden rice to enhance the same in the rice grain; however, the progress is different.

3.1.1 Rice for Grain Protein and Amino Acids

Many landraces with high crude protein are ARC10063 (16.41%), Kullakar (12.88%), Kempunellu (12.58%), Ambemohar-1 (12.50%), Ambmohar-2 (12.42%), Antarsali (12.31%), Balam rice (B2: 12.4%) of Bangladesh, black rice genotypes of Southern India, viz., BPT 2848 (13.11%), and BPT 2858 (12.82%) (Hanamaratti et al. 2015; Ahmed et al. 2015; Chattopadhyay et al. 2011; Velprabakaran et al. 2020; Sridevi et al. 2021). Two high-yielding varieties with high grain protein content are CR Dhan 310 (10.3% in milled rice), CR Dhan 311 (Mukul) with protein 10.1% in milled rice, and moderately high Zn (20 ppm) (Chattopadhyay et al. 2019).

Some mutant lines with enhanced amino acids are Mtr1 (mtr1-D) mutant rice of Norin-8, with increased accumulation of tryptophan (11.4–16.1%), and mutant of OASA2 (subunit of anthranilate synthase) in Nipponbare with 230-fold higher level of tryptophan (Yamada et al. 2008; Saika et al. 2011). A weedy rice morphotype of *Oryza sativa* from North Macedonia weedy accession, WR1323232, reported having high protein (12.12%) (Dimitrovski et al. 2021). In wild rice species, *O. rufipogon* of the primary gene pool, *O. officinalis* of the secondary gene pool, and *O. meyeriana* of the tertiary gene pool having a high crude protein content of 14.87 mg/100 mg, 15.12 mg/100 mg, and 15.56 mg/100 mg dry seed weight, respectively, were reported (Jiang et al. 2014).

3.1.2 Rice for Vitamins

Particular black rice landraces like Huggi Bhatta, Kalo Bhat, Tiki, and Chak Hao Poireithon were reported to contain the highest concentration of total carotenoid, the precursor of vitamin A (32.86 μg/g; 29.73 μg/g; 21.19 μg/g; 15.39 μg/g,respectively), implying their therapeutic potential in human health and nutrition (Roy et al. 2021). Golden rice, a genetically engineered rice introgressed with two major genes of β–carotene biosynthetic pathway (phytoene synthase from maize, β-carotene desaturase from bacteria *Erwinia uredovora*) into rice endosperm, is another source

of vitamin A. Golden rice 2 contains as much as 37 μg total carotenoids per gram of dry grain weight, of which 31 μg/g is β-carotene (Paine et al. 2005).

Rice landraces with higher vitamin E are some of the Japanese varieties such as Hirayama, Moritawase, and Kaneko that were found to have the highest vitamin E or tocotrienol (80–86%). Landraces of Northeast Thailand, such as Jao Dang (δ-tocotrienol: 8.87 mg/kg), Khao Hawm (γ-tocopherol: 9.78 mg/kg), Tan gun (α-tocopherol: 6.29 mg/kg), Nahng Boon Ma (γ-tocotrienol: 21.6 mg/kg), Ma phai (α-tocotrienol: 9.94 mg/kg), Indian rice landrace like Mapillai samba (26.73 ± 0.49 μg/g), were reported to have the highest vitamin E content (Sookwong et al. 2007; Sudtasarn et al. 2019; Rajendran and Chandran 2020). Mutant varieties with enhanced levels of tocopherols are Shangshida No. 5′ with 2.2-fold and MRXII mutant rice lines of japonica rice cultivar 'Dongan' with 23% higher tocopherol level than that in wild type (Wang et al. 2013; Hwang et al. 2014).

Rice landraces with maximum content of different water-soluble vitamins are Kalajirajaha (0.38 mg thiamin/100 g), Hati bandha (0.09 mg riboflavin/100 g), Kutchi gism (3.87 mg niacin/100 g), Mimittimmidokru (3.1 mg pantothenic acid/100 g), and Mimittimsokmil/mim-kudep (0.17 mg pyridoxine/100 g) (Longvah and Prasad, 2020). Further, the medicinal rice landrace Kullakar with high thiamine content (0.53 ± 0.01 mg/100 g) and Karikalaveya with high riboflavin and niacin content (0.08 ± 0.01 mg/100 g and 16 ± 0.58 mg/100 g, respectively) were identified as a rich source of vitamins (Isaac et al. 2012).

3.1.3 Rice for Minerals

Some of the essential landraces and genotypes with high Fe and Zn and other minerals in brown rice are Maubinni (Fe: 27.3 ppm), Madhukar (Fe: 17.3 ppm; Zn: 53.7 ppm), Thanu (Zn: 55 mg kg^{-1}), and NDR-6279 (Fe: 45.1 mg kg^{-1}); Fe-dense (≥40 ppm) genotypes are Tikimahsuri (52.15 ppm), Jabaphulla (52.15 ppm), Kala Kusuma (52.1 ppm), CR 2327-23 (51.4 ppm), Budhidhan (51.15 ppm), Kalamakhi (50.15 ppm), Nikipankhia (47.2 ppm), ORM 405-8 (45.05 ppm), Jadumani (42.75 ppm), Basudha (41.45 ppm), Malliphulajhuli (41.35 ppm), and Tulasibasa (40.35 ppm); Kuttadan, a landrace of Kerala, was reported being rich in Zn (30.63 ppm) (Longvah et al. 2012; Anuradha et al. 2012; Jagadeesh et al. 2013; Pillai et al. 2020; Tripathy and Dash 2021). The black rice landrace, 'Chak Hao', also harbors many elements (Al, Si, Mg, Cl, K, Ca, P, and S) (Tripathy and Patra 2021).

In polished rice, landraces like Chittimutyalu (Fe: 14.0; Zn:25.7 ppm), Munga (Fe: 15.8; Zn: 28.7 ppm), Basmati 386 (Fe: 13.1; Zn: 27.7 ppm), Ranbir Basmati (Fe: 10.4; Zn: 30.9 ppm), deep water rice Madhukar (Fe: 11.2; Zn:24.2 ppm), TKM 9 (Zn: 24.7 ppm), Thanu (Zn: 23.50 ppm), IR36 (Fe: 23.0 ppm), MTU 3626 (Fe: 19.72 ppm), and NDR 6279 (Fe: 19.60 ppm) were reported as elite Fe, Zn rice genotypes (Ravindra Babu 2013; Jagadeesh et al. 2013).

High-yielding high Zn rice varieties of Bangladesh are BRRI Dhan 62 (19 ppm), BRRI Dhan 64 (25 ppm), high Fe variety, and BRRI Dhan 48 (14.03 ppm) (Khatoon and Islam 2020). High Zn high-yielding varieties of India are DRR Dhan

45 (22.6 ppm), DRR Dhan 48 (24.0 ppm), DRR Dhan 49 (25.2 ppm), Zinco rice MS (27.4 ppm), CR Dhan 311 (protein: 10.1%; Zn: 20.1 ppm), and CR Dhan 315 (Zn: 24.9 ppm) (Yadava et al. 2020). Mutant lines with a rich source of Zn in brown are P44 mutant Sel.-1 and OR CZ 75-3 (51.95 ppm) (Tripathy and Dash 2021).

Wild species of rice such as *O. nivara*, *O. rufipogon* of the primary gene pool, *O. latifolia*, *O. officinalis* of the secondary gene pool, and *O. granulate* of the tertiary gene pool contain around two to three-fold higher Zn than in the cultivated rice, with Zn concentration varying from 37 to 55 mg/kg in nonpolished grains (Anuradha et al. 2012).

3.1.4 Rice for Low Phytic Acid

Some of the low phytic acid (lpa) landraces with low seed phosphorous levels are P 1490-03(3.48 mg/g), *indica* rice cultivar ZN 60 (3.99 mg/g), Yamukh (2.03 mg/g), and Amkei (2.13 mg/g) landraces of Arunachal Pradesh (Wang et al. 2011; Longvah and Prasad 2020; Gyani et al. 2021).

Improved rice varieties such as Goldhull, with a 45% reduction in phytic acid (PA); OM4498, OM5731, DS2000 (mean: 0.465 μg P); Basmati rice, with 54–63% reduction in phytic acid are also reported as low PI rice (Rutger et al. 2004; Lang et al. 2007; Qamar et al. 2019). Low lpa mutant lines are 'Kaybonnet' lpa1–1, with 45% reduction in bran PA with high Zn, mutant lines of MIk gene with 34–64% reduction in PA, Os-lpa-XS110-1 developed from wild type variety 'Xiushui 110' with 46% reduction in PA, N15-186 and N15-375 line with 75% and 43% reduction in seed PA, Pusa LPA Mutant 11 (PLM11), with 70% reduction in PA, Os-lpa-XS110-1 (japonica variety: Xiushui110) with 45.30 mg/kg of Zn and 4.06 mg/g PA compared to wild type (Liu et al. 2004, 2007; Frank et al. 2007, 2009; Kim et al. 2008; Gyani et al. 2021; Wang et al. 2021).

3.1.5 Rice with High-Resistant Starch

Many rice landraces with high-resistant starch (RS) are Kataribhog, Sadanunia, and Chakhao, with RS of 45.72%, 60.49%, and 59–61%, respectively (Mondal et al. 2021). Many mutant rice lines with highly resistant starch areami-BEIIb with an amylose content of 41.2% were obtained through mutation in starch branching enzyme IIb; sbe3-rs mutant line with 60.4% of RS obtained by crossing japonica mutant 'Jiangtangdao 1' with an indica cultivar 'Miyang 23'; ss3a/sbe2b double mutant-resistant starch lines with high amylose content (45%); IR 36 is another line with resistant starch of 44%; be1 be2b is double mutant rice cultivar with an amylose content of 51.7% (Butardo et al. 2011; Yang et al. 2012; Asai et al. 2014; Guzman et al. 2017; Miura et al. 2021).

3.1.6 Low Glycemic Index Rice

Low glycemic index (GI) landraces are CGMD-55 belonging to the Gurmatiya group with a GI value of 55. Karuthakar Poha and Chak Hao Poreiton have a low GI of 52 and 53, respectively (Chandel et al. 2016; Rajendran and Chandran 2020). Improved cultivar such as Laila, a Basmati rice, Australian Doongara rice,

Sinandomeng of Philippines, high-yielding varieties of Bangladesh, BRRI16, BRRI dhan46, and BRRI dhan69; Bangladesh black rice, BBK1 (GI values 48 and 51 in brown and mulled rice); Sona Masoori (GI:51), improved Samba Mahsuri (GI: 50.99) and Madhuraj (GI: 55); two Thailand varieties, PK + 4#20A09 (GI:48.1) and PK + 4#1_E06 (GI:54.6); Indonesian rice cultivar, Logawa GI (54.39 ± 1.49); red rice of South India Karungkuruvai, Kavuni, Kalanamak, and Kullakar are low GI (50–55); GQ02497 with GI value 51.1; the line MAKRO:IRGC 74,763-1 with low GI of 52.91; redfragrant, a variety of Sri Lanka with GI value of 47; Lalat (GI: 53.17), BPT 5204(GI: 51.42), and Sampada (GI: 51) are with low GI values (<55) (Sun et al. 2018; Fitzgerald et al. 2011; Tripathy et al. 2017; Shozib et al. 2017; Shozib 2018; Sarkar et al. 2018; Sundaram et al. 2018; Nounmusig et al. 2018; Kusmiyati et al. 2019; Pushpam et al. 2019; Anacleto et al. 2019; Selvaraj et al. 2021; Abeysiriwardena and Gunasekara 2020; Sanjeeva Rao et al. 2022). Mutant rice line, Frontiere, a new breed of low GI (41) and high protein rice (11%), sold as Parish Rice and Cahokia Rice, has the lowest glycemic index of any rice (Wenefrida et al. 2017).

3.1.7 Phenolics and Flavonoids

Superior landraces enriched with the phenolics and flavonoids are medicinal rice of Kerala, Njavara; black/purple landraces of northeast India, Mamihunger (anthocyanin: 96.71 mg/100 g; gammaoryzanols: 0.98 mg/g), Manipuri black (anthocyanin: 96.22 mg/100 g); Kala namak rice of Uttar Pradesh with the highest phenolic content (43.19 ± 0.54 mg/g) and total flavonoid content of 7.18 ± 0.52 mg/g; Mapillai samba of Tamilnadu with anthocyanin content 42.21 mg/g; Chakhao, an aromatic landrace from northeast India, as a rich source of anthocyanins: 275.8 mg/100 g, phenolics: 700 mg GAE/100 g, DPPH antioxidant activity: 65.7%; Kalobhat from West Bengal; Kola bora, a rice landrace of Assam with high anthocyanin content of 328.26 mg/100 g are a rich source of phenolics and flavonoids (Isaac et al. 2012; Sanghamitra et al. 2017, 2018; Rajendran and Chandran 2020; Bhuvaneswari et al. 2020; Kalita and Hazarika 2022).

Many high-yielding pigmented rice varieties enriched with phenolics and flavonoids are black rice cultivars of Japan, Okuno-Murasaki and Asamurasaki; Kuang-fu-Shiang-waxy (KFSW, a waxy indica rice with red-colored bran) and Taikeng 16 (TK16, non-waxy japonica rice) of Taiwan; Thailand aromatic rice, "Rice berry," a deep purple indica-type rice variety; the red rice Rubi and the black rice, Onix of Brazil; black rice genotypes of India with high phenolic content, antioxidant activity, and flavonoids are BPT 3140 (214.34 ± 0.25, 108.83 ± 0.28, 590.12 ± 7.0, respectively), BPT 2848 (23.31 ± 0.26, 86.63 ± 0.65, 784.54 ± 21.6 respectively), BPT 2858 (174.48 ± 0.21, 89.07 ± 0.56, 548.72 ± 7.6, respectively), BPT 3111 (95.50 ± 0.17, 110.09 ± 0.18, 410.61 ± 8.9, respectively) (Mbanjo et al. 2020; Lin and Lai 2011; Takita et al. 2001; Wickert et al. 2014; Sridevi et al. 2021). Chinese wild rice of the tertiary gene pool, *Zizania latifolia,* with higher phenolic content and antioxidant activity, was reported as a potential source of natural antioxidants (Yu et al. 2021).

3.1.8 Rice for Medicinal Use

Certain pigmented rice with medicinal value are used to treat skin diseases, blood pressure, fever, paralysis, rheumatism, and leucorrhea, and even as the basis of a general health tonic (Ahuja et al. 2007). The rice landraces of Madhya Pradesh, such as Gathuan, are used for the treatment of rheumatism; Laichais is used to prevent eponymous skin diseases; Karhani for the treatment of paralysis; Nagkesar for the treatment of lung disease; Resairi for the treatment of chronic cough; and Rakthasali (a kind of red rice) is efficient in subduing disturbed tumors of the body and good for fevers and ulcers; improves eyesight, health, voice and skin health; and increases fertility (Das and Qudhia 2001; Bhat and Riar 2015; Ahuja et al. 2008).

Najvara rice from Kerala is used to treat cervical spondylitis, paralysis, rheumatoid arthritis, neuromuscular disorders, psoriasis, skin lesions, reduce backache, stomach ulcers, and snakebite; and Nivara rice is also used in the preparation of weaning food for underweight babies (Ahuja et al. 2008). In Himachal Pradesh, red rice landraces Matali and Lal Dhan are used for curing blood pressure and fever (Chaudhari et al. 2018). Black rice variety Kalanamak enriched with potassium is used to cure skin diseases and regulate blood pressure. Karuthakar is used to maintain the sugar level under control and cure piles on regular consumption; Kattuyanam rice controls diabetics. Kodai samba rice cures Vatha-related diseases. Karun kuruvai enriched with protein, fat, and phosphorus is used to cure skin ailments and venomous bites and stings (Chaudhari et al. 2018; Pushpam et al. 2019).

The purple pericarp is governed by two genes: purple pericarp b (Pb synonym Prp-b on chromosome 4) and purple pericarp p (Pp, synonym Prp-a on chromosome 1). These genes also show epistatic effects. Dark purple seeds were observed with Pb_PpPp, medium purple seeds with Pb_Pppp, brown seeds with Pb_pppp, and white pericarp seeds with pbpbpppp combination (Mackon et al. 2021).

It is believed that less than 1% of germplasm resources have been exploited by several thousands of accessions. Parallel germplasm screening for all or targeted nutraceuticals should be a continuous process to identify better donors and new genomic regions through genome-wide association studies (GWAS), metabolic pathways, transcription factors, etc.

3.2 QTL Mapping

As most of the grain nutrient traits are controlled by several genes/QTLs, interventions from novel and recent technologies would expedite the development of biofortified rice varieties. The breeding strategies could be fine mapping, marker-assisted selection/backcrossing, association mapping analyses, and natural allelic variation (Priyadarshi et al. 2021). Using bi-parental mapping populations, 22 independent studies have reported 220 QTLs for grain Fe and Zn in rice using simple sequence repeat (SSR) markers or candidate gene-based markers (Raza et al. 2019) (Table 9). Interactions among the identified QTLs for grain Zn were also studied for characterization of QTL interaction effects on the phenotypic expression of the trait

3.3 Nutritional Improvement in Rice Quality Using a Genetic Engineering Approach

A deficiency of vitamin A is widespread in countries with cereals as a staple food (Garg et al. 2021). As a natural variation of β-carotene in rice grain is unavailable, the provitamin A pathway into the rice endosperm was introduced through genetic engineering. Several international funding agencies like the Rockefeller Foundation, the Bill & Melinda Gates Foundation, USAID, the Philippine Department of Agriculture, HarvestPlus, the European Commission, Swiss Federal Funding, and the Syngenta Foundation have funded the project of golden rice. Radio-labeled C^{14} indicates that enzymes required for the conversion of isopentenyl-pyrophosphate to geranyl-geranyl-pyrophosphate are available in rice. However, phytoene synthase (*psy*) is unavailable; hence, *daffodil* PSY was introduced with the host (rice) or tissue-specific glutelin promoter, producing a higher amount of phytoene than the *CaMV-35S* promoter. A bacterial *CrtI* gene was chosen over plant sources to avoid

multiple enzyme requirements to convert phytoene to lycopene (Potrykus 2001). However, considering the lower levels of β-carotene, orthologs of PSY were explored, and among them, maize (*ZmPSY1*) was the best, followed by rice (*OsPSY1*). Change in aspartate to alanine in *PSY2* increased the root carotenoid content (Welsch et al. 2010). Provitamin-A noted a half-life of 25 days after harvest, followed by a plateau (3–5 μg/g) of bound (protein) form in the chromoplast (Schaub et al. 2017), and this bound form may be enhanced to increase its quantity and stability (Welsch and Li 2022). Provitamin-A-containing variety (BRRI Dhan 69) was released in Bangladesh. Interestingly, a native provitamin A (49.16 ± 5 μg) pathway was detected in a purple rice (Chettry et al. 2019). Through *Agrobacterium*-mediated transformation, the genetic construct consisted of a plant phytoene synthase (*psy*) originating from daffodil (*Narcissus pseudonarcissus*), a bacterial phytoene desaturase (*crtI*) originating from *Pantoea ananatis* and lycopene ≈-cyclase (*lcy*) from daffodil was introduced into a japonica rice variety as a proof of concept. Second-generation golden rice (GR2) with higher β-carotene levels up to 37 μg/g carotenoids, GR2, was developed using the bacterial phytoene desaturase (*crtI*) originating from *P. ananatis* and phytoene synthase of maize (Paine et al. 2005). Using the backcross breeding program, popular rice varieties of South Asia and Southeast Asian countries, viz., IR64, PSBRc82, and BRRI Dhan29, were introgressed with transgenes associated with golden rice through the backcross breeding approach (www.goldenrice.org). Agronomic evaluation of transgenic and non-transgenic BRRI Dhan 29 showed promising performance for yield (Biswas et al. 2021). Studies have assessed golden rice to be safe as per food safety approvals in various countries (Owens 2018; Oliva et al. 2020). In 2021, golden rice was approved for commercial cultivation in the Philippines (www.goldenrice.org). Regulatory constraints for transgenic rice in several countries are slowing the adoption of transgenic biofortified genotypes.

Transgenic rice lines with high-grain protein content are MH86 (12.87%); Nipponbare line with 6.0% elevation in lysine content; pSBM-35DHPSM rice lines with 2.5- to 4.0-fold increase in the free lysine in the seeds; Kitaake lines with 56% enhancement in lysine level; japonica cv. 9983 with 35% enhancement in lysine; Chinese transgenic male sterile line; Peiai64S (PA64S), with 30% more lysine compared to wild type; another transgenic line of Nipponbare with increased lysine (33.87%), threonine (21.21%), total amino acids (19.43%), and crude protein (20.45%); Taipei 309 line (IRGC accession 42576) with 2.4, 2.0, 1. 4, and 4.8 fold increased cysteine, glutathione, free methionine, and methionine respectively compared to wild type (Zheng et al. 1995; Lee et al. 2001; Kawakatsu et al. 2010; Wong et al. 2015; Liu et al. 2016; Jiang et al. 2016; Xu et al. 2017; Nguyen et al. 2012).

Transgenic rice lines with enhanced vitamin E are WY3 rice lines transformed with *Arabidopsis* γ-tocopherol methyl transferase (γ-TMT gene/AtTMT) driven by the constitutive maize ubiquitin (Ubi) promoter, ASD16 Indica rice lines transformed with two genes from *Arabidopsis thaliana* [tocopherol cyclase (TC) and homogentisate phytyltransferase (HPT)] involved in tocopherol biosynthesis pathway (Zhang et al. 2013; Sundararajan et al. 2021).

Transgenic vitamin B9 or folate rice with increased folate content are Kitaake (14.5–27.2%) (Dong et al. 2016), second-generation folate-enriched transgenic lines GA9.15 and GA26.5 of japonica rice. Nipponbare with improved folate stability was developed by following folylpolyglutamate synthetase (FPGS) strategy that allows folate polyglutamylation that contains 500 μg of folates per 100 g cooked rice that could satisfy the requirement of an average adult (300–400 μg) in three servings of 100 g cooked rice (Blancquaert et al. 2015).

Transgenic rice with enhanced vitamin B1 was developed from the Japonica variety, Kitaake. transformed with two thiamin biosynthesis genes, 4-methyl-5-β-hydroxyethyl thiazole phosphate synthase (THI) and 4-amino-2-methyl-5-hydroxymethyl pyrimidine phosphate synthase (THIC), under the control of the constitutive ubiquitin promoter having fivefold enhanced thiamine in the unpolished, brown rice grain (Dong et al. 2016). Another *japonica* rice Taipei 309 (TP309) has enhanced vitamin B6 (3.1-fold) transformed with two *Arabidopsis thaliana* genes from the vitamin B6 biosynthesis de novo pathway, AtPDX1.1, and AtPDX2, under the constitutive CaMV 35S promoter (Mangel et al. 2019).

Many transgenic lines with enhanced mineral content are transgenic Fe rice (Table 10). Kitaake was transformed with soybean ferritin, SoyferH-1 gene, under the control of the rice seed storage glutelin gene promoter, *GluB-1*, and the rice seed storage globulin gene promoter, Glb-1 with 3.0-fold Fe and 1.1-fold increase in Zn; *OsNAS3-D1* transgenic rice plants was transformed with nicotinamine synthase gene (*OsNAS3*) driven by 35S promoter, with enhanced Fe (2.9-fold), Zn (2.2-fold), and Cu (1.7-fold); *japonica* cv. Taipei 309 transformed with *Arabidopsis thaliana* nicotinamine synthase (*AtNAS1*), *Phaseolus vulgaris* ferritin (*Pvferritin),* and *Aspergillus fumigates* phytase (*Afphytase)* with 6.3-fold Fe and 1.6-fold Zn. Tsukinohikari was transformed with yellow strip-like gene (*OsYSL2*) driven by the sucrose transporter promoter (*OsSUT1*), with 4.4-fold Fe; the japonica variety 'Xiushui 110' was transformed with the rice nicotianamine synthase gene (*OsNAS1*) fused to a rice glutelin promoter (*GluB1*) with 3.0-fold Fe and 2.7-fold Zn; the "Paw San Yin" Myanmar transgenic variety was transformed with nicotianamine synthase gene HvNAS1 driven by 35S promoter, nicotianamine transporter gene *OsYSL2,* and Fe storage protein gene *SoyferH2* driven by endosperm-specific globulin promoter with 3.4-fold Fe and 1.3-fold Zn increase compared to the wild type (Lee et al. 2009a, b; Qu et al. 2005; Wirth et al. 2009; Ishimaru et al. 2010; Zheng et al. 2010; Aung et al. 2013).

Transgenic lpa rice lines are Kitaake lines with 68% reduction in the PA by suppression of RINO1 gene expression driven by the glutelin B-1 (GluB-1) and 18-kDa oleosin 18 (Ole 18) promoters (Kuwano et al. 2009); PusaSugandhi II (IO6-97) with 69% reduction in PA level developed by silencing the IPK1 gene (inositol 1,3,4,5,6-pentakisphosphate 2-kinase) using the Ole 18 promoter in an RNAi-mediated approach (Ali et al. 2013). Wild rice genotypes (*Oryza rufipogon*) Lua Vang and Lua Hoang of the primary gene pool were reported having a low phytic acid content of 0.930 μg P and 1.395 μg P, respectively (Lang et al. 2007).

Genetically engineered high-resistant starch lines are indica rice variety, Teqing-resistant starch rice line (TRS) enriched with high amylose (60–64.8%) developed

by Antisense RNA inhibition of starch branching enzymes, SBEIIb and SBEI (Zhu et al. 2012). Genome-edited high-resistant starch rice line is *Japonica* cv. Kitaakelines were developed through CRISPR/Cas9-mediated target gene editing of starch branching enzymes, SBEIIb, and SBEI, with a 9.8% increase in resistant starch (Sun et al. 2017).

Genetic engineered rice varieties enriched with phenolics and flavonoids are the transgenic line, Hwa-Young, transformed with maize *C1/R-S* regulatory genes using the promoter of a rice prolamin gene produces numerous kinds of flavonoid compounds in the endosperm; Taichung 65, transformed with regulatory gene OSB2, encodes a transcription factor for anthocyanin synthesis developed by using OSPR 1.1 promoter; GluBpro-Naringenin and Olepro-Naringenin transgenic rice with enhanced flavonoids content were developed by overexpression of maize C1 and R-S regulatory genes [Myb-type and basic helix-loop-helix-type transcription factors:phenylalanine ammonia-lyase and chalcone synthase (CHS) genes]; lines of white rice Nipponbare and Taichung 65 were transformed with Myc-type bHLH gene *OsB2* from the black rice variety Khum by using *Agrobacterium tumefaciens* with enhanced anthocyanin synthesis (Shin et al. 2006; Kawahigashi et al. 2007; Ogo et al. 2011; Sakulsingharoj et al. 2014).

Recently genetically engineered 'Purple Endosperm Rice' (Zijingmi) were developed from the *japonica* variety Zhonghua 11 (ZH11) and the *indica* variety Huaguang 1 (HG1) and transformed with a transgene stacking system (TS II) containing two regulatory genes (maize *leaf color, ZmLc,* which encode the bHLH-type and maize purple leaf, *ZmPl,* which encode the MYB-type transcription factors, that activate the anthocyanin biosynthesis genes) and six structural anthocyanin-related genes from *Coleus*. These are driven by eight endosperm-specific promoters (ESPs) from rice. It has high anthocyanin content and antioxidant activity in the endosperm (Zhu et al. 2017).

p-Coumaroylserotonin and feruloyl serotonin polyphenol compounds are two important serotonin derivatives known for antioxidative activity. Transgenic rice with higher radical scavenging activities express pepper hydroxycinnamoyl-CoA: serotonin N-(hydroxycinnamoyl) transferase gene. This transgenic rice was observed with a serotonin content of 274 ng/g seed weight ninefold higher than wild type (30 ng/g seed weight) (Kang et al. 2005).

Coenzyme Q (CoQ), or ubiquinone, is a lipid-soluble antioxidant. It is also an electron transfer molecule in the respiratory chain. Most cereal crops produce mainly CoQ9, which has nine isoprene units. At the same time, CoQ10 is the typical food supplement human beings use. Transgenic rice CoQ10 (Nipponbare) introgressed with decaprenyl diphosphate synthase is responsible for synthesizing 10 isoprene units for the CoQ side chain from Gluconobacter suboxydans 3 are able to produce 1.3–1.6 times more CoQ10. This gene was transferred into rice sugary and shrunken mutants of Nipponbare deficient in starch biosynthesis and had a wrinkled seed (Takahashi et al. 2010).

During rice domestication, wild rice species having pigmented pericarp (Rc) were deselected for nonpigmented pericarp rice having an independently evolved loss-of-function mutation *rc* (C → A substitution in exon 7). However, in US and Italian

cultivars, the two reversal (rc to Rc) mutations are found, 1-bp deletion located 20-bp upstream and 1-bp deletion located 44-bp upstream of the original 14-bp deletion, respectively, and many more might be present in the cultivars available across the world. Sequence analysis of the 4 MB region around the Rc in 156 rice indicates that the reverse mutations are not responsible for pigmentation in weedy rice, which contains haplotypes that are either rare or absent in cultivated rice (Gross et al. 2011). Therefore, it appears reasonable to sequence this region in all accessions or core sets of pigmented rice to understand this phenomenon.

A multidrug resistance-associated protein (*Os*MRP) activates a membrane-bound protein (*Os*MRP15) that aids in anthocyanin uptake into the vacuole. The introduction of nonsense mutation in OsMRP15 gene (CRISPR/Cas 9) resulted in the formation of green leaves in the mutant, while the wild-type leaves were purple (Ma et al. 2015). The expression of anthocyanin synthesis genes is activated by binding the MYB (myeloblastosis) proteins to DNA. Rice has multiple gene copies (paralogues) responsible for production in different patterns or cell types. Many transgenic rice varieties show purple and black endosperm, having good nutritional and medical values that are useful to the nutraceutical and pharmaceutical industries.

4 Genomics-Aided Breeding for Health-Related Traits

With recent advances in high-throughput sequencing, phenotyping platforms, and genotyping technologies, molecular breeding has been transformed into genomics-aided breeding (Kole et al. 2015). Both classical genetics and NGS platforms, a sequencing-based trait mapping, aid in identifying/mapping nutrition traits at a higher resolution (Sinha et al. 2021). Genome-wide association analyses have elucidated the genetic architecture, marker–trait association, and haplotypes in different populations and germplasm panels (Sahu et al. 2020). Genetic analysis of both GWAS and genomic selection (GS) helps precise nutritional enrichment in rice grain (Zaghum et al. 2022). A core collection of 3000 rice accessions (3K) has been screened for large-scale discovery of novel alleles for different traits by applying various bioinformatics and genetic approaches. Key genes influencing Fe and Zn have been surveyed in the 3K rice genome panel (Abbai et al. 2019). Implementing advanced genomics, transcriptomics, nutrigenomics, and proteomics-based technologies enhances and regulates the nutritional value of rice.

4.1 GWAS

In rice, the GWAS approach has been demonstrated to identify several genes and genomic regions associated with important agro-morphological traits (Huang et al. 2012, 2015). GWAS is based on genetically diverse genotypes with several historic recombination events and high-throughput markers like single-nucleotide polymorphisms (Crowell et al. 2016; Yano et al. 2016). Using SNP markers, genomic regions for grain nutrients and bioactive compounds have also been identified in rice using

genome-wide association studies (GWAS) (Norton et al. 2014, Zhang et al. 2014; Pradhan et al. 2020; Bollinedi et al. 2020; Cu et al. 2021; Alpuerto et al. 2022) and also in multi-parent advanced generation inter-cross (MAGIC) population (Descalsota et al. 2018).

4.2 Sequencing/Resequencing

After completing the International Rice Genome Sequencing Project, several rice genotypes have been sequenced and assembled, resulting in high-quality genome sequences in rice with the advent of high-throughput short-read and long-read sequencing technologies (IRGSP 2005). Highly continuous and accurate chromosome-level assemblies with minimum gaps are made possible by deploying ultra-long reads and new assembly tools. Using low-cost sequencing technologies leading to resequencing of the popular donors and functional genomics approach, candidate genes associated with nutrient metabolism are being identified (Wang and Han 2022).

4.3 Wild Species

Wild rice species is a valuable resource of several agro-morphological traits such as yield, quality, and resistance to biotic and abiotic stresses (Fan et al. 2019). Identifying new genes or genomic regions associated with nutrients and antinutrients in wild species appears promising, as reported in *Oryza rufipogon* and *Oryza longistaminata* (Garcia-Oliveira et al. 2009; Anuradha et al. 2012; Hu et al. 2016; Liu et al. 2020). Recent genome sequencing projects involving wild rice species have revealed enormous sequence and allele diversity that can be fully exploited and utilized in rice improvement programs (Jacquemin et al. 2013; Mussurova et al. 2020). Marker-delimited genomic region for Fe and Zn contents from *O. longistaminata* could be a basis for subsequent gene cloning (Liu et al. 2020).

4.4 3K Rice Panel

A germplasm panel constituting 3010 genotypes (3K) from the core collection of Asian cultivated rice germplasm from 89 countries was resequenced by the International Rice Research Institute (IRRI) and Chinese Academy of Agriculture Science (Wang et al. 2018). This resource is now being phenotyped worldwide for various traits toward identifying genes/genomic regions for traits of interest. Genotype data is available as 29 million single-nucleotide polymorphisms (SNPs), around 2.4 million small insertions and deletions (indels), and >90,000 structural variants for 3K with 23,876 gene families, 14,826 core genes, and 9050 species-specific genes/gene families (Sun et al. 2017). The most exciting aspect was the 12,465 novel genes identified in the 3K panel, which were not present in the Nipponbare reference

genome. 3K has also been characterized for gene–coding sequence–haplotype (gcHap) diversity of 45,963 rice genes (Zhang et al. 2021). The 3K panel has been preliminarily surveyed for nutrient-related genes in rice (Abbai et al. 2019).

4.5 Genomic Selection

The methodology of GS comprises the prediction of genome-estimated breeding values from a training population with known genotype and phenotype and the prediction of the phenotype of the test population without the genotype information (Crossa et al. 2017). The GS strategy can be applied in rice breeding as genotype information is available for several germplasm panels and has been successfully demonstrated in hybrid prediction, grain filling, and other agro-morphological traits (Xu et al. 2018). According to the breeder's equation, even a slight increase in predictive ability can be converted into a massive gain with a vigorous selection intensity (Xu et al. 2021b). By deploying a synthetic population comprising upland rice cultivars and evaluating at two locations, the early genomic prediction has reported a predictive ability of 0.51 for grain Zn concentration (Baertschi et al. 2021).

4.6 Functional Genomics

While the structural genomics of rice has been deciphered through genome sequencing, functional genomics of identified genes is essential to validate the function and characterization of identified genes. Many genes have been characterized by the generation of full-length cDNA libraries, gene expression microarrays, and RNA sequencing technologies (Li et al. 2018). Two cDNA databases of *japonica*, Knowledge-Based *Oryza* Molecular Biological Encyclopedia (KOME) and *indica* as Rice indica cDNA Database (RICD), are made available. The specific expression profiles of various tissues for hybrid and its parental lines are also being deposited in the collection of the Rice Expression Profiles (CREP) database. Another database that rice researchers extensively use is the Rice Expression Profile Database (RiceXpro), which is a repository of gene expression profiles derived from microarray analysis of tissues and organs across the entire growth of the rice plant. RNA sequencing is another methodology that is frequently applied to identify tissue, stage, and situation-specific gene expression that is being deployed to characterize various genes associated with grain nutrient metabolism (Neeraja et al. 2018; Kar et al. 2021; Li et al. 2020). Gene expression databases constituting functionally related genes in various biological pathways and metabolic processes are also available.

4.7 Bioinformatics

With the application of various next-generation sequencing (NGS) technologies, several public databases are made available for genome sequences, transcriptomes,

proteomes, metabolomes, and phenotype traits. Several bioinformatics websites are available for genome annotation, gene expression, gene function, and interaction (Li et al. 2018; Jia et al. 2021; Chen et al. 2022). Recent bioinformatics databases in rice also encompass information about both functional and regulatory elements. A few comprehensive databases include information about genotypes, genome sequence and phenotypes such as SNP-Seek, RiceVarMap, and Rice Pan-genome Browser (RPAN) (Zhao et al. 2015; Sun et al. 2017; Mansueto et al. 2017).

4.8 Whole-Genome Selection and Breeding Chips

Based on publicly available genome information, several SNP chips ranging from low to high resolution have been developed for genetic diversity analyses, QTL identification, genome-wide association studies, marker-assisted selection, and genomic selection such as RICE6K, with 5102 SNPs and indels, with an average spacing of 6.4 kb between adjacent SNPs (Yu et al. 2014; Thomson et al. 2017); RICE60K (also known as RiceSNP50) with 43,386 SNPs and RICE90K with 85,000 SNPs (Chen et al. 2014; Qiu et al. 2018). Another 50K chip with 50,051 SNPs from 18,980 different genes spanning 12 rice chromosomes, including 3710 single-copy (SC) genes conserved between wheat and rice, 14,959 SC genes unique to rice, 194 agronomically essential cloned rice genes, and 117 multi-copy rice genes were also made available (Singh et al. 2015). A 700 K rice and 44K array chips were also developed mainly for GWAS (McCouch et al. 2016; Zhao et al. 2011). Recently 1k-RiCA chip with 995 SNPs with an average 1.53 cM marker distance was also made available to be deployed by breeders (Arbelaez et al. 2019).

4.9 Genomics-Assisted Breeding

Taking a cue from the Green Super Rice strategy, the following methodology is being proposed for developing varieties with high grain nutrient levels (Yu et al. 2022b). Identifying a recipient parent, mostly an elite cultivar with desirable yield levels and quality parameters, and its characterization through whole-genome sequencing is essential. Further identification of a matching donor with target alleles, viz., high grain nutrient followed by the most efficient scheme of crossing, thus generates a series of near-isogenic lines (NILs), which can be directly evaluated for varieties and as parents for stacking genes. Further, designed QTLs pyramiding combining key grain nutrient traits from promising selective-introgression lines (SILs) were derived from different donor lines but with a common recipient parent. These essential nutritional traits could be genetically mapped and, at the same time, since they are already in elite backgrounds, could be quickly released as varieties with superior nutritional value. Further, designed QTL pyramiding of the nutritional traits from different donor backgrounds could be stacked into a common recipient parent by crossing the different SILs in less than 3 years.

5 Role of Genome Editing Technology in Rice Nutritional Quality Improvement

Among several strategies/approaches toward supporting the development of rice biofortified genotypes, CRISPR-based genome editing appears to be the most promising owing to its targeted gene editing (Kumar et al. 2022). Because of its straightforward design, low methodology cost, high efficiency, good reproducibility, and quick cycle, this system is being deployed in several crops like rice, wheat, barley, maize, potato, and tomato. Several genes for grain dimension, viz., *Gs3*, *Gn1a*, *GL2/OsGRF4*, *OsGRF3*, *GL3.1*, *OsGBSSI,* and *Wx,* were targeted for genome editing (Shen et al. 2018; Hao et al. 2019; Zhou et al. 2019; Yuyu et al. 2020; Huang et al. 2020; Achary and Reddy 2021). The aroma was also enhanced through gene editing of the *BADH2* gene (Ashokkumar et al. 2020; Hui et al. 2022).

The genes for (GABA) content were phytic acid and protein content (Akama et al. 2020; Khan et al. 2019; Wang et al. 2020).

The precision and specificity of genome editing can be utilized to engineer metabolic pathways controlling nutraceutical properties of major crop produce. The successful knockout of FAD2-1A, FAD2-1B, and FAD3A genes by TALEN was employed in soybean to enhance the oleic acid content >80% in oil. These genes play a central role in metabolizing the oleic acid (monounsaturated fatty acid) into linoleic acid (polyunsaturated fatty acid) (Demorest et al. 2016). Recently, biofortified tomatoes enriched with vitamin D have been developed using genome editing. 7-Dehydrocholesterol reductase (Sl7-DR2) gene was knocked out using CRISPR/Cas9 for higher accumulation of provitamin D3 in genome-edited tomatoes. In rice also, increased resistant starch and low casein accumulation traits have been attempted by targeting SBEI, SBEIIb, and OsHAK-1 genes through CRISPR/Cas9 approach. These genes regulate amylose content and calcium uptake phenotypes (Nagamine and Ezura 2022). The key regulatory genes regulating grain iron and zinc content in rice can be edited through various approaches of genome editing, including base editing and prime editing, to create superior alleles in popular rice cultivars. This approach can be instrumental in achieving the mission of nutritional security.

6 Conclusion

Rice, the paramount grain for ages, has shaped human civilization and played a critical role in food security. With the increasing population, the concomitant development and release of high-yielding rice cultivars played a significant role in feeding >7.98 billion people on this planet. The past two decades have brought revolutionary changes in breeding technologies. We have witnessed the wise and efficient use of marker-assisted breeding, genomics, transgenics, and genome editing to accelerate breeding efforts and make them more precise and targeted. Several cultivars with added traits of economic importance have been developed using these biotechnology-based breeding approaches. In particular, CRISPR/Cas9 genome

editing technology can address many unsolved breeding questions and can be smartly used to breed new cultivars for present and future needs (Fig. 6).

While food security will always remain a primary goal, nutrition security is equally essential, specifically in the developing world. Special programs by various governments have been implemented to minimize the adverse effects of malnutrition. However, it is still prevalent in places where rice constitutes the central portion of the diet. Therefore, enriching the rice grain with micronutrients and vitamins can address the severe issue of malnutrition. New genomics and genome modification approaches can be used to biofortify rice crops. In addition to discovering new genes and alleles, the known genes and natural genetic variations must be exploited through breeding and genetic engineering to develop biofortified rice varieties. The regulatory genes and transcription factors determining the loading of micronutrients in rice grain are primary targets for making the rice grain more nutritive. In addition, efforts should be made toward reducing the antinutritional factors such as phytate in rice grain. Targeted breeding programs and the introduction of nutrition-rich rice in the food supply chain will play a key role in achieving the goals of "food and nutritional security." To promote the cultivation of biofortified crops, incentives by the government and special prices for farmers' produce will significantly impact the success of these programs. The goal of zero hidden hunger and starvation is achievable with the focused and coordinated efforts of researchers, funding agencies, policymakers, industries, and farmers.

Abstract

Wheat is humanity's second most important cereal crop, consumed widely in developed and developing countries and constituting a major source of protein and energy, especially in the developing world. Wheat grain, including the bran and endosperm, furnishes diverse macro-and micronutrients required for the normal physiological and biochemical functioning of the human body. Dietary deficiencies of micronutrients such as iron (Fe) and zinc (Zn) lead to severe health consequences in children below 5 years of age and in pregnant women and lactating mothers. Increasing the nutritional value of wheat grain can largely address micronutrient malnutrition for the world's growing population. The recent availability of wheat genome sequence library in the public domain, together with the expanding horizon of next-generation sequencing, and genome editing technologies, holds great promise for trait-based molecular breeding to develop nutrient-rich wheat cultivars. Modern biofortification techniques, including conventional breeding, transgenics, and agronomic biofortification, have already increased wheat grain nutrient content and the nutrient-rich biofortified wheat cultivars grown over 2 million ha area in South Asia & Latim America. This chapter discusses the importance of wheat in the human diet, wheat grain's nutritional composition, and advances in molecular and transgenic and genome editing approaches to develop health-related traits in wheat grain.

Micronutrients · Malnutrition · Genome editing · Genomic selection · QTLs · Genetic engineering

1 Introduction

1.1 The Importance of Wheat

Wheat, an annual herb belonging to the family Gramineae or Poaceae, is a food crop grown and consumed in nearly 100 countries and imported and consumed in many others where western-style diets are being adopted (Cummins and Roberts-Thomson 2009; Shewry 2009). Common hexaploid wheat (*Triticum aestivum* L., 2n = 6x = 42, AABBDD) is one of the most important staple crops in the world, serving as a key food source for 30% of the human population and contributing approximately 20% of its energy needs (calories) and 25% of its dietary protein (Borisjuk et al. 2019). Its grain is used in bread, supporting the baking industry, and popular foods such as chapatis, noodles, and cookies, to name just a few. Worldwide wheat cultivation ranges from 67° N in Scandinavia and Russia to 45° S in Argentina, including elevated regions in the tropics and sub-tropics (Feldman 1995; Shewry 2009). About 95% of wheat grown worldwide is hexaploid bread wheat (*Triticum aestivum* L.), with most of the rest being tetraploid durum wheat (*T. turgidum* var. *durum*), which

is adapted to dry, Mediterranean climates and used in pasta. Minor amounts of primitive wheats are also grown mainly for specialty health foods, including einkorn (diploid *Triticum monococcum*), emmer (tetraploid *T. turgidum* var. *dicoccon*), and spelt (hexaploid *T. aestivum* var. *spelta*) in certain areas of Spain, Turkey, the Balkans, and the Indian subcontinent. The latter differs from bread wheat essentially in that the hull is not removed by threshing, resulting in a higher fiber content when consumed as whole grain (Brouns et al. 2013).

Cultivation of wheat started about 10,000 years ago as part of the Neolithic Revolution, when humans switched from hunting and gathering to settled agriculture. The earliest cultivated forms were diploid (einkorn with genome AA) and tetraploid (emmer with genome AABB) wheats from southeastern Turkey (Brouns et al. 2013; Dubcovsky and Dvorak 2007). Hexaploid bread wheat (AABBDD) is believed to have emerged some 9000 years ago through spontaneous hybridization between a cultivated tetraploid (*Triticum turgidum;* AABB) and goat grass (*Aegilops tauschii;* DD) (Brouns et al. 2013; Feldman 2001). The earliest cultivated forms were landraces presumably selected from wild populations by ancient farmers, considering their superior yield and other agronomical important characteristics, a domestication that separated modern wheat genetically and phenotypically from its wild relatives and early forms.

Wheat grain production amounted to over 780 million tons (t) harvested from more than 225 million hectares (ha) in 2019–2020 (http://www.fao.org/faostat); but wheat is still the third major food crop, lagging behind maize and rice both in yield and the application of genomic tools for crop improvement (Borisjuk et al. 2019; Uauy 2017). Average wheat yield worldwide increased nearly three-fold during the Green Revolution of the mid-to-late twentieth century, largely due to expanded irrigation, intensive fertilizer application, and advanced breeding methods (Evenson and Golin 2003a), but the current global average yield around 3 t/ha is far below the crop's genetic potential (Langridge 2013), aside from yield gaps relating to crop management. As estimated by Langridge (2013) and Henry et al. (2016), to meet the wheat consumption demands (expected to rise 1.6% annually) of an estimated 9.5 billion world population by 2050, wheat yields should grow by over 60% to approximately 5 t/ha, coupled with maintaining or improving its nutritional characteristics and using currently available land. Facing this challenging scenario, which includes rising temperatures and alarming water scarcities, the emphasis must be on improved productivity and adapting to environmental challenges (Borisjuk et al. 2019).

1.2 Wheat's Importance in Times of Chronic Disease and Malnutrition

Malnutrition can be classified as under-nutrition (hunger, micronutrient malnutrition/hidden hunger) and over-nutrition (overweight/obesity). For malnourished children under 5 years of age, 149 million are stunted, 49.5 million are wasted, and 40 million are overweight (Development Initiatives 2020; Poole et al. 2021). About 45% of

mortality among children aged five and below is associated with malnutrition, chiefly in low- and middle-income countries. In the early 2000s, more than 3 billion people were micronutrient malnourished (Šramková et al. 2009). More recently, some 528 million (29%) women of reproductive age are anemic from a lack of dietary iron, making iron deficiency the most widespread micronutrient deficiency in the world (Choge 2020). Dietary deficiencies of zinc, a critical micronutrient, are widespread, accounting for malnutrition-related developmental impediments across all age groups. Lethal effects amount to 800,000 child deaths annually, with vulnerability concentrated in sub-Saharan Africa and South Asia. Staple cereals such as wheat are significant sources of both minerals, contributing 44% of the daily intake of iron (15% in bread) and 25% of the daily intake of zinc (11% in bread) in the UK (Henderson et al. 2007; Shewry 2009). According to an estimate, almost 690 million people suffered from hunger in 2019, worsened by the worldwide COVID-19 health pandemic. The number of hungry people is expected to exceed 840 million by 2030 – almost 10% of the global population (Poole et al. 2021). While humankind is fighting malnutrition on one front, over-nutrition is increasing globally: nearly half of the world's adult population is overweight or obese, and three-quarters of those persons live in low- and middle-income countries (Poole et al. 2021). Worldwide incidences of diabetes (44%), ischemic heart disease (23%), and certain cancers (7–41%) are linked to being overweight and obese.

Child stunting often results from micronutrient malnutrition tied to imbalanced diets in children and mothers, especially among the poor. Food-based approaches to prevent malnutrition and which focus on micronutrients can help address "hidden hunger." Cereal-based allergies and intolerance have also posed serious concerns. Major chronic diseases include obesity, heart ailments, cancer, and celiac disease, among others, taking a heavy toll on health and the world economy. In the current context of chronic diseases, wheat, its bioactives, and products assume relevance and need to be deliberated in a multifarious context.

1.3 The Limitations of Conventional Breeding and Rational for Next-Generation Breeding: Nutritional Perspectives

Wheat underwent hybridization and genome duplication to generate its hexaploid genome ($2n = 6x = 42$, AABBDD). Bread wheat possesses a sesquipedalian genome – 17 gigabases – which is over 5 times larger than the human genome and 40 times the size of the rice genome. Recent estimates document 107,891 high-confidence genes in bread wheat, with over 85% repetitive DNA sequences, representing a three-fold redundancy associated with being hexaploid. Every year, conventional commercial breeding produces a large number of new crop varieties to improve productivity and nutrition, strengthen food security, and increase consumer acceptability (Govindan et al. 2022). The conventional breeding process has evolved to provide an effective framework for improving crop performance while also assisting in the development of safe and nutritious foods. Conventional plant breeding entails identifying desirable parents in order to create favorable combinations in the next generation (Kaiser et al. 2020). This selection of a few individuals

from a large population is an important component of the plant breeding process (Kaiser et al. 2020). Conventional breeding has made significant contributions to large-scale cultivation, yield potential, and the frequency of desirable traits in wheat; however, it has certain boundaries that should be considered under current conditions, and a new wheat breeding strategy is required (Borisjuk et al. 2019).

Wheat's hexaploid genome and associated functional gene redundancy make genetic advances to selecting a desired phenotype difficult, if not impossible, due to gene linkage or gene drag. Further advancement in wheat breeding is dependent on understanding of functional genomics. Grain yield and quality can be improved by identifying the most important key genes, as well as their structures, roles, and functions in wheat plant development. This functional genomics knowledge can then be used to change the structures and functions of selected key genes via genetic manipulation (Borisjuk et al. 2019), a broad term used here to describe molecular methods whose products fall outside the traditional definition of "genetically modified" (GM) such as RNA interference (RNAi) and clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein (CRISPR/Cas9) Borisjuk et al. 2019). Such approaches will be critical in determining the functions of wheat genes. By using cutting-edge technology like genome sequencing and targeted mutations using genome editing methods like CRSPR-Cas and RNAi, it is possible to increase the resilience of wheat while reducing environmental pollution (Gupta and Karkute 2021). However, the use of CRISPR/Cas systems depends on knowledge of the targeted gene's sequence. Through homology directed repair (HDR), precise substitution of an existing allele has substantially benefited crop improvement with elite alleles in commercial types. Base editing, prime editing (PE), genome sequencing, genome-wide association study (GWAS), speed breeding, high-throughput genotype and phenotype profiling, and synthetic biology are a few examples of contemporary methods (Gupta et al. 2022). The ability to accurately replace one base with another by base editing, an alternative and powerful method for HDR-mediated gene replacement, has made it possible to accurately replace an allele with a single nucleotide polymorphism (SNP) (Komor et al. 2016). Many base substitutions (12 types) and minor insertions-deletions (indels) are made possible by prime editing (PE), which increases the reach and potential of precision genome editing. Recent studies have shown that RNAi, a frequent mechanism for controlling gene expression in eukaryotic cells, is a reliable tool for functional genomics and the engineering of novel phenotypes. The method relies on the expression of small interfering RNA (siRNA) molecules, such as antisense or hairpin RNAi constructs, to affect post transcriptional gene silencing in a sequence-specific manner (Borisjuk et al. 2019). RNAi applications in wheat.

2 Detailed Nutritional Composition of the Wheat Grain

Grain is the harvested and economically important part of the wheat plant, and its biochemical composition determines its nutritional and health properties (Shewry 2009). Table 1 details the generalized composition of various chemical constituents. On a dry weight basis, a wheat grain can be divided into three distinct parts: mealy

Table 1 Contents and variations in chemical composition of wheat grains (dry weight)

Parameter	Range (%)	References
Carbohydrates (%)	85	Stone and Morell (2009)
Starch (20–30% amylose and 70–80% amylopectin)	55–75	Borisjuk et al. (2019)
Dietary fiber/non-starch/cell wall polysaccharides (%)	11.5–15.5	Andersson et al. (2013)
Fats (%)	2.0–2.5	Gonzalez-Thuillier et al. (2015)

endosperm (80–85%), outer bran (13–17%), and germ (2–3%). (Belderok et al. 2000). The endosperm occupies the majority of the wheat grain, primarily consisting of starch and proteins with small amounts (2%) of fiber. The endosperm provides energy to the seed, making available carbohydrates and proteins during germination. The germ, the smallest segment of grain, contains lipids, sterols, antioxidants, vitamins (B, E), minerals, and enzymes, as well as nourishing the seed. The bran is a seed's outer shell that contains fiber, vitamins, and trace minerals. The outer pericarp (3–5%) contains insoluble dietary fibers and bound phenolic acids (which act as antioxidants), whereas the aleurone layer (6–9%) contains dietary fibers, proteins, enzymes, phenolic compounds, vitamins (B-complex), minerals, and phytates. The testa (1% of the total) contains trace amounts of alkylresorcinols, sterols, and steryl ferulates. Wheat bran may typically contain dietary fiber (42.8%), other carbohydrates (21.7%), protein (15.6%), ash (5.8%), and lipids (4.3%).

There is a need for suitable and efficient methods to test diverse wheat genotypes for various quality parameters, as documented in the updated listing by Gupta et al. (2022). Model-based methodologies are being developed to identify superior wheat lines in early generations of breeding cycles (Mohan et al. 2022).

2.1 Carbohydrates

Carbohydrates account for the majority of wheat grain (up to 85%) (Stone and Morell 2009). Starch accounts for the majority of stored carbohydrates, accounting for 55–75% of grain dry weight (Borisjuk et al. 2019). Fibers and low-molecular-mass mono-, di-, and oligo-fructans are examples of others (Table 1). Wheat grain starch is found in either large lenticular granules of 25–40 m, which develop during the first 15 days after pollination, or small spherical granules of 5–10 m, which develop 10–30 days after pollination and account for approximately 88% of total grain starch granules (Belderok et al. 2000). Starch is a polymeric form of glucose that is chemically classified as amylose and amylopectin. Amylose has a molecular weight of around 250,000 and may contain nearly 1500 glucose units with wide variations. Amylose is thought to have a linear polymer structure, with -(1,4)-glycosidic linking glucose moieties together and a degree of polymerization (DP) of 1000–5000 glucose units. The structure of this polymer was previously assumed

to be primarily linear, but this appears to be true for only a portion of the amylose; the remainder is slightly branched. The branching in amylopectin is to a much greater extent than in amylose and the average unit chain of amylopectin has only 20–25 glucose molecules, with an average molecular weight of about 10^8. Amylopectin is a much larger polymer with a DP ranging from 105 to 106 glucose units tethered via α-(1,4)-linked glucose polymers, which are further connected by α-(1,6)-linkages (5–6%).

2.2 Dietary Fiber

Dietary fiber is defined as lignin plus plant polysaccharide components that are indigestible by human digestive enzymes. While soluble fiber (pectic substances, hydrocolloids, -glucans) is water soluble, insoluble fiber (cellulose, hemicellulose, lignin, arabinixylans) is not. Regular consumption of dietary fiber, which is primarily found in whole grains, protects against heart disease, hypertension, hyperlipidemia, type 2 diabetes, obesity, constipation prevention, diverticular disease, esophageal disease, and a variety of cancers (Poole et al. 2021; Weickert and Pfeiffer 2008). Soluble fiber such as β-glucan [(1→3,1→4)-β-D-glucan] effects glycemic index and appears to help prevent chronic diseases like diabetes and obesity and, possibly, negative effects associated with FODMAPS (fermentable oligo-, di-, monosaccharides and polyols) (Poole et al. 2021). Arabinoxylans (AX) and (1→3), (1→4)-β-glucans are housed primarily in wheat endosperm cell walls. Arabinoxylans yield short-chain fatty acids, particularly butyrate, in the colon. It is conjectured that high butyrate concentrations in the colon improves bowel health and lower cancer risk.

2.3 Proteins

Proteins are required for various body functions, ranging from enzymatic, structural to locomotory and many more. Protein content in wheat grain ranges from 10 to 15% (dry wt.) (Borisjuk et al. 2019). Wheat proteins are classified according to their extractability and solubility as per Osborne and have been highlighted in Table 2 In general, cereal proteins are low in the essential amino acids lysine (1.5–4.5% vs. 5.5% of WHO recommendation), tryptophan (Trp, 0.8–2.0% vs. 1.0%), and threonine (Thr, 2.7–3.9% vs. 4.0%).

2.4 Lipids

Lipids are present in small amounts (2–2.5%) in wheat but have a significant impact on food quality and texture because they can bind to proteins and starch to form inclusion complexes. The germ contains nearly 11% of total lipids, but significant amounts are also associated with the endosperm's bran, starch, and proteins

Table 2 Types of wheat proteins with their solubility and other features

Protein name	Solubility	% of Total protein	Features
Albumins	Water soluble	Smallest in size (10%)	Most of physiologically active enzymes belong to these two; both proteins are present in the seed coat, the aleurone cells and the germ, with a lower concentration in the mealy endosperm; both make up 20–25% of total wheat proteins
Globulins	Insoluble in pure water; soluble in dilute NaCl solutions, but insoluble at high NaCl concentrations	Size more than albumins (10%)	
Gliadins	Soluble in 70% ethyl alcohol	Size more than above two (45%)	High-molecular-weight storage proteins for future use by the seedling located in the mealy endosperm; both constitute 75–80% of total wheat proteins; both are unique, being biologically active: though they have no enzyme activity, they function in dough formation through gas retention, producing spongy baked products
Glutenins	Soluble in dilute acid or sodium hydroxide solutions	Low- and high-molecular-weight types (35%)	

Source: Belderok et al. (2000), Borisjuk et al. (2019), Šramková et al. (2009)

(Poole et al. 2021). All fractions contain significant amounts of free fatty acids and triacylglycerols (Gonzalez-Thuillier et al. 2015). Phosphatidyl choline, phosphatidyl ethanolamine, and phosphatidyl serin are the most common bound lipids, followed by lysophosphatidyl derivates with one free hydroxyl group on the glycerol moiety. The main sterols were identified as -sitosterol, campesterol, and saturated sterols C28 and C29. Numerous studies have shown a high level of linoleate (C18:2) in both the total lipid and the triglycerides.

2.5 Vitamins

Over 3 billion people are currently micronutrient malnourished, which means their diets are deficient in micronutrients such as vitamins. Vitamins are a diverse group of food-based, essential, small organic substances that are synthesized by plants and microorganisms rather than the human body. They do not provide energy but are essential micronutrients for humans, acting as coenzymes or their precursors (niacin, thiamin, biotin, pantothenic acid, vitamin B6, vitamin B12, and folate) or in specialized functions such as vitamin A in vision and ascorbate in specific hydroxylation reactions. Vitamins play roles in human genetic regulation and genomic stability (folic acid, vitamin B12, vitamin B6, niacin, vitamin C, vitamin E, and vitamin D) as well as antioxidative defense systems (vitamins C and E and some carotenoids) (Poole et al. 2021). The vitamins in wheat and their range are presented in Table 3.

Table 3 Vitamins, phenolics, minerals, and anti-nutritional factors composition in wheat grains

Major component	Name	Range	References
Vitamins	Vitamin B1 (Thiamine) (mg/kg)	5.53–13.55	Shewry et al. (2011)
	Vitamin B2 (Riboflavin) (mg/kg)	0.77–1.40	
	Vitamin B3 (Niacin) (mg/kg)	0.16–1.74	
	Vitamin B5 (Pantothenic acid) (mg/kg)	0.88–4.04 (Durum)	Tekin et al. (2018)
	Vitamin B6 (Pyridoxine) (mg/kg)	1.44–3.05	Batifoulier et al. (2006)
	Vitamin B9 (Folates) (mg/kg)	0.323–0.774	Piironen et al. (2008)
Minerals	Magnesium (mg/kg)	600–1400	Oury et al. (2006)
	Iron (mg/kg)	18–40	Ram and Govindan (2020)
	Zinc (mg/kg)	21–63	
	Copper (mg/kg)	1.8–6.2	
	Manganese (mg/kg)	24–37	
Phenolics	Phenolic acids (μg/g)	326–1171	
Anti-nutritional factors	Phytic acid (mg/g)	12–18	

2.6 Tocols

The germ fraction of t einkorn accessions and some bread wheat seed showed the highest concentrations of -tocopherol and total tocols. The bran fraction had the highest levels of -tocotrienol, but significant amounts were also found in the flour.

2.7 Minerals

Table 3 summarizes the minerals that are available in wheat, as well as their generalized availability ranges. The topic of two vital minerals, iron and zinc, has been addressed here. Plants primarily store iron in the form of ferritin structures, which accumulate primarily in non-green plastids, etioplasts, and amyloplasts (Borisjuk et al. 2019). Iron has been found primarily in the aleurone layer (bran) of wheat grains, where it has complexed with phytate (myo-inositolphosphate 1,2,3,4,5,6-hexa-kisphosphate). These complexes are insoluble, limiting iron bio-availability in humans and livestock. Scientists are experimenting through breeding to express phytase enzymes in developing grain and thus increase mineral availability. The discovery of a heat-stable form of this enzyme would allow phytate complex hydrolysis to occur during food processing. Another option is to increase the concentration of Fe in grains. In 1994, Fe concentrations in a wheat variety grown at the CIMMYT research station in El Batán, Mexico, ranged from 28.8 to 56.5 mg/kg (mean = 37.2 mg/kg). Peleg et al. (2008) reported new wild emmer wheat accessions with very high Fe (up to 88 mg/kg) and Zn (up to 139 mg/kg)

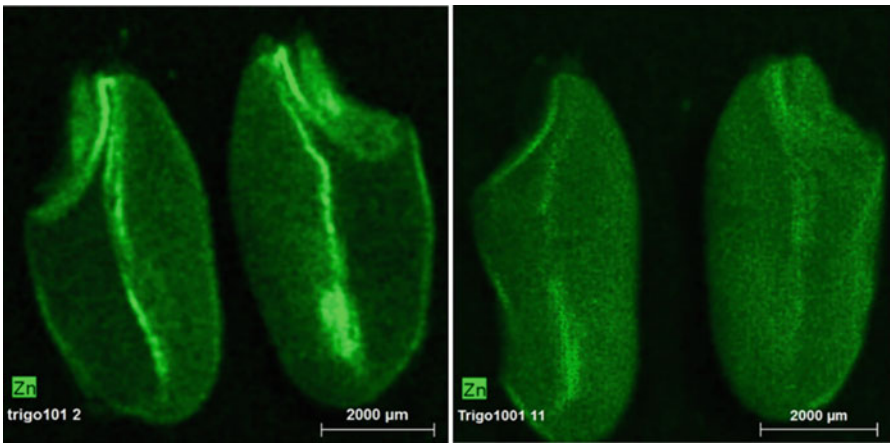

Fig. 1 Localization of zinc in wheat grain with µXRF (left high zinc wheat 'Zinc-shakti', right CIMMYT control variety 'Baj')

concentrations, as well as high protein content (up to 380 g/kg) and tolerance to drought and Zn-deficient soils.

Zn deficiency causes nearly 500,000 deaths in children under the age of five each year (Borisjuk et al. 2019). Micronutrient levels in modern elite wheat cultivars are typically suboptimal. Given the high concentrations of Zn and Fe in the outer husk, aleurone, and embryo, both micronutrients are lost during milling and polishing. Phytate, an anti-nutritional factor, reduces micronutrient availability in the human digestive tract. Zn deficiency affects nearly 33% of the world's population, resulting in health complications such as stunted physical development, weakened immunity, and decreased learning ability, among other things. According to a variety of reports and survey studies, the average Zn concentration in whole wheat grain is from 21 to 63 mg/kg (Ram and Govindan 2020). Most of wheat grain Zn is in the embryo and aleurone layer, with a small portion in the endosperm (Fig. 1).

3 Marker-Assisted Breeding for Health-Related Traits

Genetic tools can accelerate genetic gains for yield and stress resilience by assisting in precise and accurate selection, saving time, money, and labor in crop improvement. Breeding approaches combine modern cutting-edge genomic tools and breeding tools to accelerate breeding progress. Molecular marker-assisted selection (MAS), backcross breeding (MABB), and recurrent selection (MARS) aid in the early identification of favorable alleles for economically important traits (Bonnett et al. 2005). It should also be noted that the requirements for selecting markers, as well as overestimation of marker effects with minor contributions, can limit the effectiveness of using molecular markers in MAS. In wheat, MAS aids in the improvement of agriculturally important traits by allowing efficient screening of

difficult-to-estimate traits, the transfer of genomic regions from genetic stocks rich in desirable traits into better backgrounds, and the pyramiding of different polygenic characters. The discovery of numerous QTL-specific molecular markers for monogenic and polygenic traits in recent years has accelerated the deployment of molecular markers for regions associated with biotic and abiotic resistance, as well as other economically important traits. The cost of more precise genotyping, high-throughput genotyping and phenotyping, and the use of imaging and computational traits have all reduced the cost of biotechnological tools.

3.1 Germplasm Characterization

The high level of variability in nutritional traits found in wild relatives and land races of wheat allows for the development of high-yielding nutrient-rich wheat varieties (Cakmak 2008). The traits required for desirable processing and end-use quality, as well as nutritional traits, are being transferred from wild relatives of wheat, such as *Aegilops tauschii*, *Triticum turgidum* ssp. *diccocoides*, *Triticum turgidum* ssp. *dicoccum*, and *Triticum aestivum* ssp. *spelta* species, to high-yielding bread wheat lines that feature high yield and better adaptation (Guzmán et al. 2014). *T. dicoccon*-based synthetic hexaploids, landraces from Iran, Spain, and Afghanistan, and *T. dicoccoides* from Israel and adjacent regions are being used to improve micronutrients. CIMMYT Mexico has a large collection of genetic resources in its germplasm bank near Mexico city.

Screening for micronutrient variability has demonstrated that landraces and wild relatives of common wheat such as *T. spelta* and *T. dicoccon* have the ample amount of Zn and Fe. Contemporary breeding methods employ limited backcrossing procedure to introgress high-Zn/Fe genes from *T. spelta,* synthetic hexaploids, and landraces into better agronomy genotypes available with the breeders.

Ae. peregrina accessions have more than double grain Fe and Zn concentrations than elite wheat cultivars. Some of the derivatives of fertile wheat x *Ae. peregrina* with bolder seeds, better harvest indexes comparable to those of elite wheat lines, and higher micronutrient concentrations demonstrated that *Ae. peregrina* possesses a separate genetic system for biofortification, similar to that of *Ae. kotschyi*. The fertile BC_2F_2 plants with one or more additional chromosomes from *Ae. peregrina* showed a 100–200% enhancement of grain Fe and Zn levels over those of normal, elite wheat lines. Further analysis showed that the two chromosome groups 7 and 4 of *Ae. peregrina* had genomic regions for micronutrient content in wheat.

3.2 Marker-Assisted Gene Introgression

The use of MAS can make conventional wheat breeding programs more cost-effective and time-efficient (Gupta et al. 2010). It has primarily been used in wheat for foreground for carrier chromosome or segment selection and background selection for maximum genome recovery. It has recently been used successfully to

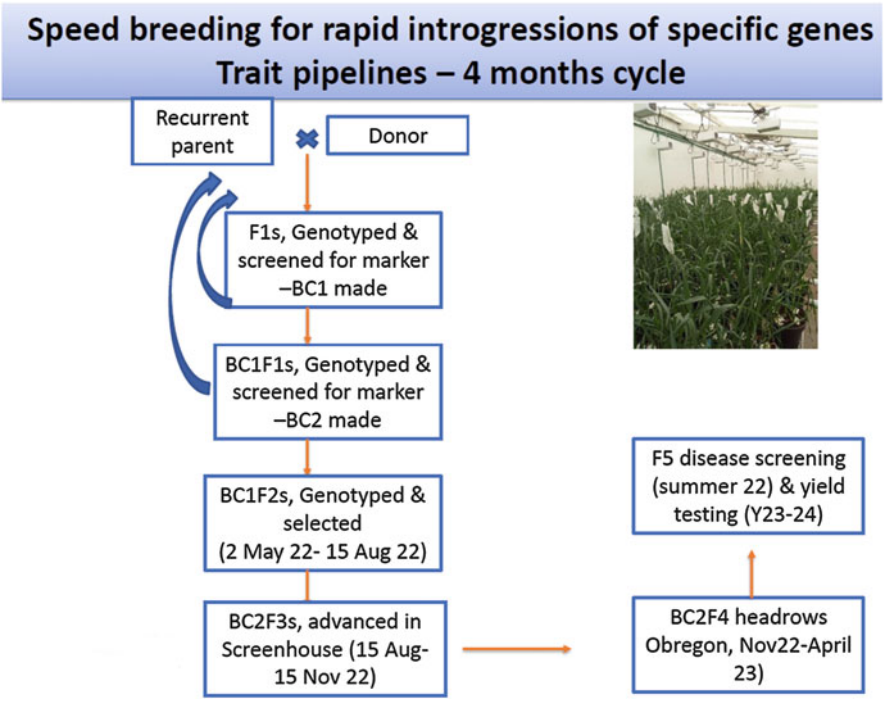

Fig. 2 Trait augmentation program at CIMMYT, Mexico

introduce and pyramid major genes/QTL for desirable wheat characteristics of a major locus (Gpc-B1) on chromosome 6BS that was introgressed from wild emmer wheat (*Triticum turgidum* ssp. *dicoccoides*) has improved Fe (18%), Zn (12%), and protein (38%). A marker called *Xuhw89*, which is closely related to the (0.1 cM) *Gpc-B1* locus (Distelfeld et al. 2006), has aided in the development of wheat varieties with high Fe, Zn, and protein concentrations. Many RFLP, SSR, and CAPS markers have been linked to this marker *Xuhw89* (Distelfeld et al. 2004). With the cloning and characterization of *Gpc B1* locus, a gene-specific marker and the locus has been introduced in wheat, improving GPC without a yield penalty (Kade et al. 2005). This has occurred mostly in many wheat growing regionssuch as India where it has transferred to elite cultivars. The wheat breeding program at CIMMYT recently embarked upon to introgress key agronomic, disease resistance and nutritional quality traits through its speed breeding pipeline (Fig. 2).

3.3 Gene Pyramiding

Functional markers are critical for gene stacking, genomic region transfer, and gene editing procedures. So far, 97 functional markers in bread wheat have been used to establish 30 loci from 93 alleles (Alotaibi et al. 2021). With the advancement of

genomic studies, the number of alleles has increased, and approximately 157 markers for 100 loci for various traits of economic importance have been identified. Few genes, including *VRN1* and *Gpc-B1*, have been successfully incorporated using the conventional positional cloning approach in wheat. Similarly, genes related to grains, such as *TaGS5*, *TaGS3*, and *TaCwi-A1* related to grain size; the *Psy1* (He et al. 2009) phytoene synthase gene and *Zds1* related to zeta-carotene desaturase have been reported using competitive genomics methods.

4 Identification, Cloning, and Characterization of Health-Related Genes/QTLs

Micronutrient effectiveness has a complex nature that is influenced by the environment. It is critical for MAS and map-based cloning to identify the genes/QTLs that influence micronutrient content. Map-based cloning is a method for cloning the gene of interest without prior knowledge of its product. The basic requirement for map-based cloning is a population that has been systematically developed for the desired trait and is suitable for fine mapping. Precision genotyping and phenotyping for the trait aid in the generation of an accurate genetic map indicating the location of the gene. To determine the physical location, two nearby markers are used to screen BAC libraries. The candidate genes are discovered through chromosome walking and target interval sequencing. Significant progress has been made since cloning of the first gene. The gene *Gpc-B1* has been positionally cloned in wheat; it is 7.4 kb (md) long and encodes for NAC transcription factors controlling senescence, protein content, and Zn and Fe content.

A major QTL (18.3% phenotypic variation) in rice for Fe content on chromosome 8 of rice and shows synteny with chromosome 7 of wheat. Similarly, in a *T. durum x T. dicoccoides* cross combination, Peleg et al. (2008) discovered a major locus Fe content on chromosome 4 and two co-located loci on chromosome 7 for both Fe and Zn. Discovered major QTL on chromosome 7A for both micronutrients in a *T. boeoticum* and *T. monococcum* population. Xu et al. (2012) discovered 9 additive and 4 epistatic QTL on the 4B and 5A chromosomes, indicating a shared inherent basis for the three nutritional traits. Populations of diploid wheats, durum wheats, and wild Emmer wheat (Peleg et al. 2009), as well as synthetic wheats and *T. spelta*, were used to map QTLs for grain Zn and Fe concentration. In a separate report, Srinivasa et al. (2014) identified 10 QTLs (five each for Zn and Fe accumulation) that were widely distributed across 7 chromosomes. In a DH (doubled haloid) population, two QTLs for Zn content were found on chromosomes 1B and 2B. In addition, four genes governing the inheritance of grain Zn content were discovered in two mapping populations derived from a *T. spelta* x bread wheat combination (Srinivasa et al. 2014). Identified several QTLs on chromosome 7B accounting for 32.7% of total phenotypic variation for Zn concentration and a single QTL location on 4A accounting for 21.14% of total phenotypic variation for grain Fe content in two RIL populations derived from *T. spelta* L. and synthetic hexaploid wheat crosses. The majority of studies have found a statistically significant positive

relationship between grain Zn and Fe concentrations in various environments where QTLs or similar genetic effects have regulated the Fe and Zn content in wheat. Co-localization of Fe and Zn concentrations has also been shown on chromosomes 2A, 2B, 4BS, and 5A (Xu et al. 2012) and 6B. This co-location of QTLs offers an opportunity to pursue a single marker-assisted program to enhance the concentrations of both Zn and Fe content. Table 4 provides a comprehensive list of major genes/QTLs identified in wheat for various quality traits.

5 Genomics-Aided Breeding for Heath-Related Traits

In wheat, genome-wide association studies (GWAS) have been widely used to investigate the genetics of quantitative traits. In comparison to traditional QTL mapping, GWAS provides better QTL resolution and wider allelic coverage, and it can be used on a larger population of genetic resources, landraces, varieties, or advance lines. Only a few studies in wheat have been conducted to better understand the genetic mechanism of quality characters. Nonetheless, improved genotyping facilities and access to the wheat genome reference sequence, RefSeq v.1.0, can speed up the identification and prediction of markers and their effects on trait. It would improve trait mapping, gene discovery. Detection of SNP markers that are distributed genome wide offers new avenues for genetic improvement of bread wheat for yield and traits of economic importance (Juliana et al. 2019).

GWAS and interval mapping studies in wheat have resulted in the identification of hundreds of markers for improving Fe and Zn concentration, but only a few have been used in marker-assisted breeding for nutritional traits. The only example is the *Gpc-B1* gene, which has been used to improve Fe, Zn, and Protein concentration in wheat using a MAS approach. Developed chromosome substitution lines in the variety 'Langdon' (LDN) and reported that a locus *QGpc.ndsu-6B* with a phenotypic variation of 66% is located on the 6B chromosome and contributes to high GPC. The wild allele at the locus accelerates leaf senescence and reduces grain size, resulting in yield reduction. *Gpc-B1* regulates senescence and nutrient remobilization, according to studies. Normally, wheat cultivars carry a non-functional *NAM-B1* allele, which is produced by a frame shift mutation in the wild allele, and this non-functional allele was preferred during wheat domestication. The presence of this allele on chromosome 6BS in wheat (Brevis and Dubcovsky 2010) allows for more time for grain development, which increases grain size and yield. In a study of 367 global bread wheat genotypes, only 5 Fennoscandian cultivars were found to have functional *Gpc-B1* or *NAM-B1* alleles, and these genotypes were only present for a short time in northern Europe. According to the wild-type/functional *Gpc-B1* allele has been conserved during the process of domestication. The MAS to transfer the wild-type *Gpc-B1* gene from Canadian to Australian varieties and found no yield penalty. Reported function loss caused by GPC1 and GPC2 mutations. GPC was found to be negatively associated with grain yield and influenced by genetic background in the majority of studies (Brevis and Dubcovsky 2010), and it is positively correlated with protein, iron, and zinc content with slight negative effect on yield. It is also suggested

to transfer low phytic acid (LPA)-GPC in the cultivars for enhancing Fe and Zn concentration along with grain protein content without yield penalty.

Several marker-trait associations (MTAs) for nutritional traits in wheat have been used. A total of 39 Zn MTAs were discovered in two studies, one involving 330 bread wheat genotypes and the other involving 320 genotypes from the Spring Wheat Reference Set (SWRS), with two large-effect QTL regions discovered on chromosomes 2 and 7. CIMMYT developed new biofortified varieties that are 20–40% superior in grain Zn content and agronomically on par with or better than popular South Asian wheat varieties. A GWAS study for grain Zn concentrations in 369 European wheat genotypes identified 40 MTAs on chromosomes 2A, 3A, 3B, 4A, 4D, 5A, 5B, 5D, 6D, 7A, 7B, and 7D, with the important and reliable MTAs having significant effects were localized on chromosomes 3B (723,504,241–723,611,488 bp) and 5A (462,763,758–466,582,184 bp). Reported an increase in the number of MTAs to 161 genomic regions, including recently identified candidate genes for Zn uptake and transport. A GBS study on a panel of 167 Ae. tauschii accessions revealed 5249 markers, as well as wide variability in micronutrient concentrations. Overall, 19 SNP MTAs were found on all 7 chromosomes, with positive associations found for 5 with grain Fe and 4 with Zn content. These associations were found to be associated with

genes that code for transcription factor regulators, transporters, and phytosiderophore synthesis. With improved genomic prediction accuracy and lower genotyping costs, genomic selection in wheat breeding has gained traction (Juliana et al. 2019; Charmet et al. 2020). In the coming years, the ability of genomic selection to increase genetic gain for quality traits will further transform wheat improvement methodologies. Genomic selection would aid in the rapid selection of desired plant types by using widely distributed markers, estimating the effects of all loci, and accurate prediction of genomic estimated breeding values with precise genotypic and phenotypic data (GEBV). Linear prediction models such as G-BLUP and machine learning algorithms are used to recognize complex data patterns and draw appropriate conclusions, as well as to exploit GxE interactions. Using multi-trait and multi-environmental models improves prediction accuracy and performance in selected breeding. Overall, genomic selection improves selection accuracy while decreasing time and cost for varietal development, particularly for complex characters with low heritability that are difficult to improve using traditional plant breeding methods (Heffner et al. 2009). An efficient genomic selection approach optimizes the statistical prediction model for developing GEBVs based solely on genotyping data for an un-phenotyped population using a precisely genotyped and phenotyped "training" population. This reduces the breeding cycle and allows breeders to dispense with avoidable multi-location and multi-environmental testing of genotypes.

When predicting the genotypic value of one panel based on another, prediction accuracy decreased. These findings are consistent with those of who demonstrated the high prediction accuracy in a germplasm set with high variation is used as training population as it has high genomic coverage. The use of efficient genomic selection models in conjunction with precision phenotyping on genetically variable populations will improve prediction accuracy, selection efficiency, and speed up the varietal development process. The addition of GWAS and genomic selection to MAS will undoubtedly shorten breeding cycles and improve the breeders' equation. As a result, there is enormous potential for scaling up biotechnological approaches with traditional plant breeding for varietal development.

6 Role of Nanotechnology for Nutritional Improvement of Wheat

Nanotechnology has recently emerged as one of the outstanding technologies that can be gradually applied in agriculture for crop biofortification and can largely avoid the drawbacks associated with genetic and traditional agronomic biofortification. Nanomaterials have a variety of advantageous properties, including controlled and slow discharge at target sites, significantly higher absorption capacity, and a high volume to surface ratio for effective use in the production of nanofertilizers (NFs). Because nanofertilizers are used in minute quantities, they prevent the accumulation of residual by-products of chemical fertilizers in soil and thus have a lower environmental impact. Furthermore, nanofertilizers can be generated using biosensors based on soil status and crop nutritional demand.

Furthermore, NFs have been shown to improve crop performance under various stresses by modulating carbohydrate and protein synthesis, seedling growth, nitrogen metabolism, photosynthesis, and nutrient mobilization from the rhizosphere to specific plant parts. Because of its target-bound slow delivery, even a trace amount of NFs can effectively improve micronutrient levels in grain without negatively impacting the environment. Wheat, as a major staple crop, has always been a driving force behind its use in various types of biofortification and fortification. As with other biofortification strategies, a number of greenhouse or small-scale field studies show that nanomaterials have a positive effect on wheat nutritional content. Large-scale experiments in open and enclosed areas are required to assess the benefits and drawbacks of NF-based wheat nutrient enrichment. To increase the use of NFs in large-scale wheat biofortification programs, we must first understand how different nanomaterials, their combinations, and application strategies affect target nutrient levels in different wheat genotypes. Significant attention has recently been directed toward developing appropriate methodologies for applying nanoparticles, as this significantly affects the extent of micronutrient accumulation in wheat plants.

7 Role of Genome Editing Technology in Wheat Nutritional Quality Improvement

Gene editing technology has proven to be an effective tool for modifying desired traits in a variety of crop plants, including wheat. Modifying nutritional traits in crop plants provides several health benefits, particularly in staple crops like wheat. In this section, we will discuss the current progress made in the use of gene editing technology to improve the nutritional quality of wheat. Liang et al. (2017) demonstrated direct editing of the *TaGASR7* and *TaGW2* genes by introducing the CRISPR-Cas9 ribonucleoprotein complex into immature embryos of the wheat varieties Kenong 199 and YZ814. Created heritable mutations in the *TaLpx-1, TaGW2,* and *TaMLO* genes. They also demonstrated that the seed size and thousand grain weight were significantly larger (TGW). They also discovered that TaGW2 has a negative effect on grain size in wheat. In 2019, Jouanin and colleagues investigated the possibility of simultaneously editing multiple genes in the large – and – gliadin gene families.

8 Nutritional Improvement in Wheat Quality Using Genetic Engineering

Biotechnological crop improvement interventions have proven their worth for a variety of crops, including cereals, over the last 2–3 decades. Bt cotton, maize, and golden rice are a few examples. In the case of wheat, various genes determine traits such as starch composition, nutritional profile, and final end product formulation, all of which affect final grain quality. The cloning of the NAC gene *Gpc-B1* for

grain protein content from this accession's chromosome arm 6BS encodes a transcription factor that accelerates senescence in plant vegetative parts, resulting in increased nutrient mobilization and mineral (iron and zinc) transfer to the grain (Shewry 2009). This could help in the fight against malnutrition. According to USDA World Wheat Collection research, the protein content of wheat grain can range from 7 to 22%, with 33% controlled by genomics and the rest by environmental factors, making breeding for this trait difficult (Vogel et al. 1978). This bottleneck can be circumvented by incorporating sources of variation from exotic bread wheat lines or related wild species, such as Atlas 50 and Atlas 66, which are derived from the South American line Frandoso. Both lines appeared to have multiple genes for high protein content in grain and have been extensively used in Nebraska breeding programs. Johnson et al. (1985) successfully inserted the Atlas 66 gene into the commercial variety Lancota (Johnson et al. 1985; Shewry 2009).

Biotechnological interventions have been attempted to increase grain starch while also modulating its quality (Borisjuk et al. 2019). *TaRSR1*, a wheat homolog of Rice Starch Regulator (*OsRSR1*), is a transcription factor that negatively regulates the gene expression pattern of some starch synthesis-related enzymes in wheat grains. Downregulation of *TaRSR1* resulted in a nearly 30% increase in starch content and a 20% increase in yield (Kang et al. 2013). Increased amylose in starch contributes to resistant starch (RS) in food, which can offer protection from health conditions such as diabetes, obesity, and cardiovascular diseases, many of which are chronic diseases (Borisjuk et al. 2019; Meenu and Xu 2019). A number of experiments focused on downregulation of starch branching enzymes SBEIIa and SBEIIb, leading to substantially elevated levels of amylose and resistant starch in wheat, which could benefit human health viz. obesity (Vetrani et al. 2018).

The level of free amino acids in wheat was significantly altered when the GCN2-type protein kinase gene was overexpressed. In another experiment, the pA25-TaGW2-RNAi DNA construct was implanted into the immature embryos of the wheat variety 'Shi 4185,' resulting in *TaGW2* gene suppression and increased grain weight and width. Using *Pina-D1a* and *pinb-D1b* genes, indicated the interaction of *PINA* with *PINB* to form friabilin which ultimately modulate the wheat grain texture.

Aggarwal et al. (2018) created a TaIPK1:pMCG161 RNAi construct that was then mobilized into C306 wheat genotypes. The transgenic lines reduced phytate by 28–56%, increasing the molar ratios of iron: phytic acid and zinc: phytic acid. Similarly, demonstrated a reduction in phytate of 22–34% using the TaABCC13: pMCG161 RNAi construct. Furthermore, several genes for Fe and Zn homeostasis in wheat have been identified, which are associated with four key pathways: the methionine cycle, phytosirophore biosynthesis, the transport system, and the antioxidant system. These genes could be used for gene editing or genetic engineering to increase the amount of Fe and Zn in wheat grain and its bioavailability. In general, there is ample scope to improve wheat nutritional quality components using modern approaches to improve the quality standards of commercial wheat.

9 Conclusion and Future Perspectives

Wheat grain contains various compounds which have potential nutraceutical functions. Wheat nutritional properties can be exploited in variousforms to prevent malnutrition and deadly diseases. For instance, wheat brans are the rich sources of flavonoids, phenolic acids, tocopherols, lignans, phytosterols, and carotenoids, which provide many health benefits. Wheat products contain a variety of high-value compounds, mainly bioactive compounds with significant health benefits. They can be exploited as food ingredients, supplements, additives, or extracts that are high in functional molecules and micronutrients, such as zinc, iron, and manganese, phenolic compounds, novel carbohydrates, carotenoids, biopeptides, bioactive fatty acids, amino acids, prebiotics, vitamins, and mineral elements. Bioactive compounds derived from wheat can be used as antioxidants and preservatives, reducing lipid oxidation and microbial growth. Furthermore, processing technologies to improve nutritional characteristics and sensory features also been targeted to increase the functional food value, and nutrients bioavailability, while reducing the anti-nutritional factors of cereal by-products. In the near future, more studies are necessary on the nutraceutical properties of wheat including bioactive compounds for use as nutraceuticals or as ingredients in the development of functional products. Some of these traits can be integrated in the wheat breeding activities as it is a key set of characteristics for the trading and commercialization of the grain. Grain nutritional quality should be an integral part of the breeding process and considered within the variety development process to deliver new products with better nutritional properties to consumers.

Abstract

Maize (*Zea mays*) is known as the queen of cereals because of its higher grain yield potential, wider adaptability, genetic diversity, use as food, feed, and industrial use among cereals. The growing population is a threat to nutritional security, and demand for a cost-effective and promising strategy for the food system. Every year around two billion of the world's population is prone to malnutrition caused by essential micronutrients, proteins, and vitamins. Biofortification is one of the most promising approaches to enhance the nutritional quality of maize grains and reduce the risk of hidden hunger globally. Maize possesses several naturally existing mutants for nutritional quality traits and is considered as a model crop for biofortification. Effective utilization of recent advances in genomic, molecular tools, crop improvement techniques, machine learning, and artificial intelligence can pave the way in developing nutritionally rich maize. This chapter provides insight on the importance of maize in global nutritional food security, approaches for biofortification, genetic resources, and genetic diversity for nutritional quality traits, map-based gene cloning, trait mapping and finding major quantitative trait loci (QTLs), conventional and genomic-assisted breeding strategies for enhancing corn nutritional

quality. Further this chapter emphasizes the genetic engineering approach, novel genome editing techniques, nanotechnology, and available bioinformatic databases to carry out omics research for designing nutritional rich maize.

Keywords

Maize · Biofortification · Genomics · QTLs/genes · Molecular breeding · Maize genome database · Genetic engineering

1 Introduction

Corn, also called maize (*Zea mays* L.), is most prominent and versatile among cereals due to its adaptability, diversity, and use as food source for humans and animals, and wider industrial use. The literal meaning of maize is "that which sustains life." Corn is the second most widely grown crop globally in temperate, tropics, and subtropical regions. There are different types of corn such as, field corn (sweet corn, baby corn, popcorn) and specialty corn (quality protein maize (QPM), high-oil maize, waxy maize etc). In 2021, a total of 1.2 billion metric tons of corn was produced globally and the United States was the largest producer of corn followed by China and Brazil (Statista.com). Globally, 61% of corn is used as feed, 17% as food and 22% for industrial (starch and biofuel) use, and therefore corn is considered as a driver for agricultural economy. Corn consists of 72% starch, 10% protein, 4% lipid, and various vitamins except for vitamin B12. Corn germ contains 80% of mineral content whereas, less than 1% resides in the endosperm. On a dry basis, maize provides approximately1400 Kcal/100 gm of energy to perform various physiological activities. Maize is a good source of fat, dietary fibers, essential amino acids, proteins, carbohydrates, starch, b-complex vitamins (histamine, folic acid, riboflavin, niacin, pantothenic acid), fat soluble vitamins (A, D, E, K), minerals and trace elements, organic acids, polyphenols, phytosterols (Table 1).

Growing population is a threat to nutritional security, and there is a stealthy form of hunger called "micronutrient malnutrition" or "hidden hunger." Every year around two billion of the world's population is prone to malnutrition caused by key micronutrients Fe and Zn, and, provitamin A. Micronutrients play an important role to perform functions of the human body and inadequate consumption of micronutrients causes criticalities and several effects on biological A deficiency. Deficiency of protein causes marasmus, and kwashiorkor, fiber deficiency leads to diverticulitis, and constipation, whereas iron and vitamin A deficiency causes anemia and night blindness, respectively. Calf muscle pain and heart muscle weakening happen due to thiamine deficiency. Pyridoxine and niacin deficiency causes angular stomatitis and diarrhea, dermatitis, and dementia, respectively. The megaloblastic anemia is caused by folic acid deficiency, and, antioxidants deficiency decreases immunity. Thus, to minimize risk of malnutrition, foods rich in micronutrient content need to be included in the human diet. Fruits and vegetables are good sources of micronutrients. In developing countries where most of the population relies on staple cereal-based food diets either cannot have access or

Table 1 Nutrient content of maize

Nutrients	Nutritive value (as per 100 gm of edible portion)
Protein (g)	8.80 ± 0.49
Total fiber (g)	12.24 ± 0.93
Carbohydrates (g)	64.77 ± 1.58
Lysine (g)	2.64 ± 0.18

affordability of fruits and vegetables. Therefore, for nutrient security of cereals various approaches need to be adopted such as, supplementation, diversification, and fortification. Biofortification is the enhancement of micronutrients in the edible part of the crop and is a most promising approach to alleviate malnutrition. As there are several naturally existing mutant alleles for nutritionally important genes have been found in corn, it is considered a model crop for biofortification (Sagare et al. 2018).

2 Methods of Biofortification

Improvement of nutritional quality of a crop should be done by elevating the micronutrient content of the edible portion without compromising yield and yield attributing characters. For enhancing nutritional quality of food grains, three

different biofortification methods are used, agronomic biofortification, transgenic biofortification and conventional biofortification. In conventional biofortification, the high yielding and popular varieties are a cross breed with nutritionally rich varieties, and then backcrossed to develop staple crops with higher nutrient content. In the genetic biofortification approach, a foreign gene (bacterial/plant) is introduced or manipulated genomic regions controlling nutritional related genes, to enhance micronutrient content in edible parts of the plant. In agronomic biofortification, application of micronutrient fertilizers, soil conditioning, or seed amendment is conducted to increase micronutrient content of dietary field crops. Soil amendment manages pH of the soil and makes micronutrients available in the root zone for plants to uptake. Soil amendment is done by application of lime, biochar, biosolids, elemental sulfur, gypsum, plant residues, animal manure, organic manure etc. Biofortification can also be done through nanotechnology, nanoparticles are incorporated into micronutrient fertilizers and exploited for their role in nutritional and yield enhancement. In corn, foliar application of zinc hydroxide nitrate (Zn5 (OH)8 $(NO_3)_2 \cdot 2H_2O$) led to accumulation of Zn content in endosperm (Ivanov et al. 2019). The conventional approaches are time consuming and are unable to fortify multiple micronutrients. In the recent past the genomic advances led to identifying various nutrition related genes and novel approaches such as, trait mapping, molecular-genomic breeding, genomic selection can accelerate breeding of staple food crops to enhance biofortification.

3 Genetic Resources for Nutritional Quality Improvement

Maize belongs to the family Poaceae and tribe Maydeae/Andropogonodae that comprises seven genera, viz. *Coix* (2n = 10 or 20), *Sclerachne* (2n = 20), *Trilobachne* (2n = 20), *Chionachne* (2n = 20) and *Polytoca* (2n = 20) (Old World groups) and *Zea* and *Tripsacum* (New World groups). Two new world group genera, *Zea* and *Tripsacum* forms the genepool of maize, and comprises subtribe Tripsacinae, tribe Andropogoneae, and subfamily Panicoideae of family Poaceae (Barker et al. 2001). A gene pool categorization of cultivated crops was proposed based on the feasibility of gene flow/transfer from those species to cultivated crop species. The categories are, primary, secondary, and the tertiary gene pools. Biological species that have no gene exchange barrier fall under the primary gene pool that comprises wild and progenitors of cultivated crop species. Secondary gene pool comprises distantly related crop species and has crossability issues. Outer limits of potential genetic resources are considered as tertiary gene pools. *Zea mays* (ssp. *mays*) represents the primary genepool, other taxa in the genus *Zea* (*teosintes*) represents secondary genepool (subspecies *parviglumis, mexicana, huehuetenangensis*, and other zea species *luxurians, nicaraguensis, diploperennis, perennis*), and all the species in the genus *Tripsacum,* sister genus to *Zea* (new world perennial, polyploid grasses) represents tertiary genepool. About 9000 years ago maize (*Zea mays* ssp. *mays*) was domesticated from wild species ancestor, teosinte (*Zea mays* ssp. *parviglumis*).

The wild relative serves as, great source genetic diversity and valuable resources of economically important genes viz., biotic and abiotic stress resistance, yield related genes and genes comprising higher nutrient content, and can be used in crop improvement. Wild relatives are a source of alleles for important traits such as insect resistance and gray leaf spot (GLS) resistance from *Z. mays* ssp. *mexicana* (Lennon et al. 2016), waterlogging resistance from *Z. diploperennis* and *Z. nicaraguensis*, resistance to the parasitic weed Striga from *Z. diploperennis* (Amusan et al. 2008), higher yield from *Z. mays* ssp. *Parviglumis* (Wang et al. 2008). Several nutritional quality-related mutant alleles were identified from cultivated wild relatives and landraces viz., *waxy1* for high amylopectin, *opaque2* for high quality protein, *Y1* for high carotenoid content (Amusan et al. 2008). Maize lines rich in methionine, tryptophan and lysine were obtained by allelic introgression from *Z. mays* subsp. *mexicana* (Wang et al. 2008). Teosinte possesses several functional variations for nutritional quality traits, protein content, provitamin A carotenoids, Starch and oil content (Harjes et al. 2008; Karn et al. 2017), therefore, it could serve as a potential donor for maize biofortification.

4 Genetic Diversity Analysis for Nutritional Quality-Related Genes

Genetic diversity changes over time and space can be defined as the range of genetic characteristics presented within a crop or species (Swarup et al. 2021). Genetic diversity analysis plays a fundamental role in breeding, plant genetics, biological evolution, and biodiversity conservation. Understanding maize genetic difference and its distribution is particularly important for selecting diverse parental maize materials to improve maize quality. The analyses of genetic diversity can be classified as two categories: one is the phenotype-based diversity analysis which focuses on the observation of morphological traits such as height and color, while the other one is molecular-based analysis which focuses on the examination of DNA variations. The maize genetic diversity has strong relationships with its wild relatives, so conserving and utilizing wild relatives could help improve maize breeding. In addition, the distribution of maize genetic diversity shows obvious geographical characteristics (Mir et al. 2013).

4.1 Morpho-Pheno-Biochemical Traits-Based Diversity Analysis

Morpho-phenotype-based genetic diversity analysis refers to the use of analysis of phenotypic differences among plants to further infer genetic diversity, whereas, biochemical-diversity reveals the nutrient content of the seeds. It is widely used in new cultivar breeding, evaluation of genetic response to environment, and crop management such as biological pest control (Swarup et al. 2021). Diversity analysis based on kernel composition, and zein profiles in a diverse set of modern inbred lines, teosinte accessions, landraces, intermediate between inbred and teosinte, revealed

in-spite of having smaller seed size teosinte possesses twice the protein content of landraces and inbred lines. The diversity analysis study based on morpho-phenotypic (plant height, kernel length, grain weight, kernel rows per cob, cob diameter etc.), biochemical/nutritional content (tryptophan) and kernel color (orange, white, yellow) traits in 1348 accessions of 13 maize populations belonging to stiff and non-stiff stalk heterotic groups, revealed variable relationships between and within total diversity among morpho-pheno-biochemical traits (Jaradat and Goldstein 2013). The diversity analysis study conducted in 51 accessions of maize landraces from north west Himalayas of India based on agro-morphological (grain yield per plant, plant height, ear height, kernel rows, kernels per row etc.) and nutritional quality (tryptophan content) traits, revealed significant differences among the accessions (Kumar et al. 2015). A total of 1279 accessions conserved in the Indonesian Agency for Agricultural Research and Development-Indonesian Center for Agricultural and Biotechnology and Genetic Resources Research and Development Gene Bank (IAARD-ICABIOGRAD Gene Bank) were assessed for their kernel characteristics (morphological- color, size, and shape) and a moderate-high genetic diversity among accessions was observed (Risliawati et al. 2022). Morpho-phenotype-based diversity analysis can detect unique traits or genotypes that can be used in breeding programs. A weakness of phenotype-based diversity analysis is that homozygotes and heterozygotes are not distinguishable. Also, as phenotype is affected not only by genes but also by environment, morpho-phenotype-based diversity analysis may need to be further validated by other methods such as molecular marker assistant analysis. Whereas, biochemical or nutritional content based genetic diversity is very much important to find out nutritionally rich germplasm and their subsequent utilization in breeding nutritionally rich crops.

4.2 Molecular Marker-Based Diversity Analysis

A molecular marker is a DNA sequence that reveals mutation or variation and can be located and identified in the genome. A number of metrics are used to evaluate genetic diversity such as the number of alleles, genetic differentiation index, observed or expected heterozygosity, percentage of polymorphic loci, genetic distance, and polymorphism information content. Moreover, hierarchical analysis of molecular variance and principal coordinate analysis are also widely used in genetic diversity analysis (Wu et al. 2021). Several studies have been taken up for molecular marker based genetic diversity for nutritional quality traits. Molecular diversity in 20 inbred lines with varied Kernel tryptophan, Lysine, provitamin A, Fe and Zn content, using 25 simple sequence repeat (SSR) markers, revealed high levels of polymorphisms, and the nutritionally contrasting could and genetically diverse lines can serve as potential sources for hybrid development program as well as for further studies on quantitative trait locus (QTL) analysis of kernel micronutrient traits (Jaiswal et al. 2019). A biochemical (α-tocopherol or vitamin E content) and molecular analysis (SSRs-based diversity) of set of 24 inbreds possessing favorable alleles of **γ-***tocopherol methyltransferase* (*ZmVTE4*) identified set of potential cross

combinations for developing high yielding vitamin E rich hybrids, and to map additional genes affecting accumulation of α-tocopherol (Das et al. 2019).

5 Classical Genetics and Traditional Breeding for Nutritionally Rich Maize

Classical genetics studies the mechanism of how certain characteristics are passed from parents to offspring without knowing the molecular details, and traditional breeding is based on the variations of observable traits. Breeders look for desired traits and use traditional methods such as mass selection, recurrent selection, hybridization, and synthetic variety development to create new cultivars.

5.1 Genetics of Nutritional Quality-Related Genes

Starch accounts for about 70% of maize kernel weight and is critical for grain yield and quality. In maize kernel sucrose is firstly converted to glucose and then further to starch, and starch is composed of amylopectin and amylose. Genetics studies reveal that starch production in maize is regulated by a wide range of genes such as *sh1, sh2, bt2, wx1, ae1*, and *su1*. These genes act in different pathways. For example, *sh1* helps the formation of glucose, *sh2* and *bt2* help the conversion from UDP-glucose to ADP-glucose, *ae1* and *su1* aid to form amylopectin, and *wx1* helps form amylose. About 10% of maize kernel weight is protein, made up of amino acids, and some of these are essential for human health. Proteins can be classified to two types: zein protein and non-zein protein. Zein protein accounts for about 70% of total protein in the maize kernel and is affected by abundant gene mutation. Some genes such as *De-B30*, *mc*, *fl2*, and *fl4* encode zein protein, while others such as *fl1* and *o1* encode non-zein protein. Moreover, genes can also regulate endosperm metabolism enzymes (*o5*, *o6*) or transcription process (i.e., *o2*, *fl3*) and ultimately affect protein (Khan et al. 2019). Probably, the most widely studied gene is *o2* which can be used to breed quality protein maize, as *o2* can reduce alpha zein accumulation but increase lysine and tryptophan contents that are important for human health (Holding 2014). Oil is also a major component in maize seed and is rich in polyunsaturated fatty acids and energy. The quality of maize oil is determined by not only the oil content but also the composition ratios among fatty acids. Genetic studies have identified several main genes that control oil-related traits. For example, *DGAT1-2* encodes diacylglycerol acyltransferase which catalyzes the final step of oil synthesis, *fad2* encodes oleate desaturase that affects oleic acid composition, and *ZmWRI1* encodes a transcription factor that can increase oil content.

5.2 Breeding Objectives

In maize breeding, selection is the main method used to eliminate or exhibit target characteristics, and it could be either natural selection or artificial selection or

selective breeding. Selective breeding aims to produce offspring that have desirable traits which can be passed to future generations via genes. The selection of multiple traits simultaneously is conducted by developing a selection index to maximize genetic gains. From the selection objectives point of view, the selection could also be classified as positive selection and negative selection, which can be translated as keeping the favorable traits and eliminating detrimental traits, respectively. Breeding varieties with enhanced nutritional qualities such as high vitamin A content, high-quality protein content, and high zinc content, while having stable yields under disease damage and/or environmental stress such as heat and drought, may be an ideal breeding objective to bred nutrition-rich maize. However, breeding objectives should also consider temporal and spatial conditions to address local specific challenges.

5.3 Classical Breeding Achievements

In the past decades, breeders have bred many nutritious maize varieties such as high-amylose maize, high-oil maize, high-vitamin maize, sweet maize, waxy maize, and quality protein maize, using traditional methods. High-amylose maize is widely used in the food industry as the high-amylose starch in maize produces opaque gels that are good materials for confectionery and thickener. The high content of amylose in maize starch is mainly controlled by a recessive gene *ae*. Through hybridization, random mating, and mass selection, breeders managed to develop the SU amylose-extender maize cultivar with apparent amylose content ranging from 53.3% to 69% with an average of 61.7%. However, the yield of the amylose-extender maize was low (3–4 tons per ha) compared with normal maize hybrids. The Germplasm Enhancement of Maize project of the United States Department of Agriculture reported that the apparent amylose contents of their *ae*-inbred lines (H99ae, OH43ae, B89ae, and B84ae) were from 61.7% to 67.7% (Li et al. 2008). Another high-amylose maize germplasm was reported by Campbell et al. (2007) whose research showed that the apparent amylose starch content of GEMS-0067 inbred line was at least 70% and had good potential for future high-amylose maize breeding. Quality Protein Maize (QPM) is another achievement. QPM contains two enhanced amino acids: lysine and tryptophan which are essential for human and animal growth and development. The breeding of QPM started in the 1960s since scientists discovered some gene mutants such as *o2* and *fl2* could improve the contents of lysine and tryptophan (Prasanna et al. 2001). The International Maize and Wheat Improvement Center (CIMMYT) successfully developed a group of *o2* based QPM gene pools (Table 2), using backcross recurrent selection. Later, by using CIMMYT's germplasm, researchers around the world bred many local QPM hybrids or open-pollinated varieties to adapt local ecosystems such as HQ INTA-993 in Nicaragua, ICA in Colombia, INIA in Peru, FONAIAP in Venezuela, BR473 and Assum Preto in Brazil, H-553C and VS-538C in Mexico, Susuma in Mozambique, Obatampa in Bein and Guinea, Obangaina in Uganda, GH-132-28 in Ghana, QS-7705 in South Africa, BHQPY545 and AMH760Q in Ethiopia, Zhongdan

Table 2 the QPM gene pools and their corresponding protein contents. (Source: Prasanna et al. 2001)

Gene pool number	Ecological adaptation	Maturity	Lysine content (%)	Tryptophan content (%)	Protein content (%)
Pool 15	Tropical	Early	4.2	0.94	9.1
Pool 17	Tropical	Early	4.5	1.04	8.9
Pool 18	Tropical	Early	4.0	0.93	9.9
Pool 23	Tropical	Late	3.8	1.03	9.1
Pool 24	Tropical	Late	3.8	0.92	9.4
Pool 25	Tropical	Late	4.0	0.94	9.8
Pool 26	Tropical	Late	4.1	0.90	9.5
Pool 27	Subtropical	Early	4.2	1.05	9.5
Pool 29	Subtropical	Early	4.3	1.06	9.2
Pool 31	Subtropical	Medium	4.1	0.96	10.2
Pool 32	Subtropical	Medium	4.2	1.04	8.9
Pool 33	Subtropical	Medium	–	1.05	9.3
Pool 34	Subtropical	Medium	4.1	1.10	9.1

9409 and Yunrui1 in China, Shaktiman in India, and HQ-2000 in Vietnam (Prasanna et al. 2001; Teklewold et al. 2015). Besides QPM, other amino acids enriched maize varieties are also reported. For example, high-methionine inbred lines derived from A632, B73 and Mo17 are registered in the United States. Breeding high-oil maize is challenging because oil content and grain yield has a negative relationship. With decades of effort, the University of Illinois selected two high-oil synthetics: Alexho Elite and UHO with oil contents accounting for 21.2% and 15%, respectively. By using this two high-oil germplasm, Lambert et al. (1998) managed to breed high-oil maize hybrids (oil content ranged from 7% to 9%) without grain yields decreasing. However, if the oil contents were increased to a range of 10–15%, the grain yield decreased. By incorporating CML171 (a tropical high-oil inbred line) and YML107 (an inbred line derived from Suwan1), the high-oil hybrid Yunrui8 is developed with oil content of 9% and yield of 9.8 ton per hectare. From 2005 to 2015, Yunrui8 has cultivated over 0.6 million hectares cumulatively in Yunnan and other Chinese provinces.

5.4 Limitations of Traditional Breeding and Rationale for Molecular Breeding

The general process of traditional breeding can be simply described as; setting breeding objectives, germplasm creation, crosses and selections, field trials and evaluations, and finally the release of new cultivars. If desirable traits do not appear, breeders need to create more mutations or introduce other germplasm and repeat the above process to obtain desirable varieties. Although traditional breeding has had many successes and contributed greatly to global food security, its limitations cannot

be ignored such as (1) longer time required to breed pure lines that have stable and inheritable traits, (2) the offspring of hybrid F_1 have inferior performance compared with F_1 hybrids, causing farmers to buy F_1 seeds annually, (3) the artificial selection narrows the gene pool, (4) the interested traits are not precisely transferred when plants are crossed, and (5) crosses can only be done between two maize plants that can be sexually mated, it is thus impossible to add useful traits or genes from other species to maize.

Given the limitations of traditional breeding, molecular breeding can overcome some of these disadvantages. By using molecular tools to track within-genome variations, molecular breeding can monitor the recombination of specific genes or marker profiles in the breeding process.

6 Mapping Grain Quality Genes and Quantitative Trait Loci (QTLs)

Maize being an economically important cereal, attention has been paid to enhance maize grain quality (Protein, oil content, Fe, Zn, provitamin A, starch). Genetic studies have revealed that nutritional quality of maize kernels is possessed by quantitative traits. The recent advances in molecular and genomic research, and high throughput phenotypic techniques have accelerated genetic dissection of nutritional quality in maize by QTL mapping. Several nutritional quality-related quantitative trait loci (QTLs) in maize have been mapped using various DNA based markers viz., amplified fragment length polymorphisms (AFLPs), restriction fragment length polymorphisms (RFLPs), simple sequence repeats (SSRs), and single nucleotide polymorphisms (SNPs), and mapping populations F_2, $F_{2:3}$, DH (doubled haploids), BC (backcross), RILs (recombinant inbred lines), NILs (near isogenic line).

6.1 QTLs for Quality Protein Maize (QPM)

Maize kernels lack essential amino acids, lysine and tryptophan, and discovery of a spontaneous mutant with opaque and soft grains called *opaque2* (*o2*) during 1940s led to the development of QPM. The homozygous recessive *o2* allele was found to enhance lysine and tryptophan content (+69%) in maize grain endosperm. Several other mutants having different effects on lysine content in maize grain were identified viz., *floury2* (*fl2*), *opaque7* (*o7*), *opaque6* (*o6*), *floury3* (*fl3*), *mucronate* (*Mc*), *defective endosperm* (*De-B30*), *opaque7749*, *opaque7455* (*o11*), and *opaque16*. In the early 90s a total of 22 loci associated with protein and two major QTLs involved in *o2* modifications were reported. Recessive mutant *opaque 16* on chromosome 8 from Robertson's Mutator stock, and two SSRs umc1141 and umc1149 linked with the *o16* mutant were reported in late 90s. Research at CIMMYT identified markers representing grain hardness (endosperm modifiers) and high amino acid contents (amino acid modifiers) in elite QPM × QPM crosses. Babu and Prasanna 2014 performed BSA (bulk segregant analysis) in phenotypically contrasting progenies of

seven QPM × QPM populations using genome-wide SNP and found genomic regions associated with grain hardness and high tryptophan contents. Babu et al. (2015) mapped a total of five significant QTLs on chromosomes 5, 7, and 9 for tryptophan content in the $F_{2:3}$ population from a cross between two isogenic QPM lines VQL2 and VQL8.

6.2 QTLs for Oil Content

Maize oil is high in polyunsaturated fatty acids and low in linolenic acid, making it a desirable vegetable oil (Lambert 2001). Improving the quantity and quality of maize kernel oil content is an important target for breeding. Number of QTL mapping studies for oil content in maize kernels have been conducted. More than 120 QTLs for oil content using different mapping populations and markers have been reported till date. A major QTL located on chromosome 6 was identified from different populations (F_2, BC, RILs) and was consequently cloned. The oil content is influenced by a few QTLs with large effects, and epistasis is also crucial in the genetic basis of maize kernel oil content.

6.3 QTLs for Starch Content

Starch is the most important component of maize kernels, accounting for 70% of the kernel weight. It is used as a raw material in industries and in the production of other products like high fructose corn syrup, polymer-based fibers, and fuel ethanol. As a result, manipulating starch quality and quantity in maize kernels is a critical goal in maize breeding. QTLs for maize starch content are reported on all ten chromosomes. More than 50 QTLs for starch content has been reported so far. Recently, a major QTL *Qsta9.1* for starch content in a 1.7 Mb interval on chromosome 9 in the RIL population has been reported by Lin et al. (2019).

6.4 QTLs for Fe, Zn, and Provitamin A Content

Micronutrient malnutrition, particularly zinc (Zn), iron (Fe), and vitamin-A deficiency in diets, has sparked global concern. The genetic dissection of these traits in major cereal grains is a prerequisite for a biofortified breeding program. A few QTL mappings have also been conducted on micronutrient content in maize. For Fe and Zn content several QTLs (>50) and metaQTLs were reported, in different populations viz., RIL population, F_4 population, $F_{2:3}$ populations. The two informative genomic regions, bins 2.07 and 2.08 are associated with higher Zn and Fe content QTLs. The dissimilar number and position of QTLs for Fe and Zn noticed in different studies indicated their complex nature and it also depends on genetic material and environment.

Yellow kernel maize is grown and consumed globally but the provitamin A content is much less (~2ug/g), and efforts were taken up to identify QTLs/genes associated with higher provitamin A content of maize kernel. So far >120 QTLs are reported to be associated with provitaminA content in corn kernel, and major QTLs are co-localized with *zeta-carotene desaturase* (*ZDS*), *y1*, *y9, phytoene synthase, carotene dioxygenase* genes. The carotenoid biosynthesis pathway in maize is well studied, the significant allelic variations in two key genes of the pathway i.e., *lycopene-Ɛ-cyclase* and *β-carotene hydroxylase 1* controls accumulation of provitaminA carotenoids in maize endosperm (Harjes et al. 2008).

7 Association Mapping for Quality Traits

A genome-wide association study (GWAS) is a method used in genetic research to correlate specific genetic differences with specific traits. Due to the large coverage of historical recombination events prominent to the rapid decay of linkage disequilibrium (LD), GWAS analysis is the best approach to efficiently fine map QTL. Maize is the most suitable crop to perform GWAS due to abundant genetic variability, distinct subpopulations, plenty of SNP information, and rapid decay of LD. GWAS revealed a loci *Zmfad2* responsible for the changes in oleic acid content. Similarly, a strong candidate gene *DGAT1–2* controlling oil content on chromosome 6 was identified through GWAS. Genome-wide SNP scanning of contrasting lines for tryptophan content revealed many polymorphic regions, most notably 2.07, 5.03, and 10.03, which are associated with grain modifications and tryptophan contents. Cook et al. (2012) conducted Joint-linkage mapping (JLM) and GWAS in a nested association mapping population, and identified 21–26 QTLs through JLM for kernel oil, starch, and protein content; whereas from GWAS a gene *Acyl-CoA: diacylglycerol acyltransferase1–2*, controlling oil composition and quantity. Li et al. (2013) revealed 74 loci associated with kernel oil and folic acid composition in GWAS study using 1.03 million SNPs, further these loci were validated by expression QTL mapping and co-expression analysis. A coding region of the carotenoid biosynthetic genes *zep1* and *lut1*, as well as previously associated *lcyE* and *crtRB1* genes were identified by Owens et al. (2014) in a GWAS across 281 maize inbreds.

A *CrtRB1* gene on chromosome 10 related to β-carotene was identified from GWAS using CIMMYTs CAM panel of 380 diverse tropical and subtropical inbred lines (Suwarno et al. 2015). GWAS carried out by Liu et al. (2016) with a set of 263 maize inbred lines genotyped with the SNP50 BeadChip maize array, identified four QTLs and four genes within the 100-kb intervals and 77 candidate genes associated with starch synthesis; they further reported, *Glucose-1-phosphate adenyltransferase* (APS1; *GRMZM2G163437*) as a key controller of kernel starch content. GWAS using three RIL populations conducted by Deng et al. (2017) revealed 247 and 281 significant loci associated with grain protein controlling genes in two different environments, and reported that the *O2 (GRMZM2G015534)* gene is located approximately 98 Kb downstream of the lead SNP on chromosome

7 and regulates endosperm storage protein genes such as 22 kD and zein. A significant association between several SNPs on chromosome 9 and amylose content was revealed in a GWAS analysis (Li et al. 2018). Association mapping using high-density SNPs in 923 inbred maize lines was evaluated for Fe and Zn by Hindu et al. (2018), and a total of 20 and 26 SNPs were found to be significantly associated with Kernel Zn and Fe concentrations.

The carotenoid biosynthesis genes *crtRB1, lcyE,* and *ZEP1* were discovered in a GWAS performed using 130 diverse panels of yellow maize tropical inbred lines (Azmach et al. 2018). Furthermore, several transcription factors viz., RING zinc finger domain, and HLH DNA-binding domain superfamily proteins involved in the regulation of carotenoid biosynthesis were reported. A total of 49 SNPs significantly associated with five-grain quality traits, and three candidate genes for protein content, three for oil content, and three for starch content were identified using 83,057 SNPs in a GWAS with 248 diverse inbred lines (Zheng et al. 2021).

8 Marker-Assisted Breeding

Marker-assisted breeding (MAB) selects plants for inclusion in the breeding program at an early stage of development by using molecular markers associated with desirable traits. MAB uses molecular markers, molecular biotechnology, genomics and linkage mapping in conjunction with genotypic analyses to improve plant traits. Marker-assisted selection (MAS), marker-assisted backcrossing (MABC), marker-assisted recurrent selection (MARS), genomic selection (GS), and genome-wide selection (GWS) are all synonyms for this term. MAB has been used successfully to improve the genetics of various nutritional traits in maize. The important QTLs/genes to be utilized in molecular or genomic breeding, advanced tools and techniques to develop nutritional rich maize are depicted in Fig. 1.

8.1 MAB for Quality Protein Maize

The initiation of MAS for QPM development was accomplished with *o2*-specific SSR (Gupta et al. 2009; Shetti et al. 2020). Through MABB, the Institute of Crop Science and the Chinese Academy of Agricultural Sciences (CAAS) established several diverse QPM lines with different genetic backgrounds (Tian et al. 2004). The introgression of *o2* allele into normal maize inbred lines has resulted in a 41% and 30% increase in tryptophan and lysine contents, when compared to non-QPM hybrids. The MAS-derived QPM version of "Vivek Hybrid 9" was designated as "Vivek QPM 9" possessing significantly improved amino acid profile (tryptophan increased by 41%, lysine increased by 30%, histidine increased by 23%, and methionine increased by 3.4%), and was released in India in 2008 (Gupta et al. 2009). Liu et al. (2016) identified *q27* as a functional marker associated with endosperm modifications, which has opened up a new avenue for QPM breeding. Shetti et al. (2020) introgressed *o2* allele into parental lines of popular maize hybrids

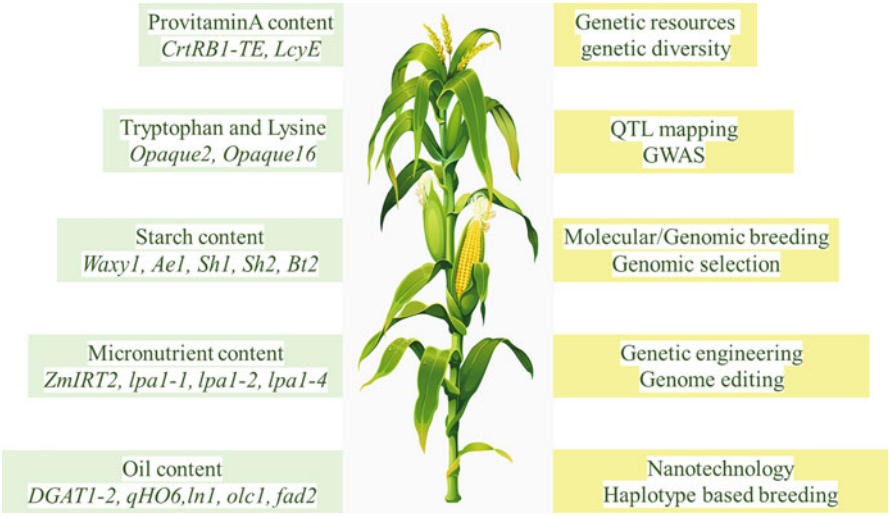

Fig. 1 Genomic designing for nutritionally richmaize

and observed 20–40% higher tryptophan content in converted lines. Sarika et al. (2018) investigated F_2 populations derived from crossing normal maize lines (CML533 and CML537) with a mutant *o16* donor line (QCL3024) and observed that the *o16o16* mutant combination results in genotypes with approximately two times the lysine and tryptophan content than of normal maize.

Indian Agriculture Research institute (IARI) have developed several QPM hybrids such as "Pusa HM-4 Improved," "Pusa HM-8 Improved," and "Pusa HM-9 Improved," and released for general cultivation in India in 2017 (Hossain et al. 2018). Four commercial QPM hybrids, HQPM-1, HQPM-4, HQPM-5, and HQPM-7 developed in India via *o16* MABB introgression in their parental lines have 49–60% increase in lysine and tryptophan contents (Sarika et al. 2018). Through MABB, CIMMYT recently developed several QPM versions (CML244Q, CMl246Q, CML349Q, and CML354Q) of popular inbred lines (CML244Q, CMl246Q, CML349Q, and CML354Q). The performance of these QPM versions is comparable to that of their normal versions (Qureshi et al. 2019).

8.2 MAB for Oil Content

The *DGAT1-2* gene has been majorly used in MAS for oil improvement of maize kernels. Hao et al. (2014) used MABC to transfer the *DGAT1-2* from the high-oil inbred line (By804) into two parents of Zhengdan958 and effectively improved the oil content without changing grain weight. The major QTL *qHO6* for enhancing oil content in maize grain located on chromosome 6 has also been extensively used in MABB (Hao et al. 2014) and developed high-oil populations and hybrids, namely Illinois 6021, 6052, 6001, and Burr white.

8.3 MAB for Starch Content

The discovery of the *ae* (amylose-extender) mutant alleles led to development of high-amylose plants. Amylose content is significantly higher in maize endosperm with the *ae* recessive alleles. Chen et al. (2010) described the use of *ae* (amylose-extender) recessive mutant alleles to create high-amylose cultivars and able to detect *ae* alleles in a backcross and its second generation with this marker more efficiently (53.3 and 73.3%, respectively) than without marker selection.

8.4 MAB for Provitamin A Content

Naturally existing alleles of two key genes of carotenoid pathway were identified, Carotene hydroxylase1 (*CrtRB1*), and lycopene epsilon cyclase *(LcyE*) (Harjes et al. 2008). The favorable allele at *CrtRB1* reduces hydroxylation of β-carotene into β-cryptoxanthin, whereas *LcyE* reduces flux into the α-branch of the pathway. Babu et al. (2013) validated the effects of 3 functional polymorphisms (*LcyE5′TE, LcyE3′Indel* and *CrtRB1-3′TE*) and observed around twofold to tenfold increase in β-carotene (BC) and total provitamin A (proA) content. The *CrtRB1-3′TE* allele have large, significant effect on enhancing BC and total ProA content, irrespective of genetic constitution for *LcyE5′TE* and genetic background (Babu et al. 2013; Sagare et al. 2019), and the favourable*CrtRB1* allele is more effective in increasing PVA content than the favorable *LcyE* allele (Babu et al. 2013). Muthusamy et al. (2014) introgressed favorable allele of *CrtRB-1* into seven elite inbreds and observed β-carotene concentration varied from 8.6 to 17.5 μg/g among the *crtRB1*-introgressed inbreds which was 12.6-fold higher than original lines. Several inbred lines and hybrids have been developed in recent past possessing favorable alleles of *CrtRB-1* and *LcyE* through molecular breeding to enhance provitamin A content (Babu et al. 2013; Azmach et al. 2013; Muthusamy et al. 2015; Yang et al. 2018; Maqbool et al. 2018; Sagare et al. 2019; Mehta et al. 2020; Natesan et al. 2020), and the increase in provitamin A content varied from 5 to 18 μg/g in introgressed lines and hybrids. Recently, Natesan et al. (2020) conducted MABC to transfer the β-carotene gene, *crtRB1*, into UMI1200 and UMI1230 using HP467-15 as the donor parent using one gene-specific marker (*crtRB1 3′TE*), and using the improved lines, five hybrid combinations were developed and ACM-M13-002 was identified as a superior hybrid with a 7.3-fold increase in β-carotene concentration.

8.5 Pyramiding Grain Quality Genes

Gene pyramiding is the process of combining desirable traits by stacking multiple genes into a single genotype. Via molecular breeding approaches several grain quality genes/ QTLs have been pyramided in maize (Table 3) without compromising grain yield. In India, QPM was introgressed with provitamin A, resulting in the provitamin A-enriched elite QPM inbreds CML161 and CML171, Pusa HQPM-5

Table 3 Pyramiding nutritional quality traits in maize through molecular breeding

Traits	Gene combination	Nutritional trait value	Reference
QPM and ProvitaminA	*CrtRB1* in QPM inbreds	5.25–8.14 μg/g provitaminA, 0.35% Lysine	Liu et al. 2015
QPM, ProvitaminA, Vitamin E	*CrtRB1*, *LcyE*, and *VTE4*	16.8% μg/g α-tocopherol, 11.5 μg/g provitaminA, 0.367% Lysine, 0.085% Tryptophan	Hossain et al. 2018
QPM, ProvitaminA, Low phytate	*lpa1-1*, *lpa2-1* in provitamin enriched QPM inbreds	8.3–11.5 μg/g provitaminA, 0.081–0.087% Tryptophan, 0.323–0.372% Lysine, 30–40% reduction in phytic acid phosphorus	Bhatt et al. 2018
QPM and ProvitaminA	*CrtRB1* in QPM inbreds	10.75 μg/g provitaminA, 0.080% Tryptophan, 0.303% Lysine	Goswami et al. 2019
QPM and ProvitaminA	*CrtRB1* in QPM inbreds	6.25–6.80 μg/g provitaminA, 0.080% Tryptophan, 0.334% Lysine	Sagare et al. 2019
QPM and ProvitaminA	opaque2 in β-carotene riched lines	6.12–7.38 μg/g β-carotene, 0.073–0.081% Tryptophan, and 0.294–0.332% Lysine	Chandran et al. 2019
QPM and ProvitaminA	*sh2, opaque2, lcyE and crtRB1* in parental lines of sweetcorn hybrid	18.98 μg/g Provitamin A, 0.39% Tryptophan, 0.10% Lysine, 17.04% brix	Mehta et al. 2020
QPM, Provitamin A, kernel sweetness	*shrunken2, opaque2, lcyE* and *crtRB1* in sweetcorn hybrid	0.390% Lysine, 0.082% tryptophan, 21.14 ppm Provitamin A, 18.96% brix	Baveja et al. 2021
Low amylopectin	waxy1 in white and yellow kernel maize inbreds	96.7% Amylopectin	Talukder et al. 2022
QPM and low amylopectin	*waxy1* and *opaque2* in inbreds	98.84% Amylopectin, 0.102% Tryptophan, and 0.384% Lysine	Talukder et al. 2022

improved, PVCBML6, PVCBML7, Pusa HQPM-7 improved, HKI1128Q, and Pusa Vivek QPM9 improved (Goswami et al. 2019; Liu et al. 2015; Muthusamy et al. 2014; Sagare et al. 2019). Hossain et al. (2018) reported the introgression of QPM with provitamin A and vitamin E, which resulted in the development of improved QPM and provitamin A-rich hybrids (HQPM-1-PV, HQPM-4-PV, HQPM-5-PV, and HQPM-7-PV) with higher α-tocopherol contents. Bhatt et al. (2018) attempted introgression of QPM, provitamin A content, and low phytate content which resulted in the development of improved versions of elite inbreds (HKI161-PV, HKI163-PV, HKI193-1- PV, and HKI193-2- PV) with higher protein quality, higher provitamin A content, and lower phytate content. Chandran et al. (2019) attempted o2 gene introgression (from HKI163 donor) to β-carotene-rich inbred lines (UMI1200β) and improved lines showed higher lysine (0.29–0.33%), tryptophan (0.07–0.08%), and β-carotene (6.12–7.38 μg/g) contents, along with improved agronomic performance. Parental lines of shrunken2 (*sh2*)-based sweet corn hybrids (ASKH-1 and ASKH-2) were subjected to *crtRB1* and *o2* gene introgression through use of

MABB, and reconstituted hybrids with converted lines was found with higher levels of provitamin A (18.98 μg/g), lysine (0.39%), and tryptophan (0.10%), and on par yield as original hybrid (Mehta et al. 2020). Talukder et al. (2022) deployed GAB to pool recessive *waxy1 (wx1)* and *o2* genes in the parental lines of four popular hybrids (HQPM1, HQPM4, HQPM5, and HQPM7) using the gene-based markers. The re-formed hybrids showed 1.4-fold increase in amylopectin and 14.3% and 14.6% increase in lysine and tryptophan respectively over the original hybrids (lysine- 0.336%, tryptophan- 0.089%). Three promising maize hybrids derived from MABB (improved Pusa Vivek Hybrid-27 – provitamin A), Pusa HQPM5 Improved – QPM and provitamin A, and Pusa HQPM7 Improved – QPM and provitamin A) have all been developed and approved for commercial cultivation in India in 2019 (Prasanna et al. 2020). MAS was used to introduce QPM with various nutritional traits such as provitamin A, vitamin E, and low phytate content.

9 Cloning of Grain Quality-Related Genes

The approach of determining the genetic basis of a mutant trait by exploring the linkage with markers whose physical location in the genome is known is referred as map-based cloning, also known as positional cloning. Because of the large amounts of repetitive DNA in maize, positional cloning was thought to be nearly impossible in the last century. However, now that maize physical maps and large number of available markers, and, most importantly, synteny conservation across cereal genomes, make it possible to consider a chromosome walk in less time than cloning by transposon tagging (Bortiri et al. 2006). The following factors pose significant challenges to gene discovery in maize: (1) large genome size, (2) variation in gene order and genome size, (3) a higher rate of multicopy genes, and (4) repetitive sequences and transposons. In maize, the genetic basis of various traits varies greatly. Positional cloning was done for different traits in maize such as disease-resistant, male sterility, fertility restoration, plant architecture etc. But very less work of positional cloning is done on health-related/grain quality traits. Till date several genes related to maize nutritional quality have been cloned such as, opaque1 (*o1*), foury4 (*f4*) and Mucronate (*Mc*) for protein quality, linoleic acid1 (*ln1*), Oleic acid content1 (*olc1*), fatty acid desaturation 2 (*fad2*), and fad6 for oil content, and some of the starch content related genes – Shrunken1 (*Sh1*), *Sh2* and Brittle2 (*Bt2*).

Buckner et al. (1990) cloned the *y1* locus of maize involved in the carotenoid biosynthesis. A maize cDNA encoding phytoene desaturase, an enzyme of the carotenoid biosynthetic pathway was characterized and cloned by Li et al. (1996). The key genes involved in the starch biosynthesis pathway have been cloned, including starch branching enzyme amylose-extender1 (*Ae1*), brittle2 (*Bt2*), Suc synthase shrunken1 (*Sh1*), large subunit of AGPase shrunken2 (*Sh2*), isoamylase-type DBE sugary1 (*Su1*), and granule-bound starch synthase waxy1 (*Wx1*). Zhang et al. (2019) found that wild-type *Se1* is a gene *Zm00001d007657* on chromosome 2 and deletion of this gene causes the sugary enhancer1 (*se1*) phenotype, which is actively involved in starch metabolism in maize endosperm. Recently, Li et al. (2022)

isolated a novel gene from maize (*ZmIRT2*), which exhibited highly homologous to *ZmIRT1*. *ZmIRT2* was expressed in roots and anther and was induced by Fe and zinc (Zn) deficiencies. *ZmIRT2* overexpression in maize led to elevated Zn and Fe levels in roots, shoots, and seeds of transgenic plants. *ZmIRT1* transcript levels were higher in the roots of *ZmIRT2* transgenic plants. According to this study, *ZmIRT2* may only work with *ZmIRT1* to mediate Fe uptake in roots, and *ZmIRT2* could also be used in fortification efforts to increase Zn and Fe levels in crop plants.

10 Recent Concepts and Strategies Developed

10.1 Gene Editing

Genome engineering technologies such as ZFNs (zinc finger nucleases), TALENs (transcription activator-like effector nucleases) and CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats (CRISPR)-associated 9 (Cas9) endonucleases) along with tissue specific expression of functional genes have accelerated molecular/genomic breeding (Chilcoat et al. 2017) Maize has large number of commercialized transgenic events (Yadava et al. 2016), this demonstrates that maize improvement has always been taken prominently and genome engineering is powerful technology to pave the way for enhancing and stacking nutritional quality traits in maize.

The phytate content in maize was reduced by blocking IPK1 gene encoding inositol-1,3,4,5,6-pentakisphosphate 2-kinase using ZFNs (Shukla et al. 2009). Three genes of phytate biosynthetic pathway, *ZmIPK1A*, *ZmIPK*, and *ZmMRP4* were knocked out using CRISPR/Cas9 and TALENS (Liang et al. 2014). RNA interference (RNAi) and CRISPR/Cas9 knockout *ZmMADS47* gene encoding a MADS-box protein, that interact with *o2* to activate zein gene promoter, and the reduced zein content 16.8 and 12.5% were observed in the kernels of *ZmMADS47 RNAi* and MADS/CAS9-21 lines, respectively (Qi et al. 2016). Starch metabolism in maize was altered using CRIPSR/Cas9 to disrupt the waxy gene (*Wx1*), which encodes GBSS being responsible for synthesizing amylose in maize (Waltz 2016). Several nutritional quality traits such as, QPM (*o2, o16*), provitaminA (*CrtRB1, LcyE*), kernel sweetness (*Shrunken2*), low amylopectin (*waxy1*), etc have been well characterized and gene editing could serve as a powerful system for stacking these traits in agronomically superior and high yielding genetic backgrounds (Table 4).

10.2 Nanotechnology

Nanotechnology is a study of nanoparticles (NPs) with unique physical, chemical and biological properties, and in recent past use of nanotechnology in agriculture has been accelerated due to its wide range of applications in crop improvement. The major applications of nanotechnology in agriculture includes; improved seed

Table 4 Potential targets for gene editing to improve nutritional quality in maize

Trait	Genes	Protein function	Gene editing strategy
Starch content	SBE1, SBE3, SBE4, AE1	Starch branching enzymes	Knockout
	SS1, SS2, SS3, SS4, SS5, SS6, SS7, Du1, Su2	Starch synthase	Overexpression
	Waxy1, GBSS1	Granule bound starch synthase	Overexpression
	GPM177	Protein targeting to starch	Overexpression
Oil content	PEP1	Phosphoenolpyruvate carboxylase	Knockout
	ACC1, ACC2, TIDP3607	Acetyl-CoA carboxylase	Overexpression
	LN1, DGATI2	Diacylglycerol acyltransferase	Overexpression
	OLE1, OLE3, OLE4	Delta-9 desaturase	Overexpression
	FAD2	Delta-12 fatty acid desaturase	Knockout
	KCS1, KCS16	Fatty acid elongase	Knockout
Essential amino acid content	VSP1, VSP2, BIP1, BIP2, BIP3	Storage protein	Overexpression
	HNT1	Homocysteine S-methyltransferase	Overexpression
	GOT1, GOT2, GOT3, GOT4	Aspartate aminotransferase	Overexpression
	ASN3, ASN4	Asparagine synthetase	Overexpression
Vitamin content	VP5	Phytoene desaturase	Overexpression
	DXS1	1-deoxyxylulose 5-phosphate synthase	Overexpression
	DXR1, DXR2	Deoxy-D-xylulose 5-phosphate reductoisomerase	Overexpression
	NCED6, NCED8	Carotenoid cleavage dioxygenase	Knockout
	HPT1	Homogentisatephytyltransferase	Overexpression
	SXD1	Tocopherol cyclase	Overexpression
	DHFS1, DHFS2	Dihydrofolate synthetase	Overexpression
	FGP2, BM4	Folylpolyglutamate synthase	Overexpression
Mineral content	NAS1, NAS2, NAS3, NAS4, NAS6, NAS8, NAS9, NAS10	Nicotianamine synthase	Overexpression
	NAAT1, PCO115235C	Nicotianamine aminotransferase	Overexpression
	IDP871	Small GTPase	Overexpression
	MIPS2	Myo-inositol-1-phosphate synthase	Knockout
	PAP2, PAP22	Phytase	Overexpression

germination using nanoformulations, nanofertilizers for nutrient use efficiency in crop that helps in accumulation of nutritional quality components in the edible portion, weed control using herbicides, disease and pest control using nanopesticides and nanosensors, nanopackaging for improving shelf life of produce, nanosensors for post-harvest quality analysis. Research on NPs for improving nutrition quality-

related traits in cereals has gained attention in the recent past (Bajpai et al. 2020). In the agronomic biofortification approach, application of nanofertilizers to enhance nutrient use efficiency of crop and subsequently to improve nutritional quality of maize is an emerging approach. Surface-modified zeolite enhances phosphate and sulfate uptake (Li and Zhang 2010), Montmorillonite and Zeolite improves nitrogen uptake via xylem (Manikandan and Subramanian 2014), Nanocomposites containing organic polymer intercalated in the layers of kaolinite clays increases uptake of wide range of micronutrients. Recent developments in genetic engineering and engineered nanomaterials based targeted delivery of CRISPR/Cas mRNA, and sgRNA for the genetic modification of crops is a noteworthy scientific achievement and this will pave the way to enhance the nutritional content of major cereals like rice, corn, and wheat.

11 Genetic Engineering for Nutritional Quality Traits

Biosynthetic and metabolic pathways of nutritional traits of maize are well studied. Genetic engineering (GE) approach provides opportunity to enhance nutrition content of maize via several approaches viz., transformation of single gene, transformation with multiple genes (encoding different nutrients) in a single cassette, overexpression of nutrient transporters, silencing of feedback inhibition enzymes of nutrient biosynthesis pathways, overexpression of major enzymes of pathways. Genetic engineering for enhancing nutrient content of crops by modifying biosynthesis pathways is called metabolic engineering.

11.1 GE to Enhance Essential Amino Acids

Zein are the major proteins in maize and deficit in essential amino acids lysine and tryptophan. T-DNA mediated mutations in 19- and 22-kD α-zeins in maize enhanced seed Lys and Trp content and reduced zein levels. A genetically engineered high lysine maize (0.360% vs. 0.255% in common maize kernel), LY038 was developed by transformation of the *cordapA* gene from *Corynobacterium glutamicum*, a soil bacterium, into the maize genome (Lucas et al. 2007). LY038 is the first genetically modified (GM) maize, approved for commercial use in countries like Colombia, Mexico, Canada, the Philippines, the USA, and Japan (EPA 2020). Tryptophan synthesis is feedback regulated by inhibiting Anthranilate synthase (AS), and 1.1- to 50-fold increase in free amino acid content in maize transformed with feedback altered AS gene than in non-transformed maize is reported.

11.2 GE to Enhance Micronutrients

Phytic acid (phytate) is a chelator, reduces bioavailability of essential micronutrients such as Fe, Zn, Ca, Cu, Mn etc. The *low phytic acid* (*lpa*) mutant of

maize viz., *lpa1-1* and *lpa2-1*, *lpa241* were found with 50–90% reduction in phytate, but have negative effect on seed germination and plant growth. Genetic modification of *lpa1-1* maize by endosperm specific overexpression of soybean ferritin gene was resulted in more than twofold improvement in iron bioavailability, and transgenic *lpa1-1* seeds were having higher germination rates and seedling vigor compared to non-transgenic seeds (Aluru et al. 2011). A significant enhancement in bioavailable Fe was observed in transgenic maize lines generated by endosperm specific co-expression of recombinant Soybean ferritin and *Aspergillus* Phytase genes.

11.3 GE to Enhance Carotenoids

Multiplex transgenic maize developed by transferring 5 carotenogenic genes, *Zmpsy1* (*Zea mays phytoene synthase 1*), *PacrtI* (*Pantoeaananatis phytoene desaturase*), *Gllycb* (*Gentiana lutea lycopene-cyclase*), *Glbch* (*Gentiana lutea carotene hydroxylase*), and *ParacrtW* (*Paracoccus*carotene ketolase) driven by different endosperm-specific promoters have resulted in 50- to 60-fold increase in total carotenoids. Carotenoid intermediates such as, keto-carotenoids, asthaxanthi, adonixanthin, 3-hydroxye chinenone, echinenone were engineered in transgenic maize. Genetic modification in maize by transferring *ZmPSY1 cDNA* (with LMW glutenin promoter from wheat), *Crt1* gene from *Pantoeaananatis* (with barley Dhordein promoter), *Osdhar* gene (for ascorbate) and E. coli *folE* gene (for folate) were found to possess 169-fold higher β-carotene, 6-fold higher ascorbate, and double amount of folate than non-transformed maize (Naqvi et al. 2009). Transgenic maize produced by overexpression of *Psy*gene and silencing *LcyE* gene resulted in diverting carotenoid biosynthesis pathway toward β-branch, and thus, with increasing high value astaxanthin carotenoid in the kernel (Farre et al. 2016). Overexpression of the *IbOr* gene in maize inbred lines under the control of maize seed-specific promoter globulin 1 (*Glo1*) resulted in 10.36- and 15.11-folds increase in total carotenoid and ß-carotene contents (Tran et al. 2017).

11.4 GE to Increase Oil and Starch Content

Maize transformed with *Puroindoline* genes (*Pina* and *pinb*) from wheat resulted in 25.23% increase in a total oil content (Zhang et al. 2010). Overexpression of *ZmWRI1* (*WRINKLED1*) gene in maize resulted in enhancing oil content without affecting seed germination, plant growth and grain yield (Shen et al. 2010). The maize transformed with fungal *diacylglycerol acyltransferase2* (*DGAT2*) genes from *Umbelopsisramanniana* and *Neurospora crassa* under the control of embryo enhanced promoter, showed 26% increase in kernel oil content compared to non-transgenic maize (Oakes et al. 2011).

11.5 GE to Increase Starch Content

Genetic transformation of maize with *Bt2* and *Sh2* genes from wild maize under the control of endosperm specific promoter resulted in increased starch content in transformed lines (Li et al. 2008). Overexpression of *Bt2*, *Sh2*, *Sh1* and *GbssIIa* genes, and silencing *SbeI* and *SbeIIb* by RNA interference to enhance activity of sucrose synthase, AGPase and granule-bound starch synthase, and to reduce the activity of starch branching enzyme in maize, resulted in 2.8–7.7% increase in kernel starch and 37.8–43.7% increase in amylose content (Jiang et al. 2013). The overexpression of the mutated *ZmDA1* and *ZmDAR1* genes driven by maize ubiquitin promoter resulted in improving the sugar imports into the sink organ and starch synthesis in maize kernels (Xie et al. 2018).

12 Role of Bioinformatics in Maize Metabolome Improvement

Maizeis a model cereal crop in omics research programs across the world, and studies on maize using multi-omics datasets could help to understand more about domestication, selection, and evolution of maize over the period of time. In 2009 the first maize reference sequence B73 was released, further using high-density SNPs several maize lines and population were re-sequenced and mapped against B73 reference genome to expandnutritional related genomics such as oil and vitamin metabolism (Wang et al. 2018). Currently in maize genome database several additional maize genome sequences have been reported such as, PH207, Mexicana, Mo17, W22, HZS, and SK. For successful maize breeding and improvement programs timely utilization of multi-omics tools, datasets, and web-resources could be most imperative (Table 5) These genome sequences, datasets and omics platforms are playing crucial role in maize metabolome improvement, and assisting in diversified breeding purposes to bred varieties with high yield and nutritional quality

13 Conclusion and Future Perspectives

The early generation crop breeding approaches such as, phenotypic selection, cross breeding, mutation breeding have been developed several high yielding, biotic and abiotic stress-resistant varieties and hybrids. And, also identified diversity and resources for traits contributing nutritional quality. These conventional/ traditional breeding approaches are tedious and time consuming and creates difficulty in breeding quantitative traits. The recent advances in molecular tools, techniques, genome sequencing technologies, novel genomic tools such as trait mapping, identifying trait specific major QTLs and genes, haplotype-based allele mining, enriched bioinformatic databases, rapid generation advancement through speed breeding and

double haploid, genomic selection, genome editing, nanotechnology, machine learning, and artificial intelligence has led to current generation crop breeding such as, biotech breeding and design breeding. The pathways of nutritional traits are well studies, the information on key enzymes, associated genes/QTLs, genetic diversity

and resources is publicly available. The genome editing technologies and speed breeding approaches are assisting haplotype-based breeding/design breeding which can assist in developing tailor-made maize with higher nutrition.

Barley: From Molecular Basis of Quality to Advanced Genomics-Based Breeding

Franca Finocchiaro, Valeria Terzi, and Stefano Delbono

Contents

Abstract

Barley (*Hordeum vulgare* L.) is a cereal crop that belongs to the family of Poaceae (Gramineae) and tribe Triticeae. This cereal ranks fourth in the world production of cereals. Barley is one of the cereals having greater genetic diversity. It is largely used for animal feed and malting, with only a minor part used for human consumption. Barley can be considered an excellent cereal to produce functional foods, thanks above all to the presence of soluble fiber (β-glucans). In barley grains, it is possible to find a lot of bioactive compounds: from carbohydrate polymers (like β-glucan, arabinoxylan, and hemicellulose), to vitamin E (tocopherol and tocotrienols), to secondary metabolites like phenols. Over the

years, breeding programs have therefore been implemented to improve the content of bioactive compounds in barley. Genomics has developed very quickly in the last years, providing tools and technologies that help us to lend precision and efficiency to barley breeding programs for the development of new varieties with healthier properties and resilient to climate changes.

1 Introduction

1.1 Agricultural Importance of the Crop

Barley (*Hordeum vulgare* L.) is a cereal crop that belongs to the family of Poaceae (Gramineae) and tribe Triticeae (Fig. 1).

This cereal is the fourth in the world production of cereals, after wheat, maize, and rice. It is a crop that can grow under a wide environmental condition, stress tolerant, and, for these reasons, barley is particularly used in some developing countries that present arid climate condition, being the most important staple food resource. Currently, barley is grown on 48 million hectares in moderate, continental, and subtropical climates. It is mainly employed for animal feeding, to produce beer and

Fig. 1 Barley spike

spirits, and to an ever-increasing extent, for human consumption. The barley world production was about 147.05 million metric tons in the 2021/2022 crop year, with a reduction of about 14.0 million metric tons compared to 2020/2021 (https://www.statista.com/statistics/271973/world-barley-production-since-2008/). Besides being an agronomically relevant crop, barley is considered a very good model for the Triticeae, especially bread, which possess very complex polyploid genomes. Barley is diploid with a genome size of about 5.3 Gb distributed over seven chromosomes.

Barley was one of the first cereals being cultivated: archaeological finds have been found in areas corresponding to the Fertile Crescent and its domestication has been traced back to about 8000 years BC (Giraldo et al. 2019). Since its domestication, barley was a staple food, with considerable nutritional importance. At the time of the Romans, for example, it was used in the training diet of gladiators, a term that in Latin means *Horderarii*, literally "men of barley." It has been the staple food especially in areas characterized by unfavorable environmental conditions and low productivity, as in the developing countries. It is still a staple food in some world areas, like North Africa and Near East regions and in the mountain region of Central Asia and South America. Something changed during the Middle Ages as wheat reached more significance in breadmaking, while barley almost disappeared from the diet of many countries, while its most important employment was for feed and, to a lesser extent, in alcohol beverages production (Giraldo et al. 2019). The cause can be found in the low gluten content, which determines less swelling of the loaf, and lower quality in general.

Barley is one of the cereals having higher genetic diversity. According to the sowing period, there are winter, spring, or alternative types. According to the morphology of the spike, there are two- and six-rowed types. The grain is generally hulled (covered or dressed) with an outer structure around the grain, but hull-less (naked) grains, in which the outer hulls detach easily, as in wheat, also exist. Based on starch composition of the grain, normal, *waxy,* or high amylose barley type can be distinguished; high lysin, high β-glucan, and proanthocyanin-free varieties are also available. Two-rowed barley is the wild one that is grown in Europe, whereas the six-rowed is developed by gene mutation and has a triple crop yield. Both two-rowed and six-rowed barley genotypes have winter and spring types. Winter type is cultivated in fall (especially in Europe, the United States, and Canada), whereas spring cultivar is cultivated in spring or summer in the Mediterranean region (Farag et al. 2022).

Most of the cultivated barley, about 65%, is employed for animal feed, about 33% is destined for malting production, while only 2% is used for human consumption as an ingredient of several food products (Farag et al. 2022). Historically, barley has been an important food source in many countries, including the Middle East, North Africa, and Northern and Eastern Europe (Farag et al. 2022). However, better product quality of food products prepared from wheat and rice compared to barley considerably decreased the use of barley as food, especially in the nineteenth and twentieth centuries. In the past, barley has received more attention from breeders and researchers thanks to the growing requests of healthy and more traditional food, which has led to the development of breeding programs aimed to obtain new barley varieties with a high level of healthy substances in the grain.

The growing world population is causing a higher demand for food and puts high pressure on soil and production systems. The future of agriculture will have to take into account the improvement of the nutritional quality of its products, trying to mitigate the environmental impact.

1.2 An Overview of Barley Composition

Barley grain consists of about 65–68% starch, 10–17% protein, 4–9% β-glucan, 2–3% free lipids, and 1.5–2.5% minerals. β-Glucans, part of soluble fiber, constitute about 75% of the barley endosperm cell walls together with 20% arabinoxylans and protein. Genotype, environment, and crop management practices used during the crop-growing cycle determine grain composition and structure. β-Glucans, which represent normally about 5–10% of the caryopsis weight, have a very significant effect on technological and quality properties of barley. For example, both β-glucans and arabinoxylans are fundamental in malting quality as they are responsible for wort viscosity and beer filtration rates and block hydrolytic enzymes, which in turn break down starch and protein within the cell walls. Moreover, for malting quality and brewer production, the beer foam stability is linked to a minimal amount of β-glucans in the malt (Farag et al. 2022). Accordingly, low β-glucan content of grain and/or its breakdown during malting are critical issues in brewing and most barley breeding has produced barley cultivars that are normally low in β-glucans.

Chemical and nutritional compounds of barley caryopsis can significantly vary due to genotype, agronomical practices, and environmental condition. The most abundant compounds of barley kernel are starch, fiber (including β-glucans), and proteins: varying the content of one of these substances will have a direct effect on the other two. Starch content is inversely correlated to protein and fiber. The *starch* is localized in the endosperm layer and is quite variable in composition, representing 54–75% of the grain weight. The starch of the normal or nonwaxy barleys has relatively high amylose (25%) and low amylopectin (75%), whereas waxy barleys have a low concentration of amylose (0–5%) and high amylopectin (100–95%). There are also high amylose barley mutants (up to 45% amylose fraction) (Farag et al. 2022).

The *nonstarch polysaccharides* of barley caryopsis are structural molecules of the cell walls in hull, aleurone, and endosperm tissue. These polysaccharides are included in the total dietary fiber. In contrast to starch, they are not digested by human digestive system, but they are fermented by intestinal microbiota, producing several breakdown products, including short-chain fatty acids. The major nonstarch polysaccharides in barley are β-glucans, arabinoxylans, and cellulose. Cellulose is mainly located in the hull of the grain.

Arabinoxylans are located mainly in the aleurone, where they consist about 71% of the fiber content; arabinoxylans are also present in the endosperm, where they account for 21% of the fiber content. Generally, arabinoxylan ranged from 3.8% to 6.0% based on genetic and environmental factors. Six-rowed genotypes contained higher levels of arabinoxylan than two-rowed varieties.

β-Glucans are structural cell component that forms the cell wall in barley endosperm that accounts for 75% of the endosperm cell wall mass. The level of β-glucans in barley has a significant genetic variation, ranging from 3.0% to 15–17% (Farag et al. 2022). *Waxy* barley showed higher concentration of β-glucans. β-Glucan content is also affected by environmental factors: for example, the concentration increases under dry and hot conditions, while decreases under moist conditions.

The level of *protein* in barley is highly variable: it is reported to vary from 8% to 30% as a percentage of total mass (Jaeger et al. 2021), although the level in typical barley is more commonly reported between 9% and 13%.

The grain protein content is a valuable quality factor, defining barley grain end-use value: high protein grains would be desirable for feed, while a lower level (between 10% and 12%) is desirable for malting (Jaeger et al. 2021). The protein content is highly variable and can be affected by genotype, environmental conditions, and the use of fertilizers.

Hordeins are the most abundant protein fraction: they belong to the prolamin class, namely storage proteins, characterized by a high content of glutamine and proline. These protein types are complex polymorphic mixtures of polypeptides. The other barley proteins are represented by a mixture of albumins, globulins, and glutenin (Jaeger et al. 2021). Prolamins are composed of high content of the amino acids glutamine, proline, and low level of essential amino acids such as lysine, threonine, and tryptophan.

After hordeins, glutelin are the second most abundant storage proteins: they contain high levels of glutamine, proline, and glycine, and other hydrophobic amino acids (Jaeger et al. 2021).

Albumin and globulin are minor protein forms in the aleurone grain and embryo (Farag et al. 2022).

The protein in barely includes both essential (about 28%: leucine, valine, threonine, phenylalanine, isoleucine, lysine, histidine, methionine) and nonessential amino acids (72%: glutamic acid, aspartic acid, proline, tyrosine, glycine, and cytosine), potentially making barley a good source of protein in food supplements. Among the essential amino acids, barley is lacking in lysine (Farag et al. 2022).

1.3 Importance of Barley in the Prevention of Chronic Diseases

There is growing evidence that higher intakes of whole grains are associated with reduced incidence and mortality from several chronic diseases.

Reynolds et al. (2019), in a recent systematic review and meta-analyses, showed that the data for whole grain consumption, from prospective studied and clinical trials, exhibit a reduction in all-cause mortality, coronary heart disease, cancer death, incidence of type 2 diabetes, and stroke mortality. The observed reductions in risk were high, typically around 20% with significant dose–response relationships. Among the bioactive components of whole grains, total fiber tended to explain the association to lower risk of CVD-related outcomes.

Barley is a cereal with a high level of dietary fiber, particularly the soluble fiber β-glucans, which is mainly credited for barley's health benefits, such as a reduction in cholesterol and glycemic response, the modulation of gut microbiota, the management of blood pressure, and a reduction in the incidence of metabolic syndrome (Murphy et al. 2020). In the scientific literature, there is a lot of evidence of the positive role of these compounds on physiological effects and the correlation between the consumption of β-glucans and blood cholesterol levels is now clarified. Several mechanisms have been proposed to elucidate the health effects of β-glucans and are still under study, but the factor thought to be the most responsible is the capability of soluble β-glucans to form viscous solution in the stomach and intestinal tract. The viscosity of β-glucan is related to its molecular weight, size, and its concentration in solution (Bai et al. 2019).

Cultivar, growing conditions, processing, and food matrix affect the physicochemical and health properties, particularly molecular weight and solubility, of β-glucans. For these reasons, when clinical trials and new "functional foods" are developed, these aspects should be strongly considered.

With consumers' increasing awareness of the importance of nutrition and health, food is not only regarded as a medium for satiety but also as a means for disease prevention and control; such desire has created a rapidly increasing demand for "functional foods," defined as foods that have an additional physiological benefit besides providing basic nutritional needs and opened markets for a broad range of processed foods, including beverages with specific health attributes (Shvachko et al. 2021).

Barley can be considered an excellent cereal to produce functional foods, thanks above all to the presence of soluble fiber (β-glucans). The strong scientific evidence regarding the metabolic effects of the consumption of β-glucans has led the EFSA to authorize the use of specific nutritional and health claims, thus allowing and regulating the communication to the public of the benefits associated with the consumption of nutrients, provided they are present in the final product in adequate quantities and in a form that can be used by the body. Therefore, it has ordered the claim for barley and oat-based products so that it can be reported that consume 3 grams per day of β-glucans, or 0.75 g per serving in the four main meals, helps reduce plasma levels of total cholesterol and low-density lipoprotein (LDL) (ESFA 2011).

In the past, thanks to the reported physiological properties of β-glucans, researchers have extensively studied the possibility to incorporate β-glucans in several food types with the aim to develop functional foods. Barley fractions enriched in β-glucans can be incorporated into wheat blends to make bakery good with improved nutritional properties. Finocchiaro et al. (2012) used two β-glucan-enriched flour fractions, from two hull-less barley cultivars with normal starch type and a high-β-glucan *waxy* genotype, mixed with bread wheat flour. The two flour blends were used to make bread, and the postprandial glucose response was determined. The results showed that incorporation of high level of β-glucans (6% in the final blend) from the non*waxy* cultivar lower the GI significantly. Blandino et al. (2015) used pearling fractions obtained from naked barley to substitute conventional refined wheat flour for breadmaking. These fractions resulted in abundant insoluble

and soluble dietary fiber (particularly β-glucans) and other bioactive compounds. The various healthy components present in barley kernel are not homogeneously distributed, and sequential pearling has shown to be an effective process to obtain fractions enriched in bioactive compounds (Blandino et al. 2015). Martínez-Subirà et al. (2020) obtained biscuits rich in β-glucans and antioxidants using barley flour from a purple hull-less cultivar. A single biscuit gives more than 0.75 g of β-glucans. In this way, it is easy to reach the target of EFSA recommendation and obtain the label lettering of "reduces blood cholesterol and risk of heart disease" (Martínez-Subirà et al. 2020).

Incorporation of β-glucan into pasta products revealed a lower glycemic response. A study on spaghetti enriched with barley β-glucans showed a β-glucan dose-dependence reduction of GI, with a reduction of up to 54% of GI with the incorporation of 10% of barley β-glucans (Tosh and Bordenave 2021). Similarly, a reduced glycemic index was reported in β-glucan-enriched breakfast bars (Mejía et al. 2020).

Diets and foods rich in β-glucans and with low glycemic index may have an effect on the prevention of important disease as coronary heart diseases and diabetes (Murphy et al. 2020). The simplest and most frequent use of β-glucan is their incorporation in cereal-based products, but their inclusion in beverages and dairy products has been also evaluated; it can also find some applications in the production of low-fat ice creams and yogurts (Mejía et al. 2020).

2 Barley Bioactive Compounds

In barley grains, it is possible to find a lot of bioactive compounds: from carbohydrate polymers (like β-glucan, arabinoxylan, and hemicellulose), to vitamin E (tocopherol and tocotrienols), to secondary metabolites like phenols, folates, and lignans. The focus of this section is to describe the bioactive phytochemicals that most characterize barley grain for its effects on human health: **β-glucans**, **tocols**, and **phenol/polyphenol compounds**.

2.1 β-Glucans

2.1.1 β-Glucans: Structure and Contents

Mixed-linkage (1→3),(1→4) linear β-D-glucans (β-glucans) are major constituents of endosperm cell walls of cereals such as barley (Fig. 2), oat, and to a lesser extent wheat and rye.

In barley, β-glucans account for 75% of the total cell wall polysaccharides, the remaining portion is made up of arabinoxylans, cellulose, glucamannans, and proteins. A unique feature of barley grain is that the β-glucan is uniformly distributed in the endosperm while it is concentrated in aleurone layers in oat grain, thus pearling or removal of the outer layers does not significantly affect the β-glucan content in barley (Murphy et al. 2020).

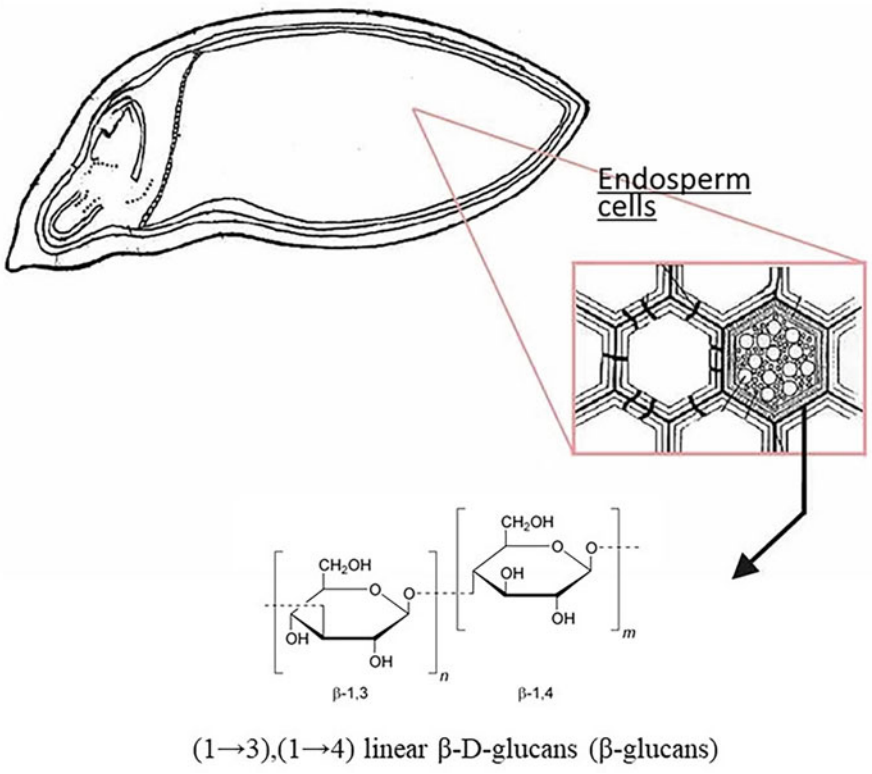

Fig. 2 Barley β-glucan structure and localization in the grain

β-Glucans are complex nonstarchy polysaccharides consisting of D-glucose monomers linked through β-glycosidic bonds, which widely exist in plants and microorganisms. Different sources of β-glucans lead to different structures and physicochemical properties (Bai et al. 2019).

Barley β-glucans are composed of linear homopolysaccharides of D-glucopyranosyl residues with β-(1→3) and β-(1→4) linkages. About 90% of glucose units are organized into blocks of cellotriose residues (three glucose molecules) and cellotetraose residues (four glucose molecules) joined by β-(1→3) bonds, while the rest are composed of segments longer cellulosics, composed of multiple glucose units (Bai et al. 2019).

As already discussed earlier, the molecular characteristics of β-glucans seem to determine their physical properties, such as water solubility, dispersibility, viscosity, and gelation properties, as well as of their physiological function. The chemical composition of β-glucans determines their partial solubility in water. For example, β-glucans containing blocks of adjacent β-(1→4) linkages can show lower solubility thanks to interchain aggregation (Bai et al. 2019). Therefore, in addition to the physiological benefits of soluble dietary fiber, cereal β-glucans also show health

properties typical of insoluble fiber, such as increased fecal bulk to reduce constipation and improve weight loss.

Barley and oat are primary cereal sources for β-glucans. Total β-glucan content of barley grains ranges from 2.5% to 11.3% by kernel weight, but they most frequently fall between 4% and 7%. However, some genotypes demonstrate to accumulate up to 13–17% of total β-glucans (Farag et al. 2022).

The variances in barley β-glucan concentration have been attributed to environmental growing conditions, although the genotype is the main factor in determining the final concentration of β-glucans in barley kernel. Naked barleys often have higher β-glucan contents (Farag et al. 2022) and are mainly used as human food thanks to easier processing after harvesting and consumption. Barley genotypes show also differences in the amylose/amylopectin ratio and genotypes with both *waxy* starch (with up to 100% amylopectin) and high amylose (over 35%) are available. Interestingly, these genotypes with different starch composition are also characterized by higher β-glucan concentration (Ferrari et al. 2009).

Barley generally contains high molecular weight β-glucans that determine high-viscosity solution and are responsible to enhance gut viscosity that is correlated to barley physiological activities (Murphy et al. 2020).

2.1.2 β-Glucans: Biochemical Pathway of Production

β-(1→3),(1→4) at 4–5 days after pollination (DAP) and are uniformly distributed in the tissue by 10 DAP. β-(1→3),(1→4)-glucan content increases considerably within 16–36 DAP, coinciding with the grain filling and maturation stages (Garcia-Gimenez et al. 2019).

The synthesis of β-glucans in barley is regulated by members of the cellulose synthase-like gene families, *CslF* and *CslH*. Seven *CslF* and one *CslH* (cellulose synthase-like genes) are responsible for β-glucan synthesis, and a UDP-glucose 4-epimerase (*UGE*) is also implicated. Among these, *HvCslF6* is the most highly transcribed and is the most important gene for β-glucan synthesis in barley kernel. *HvCslF6* was well characterized as a (1→3),(1→ 4)-β-glucan synthase and it is expressed throughout grain development. This was confirmed in cslf6 mutant lines (called beta-glucanless or *bgl*) that have very low levels of mixed linkage β-glucan. During grain development, *HvCslF6* and *HvCslF9* are the predominant expressed genes, and a mutation in the *HvCslF6* locus led to a loss of β-glucans accumulation. Burton et al. (2011) succeeded in overexpressing *HvCslF4* and *HvCslF6* in transgenic with extra copies of these genes, and the final result was an increase in grain β-glucan content of more than 50% and 80, respectively (Garcia-Gimenez et al. 2019).

β-Glucan concentration is a quantitative trait, and there are several associated QTLs: for example, one QTL is located on chromosome 7H, within 5 cM of the *Nud* gene; this suggests a possible linkage effect. Many QTLs involved in β-glucan accumulation overlap with QTLs for amylose content probably due to co-localization or interaction between genes (Meints et al. 2021).

In addition, several researchers suggested that variation in barley (1→3), (1→4)-β-glucan levels was also affected by polysaccharide remodeling and degradation pathways. Two barley genes, *HvGlbI* and *HvGlbII*, encoding for (1→3),

(1→4)-β-glucan end hydrolases, have been reported to contribute to this trait, having an impact on modification on β-glucans during the malting process (Garcia-Gimenez et al. 2019).

2.1.3 β-glucans: Physiological Properties and Functions in Relation to Human Health

β-Glucans play important roles, particularly in healthy foods and pharmaceutical products, due to their widely known beneficial effects, including immunomodulation, antitumor activity, serum cholesterol and glucose reduction, and obesity prevention (Bai et al. 2019). The degree and type of biological activity appear to be strictly correlated to β-glucans structural properties.

Physiological Properties of β-Glucans: Glycemic Control

The reduction of the glycemic response after consumption of food (glycemic control) is among the most intensely studied and well-documented properties of barley β-glucans. This effect has been investigated in numerous animal and human studies using model food systems.

There is evidence that increasing molar weight and/or viscosity of β-glucans improves the postprandial glucose regulation, indicating that this effect is based on the formation of a high-viscosity gel in the intestine. A proposed mechanism for these observations is that high viscosity of the intestinal content may slow down digestion of starch (by decelerating the diffusion of α-amylase toward its starch substrate) and the absorption of glucose (Tosh and Bordenave 2021).

β-Glucan molecular weight should be an important trait in glycemic response, but to date, there are still contradicting results regarding the importance of this trait on glycemic response. Some researchers found that high molar mass and viscosity are essential parameters for healthy effects, such as glycemic control (Schmidt 2022). In contrast, recent studies reported no differences in the control of blood glucose and cholesterol lowering between hydrolyzed and native barley β-glucan in mice (Schmidt 2022).

Physiological Properties of β-Glucans: Cholesterol Lowering

Another well-studied health-promoting property of barley β-glucans is the ability to lower blood cholesterol levels. While high-density lipoprotein (HDL) cholesterol remains unaffected by β-glucans, the reduction in low-density lipoprotein (LDL) cholesterol, an important marker for the risk of cardiovascular diseases, is recognized (Schmidt 2022). The generally accepted mechanism behind this is based on the formation of a highly viscous gel inside the human intestine. The gel interacts with the bile acids present in the gastric system, preventing their readsorption and thus promotes the de novo synthesis of such acids. Since cholesterol is used for the bile acid synthesis, it is captured from blood and its concentration decreases (Schmidt 2022).

Based on this data, the EFSA and FDA have concluded that the regular consumption of at least 3 g of β-glucans from oat and/or barley per day is required to achieve a substantial cholesterol-lowering effect (EFSA Panel on Dietetic Products, Nutrition and Allergies (NDA) 2011; FDA_b-glucan health 2006).

Physiological Properties of β-Glucans: Effects on Gut Microbiota

The role of microbiota in maintaining good health is now clearly established, and whole-grain barley can support the growth and maintenance of gut microbiota (Tosh and Bordenave 2021). Fermentable fiber and β-glucan are a fundamental part of it and could actively impact the microbiota.

β-Glucans perform their function of regulating blood cholesterol levels through the modulation of the microbiota, which is directly related to the metabolism of bile acids. β-Glucans are resistant to digestion, reach the small intestine, and are fermented by gut microbiota producing short-chain fatty acid (SCFA), limiting HMG-CoA activity, improving cholesterol catabolism (Murphy et al. 2020).

Through dietary fiber fermentation, intestinal microbiota produces short-chain fatty acids (SCFA) (acetic, propionic, and butyric acids): butyric acid, in particular, plays an important role in promoting and maintaining colon health, while propionic acid, after supplementation of β-glucans, showed hypocholesterolemic properties. Furthermore, SCFA have been found to modulate the immune system (Murphy et al. 2020).

β-Glucans are considered prebiotic as they improve indirectly gastrointestinal function by enhancing the intestinal microbiota (Murphy et al. 2020). They elicit the growth and activity of commensal bacteria in the colon. Both in vitro and in vivo models have confirmed that the growth of normal intestinal bacteria (*Lactobacilli* and *Bifidobacteria* species) is increased by β-glucans (Murphy et al. 2020).

The intestinal microorganism can also influence hormone secretion. In particular, insulin sensitivity may be improved by the promotion of gut hormone secretion from enteroendocrine cells by SCFAs (Murphy et al. 2020).

2.1.4 Methods of Nutraceutical Improvement: Agronomic and Postharvesting Techniques

β-Glucan content is a trait highly influenced by genotype, and this is a good point to develop new genotypes with the aim of functional food production. The environment and agronomic practices can also impact β-glucan levels. Supplementation of soil nitrogen can cause an increase in β-glucan levels, while increased irrigation has shown to lower β-glucan content (Choi et al. 2020). Dry and hot weather can also determine an increase in β-glucan concentration, while cooler, wetter conditions are generally correlated to a reduction in β-glucan content (Meints et al. 2021).

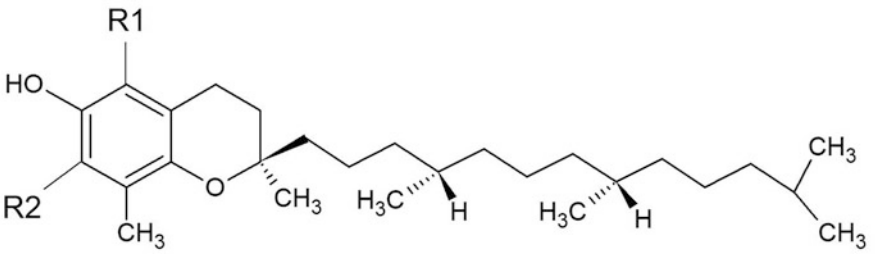
Given the nutraceutical importance of β-glucans, over the years, methods have been developed to incorporate barley flours into baked products to make them functional foods. As β-glucans are water-soluble compounds, barley fractions enriched in β-glucans were obtained by extraction with aqueous solvents (Mejía et al. 2020).

However, these procedures are highly energy-consuming and sometimes use dangerous solutions like sodium hydroxide or organic solvents, residues of which are forbidden in human foods. Otherwise, a way to increase β-glucan content is to mill and sieve barley flours to discriminate β-glucan-rich fraction (Mejía et al. 2020). The addition of barley flour, however, significantly worsens the quality characteristics of bakery products.

2.2 Tocols

2.2.1 Tocols: Structure and Content

Tocopherols (vitamin E) and tocotrienols, grouped as tocols, are a class of lipid-soluble antioxidants only synthesized by plants and other photosynthetic organisms. They are amphipathic molecules with a polar head group, the chroman ring, and a hydrophobic tail, which is either saturated (tocopherols) or contains three double bonds at positions 3, 7, and 11 (tocotrienols). Four homologs (α-, β-, γ-, δ-) exist for each tocol class, differing only in the number and position of methyl substitutions on the aromatic ring (Tiwari and Cummins 2009) (Fig. 3).

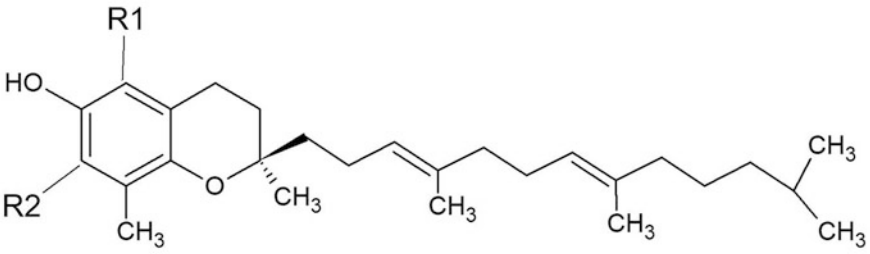


α-tocopherol R1= R2= CH_3

β-tocopherol R1= CH_3, R2= H

γ-tocopherol R1= H, R2= CH_3

δ-tocopherol R1= R2= H



α-tocotrienol R1= R2= CH_3

β-tocotrienol R1= CH_3, R2= H

γ-tocotrienol R1= H, R2= CH_3

δ-tocotrienol R1= CH_3, R2= H

Fig. 3 Structure of barley tocols

Oils from vegetable sources are the main forms of tocols, but also cereals, like barley, oats, wheat, rye, and rice are reported to be an excellent source of this class of compounds. The tocol composition of barley is unique as it includes all eight homologs (Obadi et al. 2021).

In the barley grain, tocopherols and β-tocotrienol are mainly located in the germ, while hulls and endosperm have substantial tocotrienols concentration (Obadi et al. 2021) and accumulate during grain development (Obadi et al. 2021). Among cereals, barley is one of the best sources of tocopherols and tocotrienols due to a high level and favorable distribution of all eight biologically active homologs (Obadi et al. 2021). In whole-grain barley, α-tocotrienol is the most individual tocol homolog, contributing about 47.7% of the total tocol content, followed by α-tocopherol, γ-tocotrienol, γ-tocopherol, β-tocotrienol, and δ-tocotrienol (Idehen et al. 2017). The total tocotrienol level is markedly higher than the total tocopherol level (Idehen et al. 2017).

There is a wide variation, influenced by genotypes and environment, in quantities of tocols in barley. Temelli et al. (2013) examined the total tocol content of whole-grain barley varieties, which ranged from 40 mg/kg to 151.1 mg/kg. Hulled barley has been shown to possess more tocols than hull-less barley (Idehen et al. 2017). Cavallero et al. (2004) also reported higher tocol and α-tocotrienol contents in hulled barley (53 and 61 mg/kg) than in hull-less barley (50.9 and 53.1 mg/kg). This was explained by the presence of tocols in the hull of barley.

2.2.2 Tocols: Physiological Properties and Functions in Relation to Human Health

The presence of the phenolic hydroxyl group in tocopherol and tocotrienols is essential for the antioxidant activity of vitamin E due to the ability to donate a phenolic hydroxyl group of the chromanol ring to blocking peroxidation of lipids in cell membranes (Tiwari and Cummins 2009). α-Tocopherol content is important from a nutritional point of view as it is the tocol homolog with the highest vitamin E activity. The other homologs of tocols exhibit vitamin E activity in the following order: α-tocopherol > β-tocopherol > α-tocotrienol > γ-tocopherol > β-tocotrienol> δ-tocopherol (Gangopadhyay et al. 2015). Although α-tocopherol has the highest vitamin E activity, α-tocotrienol has been found to possess 40–60 times higher antioxidant activity than α-tocopherol (Gangopadhyay et al. 2015).

In addition to antioxidant properties, studies have shown that tocotrienols have several beneficial functions. For example, thanks to the capacity of inhibition of cholesterol biosynthesis, they determine a protective effect by lowering LDL cholesterol (Tiwari and Cummins 2009). The hypocholesterolemic effect of α-tocotrienol is due to the suppression of hydroxyl-β-methylglutaryl co-enzyme A reductase, the key enzyme of cholesterol synthesis (Tiwari and Cummins 2009). Moreover, the tocol content of cereals can confer human health benefits, including modulating degenerative diseases like cancer and cardiovascular diseases (CVD) (Obadi et al. 2021).

2.2.3 Tocol Biosynthesis

The biosynthesis of tocopherol occurs in plastids of plant cell, except for the first step of tocopherol biosynthesis (biosynthesis of chromanol head) that occurs in a plant's cytoplasm (Fritsche et al. 2017).

The biosynthesis starts through the formation of the chromanol ring, which is derived via the shikimate pathway from homogentisate. The polyprenyl side chain (phytyl diphosphate, phytyl PP/PDP) is suggested to originate from DOXP (1-deoxy-D-xylulose-5-phosphate) pathway, as well as from the recycling of free phytol derived from the chlorophyll degradation process (Fritsche et al. 2017). In tocopherols, the prenyl tail attached to the chromanol ring is derived from phytyl diphosphate (PDP). In tocotrienols, it originates from the condensation of HGA and phytyl diphosphate (PDP), which is catalyzed by the plastid-localized enzyme HGA phytyl transferase (HPT) (Yang et al. 2011). Plant tissues vary enormously in their tocol content and composition with photosynthetic tissues generally containing low levels of total tocols and a high percentage of α-tocopherol, whereas seeds contain 10–20 times this level of total tocols, but α-tocopherol is often a minor component (DellaPenna and Pogson 2006).

2.2.4 Methods of Nutraceutical Improvement: Agronomic and Postharvesting Technique

Food processing significantly influences the level and stability of tocols (Tiwari and Cummins 2009). After harvesting, cereal grains undergo substantial changes in composition before being consumed; for example, tocol cereal content is influenced by pearling, milling, extrusion, cooking, malting, and baking (Tiwari and Cummins 2009).

Pearling (which causes the removal of hull, aleurone, and germ) significantly decreased tocol concentration, if compared to the whole seed, suggesting that dehulled seed is not a rich source of tocols, whereas its by-product (the removed material during pearling) is rich in tocols (Farag et al. 2022). Tocol level was not affected by malting process, although brewers' spent grains were enriched in tocols (Peterson 1994), becoming a good source of tocols. This attribute could make them valuable additions to food products, particularly as they will contain substances that have favorable effects on cholesterol levels and may offer remarkable economic and waste management opportunities.

Storage is another factor that has an influence on the tocol content. Antioxidants and, among them, the tocols can be easily affected by light, water, and heat. Generally, after being harvested, barley will be stored for periods ranging from 4 to 18 months before processing. The storage may have an effect on vitamin E content and antioxidant capacity. Do et al. (2015) measured tocol content and antioxidant capacity in 25 barley cultivars before and after 4 months storage at 10 °C. They observed that six homologs (α- T, α-T3, β-T, β-T3, γ-T, and γ-T3) were detected in barley genotypes after 4 months storage, but the amounts of δ-T and δ-T3 were minimal. The total vitamin E content changed from 6% to 30% after 4 months of storage.

Liu and Moreau (2008), on the other hand, found the storage at 35 °C with 75% relative humidity for 3 weeks caused no change in oil and tocopherols, but significant changes in tocotrienols. The changes were differential among T3 homologs, with α-tocotrienol decreasing and δ-tocotrienol increasing. The reduction in α-tocotrienol was accelerated in fractions characterized by a higher proportion of endosperm tissue. When the storage was prolonged for 6 months, the authors

confirmed these findings. These results and practical information can help us to produce barley fractions enriched with functional lipids and maintain stability of their products.

2.3 Simple Phenols and Polyphenols

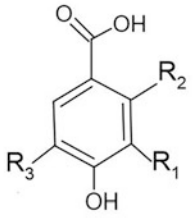
Phenolic compounds comprise a large heterogeneous class of secondary metabolites. Phenolics possess one or more aromatic rings with one or more hydroxyl groups and can be classified into different ways, based on their chemical structure, and distribution in nature.

Barley is considered a good source of many classes of phenolic compounds, such as phenolic acids, proanthocyanins, quinones, flavanols, chalcones, flavones, and flavonones. These compounds may exist in free, conjugated, or bound forms. Due to the high level of phenolics in barley grains, this cereal can be considered a good dietary source of antioxidants, which have antiradical and antiproliferative capacity and are correlated to the potential prevention of several chronic disease and health well-being (Farag et al. 2022).

2.3.1 Phenolics Acids: Structure and Content

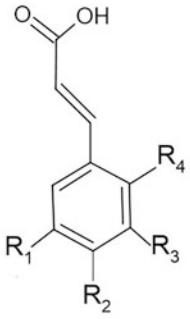
Benzoic and cinnamic acid derivatives (grouped as phenolic acids, Fig. 4) are the dominant class of phenolics in barley and are in the outer layers of the kernel (Idehen et al. 2017).

In barley, they are mainly present in the bound form, some are present in conjugated form, and only to a lesser extent are present in the free form. The free



Benzoic acids

p-Hydroxybenzoic acid	R_1= R_2= R_3= H
2,4-Dihydrixybenzoic acid	R_1= R_3= H, R_2= OH
Vanillic acid	R_1= OCH_3, R_2= R_3= H
Syringic acid	R_1= R_3= OCH_3, R_2= H



Cinnamic acids

o-cumaric acid	R_1= R_2= R_3= H, R_4= OH
p-cumaric acid	R_1= R_2= R_4= H, R_2= OH
Ferulic acid	R_1=OCH_3, R_2= OH, R_3=R_4= H
Sinapic acid	R_1= R_3= OCH_3, R_2= OH, R_4= H

Fig. 4 Structure of barley phenolic acids

forms are concentrated in the outer layers of the pericarp, whereas the bound forms are esterified to cell wall constituents, such as lignin, cellulose, arabinoxylans, and other polysaccharides (Loskutov and Khlestkina 2021). Ferulic and *p*-coumaric acids are phenolic compounds abundantly found in whole grains of barley; they exist in free, bound, and soluble-conjugated forms. The composition of phenolic compounds depends upon the grain type, cultivars, and morphological fraction used for analysis.

Deng et al. (2020) analyzed different hull-less barley genotypes for phenolic composition and content: bond ferulic acid resulted the predominant one, and the content varies from 50.16 to 54.65 mg/kg. In the study conducted by Šimić et al. (2019), ferulic acid content was found to have a wide range (4.5–102.7 mg/100 g dry weight) among different fractions of hull-less barley. They reported that ferulic acid was distributed mostly in the outer bran and has the lowest content in the endosperm. *p*-hydroxybenzoic (3.43–17.44 mg/kg), gallic (3.50–32.90 mg/kg), and vanillic (3.20–24.70 mg/kg) acids were the predominant phenolic acids present in the free form (Šimić et al. 2019).

Martinez et al. (2018) observed a considerable variation in the content of total ferulic acid concentration, analyzing a set of barley genotypes, hulled and hull-less, with different origin. The content of some bound phenolic acids was related to the occurrence or lack of hull, with significantly higher levels of these compounds observed in the hulled genotypes compared to the hull-less samples.

2.3.2 Flavonoids: Structure and Content

Flavonoids (Fig. 5) are a phenolic class with a C6–C3–C6 skeleton (two aromatic rings joined by a three-carbon link).

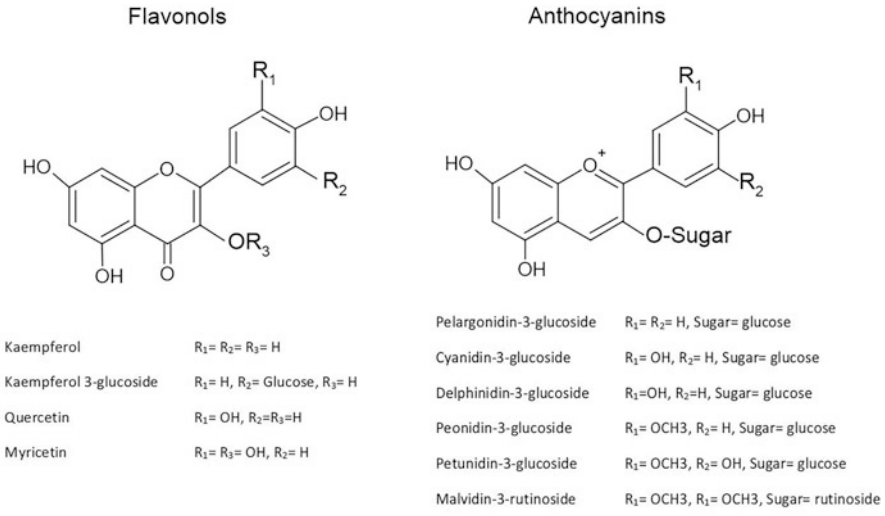


Fig. 5 Structure of barley flavonoids: flavonols and anthocyanins

Clinical trials indicate that flavonoids may be the phytochemicals present in cereal grains correlated to the moderation of many diseases, like cancer and coronary heart diseases (Idehen et al. 2017).

Flavonoids are a subclass of plant phenols and have been shown to have many health benefits, such as antioxidant, anticancer, antiallergic, and anti-inflammatory.

Naringin (flavanone), catechin (flavonol), and quercetin (flavon) were reported to be the three predominant flavonoids in hull-less barleys with contents varied from 0.8 to 9.8, 0.1–20.5, and 1.4–8.7 mg/100 g (dry weight), respectively (Deng et al. 2020).

Zhu et al. (2015) reported that total flavonoids (free and bound) in four hull-less barley varieties ranged between 145.5 and 247.4 mg catechin equivalents/100 g, dry weight basis, observing that it was higher than other grains like corn, wheat, oat, and rice (Zhu et al. 2015).

Anthocyanins are water-soluble flavonoids, located in the vacuole, and they are mainly present in the pericarp or the aleurone layers of barley kernel, determining the purple or blue grain pigmentation, respectively. This class of flavonoid is normally present as glycoside in the grains. A range of anthocyanin compounds have been identified in barley kernels by various authors. Martinez et al. (2018) identified up to 27 anthocyanins in different barley genotypes. The most common anthocyanin in purple barley is cyanidin 3-glucosode, followed by peonidin 3-glucoside and pelargonidin 3-glucoside. Delphinidin 3-glucoside was found to be the main anthocyanin in blue and black barley varieties (Martínez et al. 2018) (Fig. 5).

Martinez et al. (2018) found that purple and blue barleys contained higher average level of anthocyanins than the black barleys tested. This could be explained because the black pigmentation present in barley is linked to the presence of melanin-like pigment. So, it could be assumed that the color of the black barley genotypes is probably a result of co-pigmentation between anthocyanins and melanin-like pigments (Glagoleva et al. 2022).

Proanthocyanidins (PAs), or condensed tannins, are a group of polyphenols that naturally occur in a wide range of plants, including barley (Fig. 6).

PAs can be structurally distinguished by the different hydroxylation patterns of the basic flavan-3-ol units and by the nature of the bond among monomers. The common basic units are (epi)gallocatechins, (epi)catechins, and (epi)catechins, resulting in the formation of prodelphinidin, procyanidin, and propelargonidin structures, respectively. The units are commonly linked through B-type bonds (C4→C6or C4→C8 linkage), while an additional linkage (C2→O5 or C2→O7) contributes to the formation of A-type bonds (Zhu 2019).

Different proanthocyanidin composition and concentration has been observed and linked to genetic diversity in barleys. For example, Verardo et al. (2015) found that PA concentrations in 14 barley genotypes ranged from 293 to 653 mg/kg. The HPLC-MS analysis revealed the presence of catechin/epicatechin monomers, procyanidin dimer, prodelphinidin dimer, procyanidin trimer (36.7–167 mg/g), prodelphinidin trimer I (monogalloylated), prodelphinidin trimer II (digalloylated), procyanidin tetramer, prodelphinidin tetramer, and procyanidin pentamer (Verardo et al. 2015).

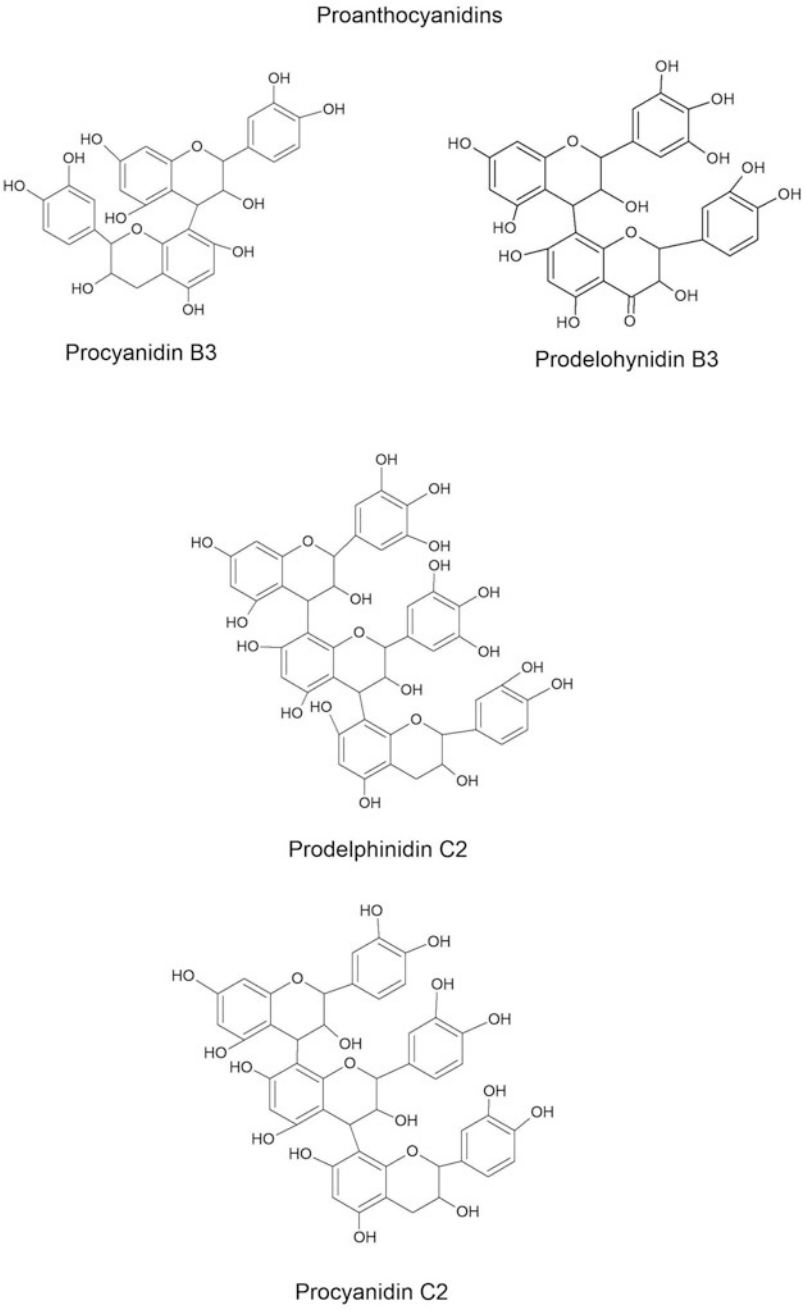

Fig. 6 Structure of proanthocyanidins found in barley

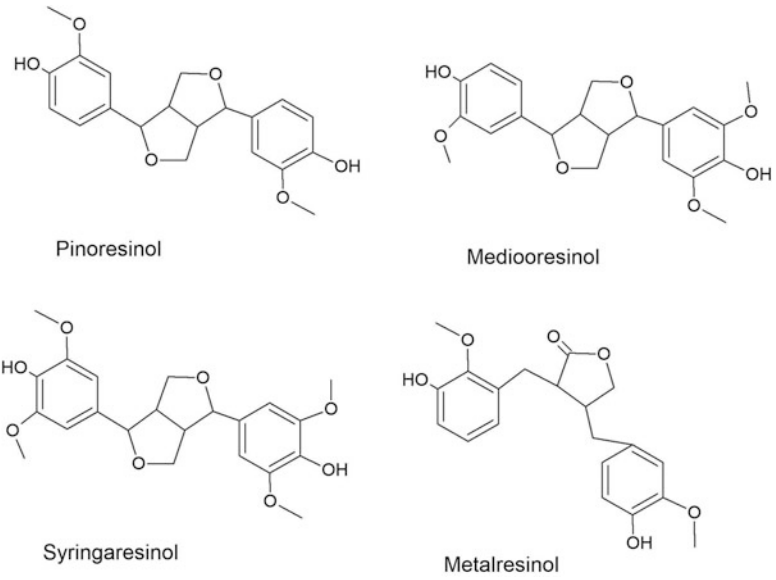

Fig. 7 Structures of major lignans in barley

Lignans (Fig. 7) are natural polyphenols widely distributed in the plant kingdom and are recognized as natural defense compounds.

They possess a phytoestrogens-like activity due to their structural and functional similarity to 17-β-estradiol. Lignans have been suggested to have a wide range of biological effects, such as antioxidant, antitumor, antimicrobial, antifungal, estrogenic, and antiestrogenic activities, and protect against coronary heart diseases. There is little information in the literature about the structure and concentration of lignans in barley. Smeds et al. (2007) analyzed lignan content in barley: the authors reported the presence of pinoresinol (71 mg/100 g), medioresinol (22 mg/100 g), syringaresinol (140 mg/100 g), lariciresinol (133 mg/100 g), cyclolariciresinol (28 mg/100 g), secoisolariciresinol (42 mg/100 g), secoisolariciresinol-sesquilignan (24 mg/100 g), matairesinol (42 mg/100 g), oxomatairesinol (28 mg/100 g), and 7-hydroxymatairesinol (541 mg/100 g) as major lignans and todolactol (127 mg/100 g), α-conidendrin acid (33 mg/100 g), nortrachelogenin (15 mg/100 g), and lariciresinol-sesquillgnan (6.6 mg/100 g) as minor lignans.

2.3.3 Simple Phenols and Polyphenols: Physiological Properties and Functions in Relation to Human Health

Free radicals in human body can induce a series of diseases such as cancer diabetes, atherosclerosis, and reproductive endocrine dysfunction. Phenols, in this sense, can have an important function as they act as scavengers of free radicals and could play a major role in moderating cardiovascular diseases. Several in vitro experiments

evidenced the bioactivities of barley phenols (Idehen et al. 2017). The most studied and reported bioactivity are the in vitro antioxidant capacity and free-radical-scavenging activity determined by different chemical tests, including DPPH, ORAC, FRAP, and ABTS (Obadi et al. 2021). Blue hull-less barley varieties evidenced higher antioxidant activities than regular barley varieties: these genotypes showed higher antioxidant than Canadian, Egyptian, and Tunisian barley (Yang et al. 2018). Li et al. (2019) demonstrated strong correlations between antioxidant capacities of barley grains and phenolic concentration, denoting that the phenolic compounds represent the main responsible for the antioxidant activity of whole naked barley flours. Abdel-Aal et al. 2012 selected Canadian and Egyptian barleys and investigated phenolic acid composition and antioxidant capacity against DPPH and ABTS radicals, and inhibition of oxidation of human low-density lipoprotein (LDL) cholesterol of whole grain flours and pearling fractions. The data showed significant variations among barley wholegrain flour and pearling/milling fractions in terms of phenolic acid composition and antioxidant capacity.

Health benefits of barley phenols have also been reported in in vivo experiments using animal and clinical models. Mice that were fed with 600 mg/kg BW of polyphenol extract from black highland barley showed a significant reduction in total cholesterol (23.33%), LDL cholesterol (26.29%), and atherosclerosis index (38.70%), and an increase in high-density lipoprotein cholesterol (HDL, 17.80%) (Shen et al. 2016). Lee et al. (2015) also demonstrated that extracts from barley sprouts containing polyphenols regulated AMP-activated protein kinase, a cellular sensor of energy metabolism and a regulator for cholesterol metabolism. Oxidative stress, which has a key role in pathology like diabetes and obesity, can be reduced by phytochemicals present in barley, particularly phenolic compounds (Idehen et al. 2017).

As previously reported, a large part of phenol compounds is bonded to cell wall constituents (i.e., cellulose, lignin, etc.), and therefore they are a part of dietary fiber. There is evidence that dietary fiber provides various beneficial health effects, among which are the decrease of the risk of cardiovascular disease, metabolic syndrome, diabetes, obesity, and cancers (Murphy et al. 2020); these health properties may be attributed to phytochemicals bound to or trapped within dietary fiber, especially phenolic compounds (Tosh and Bordenave 2021).

2.3.4 Simple Phenols and Polyphenols: Biosynthesis

Barley grains accumulate a large amount and type of phenolic compounds, which are a product of secondary metabolism in plants. Moreover, different barley genotypes present different grain coloration: the most studied are yellow, purple, red, blue, and black. The yellow color is linked to the presence of proanthocyanidins synthesized in seed coat of the kernel; purple and red pigmented genotypes are characterized by the presence of anthocyanins, synthesized in pericarp and glumes; blue color is caused by anthocyanins synthesized in aleurone layer of the grain. In white barley grains, the pigments are not present (Shoeva et al. 2016).

In barley, phenol biosynthesis metabolic pathway is well characterized: structural genes encoding enzymes of the pathway, as well as regulatory genes, have been described (Deng and Lu 2017) (Fig. 8).

The fists step in phenylpropanoid biosynthetic pathway is the phenylalanine synthesis from the shikimate pathway. Phenylalanine ammonia lyase (PAL) catalyzes this first enzymatic step, which cause the deamination of phenylalanine to generate cinnamic acid, which in turn is hydroxylated to *ρ*-coumaric acid, catalyzed by cinnamate 4-hydroxylase (*C4H*). 4-Coumaroyl CoA ligase (*4CL*) is involved in the catalysis of the formation of ρ-coumaroyl-CoA from ρ-coumaroyl acid.

The initial steps of the phenylpropanoid pathway are jointly known as the general phenylpropanoid pathway (GPP) (Deng and Lu 2017). After GPP, the pathway is branched leading to the synthesis of flavonoids, stilbenes, monolignols, phenolic acids, and coumarins. In the barley genome, the Chalcone synthase (CHS) characterize a gene family with at least seven copies. One of the *Chs* gene copies has been mapped to the short arm of chromosome 1H. Three nonoverlapping genetic markers for the *Chs* gene have been mapped to chromosomes 1HS, 1HL, and 6HS (Shoeva et al. 2016). The gene related to chalcone flavanone isomerase gene (*Chi*) has been identified and mapped to the long arm of chromosome 5H. Flavanone 3-hydroxylase gene (*F3h*) has been also characterized, and the gene has been localized to chromosome 2HL. Barley dihydroflavanol reductase gene (*Dfr*) has been mapped on the long arm of chromosome 3H. Other important genes coding for key enzyme have

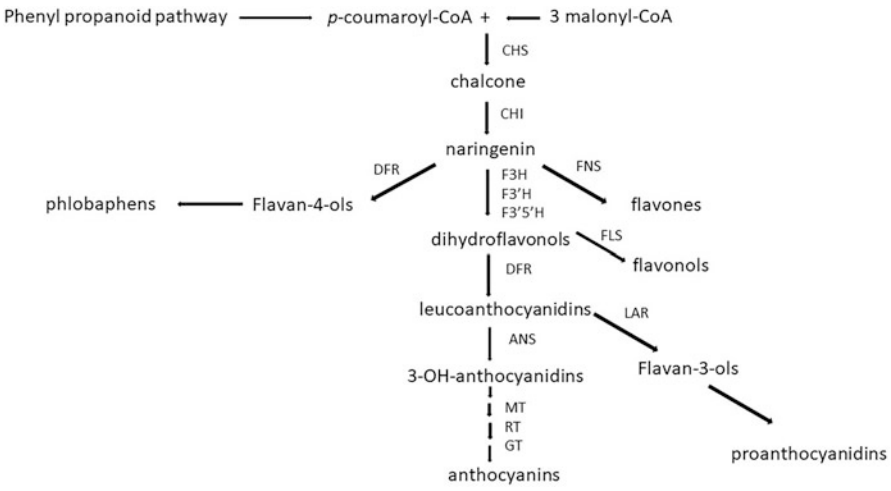

Fig. 8 A schematic presentation of the flavonoid biosynthetic pathway in barley. The enzymes reported are CHS (chalcone synthase); CHI (chalcone-flavanone isomerase); F3H (flavanone 3-hydroxylase); FLS (flavonol synthase); FNS (flavone synthase); F3′H (flavonoid 3′-hydroxylase); F3′5′H (flavonoid 3′,5′-hydroxylase); DFR (dihydroflavonol 4-reductase); ANS (anthocyanidin synthase); GT (glycosyltransferase); MT (methyltransferase), RT (rhamnosyltransferase); and LAR (leucoanthocyanidin reductase)

been identified in barley: barley leucoanthocyanidin reductase (LAR) and gene for UDP glucose-flavonol 3-O-glucosyltransferase (UFGT), which mapping on the short arm of chromosome 7H. Flavonoid 3'-hydroxylase (*F3'h*) and anthocyanidin synthase (*Ans*) genes were identified and localized on chromosomes 1H and 5HL, respectively (Shoeva et al. 2016).

In barley, anthocyanin pigmentation of the kernel pericarp is controlled by two complementary genes, *Ant1* (MYB) and *Ant2* (bHLH), which are located on chromosomes 7H and 2H, respectively (Glagoleva et al. 2020). They form, jointly with the transcription factor WD40, the MBW complex, which controls the anthocyanins biosynthetic pathway in a tissue-specific manner. Accumulation of blue anthocyanins in barley aleurone is controlled by *HvMyc2* gene, a paralog of *Ant2* (Strygina et al. 2017).

Melanins are the product of enzymatic oxidation of phenolic precursors, such as tyrosine, cinnamic acid derivatives, and catechol, to quinones, which then undergo subsequent polymerization. Melanin biosynthesis in barley is under the monogenic control of *Blp1* located on chromosome 1H (Long et al. 2019). Purple pigmentation (characterized by anthocyanins) and black pigmentation (characterized by phytomelanins) are under different genetic control, so these pigments can be both accumulated in the kernel combining genes controlling the two traits (Glagoleva et al. 2022).

2.3.5 Methods of Nutraceutical Improvement: Postharvesting Techniques

Many authors have investigated the effects of grain type, genotype, and environment effect on the accumulation of phytochemical in barley grain. The most important goal of these studies is the possibility to select barley varieties, with improved nutritional characteristics. Several studies reported that pigmented barley genotypes accumulate a high concentration of different classes of polyphenols, like anthocyanins in blue or purple barley. This class of flavonoid had demonstrated important healthy properties. Moreover, there is a large variation in composition among the phytochemical composition in different cultivars, reflecting factors related to genetic diversity, indicating the need for proper selection of genetic material (Irakli et al. 2020).

One of the most effective methods to improve nutritional value of seeds is germination. Several authors have demonstrated that germination can enhance the content of many phytochemicals, like phenolic compounds and other bioactive substances in grains, as well as remove antinutritional factors such as enzyme inhibitors. Tang et al. (2021) investigated the effect of germination on the polyphenol content, antioxidant capacity, and physicochemical properties of three different pigmented cultivars of hull-less barley. They observed that the germination determined an increase in the total phenolic and flavonoid content, as well as antioxidant properties. This could be due to the improved biosynthesis of polyphenols during germination.

Also, malting process significantly affects the polyphenol content in grains. During the malting process, barley grains undergo different biochemical and physical changes: hydrolytic enzymes are released in the shoot or root developed during the malting process are removed physically (Sharma et al. 2022). Moreira et al. (2013) studied the antioxidant properties of brewer's spent grain and reported that malt produced at lower temperature (light malt) had the higher total phenol content than raw barley. Fogarsi et al. (2015) observed that barley total phenols significantly increased after malting process. The germination and malting process increased the phenolic contents in barley due to the release of bound phenolic content by inherent enzymes (Sharma et al. 2022).

Pearling, an important primary process in food-barley utilization, is a milling approach that gradually removes grain tissue by abrasive action and that, consequently, modulates the distribution of nutrients and phytochemicals in barley flour. Irakli et al. (2020) evidenced that bioactive components, including phenolic acids and flavonoids, exhibit a decreasing concentration from the external layers to the center part of barley grain among all barley cultivars tested, in contrast to what happens for β-glucans.

3 Next-Generation Breeding for Phytochemicals and Nutrient Contents

In recent years, scientists and the food industry developed and studied a wide range of new cereal products designed with healthy properties. Cereals, and among them barley, are a very rich source of several nutrients, micronutrients, and phytochemicals as already discussed in Sect. 2. Breeding techniques can help us to obtain new genetic materials with high a concentration of these cereal phytochemicals, and at the same time help to develop high-yielding genotypes, being able to combine the maximum level achievable for nutritional compounds and high-quality indicators, like yield, disease resistance, etc. (Loskutov and Khlestkina 2021).

The genetic diversity existing among genotypes is at the base of all crop improvement programs. Diversity can be described as the degree of differentiation between or within species. The existence of genetic diversity within and between crop species permits the breeders to select superior genotypes to be used as parent in breeding programs. Wild species, related species, mutant lines, etc., represent the important source of genetic diversity and may provide new and favorable alleles (Bhandari et al. 2017).

Thanks to the genetic diversity existing between the breeding parents, it is possible to obtain heterosis and transgressive segregants. Genetic diversity helps breeders to develop varieties for specific traits like quality improvement and tolerance to biotic and abiotic stresses. Another very important aspect, especially with respect to the continuous and recent climatic changes, is that genetic diversity is an aspect that helps crop plants to adapt to different environments and to variations in the environment itself (Bhandari et al. 2017).

3.1 Tools for Assessing Genetic Diversity in Genomic Era

As genetic diversity is a fundamental aspect in breeding, the assessment of this diversity is crucial to ensure sufficient further genetic gain and make informed selection decisions. DNA-based methods are the most used for genetic diversity assessments. They can be divided into fragment analysis-based methods, in which DNA polymorphisms are determined by different sizes of DNA fragments; hybridization array-based methods, where DNA polymorphisms are detected by hybridizing the sample DNA to arrayed probes; and sequencing-based methods, where sequencing is used to detect polymorphisms. With these DNA-based methods, even thousands of polymorphisms may be assessed simultaneously in a lot of sample plants, making the analysis more cost-effective. Some of these can detect both coding and noncoding regions of the genome, which provides a broad view of genetic diversity and could potentially be employed to find genomic loci under selection. In recent years, DNA sequencing technologies have been subjected to considerable development, also allowing the analysis of complex genomes and the study of their genetic diversity (Loera-Sánchez et al. 2019).

Thus, DNA-based molecular markers started to be used to examine the genetic basis of agronomic traits and improve crops through genome-based methods, including marker-assisted selection (MAS) and, in recent years, genomic selection. One of the disadvantages of traditional phenotype-based selection is the time needed to develop new varieties. Compared with traditional phenotype-based selection, genome-based breeding can directly find favorable alleles underlying the desired traits, and thus leads to precise selection that significantly reduces the time needed to develop new varieties (Liu et al. 2021).

The fundamental characteristics of molecular markers are that they are correlated with phenotypic expression of a genomic trait, and that they are stable and detectable in all tissues despite of plant growth stage, and differentiation and status of the cell; moreover, environmental, pleiotropic, and epistatic effects do not influence them.

3.2 Connecting Genotype to Phenotype

3.2.1 Marker-Assisted Selection (MAS)

As mentioned above, the development of molecular marker technology made plant breeding became more efficient by means of marker-assisted selection (MAS).

Molecular markers are sequences of nucleotides and can be explored through the polymorphisms present between the nucleotide sequences of a given population. The polymorphism is highlighted through the identification of deletions, insertions, gene mutation, duplication, and translocation of a precise sequence, and they do not really influence the function of genes. There are five important considerations for the application of DNA markers in MAS: reliability (markers must be firmly connected to the target loci); quality and nature of required DNA; amount of DNA required; methodology for marker examination (high-throughput, straightforward techniques

are required); cost-effectiveness; the level of polymorphism (ideally, the marker should be highly polymorphic in the breeding material): the suitability of a given molecular marker is dependent on its capacity to identify polymorphisms in the nucleotide sequences permitting segregation between the different alleles (Hasan et al. 2021).

Different types of molecular markers have been used over the last few decades: restriction fragment length polymorphism (RFLP), random amplification of polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), microsatellite or simple sequence repeat (SSR), sequence characterized amplified region (SCARs), cleaved amplified polymorphic sequences (CAPS), single-nucleotide polymorphism (SNP), and diversity arrays technology (DArT) markers. Among these, SNP markers were the most widely used (Hasan et al. 2021).

Molecular markers are powerful genomic tools for the assessment of genetic diversity within and between populations and offer the possibility to improve the performance of plant breeding program, especially in QTL identification, which help us to identify and locate genes on chromosomes. Moreover, if the identified marker is closely related to important agronomic traits, it can be used in MAS and thus increase the efficiency of selection, allowing acceleration of the total breeding process (Al-Abdallat et al. 2017).

Marked-assisted selection combines information derived from mapping position of agronomical importance traits with and the linked molecular. The success of MAS depends on several factors, such as the number of individuals that can be analyzed, the genetic nature of the trait and the background in which the target gene must be transferred, and it is achieving increasing importance in breeding programs.

Regarding the implications of barley breeding for nutrition quality traits, recent findings of regulatory features of anthocyanin biosynthesis in barley were useful for both MAS approach and genetic editing-based breeding strategies.

Strygina et al. (2017) identified and characterized components of the anthocyanin synthesis regulatory network in the aleurone layer of barley. The genes identified and characterized included elements of the regulatory complex MBW, from which *HvMyc2*aMYC-encoding gene appeared to be the main factor determining variation of barley aleurone pigmentation.

Gordeeva et al. (2019) applied a marker-assisted backcrossing approach evidencing its efficacy in creating barley genotype with favorable alleles of anthocyanin regulatory genes: they developed a set of near isogenic lines (NILs) and revealed specific features of the anthocyanin biosynthesis regulation in barley pericarp: the dominant alleles of both the *Ant1* and *Ant2* genes were required for anthocyanin accumulation in pericarp. The dominant allele of the two genes was upregulated in purple-pigmented line. The activity of these genes also influenced the expression of the *F3'h* and *Ans* structural genes. In addition, positive effect between *Ant1* and *Ant2* was detected. The results achieved in this work represent a strong basis for target manipulation to modulate the content of anthocyanins in barley grains.

Since domestication, introgression breeding has been successfully used to improve barley, and it remains a key system for augmenting genetic diversity to deal with current and future challenges to crop production (Hernandez et al. 2020). Introgression essentially implies the transfer of a particularly and desirable trait from

one plant species to another with the help of hybridization and frequent back-crossing. Introgression of favorable alleles using marker-assisted selection is now faster and more efficient due to the development of high-throughput tools and technologies.

In the past century, breeding strategies were aimed to develop highly productive but uniform cultivars of cereals like wheat, barley, and other crops, leading to a constant decrease in genetic diversity. It is therefore necessary to find and improve strategies to increase the range of diversity especially in key quality traits. An important source of genes, alleles and genetic variation can be found in the ancestor of cultivated barley (*H. vulgare* subsp. *spontaneum*), landraces, and germplasm collections. Landraces have been used for the introgression of allele into adapted genotypes. Germplasm collections are excellent sources of genetic diversity. There are several germplasm collections in different part of the world, for example, Leibniz Institute of Plant Genetics and Crop Plant Research (IPK, Germany), the Okayama University Barley and Wild Plant Resource Center (Japan), the International Center for Agricultural Research in the Dry Area (ICARDA), and the United States Department of Agriculture National Small Grains Collection (USDA-NSGC, the United States). All the collections from these institutions are an excellent source of generic diversity and were well characterized for gene and alleles linked to disease resistance, abiotic stress resistance, and yield performances (Hemshrot et al. 2019; Visioni et al. 2013; Monteagudo et al. 2019).

3.2.2 QTLs

Genetic mapping of major genes and quantitative trait loci (QTLs) were widely used for many important agricultural traits and integrated with the conventional breeding process.

A genome-wide association study (GWAS) has the same approach as the QTL mapping study, but using natural populations, landraces, cultivar collections released over years, and genotypes with little or no pedigree information. It is used to reveal the relationship between markers and phenotypic traits based on linkage disequilibrium (LD), considering that associated markers resulting from GWAS could be used in new MAS programs. GWAS approaches were used to identify novel QTLs for traits with practical implications on barley agronomical performances, quality, and disease-related traits.

β-Glucan content is a quantitative trait with many associated QTLs found on chromosomes 1H, 2H, 5H, and 7H; they have been mapped in several populations, and candidate genes have been identified and validated. The QTL located on chromosome 7H and is within 5 cM of the *Nud* gene (Swanston and Middlefell-Williams 2012), indicating a possible linkage effect. A pleiotropic effect between β-glucan and the recessive allele at the Waxy (*WX*) locus has been demonstrated (Meints et al. 2021). The Waxy gene codes for a granule-bound starch synthase I (*GBSSI*) (Li et al. 2021). Li et al. (2021) carried out a genome-wide association study (GWAS) and found several new QTLs that were related to starch content; these candidate genes and alleles can be used in future breeding programs focusing on amylose and amylopectin content. It has been also shown that mutations at the *Lys3*

and *Lys5* loci can modify β-glucan content, as well as other healthy compounds. Despite the shriveled endosperm, genotypes containing these mutations revealed higher amounts of β-glucans, fructans, arabinoxylans, and resistant starch (Meints et al. 2021).

In the study of Steele et al. (2013), a breeding program for nutraceutical compounds in barley was developed using a large segregating population, developed from crosses between naked and hulled parents, selecting naked barley that were more than 65% genetically similar to UK hulled barley. With another approach, the authors obtained lines from a mapping population, with β-glucan contents ranging from 1.4% to 8.6% with transgressive segregation occurring in both directions; they also evidenced no significant association of β-glucan content with the nude gene (*nud*).

A QTL describing about 30% of the β-glucan inheritance was found on chromosome arm 7HL, approximately 15 cM above *nud*, and *CslF6* is the most probable candidate gene (Steele et al. 2013).

If QTLs linked to β-glucan content and QTLS for yield components are combined, it is possible to develop new higher yielding functional food barley.

The other quality barley trait of particular interest, related to the importance that antioxidant compounds have risen in recent years, is phenolic compound accumulation in the grain. To improve this quality trait, it is essential to identify genes and/or QTLs responsible for phenolic metabolism, but there are only a few studies on QTLs associated with phenolic compounds in barley. Han et al. (2018) determined total phenolic total flavonoid content and antioxidant capacity in grains of Tibetan barley, analyzing both wild and cultivated accessions. The results showed wild barley had higher content and broader genetic diversity of phenolic compounds than cultivated genotypes. The authors identified 20 unique QTLs associated with total phenolic compounds, total flavonoids, and antioxidant activity in Tibetan wild barley. Wild and cultivated barleys showed clearly different presence of QTLs linked to phenolic compounds, highlighting a significant genetic difference between the two different genetic materials and showing that Tibetan wild barley is suitable for barley breeding for phenolic compound content.

The flavonoid class of compounds that characterized the pigmentation of barley pericarp are anthocyanins (Zhu 2018). Zhang et al. (2017) studied the genetic control of major anthocyanin compounds, peonidin-3-glucoside, P3G, and cyanidin-3-glucoside, C3G, which characterized the purple pericarp of barley using a segregating population suitable for QTL mapping. Both anthocyanin compounds were linked to two loci, one located on chromosome arm 2HL and the other on 7HS. The two different anthocyanins appear to be controlled by the different interactions of the two loci. The impact of the 7HS locus on P3G and C3G was not so clear if before the effect of the 2HL locus was removed. The biosynthesis of peonidin-3-glucoside needs at least one copy of 2HL alleles. This does not seem to be the case for the accumulation of cyanidin-3 glucoside that was produced regardless of the allele combinations between loci. The inheritance of purple pigmentation of the barley grains showed a typical maternal effect. The different anthocyanins present in pigmented barleys, their different concentrations, and their different genetic control

suggest the development of breeding programs, and consequently food processing, directed to individual anthocyanins.

Mohammadi et al. (2014) conducted an association mapping study on physicochemical properties of barley that play a role in its nutritional quality, like total phenolics, amylose, and β-glucan content. They used 3.069 breeding lines, including two-row and six-row spring barley, from US breeding programs, and 2.041 SNP markers for association mapping. For total phenolics, they identified three significant regions on 3H, 4H, and 5H chromosomes. Two regions on 2H and 7H were associated with β-glucan. They also identified several markers associated with amylose content on chromosome 7H.

The future of breeding will be, at genomic level, the development of genotypes that contain the most favorable alleles for every gene for target compounds. Thanks to new genomic technologies, which allows the employment of genome-wide marker assays, accurate and high throughput, and in combination with new methods like gene editing and rapid generation turnover such as genomic selection (GS), have the capacity to accelerate the rate of genetic gains in crop breeding programs.

Traits linked to quality and nutritional value of grains are the result of human selection in the relatively short period of 10,000 years since domestication began compared to other more complex traits like grain yield. As a result, many of these traits are relatively simple and controlled by one or a few major genes that have been selected by humans (Kumar Id et al. 2019). If we can use genomics to find and characterize these genes selected by humans, we can improve breeding strategies to obtain high-quality grains for breeding for grain quality.

3.2.3 Omic Technologies for Functional Food

The application of *omics* technologies to crop breeding is strongly growing in interest. Foodomics include different *omic* technologies in relation to food and nutrition science, with the aim of improving human health and well-being. The *omic* topics comprise four major broad areas like genomics, transcriptomics, proteomics, and metabolomics.

Genomics includes the sequencing of whole genomes, assembly and annotation of the sequences, identification and development of molecular markers and quantitative trait loci (QTLs) for target traits, genomics-assisted breeding, genomic selection, etc. (Nayak et al. 2021), and all these tools can be used for the improvement of the nutritional and functional quality of cereal species. The characterization of key genes involved in defining grain quality traits can be achieved by conventional genetic mapping techniques, but direct genomics approaches are helpful for the purpose. For example, genome resequencing of a large number of genotypes that differ for a specific trait can allow association with the quality trait.

Transcriptomics refer to the study of how genes are expressed, changed, and interconnected in specific tissue at a particular stage. The differential gene expression can be studied and quantified by using different molecular biology techniques such as RNA sequencing, microarrays, Serial analysis of Gene Expression (SAGE), qRT-PCR, etc. While microarray, SAGE, and qRTPCR technologies are used for defined transcripts, the RNA sequencing has the advantage of high-throughput

sequencing and captures all expressed genes (Nayak et al. 2021). Analysis of differential expression between genotypes that differ for specific traits is also a step to gene identification. RNA-seq analysis is now a well-established tool for analysis of differences in the transcriptome, which represent the sum of all RNA transcripts of a specific organism. The RNA-seq analysis of developing and mature grains can reveal the genetic determinants of grain composition and, as a consequence, grain quality. Chen et al. (2014) made a de novo transcriptome analysis of developing barley grains using two Tibetan hull-less barley landraces, focusing the attention on gene expression levels related to the biosynthesis of storage components (starch, protein, and β-glucan); the temporal and spatial patterns of these genes were deduced from the transcriptome data of cultivated barley Morex. The results of this study showed how the genes related to important nutritional traits changed the expression during germination and developing of the seed. Moreover, the characterization of these genes provides resources to identify genes that can help in nutritional quality improvement of hull-less barley.

Proteomics can be effectively used to study protein structure, function, and interaction with other proteins or other bioactive compounds. Advanced techniques like matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) and liquid chromatography coupled to mass spectrometry (LC-MS) can detect and identify proteins differentially expressed (Nayak et al. 2021).

Metabolomics is a systematic study of all the metabolites of organism, tissue, cell, and can be considered as a phenotyping tool. A typical and practical application of this *omic* science concerns the identification and quantification of specific metabolites present in a sample. Metabolomics can be used for quantification of biologically active compounds, food fingerprinting, and food profiling. Techniques like gas chromatography coupled to mass spectrometry (GC-MS), liquid chromatography coupled to mass spectrometry (LC-MS), and nuclear magnetic resonance (NMR), have been largely used for the purpose of identification and quantification of metabolites (Nayak et al. 2021). Metabolomic analyses have been generally classified as targeted or untargeted. Targeted analyses focus on a specific group of compounds, requiring their identification and quantification. Targeted analyses are important for assessing the behavior of a certain class of metabolites in the sample under specific conditions. Moreover, targeted metabolomics usually requires higher level of purification and selective extraction protocols. In contrast, with untargeted metabolomics the attention is focused on the detection of as many groups of metabolites as possible to obtain patterns or fingerprints without necessarily identifying or quantifying all compounds. Untargeted analyses have been used for the fingerprints of biological events, such as plant diseases. The development of untargeted metabolic approaches was facilitated by the rapid advance in analytical techniques allowing the simultaneous detection of a wide range of compound classes. The techniques most commonly used for the characterization of compounds are mass spectrometry (MS) and NMR. Several *omics* technologies have been used for barley especially for the study of disease resistance and yield-related traits. However, there are only a few reports related to the functional compounds and quality properties in barley (Han et al. 2018; Chen et al. 2014).

Liang et al. (2022) employed an untargeted metabolomics approach using UPLC-MS/MS to investigate the metabolic differences of five hull-less barley with different grain colors. The authors annotated more than 600 metabolites, including flavonoids, amino acids, and phenolic acids. Colored hull-less barley cultivars were rich in flavonoids and possessed specific metabolite profiles that differ from the white hull-less barley, and these flavonoids also vary between the different colored cultivars. These results improve the understanding of the metabolic pathways and health value associated with different barley pericarp colors.

Plant metabolomics is a powerful tool to explore the metabolic and molecular regulatory mechanisms of plant growth, stress responses, and the improvement of crop productivity and quality. Thanks to next-generation sequencing technologies, metabolome-based GWAS (mGWAS) has been used to study genetic pathway that determines metabolic diversity and their associations with complex traits in plants (Scossa et al. 2016). Metabolomics combined with other *omics* could be a key issue of agronomic performance that was not resolved previously. Besides the chemical information, plant metabolomics can provide data on correlation among the different metabolites and agronomic important traits. Even more promising is the possibility of studying the relationship between metabolite modification and the resulting phenotype (Scossa et al. 2016; Zeng et al. 2020). This approach has accelerated to elucidate flavonoid pathways in cereals, including barley. Zeng et al. (2020) conducted comprehensive metabolic profiling and a metabolite-based genome-wide association study (mGWAS) in the grain and leaf of 196 hull-less and hulled barley accessions. They identified a total of 90 loci associated to metabolites from different branches of the phenylpropanoid pathway, which are also involved in UV-B protection; some alleles related to high-level metabolite trait were found to be significantly enriched in naked barley, suggesting co-selection of various phenylpropanoids. They also identified some genetic determinants regulating natural variation of phenylpropanoid content, including three novel proteins, a flavone C-pentosyltransferase, a tyramine hydroxycinnamoyl acyltransferase, and a MYB transcription factor.

Besides these *omics* approaches, genome-editing tools like RNAi, CRISPR/Cas9, TALENs, and ZFNs can be utilized to improve the crop plants. Use of computational and bioinformatics tools is essential and indispensable while using all these technologies (Nayak et al. 2021).

Genome editing (also called gene editing) is one of the most powerful tools to study the function of genes and an approach by which it is possible to obtain desirable traits in crops. It consists of cutting the genome with a nuclease and then introducing new mutations through DNA repair pathways. Three genome-editing systems, ZFN (zinc-finger nucleases), TALEN (transcription activator-like effector nucleases), and CRISPR-Cas (clustered regularly interspaced short palindromic repeats/CRISPR-associated protein), have been well developed and reported for plants (Nadakuduti and Enciso-Rodríguez 2021). CRISPR-Cas9 is, so far, the most promising and versatile genome-editing technology and has been applied in barley to manipulate grain quality traits (Garcia-Gimenez and Jobling 2022).

3.3 Genetic and Genomics Resources

Several genomic resources have been developed to study partial or total genomic sequences and the related gene function in barley. High-quality barley genetic maps have been developed, based on mutant phenotypes, and these results updated and complemented with genome-wide genetic maps generated from molecular markers.

The open accessibility of barley sequencing data allowed us to understand the genetic and regulatory functions of genes related to agronomically important phenotypes. The haploid genome of barley is about 5.3 Gb in size distributed across seven chromosomes. In 2012, the International Barley Genome Sequencing Consortium published the first reference genome derived from the cultivar Morex (Mayer et al. 2016); this reference genome has been then improved in sequence depth, genome assembly, and annotation (Monat et al. 2019; Mascher et al. 2017) and can be accessed at http://barleysequence.org/.

With the release of the barley genome sequence and the open availability of data, barley breeding is now in the "genomic" era, while barley research is in the postgenomic era. A number of genomic databases for barley have been produced, most of them freely available, and they are being used in different ways to identify or map the specific genes or genomic regions (Riaz et al. 2021) (Table 1).

4 Barley Gene Pools

Wide genetic variability can be found inside the three barley gene pools, characterized by different levels of fertility with cultivated barley (Wendler 2018). The primary gene pool includes barley itself (*Hordeum vulgare* spp. L), collecting landraces, obsolete, and modern varieties, and *H. spontaneum*. The accessions belonging to this gene pool can easily produce hybrids and are therefore the basis of barley improvement.

H. bulbosum is the only member within the secondary gene pool. A relatively large set of hybrids, substitution, and introgression lines between barley and *H. bulbosum* have been obtained and characterized via genotyping-by-sequencing and Exome Capture to unlock these genetic resources.

The tertiary gene pool, including more than 31 wild species, has severe barrier to fertility respect to cultivated barley and its role in breeding programs is limited. An exception is represented by Tritordeum, an amphiploid derived from the cross between the wild barley *Hordeum chilense* and durum wheat. Tritordeum, from a nutritional point of view, has some peculiarities in comparison with the parentals, that is, the high carotenoid content and very low gluten content. The success of this new species underlines the importance of genetic resources for the development of new innovative products for agriculture and industry, as reviewed by Avila et al. (2021).

The three gene pools are the building block to obtain the species pan-genome and genus super-pangenome. A key tool for the study of the barley pangenetic diversity

Table 1 Barley genomic resources (Riaz et al. 2021; Jayakodi et al. 2020; Tan et al. 2020; König et al. 2020)

Database/Website URL	Application	Tools

and its exploitation for crop improvement is in fact the genome sequence. However, a single reference genome cannot capture the full complement of barley sequence diversity. The genomes of 20 barley accessions belonging to primary gene pool, including landraces, varieties, and one *Hordeum spontaneum*, have been sequenced. From the assembly of multiple high-quality sequences, the so-called barley pan-genome has been obtained that can be considered a genomic infrastructure able to capture the full complement of sequence diversity of a crop species (Jayakodi et al. 2020). The use of structural variants individuated has been investigated in 300 GenBank accessions. The authors concluded: "*This first-generation barley pan-genome makes previously hidden genetic variation accessible to genetic studies and breeding.*" At an even higher level of complexity, it is assumed that the so-called super-pangenome can also be developed for crops, including barley. The super-pangenome is the assembly of the pangenomes of different species, able to capture the genomic diversity at the genus level. Pangenomics of wild relatives belonging to the different gene pools can complete gene repertoire of a genus (Khan et al. 2020).

5 Conclusion and Future Perspective

Providing safe, nutritious, and accessible food continues to be a major challenge for agriculture.

Barley is characterized by the presence of a large set of phytochemicals with the potential, and sometimes already demonstrated, impact on human health, so they are expected to play an ever-growing role in food industries, which are always looking for new healthy food for the general population. Consequently, plant breeders were driven to develop new breeding programs aimed to obtain cereal crop cultivars with higher contents of bioactive components in the grain (Loskutov and Khlestkina 2021).

The progresses in genomics provide new modern tools for make breeding programs more efficient. Especially, the assembly of the first barley reference genome offered great opportunities for the application of genomics in plant breeding. Genomic information in combination with sequencing, resequencing, and genotyping

datasets is being utilized to study important agricultural traits and their linked genes (Riaz et al. 2021). Moreover, the integration of genomics with other omics approaches in barley science aims to provide a nutritionally rich and safe cereal (Nayak et al. 2021). Another important aspect is that genomic tools will have a primary role to understand the impact of several environmental factors such as heat, drought, and plant diseases on crop quality, and this will become essential in adapting to a changing climate.

Abstract

Oat, of *Poaceae* grass family, is an important multipurpose cereal, cultivated for grain, food, feed, fodder, and straw, alone, in mixture, or as a dual-purpose crop. This cereal ranks sixth in world production statistics, following wheat, maize, rice, barley, and sorghum. Recently, an increased interest in oat arose due to its unique health-related properties. This cereal produces valuable and unique macro-, micro-, and phytonutrients, is rich in soluble fibers (mainly β-glucan), polyphenols, galactolipids, and contains a relatively high quantity of protein. In addition, oat is an important source of phenolic acids being the only cereal that contains avenanthramides, a group of phenolic alkaloids with beneficial effects on cardiovascular diseases and colon cancer prevention. Moreover, oat bran is an excellent source of B complex vitamins (B1, B2, B3, and B6) and tocopherol (vitamin E). The lipidic amount of whole-grain oats is doubled compared with other cereals and mainly consists of unsaturated fatty acids such as linoleic, oleic, and linolenic acids. Considerable genetic resources exist with large collections of landraces, wild relatives, and cultivars; therefore, sources of genetic variation are available for breeding purposes. The traditional breeding has been directed to improve yield and agronomical traits, such as abiotic and biotic stress resistance, lodging resistance, growth habit, together with a few quality-related traits, namely protein and starch content. During the last years, oats turned out to be a very interesting source of dietary and curative compounds. This newly found interest shifted the breeding paradigm from agronomic to health-related purposes. New breeding programs are aiming to develop "specialized" genotypes with high levels of bioactive compounds, vitamins, dietary fibers, and oils.

Avena sativa · Oats · Beta-glucans · Avenanthramides · Breeding for HR molecules

1 Introduction

Oat is a cereal grain from the *Poaceae* grass family that originated in the Mediterranean area, also named "brome" and "wild wheat" (Tang et al. 2022). It is an important multipurpose cereal, cultivated for grain, food, feed, fodder, and straw, alone, in mixture, or as a dual-purpose crop. Oats are primarily used as livestock feed that accounts for more than 70% of the total world's usage. Recently, an increased interest in oats arose due to the unique properties of the grain and the nonfood-related applications. In parallel, an increased oat consumption as food has been vastly observed, reaching, in some countries (e.g., the United Kingdom), up to 70% of total oat grain usage. Several products containing oats became of daily use such as breakfast cereals (oatmeal and biscuits), beverages (oat raw or fermented milk), bread, and infant foods.

This cereal plays a key role both in production and sustainable agricultural systems due to its importance in crop rotation and its economic benefits compared to barley production. It is, in fact, a low-input cereal growing relatively well on marginal land or in unsuitable conditions for wheat, barley, or maize production.

Oats are mostly cultivated between 35° and 60° latitude, which correspond to cool and moist climate. Spring-sown oats are the most cultivated in cold environments, while autumn-sown oats (winter oats) are grown mostly in mild climates, such as the United Kingdom, Southern Europe, and the Mediterranean areas. Winter oats have high yields, deep roots, long growth cycle, and early maturity; on the other hand, they lack winter hardiness, making them unfit to be cultivated in very cold areas. In addition, in southern areas, winter sowing allows oats to partially avoid harsh late summer temperatures, even though drought and diseases are still the major causes of yield instability. In spite of this, thanks to new, high-yielding and stress-resistant cultivars, it is gaining popularity also in southern subtropical regions (Sánchez-Martín et al. 2014).

Oat ranks sixth in world cereal production statistics, following wheat, maize, rice, barley, and sorghum (Ahmad et al. 2020).The numbers of total world production in the last years are the following: cultivation area of 9.5 million hectares, yield of 2.4 metric tons per hectare, and production of 23.5 million metric tons. The global oats market amounted to 4.90 billion dollars in 2018 and is estimated to grow by 5.5% over the next 5 years (Kouřimská et al. 2021). During the marketing year 2020/21, approximately 4.72 million metric tons of oats have been yielded in Russia, the world's leading producer, followed by Canada, Spain, Australia, Poland, and China (Fig. 1).

Despite the yield increase of the last 50 years, obtained through new varieties and agronomic practices improvement, the share of minor cereals, that is, oats, rye, and triticale, decreased worldwide. For instance, the total cereal area in Europe downsized from 30% to 18% between 1961 and 2010 (http://faostat.fao.org/), while that of

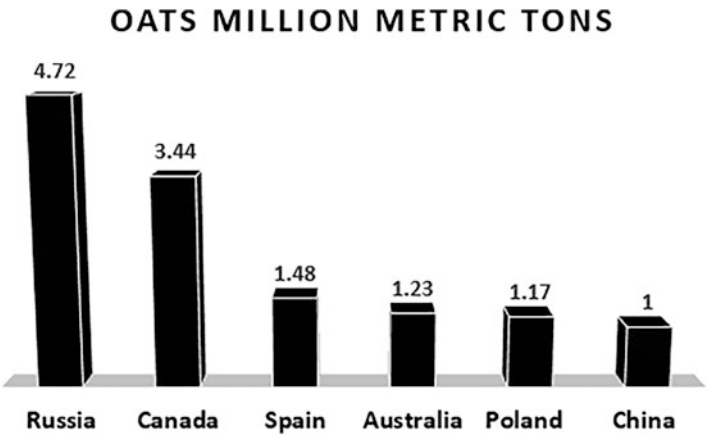

Fig. 1 Leading oats producer countries (Meenu et al. 2021)

the major cereals increased. This proliferation of maize and wheat monocultures means a greater dependence on these crops and consequently higher social and economic vulnerability to risks of soil-borne disease buildup and weed problems. Crop diversification is, therefore, supported, and oats, as low-input crops with higher nutritive efficiency and lower pesticide requirements, are highly appropriate for sustainable cropping systems and of great relevance to agricultural policies development. On the other hand, oats yield is stagnant since the 1980s; therefore, improved oat lines with higher yield and of better quality are urgently required to ensure competitiveness in modern agriculture.

2 Nutritional Composition of Oat

Oat contains valuable and unique macro-, micro-, and phytonutrients. The grains are rich in soluble fibers (mainly β-glucan), polyphenols, galactolipids, and are relatively high in protein content (15–20%) (Kumar et al. 2021), which is quite different when compared with that of other main cereals. It is mainly composed of globulins, prolamins, albumins, and glutelins, which have a superior amino acid profile rich in lysine and threonine. For this reason, oats-based products could be considered ideal plant-derived protein sources for both animals and humans. In addition, oat is an important source of phenolic acids being the only cereal that contains avenanthramides, a group of phenolic alkaloids with beneficial effects on cardiovascular diseases and colon cancer prevention (Dimberg et al., 1993; Soycan et al. 2019). The presence of polyphenols combined with other antioxidant compounds is reported to exert beneficial effects on the human health (Ryan et al. 2011).

Oat carbohydrates content is 99% polysaccharides plus a low fermentable fraction of mono- and oligosaccharides (Bouchard et al. 2022). Starch and fiber (soluble and nonsoluble) are the principal polysaccharides found in oats. Regarding the on-starchy fraction, β-glucan is the most promising water-soluble dietary fiber.

Moreover, oat bran is an excellent source of B complex vitamins (B1, B2, B3, and B6) and tocopherol (vitamin E). The lipidic amount of whole-grain oats is doubled compared with other cereals and mainly consists of unsaturated fatty acids (65%) such as linoleic, oleic, and linolenic acids.

In the light of the above information, we can assume that the peculiar oat grains composition (Table 1), a bran rich in minerals, vitamins, antioxidant, soluble dietary fibers, and an endosperm and aleurone layer rich in proteins, are eligible features to consider oat among the healthiest cereals.

To give a general overview:

- Oats are a good source of proteins, with favorable amino acid contents, high in starch, fats, and vitamins, making them of high nutritional value. Oats have in fact the highest oils (6–12%) and protein (12–20%) contents in de-hulled grains among cereals.
- Oats are rich in beta-glucans: The presence of these polysaccharides resulted in the approval of a health-related claim from the EFSA and the FDA given their

Table 1 Main oat grain nutrients, their variation ranges, and properties, as inferred from recent literature

Nutrients	Total content	Principal compounds	Properties	References
Fiber	10–15.4 g/100 g	Nonsoluble: lignins, cellulose, hemicellulose Soluble: β-glucan (1.73–5.7 g/100 g)	Antidiabetic, antibacterial, cardiovascular protection	Raguindin et al. (2021), Zhang et al. (2021), Chen et al. (2021), Bouchard et al. (2022)
Saponin	49.6–443 mg/kg	Avenacins, avenacosides A (37.7–60.6%) and B (13.8–55.2%)	Antioxidant, lowering cholesterol, affecting immune systems	Shi et al. (2004), Yang et al. (2016), Raguindin et al. (2021)
Phenolics	180–576 mg/100 g	Alkaloid A/p-coumaric acid, alkaloid B/caffeic acids, alkaloid C/ferulic acid (max 149.36 mg/100 g) lignans		Zhang et al. (2021), Raguindin et al. (2021), Soycan et al. (2019)
Flavonoids	n.a.	Quercetin (max 8.9 mg/100 g in husked oats) Rutin (max 0.47 mg/100 g)		Raguindin et al. (2021)
Phytosterols	35–68.2 mg/100 g	β-Sitosterol (59.1–64.9%), campesterol (7.6–9.1%)	Anti-inflammatory, antioxidant, anticancer, preventive and therapeutic for hypertension and coronary heart disease	Raguindin et al. (2021)
Avenanthramides	0.5–71.85 mg/100 g	AVA 2p, AVA 2f, AVA 2c (65–70%)	Antiproliferative, anti-inflammatory, antioxidant, antiatherogenic	Raguindin et al. (2021), Soycan et al. (2019), Liu and Wise (2021)
Fatty acids	6.25–7.5 g/100 g	Unsaturated (65%): linoleic acid, oleic acid, linolenic acids Saturated: myristic acid, palmitic acid, stearic acids	Cardiovascular protection, antiperoxidation of fat	Chen et al. (2021), Bouchard et al. (2022), Kim et al. (2021a, b)
Protein	15–20%	Globulins (50–80%), prolamins (avenins 4–15%), albumins (1–12%), glutelins (10%)		Boukid (2021), Kumar et al. (2021)
Amino acid		Lysine (675 mg /100 g), threonine		Tang et al. (2022)

(continued)

Table 1 (continued)

Nutrients	Total content	Principal compounds	Properties	References
Vitamins		B1/thiamine (0.73 mg/100 g), B2/riboflavin (0.13 mg/100 g), B3/niacin (0.88 mg/100 g), B6 (0.1–0.22 mg/100 g), E/α-tocopherol (0.45–1.2 mg/100 g)	Antioxidant	Chen et al. (2021), Bouchard et al. (2022)
Element and minerals in trace		Calcium (45–58 mg /100 g), phosphorus (325–734 mg/100 g), iron (3.5–5.41 mg /100 g), zinc (3.11–3.64 mg/100 g), manganese (3.63–5.63 mg/100 g), chromium		Chen et al. (2021)

cholesterol-lowering effects. Several other claims, specific to oats and related to reducing the impact of chronic diseases (such as type 2 diabetes, obesity, hypertension, immune-related diseases), are under development. Moreover, oats display higher percentages of soluble beta-glucans in comparison with barley and contain other dietary fibers, notably arabinoxylans.

- Recent investigations on health implications demonstrated that oats' nutritional benefits to human diets go well beyond those currently recognized. Key molecules in this research include polar lipids, antioxidants, and minor bioactive compounds such as avenanthramides.

Because of the grain composition, an increase in oats use for human nutrition has been observed, especially in Europe and North America. The expanding knowledge of the grain composition and its potential end uses are leading to the proliferation of oat-derived products. Table 1 reports the main oat grain nutrients and their ranges of variation depending on cultivation environment, genotypes, and their interaction.

3 Growing Importance in Chronic Diseases and Malnutrition Prevention

Increasing evidence suggests that dietary improvements are important strategies to prevent chronic diseases. Oats possess a variety of health benefits and pharmacological properties. They, potentially, exert antioxidant, anti-inflammatory, antidiabetic, and anticholesterolemic effects. These features could be exploited in functional ingredients production and innovation of traditional foods.

Oat product intake is associated with a reduction in serum cholesterol levels, hence modulation of cardiovascular disease risk (Joyce et al. 2019; Sun et al. 2019). Flavonoids, from whole-grain oat, improve serum lipid profile and decrease lipid deposition contrasting hyperlipidemia (Ren et al. 2021). Studies demonstrated that oat consumption can significantly reduce insulin response, fasting blood glucose levels, and postprandial hyperglycemia incidence.

Beta-glucans' health benefits have been clearly demonstrated. Epidemiological investigations constantly denoted that diets rich in whole-grain products and fibers are associated with a decreased risk of chronic disorders such as type II diabetes, cardiovascular diseases, and cancer.

Furthermore, oats contain plenty of primary and secondary metabolites, ranging from proteins (glutamine in particular) to microelements (copper, iron, selenium, zinc) and polyphenols. These components, together with beta-glucans, exert an immunomodulating role, that is, are able to stimulate the innate and adaptive immune system's response and can inhibit the growth of various bacteria, viruses, fungi, and parasites.

Moreover, oats wield a positive effect on gut's microbiota and related metabolites (Chen et al. 2021) thanks to their dietary structure, resulting in amelioration of chronic problems and improved quality of life. Oat increases *Bifidobacteria* and *Lactobacillus* growth, which exert an antitumoral effect due to short-chain fatty

acids formation, such as butyrate, an important metabolite for intestinal microbial fermentation of carbohydrates (Ren et al. 2021).

Oats consumption can regulate intestinal transit times and increase butyrate production and/or other fecal short-chain fatty acids synthesized by the gut microflora. Patients suffering from inflammatory bowel disease, ulcerative colitis, colorectal adenoma, or cancer can, therefore, benefit from a regular dietary intake of oats.

Of great interest are the different oil fractions and components, for example, polar lipids. Such polar lipids can be used to produce liposomes, which have been demonstrated useful to increase satiety and improve intestinal health (Härröd and Larsson 2011). The studies of Ohlsson et al. (2014) and Hossain et al. (2021) showed that polar lipids regulate hormones involved in human appetite. In the frame of Scan Oats consortium (www.scanoats.se), the combined consumption of lipids and β-glucans has been studied, finding that these two classes of molecules can lower the glucose response, but no synergistic effects have been demonstrated (Cloetends 2022).

Thanks to their fibers and lipids content, oats effectively reduce obesity and are efficient indexes of serum lipid levels and liver function.

Oats and oat products-positive effects are attributed to their fiber amount (especially β-glucan), but also to protein content, balanced amino acids profile, and bioactive substances such as starch, polyphenols, saponins, avenanthramides, and flavonoids. Ingredients derived from oat protein isolates and concentrates could be an added value in foodstuff, especially if considered in combination with the unique functional properties of this cereal (Kumar et al. 2021).

Oats are rich in selenium, involved in DNA repair, and associated with a reduced risk for cancer, especially colon cancer.

Several European countries, the United States, and Canada currently permit oats to be included as an ingredient in gluten-free diets, provided that the gluten contamination is below 20 ppm. Very recently, the proposal to remove oats as priority allergen in Codex Alimentarius has been submitted to FAO/WHO (Tye-Din 2022). Multiple studies reported in fact that oats' prolamin storage proteins or "avenins" do not contain any of the known coeliac disease epitopes from gluten of wheat, barley, and rye (Gilissen et al. 2016; Smulders et al. 2018). Others found that oats have a very low or null immunogenicity, depending on the different cultivar (Comino et al. 2015; Kosová et al. 2020). Recent genomic studies suggested that *A. sativa* has low copy number of genes encoding celiac disease epitopes, low occurrence of highly immunogenic proteins, and low proportion of avenins within total oat proteins (Tye-Din 2022; Kamal et al. 2022). Long-term studies confirmed the safety of oats for celiac disease patients and the positive health effects of oat products in a gluten-free diet. Controlled avenin feeding studies concluded that protracted oat ingestion should not be harmful, even if a small sensitive subset of patients are likely to exist (Tye-Din 2022). Inclusion of oats in a gluten-free diet might be valuable due to their nutritional and health benefits, provided that no contamination from other small grain cereals can be guaranteed in the supply chain (Comino et al. 2015). Wheat, barley, or rye contamination is in fact a major problem in oats' conventional production chains.

Oat is different from other cereal grains as the whole de-hulled kernel is used. Many food products are available, for example, porridge or oatmeal, hot cereals, bread, biscuits, infant food, muesli, or granola bars and dairy substitutes, such as oat milk, yogurt, and ice cream. The technological processes applied to the production of different oat-based food can impact nutritional properties. For example, the three thermal treatments coupled to a starvation step used for the preparation of traditionally oat-based Chinese food impact the β-glucan and protein MW and on GI (Hu 2022). Starting from the numerous positive effects on human health, the consumption of oats and derived products can be encouraged. The diffusion of these products should be based on informative campaigns toward consumers, backed by robust scientific results. This will provide new markets for higher added value products and higher profitability in the oat-related agrofood sector.

4 Health-Related Molecules Unique to Oat

Oats gained a great deal of interest as a healthy and highly nutritive food, rich in secondary metabolites of great functional value. Two classes of HR compounds' characteristics of oats are beta-glucans and avenanthramides (AVNs). β-Glucans have hypocholesterolemic, hypoglycemic, antitumor, immunomodulatory, antioxidant, and anti-inflammatory activities (Kim et al. 2021a, b). AVNs have strong and widely demonstrated anti-inflammatory activities. Tranilast, a commercially available antiallergic drug similar to AVN, has been demonstrated to potentially prevent exacerbation of COVID-19 by affecting different pathways such as NLRP3 inflammasome, signaling pathways, cytokines and chemokines, and cell adhesion molecules (Saeedi-Boroujeni et al. 2021).

4.1 β-D-Glucans

(1 → 3), (1 → 4) β-D-glucans (Fig. 2) are nonstarchy polysaccharides found in aleurone, subaleurone, and starchy endosperm cell walls. They represent the major component of the soluble fiber in oats. They are composed of glucose monomers in long linear glucose polymers, linked by β (1 → 4) (70%) and β (1 → 3) (30%) glycosidic bonds (Bouchard et al. 2022).

The difference between soluble and insoluble β-D-glucans is based on the ratio of the two bonds. In fact, the presence of β (1 → 3) gives greater flexibility to the molecule; consequently, more solubility and viscosity. Bonds formation is influenced by genotype and growing environment (Redaelli et al. 2013).

Moreover, about 90% of glucose units are organized in trimers and tetramers joined by β (1 → 3) bonds; their ratio influences structural variability and consequently the differences in some physical properties. The ratio between cellotriose and cellotetraose is characteristic of every different cereal with a smaller value for oats (1.9–2.4), a higher percentage of cellotetraose makes the molecule less soluble (Bouchard et al. 2022; Bai et al. 2019; Wang and Ellis 2014). Higher molecular

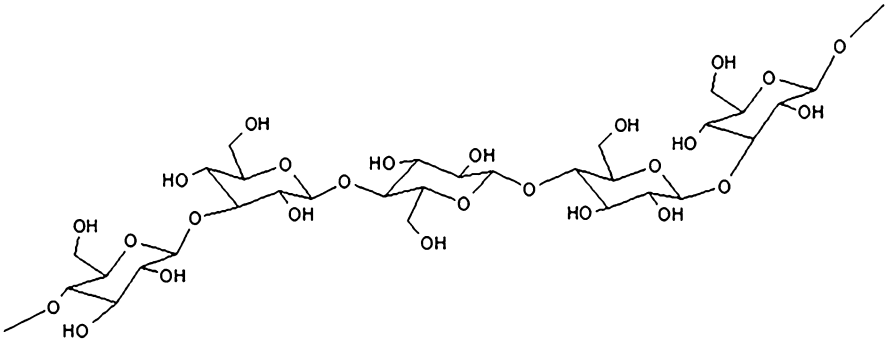

Fig. 2 Chemical structure of (1 → 3), (1 → 4) β-D-glucans

weight and lower cellotriose/cellotetraose ratio β-glucans tend to have higher viscosities than those with lower molecular weight and higher cellotriose/cellotetraose ratio (Bouchard et al. 2022).

The biosynthesis of (1 → 3), (1 → 4) β-D-glucans depends on an enzymatic complex consisting of a cellulose-synthase-like enzyme (*Csl* gene), which leads to the formation of cellobiose, units of cellodextrin, and a glycosyl-transferase enzyme, which adds another glycosyl residue to form cellotriose and higher odd-numbered chains units (Izydorczyk and Dexter 2008). *CslF6* is the major gene responsible for the biosynthesis of (1,3; 1,4) -β-d-glucans. It is highly expressed in different tissues, especially in the developing endosperm, and produced in the Golgi apparatus, then is channeled through the secretory pathway to the plasma membrane. Changes in the *CslF6* gene, of even a single amino acid, can alter the fine structure of the (1,3;1,4)-β-D-glucans (Chang et al. 2021).

Oat is rich in both soluble, particularly β-glucan, and insoluble fiber, particularly cellulose, lignin, and hemicellulose. A diet high in fiber is known to be beneficial in the prevention of many diseases.

4.1.1 Reduction of Cholesterol and Postprandial Glucose in the Blood

Soluble β-glucan can increase the viscosity of the food bolus by delaying stomach emptying, improving intestinal filling, and slower absorption of nutrients. More voluminous stools accelerate intestinal motility by reducing the time of exposure of the intestinal wall to irritants and carcinogens present (Singh et al. 2013).

The increase in gastrointestinal viscosity also causes cholesterol and bile acids to be trapped, reducing their absorption; consequently, the bile acids necessary for digestion must be synthesized from cholesterol by reducing their concentration. β-Glucans have been shown capable of reducing the total and LDL-cholesterol level, in the blood of normo- or hypercholesterolemic subjects, reducing the risk of heart disease. The physiological response depends on solubility, concentration, molar mass of β-glucan, and molecular weight, all contributing to increase viscosity (Singh et al. 2013; Zhang et al. 2021).

β-Glucan solutions' high viscosity is able to reduce postprandial glucose by interfering with the transfer of released glucose to enterocytes. Another pathway is oat β-glucans consumption by the intestinal microbiota in the colon; hence, they are not digested in the upper gastric tract. Fermentation produces short-chain fatty acids, such as propionic, butyric, and acetic acid, which can regulate the expression of insulin-sensitive glucose transporter type 4 (GLUT-4) imputed to maintaining glucose concentration gradient across cell membranes and allowing the transport of glucose (Zhang et al. 2021).

The reduction of postprandial glucose and therefore of inflammation caused by glucose is consequently reducing the general inflammatory state (Chen et al. 2021).

The hypoglycemic function of β-glucans is influenced by its molecular weight, a higher value is associated with a greater decrease in fasting blood glucose levels and better control of blood glucose levels after meals. β-Glucan can lower the glycemic index (GI) of foods by delaying digestion and absorption of starch as a result of amylase activity reduction, thus obtaining a hypoglycemic effect, and the GI value is decreased with increasing molecular weight and viscosity of β-glucan (Tang et al. 2022).

Scientific evidence about these beneficial effects of oats and its β-glucans led to the authorization of specific health claims that can be reported on labels of foodstuff constituted of oats and barley in order to clearly communicate benefits and limitations associated with consumption to the consumer.

The European Food Safety Authority (EFSA) authorized the claim that β-glucan contributes to the maintenance of normal cholesterol levels in the blood and the beneficial effect is obtained with a daily intake of 3 g of beta-glucans from oat or oat bran, barley, or barley bran or mixtures of these (EFSA 2009; Commission Regulation EU 2012). In a subsequent opinion, EFSA established that a reduction in cholesterol can diminish the risk of (coronary) heart disease and the amount of β-glucan to be taken throughout the day must be part of a balanced diet (EFSA 2010).

The use of the claim has also been approved by the Food and Drug Administration (FDA) in the United States, indicating that soluble fiber, 3 g or more per day of β-glucan from either whole oats or barley, or a combination of whole oats and barley, can reduce the risk of coronary heart disease through the intermediate link of blood cholesterol or total LDL cholesterol in the blood (Code of Federal Regulations, 21CFR101.81), recognized also by Health Canada and Food Standards Australia New Zealand.

Another claim approved by EFSA and based on scientific evidence is that the consumption of β-glucan from oats or barley as part of a meal contributes to the reduction of high blood glucose after a meal. The claim can be used only for food containing at least 4 g of β-glucan from oats or barley for every 30 g of carbohydrates available in a quantified portion as part of the meal (EFSA 2011).

4.1.2 Effect on the Immune System, Cancer Prevention, and Antimicrobial Activity

Oats β-glucans improve immunity and anticancer activity, and moreover, can kill the malignant cancer cells, sarcoma cells, and melanocytes. The inhibition exerted on

different types of intestinal, liver, and breast carcinomas is similar to anticancer drugs but without any side effects (Tang et al. 2022).

β-Glucans have an immunostimulant effect altering the microflora of the colon with the production of short-chain fatty acids (Singh et al. 2013).

The fermentation of soluble fiber with the production of short-chain fatty acids, in particular butyric acid, favors the development and colonization of probiotics. Short-chain fatty acids improve cell proliferation of the colon mucosa, reducing the risk of cancer (Singh et al. 2013).

Short-chain fatty acids (SCFA), bacterial metabolites of dietary fibers, stimulate the production of mucus and antimicrobial peptides, increase the expression of tight junction proteins, and modulate immune system (Chen et al. 2021). Multiprotein junctional complex plays a key role in osmose balance maintenance and transcellular transport of specific molecules.

Fermentable fibers can reduce the amount of mucin used during fermentation; mucin acts as a barrier against pathogenic microorganisms, and fiber contributes to intestinal microbiota maintenance by reducing the chance of opportunistic pathogens to prevail (Chen et al. 2021).

β-Glucan concentration has a positively proportional antibacterial effect. Low molecular weight β-glucan entering microbial cells would cause their lysis and death (Tang et al. 2022).

4.1.3 Blood Pressure Reduction

β-Glucans can reduce blood pressure, likely due to their viscosity. Insulin resistance, an important indicator of hypertension, has been linked to β-glucans viscosity. The intake of viscous fibers influences renal sodium absorption and transmembrane ion transport, causing a reduction in blood pressure (Bai et al. 2019).

4.1.4 Antioxidant and Anti-inflammatory Activity

Low molecular weight β-glucans transfer hydrogen from molecules that can act as free radical quenchers under physiological conditions (Bai et al. 2019). They have free radical "scavenger" activity and the ability to relieve inflammatory conditions.

4.2 Avenanthramides

Oats are rich in phenolic compounds that are interesting for their high antioxidant capacity and the potential health benefits (Boz 2015). Phenolic compounds consist of aromatic rings with one or more hydroxyl groups (Bouchard et al. 2022). Oats contain mainly simple phenols such as phenolic acids, flavonoids, and avenanthramides compounds (Tang et al. 2022). Avenanthramides were originally identified as phytoalexins produced by the plant when exposed to pathogens (Perrelli et al. 2018).

The avenanthramides (AVAs) are a group of phenolic alkaloids typical of oats (Fig. 3); they are low molecular weight-soluble phenolic compounds (Boz 2015)

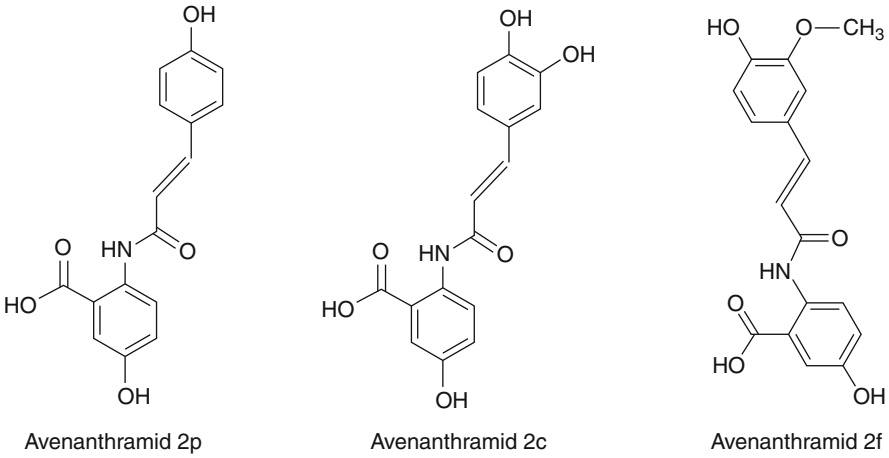

Fig. 3 Chemical structure of avenanthramides

consisting of anthranilic acid and hydroanthranilic acid linked to hydroxycinnamic acids by amide bonds (Singh et al. 2013).

Oats contain approximately 40 different types of AVAs, the predominant are esters of 5-hydroxyanthranilic acid with p-coumaric (AVA-A or 2p), ferulic (AVA-B or 2f), and caffeic (AVA-C or 2c) (Boz 2015). Among cereals, only oats contain AVAs; they can be found in almost all fractions of the kernel but particularly in bran (Bouchard et al. 2022) and aleurone layers (Tang et al. 2022).

While the mechanisms of biosynthesis of the main avenanthramides in oats AVA-A, AVA-B, and AVA-C are not yet fully understood, studies identified three different types of genes that encode 4-coumarate-CoA ligase (4CL), hydroxycinnamoyl-CoA, hydroxyanthranilate N-hydroxycinnamoyl transferase (HHT), and caffeoyl-CoA O-methyltransferase (CCoAOMT) enzymes, all involved in the biosynthesis process of avenanthramides. 4CL oats appear to convert p-coumaric, caffeic, and ferulic acids in their CoA thioesters, while oats' HHT are responsible for biosynthesis of AVA-A and AVA-C by the condensation process of hydroxyanthranilic acid, acyl acceptor, with p-cumaroyl-CoA and caffeoyl-CoA, acyl donor. AVA-B is synthesized by methylation of the hydroxyl group at position 3 of the aroyl group in AVA-C by the CCoAOMT enzyme (Li et al. 2019).

4.2.1 Antioxidant, Anti-inflammatory, and Antiatherogenic Activity

Avenanthramides showed antioxidant potential significantly higher than other simple phenols. Antioxidants protect cells from the oxidative damage and help prevent several chronic diseases caused by reactive oxygen species (ROS) generation. Antioxidant activity was found to be in AVA-C> AVA-B> AVA-A. AVAs inhibit calcium-induced low-density lipoprotein (LDL) oxidation in a dose-dependent manner and are shown to act synergistically with vitamin C and other antioxidant compounds. During physical activity, taking avenanthramides decreases ROS

production and related lipid peroxidation. The antioxidant potential of AVAs could be related to an effect on antioxidant enzymes, such as superoxide dismutase (SOD) and glutathione (GSH) peroxidase (Tripathi et al. 2018). AVAs are bioavailable, and their antioxidant effect on LDL reduces the risk of cardiovascular diseases (Singh et al. 2013).

AVAs also inhibit inflammatory processes that play a significant role in many diseases. AVAs' anti-inflammatory activity was detected in endothelial human aortic cells with an evident reduction of various types of molecules involved in the attachment of monocytes (blood immune cells) to the arterial walls, responsible for inflammation and stiffening, first step in the development of atherosclerosis (Singh et al. 2013). AVAs reduce production of pro-inflammatory cytokines (interleukin IL-6, IL-8, and monocyte chemoattractant protein (MCP-1)) that carry the immune cells at the stimulation site and inhibit vascular endothelial cell expression of adhesion molecules, including ICAM-1 (intracellular adhesion molecule-1), VCAM-1 (vascular adhesion molecule-1), and E-selectin (Tripathi et al. 2018; Singh et al. 2013).

Colloidal oat flour has been found to be effective as an anti-inflammatory and anti-itch in dermatitis treatment, with avenanthramides responsible for these beneficial effects. The anti-inflammatory effects of AVAs have been demonstrated in human keratinocytes. AVAs reduce the IL-8 production, and the anti-inflammatory action occurs through the NF-κB pathway. NF-κB is one of the very crucial regulatory transcription factors (Tripathi et al. 2018).

4.2.2 Antiproliferative Activity and Postprandial Glycemic Response Control

AVAs, including AVA-C and its methylated derivative, can inhibit the proliferation of colon, breast, and smooth muscle vascular cancer cells. They cause cell cycle blockage in the G1 phase by upregulating the p53-p21cip1 pathway and inhibiting the retinoblastoma protein (pRB) phosphorylation with the possible activation of an apoptosis process (Perrelli et al. 2018).

Glucose uptake can be mediated in humans by intestinal solute carriers SGLT1 and GLUT2. In a proof-of-concept study, Joseph (2022) showed that AVAs can inhibit glucose uptake in a dose-dependent manner in CaCo2 cell system.

5 Genetic Resources of Health-Related (HR) Genes

The genus *Avena* includes up to 30 recognized species, with different ploidy levels that includes diploids ($2n = 14$), tetraploids ($2n = 28$), and hexaploids ($2n = 42$). As reviewed by Loskutov (2005, 2008), the genus comprises the two sections of *Aristulatae* and *Avenae*, including both wild and cultivated species (Table 2).

Among cultivated, *A. strigosa* is a diploid with $2n = 14$ (genome As), whereas *A. abissinica* is a tetraploid that carries the two A and B genomes ($2n = 24$).The most cultivated *A. sativa* and marginally cultivated *A. abyssinica* are hexaploids with 42 chromosomes, presenting three different sets of nuclear genomes A, C, and D.

Table 2 Main oat species according to Loskutov (2005)

Section	Wild species	Cultivated species
Aristulatae	*A. claudia*	*A. strigosa*
	A. prostrata	*A. abyssinica*
	A. damascena	
	A. longiglumis	
	A. wiestii	
	A. hirtula	
	A. barbata	
	A. vaviloviana	
Avenae	*A. fatua*	*A. byzantina*
	A. occidentalis	*A. sativa*
	A. ventricosa	
	A. bruhnsualis	
	A. canariensis	
	A. magna	
	A. murphyi	
	A. canariensis	
	A. insularis	
	A. sterilis	
	A. ludoviciana	

Three gene pools can be recognized inside the genus, classified as primary, secondary, and tertiary depending on the interfertility with cultivated hexaploid oat, as reviewed by Ociepa (2019). The primary gene pool (GP-1) collects accessions, including landraces, breeding lines, modern and obsolete cultivars, belonging to the same species as the cultivated oat. The secondary gene pool (GP-2) includes species that are still crossable with cultivated oats, even if a limited number of fertile hybrids are produced. The tertiary gene pool (GP-3) includes relatives that are so distant that the crossing would require very specialized techniques such as embryo rescue, bridge crosses, and induced polyploidy.

The primary gene pool is wide and collects wild and cultivated hexaploid species, interfertile and without any recombination restrictions. New genes from wild species have been introduced in cultivated forms mainly to improve agronomic traits. *A. sterilis* has been an interesting donor of resistance genes against fungal diseases such as powdery mildew, crown rust, and stem rust. *A. sterilis* contributes even to the improvement of winter hardiness, grain yield, drought tolerance, and green mass. This same species, *A. sterilis*, is a potential donor of desirable quality-related traits, such as large grains, high protein content, balanced amino acid composition, and high oil and beta-glucan contents. *A. fatua* has also been included in oat-breeding programs as genes donor for reduced plant height, abiotic stress resistance, stem and crown rust resistance, smuts, and viroses. *A. fatua* and *A. ludoviciana* are useful sources of resistance to crown rust. Aside from agronomic traits, these two species are considered donors of important genes for health-related characters, such as high protein and oil content.

Exploitation of *A. sterilis* in breeding programs gave cultivated varieties, for example, Starter (characterized by high-protein content), Ozark (cold resistant), and Jay (resistant to crown rust).

The secondary gene pool includes the tetraploids *A. murphyi, A. maroccana,* and *A. insularis*.

The crosses between *A. sativa* and these species give partially fertile hybrids, whose fertility level can be increased by backcrossing. *A. murphyi* could be a potential source of resistance to powdery mildew and crown rust, but also donor of high protein content and high groat oil content. *A. magna* can contribute to both quality-related traits (grain size, high contents of protein, lysine, and oil) and biotic stress resistance (powdery mildew and crown rust). Crosses with *A. maroccana* resulted in varieties such as Amagalon, resistant to crown rust, and CDC Bell for green feed or oat hay production.

In the tertiary gene pool are included all diploid and tetraploids species. Resistance to crown and stem rust, Septoria, powdery mildew, together with high oleic acid and fiber contents, are interesting features of several diploid and tetraploid wild species. However, cross-incompatibility complicates the gene transfer from diploids and tetraploids to hexaploids. This problem can be mitigated using backcrosses, mutants, and genetic intermediates. The varieties Hinoat, Gemini, and Foothill, all resistant to crown rust, have been obtained by crossing *A. sativa* with the diploid, marginally cultivated, *A. strigosa*.

Considerable genetic resources exist with large collections of landraces, wild relatives, and cultivars. According to De Carvalho et al. (2013), currently, 116 major GeneBanks conserve oats' genetic resources. The major collections of oat landraces are located in Canada (Plant Gene Resources of Canada (PGRC)) at the Saskatoon Research and Development Centre (Saskatoon, Saskatchewan), Russian Federation (Federal Research Center N. I. Vavilov All-Russian Institute of Plant Genetic Resources, VIR), the United States (NSGC), and Germany (Leibniz Institute of Plant Genetics and Crop Plant Research, IPK, Gatersleben). The collections include adapted cultivars, old landraces, marginally cultivated oats such as *Avena strigosa*, *Avena abyssinica*, *Avena brevis,* and *Avena nuda*, crop wild relatives, and genetic stocks bearing defined traits. Different Gene Bank information systems have been developed (e.g., GRIN-CA/GRIN-Global-CA, GRIN-USA, EURISCO) that allow national and international clients and the public to inspect and access to the GeneBank holdings.

Significant sources of genetic variation for oat breeding are therefore mainly available in European and American GeneBanks and breeding programs, coherently with the spreading areas of this crop.

Cultivated *A. sativa* was most likely first domesticated in Europe ca. 2000–3000 BC (Zohary et al. 2012) and then spread from the East to Central–North Europe in the late Bronze Age. In the western part of the Mediterranean region originated A. *byzantine,* the main cultivated form in North Africa and Spain.

In the sixteenth century, the two *A. sativa* and *A. byzantina* species were introduced to North America. *A. sativa*, more suited to spring sowing, was mainly spread in the northern regions, whereas *A. byzantina* was used for autumn sowing in the Southern United States. In the twentieth century, new breeding programs

built on the crosses between the two species and gave many varieties currently cultivated in these environments.

6 Oat Breeding for Quality and Health-Related Traits

In the review of Loskutov and Khlestkina (2021), it is clearly reported how the oats' breeding paradigm has been recently switched from agronomic objectives to health-related ones. The traditional breeding has been directed to improve yield and agronomical traits, such as abiotic and biotic stress resistance, lodging resistance, and growth habit, together with a few quality-related traits, namely protein and starch content. During the last years, oats turned out to be a very interesting source of dietary and curative compounds. New breeding programs are aiming to develop "specialized" genotypes with high levels of bioactive compounds, vitamins, dietary fibers, oils, etc. This is in line with the Rome Declaration on Nutrition, in which integrated strategies are indicated to eradicate all forms of malnutrition, that is, not only undernutrition, but even micronutrient deficiencies, and obesity. One of the strategies is optimizing the nutritional value of crop and derived raw materials. Starting from the prominent role of small grain cereals in human nutrition, the importance of new biofortified cereal varieties, improved in essential amino acids, fatty acids, vitamins, minerals, etc., is undeniable (Shelenga et al. 2021).

Traditional breeding approach to biofortification involves crosses between genotypes high in target compounds and varieties with superior adaptability and agronomic performances (Fig. 4). This approach requires to find interesting genotypes by

Fig. 4 Scoring oat plants in traditional breeding program

evaluating the existing variability not only in accessions belonging to primary gene pool, but even in wild relatives. The breeding can then be accelerated combining traditional techniques with marker-assisted selection, next-generation breeding, and improved phenotyping strategies for specialized compound identification and quantification.

In traditional breeding programs, the evaluation of phenotypes is classically done in several environments; selection and recombination are based on the resulting data plus pedigree information, when available. Conventional crossbreeding in oats has been, up to now, based on relatively narrow genetic diversity (He and Bjørnstad 2012; Tinker et al. 2009). However, opportunities to significantly enhance genetic gain in crop breeding by combining phenotypic selection with precise molecular breeding approaches are rising. The other pillar is the exploitation of wider germplasm available in GeneBanks: genetic resources belonging to the different gene pools host interesting traits for crop improvement in various farming systems and under changing environmental scenarios. Table 3 summarizes the main targets for oat improvement.

The main task of traditional breeding has been the yield increase. However, at the beginning of the twenty-first century the yield increase obtained with the new oat varieties was just over a third of the increases recorded in other small grain cereals (Menon et al. 2016). Moreover, even smaller breeding efforts have been invested in naked oats, despite their potential both from economic and nutritional point of view. There is therefore a large genetic gain margin to improve not only the yield, but also the nutritional characteristics to utilize oat as an ingredient in functional food.

The improvement of such polygenic traits can be supported by molecular breeding strategies, such as molecular-assisted selection (MAS) and mutagenesis (TILLING), supported by QTL mapping and genome-wide association studies (GWAS).

The identification of superior genotypes can be speeded up using molecular markers linked to the trait of interest, but to unravel the genetic basis of complex traits it is necessary to associate genotypic information with the corresponding phenotypic data. Association strategies are based on three main pillars: the phenotyping, the genotyping strategy, and the genetic population used (Isidro-Sánchez et al. 2020b).

The first linkage-based QTL map was developed by O'Donoughue et al. (1995), using 71 recombinant inbred lines from a cross between *Avena byzantina* cv. Kanota and *A. sativa* cv. Ogle and restriction fragment length polymorphisms (RFLP) as molecular marker. Several other maps, at increasing density, have been developed since then. Different mapping populations were developed in combination with several classes of molecular markers such as RAPDs, ISSRs, IRAPs, SCARs, DArTs, and SNPs (Gorash et al. 2017).

The first doubled haploid linkage map for cultivated oats was created in 2008 (Tanhuanpää et al. 2008), whereas Oliver et al. (2013) developed and published the first physically anchored hexaploid oat linkage map. Tinker et al. (2014) developed the first SNP genotyping array for hexaploid oat and a linkage map of naked oats was constructed by Song et al. (2015).

Table 3 Main objectives of oat breeding. Some of the target traits have been already considered by traditional breeding, some others – mainly related to quality – are new ones

Objective	Target trait(s)
Competitiveness in cereal farming systems and supply chains	Yield potential and stability Various end user demands: food, feed, other derived products Plant architecture: dwarfing types to avoid lodging
Host plant resistance to pathogens	Crown rust *Fusarium* head blight (and minimizing mycotoxins in grains) Oat mosaic virus Powdery mildew
Adaptation to stressful environments	Cold tolerance Drought tolerance Deep root systems Competing ability against weeds
Grain quality	High kernel content Ease of dehulling Low proportion of screenings High specific weight Minimum grain blackening High protein and high essential amino acids High oil and high essential fatty acids High total and soluble fiber: β-glucan and arabinoxylan High bioactive phytochemicals: phenolics and terpenoids
Input-use efficiency and mitigating climate change	Nitrogen use efficiency Water use efficiency
Healthy food	Increased β-glucan content Increased antioxidants
Livestock feed	High metabolizable energy by increasing oil content Low lignin husk High yield, protein and oil in naked oats (for ruminants) Low trichome density in naked oats (for facilitating harvest and grain handling)

The first linkage maps have been built on bi-parental populations; however, such materials can have some limits in genetic and phenotypic variation. Other kinds of populations, showing wider variation, are under development, including multiparent advanced generation intercross (MAGIC) and nested association mapping (NAM) populations. These kinds of populations can avoid biasing the selection of marker loci toward those that are polymorphic only between specific mapping parents. Moreover, an increased mapping resolution can be reached thanks to the numerous generations of intercrossing of the original parent plants and their ability to capture a wide range of genetic and phenotypic diversity in a breeding population. Such populations form the perfect basis for quantitative trait locus mapping and MAS in multiple genetic backgrounds.

This strategy has been used to map QTL involved in β-glucan concentration (Newell et al. 2011; Asoro et al. 2013), disease resistance (Gnanesh et al. 2015; Montilla-Bascón et al. 2015), spikelet number (Pellizzaro et al. 2016), heading date (Klos et al. 2016), and frost and lodging tolerance and heading date (Tumino et al. 2016).

The marker development in oat evolved from low-throughput to high-throughput markers. An international consortium of oat researchers partnered with Diversity Arrays Technology P/L (Canberra, Australia) to develop a high-throughput DArT marker platform for oat (Tinker et al. 2009). This collaborative effort successfully developed >2700 DArT markers, of which 1295 were unique and polymorphic in a diverse set of global oat germplasm. This work has more than doubled the number of available oats markers and provided the first high-throughput marker platform in oat; it can be applied in parallel and is based on a rapid and cost-effective commercial service.

A further evolution was reached with single-nucleotide polymorphisms (SNPs) markers, as they are suitable for automation, easy to exchange among laboratories, and to score. Next-generation sequencing (NGS) approach has been addressed in a collaboration of North American and European oat researchers, resulting in the first SNP oat genotyping platform – an Illumina® 6K oat chip containing highly informative SNP markers (Tinker et al. 2014) – which is now available to oat breeders and is the first physically anchored integrated map of the complex oat genome (Oliver et al. 2013) for further use in genetic analyses. This work has reversed the declining trends in oat research by infusing the research community with the genetic resources necessary to develop new and innovative cultivars.

The SNP array has been used to evaluate the genetic diversity and population structures of American and European germplasm, whose genetic base is different (Tinker et al. 2009), and also for linkage and association mapping, thereby advancing genetic analysis and breeding. A problem in identifying informative SNPs in allohexaploid oat can be the occurrence of homeologs from the A, C, and D genomes. A number of bioinformatics tools have been developed to successfully detect and remove sequences with redundant and ambiguous polymorphism allowing efficient discovery and application of SNP markers in oats (Barker and Edwards 2009; Oliver et al. 2011). Moreover, Tumino et al. (2016) proposed to utilize SNP hybridization intensity ratios as continuous variables to better represent the allele frequencies at accession level (bulk). Using intensity ratios, SNP signals were not interpreted as discrete genotype classes but as continuous. The bulk allele frequencies can be statistically associated with phenotypes measured in bulks in GWAS. The same approach has been adopted by Montilla-Bascòn et al. (2015) in a GWAS for crown rust and powdery mildew. The main reasons supporting this strategy are the reduction of genotyping costs and the lowered risk of useful information loss given that SNP probes in allopolyploid species may or may not be subgenome-specific and therefore the genotype calling can be a challenging, time-consuming, and error-prone task.

GWAS exploits natural large genetic resources collections for the identification of genomic regions that are in linkage disequilibrium (LD) with the QTL influencing

traits of interest. This method takes advantage of ancestral recombination events and can provide higher resolution compared to traditional QTL mapping using biparental populations. Association genetics uses, therefore, large experimental populations with densely mapped genotype data and phenotypic data from multilocational field trials. An example of such populations is the Collaborative Oat Research Enterprise (CORE) panel, which consists of 635 single-panicle-derived lines representative of elite germplasm deemed important by 16 active oat breeding programs in Australia, Canada, the United Kingdom, and the United States. A further example is the AVEQ panel, developed to evaluate oat genetic resources for proteins, oils, minerals, β-glucans, antioxidants, and phenolic compounds, as well as for resistance to *Fusarium* infections and cold tolerance, assembling 600 accessions and cultivars from 25 gene banks and 31 breeding programs from 14 European countries.

The analysis is based on the nonindependence of alleles in a population called linkage disequilibrium (LD), defined as the nonrandom association of alleles at two loci. Association between marker alleles and causal alleles arises not from experimental crossing but from historical drift and mutation events. In such studies, associations between genotype and phenotype depend on historical LD broken down by many generations of recombination. For this reason, in GWAS a larger number of markers are required to assure LD between markers and causative alleles throughout the genome, thus enabling finescale mapping. This allows us to map causal loci more accurately than with traditional linkage analysis.

The genetic distance over which LD is maintained in a population determines the resolution of mapping that is possible, and the marker density required for association analyses. A key point is the population structure deriving from admixture, mating system, genetic drift, artificial or natural selection during evolution, domestication, and breeding. Population structure can be responsible for false associations between polymorphic markers and phenotypic trait variations. Several statistical approaches are therefore available to describe population structures and genetic relatedness of the lines in the association panel. A lot of studies showed that population structure in oats is weak (Montilla-Bascón et al. 2015; Newell et al. 2012; Tumino et al. 2017; Winkler et al. 2016) in comparison with other cereals (Hamblin et al. 2010) probably due to admixtures and spring and winter types interbred species (Newell et al. 2012). Consequently, numerous GWAS for oats have been successfully concluded (Asoro et al. 2013; Klos et al., 2016; Foresman et al. 2016; Montilla-Bascón et al. 2015; Newell et al. 2012; Tumino et al. 2016, 2017; Winkler et al. 2016).

NGS combined with the reduction in genome complexity enables genotyping-by-sequencing (GBS) approaches (Bekele et al. 2020). This combines marker discovery and genotyping to produce high-density markers at a relatively low sample cost (Poland and Rife 2012). The development of such tools would enable genomic selection (GS) to be used in oats (Mellers et al. 2020). This has recently been proposed to overcome the limitations of current MAS approaches for complex traits governed by many genes. Instead of analyzing markers individually for their association with a phenotype, GS analyzes all the markers jointly to explain the total genetic variance by summation of all marker effects. These are then used to predict

the breeding value of individuals. The development of high-density SNP maps and of high-throughput genotyping platforms makes GS a practical proposition for oat breeding (Asoro et al. 2011), as already established in other cereals (Poland and Rife 2012).

A very high number of different molecular maps both for hexaploidy and diploid oats have been developed (Blake et al. 2019), and several of these can be found in GrainGenes database (https://wheat.pw.usda.gov/GG3/). The same database hosts reference genomes of hexaploidy oat and of *A. insularis*, *A. longiglumis*, *A. atlantica,* and *A. eriantha*.

Chip-based SNP assays and GBS approaches are ideal genotyping platforms for GWAS and GS, but breeders often require screening large numbers of plants with small numbers of mapped markers associated with key traits of interest. KASPar SNP genotyping answer to this need as it is a flexible and cost-effective system able to discriminate SNPs even in hexaploidy species. KASPar assays can also identify heterozygous individuals, and this can be important in breeding and backcrossing programs, where marker-assisted selection often requires the resolution of heterozygous from homozygous classes.

To map populations and germplasm collections, TILLING (targeting-induced local lesions in genomes) populations, obtained with an advanced mutation breeding method, can be employed. This nongenetically modified technology combines the traditional mutagenesis with high-resolution mutation screening and allows to expand the genetic variability and detect point mutations in individual plants (Parry et al. 2009). In oats, TILLING was applied by Chawade et al. (2010) to obtain mutant seed lines that have been used to study key genes in the lignin and β-glucan biosynthetic pathways. Vivekanand et al. (2014) studied the lignin-level variability inside this same population and in Belinda variety, from which population was obtained, with the aim to identify more digestible mutants.

Finally, González-Barrios et al. (2021) demonstrated how speed breeding and early panicle harvest can accelerate oat breeding cycles. By modulating growth temperatures and photoperiod, a significant acceleration in flowering time has been obtained and acceptable germination levels are present 21 days after flowering. Breeding programs where single-seed descent are used can be therefore greatly accelerated.

6.1 Genetics of FHB Resistance

Mycotoxins are secondary metabolites produced by different types of fungi such as *Aspergillus, Penicillium, Alternaria,* and *Fusarium*. These toxins can enter the food chain through contaminated crops used in food and feed production. The mycotoxigenic molds can invade both agricultural crops in the field and agricultural raw materials during storage and processing (Mielniczuk and Skwaryło-Bednarz 2020). Oat contamination by mycotoxin is of great concern for human and animal health (Perrone et al. 2020). Several mycotoxins can be detected in oats, but the ones considered most important are deoxynivalenol (DON, vomitoxin), zearalenone

(ZON or ZEN), HT-2 toxin (HT2), and T-2 toxin (T2). DON and ZON are produced by several *Fusarium* species, the dominant being *F. graminearum*. HT2 and T2 are produced by several other *Fusarium* species, the dominant being *F. langsethiae* (Edwards et al. 2012). The *Fusarium* species invade the plant at flowering stage causing Fusarium Head Blight (FHB). Legislative limits for the mycotoxins DON and ZON for unprocessed cereals, intermediate products (e.g., flour), and finished products for human consumption have been fixed in several countries.

Screening for sources of resistance to FHB is of key importance for the development of new oat cultivars. However, resistance to FHB is a quantitative trait (He et al. 2013; Bjørnstad et al. 2017), controlled by genes that are still largely unknown. Resistance can be divided into several different components, as reviewed by Hautsalo et al. (2018), resistance against initial infection and spreading of infection (respectively known as type I and II), mycotoxin (type III), kernel infection (type IV), and tolerance (type V). In addition, disease escape mechanisms exist, and are based on morphological features, such as plant height, degree of anther extrusion (Tekle et al. 2020), or physiological characteristics (flowering time). Moreover, mycotoxin accumulation is strictly linked to the fungal species, and infection success is strictly linked to agronomic practices and weather conditions (Hautsalo et al. 2020).

Oat genetic resources have been screened to identify the potential source of resistance (Bjørnstad et al. 2017; Loskutov et al. 2017; Hautsalo et al. 2020; Gavrilova et al. 2021). Screening procedure itself has been demonstrated to be a nontrivial point to obtain reliable indication about resistance (Tekle et al. 2018). A ranking of oat cultivars with respect to the content of DON can be informative when repeated several years in a specific environment, as reported by Tekle et al. (2018) and Yan et al. (2010).

Haikka et al. (2020) evaluated North European germplasms and breeding lines for DON and agronomic traits and compared two strategies, GWAS and genomic prediction, for their potentialities of application. Genomic prediction was identified as a promising method applicable in oat breeding programs for FHB resistance.

Of particular concern in oat is the asymptomatic infection caused by *Fusarium langsethiae*, a pathogen able to produce the highly toxic T-2 and HT-2 mycotoxins. Isidro-Sánchez et al. (2020a) inoculated 190 spring oat varieties with a mixture of three isolates of the pathogen. Varieties were genotyped using 16,863 genotyping by sequencing markers. GWA identified a single QTL in the linkage group *Mr06* associated with T-2 + HT-2 mycotoxin accumulation. In the QTL, the locus *avgbs_6K_95238.1*encodes lipase precursor that is associated with resistance to fungi. Lipid-derived secondary metabolites produced by the plants are known to play a crucial role in host–pathogen communication. The authors concluded that *Mr06* linkage group plays an important role in *F. langsethiae* resistance.

Willforss et al. (2020) carried out the first proteogenomic study to understand the molecular response of oat when exposed to FHB. The proteomes of resistant and susceptible cultivars were compared, and candidate proteins of interest were identified and linked to protein sequence variants.

6.2 Breeding for Grain Size, Milling, and Naked Grains

Some traits are relevant for processing efficacy and determine quality perception in oat raw materials. A lot of characteristics, such as groat to hull ratio, ease of dehulling, uniformity of groat size, uniformity of mature kernels from top to bottom of the panicle, overall groat size in the medium to large range, few trichomes, husk content, test weight, grain size and weight, and milling yield, are not strictly definable nutritionally important characteristics but from an agronomic and industrial point of view are crucial. Grain yield and kernel size, shape, and morphology have been targets of traditional breeding programs (Fig. 5). Such traits can be positively or negatively linked with health-related characteristics. Negative correlations have been shown among water binding capacity, ß-glucans, intensity of odor, toasted odor, and flavor (Lapveteläinen et al. 2001). High oil concentration was associated with low groat weight and with long and slim seeds (Peterson and Wood 1997). In *A. sterilis,* negative correlations have been found between protein vs. groat size and oil (Rezai and Frey 1988). Selection for high yield and seed weight during oat breeding may have caused a loss of valuable characters health-wise and taste-wise (Lapveteläinen et al. 2001); all the traits can be made available from less developed materials.

Fig. 5 Oat seed biodiversity

Recently, 57 QTLs, influencing one or more of 6 key milling traits, were identified by Klos et al. (2021) in a genome-wide association study involving 501 accessions from the Collaborative Oat Research Enterprise (CORE) panel. The Qkernel QTL was identified as the prominent one, influencing several milling traits. The comparison of QTLs associated with kernel morphology, grain yield, test weight, and chemical groat composition, with those affecting quality-related traits can be important for MAS (Groh et al. 2001). In breeding programs where selection is based on markers linked to specific QTLs, the potential negative associations among characteristics can be a serious limit, suggesting that it is important to have a deeper knowledge of the epistatic impact of specific QTLs.

Naked oats are very interesting materials in the frame of human nutrition; however, few naked cultivars have been developed in comparison to covered types. For example, the naked oats varieties registered in European catalog are one-tenth compared to covered oats. The modern naked varieties are not fully naked but have a percentage of covered kernels, depending on the environment and on the genotype.

The genetics of hulless character is in fact complex. N-1 locus has been identified as the major gene controlling naked trait in oats (Ubert et al. 2017); however, it is incompletely dominant, and the phenotype is the result of the interaction among N-1 gene with modifying genes *N-2, N-3,* and *N-4.* Different level of nakedness is observed depending on the alleles present at each of the four loci. Even the environment can influence this character. The naked character is in fact under genetic control but can be influenced by temperature and humidity.

The yield of naked oats has been traditionally considered lower in comparison to covered varieties. Several explanations have been proposed, for example, the flower morphology (Valentine 1995; Burrows et al. 2001). A high number of varieties was taken into account in the study of Buerstmayr et al. (2007), demonstrating that the yield of covered lines was significantly higher than that of naked lines. Other studies deny the association between naked seeds and lower productivity. Peltonen-Sainio (1997) studied three naked and two covered lines at varying nitrogen fertilization and seeding rates in Finland and found that, under northern growing conditions, groat yield of naked oats was already similar to that of covered oats. Burrows et al. (2001) compared near-isogenic naked and covered lines and showed there was no significant difference in groat yield between the covered and naked isolines. Doehlert et al. (2001) found that the naked oat cultivar Paul produced more than covered oat cultivars over 12 environments during 3 years in the United States. Similar results were obtained by Moudrý et al. (2004), whereas Maunsell et al. (2004) found no significant difference between covered and naked lines for groat production during 2001–2002 in the United Kingdom.

To summarize, naked oats have some disadvantages, such as the lower grain yield and the reduced level of germination, that have limited the use of these cultivars, but have unique end-use advantages, suggesting that specific breeding programs are a crucial step to identify the suitable naked oat genotypes to produce foods of high nutritional value (Redaelli et al. 2015).

6.3 Breeding for β-Glucans

The AVEQ project (Avena Genetic Resources for Quality in Human Nutrition) confirmed the existence of variability for beta-glucan content in a panel of European oats varieties and wild relatives (Redaelli et al. 2013). Although there is genetic variability for β-glucan content and the interest from a nutritional point for this trait, the development of varieties with improved content of β-glucans has been, until now, very slow. Three main reasons slowed down the breeding for this trait: (i) the limits in phenotyping for β-glucan content; (ii) the poorly understood genetics of this complex trait; and (iii) the influence of environment.

From a genetic point of view, the *β*-glucan content is controlled by many loci with additive effects and is also influenced by the environment. The broad sense heritability of this trait has been found ranging from 0.27 to 0.58 (Holthaus et al. 1996; Humphreys and Mather 1996; Kibite and Edney, 1998). *β*-Glucan content is therefore influenced by the environment, but the genotype has a major impact on the expression of this trait (Dvončová et al., 2010). Moreover, genotype–environment interactions have been evaluated, obtaining contrasting indications.

The selection for beta-glucan content is expensive: the most common method for their determination is enzymatic, based on the specific enzymatic degradation of the carbohydrate followed by quantification of the products. In addition, other chemical and physical approaches have been developed, together with fast method of screening, mainly based on NIR.

Because of the complex genetics and the expensive phenotyping, this trait is an ideal candidate for its molecular quantitative trait dissection and selection assisted by molecular markers in breeding programs.

Kianian et al. (2000) suggested that, because of the complexity of the character, a mapping population with a large number of individuals is needed to detect small phenotypic effects. In their work, two recombinant inbred populations with the common parent Kanota were evaluated for beta-glucan content in multiple US environments and two genomic regions hosting the markers Xcdo665B and Xcdo400 were identified able to explain more than 20% of the phenotypic variance of the character in both populations.

Several other studies were focused on the molecular mapping for β-glucan content in oats.

De Koeyer et al. (2004), in a mapping population derived from a hulless spring oat found in North America, detected five QTLs influencing β-glucan content and explaining 23% of the phenotypic variance. Marker cdo484a was identified as associated with the most consistent region.

In the double haploid oat mapping population “Aslak” × “Matilda” (AM), four relevant QTLs were found as responsible for more than one-third of the phenotypic variation for β-glucan content (Tanhuanpää et al. 2012). Two of these QTLs were environment-specific, and two of them are coincident with those identified by Kianian et al. (2000).

Herrmann et al. (2014) identified three loci influencing β-glucan content in two mapping populations grown at three sites in Germany over a 3-year period. The QTL

with the largest effect was QBg1.jki.A-1. This QTL is flanked by the markers E36M55_1 and E36M52_3, explains 31% of the phenotypic variance, and is located on a linkage group putatively homologous to KO_6 of the KO map.

GWA mapping studies have also been published.

Newell et al. (2012), using an oat panel composed of 431 genotypes, identified three markers associated with β-glucan content. One of the markers had high sequence homology to rice chromosome 7 in a region adjacent to CslF gene family members.

Studying 446 oat lines genotyped with 1005 diversity array technology (DArT) markers, Asoro et al. (2013) identified 37 markers explaining β-glucan content. These authors compared efficiency of genomic, marker-assisted, and best linear unbiased prediction (BLUP) for selection for *β*-glucans concentration and concluded that, despite genomic method being more efficient in improving *β*-glucan concentration, it also leads to faster loss of genetic diversity.

Zimmer et al. (2020) evaluated in multiyear trial the beta-glucan content of 413 accessions belonging to the UFRGS Oat Panel, characterized by a weak population structure. The beta-glucan content was associated to seven QTLs located in genomic regions synthenic with barley.

In summary, despite several studies, the genetics underlying the beta-glucan synthesis and regulation in oats is still largely unknown. Important candidate genes for enzymes involved in the beta-glucan synthesis belong to the CLS (cellulose synthase like) gene family. Fogarty et al. (2020), in a genome-wide association study (GWAS) on three panels of elite accessions (spring, winter, world diversity) of oat grown in multiple North American locations, identified 58 significantly associated markers. The homology among the QTLs identified suggested that multiple copies of β-glucan biosynthesis genes are present in the three sub-genomes of oats and contribute to the overall phenotype. In particular, the high expression level of AsCslF6_A and AsCslF6_D genes, located respectively on A and C sub-genomes, is shared by high beta-glucan varieties.

6.4 Breeding for Oil

Oats are richer in oil (~6–10%) than any other cereal, and recurrent selection breeding resulted in lines with up to 18% oil. The oils are mainly concentrated in bran and endosperm and not in the germ, such as other cereals, for example, maize. The localization of the majority of oat grain oil to the endosperm suggests that there is a great potential to increase the oil content of this crop since this storage tissue is the major part of a cereal grain. Oat grains are rich in linoleic acid (Leonova et al. 2008; Leonova, 2013), polar lipids, and peculiar galactolipids with esterified hydroxyl fatty acids (Moreau et al. 2008).

Cultivars with high- or low-oil content have different uses in human and animal nutrition and are both necessary, depending on the destination and on the different technological treatments. For example, low-oil cultivars are generally preferred for rolled oats to simplify the milling procedure and in general are for low-fat foods. On

the contrary, high-oil oats are preferred for feed because more energetic, as well as to produce "oat milk" for human consumption due to the higher nutrition value. Breeding efforts, therefore, must be directed both to the selection of high- and low-oil content oats and even to oats enriched in beneficial PUFA.

Oil content has a high heritability due to additive gene action (Bjørnstad et al. 1994). Negative correlation has been identified between fat and starch contents. Contrasting results have been obtained studying the correlation among fat level, β-glucan, and protein content. It was, in fact, found that the protein concentration increases with nitrogen fertilization and the oil decreases, but there are even cultivars with high protein and oil levels.

An interesting point is the beneficial PUFA 18:2 (linoleic acid) and 18:3 (linolenic acid) content of oats. Leonova et al. (2013) reported that the cultivated oats are richer in such molecules in comparison with wild relatives, even if these last have the highest total oil content. This observation has been confirmed by Dhanda (2011) in an extensive study on 917 oat accessions. The cultivated hexaploidy oats confirmed the elevated levels of linoleic and linolenic acids in different cultivation environments. The environmental impact on the total oil content has been observed, but its influence is still controversial on the oil composition, as reviewed by Stewart and McDougall (2014).

Carlson et al. (2019) used multivariate GWAS methods for identifying genetic associations with metabolites that share lipid biosynthetic pathway. The authors analyzed ten fatty acids simultaneously with multi-trait GWAS methods and found a panel of SNPs that were not detected by traditional, univariate GWAS. They suggested how such multivariate GWAS may increase analysis sensitivity and be advantageous for oat, where the effect of a single locus may be buffered by the activity of its homeologs.

Campbell et al. (2021) developed a trait-specific genomic relationship matrices (TGRMs) model as a prediction tool for the oil content in oats. This model is based on the relationships between individuals using genome-wide markers (SNPs) and place greater emphasis on markers relevant to the trait. In the first step of their work, nine fatty acids were quantified in a panel of 336 genotyped oat lines and the markers effects were used to construct TGRMs. In the second step of the study, the model was validated to predict total seed lipid content in an independent panel of 210 oat lines. The results obtained sustain the utility of using TGRM and improve genomic prediction for a conventional agronomic trait.

The oat oil content is linked with lipase level. Oat lipases are a postharvest problem, which negatively impact on the seed storage, because of the transformation of oils into free fatty acids and the rancid flavor development. In the frame of CropTaylor project, 900 EMS mutation lines were screened for lipase content with the final aim to select low-lipase oat lines (Marmon 2022). Alternatively, or additionally, oat-based antioxidative extracts have been evaluated to prolong oat oil stability. AVA-rich extracts were found to inhibit lipase action and protect toward oxidation. Such natural extracts have therefore the potentialities to be used in oat-based food preservation (Tullberg 2022).

6.5 Breeding for Avenanthramides

Avenanthramides (AVNs) have not been yet a direct target in oat breeding; however, varietal differences in a range from 40 to 132 mg/kg have been found (Dimberg et al., 1993). Moreover, their abundance has been found modulated by the environment (Redaelli et al. 2016). AVN concentration is a heritable trait, as demonstrated by Michels et al. (2020). These authors quantified AVNs in 100 at accessions in a multilocation and multiyear trial, finding that, despite environmental influence, genotype has the largest impact on all three AVN major types of production.

In the review by Shelenga et al. (2021) are reported several screening works in which AVN concentration was measured in several accessions of different origin and species grown in European, Asiatic, and American environments. The highest range of variation for AVN was reported in the study of Leonova et al. (2020), who analyzed the AVN content and composition in 32 wild and 120 cultivated oat accessions, finding a great variability for this trait, with AVN ranging from 4 to 1825 mg kg^{1}.

Brzozowski et al. (2022), in an oat germplasm screening, found, in modern varieties, a reduced genetic variation for these molecules in comparison with obsolete cultivars and landraces. Modern varieties show that the abundance of these molecules increases with the seed size.

Moreover, GWAS and TWAS analyses indicate that the enzymes preceding committed biosynthetic steps seem to have a key role in avenanthramide content. Hernandez-Hernandez et al. (2021) proposed mutagenesis coupled with high-precision biochemical selection as useful method to develop stable lines with a high concentration of total and/or individual AVNs in the oat seed grain.

6.6 Breeding for Protein

Oats are interesting from the point of view of protein content: it is in fact a low-cost protein source and has a higher level of protein in comparison with other grains, including cereals, legumes, and oil seeds. Higher protein is a desirable characteristic of oats used for both food and feed purposes. Moreover, a diet rich in plant protein is gaining attention as it is perceived as healthier for the consumer and more sustainable for the planet in comparison with animal proteins (Kumar et al. 2021).

Proteins in oats are mainly localized in the germ and the bran and less in the endosperm (Boukid 2021). They differ in structural and distributional properties from other cereals that are rich in prolamins and poor in lysine. Globulins are the primary storage protein in oats; they also contain higher concentration of lysine and other essential amino acids, thus making them a superior protein source (Valentine and Cowan 2004).

To improve protein concentration, emphasis has been given to breeding and selections. Sunilkumar et al. (2017) identified, in a mutagenized population, 15 oat

lines with a protein content ranging from 17% to 24%. Such lines, increased in globulin-like proteins, are stable for this character and can be the starting point for the development of a high-quality, high-protein oat variety, both for food and feed. Batalova et al. (2019) worked on naked oats to obtain the high-protein Vitovet cultivar.

7 Are Oats Genetically Modified Crop?

Oats are not genetically engineered crop. No genetically modified oat variety is present on the market. Several reasons are behind this: the complex oat genome is one, but the most important is the almost nonexistent demand to justify the expensive research that goes into developing genetically modified seeds.

Genetically modified oat plants have been obtained with the unique aim to identify suitable protocols for transformation or to study specific gene functions. Oats can be transformed, and to this aim some protocols have been developed for a long time. In the pioneering work of Somers et al. (1992), friable, embryogenic oat callus cultures were obtained following microprojectile bombardment with a plasmid encoding the *Streptomyces hygroscopicus bar* gene and the *Escherichia coli uidA* gene. Pawlowski and Somers (1998) proposed a mechanism of transgenes integration in oat genome at multiple clustered DNA replication forks to explain the observation that all transgenic lines analyzed exhibited genomic interspersion of multiple clustered transgenes. Zhang et al. (1999) transformed shoot meristematic cultures derived from seedlings of commercial varieties.

8 The Oat Genomes

A. sativa is allohexaploid ($2n = 6x = 42$) with a large and complex genome (> 12 Gb), composed of the three AACCDD subgenomes, highly repetitive and characterized by duplications and intra- and intergenomic rearrangements. All these features made full genome assembly a difficult task to reach. An oat reference genome has been therefore missing for decades.

Common oat is thought to have been domesticated from wild-weedy *A. sterilis* L. (Zhou et al. 1999), an allotetraploid carrying CCDD subgenomes and an A_sA_s diploid (Yan et al. 2016). Several diploids carrying A genome variants (A_c, A_d, A_l, A_p, and A_s) (Loskutov and Rines, 2011) are known to be potential source of genes relevant for qualitative trait, for example, improving soluble fiber and protein (Welch et al. 2000).

The C-subgenome carries a putative *CSlF6c* locus that likely has a negative effect on seed soluble fiber content (Coon 2012; Jellen et al. 1994).

Maughan et al. 2019 produced the first, reference-quality, whole-genome reference assemblies for A_s- and C_p-genomes, using *A. atlantica* and *A. eriantha* as plant materials and a hybrid approach for sequencing, involving PacBio long reads, Illumina short reads, and both in vitro and in vivo chromatin-contact mapping.

All these genomic data, together with genetic, germplasm, and phenotypic datasets for oats, are available in GrainGenes (https://wheat.pw.usda.gov or https://graingenes.org), the international centralized repository for curated, peer-reviewed datasets of small grain cereals, including oat. Since 1992, GrainGenes has been a useful source of data and information for oat geneticists and breeders in both public and private sectors worldwide (Blake et al. 2019).

Very recently, the challenge of obtaining a reference genome for *Avena sativa* was also met. PepsiCo announced in 2021 to have completed, in the frame of a public–private collaborative work, the 21 chromosome DNA assembly of the North American oat variety OT3098 using the long-read PacBio technology. The assembly has been made publicly available via the GrainGenes website: the data are hosted on the USDA Agricultural Research Service's GrainGenes website at https://wheat.pw.usda.gov/jb/?data=/ggds/oat-ot3098-pepsico and the datasets can be downloaded at https://wheat.pw.usda.gov/GG3/graingenes_downloads/oat-ot3098-pepsico.

In 2022, Kamal et al. (2022) presented the high-quality reference genome of *A. sativa* and of its diploid progenitor *A. longiglumis* and *A. insularis*. The mosaic structure of the oat genome was revealed, characterized by large-scale genomic reorganization during the polyploidization process. The availability of the high-quality reference genome was exploited to clarify some genetic features of health-related traits. For example, the high content and quality of β-glucans are driven in oat by allelic variation and are modulated by transcription factors.

Such studies are the starting point for the future challenge of obtaining oat's pangenome (Mascher 2022). The international PanOat consortium is working on this, with the aim to produce a pan genome deriving from the sequence assemblies of 20 carefully selected oats.

9 Conclusions and Future Prospects

The value of oats in human health is indisputable and therefore is more than rational to focus on this crop through various improvement and enhancement actions. This means new opportunities for using oats through advanced fractionation and the development of innovative nutritious food products. Moreover, oat is a low-input cereal, and its adoption also increases environmental and economic sustainability of cereal-based rotations.

From a policy perspective, the sustainable production of resilient cereal-based crop systems must be combined with systems capable of adapting (to) and mitigating climate change as well as protecting our soils and water courses and maintaining or enhancing biodiversity.

To expand oat cultivation and increase its use, future oat production will need to meet the challenges posed by climate change and the demands of various end users by identifying cultivars with higher and more stable yield, enhanced grain quality, and reduced environmental impacts. This will be complemented by the identification and development of new markets for improved and innovative food, products from oats. Powerful enabling technologies for the identification of specific genes and markers

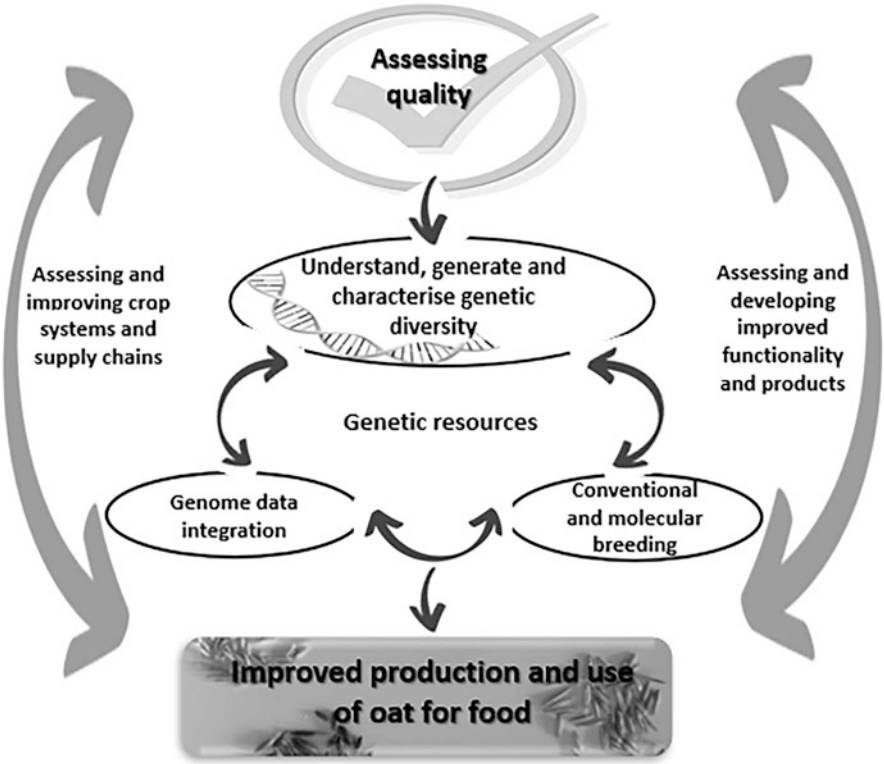

Fig. 6 Interactions aimed at oats valorization for food chains

and accessing genetic diversity will drive the development of breeder-friendly tools accelerating the production of more prolific and resilient oat cultivars. This approach, depicted in Fig. 6, will rely on the use of oat genetic resources, thus enhancing their conservation through plant breeding and deployment of newly bred cultivars with desired traits. An integrated approach is required to bring together academic researchers and applied R&D teams to maximize the translation of research outputs into impact through commercial practice. An example of such interaction is the Scan Oat consortium, whose activities are based on six pillars, ranging from genetics and agronomy to technology and industrial applications, and aimed to "develop food industry using oat as fundamental ingredients" (L. Bülow, https://scanoats.se).

climatic conditions. The nutritional profile of sorghum is comparable with that of other cereals, but is unique in that it has various bioactive compounds such as phenolic acids, procyanidins, flavonoids, and anthocyanins. The protein (kafirin) of sorghum is, however, poorly digestible, and genetic improvement of protein digestibility has remained a challenge. Large genetic variability has been shown for almost all the bioactive compounds in tested sorghum accessions, but there is a large gap in the knowledge of the genetics underlying their expression. There are a number of sorghum germplasm collections, reference genome sequences, association panels, and mutant populations available in the world, which could be used to screen for genetic variation and determine genetic architecture, in order to improve sorghum nutraceutical content. Genetic engineering techniques have been applied to improve kafirin digestibility and carotenoid content, and have significant potential for improving nutraceutical content in the future. Information on the genes linked to nutraceuticals and the gene action involved in their expression will allow improvement of nutraceutical content through conventional breeding and by use of molecular markers, genomics, and genetic engineering. All available information on grain nutraceuticals and other nutritional components in sorghum should be integrated as a resource to be used by the sorghum community for sorghum improvement and genetic studies of nutraceuticals.

Sorghum · Phenolic compounds · Kafirin · Genetic resources · Genomics · Genetic engineering

1 Introduction

Sorghum [*Sorghum bicolor* (L.) Moench] is a stress-tolerant C4 plant, which belongs to the *Poaceae* family, which is well adapted to arid growing conditions. It is a versatile ancient cereal grown mainly by subsistence farmers. This annual crop is mostly photoperiod insensitive and completes its life cycle in 4 months. It is seen as a potential food security crop highly suited to climate change conditions. Maize, rice, and wheat are the most important cereals in the world, with sorghum ranking fifth in terms of importance. It is a staple food to more than 500 million people in Africa and Asia (Xin et al. 2021). The annual sorghum production is over 57 million tons (FAOSTAT 2019). In developed countries, it is mainly used for animal feed, biofuel production, and bioproducts, but it is a staple food in many developing countries (Xin et al. 2021).

Nutraceuticals are, by definition, bioactive compounds, which are biologically active, and are found in food. Various phytochemical substances are regarded as bioactive compounds, including the polyphenols. Dietary fiber, polyunsaturated fatty acids, micro- and macronutrients, vitamins, oligosaccharides, lactic acid bacteria, choline, and lecithin are all bioactive compounds (Chaudhari et al. 2017). Biopeptides, which are biologically active peptides, are also nutraceuticals.

Nutraceuticals have possible antioxidant properties and various other effects on the human body. Protein is a natural source of biopeptides, including antioxidant biopeptides (Hu et al. 2021). Certain amino acids, peptides, and proteins are also possible bioactive compounds (Szerszunowicz and Kłobukowski 2020). Reactive oxygen species (ROS) is important in metabolism and aging of humans, and some nutraceuticals contribute to decreasing the levels of ROS formed in the body through antioxidant activity (Li et al. 2021a). Human consumption of foods containing nutraceuticals have many therapeutic advantages. These compounds contribute to longevity, delaying aging, and preventing the development chronic diseases such as diabetes and hypertension, among others (Szerszunowicz and Kłobukowski 2020). Nutraceuticals can contribute to the prevention and management of viral infections (Li et al. 2021a). Different kinds of biological properties and activities have been ascribed to bioactive compounds, including antioxidant, anti-inflammatory, and antimicrobial properties, which can contribute to protection against human disease (Omrani et al. 2020).

Sorghum grains consist of carbohydrates, kafirin (protein), fiber, polyunsaturated fatty acids, and resistant starch (Khalid et al. 2022). Sorghum has a nutritional profile comparable with other cereals, but is unique to other cereals in that it contains different bioactive compounds such as anthocyanins, flavonoids, phenolic acids, and procyanidins (Ofosu et al. 2021). The extensive biological activities of sorghum grains have been shown in a number of in vitro and in vivo studies. Sorghum bioactive compounds have been shown to inhibit oxidative stress, cardiovascular disease, high lipid levels, and hypertension. It has anticancer and antidiabetic properties and could lower cholesterol index and obesity through antioxidant and anti-inflammatory mechanisms (Li et al. 2021a). The phenolic compounds having bioactive properties include phenolic acid, flavonoids, stilbenes, and tannins. Sorghum grain also contains B-complex vitamins, fat-soluble vitamins A, D, E, and K, as well as minerals, including magnesium, potassium, phosphorus, and zinc. Some sorghum polyphenols, including tannin (proanthocyanidin) and 3-deoxyanthocyanidin, have the potential to protect individuals against inflammation, diabetes, and oxidative stress. Flavonoids are also known as antioxidants, which could positively influence inflammatory and neurodegenerative diseases, as well as cancer and diabetes. Sorghum grain also have a high fiber content, which can reduce blood cholesterol and glucose levels (Khalid et al. 2022). As sorghum is a good source of B vitamins, minerals, carbohydrates, and is also gluten free, it has significant potential as a source of food and beverages and gluten-containing replacement diets for people with celiac disease (Bouargalne et al. 2022).

Although sorghum is known for various phytochemicals, which contribute to human health, it is often not valued for these attributes due to the poor digestibility of its proteins (Duressa et al. 2018). Extensive research has been done by various research groups on sorghum protein digestibility. There have been sustained (although limited) global research efforts focusing on unraveling the biochemical and genetic basis of low protein digestibility and the improvement of kafirin bioavailability. The sequencing of the sorghum genome has supported these efforts, leading to a better scientific understanding of kafirin chemical properties, the

genetics underlying kafirins, and its protein body structure. Despite this, there have been several challenges in the genetic improvement of protein digestibility, as increased protein digestibility is linked to agronomically undesirable traits such as the opaque (soft) endosperm phenotype. It is technically possible to develop high-protein digestible sorghum with hard endosperm, as was the case with quality protein maize, especially with the help of marker-assisted breeding (Duressa et al. 2018). Li et al. (2021a) stated that kafirins are some of the best nutraceutical sources.

Significant genetic variability has been reported for almost all the bioactive compounds in numerous sorghum accessions, indicating the possibility for genetic improvement through selection. Despite this, very limited research has been done on the genetic basis of bioactive compounds in sorghum and its possible improvement through conventional breeding, the use of DNA markers, genomics, or genetic engineering. To improve sorghum, it is critical to use the available genetic variation. These genetic resources should be screened for valuable genes underlying the synthesis of nutraceutical compounds (Bouargalne et al. 2022).

In the world, there are a number of sorghum germplasm collections, reference genome sequences of good quality, and association panels, which can be used for genome-wide association studies for food and quality related traits. There are also mutant populations, which are useful to discover genes, which can be applied for sorghum improvement, as well as information on gene expression. Genetic engineering is becoming increasingly important in sorghum nutritional content research, and the technology has developed significantly in recent years.

The aim of this chapter was to determine the current status of sorghum as a source of nutraceuticals, to assess current genetic resources in sorghum for possible genetic manipulation and improvement of nutraceutical content, and the use of new technologies such as genomics and genetic engineering to improve sorghum as a source of nutraceuticals in the human diet.

2 Sorghum Grain Chemical Composition

Sorghum grain composition is similar to that of maize and millet. It consists of starch, lipids, protein, as well as non-starch polysaccharides. It also contains B vitamins and vitamins D, E, and K (fat-soluble), as well as minerals (Przybylska et al. 2019). Sorghum seed was reported to consist of protein (4.4–21.1%), fat (2.1–7.6%), crude fiber (1.0–3.4%), total carbohydrate (57.0–80.6%), starch (55.6–75.2%), and total minerals as ash (1.3–3.5%) (Cabrera et al. 2020). In contrast to other cereals, sorghum is also a rich source of phenolic compounds.

2.1 Phenolic Compounds

Sorghum has the highest amount of phenolic compounds of all cereals. A variety of phenolic compounds are present in sorghum grains, including phenolic acids, flavonols, 3-deoxyanthocyanidins, flavanones, flavones, and condensed tannins

(Shen et al. 2018). The outer layer of the grain (bran) has a high concentration of most of these compounds, which is unfortunately often removed during milling by decortication, which leads to significant reduction of sorghum health benefits. Therefore, the consumption of whole grain sorghum has many key health benefits, such as free radical scavenging activity (Kumari et al. 2021).

Two main categories of phenolic compounds have been identified, namely soluble and insoluble. The soluble compounds like flavonoids, quinones, and phenylpropanoids are found in the vacuole of plant cells, while the insoluble compounds like lignins, condensed tannins, and hydroxycinnamic acid are attached to the cell wall (Gharaati 2019). The phenolic compounds are important secondary metabolites and are major contributors to the antioxidant properties of sorghum, having significant physiological benefits for humans. For this reason, the consumption of sorghum-based foods with high levels of polyphenolic substances can contribute to the prevention and reduction of the risk of chronic diseases, including some cancers and diabetes. The sorghum variety or genotype, the grain pericarp color, and the testa pigmentation all influence the phenolic compound profiles in sorghum. There are four classes of pericarp color in sorghum, which are white, yellow, red, and black. Genetically, black sorghums are actually red, as sunlight during the maturation process causes the red color to turn black. The white sorghums, also known as food-type sorghum, have very low levels of total extractable phenol and usually have no tannins or anthocyanins. Red sorghum is caused by a red pericarp and contains significant levels of extractable phenols, although they have no tannins. Black pericarps lead to black sorghums, which have very high levels of anthocyanins, while the brown sorghums have varying levels of phenolic compounds and pigmented pericarps (Khalid et al. 2022).

The presence of total phenolic compounds in most sorghum whole grain is 0.46 ~ 20 mg gallic acid equivalent (GAE) per gram. The highest total phenolic compound content of almost 48 mg GAE/g was reported in whole grain red sorghum. Total phenolic content in sorghum bran varies even more than in seed. The total phenolic content of red sorghum bran was 20-fold that of white sorghum bran and 8.9-fold that of yellow sorghum bran, while that in black sorghum bran extracts was 7.5-fold that of white sorghum bran and 3.3-fold that of yellow sorghum bran extract (Burdette et al. 2010). It must be kept in mind that the variations in the quantities of total phenolic compounds reported in different studies could have been influenced by different extraction procedures and the solvents used, the specific genotypes tested, and environmental conditions in which plants were grown (Li et al. 2021a).

Free and bound forms of phenolic compounds are found in sorghum, but 70–95% of phenolic acids are in a bound form. Despite this, far more research has been done on the identification and biological activity of free phenolic compounds in sorghum than on the bound compounds (Li et al. 2021b). Bound phenolics bind to structural compounds of the cell wall, thereby reducing bioavailability. It is therefore important to find novel ways to promote the release of bound phenolic compounds in order to increase their bioavailability. The molecular bonding can be severed by creating an acidic or basic environment and by elevating the temperature, which can cause release (Li et al. 2021a; Espitia-Hernández et al. 2022).

Phenolic compounds can act as natural antioxidants by decreasing the oxidative damage of biomolecules, which reduces the effects of reactive oxidants. Phenolic extracts from sorghum were shown to decrease and inhibit the growth of cancer cells in organs such as the colon, liver, and esophagus (Kadri et al. 2017). Phenolic compounds vary significantly between sorghum seeds of different colors (black, brown, red, and white). The amount of phenolic compounds is highly correlated with antioxidant properties. Due to their phenolic compound content, sorghum grains are important as an ingestible form of antioxidants in the diet. The development of sorghum varieties with high levels of antioxidants can increase its nutritional value and health benefits. Sorghum tannins also have medicinal properties (Choi et al. 2019).

2.1.1 Phenolic Acids and Flavonoids

Various studies have reported different types and numbers of phenolic acids, but the most frequently reported phenolic acids isolated from sorghum were caffeic acid and ferulic acid, 3-deoxyanthocyanidins (luteolinidin and apigeninidin), flavanones (naringenin), flavones (luteolin and apigenin), and dihydroflavonol (taxifolin) (Wu et al. 2017). Caffeic acid, p-coumaric acid, sinapic acid, gallic acid, protocatechuic acid, and p-hydroxybenzoic acid have also been reported quite frequently. Ferulic acid is the predominant phenolic acid, especially in red and brown sorghum, and is uncountable for about 90% of the combined phenolic acids. In red sorghum, ferulic acid was the predominant phenolic acid, and p-coumaric, caffeic, and 3,4-dihydroxybenzoic acids were also identified, but there was a large genotype influence on phenolic acids (Li et al. 2021b). Red and brown sorghum grains had the most luteolinidin and apigeninidin, followed by black grains, while white pericarp varieties had very low amounts of these compounds. Many phenolic acids have been assayed, and of these, ferulic, p-coumaric, and protocatechuic acids were seen in the highest concentrations in both red and white sorghum grain (Przybylska-Balcerek et al. 2018).

The outer layers of the grain contain most of the flavonoids, which contribute to the coloring of the pericarp. Sorghum grains have been found to contain many flavonoids. As in the case of phenolic acids, a large genotype effect was seen (Li et al. 2021b). Both the color and thickness of the pericarp influence flavonoid concentrations and profiles. Flavonoids have antioxidant properties, and the daily consumption of foods with significant amounts of flavonoids can help to reduce the risk of cancers of the breast, colon, and pancreas. The main flavonoids in sorghum are anthocyanins, which are a group of anthocyanidin glycosides (Wu et al. 2017). Anthocyanin content in sorghum bran was three to four times higher than that of the flour. The highest anthocyanin content was reported in black sorghum bran (Kumari et al. 2021).

The most frequently reported flavones in sorghum grains are luteolin, apigenin, and naringenin. The widest known flavonols in sorghum grain are kaempferol and quercetin, and the most researched flavanol is iscatechin, and for dihydroflavonol, it is taxifolin (Luo et al. 2020). Ofosu et al. (2021) were the first to report the presence of formononetin, glycitein, and ononin in sorghum. High concentrations of flavanones were identified in yellow-pigmented sorghum genotypes, and those with colored testas had a higher content of condensed tannins (Szerszunowicz and

Kłobukowski 2020). A high concentration of flavones was reported in red-brown sorghum bran (576.47 μg/g) and lower amounts in yellow sorghum flour (15.3 μg/g). The flavanone concentrations were higher in yellow bran (1773.47 μg/g) and lower in brown sorghum flour (4.29 μg/g). Flavanone concentrations were consistently higher in bran than in flour (Kumari et al. 2021). Some of the sorghum flavones had estrogenic effects, as well as anticancer effects in vitro (Cox et al. 2019).

Of all the cereals, only sorghum is a dietary source of 3-deoxyanthocyanidins (3-DXAs). These occur mainly as luteolinidin and apigeninidin, which are mostly water-soluble pigments (Luo et al. 2020). They produce yellow (apigeninidin) and orange (luteolinidin) colors in acidic solvents. They are effective natural colorants and have good antioxidant properties, which are beneficial for human health. Li et al. (2021a) reported that luteolinidin was the predominant 3-DXA, with its total content accounting for 40.55–78.36% of the total 3-DX. The concentration of 3-DXA was three to four times higher in black testa seeds than red or brown testa seeds (Shen et al. 2018). Kumari et al. (2021) reported that red-brown sorghum bran had the highest 3-DXA (4479.16 μg/g), while yellow sorghum flour had low 3-DXA levels (14.14 μg/g). Results from in vitro tests in sorghum showed that 3-DXA had both anticancer and antioxidant properties (Cox et al. 2019). The main antidiabetic substances in sorghum flavonoids have likewise been ascribed to condensed tannins and 3-DXAs (Li et al. 2021a).

2.1.2 Stilbenoids

Stilbenoids are a group of phenolic compounds, and they have a number of benefits for human health. Sorghum can produce stilbenoid metabolites, but very limited research has been done on this. The total stilbenoid content is related to grain color. One study reported 0.4–1 mg/kg of trans-piceid in white sorghum and up to 0.2 mg/kg trans-resveratrol in red sorghum grains (Bröhan et al. 2011).

2.1.3 Tannins

The growing knowledge on the health benefits of tannins have led to tannins receiving more attention in the last years. They are heterogeneous polyphenolic polymers. Tannins in sorghum occur mainly in the pericarp and are polymerized products of flavan-3, 4-diols, and/or flavan-3-ols. Tannin content in sorghum bran is higher than in the flour. Bran from brown and red-brown sorghum varieties had significantly higher tannin content than bran of red and yellow varieties (Kumari et al. 2021). Tannins have many health benefits as they have antioxidant properties and are radical scavengers. They were also reported to improve immunity and have anticancer and anti-inflammatory properties. They are cardioprotective, are vasodilators and have antithrombotic effects (Queiroz et al. 2018). Sorghum is an excellent source of tannins compared to other cereals. Seyoum et al. (2016) reported tannin concentration ranging from 0.2 to 48.0 mg/g in sorghum, with grain with a black testa having the highest tannin level. A significant growing season effect was evident on the tannin content and activity in sorghum. Sorghum with a high tannin content generally has good resistance to birds, insects, and molds.

Tannins, unfortunately, also have anti-nutritional effects, as they form complexes with protein and iron. This impairs the digestibility of the protein and reduces iron absorption (Iyabo et al. 2018). Apart from their interaction with protein, tannins also affect carbohydrates, especially starch, hemicellulose, cellulose, and pectin, reducing their digestibility. Based on their biological and chemical characteristics, tannins have been grouped into hydrolyzable and condensed (known as proanthocyanidins) tannins. Hydrolyzable tannins are complex polymeric compounds classified as gallotannins, when derived from gallic acid, and ellagitannins, when derived from ellagic acid, which is a dimer of gallic acid. Many and varied hydrolyzable tannins have been isolated from edible and inedible plants. They have anticancer, antidiabetic, and antibiotic effects. Condensed tannins are the main polyphenolic substances in sorghum (De Oliveira et al. 2017).

Condensed tannins are especially common in sorghum seeds with pigmented testas. The testa is a structure present between the pericarp and the endosperm of the grain of only some varieties. Sorghum varieties with a brown testa generally have more procyanidins than that of other seed colors. The presence of condensed tannins is one of the reasons why sorghum has higher levels of antioxidants than any other cereal (De Oliveira et al. 2017). Proanthocyanidins in sorghum grains have antioxidant, antitumor, and lipid-lowering activities, and they play a role in the prevention of cardiovascular diseases. They are powerful radical scavengers (Yu et al. 2018). The most basic unit of composition of condensed tannins is catechin, gallocatechin, allocatechin gallate, and afzelechin (Jiang et al. 2020). Testa color is used a means to classify sorghum grains into three categories where type I is tannin-free sorghum without pigmented testa, type II sorghum has a pigmented testa layer (condensed tannins), and type III contain tannins in the testa and pericarp. The proanthocyanidins in sorghum form complexes and precipitate with proteins, probably causing both acidity and a bitter taste, which contribute to them being bird repellents (Li et al. 2021a). Procyanidins concentrations of between 10.6 and 40.0 mg/g have been reported in sorghum, depending on the genotype. This is higher than that of blueberries, known for their high procyanidin content (Yu et al. 2018). Sorghum grain extracts rich in tannin polyphenolics were shown to have in vitro and in vivo inhibitory effects against α-amylase and α-glucosidase enzymes. This could decrease hyperglycemia in diabetics (Links et al. 2015).

2.2 Carotenoids

Carotenoids have many beneficial effects on human health. The most researched carotenoids in sorghum include lutein and zeaxanthin, which are the xanthophylls, which are also the major carotenoids in sorghum, and β-carotene. Varied concentrations of carotenoids have been reported in different studies. This may be due to a genotype effect and different extraction and detection methods. In one study, the total carotenoid content in a hundred sorghum genotypes varied from 2.12 to 85.46 μg/100 g. Nine genes were reported to be involved in carotenoid synthesis or degradation, which is a contributing factor to the variability of levels of carotenoids in the grains of sorghum (Cardoso et al. 2015).

2.3 Lipids and Vitamin E

Sorghum grain has low lipid content, though higher than most other cereal grains, and its lipid profile is similar to that of maize. The oil from sorghum grain have higher levels of oleic and stearic acids and lower levels of linoleic, myristic, and palmitoleic acids, making it less saturated than maize grain oil. The fact that oil from sorghum grain is high in unsaturated fatty acids may provide the health benefit of lipid-lowering properties (Khalid et al. 2022).

Sorghum grain fatty acids are considered as bioactive compounds with health benefits, especially the phytosterols and policosanols. These fatty acids occur in the lipid fraction of the grain as the lipid group of triacylglycerols with a high linoleic, oleic, and palmitic fatty acid content. Phytosterols are steroids that originate from plants, and β-sitosterol is the main phytosterol that was found in sorghum. Campesterol and stigmasterol were also isolated. The concentration of phytosterols is largely influenced by the environment, genotype, and extraction methods. Policosanols (a class of high-molecular-weight aliphatic alcohols) also have different types of bioactivity. Different policosanols (C28, C30, and C32) were isolated from sorghum, of which C28 policosanol was the predominant one (Wongwaiwech et al. 2020).

The vitamin E contents in sorghum were reported to vary significantly, between 280.7 and 2962.4 μg/100 g (wet basis). The α-, β-, γ-, and δ-tocopherols are the most studied in sorghum, with γ-tocopherol being the tocochromanol most frequently found, followed by α-tocopherol. The genotype and the growing environment both have a significant influence on the vitamin E content in sorghum grains (Cardoso et al. 2015).

2.4 Amines

There are two classes of amines, which are the biogenic amines and polyamines, and they represent a class of low-molecular-mass nitrogenous bases. The polyamines represent 60–100% of the total amines. Amines are considered to be bioactive compounds, and sorghum was reported to be a main source of polyamines. Spermine and spermidine are the most prevalent amines, followed by putrescine and cadaverine (Paiva et al. 2015).

2.5 Carbohydrates

The major carbohydrate in sorghum grain is starch, present in a granular form in the endosperm. Starch consists of two polysaccharides, amylose and amylopectin, and can be classified as waxy and non-waxy. Sorghum starch classified as non-waxy is composed of amylose (25%) and amylopectin (75%), while waxy sorghum consists almost entirely of amylopectin. Waxy sorghum is highly digestible by enzymes, while non-waxy starch exhibits resistance to enzymatic digestion. Proteins, tannins, and starch granules interact in the sorghum grains, forming complexes, leading to very poor starch digestibility. Sorghum has the poorest starch digestibility of all cereals. Sorghum genotypes with high phenolic and tannin content were found to be

associated with enzyme inhibition and starch molecule interaction. This impairs the starch digestibility, which increases the resistance of starch, which leads to a lower glycemic index of foods in which the starch is included (Moraes et al. 2018).

2.6 Fibers, Vitamins, and Minerals

Dietary fibers are mainly non-starch polysaccharides, which have numerous health benefits, such as positive effects on diabetes, tumors, and atherosclerosis. The whole grain of sorghum consists 10–25% of bran, of which 35–48% is insoluble dietary fiber (Miafo et al. 2019). Sorghum, being a fiber-rich food, has a low glycemic index, causing a slower and lower rise in blood glucose level (Moraes et al. 2018). Sorghum grains contain many and various types of vitamins and minerals. Minerals include Ca, Fe, K, Mg, P, and Zn (Motlhaodi et al. 2018). The most prevalent vitamins are of the B-complex such as pyridoxine (vitamin B6), riboflavin (vitamin B2), and thiamine (vitamin B1), and the fat-soluble vitamins such as A, D, E, and K (Przybylska et al. 2019).

2.7 Sorghum Protein

Cereal grains generally contain up to 20% proteins, but unlike animal protein, they have a low essential amino acid content. However, cereals are widely available and are a staple in many regions throughout the world, making them an attractive protein source and a source from which peptide nutraceuticals can be released, which could eliminate reactive oxygen (Szerszunowicz and Kłobukowski 2020). A wide range of protein content in sorghum grains have been reported (6–18%), of which the biggest percentage is storage protein, or prolamins. Sorghum prolamins are called kafirins and are located in the protein bodies of the endosperm. Sorghum kafirins make up a large portion of the total protein in whole kernels (48–70%) and an even higher portion (up to 80%) in decorticated kernels, while the rest consists of the albumins and globulins (Espinosa-Ramirez and Serna-Saldivar 2016. Discrete kafirin protein bodies are formed, and in mature endosperm, these bodies form a tight matrix with starch granules. These matrices affect the processing quality of sorghum and contribute to grain hardness and digestibility. Sorghum storage proteins are classified according to solubility, structure, amino acid composition, and molecular mass. They consist mainly of albumins (water extractable fraction), globulins (dilute salt extractable fraction), and kafirins or prolamins (alkali soluble fraction) (Wong et al. 2009).

Kafirins are hydrophobic proteins and are divided into three groups based on their molecular weight: α-kafirin (23–27 kDa), β-kafirin (16, 18, and 20 kDa), and γ-kafirin (28 kDa) (Espinosa-Ramirez and Serna-Saldivar 2016). The most dominant kafirin proteins are the α-kafirins, accounting for 70–80% of total storage proteins in sorghum grain (66–71% in opaque endosperm). They occur mostly in outer layers of grain and a reduction of α-kafirins is associated with a loss of vitreous endosperm texture (Wu et al. 2013). Sodium dodecyl sulfate polyacrylamide gel electrophoresis

(SDS-PAGE) has been used frequently in the past to separate the kafirins. With this technique, the α-kafirins resolve into two distinct bands with a molecular weight of 23 and 25 kDa, although these molecular weights can range from 22 to 27 kDa depending on different laboratory protocols and conditions (Cremer et al. 2014).

The second largest group of kafirins is the γ-kafirins. They make up a large part of the total kafirins in opaque endosperm (19–21%) and a smaller part (9–12%) in vitreous endosperm. They have a molecular weight of about 20 kDa. The β-kafirin comprises about 7–8% of total kafirins in vitreous endosperm (10–13% in opaque endosperm). The outside layers of the protein bodies contain most of the β- and γ-kafirins, where cross-links are formed between proteins via disulfide bonds (Oria et al. 2000). The very minor δ-kafirins (Mr = 15 kDa) form the fourth group, accounting for less than 1% of the mature grain total seed storage protein. Sorghum protein is poorly digestible, and the improvement of protein digestibility is still a major research goal in the sorghum fraternity. Protein digestibility is strongly related with the overall grain α- and γ-kafirin content (Wu et al. 2013; Elkonin et al. 2016). Dense, spherically shaped protein bodies are formed in the seed endosperm during grain development from the accumulation of the different kafirin groups. Kafirin protein bodies are quite compact, and on the periphery of these bodies, cross-links are formed. This probably causes the structural barriers preventing enzymatic access, which reduce the digestibility of these proteins (Oria et al. 2000).

Amino acids in grains are largely obtained from storage proteins, so this is a major factor determining the nutritional quality of the grain as a source of food for humans and animals. Both maize and sorghum proteins are deficient in the essential amino acids lysine and tryptophan, reducing the nutritional value of these cereals, which is an even bigger problem in sorghum than maize. Sorghum grain has low amount of essential amino acids like methionine, lysine, and isoleucine. The main amino acids in sorghum protein are histidine, leucine, phenylalanine, tyrosine, threonine, tryptophan, and valine (Mohapatra et al. 2019).

The γ-kafirins are rich in proline, cysteine, and histidine. The β-kafirins are rich in cysteine. As the δ-kafirin fractions are so small, it could be inconsequential in influencing sorghum grain quality traits. However, it is rich in the essential amino acid methionine, which is often deficient in cereal proteins, along with lysine, threonine, and tryptophan. If the δ-kafirin fraction can be increased, it could enhance the nutritional quality of sorghum proteins (Laidlaw et al. 2010).

2.8 Other Proteins in Sorghum

Various antifungal proteins have been identified in sorghum, including chitinase, glucanase, thionin, defensin, protease inhibitor, and ribosome-inactivating proteins. There are also several bioactive proteins in sorghum such as amylase and protease inhibitors, as well as glycine-rich RNA-binding proteins, protein kinases, and glutathione S-transferase isoenzymes. Proteins involved in lysine catabolism were also isolated from sorghum, which included lysine 2-oxoglutarate reductase and saccharopine dehydrogenase (Lin et al. 2013).

3 Genetic Improvement of Sorghum Nutraceutical Content

The nutraceutical content of sorghum can be improved in breeding programs if sufficient genetic variability is available to select for higher content. Natural genetic variation can be exploited, or genetic variability can be introduced from wild and close relatives, many of which are available from conserved genetic resources. Molecular techniques such as linkage and association mapping, and more recently, genome-wide association studies, can be used to understand the underlying genetic architecture of nutraceutical content. Sorghum mutant libraries are also proving very useful to use reverse genetics to determine traits that are useful for sorghum improvement, which could include nutraceutical content. Genetic engineering and genome editing techniques can now be applied to improve important traits, which already include some nutraceuticals.

3.1 Genetic Resources for Genetic Improvement of Nutraceuticals and Nutritional Value

The sorghum genus consists of *Sorghum bicolor.* This belongs to the subgenera of *Eu Sorghum*, within which there are three species: *Sorghum bicolor*, *Sorghum halepense* (Johnson grass), and *Sorghum propinquum*. The *S. bicolor* species consists of three subspecies: *bicolor*, *verticilliflorum*, and *drummondii* (Sudan grass). The *bicolor* subspecies has 5 races (bicolor, caudatum, durra, guinea, and kafir) and 10 intermediate races (Ananda et al. 2020). There are numerous global genetic resources of conserved sorghum worldwide and over 240,000 accessions are conserved in ex-situ gene banks. Most of these are cultivated accessions (98.3%) and a small percentage are wild weedy relatives (1.7%) (Upadhyaya et al. 2016), although there may be duplicates which yet have to be identified and managed. There are at least 20 sorghum gene banks in the world. The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) in India have a collection of 37,949 accessions from 92 countries (ICRISAT 2021). The United States Department of Agriculture (USDA) National Plant Germplasm System (NPGS) at the Plant Genetic Resources Conservation Unit in Griffin, GA, maintains a collection of over 45,000 accessions (USDA 2021). The Institute of Crop Science, Chinese Academy of Agricultural Sciences (ICS-CAAS), China, holds a collection of 18,263 accessions, and the National Bureau of Plant Genetic Resources (NBPGR) of India conserves 20,221 accessions (NBPGR 2021). Wild relatives are widely used in cereal breeding programs and likewise has potential in sorghum breeding to enhance yield potential and genetic diversity.

3.2 Subset Collections as Sources for Marker-Assisted Breeding

Significant research has been done on accessions collected from Ethiopia. Usually a high number of accessions is screened in different growing environments, and then a subset of this is genotyped using a genotyping by sequencing (GBS) approach. A

core subset is then identified which best represents the genetic diversity present in the whole germplasm collection. A subset of 374 accessions followed by another subset of 1425 Ethiopian landrace accessions were analyzed (Girma et al. 2019). After that, another subset of 387 Ethiopian germplasm accessions were comprehensively phenotyped and genomic characterization was done (Girma et al. 2020). The natural variation and genetic structure of these populations were determined. Single nucleotide sequence polymorphisms (SNP) associated with important traits can be used as molecular markers in breeding programs (Girma et al. 2019, 2020).

3.3 Sorghum Linkage and Association Mapping Resources

Natural variation in populations has been shaped by natural and artificial selection, and a combination of the two. Variation is probably linked to specific agronomic adaptive traits that have ecophysiological relevance. Ecogeographical and historical information also largely determine natural variation, and analysis of this variation can shed light on the evolutionary processes that led to the genetic variation patterns. Sorghum germplasm is known to have high levels of natural variation (Boyles et al. 2019) and is very suited for genetic analysis. In linkage mapping, recombination is generated by crossing parents, while in association mapping, historical recombination events are used. Linkage and association mapping are widely used to characterize the genetic architecture of traits. This includes information of how many loci are involved and how they are distributed, the gene action determining the traits, and linkage and allele frequency. With this knowledge, scientists can hypothesize on the genes that underlie variation in studied traits.

3.3.1 Linkage Mapping Resources

Many genetic traits in sorghum have been investigated through linkage mapping in the past 25 years, such as plant and flowering traits, pigmentation, drought and cold tolerance, and disease resistance (Xin et al. 2021). Almost no research has been reported on seed composition, including nutraceutical content, with the exception of kafirins.

3.3.2 Association Mapping Resources

There has been significant developments in the methods that can be used to generate high-density genome-wide markers. This has caused a shift towards genome-wide association studies (GWAS) from linkage mapping and gene association. The sorghum association panel is currently the most widely used sorghum GWAS resource. This panel was designed to capture and represent global plant diversity, and plant function and end uses. This association panel has genotyping by sequencing (GBS) marker data (Hu et al. 2019) and is available from the Germplasm Resources Information Network (GRIN). All the sorghum association panel accessions flower in temperate latitudes. This panel has been used for GWAS studies of many traits (Mural et al. 2020). There is also a bioenergy association panel, which is another global diversity panel that is available from GRIN, where the majority of the

accessions are tropical and photoperiod-sensitive. Although this panel consists mainly of tropical accessions, sweet and forage sorghums are also included. The bioenergy association panel has associated SNP data from GBS and whole-genome resequencing (Bellis et al. 2020; Lozano et al. 2021). A sorghum collection has been made available for phenotyping and association studies, consisting of 2000 georeferenced accessions, which were genotyped with GBS. Most of these accessions are also available from GRIN (Bellis et al. 2020). A large number of landrace accessions have been collected from Africa, for which GBS SNP data are available. There are entire GRIN collections from Niger, Nigeria, Senegal, Ethiopia, and Sudan, and for sweet sorghum.

3.3.3 Multi-parent Mapping Resources

Techniques such as linkage mapping are powerful and sensitive, while association mapping has the strength of power and sensitivity, which created an interest to combine the best of these techniques in different genetic approaches. This has led to the use of multi-parent mapping approaches, which include nested association mapping (NAM), backcross NAM, and multi-parent advanced generation intercross (MAGIC), all which have been applied in sorghum research (Boyles et al. 2019). The NAM approach is based on that which was developed for maize and now applied in many crops where multiple recombinant inbred line (RIL) families are developed that have diverse founders but share a common parent (Gage et al. 2020). RTx430 was selected as the common founder line for the global grain sorghum NAM resource (primarily because it has for decades been the most important public pollinator line), together with 10 diverse global founders (all part of the sorghum association panel), from which a total of more than 2200 RILs in 10 families were developed. The common germplasm between the association panel and the NAM allows the validation and comparison of the data from these two sources (Olatoye et al. 2020).

In the past, mainly biparental linkage families were used in research, but the aim of the MAGIC approach is to increase allelic diversity and at the same time to increase the power and specificity of quantitative trait loci (QTL) detection relative to GWAS. All founder lines contribute equally to the MAGIC in order to balance allele frequencies. One sorghum MAGIC resource has been developed and is currently available from the developers (Ongom and Ejeta 2018). There is also a backcross NAM (BCNAM) approach, where backcrosses are made and selection done to recover the common elite parent phenotype, which may have more of a breeding advantage (Jordan et al. 2011).

3.4 The Sorghum Mutant Library

Xin et al. (2008) developed a pedigreed mutant library for functional genomic studies by using a systematic approach in such a way that all mutations are captured and preserved. Individual seeds from an elite inbred line, BTx623 (used to generate the first sorghum reference genome), were treated with the chemical mutagen ethyl

methane sulfonate (EMS). Seeds were soaked in various concentrations of EMS to optimize the chances to obtain desirable mutations. This mutant library is a permanent resource, which can be used by scientists to test mutants under different growing conditions, to enhance breeding efforts. Currently, 6400 independent seed pools are available in this library to breeders and scientists. These are an excellent resource for sorghum breeding, as mutants with potentially useful traits can be selected for sorghum improvement programs (Xin et al. 2021). Purdue University has followed a similar approach to generate approximately 10,000 pedigreed seed pools (Addo-Quaye et al. 2018). A wide range of phenotypes that could be used for sorghum improvement have been identified and selected within this pedigreed mutant library. The traits and phenotypes identified in this mutant library have the potential to be used in sorghum breeding programs and in genomic studies. Both forward and reverse genetic resources have been developed that can be used to explore the mutant library traits (Wang et al. 2021).

Next-generation sequencing techniques have been developing rapidly, providing large numbers of DNA markers, which are also financially affordable. The output of high-quality DNA sequences has been increasing, and next-generation sequencing has become much cheaper. Whole genome sequencing of pedigreed mutants has become a resource for reverse genetics by searching gene mutations online. Next-generation sequencing has been used to annotate SNP markers. Mutant phenotypes of interest can be studied to map and identify causal mutations through mapping-by-sequencing or next-generation mapping (Hartwig et al. 2012).

Addo-Quaye et al. (2018) introduced mutations with EMS and then sequenced 586 mutants, where they identified 1,275,872 homozygous and 477,531 heterozygous mutations. In the sorghum genome, as is the case in other crops, the mutations often have deleterious effects. The sequenced data of the mutant collections can be a very useful resource for reverse genetics. These collections can be used together with other methods, such as genome-wide association and biparental mapping of QTLs of important agronomic traits, to validate candidate genes (Xin et al. 2021). Although very limited research has been done on the genetics of nutraceuticals so far (with the exception of kafirins) compared to the adaptive and yield-related traits, the resources are there, and they should be used to generate data for genetic improvement.

3.5 Genetic Engineering Approaches for Improving Nutritional Composition of Sorghum Grain

Recent years have been marked by significant progress in sorghum genetic transformation technologies that have made it feasible to use genetic engineering and genome editing methods to improve the nutritional properties of sorghum grain. Such progress is based on improved technologies of plant regeneration in sorghum tissue culture, in particular, the use of nutrient media containing increased concentrations of phosphate, proline, and asparagine, which reduces the release of phenolic pigments characteristic of cultivated sorghum tissues and increase embryogenic potential (Elkonin and Pakhomova 2000), as well as elevated levels of copper

ions, which improve the development of the root system of regenerants. Efficient media for plant regeneration allowed substantial improvement of genetic transformation methods of sorghum either through biolistic DNA delivery (Belide et al. 2017) or *Agrobacterium*-mediated genetic transformation (Do et al. 2016). In the latter case, significant improvements are due to the use of "hypervirulent" *A. tumefaciens* strain NTL_4 or another *Agrobacterium* strain containing specially designed Ti-plasmids with additional copies of *vir*-genes ("superbinary" vectors) or containing "helper" plasmids with additional *vir*-genes that enhance the transfer of T-DNA from *Agrobacterium* cells to sorghum cells. An important factor that also contributed to the increase in the efficiency of *Agrobacterium*-mediated genetic transformation in sorghum was the obtaining of an auxotrophic mutant LBA4404 Thy – incapable of growth on a media without thymidine, the use of which made it possible to significantly simplify the transformation procedure. The creation of binary vectors carrying the genes of morphogenetic regulators BABY BOOM and WUSCHEL, which promote the direct development of embryoids from scutellum cells of immature embryos, and thereby increase the number of regenerants and the frequency of transgenic plants, also had a significant effect (Che et al. 2022).

The main goals of genetic engineering approaches for improving nutritional value of sorghum grain are improvement of the digestibility of sorghum storage proteins, modification of starch content, enrichment of sorghum grain with essential amino acids and carotene, and decreasing the level of phytate that reduces bioavailability of minerals and phosphate. Some of these goals are being successfully realized currently, while the achievement of other goals is the task of future research.

3.5.1 Improvement of Kafirin Digestibility

Kafirins are resistant to proteolytic digestion, which is one of the main causes of reduced nutritional value of sorghum grain. This resistance to proteolytic digestion not only reduces their digestibility by animals and humans but also reduces the digestibility of grain starch, since undigested kafirins prevent the amylolytic cleavage of starch granules (Duressa et al. 2018).

Significant research has been devoted to the study of the factors that cause protein indigestibility. The reasons for kafirin resistance to protease digestion are multifactorial. It is assumed that kafirin resistance to protease digestion is caused by the chemical structure of kafirins, which are abundant with sulfur-containing amino acids capable to form S–S bonds that result in the formation of kafirin olygo- and polimers resistant to protease digestion; interactions of kafirins with non-kafirin proteins and nonprotein components such as polyphenols and polysaccharides; and the organization of different kafirins in the protein bodies, with the β- and γ-kafirin located at the periphery of the protein body, while the most abundant α-kafirin is located within the protein body. Such a spatial arrangement of kafirins in the protein bodies of sorghum, apparently, is a consequence of the prolamin synthesis pattern in the process of kernel development. In maize, it was found that starting from 4 to 5 days after fertilization, protein bodies accumulate γ- and β-prolamins, while later on, intensively accumulating α-prolamins moved γ- and β-prolamins to the periphery of the protein body. Due to the peripheral occurrence of γ-kafirin (which is

considered as the most stable to protease digestion) in the protein body, it is generally accepted that it reduces digestibility of α-kafirin, which comprises up to 80% of total endosperm kafirins (Duressa et al. 2018). In addition, γ-kafirin effectively forms oligo- or polymers of high molecular weight, which has high resistance to protease digestion.

This hypothesis was confirmed by the study of a mutant, P721Q, with a high level of lysine and improved digestibility of kafirins, obtained by chemical mutagenesis. In this mutant, the protein bodies had irregular shape, having deep invaginations, while normally they have a round shape. The γ-kafirin is located only in the bottom of these invaginations and does not form a continuous layer, which prevents digestion of α-kafirin in normal sorghum. It was suggested that such a structure of the protein bodies determines the high digestibility of proteins in the P721Q mutant and lines derived from it (Oria et al. 2000). Floury type endosperm grains are formed due to this mutation and lysine content is increased. It was therefore denoted with the symbol *hdhl* (*high digestibility high lysine*). Further investigation of this mutation using two-dimensional gel electrophoresis and mass spectrometry showed an increase of non-kafirin proteins (such as cytoskeleton and chaperone proteins, and the proteins involved in amino acids and carbohydrates synthesis) and a decrease in kafirin content in *hdhl* endosperm. The overexpression of chaperone proteins, which are probably involved in the repair of protein misfolding that was caused by the mutation, is in part responsible for increased lysine content of the P721-opaque sorghum (Benmoussa et al. 2015).

Studies have been undertaken on the chromosome localization of this mutation. In the research of Winn et al. (2009), with the analysis of a hybrid population obtained by crossing highly digestible line P850029 (derived from P721Q) and the wild type line Sureno, two QTLs were identified. These QTLs (both from the high-digestibility parent) were located on chromosome 1 in genomic regions within 20 cM from each other. They were in repulsion phase, meaning one QTL (locus 1 from the HD parent) unfavorably affects digestibility and one QTL (locus 2 from the HD parent) favorably affects digestibility. Protein digestibility can be increased if this linkage in repulsion is broken, which will allow the recombination of favorable alleles. It is noteworthy that another research group found that the proteinase inhibitor gene is located on chromosome 1 (Duressa et al. 2018). Perhaps QTLs identified by Winn et al. (2009) are linked to this gene.

In another investigation of chromosome localization of the *hdhl* mutation, one major QTL was identified on chromosome 5, in the 58 Mb region that overlaps with the genomic loci of the 17-kafirin gene cluster. In this research, the F_2 population generated from a cross between a normal line (BTx623) and a high-digestible mutant, P721Q was used (Massafaro et al. 2016). The F_2 plants with highly digestible protein displayed the unique protein body structure of P721Q. The results of this investigation confirms the data obtained by Wu et al. (2013) which showed that the *hdhl* phenotype in the P721Q mutant and lines derived from it is a consequence of a point mutation in one of the genes from the *k*1*C* family located on chromosome 5, encoding the 22 kDa α-kafirin. Sequencing revealed a point mutation in the nucleotide sequence that encodes the signal polypeptide responsible

for the packaging of α-kafirin inside the protein body (substitution at position 61 G→A) (Wu et al. 2013). This mutation resulted in the formation of a missense codon at the last amino acid of the signal sequence. Despite the fact that the mutation was found in only one of the genes of this cluster, its presence was sufficient to cause significant changes in the structure of protein bodies and the digestibility of kafirins. It was hypothesized that this mutation decreases the accumulation of α-kafirin in protein bodies that leads to a change in their ultrastructure and increases their sensitivity to the action of proteases (Wu et al. 2013).

In addition, a comparative analysis of the nucleotide sequences of all 27 kafirin genes in sorghum samples with high and low digestibility revealed four α-kafirin alleles localized on chromosome 5, which are closely associated with digestibility. Three alleles were associated with high digestibility (*Sobic.005G185600*, *Sobic.005G188800*, and *Sobic.005G189000*) and one with low digestibility (*Sobic.005G192801*). In silico predictive analysis showed the variants cause missense change in the amino acid sequences of the corresponding proteins (Duressa et al. 2020).

3.5.2 RNA Interference Technology

The use of biotechnology methods, in particular, RNA interference technology, opens up much broader prospects for obtaining mutants with improved digestibility of kafirins. This technology has been widely used for a long time to modify the synthesis of storage proteins as well as starch and other nutrients of endosperm in a number of cereals (Elkonin et al. 2016).

A number of research groups have been doing studies on the induction of RNA silencing of kafirin genes (Da Silva et al. 2011a, b; Kumar et al. 2012; Grootboom et al. 2014). RNA silencing was induced by genetic constructs carrying inverted repeats of several kafirin genes (α1, δ2, γ1, and γ2) separated by the *ADH*1 gene intron sequence. mRNA transcribed from this construct forms a double-stranded hairpin and underwent enzymatic degradation. The constructs were driven by the 19-kDa maize α-zein promoter (Da Silva et al. 2011a, b). In another study (Kumar et al. 2012), the genetic construct used to induce γ-kafirin silencing consisted of the complete *γ-KAFIRIN* gene sequence under the control of its own promoter. As a terminator, the sequence of the tobacco mosaic virus ribozyme gene was used. The expression of this gene should destroy γ-kafirin mRNA. In another construct, to induce α-kafirin silencing, α-kafirin inverted repeats separated by the intron sequence of the *Arabidopsis* gene encoding the D1 spliceosome protein were used; this construct was driven by the α-kafirin promoter (Kumar et al. 2012). Later, another complex construct consisting of inverted fragments of γ1-, γ2-, and δ-kafirin genes was used to obtain transgenic sorghum plants with silencing of kafirins (Grootboom et al. 2014).

The transgenic plants obtained in these experiments had a modified protein body structure which resembled that of the P721Q mutant, and an increased digestibility of kafirins, which was observed when both raw and cooked sorghum flour was treated with pepsin. One such example is the transgenic plants of Tx430, carrying a genetic construct for silencing α- and γ-kafirin. They were identified as having

improved in vitro protein digestibility (78% and 61% for the raw and cooked flour, respectively), while in the non-transgenic control, the digestibility varied in the ranges of 40–50% and 34–40%, respectively (Da Silva et al. 2011a). The genetic construct to suppress only δ- and γ-kafirins also improved the digestibility of raw flour but did not affect the digestibility of cooked flour. In the experiments of Kumar et al. (2012), the cooked flour from transgenic kernels carrying a genetic construct for γ-kafirin suppression did not differ from the non-transgenic control, while α-kafirin suppression improved the digestibility of such flour.

Based on the hypothesis that the surface location of γ-kafirin in protein bodies is the reason for the low digestibility of sorghum protein bodies, a genetic construct (NRKAFSIL) was created that should prevent the accumulation of the γ-kafirin without affecting the accumulation of other kafirins (Elkonin et al. 2016). This construct contained the fragment of the nucleotide sequence of γ-kafirin gene (GenBank Accession No: M73688) in direct and inverted orientation, separated by the maize ubiquitin intron sequence. The construct was driven by the 35S promoter. Using *Agrobacterium*-mediated genetic transformation, this construct was introduced into two sorghum cultivars: Zheltozernoe 10 (Zh10) and Avans. Electrophoretic spectra of endosperm proteins were compared before and after pepsin digestion, showing that in the transgenic plant, the amount of undigested kafirin monomers and total undigested protein was significantly lower than in the original non-transgenic line (by 1.7–1.9 times) when quantitative SDS-PAGE analysis was done. The level of digestibility reached 85–92%, while in the original line, this value was about 60%. The effect of increased digestibility of kafirins was traced to the T_4 generation; however, in some cases, it disappeared, possibly due to the instability of the introduced genetic construct or due to its silencing.

It should be noted that RNAi silencing of the γ-kafirin gene also caused a decrease in the content of α-kafirins. This phenomenon was especially pronounced in the Avans-1/18 transgenic line (Elkonin et al. 2021). At the same time, the functioning of the construct for the γ-kafirin gene silencing did not lead to a significant decrease of the total protein content of the grain compared to the original non-transgenic cultivar (14.3% vs. 15.5%). This fact, apparently, is a consequence of the balancing of protein synthesis in the kernels.

Another feature of transgenic sorghum lines with silencing of γ- and α-kafirins is the modification of the endosperm texture, in particular, the reduction of vitreous endosperm layer and formation of kernels containing floury endosperm characteristic to the P721Q mutant (Da Silva et al. 2011b; Kumar et al. 2012; Grootboom et al. 2014). Apparently, expression of RNAi genetic constructs also affects the formation of the protein-carbohydrate matrix, which caused formation of the vitreous endosperm layer. In experiments with the genetic construct for γ-kafirin gene silencing in variety Zh10, transgenic plants were obtained that had kernels with different endosperm types (Fig. 1).

Normal endosperm with a thick or thin vitreous layer, floury endosperm, or a modified type of endosperm in which the vitreous layer developed as sectors or spots surrounded by floury endosperm were seen (Elkonin et al. 2016). In these experiments, the kernels of some transgenic plants that exhibited a thick vitreous

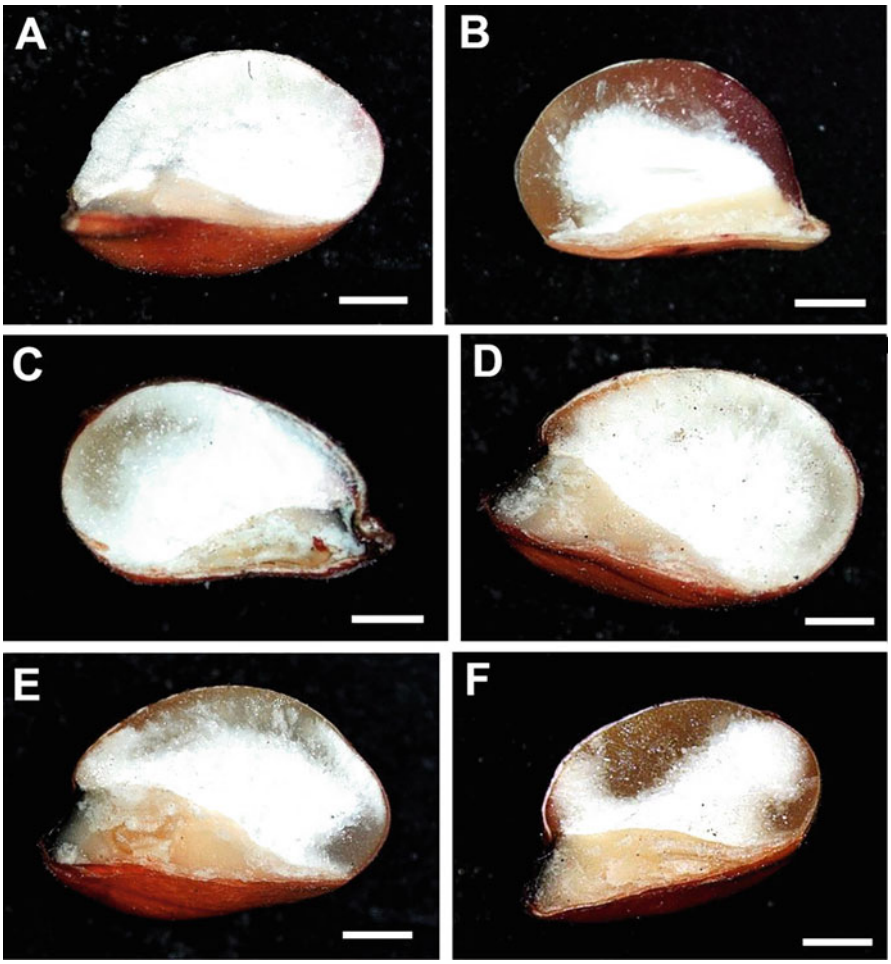

Fig. 1 Cross sections of kernels of transgenic sorghum plants with genetic construct for silencing of the γ-kafirin gene (Elkonin et al. 2016). (**a**) Kernel with floury endosperm set on the plant from T_3 generation; (**b**) kernel of original non-transgenic line Zh10 with thick vitreous endosperm (marked by arrows); (**c**–**e**) modified endosperm type with blurs and sectors of vitreous endosperm observed in kernels of different T_1 and T_2 plants; and (**f**–**h**) irregularly developed vitreous endosperm developed in kernels of T_2 and T_3 plants. Bar = 1 mm (© 2017 Elkonin LA, Italyanskaya JV, Panin VM, Selivanov NYu. Originally published in "Plant Engineering", InTech, Zagreb (Chroatia) under CC BY 3.0 license. Available from: https://doi.org/10.5772/intechopen.69973)

endosperm had a digestibility level as high as 92%, while the amount of undigested monomers was reduced by 17.5 times, and the amount of total undigested protein was 4.7 times less compared to the original lines. Previously, transgenic plants with similar endosperm texture were also observed in the Tx430 transgenic line with a construct for silencing α- and γ-kafirins.

It seems that the different types of endosperm that form are due to the particular expression of genetic constructs in the genome of the recipient line. In transgenic line Avans-1/18, in the T_1 generation, a revertant with vitreous endosperm and significantly reduced digestibility of kafirins was found (Elkonin et al. 2021). This revertant contained part of the NRKAFSIL genetic construct determining resistance to the selective agent (*bar* gene). At the same time, this revertant has a deletion in the *ubi*1 intron, which is a part of the construct for silencing of the *γ-KAFIRIN* gene, that, apparently, caused inefficiency of silencing and loss of characteristic features of mutation. These data indicate that the 588 bp *ubi*1 intron sequence can be used as a molecular marker in the screening of plants with high protein digestibility during hybridization of the Avans-1/18 mutant with various sorghum varieties.

The well-known correlation between the high digestibility of kafirins and floury endosperm was confirmed by these findings (Duressa et al. 2018). Such a correlation could hardly be explained by impaired synthesis of γ-prolamines (γ-kafirin), which are believed to play an important role in the interaction of protein bodies with starch granules, since mutants with impaired synthesis of α-kafirins also have a floury endosperm type (Da Silva et al. 2011b; Kumar et al. 2012; Grootboom et al. 2014). This correlation is possibly due to a violation of the formation of non-kafirin proteins in mutants with suppressed synthesis of α- or γ-kafirins, which form a protein matrix characteristic of vitreous endosperm. In mutants where kafirins are silenced, an increase in essential amino acid contents of lysine and threonine is seen, which appears to be due to increased synthesis of other proteins, including those with a higher content of essential amino acids. Thus, a significant increase of lysine content (an increase of 1.2 g/100 g protein compared to the non-transgenic control) was found in transgenic sorghum plants where α-, γ-, δ-kafirin genes were silenced due to the presence of complex genetic constructs for RNAi silencing and the presence of the lysine ketoglutarate reductase gene (which controls catabolism of free lysine) (Da Silva 2012).

In the transgenic plants of variety Zh10 containing the genetic construct for γ-kafirin silencing, the proportion of lysine increased 1.6–1.7 times (Elkonin et al. 2016); in the Avans-1/18 line, the increase was 75%, from 0.36% in the original line to 0.63%. It seems that the increase was caused by a decrease in amount of α-kafirins, which are poor in lysine and threonine, while the synthesis of other proteins was not affected. This caused an increase in the relative proportions of lysine and threonine. The suppression of γ-kafirin synthesis probably has no effect on the synthesis of proteins that are rich in lysine and threonine, but it prevents the accumulation of α-kafirins.

The use of RNA-interference technology, however, has a number of significant limitations: the genetic construct for silencing may undergo partial or complete destruction in the recipient genome (Elkonin et al. 2021), or its expression itself can undergo silencing. In addition, the functioning of the RNA silencing mechanism is an epigenetic process, and epigenetic processes in plants largely depend on environmental conditions (such as temperature, soil, and air humidity) (von Born et al. 2018). In the transgenic line Zh10, carrying the genetic construct for silencing

γ-kafirin, the level of digestibility of kafirins in plants grown in a field plot under natural moisture conditions was lower than in plants grown in outdoor vessels (Elkonin and Italyanskaya 2017). In some cases, off-target, nontarget, and unintended effects of genetic constructs for RNAi were observed (Christiaens et al. 2018). Besides these scientific problems, public concerns on using transgenic plants are a serious problem, which limits widespread use of sorghum lines carrying genetic constructs for RNA silencing for food and feed purposes.

3.5.3 Genome Editing Technologies

Site-directed mutagenesis using genetic constructs carrying the CRISPR/Cas system is one of the most effective technologies that are actively used to solve a variety of problems in genetics and plant breeding (Zhu et al. 2020). This approach allows the changing of the structure of the genes of plants, therefore, without introducing foreign genetic information, to change the plant metabolism in the necessary direction (Song et al. 2016). At the same time, in the offspring of mutants, due to recombination, it is possible to select plants that carry the induced mutation but are free from the genetic construct that induced it. As a result, the resulting mutants practically do not carry foreign genetic information; therefore, they are not transgenic organisms.

The CRISPR/Cas9 system includes Cas9 endonuclease and guide RNA (gRNA), which directs Cas9 endonuclease to the target nucleotide sequence (Song et al. 2016). The classical variant of the Cas9 nuclease recognizes the NGG-3′ Protospacer Adjacent Motif (PAM) sequence adjacent to the target (protospacer), which thus serves as the identification mark of the target in the edited genomic DNA. Cas9 endonuclease produces double-strand breaks in the target DNA located three nucleotides upstream of the PAM sequence. These breaks result in insertions or deletions at the target site, which can lead to frameshifts and null mutations.

The CRISPR-Cas system was successfully used to induce mutations in the nucleotide sequence of the 22 kDa signal polypeptide of α-kafirin (Li et al. 2018). Mutations were deletions ranging in size from 1 to 33 nucleotides, and, more rarely, insertions ranging in size from 1 to 16 nucleotides. In the kernels of T_1 and T_2 plants, a reduced level of α-kafirin and an altered structure of protein bodies were observed; some T_2 plants had higher protein digestibility and increased lysine levels. These results indicate the promise of using genome editing techniques to improve the nutritional value of sorghum grain.

Edited sorghum plants with mutations in the nucleotide sequences of the β- and γ-kafirin gene have also been reported (Massel et al. 2022). In this study, high efficiency of endogenous *U6* promoters (in particular, *SbU62.3* promoter) was shown to improve gene editing efficiency in sorghum of up to 90% of experimental plants.

A series of binary vectors (pC1-pC4) were created for site-directed mutagenesis of genes encoding α- and γ-kafirins (Gerashchenkov et al. 2021). These vectors contain the *Cas9* endonuclease gene under the control of the *ubi*1 promoter and gRNA nucleotide sequences that are complementary to target sites encoding signal polypeptides of α- and γ-kafirins (the *k*1*C*5 and *gKAF*1 genes, respectively). Using *Agrobacterium*-mediated genetic transformation, the constructs for site-directed mutagenesis of these genes were introduced into the genome of cv. Avans. Using

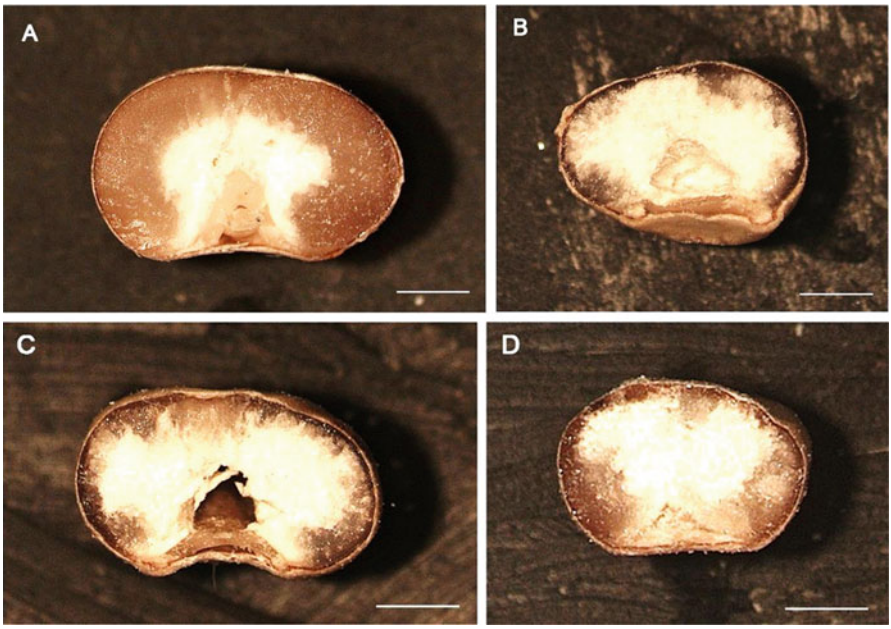

Fig. 2 Cross sections of kernels set on the panicle of the sorghum plant carrying a genetic construct for *α-KAFIRIN (k*1*C*5*)* gene editing target ((**b**), (**c**), (**d**)); ((**a**) – kernel of original cv. Avans). Bar 1 mm (Amer J Plant Sci, 2021, 12: 1276–1287, with permission)

the pC2 vector (to induce mutations in the *k*1*C*5 gene), regenerants (T_0) with kernels with modified endosperm texture were obtained, in which a significant reduction in the vitreous endosperm was observed (Fig. 2).

This demonstrates the efficiency of genome editing approaches for improvement of nutritional value of sorghum grain. The successful results obtained in these studies demonstrate the validity of the choice of kafirin signaling polypeptides as targets for improving the nutritional value of sorghum grain. However, it is likely that this approach is only one of the ways to use the CRISPR/Cas method to improve the nutritional value of sorghum grain, and other approaches will be used to solve this problem in future experiments.

3.5.4 Synthetic Biology Approaches

With the help of synthetic biology approaches, transgenic lines with increased protein digestibility and increased protein content were obtained that contain an artificially synthesized β-kafirin gene (Liu et al. 2019). This gene encoded modified β-kafirin protein with additional proteolytic cleavage sites that should improve its digestibility. Some of the resulting transgenic lines had higher protein content in the seeds (by 11–37%) and a higher digestibility of kafirins (by 11–21%) compared to the non-transgenic original variety. The protein bodies had an irregular shape with invaginations characteristic for highly digestible sorghum lines.

In order to increase the content of lysine in the grain, transgenic sorghum lines carrying the gene encoding the high-lysine protein of barley, gordotinin, were obtained. *Agrobacterium*-mediated genetic transformation was used to introduce the gene encoding the high lysine analog (HTl2 protein) of the *Hordeum vulgare* α-hordothionin protein under the control of the 27 kDa maize γ-zein promoter and terminator into the genome of two sorghum lines, P898012 and PHI391. The *A. tumefaciens* strain LBA4404 contained a "super-binary" vector with two unlinked T-DNA cassettes. The one cassette contained the lysine-rich *HTl2* gene with the second cassette containing a herbicide-resistant *bar* gene as a selectable marker. The two different T-DNA cassettes in the co-transformation vector allows the segregation of the marker and trait genes in the progeny of the primary transformants. This also allows the elimination of the marker gene and consequently marker-free transgenic plants are obtained. Three high levels of the HTl2 protein were expressed in the grain of the five independent transgenic events that were co-transformed with both genes, with a 40–60% increase of lysine.

Provitamin A is very important to human health, but sorghum grain has low levels of β-carotene or provitamin A. In order to increase β-carotene content in sorghum grain, the genetic construct encoding a number of enzymes involved in the carotenoid biosynthesis pathway has been introduced into the genome of sorghum line Tx430 (Che et al. 2016). These enzymes are: 1-deoxyxylulose 5-phosphate synthase, the precursor for carotenoid biosynthesis, *Zea mays* phytoene synthase 1, and the *Pantoea ananatis* carotene desaturase, involved in synthesis of phytoene and lycopene, respectively, which are the β-carotene precursors. This introduction resulted in an increase ofβ-carotene levels in mature seeds of transgenic plants of up to 9.1 μg/g (compared to 0.5 μg/g in non-transgenic control seeds). The β-carotene in plants can degrade during storage due to oxidation. To counter this effect, the barley *HGGT* gene encoding homogentisate geranylgeranyl transferase was introduced into the same genetic construct. Homogentisate geranylgeranyl transferase is involved in synthesis of vitamin E, and this vitamin has strong antioxidant effects. It was found that co-expression of the *HGGT* gene stacked with carotenoid biosynthesis genes, enhanced all-trans-β-carotene accumulation, and reduced β-carotene oxidative degradation. This led to stable provitamin A levels in sorghum seeds. Field trials of transgenic plants with increased carotene content showed that the all-trans-β--carotene levels were increased by about 20-fold in transgenic lines compared to the non-transgenic controls (Che et al. 2019). This is an example of how effective genetic engineering can be for modifying plant metabolism to meet human needs.

Thus, development of genetic transformation techniques allowed the development of sorghum lines with significantly improved protein digestibility, increased content of lysine and other essential amino acids, and β-carotene. However, there still remains a number of unsolved problems. Future research should focus on the development of lines with reduced phytate content, which lowers bioavailability of Fe, Zn, and phosphate, as well as lines which have high protein digestibility of seed storage proteins, and vitreous endosperm. Starch digestibility is also an important question because improving the caloric value of staple food is of great importance. Identification of the naturally occurring allele of pullulanase (*SbPUL-RA*) – starch

debranching enzyme – that confers significantly higher in vitro starch digestibility (Gilding et al. 2013) shows that this trait may be improved using a genome editing approach. These innovations, coupled with development of genomics of nutritive traits, will significantly improve the gene pool of existing varieties and hybrids of sorghum and make this important crop more in demand in world agricultural production.

4 Conclusion

Sorghum is an underutilized cereal, well adapted to changing climatic conditions, which are causing increased temperatures and an increased frequency of drought spells. The inclusion of especially whole grain sorghum in the diet may help avoid chronic lifestyle illnesses. The inclusion of sorghum grain as a regular part of the human diet has the potential to reduce the risk of cardiovascular diseases, some types of cancer, and type II diabetes. Sorghum has highly resistant starch, a high fiber content, high levels of bioactive compounds, and kafirin protein with potential benefits. The bioactivity of sorghum grain is influenced by phenolic compounds such as phenolic acid, flavonoids, stilbenes, and tannins, and it is rich in procyanidins (condensed tannins) and 3-deoxyantocyanidins. Sorghum tannins, also called proanthocyanidins, have shown anti-inflammation and anticancer properties. Sorghum also contains B-complex vitamins, fat-soluble A, D, E, and K vitamins, and minerals such as potassium, phosphorus, magnesium, and zinc. The generally high antioxidant activity of sorghum grain could contribute towards combating diseases associated with oxidative stress. Sorghum grain also has cholesterol-lowering and antimicrobial properties. It also was shown to improve glucose metabolism, which could positively affect diabetes. Sorghum is gluten-free with a high fiber content, which could benefit celiac disease patients. Sorghum could therefore be included in functional foods as a source of bioactive ingredients. Of the bioactive compounds in sorghum, phenolic compounds have been the main focus for research, so there is still a lot that is not known about the other compounds. With developing technology, new bioactive compounds may also be detected.

All the studies reported so far found significant natural genetic variation for measured bioactive compounds, although the growing environment also consistently had a large influence on the expression of compounds. As was reported above, there are many untapped genetic resources available in the form of germplasm collections, which can be screened for naturally high occurrence of bioactive compounds. Significant research has been done on the genetics of kafirin protein indigestibility and to a lesser extent on compounds like carotenoids. There is, however, a large gap in the knowledge of the genetics underlying the expression of other bioactive compounds in sorghum. Linkage and association mapping, GWAS and mutant libraries have been used to research the genetic architecture of especially adaptive traits, and yield and related traits, and genetic engineering has been applied to contribute to improved protein indigestibility and carotene levels in sorghum. There is, however, scant data on the genetics of seed composition, bioactive compounds, and traits linked to the

nutritional value of sorghum grain in general. When more is known about the genes linked to nutraceuticals and the gene action involved in expression of nutraceuticals, conventional breeding can be used to select and cross parents with good nutraceutical content, markers can be developed for marker-assisted selection, and genomics and genetic engineering could be used to improve nutraceutical content. Sorghum research is lagging behind that of other commercial crops such as maize, rice, and wheat. Likewise, research on the nutritional value of grains is lagging behind research on yield and yield-related traits, adaptive traits, and disease resistance. Databases should be generated to integrate all available information on seed nutraceutical and other nutritional components, which can be used by the sorghum community for sorghum improvement and genetic studies.

Breeding Efforts on Grain Micronutrient Enhancement in Pearl Millet

Mahalingam Govindaraj and Mahesh Pujar

Contents

Abstract

The increasing population growth essentially requires more diverse food in the future. Pearl millet is a major source of diets that provides energy and nutrition for millions of people living in India and sub-Saharan Africa (SSA). Malnutrition prevalence is estimated at 2 billion people globally affected. Malnutrition is highly prevalent in India and SSA, and progress in addressing them through

various recurrent costing interventions is slow. Biofortification is a nutrition-defined cost-competitive and sustainable approach for combating malnutrition among resource-poor households in low- and middle-income countries. Enhancing grain iron (Fe) and zinc (Zn) contents is prioritized for major staples including pearl millet as these two micronutrients are predominately deficient in human populations. HarvestPlus-supported biofortification pearl millet breeding globally accomplished significantly higher levels for Fe (80 mg kg^{-1}) and Zn (60 mg kg^{-1}) in germplasm, breeding populations, and hybrid parents using conventional breeding approaches. To date, 12 biofortified hybrids are released and are benefiting more than 120,000 households. Genetic gain for Fe and Zn is gradually increased (42 mg kg^{-1} to >75 mg kg^{-1} Fe; 30 mg kg^{-1} to 50 mg kg^{-1} Zn) and is higher than yield. Average levels of Fe (42 mg kg^{-1}) and Zn (31 mg kg^{-1}) in commercial hybrids and increased climate variability for pearl millet-growing areas will affect nutrition levels besides diminishing yield potential. Therefore, breeding for yield and nutrition should go hand in hand with mainstreaming nutrition. The use of biofortified cytoplasmic male sterile (CMS) lines and restorers, breeding pipelines in crossing, and application of improved breeding methods through precision phenotyping, genomic selection, and speed breeding options can expedite mainstreaming progress in pearl millet. Bioavailability studies confirm the improved human health significance of biofortified varieties and hybrids. Accelerated public-private partnership is essential in achieving higher nutrition in competitively yielding hybrids. Consumer preferences for nutritious millet grains have increased, thus prospecting nutrient-dense varieties for improved human nutrition in India and SSA.

Keywords

Biofortification · Micronutrients · Iron · Zinc · Genomics · Mainstreaming

1 Introduction

Over 2 billion people globally are affected by at least one or more micronutrient deficiencies, which means that one-third of the global population is at risk of essential micronutrient deficiency (WHO 2019). The increasing population growth essentially requires nutrition-rich food besides energy in the future for their health and higher productivity. Pearl millet is a major source of diet that provided energy and nutrition for millions of people in India and sub-Saharan Africa (SSA) (Serba et al. 2020). Pearl millet is generally considered a nutrition-rich crop, but facts are rapidly changing owing to pearl millet breeding entirely focused on yield improvement in the last 30 years – will have a nutrient loss like other cereals. Malnutrition is preventable since it is the consequence of daily dietary nutrition deficiency. About 40% of Indian children under 5 are stunted, and 50% of women of reproductive age are anemic (NFHS, 2015–2016), whereas 24.1% of the population is malnourished in SSA (https://www.actionagainsthunger.org/africa-hunger-relief-facts-charity-aid).

Biofortification refers to a process of breeding staple food crops with higher micronutrient content in edible parts and is proven as an essential strategy in addressing malnutrition that is sustainable and cost-effective (Bouis et al. 2011). HarvestPlus program of the CGIAR supported many CGIAR and NARS centers for biofortification breeding targeting iron, vitamin A, and zinc with the main crops being beans, sweet potato, cassava, maize, rice, banana, wheat, and pearl millet (Lowe et al., 2022). The HarvestPlus-supported targeted biofortification breeding projects at ICRSIAT explored germplasm screening and investigated the feasibility of biofortification in pearl millet and aimed to support mainstreaming breeding and its goals with novel traits (Rai et al. 2014). ICRISAT pearl millet breeding program investigated the genetic variability of various grain quality traits (iron, zinc, ß-carotene) during the inception of biofortification projects. Preliminary research results revealed inadequate variability to undertake genetic improvements for ß-carotene; thus, focus was directed to Fe and Zn improvement (Rai et al. 2012b). The justification for the pearl millet biofortification initiative was very clear on millet consumer health and appropriate for additional resource mobilization for more nutrient-specific germplasm development and supporting variety/hybrid parent research in India and Africa. The major reasons for pearl millet biofortification investment are as follows: (i) more than 60% of the population in arid and semiarid tropics is malnourished, (ii) inadequate micronutrient levels among commercially grown pearl millet hybrids, and (iii) adequate genetic variation for micronutrients in breeding population and germplasm accessions. Pearl millet is cultivated close to 30 million ha globally covering five continents, viz., Asia, Africa, North America, South America, and Australia. Despite the fact that India (8 million ha) and Africa (about 18 million ha) contribute the majority of crop area (Yadav and Rai 2013). With 8.61 million tonnes, India is the world's largest producer of pearl millet (Directorate of Millets Development 2020). The major breeding goal of the ICRISAT pearl millet program is to (i) provide trait-specific germplasm and improved breeding lines and parents to NARS and other stakeholders; (ii) cultivate inter-institutional collaboration integrated conventional, participatory, and genomics-assisted breeding methods to develop widely adapted varieties and hybrid parents; and (iii) provide need-based capacity building on advanced tools and techniques. Although ICRISAT pearl millet breeding was established in the 1980s and the national program in the Indian Council of Agricultural Research (ICAR) in 1965 in India, no serious efforts were made to improve grain nutrition in pearl millet, while just a few attempts were made for screening germplasm before its inception of CGIAR biofortification program in 2005.

Screening efforts found highly significant and larger genetic variation among breeding populations (30–70 mg kg^{-1}), hybrid parents (25–90 mg kg^{-1}), and germplasm (28–120 mg kg^{-1}) at ICRISAT and NARS. On the other hand, negative correlations reported between micronutrient content and grain yield hindered the commercial breeding prospects. These studies' materials are highly selected for yield traits and not bred for micronutrients; therefore, there is no surprise in the observed trend. Some studies indicated that nonsignificant correlations bring hope for concurrent genetic improvement. In addition, a significant positive association between

Fe/Zn and grain yield has been reported suggesting the feasibility of breeding competitive biofortified varieties and hybrids in the future. Therefore, a biofortified cultivar with improved mineral content is easily accepted by consumers as it does not require a change in dietary habits. Biofortification programs in general target to improve the micronutrient content of those cultivars which have preferred agronomic and consumption traits like grain yield. HarvestPlus has initiated the development and promotion of many biofortified cultivars with improved micronutrient content across different food crops including pearl millet (Yadav et al. 2017). Systematic deliberation with ICAR, focusing on nutritional improvement besides yield improvement, was also mandatory in pearl millet. This landmark decision was taken by the pearl millet researchers to include iron and zinc concentrations as one of the promotion criteria for promoting entries in the national coordinated trials during the 52nd Annual Group Meeting of ICAR-AICRP on Pearl Millet at PAU, Ludhiana, on April 28, 2017 (Satyavathi et al. 2021). To date, 12 biofortified pearl millet cultivars have been released in India and West Africa (Govindaraj et al. 2019) and reached more than 120,000 households (https://www.cgiar.org/innovations/high-iron-pearl-millet-for-better-health/).

2 Pearl Millet and Selected Nutrition Traits

Pearl millet has significant potential as food, feed, and fodder crop in subsistence farming in the semiarid tropics. It can produce grains with high nutritive value even under hot, dry conditions on infertile soils of low water-holding capacity, where other cereal crops fail (Khairwal and Yadav 2005). The energy value of pearl millet grain is relatively higher compared to maize, wheat, or sorghum (Hill and Hanna 1990). Globally, pearl millet is cultivated on about 27 m ha of this, and India annually cultivates 9.3 m ha and produces about 9.5 m t. Pearl millet genetic improvement in India and SSA is critical for contributing to food production in semiarid tropic regions. There are many significant milestones achieved over the five decades. For instance, grain yield significantly surpassed from 4.5 kg/ha/yr (pre-green revolution [GR] era) to 31.1 kg/ha/yr (post-GR era) that accounts for a 188% increase in productivity since the green revolution (the 1970s) in India (Yadav et al. 2019). Crop improvement efforts in enhancing further grain and fodder with biotic and abiotic tolerances are being the topmost priority in both public and private sector breeding programs. The expansion of pearl millet uses to forage and dry fodders in drylands captivated the improvement in forage and fodder quantity per unit area. This supports food for humans and fodder for livestock in subsistence farming practices. Therefore, it is very clear that smallholder farming is dominant in semiarid regions and continues to be overwhelmed by numerous issues including poverty and malnutrition (Ryan and Spencer 2001; Sharma et al. 1996: Dar 2011). In semiarid tropic regions, household income and food expenditure play a significant role in determining family nutritional status (Padmaja et al. 2019). Addressing malnutrition in semiarid tropics where poverty and malnutrition persist together is not a supreme task of crop improvement history. The inception of biofortification

initiatives demonstrated the nutrition breeding feasibility and sustainability of nutrition supply to rural remote households. Biofortification breeding in pearl millet is a recent development and was led by ICRISAT in partnership with NARS in India and SSA.

In the search for nutritional functional properties from pearl millet grains, many traits are randomly reported in the past. However, their lower levels, less relevance to predominant nutrient deficiency among populations and nonsignificant genetic variations within crop genetic resources, diverted the breeding focus of Fe and Zn and some extent to proteins (Govindaraj et al. 2022). Pearl millet has an average of 11–12% proteins with moderately balanced amino acids (Shobana et al. 2013). The contribution of pearl millet to the total nutrient intake (Fe and Zn) from all foods widely varied across rural India; however, in some parts of rural India (Rajasthan, Maharashtra, and Gujarat), contribution of pearl millet to micronutrient (Fe and Zn) intake is higher. For instance, in these regions, pearl millet contributes 19–63% of the total Fe intake and 16–56% of the total Zn intake (Parthasarathy Rao et al. 2006). Therefore, it would be highly rewarding in providing additional Fe to their regular diet. Moreover, as the micronutrient requirements in human and plant nutrition are similar, genetic enhancement for grain minerals could improve human nutrition as well as farm productivity (Ma 2007). Today, addressing malnutrition is one of the priorities of the government of India, and pearl millet is one of the target crops in its NutriFarm initiative. Furthermore, a recent clinical study reveals that the bioavailability of both Fe and Zn from biofortified pearl millet is more than adequate to meet the physiological requirements for these micronutrients for children under 2 years old and young women (Kodkany et al. 2013; Cercamondi et al. 2013). Therefore, those farmers who grow biofortified pearl millet will have easy access to nutritious foods with minimal investments for their family's well-being, and surplus productions can be marketed for greater impact in millet-consuming communities. Therefore, to meet the daily energy and nutrition requirements, dietary diversity and pearl millet biofortification are very much closer and could prove to be an essential strategy for combating micronutrient malnutrition in India and SSA in the future.

3 Pearl Millet Nutrition Profile at a Glance

Overall mineral nutrition of pearl millet is generally higher than that of other major cereals such as rice, wheat, and maize (Adeola and Orban 1995). Deep looking into the differences among the commercial and breeding lines of pearl millet collection will be much higher and may exceed two- to three fold variation for most nutrition traits. A national collection of pearl millet varieties, hybrids, and key germplasm under ICAR-All India Coordinated Research Project on Pearl Millet (AICRP-PM) screened for major nutrition recently (Goswami et al. 2022). This collection consisted of 87 genotypes (mixture of varieties, hybrids, and germplasm). The starch content ranged from 50 to 63 g/100 g. Amylose content varied from 19 to 28 g/100 g; glucose and sucrose content varied in very narrow variation (<1 g/100 g). Protein content was found significantly higher (8–18 g/100 g). The anti-nutritional factors

like phytic acid content were found in a wider range (0.54–1.43 g/100 g), while the phenol content was a negligible amount (0.04–0.21 GAE g/100 g). However, the lipid variability is quite higher in this collection of genotypes (5–9%). About 20–32% of palmitic acid (C16:0), 3–8% of stearic acid (C18:0), 32–47% of linoleic acid (C18:2), and 22–33% of oleic acid (C18:1) were observed in the same collections (Goswami et al. 2022). On the other hand, high levels of grain minerals such as calcium, phosphorus, magnesium, manganese, zinc, iron, and copper in pearl millet are higher than in maize (Adeola and Orban 1995; Govindaraj et al. 2009). Values for different possible nutrients from pearl millet were listed in Table 1. Govindaraj et al. (2021) reported the wider genetic variation for P, K, Ca, and Mg content with a mean of 369, 489, 12, and 130 mg 100 g^{-1}, respectively, from large-scale field trials (14 trials) consisting of germplasm, breeding lines, commercial hybrids, and

Table 1 Nutrition profile of pearl millet foods reported in different sources

Nutrition profile	Pearl millet
Carbohydrates (Kcal)	67.5
Protein (g)	11.6
Fat (g)	5
Energy (kcal)	361
Crude fiber (g)	1.2
Mineral matter (g)	2.3
Ca (mg)	42
P (mg)	296
Fe (mg)	8
Mg (mg/100 g)	137
Na (mg/100 g)	10.9
K (mg/100 g)	307
Cu (mg/100 g)	1.06
Mn (mg/100 g)	1.15
Mb (mg/100 g)	0.069
Zn (mg/100 g)	3.1
Cr (mg/100 g)	0.023
Si (mg/100 g)	147
Cl (mg/100 g)	39
Thiamin (mg)	0.38
Niacin (mg)	2.8
Riboflavin	0.21
Vitamin A (carotene mg/100 g)	132

Vitamin B5 (mg/100 g)	1.09
Vitamin E (mg/100 g)	19

Source: Nutritive Value (macronutrients) of Indian Foods, NIN, Hyderabad, 2007
Source: Nutritive value (micronutrients and vitamins) of Indian foods, National Institute of Nutrition (2007); MILLET in your Meals, http://www.sahajasamrudha.org

advanced parents. The range of variability for these macronutrients across trials was 275–495 mg 100 g^{-1} for P, 340–725 mg 100 g^{-1} for K, 4–40 mg 100 g^{-1} for Ca, and 94–189 mg 100 g^{-1} for Mg. Similarly, the mean micronutrient contents across the 14 trials were 53 mg kg^{-1} for Fe, 41 mg kg^{-1} for Zn, and 13 mg kg^{-1} for both Mn and Na (Govindaraj et al. 2021). The magnitude of variability for macronutrients is higher than those observed for micronutrient contents with the following order K > P > Mg > Ca > Fe > Zn > Na > Mn. The results also revealed that the variability of P, K, Ca, Mg, Fe, Zn, Mn, and Na in parents/inbred trials was particularly larger than those found in the hybrids suggesting scope for improvement in commercial hybrids in the future otherwise underutilized this nutrition potential in presently grown pearl millet varieties and hybrids (Govindaraj et al. 2022). Therefore, untapped commercial feasibility prospects for genetic enhancement of these grain minerals in pearl millet along with productivity traits would greatly enhance pearl millet as the cheapest source of nutrition supply in drylands.

4 Pearl Millet Breeding at ICRISAT

Pearl millet remains one of the important staple crops in India after rice and wheat. The breeding program at ICRISAT generally develops open-pollinated varieties (OPVs) and hybrid parents (inbred lines) to produce hybrids which are the predominant cultivar type in India that covers about 5–6 m ha spread across three pearl millet cultivation zones (A, A_1, and B) of India. All these three zones are differentiated by a range of factors including plant types and environmental variables such as soil type, rainfall, and farm inputs. For example, zone A has >400 mm annual rainfall, rainy season cultivation, and sandy loam soil; zone A_1 has <400 mm rainfall, rainy season cultivation, dual-purpose OPVs and hybrids, and light sandy soils; zone B conquers with 400–700 mm rainfall and heavy and deep soils (AICRP-PM, 2020). Trait-based germplasms and elite hybrid parents are shared through the standard material transfer agreement (SMTA) process to public and private sectors to produce commercially viable OPVs and hybrids using different cytoplasmic male sterility lines (A_1, A_4, and A_5). The breeding program focuses largely on the rainy season practices in both A and B zones that require dual-purpose (grain and stover) materials, with disease tolerance to downy mildew and blast. The lead breeder has been in place since 2012/2013. Gujarat and South Rajasthan locations are used in the summer season for screening heat tolerance. The breeding is modernized and largely segmented into product profiles that target specific adaptation zone in India and SSA (https://repo.mel.cgiar.org/handle/20.500.11766/10236). The major contribution of ICRISAT and consortia is measured as more than 60% of released and commercially grown hybrids are either based on ICRISAT-bred parental lines or parental lines developed by public and private sectors from improved germplasm supplied from ICRISAT. In 2020, ICRISAT made major efforts on mainstreaming micronutrient traits in the breeding program through the product profile metrics and stage-gate pipeline development processes. Henceforth, the biofortification breeding pipelines are being merged into mainstream pre-breeding and product development.

5 Genesis of Targeted Breeding for Nutrition Traits

The growing evidence from HarvestPlus research supports the presence of a wide range of genetic variability for grain Fe and Zn contents and significant positive association between Fe and Zn and predominance of additive gene action for Fe and Zn content in pearl millet (Rai et al. 2012a; Govindaraj et al. 2013, 2019, 2020) indicating good prospects for concurrent genetic enhancement of Fe/Zn. Though an increased understanding of association and inheritance for Fe and Zn enhances breeding efficiency, however, there is less reliable information on the influence of yield on micronutrient content and vice versa. This helps to realize the level of genetic variation in grain Fe/Zn and any possible dilution and concentration effects associated with differences in the yield potential of the genotype. Studies on pearl millet (Rai et al. 2009), wheat (Morgounov et al. 2007; Shi et al. 2008; Garvin et al. 2006; Zhao et al. 2009), sorghum (Reddy et al. 2005), and maize (Bänziger and Long 2000) reported moderate to highly significant negative relationship between micronutrients and grain yield. This relation could also be affected by specific environmental conditions and particular genetic material under investigation (Bänziger and Long 2000; Brkic et al. 2004; Simic et al. 2009). Further studies need to elucidate the underlying genetic and physiological mechanisms of these relations. Towards this end, as part of the biofortification research program at ICRISAT, the present study was undertaken with the specific objectives to fulfill the breeding efficiency gaps; examine the magnitude and nature of genetic variance; combine ability, heterosis, and G $\times$ E interaction effects for Fe and Zn with agronomic traits including grain yield; and examine the relationship between Fe, Zn, 1000-grain mass, and grain yield. This information is pertinent for the development of micronutrient-dense genotypes and for devising a sound breeding approach for the improvement of Fe and Zn content without compromising the grain yield.

6 Requirement for Nutrition Breeding

The goal of plant breeding in the past and at present focuses on achieving higher yield per unit area. This has been achieved in most crops by various contributing traits such as biotic and abiotic stress tolerances. India achieved a historical food grain production record in 2021–2022 which is about 215 m t. On the other hand, the unfortunate situation of our major food crops is poor sources of micronutrients required for human well-being. To address the problem of malnutrition and staple crops' nutritional deficiency together, greater crop improvement emphasis is required with the committed vision of nutritional trait breeding besides yield improvement. Like other major crops, the pearl millet breeding program also targeted major constraints of abiotic and biotic stress tolerances and associated traits towards the ultimate goal of achieving higher productivity but not nutrition inclusive. Consequently, grain quality trait improvement is not a core breeding trait. In the interest of academic and public health, greater progress has been made in protein, iron, and zinc content improvement in the recent past by the CGIAR program in

association with NARS. It is well-known fact that it is impossible to achieve this vision in a singular crop or organization; therefore, countrywide policies and platforms should be created and liked to global networks, nutrition, and market standards. To date, no significant progress has been made and standardized breeding approaches for most required essential nutritional traits except Fe, Zn, and provitamin A (Govindaraj et al. 2019). Therefore, to meet the daily energy and nutrition requirements, dietary diversity and biofortification are very much closer than we looked in the past, and the crop improvement program should not ignore its developmental goals and investments. HarvestPlus program extends its partnership and capacity to help national and international public and private breeding sectors to set up the nutritional standards and phenotyping platforms that enable the breeding and selection of elite nutrition-rich varieties through national and regional testing networks. The major breeding requirements for nutritional traits are (i) the status of genetic variation available within the crop, (ii) a rapid phenotyping method, (iii) genetics of traits and traits associated with yield parameters, and (iv) breeding targets and publicly available standards for given nutrition traits. These requirements were briefly discussed in the following sections.

6.1 Genetic Variability

A preliminary assessment of the magnitude of genetic variability for grain Fe and Zn content in various pearl millet materials through a random sample of 120 entries that included a diverse range of hybrid parents improved populations, population progenies, and germplasm accessions (Fig. 1). Variability among these entries was 30–76 mg kg^{-1} Fe and 25–65 mg kg^{-1} Zn content (Velu et al. 2007). Recent studies

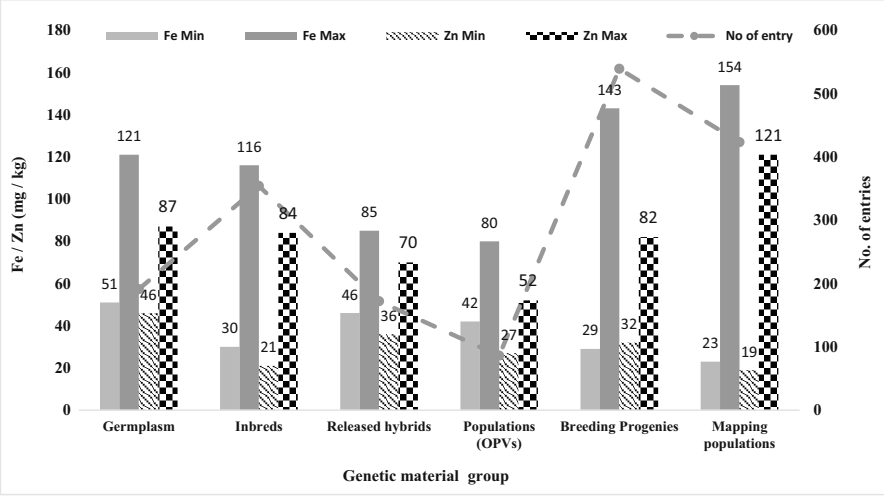

Fig. 1 Genetic variability for grain iron and zinc content in pearl millet

in the core collection germplasm accessions stored at ICRISAT differed significantly for these two micronutrients, especially with over two-fold variation for Fe (34–90 mg kg^{-1}), Zn (30–74 mg kg^{-1}), and Ca (85–249 mg kg^{-1}) (Govindaraj et al. 2020). Several field trials and research supported by the HarvestPlus Challenge Program of the CGIAR and conducted in partnerships with public and private sector research organizations have shown much large variability for Fe (30–120 mg kg^{-1}) and Zn (20–90 mg kg^{-1}) in the pearl millet germplasm and breeding lines suggesting good prospects of developing cultivars with higher levels of these micronutrients in the future without searching in unadopted germplasm as a trait source (Govindaraj et al. 2020; Rai et al. 2014).The screening of 297 Iniadi germplasm accessions from Western Africa (Togo, Eastern Ghana, Southern Burkina Faso, and Western Benin) has shown a wide variability for grain Fe and Zn content (Rai et al. 2008). Several studies in biofortification research at ICRISAT showed a wide range of variability for grain Fe and Zn densities in diverse breeding materials, for instance, Iniadi germplasm accessions (51–121 mg kg^{-1} Fe; 46–87 mg kg^{-1} Zn), population progenies (18.0–135.0 mg kg^{-1} Fe; 22.0–92.0 Zn), inbred parents (30.3–102.0 mg kg^{-1} Fe; 27.4 to 84.0 mg kg^{-1} Zn), hybrids derived from diverse inbreds (25.8–80.0 mg kg^{-1} Fe; 22.0–70 mg kg^{-1} Zn), and commercial hybrids (31.0–61.0 mg kg^{-1} Fe; 32.0–54.0 mg kg^{-1} Zn) (Govindaraj et al. 2019, 2021). Analysis of 281 advanced breeding lines exhibited substantial variability for Fe (35–116 mg kg^{-1}) and Zn (21–80 mg kg^{-1}) (Pujar et al. 2020). Overall, the mean of all the commercial hybrid grain samples assessed over sites in India indicated 42 mg kg^{-1} Fe and 31 mg kg^{-1} Zn (Govindaraj et al. 2019). Other nutrition ranges were described in Sect. 3.

6.2 Phenotyping for Grain Nutrition Traits

Sampling is a major step in nutrition estimation. A systematic study on pearl millet suggested that this crop is fortunate to qualify by the use of open-pollinated grain samples which would save time and resources (Govindaraj et al. 2011; Rai et al. 2015). More details of grain sampling are described by Govindaraj et al. (2020). In the past, two major methods were used for grain mineral estimation, namely, inductively coupled plasma optical emission spectrometry (ICP-OES) and atomic absorption spectrometer (AAS). These two were excellent tools for measuring the nutrition in plant samples; however, both are very destructive and sensitive and have higher recurring and sample cost that limits the affordability of the crop breeding program (Govindaraj and Rai 2016; Govindaraj et al. 2019). For easy breeding operation, resource efficiency, and preliminary screening purposes, HarvestPlus systematically worked with experts and manufacturers. With the great partnership and support from Waite Analytical Services (WAS) at the University of Adelaide, Flinders University, Australia, and Oxford instruments (presently the same model owned by Hitachi) brought up an innovative X-ray-based scanning tool so-called energy-dispersive X-ray fluorescence (ED-XRF). ICP and AAS methods cost 10–20 USD per sample (Rai et al. 2012b) and analyze not more than 6000 samples annually. Pearl millet breeding program handles 12,000–15,000 grain samples

every year. This would cost to program more than 120,000 USD per year in targeted biofortification breeding. Near-infrared reflectance spectrometer (NIRS), also a tool that can be used for many pearl millet grain samples, was analyzed. NIRS data are highly significant and has positive correlation with ICP values for Fe/Zn however, appeared less efficient (repeatability, low and high group distinguish) than ED-XRF in which the lines in the upper half of the Fe content were identified and lower groups were easily discarded. Selected samples at later breeding or testing stages will be screened using ICP or similar destructive methods for final validations and monitoring of any sample contaminations. After several investigations, the ED-XRF method was proven and recommended as a rapid and cost-effective screening tool for a large number of grain samples of pearl millet and other crops (rice, wheat, and sorghum). Results from this laboratory showed a highly significant and positive correlation ($r > 0.98$; Fig. 2) between ICP and XRF values, both for Fe and Zn content (Rai et al. 2012b; Paltridge et al. 2012; Govindaraj et al. 2016b). Setting up this small machine requires less space, with no recurring expenditure, and it provides nondestructive analysis of 250–300 samples per day at the cost of <2 USD/sample

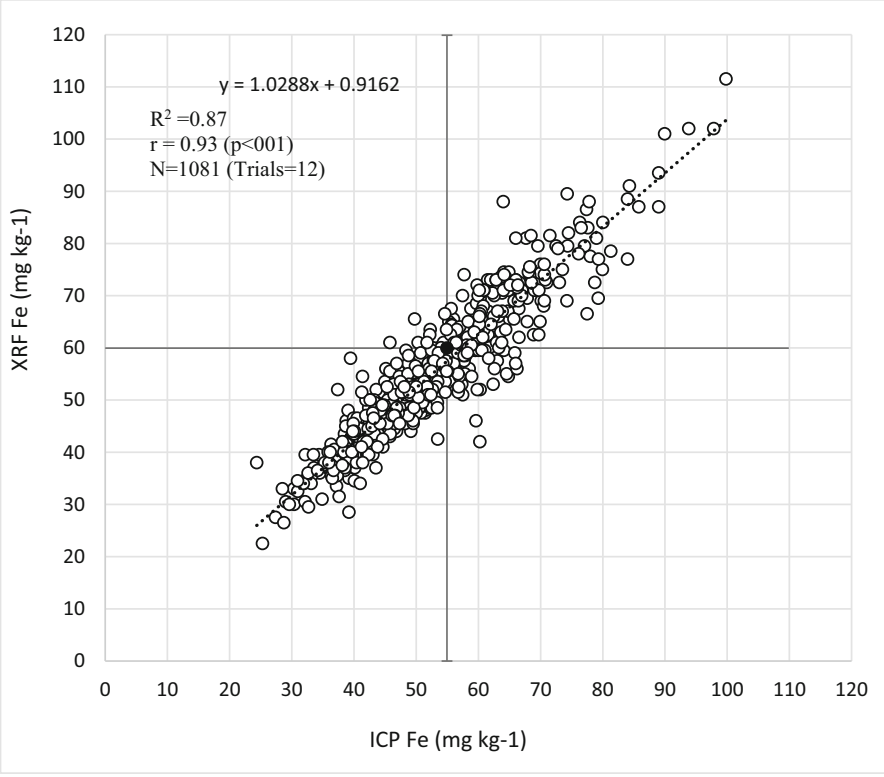

Fig. 2 Correlation between XRF and ICP data sets derived from 12 trials (1081 samples) of pearl millet

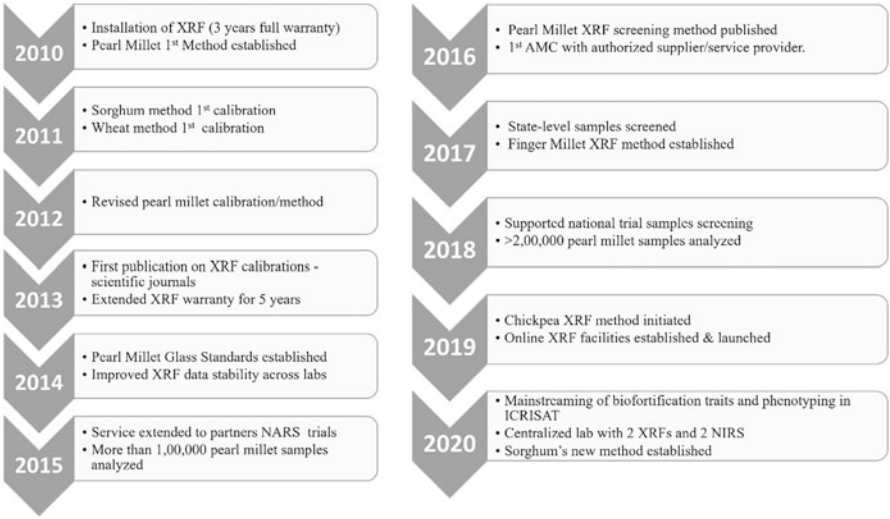

Fig. 3 Chronology of XRF tool and phenotyping facilities established at ICRISAT for pearl millet and other crops

for in-house materials. Based on these considerations, several XRF facilities were established across India (8–10 locations) and other countries (18–20 numbers) with support from HarvestPlus. Established XRF labs are key to success in accelerating and achieving the nutrition breeding targets in biofortification crops. Today, most crops have their specific standards operating screening procedures with glass standards which can ensure data quality and precision across laboratories. This tool is also being investigated for assessing other grain minerals (Ca, Se, P, and S) in the future. It is anticipated that the XRF tool can significantly reduce the cost and time not only for mineral analysis (Fe/Zn) but also for nutrition traits mainstreaming in regular breeding pipelines. Various stages of facility, development, and milestone of the XRF lab at ICRISAT are described in Fig. 3.

6.3 Nutrition Trait Genetics and Relationship with Agronomic Traits

Previous studies reported highly significant GCA and SCA effects for both Fe and Zn in pearl millet, indicating both additive and nonadditive genetic variances for controlling these two micronutrients. Both Fe and Zn contents in pearl millet are largely governed by additive genetic variance. However, all studies emphasized the magnitude of GCA variance, and its effect was much higher than SCA variance and its effect for both Fe and Zn, inferring the predominance of the additive gene for these trait expressions (Velu et al. 2011; Govindaraj et al. 2013; Kanatti 2014). In addition, other evidence indicating the grain Fe and Zn content in pearl millet is

under predominant additive genetic control included predictability ratios close to unity, a higher proportion of GCA-to-SCA ratio, and a considerably high and positive connection between the midparent value and the hybrid performance (Govindaraj et al. 2013). These findings suggest that there would be a minimal chance, if any, to take advantage of heterosis for these micronutrients in pearl millet, and breeding high Fe and Zn hybrids would require incorporating these traits into both parental lines. Since the additive genes with relatively lower G × E influence the accumulation of Fe and Zn in pearl millet grains (Govindaraj et al. 2016a; Kanatti 2014b), suggests high effectiveness of progeny selection in the pedigree selection or population breeding to develop lines and populations with increased levels of grain Fe and Zn contents. The higher additive genetic variance also prompts recurrent selection methods to improve the levels of grain Fe and Zn contents.

Besides gene action, a recent study on gene interactions performed using classical generation mean analysis revealed the existence of duplicate epistasis for grain Fe and Zn content in pearl millet and suggested avoiding the recombinant selection for high grain Fe and Zn content in early segregating generations (Boubacar Gaoh et al. 2020). The selection response and breeding behavior of the hybrid-parent breeding program are greatly influenced by knowledge of reciprocal cross differences and maternal effects. According to a study on the maternal effect on the accumulation of grain Fe and Zn content (Kanatti et al. 2018), the high-Fe trait can be incorporated into the genetic background of an elite line using high-Fe lines as either a female or male parent (considering within the seed and restorer gene pool) in a crossing program and selecting for elite agronomic performance with the high-Fe trait in the segregating populations. Furthermore, the genotype's innate ability to transmit traits from one generation to the next, or from parents to offspring, is known as heritability. Heritability is evaluated during selection and utilized as an indicator of trait transmission. Studies have shown the presence of high heritability for grain Fe and Zn contents in pearl millet indicating the genetic gain of these micronutrients can be increased by practicing simple selection.

The target attributes to be enhanced in pearl millet are grain Fe content, and Zn is improved as a related trait. This is made possible by the considerably extremely high positive correlation between Fe and Zn ($r = 0.43$ to 0.90, $P < 0.01$) (Rai et al. 2012b; Govindaraj 2012; Kanatti et al. 2016; Pujar et al. 2020). One of the important aspects while breeding for high grain Fe and Zn content is a non-compromise in the grain yield and its related attributes. Attributes such as grain size, flowering, and maturity are of economic significance that is of farmer's preference. Previous studies have shown the presence of moderate to high significant positive correlation for grain Fe and Zn content with 1000-grain weight in pearl millet (Velu et al. 2007, 2008a, b; Kanatti et al. 2014a; Pujar et al. 2020), which suggests that the improvement of Fe and Zn contents in grains would not affect the grain size. However, studies linking Fe and/or Zn with grain yield in pearl millet have found both positive and low to moderately negative associations (Gupta et al. 2009; Kanatti et al. 2014b; Rai et al. 2016; Pujar et al. 2020) and improvements for Fe and Zn in pearl millet will not reduce the grain yield since whenever the negative correlation has been detected, it is either very weak or found to be nonsignificant.

Below are key strategic findings and their breeding implications for nutrition traits

Strategic research findings	Breeding implications
• Fe and Zn are predominantly under additive genetic control and no-better-parent heterosis	• Need to breed for high Fe and Zn in both parental lines
• Mostly highly significant and positive association between line per se and general combining ability (GCA)	• Per se would be highly effective in selecting for GCA
• Large environment effect and large G × E interaction: G × E for Fe lower than for grain yield	• Need for multilocation testing through partnerships
• Cost-effective tool (XRF) for rapid analysis of Fe and Zn	• Facilitates handling of a large number of breeding lines (250–300 samples/day @ 2 USD)
• Large seed set effect, no xenia effect and dust contamination	• Open-pollinated seeds can be used for reliable estimation of Fe and Zn
• Fe and Zn highly significantly correlated, while Fe and Zn vs. grain yield mostly negatively correlated, but low to moderate and always not significant	• Simultaneous improvement for both micronutrients. High grain yield can be combined with high Fe/Zn by using large populations

6.4 Pearl Millet Breeding Priority and Product Profile

The crop breeding program has a historical target of improving grain yield per unit area through building genetically associated traits which directly or indirectly contribute to higher productivity. Breeding for nutritional traits is not an exception and has measurable as well as achievable target levels for given nutrition. Target levels were set to achieve an impact on health for the primary target population, particularly women of reproductive age and children (Pfeiffer and McClafferty 2007). Pearl millet is set to have a target increment of +30 mg kg^{-1} for Fe over the country- or region-specific baselines to achieve a required contribution to the estimated average requirement for Fe from the biofortified pearl millet. While a global baseline is estimated at 47 mg kg^{-1} and is systematically derived based on available commercial varieties at a given time, thus, in most cases, country-specific baselines may vary widely (Govindaraj et al. 2019; Govindaraj and Rai 2016). However, global breeding standards will serve as a unified reference for breeders, nutritionists, socio-economist, and market experts. Pearl millet breeding target increments (77 mg kg^{-1} Fe) are adjusted for its per capita consumption, bioavailability, and in many other processing-based crops, retention losses during processing, storage and cooking were also considered (Van Der Straeten et al. 2020). Pearl millet is generally consumed as whole grain (Govindaraj et al. 2020). WC C75 is the first ICRISAT-bred pearl millet variety which was widely grown for a long time in the 1980s and 1990s. In the initial years of biofortification research at ICRISAT, a 2-year study showed WC C75 having 42 mg kg^{-1} of Fe content (Velu et al. 2007). HarvestPlus set an ambitious working baseline of 47 mg kg^{-1} (5 mg kg^{-1}

above WC C75) and worked out a target level of 77 mg kg^{-1}, assuming 300 g/d of consumption, 90% retention, and 5% bioavailability. OPVs are the cultivars of the past, grown on <500,000 ha, while hybrids are cultivated on 4.5 million ha in India. Thus, the baseline of Fe was re-examined using more extensive hybrid trial data of this study. The relative performance of cultivars across the environment changes due to G × E interaction. However, relative means of various groups of cultivars, if the numbers in these groups are sufficiently large, are unlikely to be affected by G × E interaction. Thus, the relationship of the mean of 15 common hybrids evaluated in a two-location trial in 2011 and the ten-location trial in 2012 was used to assess the probable mean of the remaining 107 hybrids in 2012 based on their mean in 2011. And these values were used to estimate the baseline of Fe content. Product profile refers to the analysis of the resultant product to be generated through the breeding investment in terms of its performance, strength, and weakness in comparison to the already existing variety. Product profiles are defined based on the suggestions from market analysts, consumers, and multidisciplinary research and development teams. Product profile has two groups of traits: (i) must-have traits (present product preferences) and (ii) nice-to-have traits (future use). Fe and Zn are now transitioning from nice-to-have to must-have trait class in pearl millet for mainstreaming.

ICRISAT's pearl millet breeding in India has set up product profiles among which product profile 1 focuses on a 4.5 m ha area composed of A and B zones that include East Rajasthan, Central and South Gujarat, Haryana, Uttar Pradesh, Maharashtra, and Peninsular India (400–700 mm/annum). Under this, the area of prioritizations (Fig. 4) includes the development of parent lines of medium to late maturity

Trait priority		
Yield	Grain	*****
	Stover	***
Biotic Stress resistance	Downy mildew	*****
	Blast	**** (new)
	Ergot, Smut, Rust	**
Abiotic stress tolerance	Drought	** (strategic)
	Heat	** (new)
	Salinity	*
Nutrition	Iron and zinc	****(new)

** low priority and ***** highest priority*

Fig. 4 Prioritization of pearl millet genetic improvement and local testing zone in India

(70–90 days), dual-purpose (grain and fodder) nutritious (high Fe $\geq$60 mg kg^{-1} and Zn $\geq$ 35 mg kg^{-1}) hybrids with disease resistance (downy mildew and blast), for adaptation to better endowed environments. Product profile 2 focuses on Western Rajasthan and drier parts of Gujarat and Haryana. Under this, the area of prioritizations includes the development of parent lines with early maturity (65–75 days), dual-purpose nutritious (high Fe $\geq$50 mg kg^{-1} and Zn $\geq$35 mg kg^{-1}) hybrids with disease resistance for blast and downy mildew. In addition, it also focuses on the improvement in terminal drought tolerance. Figure 4 explains the pearl millet national testing, priority, and relevance for product release.

7 Status of Biofortified Hybrids and Performance

A trial consisting of 40 designated hybrid parents (20 each of seed parents and restorer parents), 30 each of improved populations and population progenies, and 20 germplasm accessions of diverse origin, was evaluated during the 2004 rainy and post-rainy seasons at ICRISAT, Patancheru. Based on the mean performance across the two seasons, 863B had the highest level of Fe (72.7 mg kg^{-1}) among the hybrid parents (Velu et al. 2007). A progeny from an open-pollinated variety released in India had 75.7 mg kg^{-1} Fe, which was the highest Fe level in the trial. These Fe levels are about twice those reported in wheat germplasm (Graham et al. 1999). It was also observed that 863B had 55.8 mg kg^{-1} Zn, ranking among the top five hybrid parents for this trait. The highest Zn level recorded for a hybrid parent in the trial was for seed parent 843B (59.6 mg kg^{-1}), while the highest Zn level for any entry in the trial was 63.7–64.8 mg kg^{-1} for the two progenies from AIMP 92901. Thus, 863B serves as an excellent source of high Fe and Zn contents in a commercial parental line. The salient features of some of the released biofortified pearl millet cultivars in India are presented in Table 2.

8 NARS Breeding Lines and Hybrids Characterized for Fe/Zn Content

The All India Coordinated Pearl Millet Improvement Project (AICPMIP) provided grain samples of hybrids tested in four different advanced hybrid trials in 2011. XRF analysis of grain samples of ten hybrids from advanced hybrid trial for A-zone (medium maturity) from Jodhpur, Rajasthan, showed the Fe content ranging from 22 to 41 mg kg^{-1} and Zn content ranging from 37 to 45 mg kg^{-1}. In the advanced hybrid trial of late maturity, the Fe content among the 16 hybrids varied from 31 to 43 mg kg^{-1} and Zn content from 33 to 43 mg kg^{-1}. In both trials, the highest Fe content was recorded for Pusa 23, a popular hybrid bred at IARI and released in 1987. The Fe content in 12 hybrids in the advanced hybrid trial for B-zone (medium maturity) at Dhule in Maharashtra varied from 43 to 62 mg kg^{-1}, and Zn content varied from 35 to 48 mg kg^{-1}. Pusa 23 and ICMH 356 (an ICRISAT hybrid released in 1993) had the highest and similar Fe content. Grain samples of 12 hybrids

Table 2 Performance and salient features of released biofortified pearl millet cultivars in India (Govindaraj et al. 2020)

Hybrid	Release year	Grain color	Grain size	Yield potential (t ha^{-1})[a]	Iron content (mg kg^{-1})[a]
Dhanashakti (variety)	2014	Dark gray	Bold	2.0	71
ICMH1202 (AHB1200Fe)	2017	Gray	Bold	3.5	70
ICMH 1203 (HHB 299)	2017	Gray	Bold	3.2	73

[a]Mean data from AICRP-PM test locations

evaluated in the advanced hybrid trial for B-zone (late maturity) were received from four locations (Dhule and Aurangabad in Maharashtra and Anantapur and Hyderabad in Andhra Pradesh). Based on the mean performance across four locations, the Fe content in these hybrids varied from 39 to 51 mg kg^{-1} and Zn content from 26 to 32 mg kg^{-1}. For the advanced hybrid trial for A-zone (late maturity) conducted in 2012, grain samples were received only from two locations. Based on the mean across the two locations, the Fe content in nine hybrids varied from 37 to 48 mg kg^{-1} and Zn content from 34 to 43 mg kg^{-1}. Grain samples of 40 breeding lines obtained from CCS Haryana Agricultural University (CCSHAU), Hisar, Haryana, and 157 breeding lines from Indian Agricultural Research Institute (IARI), New Delhi, were evaluated for Fe/Zn content. The XRF Fe content in CCSHAU lines varied from 23 to 112 mg kg^{-1}, and in IARI lines it varied from 39 to 117 mg kg^{-1}.

8.1 Commercial/Released Hybrids/OPVs Characterized for Fe/Zn Content

One hundred and twenty-eight hybrids (by name) developed by the public sector and private sector, which are released and/or under cultivation, were evaluated in 2011 under AICPMIP coordination at two diverse locations (Patancheru in peninsular India and Mandor in northern India). Based on the mean of the two locations, the ICP Fe content in these hybrids varied from 31 to 61 mg kg^{-1} and Zn content from 32 to 54 mg kg^{-1}. The highest-Fe entry in this trial was ICTP 8203, an OPV used as a high-Fe control. This variety had 73 mg kg^{-1} Fe and also the highest level of Zn

content (55 mg kg^{-1}). AICPMIP also coordinated the evaluation of 18 released OPVs at three locations in peninsular India and five locations in northern India. Based on the mean of eight locations, the ICP Fe content in these OPVs varied from 43 to 70 mg kg^{-1} and Zn content from 35 to 50 mg kg^{-1}, with ICTP 8203 having the highest levels of both micronutrients. Fifteen of the high-Fe hybrids ($\geq$50 mg kg^{-1}) for which the seeds could be available and five of the high-Fe OPVs ($\geq$53 mg kg^{-1}) identified in 2011 were re-evaluated under AICPMIP coordination at eight locations in 2012. Based on the mean performance across these locations, the XRF Fe content in the hybrids varied from 37 to 49 mg kg^{-1}. Three hybrids (86 M 86, Ajeet 38, and PAC 903) maintained their high rankings in both years. The Fe content in the OPVs varied from 39 to 64 mg kg^{-1}, with ICTP 8203 as the highest-Fe OPV. The XRF Zn content in hybrids varied from 34 to 46 mg kg^{-1}, while in the OPVs it varied from 38 to 44 mg kg^{-1}.

8.2 Elite Breeding Lines

HarvestPlus under the CGIAR consortium started the biofortification program at ICRISAT with the aim of developing high Fe and Zn biofortified hybrids and/or OPVs in pearl millet. Breeding for high Fe and Zn under the biofortification program could be able to develop several elite lines among which most of the lines were derived from the *iniadi* germplasm source. A study was conducted in which 281 advanced breeding lines (inbred lines) were evaluated for Fe and Zn contents in grains across two contrasting seasons (Pujar et al. 2020). These advanced breeding lines were collected from a diverse pool from the ICRISAT breeding program that constituted 112 restorer parents (R-lines), 110 seed parents (B-lines), 32 population progenies, and 27 germplasm progenies. The inbred performance for Fe varied from 35 mg kg^{-1} to 120 mg kg^{-1}, with an average grain Fe content of 75 mg kg^{-1}, whereas Zn varied from 19 mg kg^{-1} to 87 mg kg^{-1} with an average grain Zn content of 46 mg kg^{-1}. This accounts for three- to four-fold variability for grain Fe and Zn content among these advanced breeding lines/elite lines. Among 281 inbred lines, the top 15 elite lines with high grain Fe and Zn content identified are presented in Table 3.

9 G×E Effect on Grain Micronutrients

The grain Fe and Zn had no significant association with the available levels of these micronutrients in the soil (Govindaraj et al. 2019). In this context, it is important to note that the available Fe content at all the test locations and Zn content in most of the test locations were far above the critical levels (>2 mg kg^{-1}Fe and > 0.8 mg kg^{-1}Zn). The most extensive data on variability for grain Fe and Zn contents across the environments are available for Dhanshakti (Fig. 5), which was included as a control in several multilocation trials conducted over 3 years, giving 261 data points. Results showed that Fe content in the control variety can vary from

Table 3 Top 15 elite lines with high grain Fe and Zn contents identified in pearl millet

15	ICMR 100725	106	59

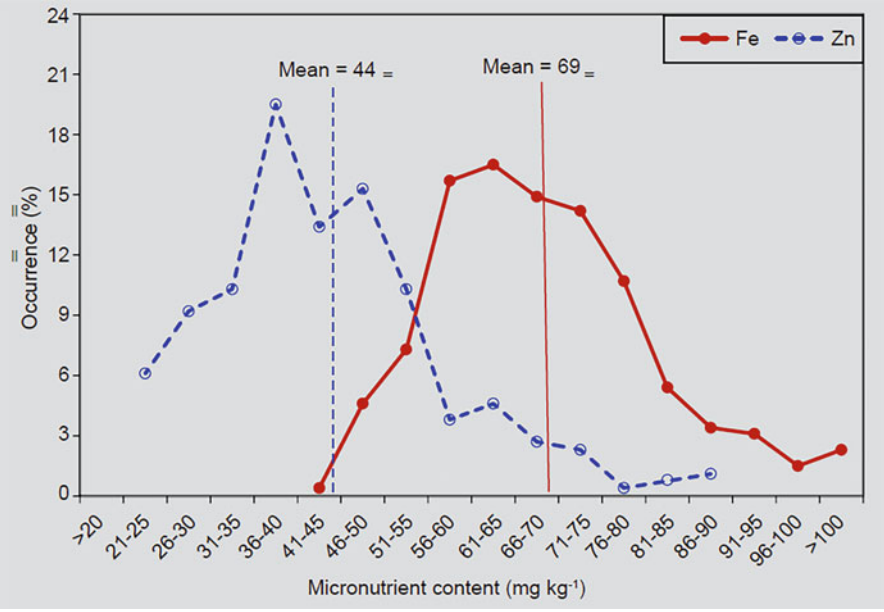

Fig. 5 Frequency distribution of Fe and Zn content in Dhanshakti across various trials pooled over location and year. (Source M Govindaraj)

40 to over 100 mg kg^{-1} and Zn content from 20 to 90 mg kg^{-1}. The mean Fe content was 69 mg kg^{-1}, ranging from 51 to 80 mg kg^{-1} in 80% of the cases, and the mean Zn content was 44 mg kg^{-1}, ranging from 26 to 55 mg kg^{-1}in 80% of the cases. This showed the extent to which Fe and Zn content can vary and the most likely levels of

these micronutrients expected in Dhanshakti. Similar variability patterns across the environments may be found in other genotypes. Significant G ×E interaction (genotype ×season) was noticed in the study conducted by Pujar et al. (2020) while evaluating 281 inbred lines for Fe and Zn contents in pearl millet grains. But it was evident that the magnitude of the effect of the environment was very less (sum of square analysis) than that due to differences caused by genotype alone. However, a trend was observed in the study wherein the magnitudes of the grain Fe content among inbreds were slightly higher in the summer season than in the rainy season, which might be due to the higher soil micronutrient absorption from the roots because of the high transpiration rate during the summer. However, the rankings of the inbreds across the seasons were consistent. A similar trend was also reported in earlier studies on pearl millet (Kanatti et al. 2014b; Govindaraj et al. 2013).

10 Conclusion

HarvestPlus-supported millet biofortification program led by ICRISAT established rapid screening platform, hybrid breeding target (72 mg kg^{-1} Fe; 45 mg kg^{-1} Zn), breeding strategy, and advanced high-Fe/Zn breeding lines that are being shared to NARS and private breeding programs. The dissemination of these nutrition-rich breeding lines and hybrid parents, and their utilization by user-research organizations (both public and private sectors) continuingly, as done so far for the non-biofortified materials, will make biofortified hybrid development a matter of routine and hence significantly contribute to improved nutrition. Mainstreaming of iron and zinc needs to be implemented in public and private sector breeding program to achieve the nutrition goal through strong national policies. Exploring other nutrition that is required for human and animal nutrition should be studied systematically, while the progress made in iron and zinc improvement will guide the process in the future. Additionally, the effects of the COVID-19 pandemic, coupled with the effects of ever-growing climate crises and food system conflicts, could exacerbate malnutrition, including micronutrient deficiencies, particularly in low- and middle-income countries (LMICs) and among young children and other vulnerable populations. Therefore, targeting most essential nutrients and vitamins including Fe and Zn besides yield and stress tolerance would be highly rewarding for millet scaling up and feeding millions of populations in semiarid tropics.

Nutraceutomics of Foxtail Millet (*Setaria italica* L.): Insights

Jyothish Madambikattil Sasi, Paramananda Barman, and Charu Lata

Contents

Abstract

Setaria italica (L.), commonly known as foxtail millet, is a C_4 model cereal with a genome sequence that is compact and completely annotated. In many parts of Asia and Africa, it serves as a primary food and feed source. In the present world, where urbanization and farmland scarcity is drastically increasing, there is an urgent need to switch to cereal crops that can be grown with less inputs, consume limited resources, withstand adverse weather conditions, and provide the majority of the human diet's essential nutrients. Under these conditions, foxtail millet is an ideal cereal crop that has the potential to significantly contribute to international efforts to improve food and nutrition security. Foxtail millet grains, which are gluten-free, are an excellent dietary staple because of their high protein, fiber, carbohydrate, calcium, zinc, iron, vitamin, and lipid content. The therapeutic

benefits of foxtail millet include antihyperglycemic, antioxidative, anti-hyperlipidemic, anti-inflammatory, and antihypertensive activities and hence are strongly recommended that this grass family member be incorporated into a person's diet on a regular basis. The purpose of this chapter is to provide an overview of the nutraceutomics of the foxtail millet and the molecular efforts employed to improve the nutritional quality along with the traditional culinary applications of foxtail millet.

Foxtail millet · Nutraceutomics · Nutrients · Omics · *Setaria* · Traditional food

1 Introduction

Millets are Poaceae family grass crops that have been cultivated for centuries. The Poaceae family consists of grasses and domesticated cereals including rice, maize, wheat, barley, millets, etc. "Millet" refers to cereal plants that produce numerous, minute seeds. Millet grains are a primary food source for many people worldwide, especially in the dry and semidry parts of Africa and Asia. Many economically relevant millets are used to produce biofuels and bioenergy products. Millets are particularly significant due to their high nutritional value and agro-industrial significance (Yousaf et al. 2021). After wheat, maize, sorghum, rice, and barley, millets are the world's sixth most important cereal grain crop. According to FAOSTAT 2020, between 2003 and 2018, nearly equal amounts of millets were produced in Asia and Africa, accounting for 96% of worldwide millet production, with the remaining 4% coming from the rest of the world (Yousaf et al. 2021). *Setaria italica* (L.) P. Beauv, commonly known as foxtail millet, is the world's second most extensively cultivated millet crop after pearl millet. Over 8000 years ago, in northern China, foxtail millet was said to have been domesticated from a wild species of green foxtail. Foxtail millet is a member of the *Setaria* genus, which consists of over 125 species predominantly spread in warm and temperate parts of the world (Lata et al. 2013). A typical foxtail millet plant attains a height of 120–200 centimeters and produces up to 13,000 seeds per plant. A thin stem terminates in a panicle of reddish or purple-hued bristles of around 5–30 cm in length. The characteristic shape of the panicle resembles a fox's tail, hence the common name "foxtail" for most cultivated *Setaria* species. *Setaria* genus members (foxtail millet [*S. italica*] and green foxtail [*S. viridis*]) are closely related to several millets, cereals, and biofuel grasses. Foxtail millet possesses a variety of beneficial characteristics, such as high photosynthetic efficiency, effective use of water and nitrogen even under unfavorable conditions, a high yield and productivity even with limited input resources, etc. In addition, foxtail millet grains are an excellent dietary staple because of their gluten-free, high protein, fiber, carbohydrate, calcium, zinc, iron, vitamin, and lipid content. The 2012 release of the *S. italica* genome sequence has substantially aided the development of large-

scale genomic resources (Bennetzen et al. 2012; Wang et al. 2012). Foxtail millet is a promising model for functional genomic studies in millets, cereals, and bioenergy grasses due to its small diploid genome (515 Mb), self-fertilization, and short cycle lengths (Lata et al. 2013; Lata and Shivhare 2017). Furthermore, because it is capable of NADP malic enzyme-type C_4 photosynthesis, it has become a model crop plant for genetic studies.

According to traditional Chinese medicine, consuming foods with pharmacological properties, such as foxtail millet, can reduce the chance of developing chronic diseases or even heal them. Foxtail millet is particularly well known in China for its beneficial effects on the digestive tract of humans. Recent research studies on foxtail millet have highlighted the anti-inflammatory, hyperglycemic, antihypertensive, and antihyperlipidemic potential (Akoh and Min 2007; Chow 2008; Hou et al. 2018; Jali et al. 2012; Li et al. 2022). Selection and, to a lesser extent, recombination breeding have primarily been used to improve foxtail millet crops (Hariprasanna et al. 2017). This crop's unique floral morphology and flowering behavior make it challenging to pursue crosses between the ideal parents. Therefore, foxtail millet has a limited potential for conventional breeding. Molecular marker-based, population studies and multi-omics approaches are needed to improve the breeding of foxtail millet.

2 Nutritional Composition and Therapeutic Values of Foxtail Millet

2.1 Nutritional Composition

The foxtail millet has more nutrients than other cereals like wheat and rice (Bandyopadhyay et al. 2017). Millet grains are a good source of nutrients, have a low glycemic index, are low in phytic acid, and do not contribute to stomach acid production. Millet is often referred to as "nutricereal" because it contains more nutrients per gram than other cereals. These include phytochemicals, micronutrients, antioxidants, and essential amino acids (except lysine and methionine) (Jali et al. 2012; Singh and Raghuvanshi 2012). According to some sources, foxtail millet (cultivar 'RAU-8') possesses the highest level of seed proteins among all millets (Chandel et al. 2014). In addition, foxtail millet ranks among the millets with the highest contents of protein, fat, ash, crude fiber, thiamine, and riboflavin (Bandyopadhyay et al. 2017).

Amino acids, both common and essential, have their foundation in proteins. Seed storage proteins (SSPs) found in millet grains are vital in facilitating seed germination after embryo development is complete. However, sulfur-containing amino acids like methionine and cysteine are more abundant in millets. All primary essential amino acids are present in foxtail millet except tyrosine (Table 1). The predominant amino acid found in foxtail millet is leucine (1040 mg/g of protein) followed by isoleucine (480 mg/g of protein) and valine (430 mg/g of protein). Foxtail millet also has the highest concentration of leucine and isoleucine of any millets (Bandyopadhyay et al. 2017). The foxtail millet has more elevated amounts of

Table 1 Nutrient composition of foxtail millet (Saleh et al. 2013; Bandyopadhyay et al. 2017)

almost all essential amino acids than rice and wheat. Vitamins, an externally supplied dietary requirement, play a crucial role in maintaining human physiological homeostasis. Foxtail millet grains, like other types of millets, are an excellent source of a wide variety of vitamins (Table 1). The crop has more significant amounts of all vitamins except vitamin B6. It has the most significant concentrations of thiamine and vitamin E among millets as well as rice and wheat (Bandyopadhyay et al. 2017). The vitamin profiling of foxtail millet revealed that it is a good source of vitamins A and E and folic acid. In addition, foxtail millet is a good source of calcium, iron, magnesium, potassium, etc. Analysis of the mineral composition of foxtail millet revealed an abundance of potassium, followed by sulfur, magnesium, chlorine, and calcium (Table 1). According to the reports, foxtail millet is one of the richer sources of zinc and iron, with levels of 2.4 and 2.8 mg/100 g of grain, respectively. Foxtail millet generally has consistently higher contents of significant minerals and can serve as an effective supplement to our conventional dietary practices. Moreover, foxtail millet is an excellent source of fatty acids such as stearic and linoleic acids, both found in relatively low concentrations in other millet varieties and in cereals that are not classified as millet.

2.2 Biochemical Pathways Highlighted in Foxtail Millet

It was shown that the foxtail millet cultivated in various locales had significantly variable metabolites, likely due to the weather conditions in those areas (Yang et al. 2021a, b). Foxtail millet's secondary metabolite profile revealed an excess of flavonoids, especially in their glycosylated forms (Li et al. 2018). This indicates the enrichment of the flavonoid biosynthetic pathway in foxtail millet. Flavonoids have a multitude of beneficial medical effects, including anti-inflammatory, antiviral, and anticancer activities. Moreover, they shield the brain and heart from damage (Ullah et al. 2020). In contrast to other cereals, foxtail millet has been shown to have a significantly higher concentration of flavone O-aglycones, which may be the product of an enriched gene duplication event. A similar accumulation of phenolamides, which are 100 times more abundant in foxtail millet than in rice, has been documented. Phenolamides have long been crucial in various biological functions, such as plant growth and development, resistance to pathogens, and protection from abiotic stressors (Li et al. 2018). Phenolamides have been found to have beneficial benefits against metabolic syndrome and neurological illnesses, in addition to their antioxidant, anti-inflammatory, anticancer, and antibacterial capabilities (Roumani et al. 2020).

2.3 Therapeutic Uses

Localized inflammation is a defensive reaction involving several cells and chemicals. It is often associated with excessive secretion of pro-inflammatory cytokines, such as IL-1b, IL-6, or TNF-a, which can cause harm to the immune

system and hamper organ function, in addition to inducing or aggravating several disorders (Favalli 2020; Guo et al. 2020; Navarro-González and Mora-Fernández 2008). Anti-inflammatory testing using grain extracts from several foxtail millet accessions showed that most foxtail millet grain extracts inhibit the generation of pro-inflammatory mediators of macrophage response (Li et al. 2022). This highlights the possibility of using foxtail millet as an anti-inflammatory agent. It is well documented that millets are an excellent source of carbohydrates, which are needed for the health and operation of the digestive tract (Flight and Clifton 2006). They give the body the fuel to function and aid in delivering vital micronutrients (Eastwood 2003). Millets, particularly foxtail millet, are low in saturated fat; nonetheless, they are an excellent source of polyunsaturated fats, which help in reducing low-density lipoprotein (LDL) cholesterol (Akoh and Min 2007). As a result, having low levels of LDL cholesterol lowers the chance of developing heart disease; hence, consuming low-LDL foods like foxtail millet is essential for ensuring adequate nutrition (Chow 2008).

Nutritional stability relies on a steady intake of essential amino acids. Lysine is a necessary amino acid for humans and animals (Tomé and Bos 2007). Therefore, the latent genetic variety of foxtail millet, which has a wide range of lysine content, may be helpful for human nutrition and animal feed. Thiamine, or vitamin B1, is essential for proper energy metabolism (Bettendorff et al. 2014). However, in economically developed countries, thiamine deficiency, which can lead to the potentially fatal disease beriberi, is uncommon due to dietary diversification and thiamine fortification of grains (Dwyer et al. 2015; Nathoo et al. 2005). However, in locations where nutritional sources of thiamine are restricted, such as Southeast Asia, thiamine deficiency does occur (Coats et al. 2012; Khounnorath et al. 2011). There is significant variation in the amount of thiamine found in foxtail millet germplasm, which suggests that it may have potential application in breeding. Increased popularity and production of foxtail millet, considered suitable food for diabetics, could contribute to reducing the worldwide prevalence of diabetes (Kam et al. 2016). In contrast to other cereal foods like rice and wheat, foxtail millet provides a steady stream of glucose without disrupting the body's metabolism (Jali et al. 2012). It is documented that incorporating foxtail millet into the diet has an antihypertensive effect (Hou et al. 2018). According to clinical trials, consuming 50 g of foxtail millet daily can reduce blood pressure, body mass index, body fat percentage, and fat mass. Additionally, this improved blood glucose levels.

3 Genetic Resources of Foxtail Millet

About 125 species make up the genus *Setaria*, which is found all over the world in warm and temperate climates (Dwivedi et al. 2012). Various phenotypic features within and across species, as well as a wide range of life cycles, ploidy levels, and breeding strategies at the genus level, suggest a highly complicated taxonomy for the *Setaria* genus, which includes both cultivated and wild species. Three separate gene

pools for the *Setaria* species have been found due to variations in genome structure. The AA genome, annotated with the genetic parameters 2n = 2x = 18, represents the primary gene pool of foxtail millet (Benabdelmouna et al. 2001a). Probably evolved from a natural cross between the diploid species *S. viridis* (green foxtail) and *S. adhaerens* (bristly grass), the weedy tetraploid species *S. faberi* (giant foxtail) and *S. verticillata* (bristly grass) both carry an AABB genome (Benabdelmouna et al. 2001b). The remaining landraces of *Setaria*, including *grisebachii, queenslandica, pumila,* and *pallide-fusca*, make up the tertiary gene pool. A diploid species known as *S. grisebachii* with a CC genome is also reported from Mexico (Wang et al. 2009). While *S. pumila* (yellow foxtail) and *S. pallide-fusca* are likewise polyploidy *Setaria* species, they lack the AA genome and are therefore not autotetraploid like *S. queenslandica* (Benabdelmouna et al. 2001a, b; Benabdelmouna and Darmency 2003). However, *S. pumila* and *S. italica* have been recognized as separate species of *Setaria* based on the appearance of their inflorescence. Both the *viridis* and the *italica* subspecies belong to the species *S. italica*. Once again, the *italica* subspecies have been classified into three races and ten subraces (Upadhyaya et al. 2011).

4 Molecular Marker Studies and QTLs Associated with Nutritional Value

The development of DNA-based molecular markers has aided in mapping genes and quantitative trait loci (QTLs) for use in plant breeding and producing genetic maps. In foxtail millet, substantial work has been conducted on developing large-scale genome-wide markers, generating maps, and tagging agronomically important genes and QTLs (Muthamilarasan et al. 2015). Intron-length polymorphisms, transposable-elements-based markers, microRNA (miRNA)-based markers, and expressed sequence tag (EST)-derived simple sequence repeats (SSRs) have all been developed due to the availability of the foxtail millet genome sequence (Kumari et al. 2013; Muthamilarasan et al. 2014; Pandey et al. 2013; Yadav et al. 2014; Zhang et al. 2014). A gene that is responsible for the "spikelet-tipped bristles" (*stb*) trait in foxtail millet was mapped by Sato et al. in 2013. This trait is essential in determining grain yield (grain number per panicle) in foxtail millet. By utilizing two F_2 populations, as well as transposon display (TD) markers and SSR markers, the location of the *stb1* gene on chromosome 2 was determined (Sato et al. 2013). Using information from the foxtail millet genome sequence, they also produced unique SSR markers, formed nine linkage groups with a total length of 1287.5 cM, and mapped *stb1* more precisely on chromosome 2. Earlier, Fang et al. (2016), by employing a Longgu7 x Yugu1 F_2 intraspecific population, detected 29 QTLs for 11 agronomic traits. In order to create a high-density genetic map, 167 members of a Yugu1 Longgu7 F_2 population were genotyped using 1013 SSR markers demonstrating polymorphism between Yugu1 and Longgu7 (Fang et al. 2016). There were 1035 loci on the genetic map, which covered a distance of 1318.8 cM at an average marker separation of 1.27 cM. In a natural population of 184 foxtail millet accessions from various regions, Gupta et al. (2014) found eight SSR markers on distinct chromosomes

that showed significant relationships with nine agronomic traits (Gupta et al. 2014). In order to investigate, extract, retain, and examine the untrodden genetic diversity of foxtail millet at the molecular level and discover the variability of its nutritional traits, Trivedi et al. (2018) analyzed 30 accessions from the Central Himalayan Region that possessed unique characteristics of agronomic significance. There was a wide variety in the nutritional aspects of husked grains, including dietary fiber, carbohydrate, protein, lysine, and thiamine content (Trivedi et al. 2018). The assembled germplasm repository might be used to generate nutritionally rich and agronomically favorable varieties of foxtail millet and to build strategies for harnessing utilizing unexploited genetic variety for food and nutrition security in agro-ecological regions. There have been many reports of molecular marker research on foxtail millet, but only a small number of these have focused on the nutritional characteristics of the crop.

5 Genomics-Aided Breeding for Nutritional Traits

5.1 Functional Genomic Studies

During the past decade, numerous studies and attempts have been made by the scientific community at large using various molecular genetic tools to investigate and enhance crop plants' nutrient use efficiency. Among these are the implementation of genome-wide association studies (GWAS), functional genomic approach, molecular marker-assisted breeding (MAB), and characterization of nutrient transporter genes. Functional genomic research on nutrient transporters is a crucial aspect of the various strategies implied. Crop plant yield, quality, and the plant's ability to overcome unfavorable conditions of low nutrient soils are all affected by nutrient use efficiency, which refers to the nutrient acquisition and utilization efficiency (Nieves-Cordones et al. 2020). The mechanism of nutrient transport in plants has been studied using foxtail millet as a model system. In addition, the recent research has opened up new possibilities for using foxtail millet as a C_4 model system to understand better and improve nutrient use efficiency (Ceasar 2022). To date, foxtail millet transporters for a variety of nutrients, including phosphate, potassium, boron, nitrogen, iron, zinc, ammonium, amino acid, and sugar, have been identified (Alagarasan et al. 2017; Ceasar et al. 2017; Liu et al. 2022; Nadeem et al. 2018; Wang et al. 2022; Yang et al. 2021a, b; Zhang et al. 2018). Uptake and redistribution of inorganic phosphate (Pi) have been linked to the phosphate transporter 1 (*PHT1*) family of candidate genes, and the expression patterns of these genes in foxtail millet have been studied (Ceasar et al. 2014; Nadeem et al. 2020). Twelve different PHT1 family members were discovered in foxtail millet (*SiPHT1;1–1;12*). Of these 12, downregulation of the *PHT1;2* genes significantly affected yeast growth, foxtail millet phenotype, and Pi transport, suggesting that this transporter is crucial for Pi uptake and export (Ceasar et al. 2017). Similarly, nitrate transporters involved in nitrate uptake in foxtail millet have been identified (Nadeem et al. 2018). Using forward and reverse genetic methods, a boron (B) transporter gene (*SiBOR1*) was

recently characterized in the cultivar Yugu 1 (Wang et al. 2022). This gene is an ortholog of the rice B transporter OsBOR1. Panicles showed prominent expression of *SiBOR1*. Overall, it appears that SiBOR1 is required for the development of the panicle to keep the grain yield in the foxtail millet stable.

Amino acid transporters (AATs) are essential for plant growth and development because they control the transmembrane transfer of amino acids. Long-distance amino acid transport, seed germination, quality development, sensitivity to pathogenic microbes, and abiotic stress are all examples (Yang et al. 2021a, b). Scientists have identified 94 AAT genes in foxtail millet, dividing them into 12 distinct subfamilies. A subclass of amino acid transporters, amino acid permeases (AAP) genes are closely associated with grain development and quality formation in numerous species. The amino acid contents of lysine, phenylalanine, leucine, and aspartic acid were found to be lower in an *Arabidopsis* AAP mutant (AtAAP6). The differential expression of SiAAP20, a homologous gene of AtAAP6, is proposed to explain the observed variation in leucine content between foxtail millet and other species. In a comparison of the two C4 plants, maize and foxtail millet, the expression of the sugar transporter, SWEET proteins, was found to be significantly higher in maize leaves (Liu et al. 2022). Higher sugar transport capacity from leaves to seeds in maize can be attributed to the higher expression of SWEET proteins in maize than in foxtail millet. It is possible that this is what keeps the carbohydrate content of foxtail millet so low compared to rice, wheat, and maize. Recent years have seen the isolation of candidate genes and gene families from foxtail millet, including resistance gene analogs, *SiNAC*, and the calcium sensor CaM gene. These have opened the door to developing functional markers for MAS and breeding for nutritional quality improvement and blast disease resistance (Puranik et al. 2011; Weng et al. 2009).

5.2 Genome-Wide Association Studies (GWAS)

Genome-wide association studies (GWAS) are essential to examine complex trait genetics. This method is preferable to interval mapping since it provides a higher resolution, uses past recombinations, allows mining a large number of alleles, and requires less time and effort. A recent report by Jaiswal et al. (2019) detailed for the first time the genetic determinants of ten nutritional elements in foxtail millet, including potassium, nickel, calcium, boron, magnesium, phosphorus, sulfur, zinc, manganese, and iron. A genome-wide association study (GWAS) was performed using 93 diverse accessions and 10,000 SNPs. Seventy-four marker-trait associations (MTAs) were connected with the ten elements listed above, with ten MTAs displaying high confidence (those associated with B, Mg, Zn, and Fe). In addition, a sizeable pyramiding effect demonstrated that connected elements might be substantially enhanced by merging numerous MTAs (Jaiswal et al. 2019). High-throughput multi-omics techniques and platforms are being developed, which will aid in metabolically deciphering the mysteries of domestication (Zhan et al. 2022). Li et al. (2022) attempted to establish a relationship between the transcriptome, metabolome, and anti-inflammatory properties of foxtail millet through a multi-omics

investigation. In order to gain a better understanding of the genetic and metabolomic variations among foxtail millet accessions, the research team conducted a high-throughput and comprehensive study on a diverse collection of foxtail millet germplasms (398 geographically diverse accessions) from China. Profiling these accessions' metabolomes revealed a significant difference in metabolites between foxtail millet and its wild relative *S. viridis*. Compared to foxtail millet, *S. viridis* displayed more fluctuation and lower overall levels of 1104 metabolites. These metabolites included serotonin, N-acetylserotonin, N-(p-coumaroyl) serotonin, trimethoprim, etc. Researchers also performed a metabolite genome-wide association study (mGWAS) to understand the genetic basis for the observed diversity in metabolic characteristics among millets. Possible causes of variance in metabolic characteristics were narrowed down to 511 genes, which were linked to 692 lead SNPs (Li et al. 2022). Li et al. (2022) used mGWAS data along with genetic and biochemical evidence to show that the foxtail millet gene *SiPSY1* encodes a limiting enzyme in the carotenoid biosynthesis pathway, thereby contributing to the millet's yellow color and the production of carotenes.

6 Traditional Practices and the Necessity of Protecting Them

Genetic resources, especially Plant Genetic Resources for Food and Agriculture (PGRFA), are essential and significant in ensuring food security. These are vital to sustainable agriculture. In addition, climate change impacts like drought, global warming, salt, temperature, and sporadic floods are the primary challenges to dependable crop production. In this way, plant genetic resources (PGR) and traditional knowledge (TK) contribute to the resilience of food crop production in the face of climate change. Despite widespread knowledge of the health benefits of millet, it is generally only consumed by indigenous peoples. This is because there are not enough convenient, accessible, or ready-to-eat alternatives to staples like rice and wheat. There have been recent efforts to make millets more accessible to consumers in more accessible forms, primarily due to their high fiber content (Deshpande and Poshadri 2011). Bread (fermented or unfermented), porridges, and snack foods are just some of the many traditional foods that can be made from millet in many parts of Africa and Asia, especially among the less privileged members of those regions' societies (Chandrasekara et al. 2012).

As a precaution against drought during sowing, Chinese farmers traditionally keep a variety of landraces that mature at different rates or are resistant to heat (Li and Wu 1996). In addition, a traditional practice of keeping specific cultivars with a short life span is also practiced in China as a precaution against drought and other natural disasters like frost and pests. Since plant thinning by hand is so time-consuming and labor-intensive, using landraces with varying growth rates could facilitate more efficient scheduling of sowing, management, and harvest. Over many years of farming, farmers developed methods for choosing the best seeds for the following year's planting. Farmers choose the best panicles in the field according to their favored ideotypes (Li and Wu 1996). The chosen panicles were allowed to dry in the open air.

As a result of the spikelets in the middle of the panicle beginning to blossom and produce grains earlier than the rest, these spikelets can obtain more nutrients that have been translocated from other organs. Each end of the panicle was removed, and the remaining parts were combined and threshed. Farmers also placed a premium on seed purity, focusing extensively on eliminating genetically diverse seed samples through a process known as "seed picking." Sun-drying, drought hardening (soaking and drying two or three times), and fumigation by burning toxic plants were common pre-sowing seed treatments used in China to improve germination vigor, drought resistance, and disease prevention, respectively (Li and Wu 1996).

Foxtail millet is also known as *tarreang* in Indonesia. This region is home to a number of local cultivars of foxtail millet, many of which are cultivated and processed by the local people into a wide range of traditional foods (Ramlah and Daryono 2020). During the festival season, the foxtail millet porridge known as *ule-uleq* is usually prepared. In addition to being processed into porridge, *tarreang* can also be processed into various other forms of local food that are processed using coconut milk. Some examples of these forms include *Sokkoltarreang*, *Jelly tarreang*, *Buras tarreang*, *Jepagollamamea*, *Jepaanjoroi*, and *Dodoltarreang* (Ramlah and Daryono 2020). Foxtail millet is the primary ingredient in Nigeria's national dish, *tuwanaduwa*, which is prepared using traditional methods (Issoufou et al. 2017). *Korramurukulu* is the name given to a beverage made from foxtail millet that does not contain any alcohol (Ramashia et al. 2021). Foxtail millet and Bengal gram flour are the two primary ingredients in the preparation of *korramurukulu*.

PGR and TK are being utilized commercially by stakeholders in developed nations due to the rapid development of technology in various domains (Salgotra and Gupta 2016). Both developing and developed countries can benefit from indigenous peoples' wisdom. However, the rewards accruing from TK use are not being distributed fairly. Developed country's stakeholders have granted IPRs on the vast majority of PGR and related sources, with benefits being shared with local and indigenous communities. However, most nations' intellectual property laws are not robust enough to safeguard their PGR and TK. The debate over IP protection for the TK of indigenous farming communities has opened a new line of inquiry into moral concerns. Due to the unawareness of TK and IP laws protecting them, most of these issues' international disputes remained contentious and unresolved. It is imperative that these issues be discussed at the international level with world organizations, stakeholders, and NGOs to find solutions to these complex problems. Indigenous peoples should be provided with up-to-date information through IPR-related awareness programs (Salgotra and Gupta 2016).

7 Conclusion and Future Prospects

Foxtail millet, one of the world's oldest and most widely grown crops, has a high tolerance for soils with low fertility. It serves as an excellent experimental platform for researching the genetics of C_4 plants. Functional genomic investigations were

hastened by the availability of the genome sequence, leading to the characterization of various dietary features. Foxtail millet's anti-diabetic, antihypertensive, anti-hyperlipidemic, and antioxidative potential makes it a vital part of any healthy diet in a society where lifestyle disorders are so prevalent. Foxtail millet, formerly an overlooked and understudied crop, is now recognized as a high-quality genetic resource with many practical applications. Although various functional genomics, proteomics, metabolomics, and population studies have been reported on foxtail millet, the number of studies concentrating on the millet's nutritional properties is minimal. Applying omics or multi-omics techniques to enhance the nutritional quality of foxtail millet could potentially open up new avenues for plant breeding initiatives using this ancient grass crop. The substantial diversity of molecular clustering and nutritional features and the correlation between the two can be utilized to build further techniques tailored to produce nutritionally dense variations.

Genetic and Genomic Resources for Harnessing the Health-Related Genes in Finger Millet

S. Antony Ceasar and B. Kalyan Babu

Contents

Abstract

Finger millet (*Eleusine coracana* (L.) Gaertn) is a nutrient-dense cereal crop grown and consumed by resource-poor farmers in India. Finger millet grains contain a higher content of minerals such as calcium (Ca), phosphorus (P), iron (Fe), and manganese (Mn) compared to other major cereals. Notably, it has a tenfold higher Ca in seeds than other major cereals. This chapter covers the wider information on finger millet, including nutrient profile, nutritional importance, genetic resources of health-related (HR) genes, genetic diversity in HR gene-rich germplasm, molecular mapping of HR genes, genomics-aided breeding for HR traits, present concepts and strategies developed including genetic engineering

and genome editing by clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein (Cas) system, and role of bioinformatic tools for finger millet improvement. Especially the genome sequence of finger millet was released recently, and the completely annotated genome sequence is also freely available for researchers for mining gene and protein sequences. The completely annotated genome sequence will aid in high-resolution genetic studies. The annotated genome sequence will also help apply the CRISPR/Cas tool for the functional characterization of key genes, such as those involved in grain calcium accumulation in finger millet. Thus, it will help improve calcium transport in other millets and non-millet cereals in the future.

Nutrition · Health-related genes · Molecular breeding · Genetic engineering · Genome editing

1 Introduction

The growing world population has put pressure on the food demand. The Food and Agriculture Organization (FAO) estimates that the world population may increase by 10 billion in 2050 (FAO 2017). Food demand is expected to increase between 59% and 98% by 2050 (McKenzie and Williams 2015). We need to improve food production to meet the food demand, especially amid the adverse effects of climate change. It is not only the quality of the crop production but also the quantity of the seeds that should be improved to meet the nutritional requirements. The quality of the crop is directly linked to human health (Cakmak and Hoffland 2012; Zhao et al. 2020). Worldwide, over three billion people suffer from various health problems due to low nutrient content in their diet (Krishna et al. 2022a, b). The major cause of malnutrition problems is the low nutrient content in the consumed food grains, mainly affecting children and pregnant women (WHO 2016). Enrichment of nutrient content in the edible part of the crop is a major area of research in the present scenario. Therefore, agriculture scientists are trying to improve crop quality in different ways.

The finger millet (*Eleusine coracana* [L.] Gaertn.) is one of the most important foods and nutritional security crops of the future (Ceasar et al. 2018; Maharajan et al. 2021, 2022a). It is well recognized worldwide due to its nutritional properties and related health benefits (Cakmak and Hoffland 2012; Thapliyal and Singh 2015). It has higher nutritional properties than other major staple grains such as rice and wheat (Shobana et al. 2013). Finger millet contains a rich source of calcium (Ca) (0.38%), other minerals (2.7%), dietary fiber (18%), phenolic compounds (0.3–3%), etc. (Poonia et al. 2012; Shobana et al. 2013; Thapliyal and Singh 2015). They are popularized for human health benefits such as antidiabetic, anti-tumorigenic, atherosclerogenic, antioxidant, and antimicrobial properties (Gull et al. 2014). Due to their nutritional value, finger millet is called nutria-millet or nutria-cereals (Swaminaidu et al. 2015). Further improvement of finger millet may provide food and nutritional security on a long-term basis in the future.

Plant breeding is essential for crop improvement. In the past, phenotype-based (conventional) breeding approaches significantly impacted crop improvement (Patra et al. 2020). Usually, it is a time-consuming process, and phenotype-based breeding approaches hamper the efficiency of crop improvement due to environmental factors (Krishna et al. 2021). Advanced finger millet research may help identify quantitative trait loci (QTLs)/genes/alleles related to nutritional traits. It provides the opportunity to improve the finger millet through breeding approaches. Nowadays, next-generation sequencing (NGS) technology provides the opportunity for precision breading through genome-assisted breeding (GAB) (Van et al. 2013). The NGS platform helps to understand the genome organization of crops through genotyping-by-sequencing (GBS) technology (Krishna et al. 2020). It easily identifies desirable traits on a genetic basis and improves breeding efficiency. It is considered a next-generation breeding approach (Ray and Satya 2014). We hope that the genome-based breeding approaches help improve finger millet quality and strengthen nutritional security.

A complete and fully annotated genome sequence is also available for finger millet which provides an opportunity to design advanced forward and reverse genetic studies like those performed in other model cereals like rice. It also helps to mine genes and proteins for any novel work. The genome sequence is also helpful in applying genome editing tools like clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein (Cas) system in finger millet for targeting specific genes. Genome editing will help characterize the key genes in finger millet and transfer such genes to other millets and cereals.

2 Nutritional Importance

With the emergence of more diabetic and coronary diseases among the world population, healthy food is becoming prime important worldwide. During the old days, people consumed many types of millet as part of their food, along with unpolished rice and wheat, which has a major role in maintaining a healthy life. However, with the advancement of technology and busy life, people are crazier toward highly polished rice, not considering millets as part of their food since there is a misconception that those are food for poor people only. Because of this, many health issues are emerging which can be tacked eco-friendly through nutritious crops. In this connection, nowadays, more awareness is created among people to consume millets, especially finger millet, for reducing diabetes, coronary health issues, and obesity and to maintain a good healthy life. In the present "nutrigenomics" era, integrating nutrition values with genomics has become popular for gene identification, cloning, and marker-assisted selection. Finger millet is considered a nutrition hub of many nutritional parameters like a high amount of Ca and protein and rich in fiber, aiding in reducing malnutrition in many developing and underdeveloped nations (Millet network of India 2010). National academies of the United States also considered finger millet as "super cereal," the most nutritious cereal crop (National Research Council 1996). It is known for its nutritional value mainly because of its rich source of Ca, which is ten times more than wheat, maize, or brown rice (Antony and Chandra 1998) and three times more Ca in

milk. Ca helps in vascular and muscular strengthening, reducing certain types of cancer, and reducing the weight of the body and also helps in the reduction of diabetes (Pittas et al. 2006). On average, finger millet consists of 340–360 mg/100 g Ca content (Shobana et al. 2013). Along with Ca, it has a high amount of iron (Fe), polyphenols like phytochemicals, and polyunsaturated fatty acids. It is also loaded with high essential amino acids like tryptophan, lysine, and methionine (McDonough et al. 2000) which are very much required for human growth. These essential amino acids are not produced by human metabolism and hence should be supplemented by external sources like food supplements like finger millet. Recently, it is called "super cereal" by some authors (Kumar et al. 2016) due to its high nutritional properties.

Human diseases like diabetes, chronic coronary cardiovascular diseases, and cancer are closely associated with reactive oxygen and nitrogen species. The seed coat in the grain of finger millet consisted of high phenolics like benzoic acid having antioxidant properties, as reported by Chandrasekara and Shahidi (2010). Even among finger millets, brown varieties have more phenolic compounds than the white seed coat finger millet varieties Subba Rao and Muralikrishna (2002). Finger millet can help in bringing down aging (Hegde et al. 2002) by shrinking the toughness of the tendon and blood vessel tissues. Finger millet also has ferulic acid and vitamin B17, which are reported to help treat cancer (Kawabata et al. 2000) and in the case of esophageal cancer (Griffin 1974). The abundance of calcium and magnesium (Mg) in finger millet decreases the type 2 diabetes risk by reducing the glucose levels in the blood. Even consuming a lesser amount of methanolic extracts of nearly 3 mg from finger millet flour aids insignificantly inhibiting glycation, which is a major part of diabetes pathogenesis (Hegde et al. 2002).

People consuming millets, especially finger millet, as part of their routine food have fewer chances for cardiovascular disease, which is proved in many reports worldwide (Lee et al. 2010). The fiber component of the finger millet reduces the low-density lipoprotein (LDL) cholesterol (bad cholesterol) and triglycerides, which are the main causes of heart-related problems. These soluble and insoluble fibers of finger millet seed coat and grains also improve digestibility and reduce gastrointestinal problems, which has become a substitute for wheat and rice since it is gluten-free (Chandrasekara and Shahidi 2012). It also arrests constipation due to its high cellulose content. Because of its multi-nutritional advantages like high Ca, protein, fiber content, antioxidant properties, high vitamins, and essential amino acids, it is popularly called super cereal. A brief review of the nutritional properties of whole millet is available (Kumar et al. 2016), which readers can access to enhance their knowledge.

3 Genetic Resources of Health-Related (HR) Genes

Finger millet has rich genetic material like landraces, wild cultivars, and traditional varieties grown by farmers who are not fully exploited for their effective use in finger millet breeding programs. All these genetic materials have very good nutritional importance, climate-resistant alleles, high genetic variability, and other useful

parameters. However, compared to major cereals like rice, maize, and wheat, the germplasm of finger millet is not much used to that extent due to less research focus on millet crops, especially finger millet, where few genetic studies were carried out.

At the global level, only one organization, i.e., International Crops Research Institute (ICRISAT), Hyderabad, a part of the Consultative Group on International Agricultural Research (CGIAR) organizations, has a good amount of genetic material collection of approximately 6000 accessions (Sood et al. 2016). Upadhyaya et al. (2006) conducted an exhaustive study to sort out this whole germplasm into a small core collection representing 6000 accessions regarding genetic diversity and morphological characteristics like qualitative and quantitative parameters. This core collection has nearly 622 accessions. Further, Upadhyay et al. (2011) developed a mini-core collection to reduce the number of accessions for easy analysis studies while maintaining all the essential parameters like genetic variation, quality parameters, and quantitative traits. The genetic material in the collection originates from South America, Asia, Europe, and Africa. The mini-core has germplasm with the origin of countries like Uganda, India, Tanzania, and Kenya. These core and mini-core collections are being shared with many research groups in the nation's interest for various studies on material transfer agreements. Babu et al. (2014) identified more than 100 genotypes having more than 0.85% of tryptophan, which can be used as a good source of essential amino acids. It was reported that genotypes like GE1437, IE6240, and GE2136 had a high amount of tryptophan and lysine and would probably be the best source to promote healthy finger millet germplasm. Likewise, they also found GPHCPB1, GE1680, and GE1621 with more protein content. The above-reported germplasm can be effectively used for alleviating malnutrition in the country. Germplasm with special traits can be used for many breeding purposes to develop abiotic and biotic stress-resistant hybrids with good nutritional properties. Yadav et al. (2020) reported very good germplasm with a high amount of calcium content, viz., GPHCPB45, GPHCPB44, and GPHCPB31, which can be used directly for avoiding malnutrition in developing and undernourished countries. This type of genetic material can be the best source of nutritional food in the world for reducing health-related issues.

4 Genetic Diversity in HR Gene-Rich Germplasm

The beginning of molecular studies in finger millet started in 1995 for studying the molecular divergence and origin of five finger millet species using first-generation molecular markers like random amplified polymorphic DNA (RAPD) and inter-simple sequence repeat (ISSR) markers (Salimath et al. 1995). However, the finger millet genetic diversity pace went very slow compared to major cereals like maize, rice, and wheat. Later in 2004, the assessment of diversity at the molecular level started again using RAPD and ISSR markers in India (Fakrudin et al. 2004). From that time onward, several workers started exploiting the landraces and locally available germplasm for molecular studies (Babu et al. 2007; Dida et al. 2008).

All these genetic diversity analyses were for morphological traits, mostly for their pre-breeding programs. However, from 2010 onward, there has been a focus on assessing molecular diversity for nutritional property germplasm using various molecular markers like RAPD, ISSR, expressed sequence tag-derived simple sequence repeat (EST-SSR), and simple sequence repeat (SSR) markers. Panwar et al. (2010), for the first time, used RAPD, SSR, and cytochrome P450 markers for the genetic diversity of 52 accessions sourced from the northwestern Himalayan region of India. The clustering pattern differentiated low-, medium-, and high-calcium-content genotypes using these markers, and they observed a very wide genetic base among the germplasm. Nirgude et al. (2014) observed high variation in protein content, and using EST-SSR markers, they studied the genetic level variation among finger millet germplasm. This study reported molecular markers for genetic variations for grain protein and Ca contents. For the Ca content of finger millet grains, several reports are available which are focused on using mainly SSR and single nucleotide polymorphism (SNP) markers (Sharma et al. 2017; Yadav et al. 2020). Sharma et al. (2017) studied the population structure of finger millet accessions collected from different regions of India, including mini-core collection. Babu et al. (2014) studied the genetic diversity and population structure of a large number of germplasm (190) using candidate gene-based EST markers and genomic markers for tryptophan and lysine content. These essential amino acids are required for human health as described in the earlier section, i.e., nutrition importance.

5 Genetics and Molecular Mapping of HR Genes

As described earlier, finger millet is a super cereal with many nutritional properties. Gene/QTL identification for these nutritional properties plays an important role in marker-assisted breeding programs. QTL mapping was started in 1998 by the John Innes Centre, a research group using restriction fragment length polymorphism (RFLP) markers, covering a total of 1100 cM distance into 27 linkage groups (Gale and Devos 1998). After that, finger millet research took a long time to construct other genetic maps. Genetic maps play a crucial role in any breeding and marker-assisted breeding for the generation of improved varieties with desirable traits. From 2007 onward, there were no genetic mapping studies for QTL identification until 2011. Bharathi (2011) studied a large number of germplasm for QTL identification on morphological traits using a limited number of SSR markers. Since the finger millet genome was not sequenced till 2018, most of the focus of the researchers was to exploit the sequence information available in closely related crops like rice, maize, wheat, and foxtail millet. For nutrition-related traits, Babu et al. (2014) found significant loci/QTL for protein and tryptophan content for the first time. They found one EST base marker (OM5) linked to tryptophan content related to the 27-KDa *gamazein* gene of maize. Likewise, the results detected one more significant QTL for the RISBZ candidate gene linked by FMO2EST1 which explained 9% of phenotypic variance. Kumar et al. (2016) identified SNP markers

linked to candidate genes of Ca transporter for variation in whole-grain Ca content. They resolved 23,000 SNPs from 33 GB of sequenced information. Sharma et al. (2017) reviewed calcium nutrition value in finger millet, its bioavailability, and genomics. Yadav et al. (2020) identified significant loci influencing Ca content through association mapping. Their results showed that UGEP60 could be a potential molecular marker to detect high Ca content lines in finger millet.

6 Genomics-Aided Breeding for HR Traits

Humans mainly depend on plant-based food for their daily lives (Sands et al. 2009). Good-quality plant foods are essential to maintain good health (Welch 2002). It also leads to preventing malnutrition issues worldwide. Plant breeders are working to develop new varieties of crops that are beneficial to human health through innovative breeding approaches. In the past, conventional breeding approaches have contributed to improving the quality of many crop plants (Tahir ul Qamar et al. 2020). But it has some drawbacks; the phenotypic-based breading is influenced by environmental factors and reduces the efficiency of crop improvement (Krishna et al. 2021). Therefore, understanding the structural and functional characteristics of the finger millet is crucial for their improvement through GAB (Krishna et al. 2022a, b). Remarkably, marker-assisted selection provided the opportunity for precise crop breeding through GAB. The genome-wide assessments of the genetic variation for the desirable traits of finger millet germplasm may help improve the quality of finger millet (Krishna et al. 2021).

NGS technology is employed for whole-genome sequencing (WGS), which helps understand the genome organization of crop plants. It helps accurately predict the genetic basis of phenotypic variation of the genotypes (Maharajan et al. 2022b). The NGS technology has provided the foundation for whole-genome scan studies such as genome-wide association studies (GWAS) and genomic selection (GS). These two approaches are helpful for the identification of desirable traits for finger millet improvement through high-throughput sequence technology like the GBS method. The GWAS and GS approaches are widely adopted for their efficiency during crop improvement. In GWAS, many valuable QTLs have been identified in cereal and non-cereal crops such as rice (Bollinedi et al. 2020; Verma et al. 2022; Zhang et al. 2020), maize (Ndlovu et al. 2021; Ruanjaichon et al. 2021; Zheng et al. 2021), wheat (Muhu-Din Ahmed et al. 2020; Rathan et al. 2022; Shi et al. 2022), sorghum (Cruet-Burgos et al. 2020; Nida et al. 2021), foxtail millet (Jaiswal et al. 2019a, b; Jia et al. 2013), proso millet (Boukail et al. 2021), pearl millet (Pujar et al. 2020; Yadav et al. 2021), etc. The GWAS can also be applied to identify QTL associated with HR traits. A little effort was paid to GWAS in finger millet compared with other cereal and non-cereal crops. However, GWAS has been used to identify finger millet's nutritional and yield-related QTL. For example, Tiwari et al. (2020) identified QTL and genes linked to seed protein and grain yield in finger millet using 2977 high-throughput SNP markers through the GBS method. In silico approaches revealed that the QTL marker was linked to the candidate gene responsible for seed protein content in finger millet

(Tiwari et al. 2020). Furthermore, the candidate gene *aspartyl protease* was found to be responsible for seed protein content in finger millet (Tiwari et al. 2020). Puranik et al. (2020) analyzed the six nutritional traits (Fe, zinc (Zn), Ca, Mg, potassium (K), and sodium (Na)) using 190 finger millet accessions by GBS method and identified the marker-trait associations (MTAs). In this study, 169,365 SNPs were generated from GBS method, and out of these 418 SNPs were associated with various nutritional traits of finger millet (Puranik et al. 2020). Sharma et al. (2018) generated SNP markers by GBS using 113 finger millet accessions and identified reliable SNP markers linked to agro-morphological traits and grain yield in finger millet. These studies provide an opportunity to improve the finger millet's nutritional quality through GWAS. The GS-related study is not yet available in the finger millet. Huge germplasm is available in finger millets; it includes cultivars, breeding materials, landraces, training populations, wild relatives, etc. Therefore, plant breeders must utilize the finger millet germplasm for GWAS and GS approaches. It may help to identify the QTL markers and candidate genes related to human health, which will strengthen nutritional security in the future. Recently, a GWAS was conducted to identify the genes related to high seed Ca content (Sharma et al. 2022). They have identified SNP markers for candidate genes, including *calmodulin-binding protein (CBP*) and *CBL-interacting protein kinase 7 (CIPK7*) of foxtail millet, and these two genes (*EcCBP* and *EcCIPK7*) were highly expressed in high calcium genotypes of finger millet (Sharma et al. 2022).

7 Recent Concepts and Strategies Developed

Genome editing is a recently added toolbox for plant scientists to precisely identify and improve crop plants' genomic regions. Especially many researchers quickly adopted the CRISPR/Cas9 system for plant improvement studies. Cas9 system has offered a quick, easy, cost-effective procedure and emerged as a potential alternative to the previously used tools like mega-nucleases (MNs), Zn-finger nucleases (ZFNs), and transcription activator-like effector nucleases (TALENs) (Doudna and Charpentier 2014; Jinek et al. 2012). Based on CRISPR/Cas9 system, which majorly works for targeted gene disruption (gene knock-out), several other variants of CRISPR systems have been developed for diverse applications such as transcriptional regulation, point mutation, and correction of a small portion in DNA. These include dead Cas9 (dCas9) for transcriptional regulation (Qi et al. 2013), CRISPR base editor for inducing point mutations (Keiji et al. 2016), and CRISPR prime editor for donor-free specific DNA editing even for small deletion or insertion mutations (Anzalone et al. 2019; Hillary and Ceasar 2022). However, these tools have not yet reached the millets, including finger millet (Ceasar 2021). CRISPR/Cas9 was the earlier tool applied widely in plant science research since it cleaves double-stranded DNA straightaway. It helps for the gene knock-out studies with a simpler construct design strategy. But this tool is not yet applied to any millet, including finger millet.

Genome editing requires a complete and fully annotated genome sequence. Genome sequence helps identify a specific gene or region of the gene to be targeted by genome editing tools. For example, CRISPR/Cas9 system requires designing specific guide

RNAs (gRNAs) to target the genomic region precisely. Thus, the gRNA design demands the plant's fully annotated genome. Now the fully annotated genome sequence of finger millet is freely available for mining genes and further annotations through the phytozome website (https://phytozome-next.jgi.doe.gov/). So the target regions for guide RNAs can be designed and applied in the finger millet for knock-out studies.

Similarly, many other CRISPR tools, like the base editor and prime editor, could also be applied in finger millet for targeted genome editing. In some cases, the annotated genome sequence is also required for resequencing the genome to confirm any off-target effects during CRISPR/Cas9 knock-out. So the annotated genome could be helpful for genome resequencing finger millet following the CRISPR/Cas9 application.

Apart from a fully annotated genome sequence, another requirement is the availability of an efficient transformation system to deliver the CRISPR constructs for the targeted genome editing. Many transformation protocols have been reported for finger millet (Vetriventhan et al. 2020; Ceasar 2021). The *Agrobacterium*-mediated transformation has predominantly occurred in finger millet (Vetriventhan et al. 2020). Direct and indirect regeneration methods were employed to recover the transgenic plants after the transformation with the concerned constructs. Shoot apex explants were predominantly used for the infection and co-cultivation with the *Agrobacterium* in the genetic transformation studies (Vetriventhan et al. 123 AD). So the transformation protocols reported for the finger millet will be useful for introducing CRISPR constructs and developing the mutant finger millet. CRISPR/Cas system has been harnessed to develop plants with superior traits in the past (Song et al. 2016). This system will be very useful in characterizing key genes involved in the Ca transport to the seeds. Such studies will help identify key genes and transfer such genes to other millets and non-millet cereals for improving nutrient transport and seed fortification.

8 Brief on Genetic Engineering for HR Traits

Significant research progress has been made in genetic engineering for crop improvement in major crops like rice. Genetic engineering helps in the genetic manipulation of crop plants with desirable traits. For example, Ceasar et al. (2017) developed a novel *Agrobacterium*-mediated gene transformation system, and it has been successfully used to functionally characterize the *phosphate transporters 1*(*PHT1*) family genes in foxtail millet. It provides the opportunity to improve crop plants efficiently. Genetic transformation protocol is crucial for crop improvement for inserting or manipulating desirable genes. Many researchers have successfully developed an efficient *Agrobacterium*-mediated gene transformation system in finger millet (Ceasar and Ignacimuthu 2011; Satish et al. 2017). So far, many HR genes/QTLs have been identified in finger millet (Kumar et al. 2015; Singh et al. 2014; Tiwari et al. 2020). The genetic manipulation of finger millet transgenic approaches may help develop a nutrient-rich improved variety. It has some problems associated with accepting transgenic crops from regulatory bodies. Crop improvement through transgenic approaches is not safe for human health.

CRISPR/Cas system discussed above offers transgene-free engineering in crop plants. It helps to alter (remove, insert, or mutate) the desirable gene in the specific genomic regions of the targeted crop (Kim et al. 2021). Many reports have been available for improving the nutritional content in crop plants through CRISPR/Cas9 system. For example, the knock-out of the *GmFAD2–1* gene using the CRISPR/Cas9 system enhanced the oleic acid content by 16–55% in soybean seeds (Chen et al. 2011). The CRISPR/Cas9 system has successfully been used to develop transgene-free soybean plants (Haun et al. 2014; Wang et al. 2019). Application of CRISPR/ system could help identify and improve the nutrition-related genes in finger millet.

9 Brief Account of the Role of Bioinformatics as a Tool

The bioinformatic tool plays a significant role in crop improvement programs. It consists of two subfields, such as (1) computational tools and (2) databases, which help to understand living systems (Xiong 2009) better. It helps analyze and interpret various data types, including nucleotide sequences, amino acid sequences, protein structures, protein domains, etc. Bioinformatic tools and databases have provided considerable progress in plant biology by providing scientists with access to genomic information. So far, many genome-based public databases and tools are available in crop plants (Lai et al. 2012). For example, Phytozome (https://phytozome-next.jgi.doe.gov/) is an easily accessible large plant genome portal of the Department of Energy's Joint Genome Institute (DOE-JGI). It helps the plant research community access, visualize, and analyze plant genomes. It also allows mining the gene and conducting comparative genome studies. The complete and annotated genome sequence of finger millet is now available in Phytozome (https://phytozome-next.jgi.doe.gov/info/Ecoracana_v1_1). Many researchers have highlighted the use and application of bioinformatics (tools and databases) in crop improvement (Arora et al. 2018; Kushwaha et al. 2017). Recently, Ceasar's group has mined and analyzed major nutrient transporters of finger millet using various computational tools (Maharajan et al. 2022a). They collected all finger millet gene and protein sequences and analyzed the phylogeny relationship. Homology modeling was also conducted with appropriate protein templates to identify the key functional residues (Maharajan et al. 2022a). We hope the annotated finger millet genome sequence could help in the future for comparative genome analysis, gene mining, protein analysis, etc. It could be helpful for the identification of HR traits for finger millet improvement.

10 Future Prospects

Indian diet is predominantly vegetarian, based on cereals and legumes. Indian people are all accustomed to the high amount of carbohydrates and protein. Therefore, many pregnant women and older people are severely affected by Ca deficiency in India. Ca supplementation with tablets is an alternative strategy used to prevent Ca deficiency.

Although Ca tablet is cheap, straightforward, and more accessible, it suffers from side effects due to excessive Ca accumulation in vascular and soft tissues like arteries and kidneys, which may lead to heart attack and kidney stones. Finger millet grains contain more minerals such as Ca, phosphorus (P), Fe, and manganese (Mn) than other major cereals. Despite possessing a rich nutrient profile, only a few candidate genes have been identified in finger millet related to nutrient transport. No candidate genes have been characterized yet for transport function. The draft genome sequence of two different finger millet genotypes (ML-365 and PR-202) was released from 2017 to 2018. The fully annotated genome sequence is also available for mining genes and proteins. The availability of genome sequence paved the way for the GWAS to find the key genes related to nutrient fortification. Reverse genetic studies using genome editing tools like CRISPR/Cas can also be applied to finger millet to dissect the key genes involved in Ca transport and grain filling in the future. Such studies will help understand and transfer such traits into millets and non-millet cereals like rice.

11 Conclusion

Finger millet is a nutrient-dense cereal majorly grown and consumed by the poor people in Asia and Africa. The mechanism of nutrient uptake from the soil and fortification in the seeds is poorly understood. Several low resolution studies using molecular-markers have been reported for grain nutrient content before the release of the genome sequence of the finger millet. The fully annotated genome sequence of finger millet is now available, which provides the opportunity to mine and characterize the HR related genes in finger millet. This will provide the opportunity for high resolution studies with genetic and genomic tools. Genome editing tools like CRISPR/Cas may also help to this end. These studies may help to understand the HR genes and transfer or engineer such genes in other millets and non-millet cereals contributing to future crop breeding to strengthen the food security.

Abstract

Proso millet (*Panicum miliaceum* L.) is a climate-resilient, ancient, and gluten-free cereal. This allotetraploid crop is healthy for humans and the environment. Its use as human food is steadily increasing, especially for people with diabetes and celiac disease due to its exceptional nutritional properties and gluten-free starch. There is no comprehensive review on proso millet seed nutraceuticals quantity, quality, characteristics, genetics, genomics (omics), and genetic improvement strategies. This review article aims to summarize published research on these aspects of proso millet seed nutrients and nutraceuticals. There are lots of reports on proso millet seed nutrients (macro, micro, and secondary metabolites) and their health benefits. There are a significant number of resources of "omics" tools for proso millet overall genetic improvement. However, no or very little genetic and genomic information (e.g., genes and genetic control mechanisms) and biosynthesis of majority of the nutraceuticals of proso millet seed are available. It may take years to see the full potential of "omics" for proso millet nutraceutomics. Phytochemical analyses and omics technologies are getting more efficient, faster, and cheaper. With this new opportunity, it is essential that proso millet scientists around the world especially food technologists, plant breeders, and geneticists of both public and private sectors work collaboratively for the genetic improvement of proso millet for nutraceutical. This will stimulate industries to use more proso millet in food products for human health and nutritional security under global climate change.

Climate-resilient · Gluten-free · Health-promoting · Omics · GWAS · Genomic selection · Nutraceuticals

1 Introduction

Proso millet (*Panicum miliaceum* L.), a small-grain, annual cereal, belongs to the *Panicoideae* subfamily of the Poaceae family. It is one of the earliest cereal crops domesticated by mankind. It was reported that proso millet was domesticated around 8000 BC in the semi-arid regions of northern China (Lu et al. 2009). This minor millet is known by different names in different geographical locations. The word "proso" is a pan-Slavik name for millet (Santra et al. 2019). In the USA, it is

commonly referred to as common millet or hog millet. Proso millet is also known as broomcorn millet in China; common millet in Japan, Korea, and other Asia-Pacific countries; Gijang in Korea; Barri in India; Mijo in Spain; Hersey millet in Germany; and French white or panic millet in France (Santra et al. 2019; Das et al. 2019). This millet is globally distributed owing to its wide adaptability to different climatic zones. The most notable countries producing proso millet are China, the USA, India, Ukraine, Russia, Nepal, Belarus, Turkey, and Romania (Das et al. 2019) (Fig. 1). Proso millet seeds were brought to the USA in 1875 by German-Russian immigrants who first cultivated this cereal along the eastern Atlantic coast of the country. Its cultivation later spread westward into the interior of the North American continent (Wietgrefe 1990; Santra 2013; Habiyaremye et al. 2017).

Proso millet plants are erect, 30–100 cm tall with hollow stems (known as *culm*) and an adventitious root system (Baltensperger 2002). Proso millet plants develop 10–45 cm long, drooping panicles which can be either open (*lax*) or compact. The grains (botanically known as *caryopsis*) are normally 3 mm long and 2 mm wide. A great deal of variation is observed in the panicle's shape and grain color. The panicle morphology can vary widely from its shape (e.g., compact, open, semi-open), attitude (e.g., erect, semi-erect, dropping), and branches (e.g., lax, medium, and dense). The grains can be white, cream, yellow, red, orange, brown, green, black, or tan (Santra et al. 2019). Proso millet is predominantly self-pollinated with ~10% cross-pollination. It is considered an allotetraploid with nine basic sets of chromosomes ($2n = 4x = 36$). The proso millet genome is estimated to be 930 megabase pairs (Mbp) (Zou et al. 2019). Hunt et al. (2014) studied the evolution of proso millet species. Proso millet was believed to have evolved through the natural hybridization of two diploid progenitors followed by the natural polyploidization. Hunt et al. reported that diploid witchgrass (*Panicum capillare* L.) and one diploid parent of the

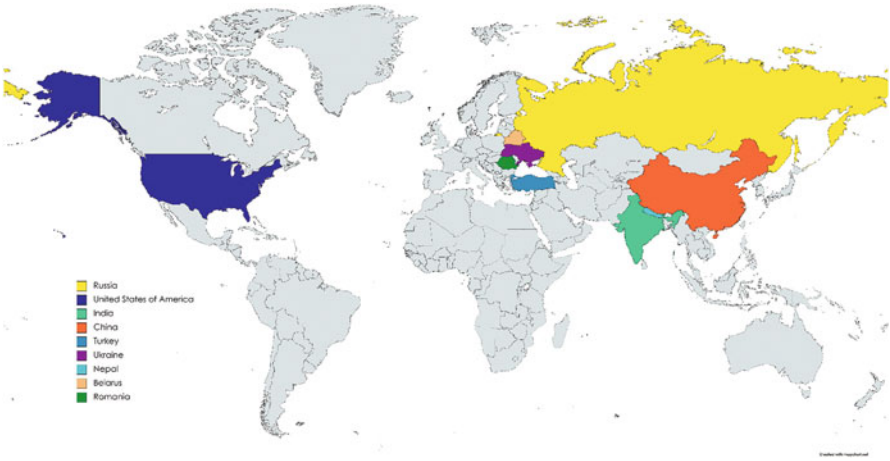

Fig. 1 Major proso millet growing countries in the world. (The map was created on mapchart.net (https://www.mapchart.net/world.html))

tetraploid torpedo grass (*P. repens*) are the probable diploid parents of proso millet (Hunt et al. 2014).

Proso millet is primarily cultivated in the predominantly winter wheat-growing semi-arid areas of the High Plains of the USA (Rajput et al. 2016). This region receives an average annual precipitation of ~400 mm. Conserving soil by minimizing water loss and maintaining high organic matter is paramount to sustaining agriculture in this dry region. The usual practice of summer fallow to preserve soil moisture often leads to depletion of soil organic matter (Nielsen and Calderón 2011). Planting wheat following corn and millet and only millet reportedly doubled the productivity in comparison with the wheat-fallow system (Anderson et al. 1999). Even though a wide selection of crops, such as corn, teff, millets, soybean, and peas, are available for crop rotation, proso millet stands out as a rotational crop for the dryland production system. This is because proso millet, being a C4 crop, has exceptional water-use efficiency and can survive harsh conditions like drought, high temperatures, and limited available nutrients (Habiyaremye et al. 2017). This cereal has a short-growing season (60–90) days, which allows it to avoid prolonged exposure to drought conditions. Besides, the shallow root system (90–120 cm) conserves deep soil moisture for the next crop (Das et al. 2019). Cultivation of proso millet lowers weed, disease, and insect pressure on wheat (Habiyaremye et al. 2017). All these attributes make proso millet an excellent choice as a rotation crop in rainfed agricultural systems under water-stress situation.

Millet is considered a nutraceutical and functional food because of its superior seed nutrients such as starch, proteins, vitamins, minerals, dietary fibers, and antioxidant activities. It also has other bioactive compounds such as resistant starch, lipids, phenolic acid, flavonoids, lignin, phytosterols, phytic acid, and tannins present in millets that have health-promoting properties (Tripathi et al. 2021). Proso millet is gluten-free and is abundant in vitamin B, iron, calcium, potassium, zinc, and magnesium (Das et al. 2019). Proso millet could be exploited as nutraceuticals and used in therapeutic applications for chronic diseases such as obesity, cardiovascular diseases, cancer, and diabetes (Majid and Priyadarshini 2020). Millets are grossly neglected as human food despite being highly nutritious primarily due to a lack of awareness. The increasing number of reports on health benefits of millets in recent years generated a renewed interest in using millets for biomedical research. Proso millet grain has protective and preventive effects against old age-related diseases such as diabetes, high blood pressure, cardiovascular diseases, cancer, Parkinson's disease, and other metabolic syndromes (Kalinová 2007).

The use of proso millet grain for human consumption predates recorded human history. This small grain was widely used for preparing traditional sweet and savory cuisines in Russia, China, and Germany thousands of years ago (Santra and Rose 2013). Proso and other millet-based food are quite common in many countries in Asia and Africa. However, this ancient grain is largely under-utilized in developed countries in Europe and North America despite its remarkable nutritional and health-promoting properties (Das et al. 2019). Proso millet grains are primarily used as birdseed and animal feed in the USA and Europe (Santra et al. 2019). Nevertheless, these grains are primarily used for human consumption in several countries

including China, Korea, Japan, India, and Russia. Many traditional cuisines and commercial food products are prepared from whole millet grains. Proso millet grains are used in porridge, rice-based meals, noodles, bread, pasta, flour, pancakes, and alcoholic beverages (Santra et al. 2019; Das et al. 2019). Proso millet grains can be used for ethanol production like corn (Rose and Santra 2013).

The term "omics" is commonly used to refer to a broad field of science and engineering focusing on the interactions among biological information objects pertaining to various "omes" (https://omicstutorials.com/home/). It involves collective quantification and characterization of collections of biological molecules that define the structural and functional attributes of an organism. The primary focuses of omics are on (1) mapping information objects such as genes, proteins, and ligands, (2) finding interaction relationships among the objects, (3) engineering the networks and objects to understand and manipulate the regulatory mechanisms, and (4) integrating various "omes" and "omics" subfields. The five major types of "omics" are (1) genomics, which deals with the analysis of the DNA sequence; (2) transcriptomics, which deals with the analysis of transcribed RNA; (3) proteomics, which focuses on proteins present in a sample; (4) metabolomics, which involves identification and quantification of all metabolites in a sample; and (5) miRNAomics, which studies regulatory mechanisms underlying control of transcription of genes. Here, we introduced a new term called "nutraceutomics" to describe the comprehensive study associated with all phytochemicals present in seeds of food crops (proso millet in this chapter) and their effects on human health and nutrition.

The goal of this chapter is to provide a comprehensive review of available literature for (1) proso millet seed composition and their impacts on human health, (2) variabilities of the seed compositions within proso millet germplasm available across the globe, and (3) genetic improvement for changing proso millet seed compositions through breeding (conventional and modern) and biotechnologies.

2 Proso Millet Seed Nutraceuticals

A nutraceutical is defined as any substance that is a food or part of a food and provides health benefits, including the prevention and treatment of disease. The term nutraceutical is the hybrid of "nutrition" and "pharmaceutical" and was coined by Stephen Defelice in 1989 (Kalra 2003). Nutraceuticals can be of two types: (1) macronutrients such as carbohydrates, proteins, lipids, and fibers (Table 1) and microelements such as minerals (Table 2) and vitamins (Table 3) and (2) secondary metabolites such as polyphenols, flavonoids, etc. These nutraceuticals in proso millet are discussed below.

2.1 Starch

Starch, a polysaccharide, is the major portion (97.1%) of the total saccharides (64.5 g/100 g) in proso millet (Kalinová 2007). Like in any other cereal, there are

Table 1 Macro nutrients composition per 100 g of proso millet and other millets

two types of starch in proso millet, namely, amylopectin and amylose. Amylose is the straight-chain polymer of glucose, whereas amylopectin is the branched-chain polymer of glucose units. In proso millet, the amylose content varies from 17.21% to 32.6% (dry basis), and amylopectin varies from 67.40% to 82.79%. The amylose content in proso millet starch is a little higher than maize (17–27%) and marginally lower than rice (28%). Native starch of proso millet has the highest digestibility (50%) in comparison to other millets (Kumari and Thayumanavan 1998), and the starch digestibility is similar to that of maize (43%). In general, grain starch has very low solubility in water. The proso millet starch is approximately 6.89% soluble at 90 °C. Moreover, millet starch exhibit a higher water-binding capacity than wheat starch and has a higher tendency to break down (~50 Brabender units - BU). Proso and foxtail millets show lower set back values (about 330 BU)compared to other millets (Kumari and Thayumanavan 1998).

The dietary patterns of many people concerned about healthy eating habit are changing across the world. Proso millet is gradually gaining attention owing to its impressive nutrient profile and gluten-free property. The eating quality and cooking parameters of proso millet grains are attributable to the starch properties. The starch granules in proso millet vary greatly in size and shape. The size of the granules range between 0.3 and 17 μm and can be round or polygonal in shape. Proso millet varieties are categorized as waxy (~1% amylose) and non-waxy (~25% amylose) types. Another important reason for consuming the proso millet is its high resistant starch content, which causes slow starch digestion, particularly in non-waxy varieties. Because of these reasons, the non-waxy starch varieties of proso-millet are widely used in food processing. The variation in amylose content and structural integrity contribute to the pasting and thermal behavior of proso millet starch. The starch of proso millet showed some promising functional properties that make it a suitable alternative to commercially available starch for food and non-food

applications. There are several reports on the use of proso millet seeds in the preparation of different food products like gluten-free bread, porridge, pasta, ready-to-eat breakfast cereals, infant foods, and distilleries (Das et al. 2019). It can be concluded that proso millet is an alternative source of starch considering its quality characteristics (Bangar et al. 2021).

2.2 Protein

The seed protein content of proso millet is comparable to maize and wheat. Proso millet seeds contain higher amount of protein than any other millets (Geervani and Eggum 1989). The protein content depends on the variety, environmental conditions, soil nutrients, and weather conditions during grain formation. The average seed protein in proso millet ranges from 11.5% to 13.0% with a maximum of about 17% (Kalinova and Moudry 2006). Varieties with a red seed coat have the lowest quantity and quality of protein (Essential Amino Acid Index, or EAAI) than light-colored grains. Dehulled grains have a little bit higher protein content (12.3–16.3%) due to the removal of the seed coat (hull) that is poor in proteins (Jones et al. 1970; Ravindran 1992). The protein quality (EAAI) of proso millet grain (51–67%) is higher than that in maize.

Proteins are complex biomolecules as they may sometimes comprise several subunits with various physicochemical and functional properties. On the basis of solubility, plant storage proteins are classified as albumin (water-soluble), globulin (saline-soluble), prolamin (alcohol-soluble), and glutelin (alkaline-soluble). Prolamin (31–50%) is the major storage protein in proso millet like in most cereals (Jones et al. 1970; Dendy 1995). Glutinous (waxy) proso millet contains a higher proportion of albumins and globulins (18–31%) than non-glutinous types (13–16%) (Parameswaran and Thayumanavan 1995). Similar to other cereals, proso millet grain protein has inadequate amount of content (3.68%). However, proso millet protein is rich of some essential amino acids (leucine, isoleucine, methionine) compared to wheat protein. Millet protein is believed to have beneficial influence on cholesterol metabolism. Proso millet is well-suited for patients on a gluten-free diet as its grains contain the specific prolamin fraction under the permitted level (Kalinova and Moudry 2006).

The proximate analysis of seed storage proteins is essential for understanding the basic physical and functional properties of proso millet cultivars to form the foundation for developing value-added products. Nine US proso millet varieties were characterized for proximate analysis by Singh et al. (2018). They observed a wide range of values for the physical properties, such as sphericity (0.86–0.91), volume 3.94 to 5.14 mm^3, bulk density (765.49–809.67 kg m^{-3}), porosity (42.49–44.20%), and angle of repose (22.98–25.74°). The varieties were also evaluated for their pasting and gelatinization properties. A high correlation was observed between amylose content and onset temperature ($r = -0.94$), peak gelatinization temperature ($r = -0.92$), peak viscosity ($r = 0.84$), final viscosity ($r = 0.91$), and setback viscosity ($r = 0.90$) (Singh et al. 2018).

The knowledge of the protein structure-function relationship is necessary to understand the nutritional properties of seed storage proteins. The physicochemical, functional, and structural properties of the storage protein fraction from two defatted proso millet cultivars, viz., Dawn and Plateau, were determined by Akharume et al. (2020). The protein recovery efficiency for the two varieties were determined to be 53.5% (Dawn) and 60.1% (Plateau). The average denaturation temperature of all fractions was 82.1 ± 3.5 °C. Surface hydrophobicity values of Dawn were 11,781, 10,594, 316, and 2225 for albumin, globulin, and glutelin, respectively, and 3415, 2865, 353, and 456 of Plateau fractions, respectively. Most of the protein fractions exhibited the highest solubility at pH 9 and lowest solubilities at pH $\leq$ 7. The solubility varied from 5.7% to 100%. Emulsifying activity index (EAI) of less than 0.25 m^2/g was estimated for most fractions, while the highest emulsion stability index (ESI) was about 60 min. Prolamin fraction showed three major peptide bands of 11, 14, and 24 kDa, while glutelin fraction revealed only a major band of 15 kDa and several minor bands of 11, 22, 24, 78, and 209 kDa. No differences in the electrophoresis pattern were observed for the fraction with or without a reducing agent (Akharume et al. 2020).

Digestibility of seed proteins of proso millet and other millets is reduced significantly after cooking due to conformational changes. Panicin, zein-like, the major seed storage protein fraction in proso millet, produced hydrophobic aggregates upon heating that are extremely resistant to protease digestion (Gulati et al. 2017). Using in vitro digestion as a measure of digestibility, aggregation reduces digestibility from about 80% to <40%. The recalcitrant hydrophobic protein aggregates that form as a result of heating are resistant to both aspartic proteases (pepsin) and serine proteases (chymotrypsin/trypsin). To estimate variation in "digestibility" as a trait, in vitro digestibility across 33 accessions of proso millet from different countries was measured and observed significant variation, ranging from 26% to 57% digestibility after heating (Gulati et al. 2018). Thus, there appears to be ample trait variation for selective breeding.

To further understand the nature of this digestibility trait, liquid chromatography-mass spectrometry (LC-MS)/MS analysis was done on the lines with high and low protein digestibility and identified three peptide sequences from the panicin fraction that were correlated with low digestibility and two that were associated with high digestibility (Gulati et al. 2018). Three peptide sequences of Gulati et al. (2018) were used to query annotated genes *Panicum miliaceum* genome (Zou et al. 2019). Seven different genes were identified belonging to the alpha family of zein proteins, the major seed storage proteins of maize. BLAST alignments identified a total of 14 members of the zein-alpha family in proso millet based on alignments showing >35% identity to the query. Phylogenetic analysis (Fig. 2a) further divided these zein-like genes into five subfamilies that are related to the PMS-1, P22.1/22A-1, and ZA1/M1 members of the 19 KDa and 22KDa zein alpha family and two members of the 10KDa prolamin-like protein family. The arrangement of the 14 zein-like proteins and the prolamin proteins on the proso millet genome (Fig. 2b) revealed an architecture suggesting that two pairs of highly related zein-like genes have arisen through chromosome duplications (Chr3-Chr4 and Chr9-Chr10), while a combination of five highly related 22 KDa zein-like genes on Chr17-Chr18 appears to have arisen from a

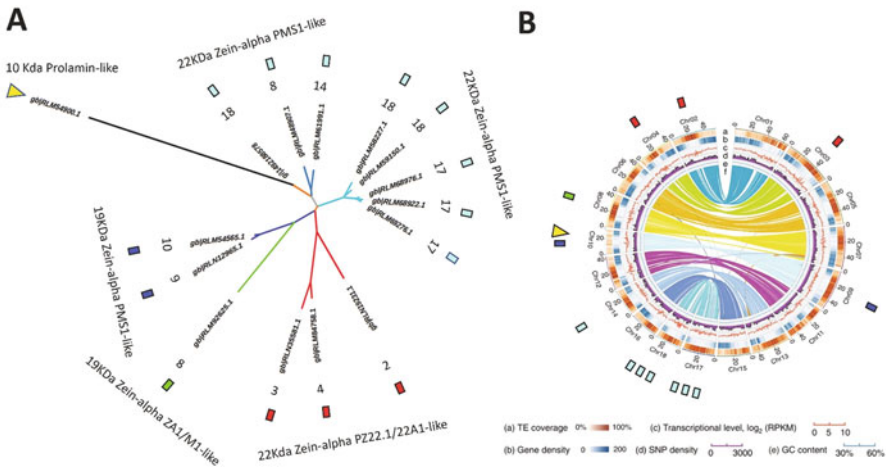

Fig. 2 Panicin (zein-like), prolamin gene family in proso millet (*Panicum miliaceum*). (**a**) Genes identified using three peptide sequences of prolamin fraction (Gulati et al. 2017) in BLAST alignment of proso millet genome sequence (Zou et al. 2019). Fourteen zein-line genes are divided into five sub-families. Chromosome number is indicated on top of each gene (unpublished). (**b**) The proso millet genome sequence assembly reported by Zou et al. (2019). This image, licensed under a Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/), was used with minor modifications.

combination of ancestral gene duplications within the progenitor of the Chr17/Chr18 chromosomes, followed by duplication of the ancestral chromosome. The four remaining genes across Chr2, Chr8, Chr14, and Chr18 form distinct families that are more distantly related. Structurally, the amino acid composition of predicted proteins from each of these zein-like subfamilies shares features common to zein proteins, including enrichment in polar amino acids, and 9–10 different stretches of repeated sequence containing poly-glutamine (QQQ) separated on average by 11 residues. Structural analysis of the maize zeins has shown the repeated sequences form alpha helices with the polar amino acids (including glutamine residues) interacting with residues on adjacent anti-parallel helices to form a bundle of multiple alpha helices in a compact structure (Argos et al. 1982; Matsushima et al. 1997).

2.3 Lipids

Dehulled grains of proso millet contain 3.5% to 6.7% of lipid (Jones et al. 1970; Ravindran 1992; Kalinová 2007). Among cereals, only oats have a higher (7.14%) lipid than that in proso millet. The germ contains about 25% of the total lipids. Proso millet gains contain 62.2% of free, 27.8% of bound, and 10% of structural lipids. Unsaturated fatty acids make up 85–89% of proso millet lipids of which 42% are polyunsaturated acids (Kalinová 2007). Polyunsaturated lipids (particularly linoleic acid) play an essential role in cholesterol metabolism. The major fatty acids of proso

millet are linolenic (38.4–66.68%), oleic (21.4–22.7%), and palmitic (6.61–11.3%) acids. The physicochemical characteristics of proso millet lipids (consistence, setting point, acid number) are similar to the lipid content of sunflower, maize, and soya (Kalinová 2007).

2.4 Fiber

Cereal grains serve as the most significant source of dietary fiber for the human diet. The fiber content in the human diet is critical for the prevention and treatment of high blood pressure and high cholesterol. The fiber content in dehulled grains of proso millet is like that of oat (0.8–1.2%). The composition of cell wall in proso millet grains is similar to that of tissues of other grass species. The cell wall comprises xyloglucan, arabinoxylan, uronic acid, arabi-nosyl, galactosyl residues, arabinogalactan, and β-D-glucans (Kalinová 2007). The β-D-glucans (glucose units linked to a long polymer chain) play an important role in human nutrition by decreasing total blood cholesterol. The β-glucans content in proso millet (0.5–1.0%) is at the same level of lentils (0.4–1.1%), maize (0.5–1.3%), rice (0.4–0.9%), spelt (0.6–1.2%), or wheat (0.5–1.0%) (Demirbas 2005).

2.5 Minerals

The majority of proso millet seed mineral is present in its pericarp, aleurone layer, and germ. The mineral content varies from 1.5% to 4.2% (Ravindran 1992; Kalinová 2007), which is higher than that in wheat grain (1.5–2.0%). The majority of minerals in proso millet are slightly higher or similar to those of other cereals (Table 2). The common food processing and dehulling reduces the mineral content to around 27–53% (Kalinová 2007). This reduction commensurate with the dehulling intensity. Proso millet is deficient in calcium, but the grain contains a high amount of phosphorus. However, the bondage of phosphorus with phytates considerably interferes with its bioavailability. Proso millet is abundant in potassium, iron, and manganese (19.5–20.6 mg/100 g) (Ravindran 1992). Its grain is almost devoid (0.01 g/100 g) of sodium. Proso millet is an excellent source of zinc, copper, and boron as well (11.6 mg/kg) (Kalinová 2007).

2.6 Vitamins

The dehulled grain of proso millet is rich in vitamin B1, thiamine (0.42–0.80 mg/100 g); B2, riboflavin (0.22–0.40 mg/100 g); B3, niacin (1.55–3.7 mg/100 g); B6, pyridoxin (0.52–0.80 mg/100 g); and E, tocopherol (0.1–2.60 mg/100 g) (Table 3). The levels of vitamins B1 and B2 are twice that of rice, wheat, or barley. Most of the vitamins are deposited in the germ and aleurone layer and therefore, decortication considerably decreases their content. The color of dehulled grains is correlated to carotene and xanthophyll content. The carotene content is relatively stable and does not vary due to

growing conditions such as soil type, level of fertilization, and interannual weather changes (Kalinová 2007). The unrefined fat extract of proso millet grain contains 8.3 to 10.5 mg of vitamin A and 87 to 96 mg of vitamin E per 100 g (Tripathi et al. 2021).

2.7 Antinutritional Factors

Knowledge of antinutritional factors such as tannins, phytates, oxalates, and enzyme inhibitors is essential to predict the nutritional value of products. Phytates affect the bioavailability of certain minerals, particularly multivalent cations including P, Ca, Mg Fe, and Zn, by binding with them. Phytic acid forms a complex with most of the free P (~67.3%) in the millets (Ravindran 1992). The phytic acid content in proso millet varies from 0.17 to 0.61 g/100 g, which is higher than that in polished rice but lower than that in wheat. Dehulling reduces the phytate content by 17–24% and thus makes more P bioavailable (Lorenz 1983).

3 Secondary Metabolites in Proso Millet

Like other millets and cereals, proso millet grain contains many secondary metabolites, which reportedly have beneficial effects on human health. The following section summarizes the secondary metabolites in proso millet.

3.1 Phenolic Compounds

Polyphenols are the major group of phytochemicals in plants, and they have numerous health benefits. Polyphenols in cereals have an adverse influence on color, flavor, and nutritional quality. These compounds are mostly localized in the aleurone layers of the grain. The polyphenol content in plants is influenced by factors such as plant part, developmental stage, and environment. Total phenolic compounds in proso millet are about 0.05–0.10 mg per 100 g of catechin equivalents, on dry basis. The bound polyphenols (1% HCl extractable) in proso millet were (2.21 ± 0.01), which was significantly lower than that in other millets such as kodo millet (81.64 ± 0.15), foxtail millet (11.59 ± 0.23), little millet (9.64 ± 0.28), pearl millet (9.14 ± 0.17), and finger millet (3.83 ± 0.18). Bound phenolic compounds have antioxidant, anti-obesity, anti-diabetic, antimutagenic, anticarcinogenic, antimicrobial, and antiviral properties (Tripathi et al. 2021).

3.2 Flavonoids

Flavonoids are a group of plant secondary metabolites with a general structure of a 15-carbon skeleton. Flavonoids such as catechin, quercetin, anthocyanin, tannin, etc. have human health-promoting properties, owing to their pharmacological activities

such as radical scavenging. There are no reports of flavonoids in proso millet. However, a few reports are there for other millets. Finger millet leaves are known to contain eight types of flavones: vitexin, isovitexin, saponarin, violanthin, orientin, iso-orientin, lucenin-1, and tricin. Pearl millet contains glucosylvitexin, glucosylorientin, and vitexin in a ratio of 29:11:4 (Kalinová 2007). Finger millet is reportedly the only millet that contains condensed tannins.

3.3 Carotenoids

Carotenoids are well-known for their provitamin A activity. Carotenoids prevent various diseases because they act as antioxidants. A recent report showed that the carotenoid content in edible millet flour varied from 78 to 366 μg/100 g with an average of 366, 199, 78, 173, and 366 μg/100 g in proso, finger, little, and foxtail millets, respectively (Asharani et al. 2010). The carotenoid contents of millets were comparable to that of wheat (150–200 μg/100 g) and sorghum (180–230 μg/100 g) but significantly lower than that in maize (1800–5500 μg/100 g) (Tripathi et al. 2021).

3.4 Phytosterols

Phytosterols, which are desmethyl sterols, are essential structural and functional components of plant cells. Phytosterol esters can potentially reduce the blood serum LDL (low-density lipoprotein) cholesterol levels down to 14% but do not affect HDL (high-density lipoprotein) levels. The risk of heart disease can be reduced by up to 40% by including proso millet in the regular diet depending on age and some other factors. Other than finger millet, there are no reports of phytosterols in proso and other millets. The sterol content of finger millet was reported to be 0.149% on a seed weight basis, whereas other millets contain only a trace amount. Phytosterol content of sorghum and corn was estimated to be 0.5 mg/g and 0.9 mg/g (Singh et al. 2003).

4 Proso Millet Grain for Human Health

Proso millet confer many beneficial effects to human health. Some of these effects are backed by more scientific evidence than others. Several epidemiological studies have shown that regular consumption of millets and their products can ameliorate the affect of chronic diseases such as diabetes, cardiovascular disease, cancers, and all-cause mortality (Table 4).

4.1 Antioxidant

Millets including proso millet are abundant in both soluble and insoluble bound polyphenols, which have high antioxidant potential with metal chelating and

Table 4 Human health benefits and contributing nutraceuticals of proso millet

Human health benefits	Nutraceutical (s)
Treating diabetes	Low glycemic index starch
Helps in anemia by increasing hemoglobin	High iron and zinc concentration
Alleviates constipation	High fiber
Anti-cancer inhibiting tumor formation	Vanillin (antioxidant)
Bone growth, development, and repair	High phosphorus (P)
Prevents stomach ulcers, preventing formation of excess acidity	Gastroprotective effect of antioxidant in millet
Helps alleviating high blood pressure and heart stress	Polyphenols, lignin, high magnesium (Mg)
Reduces respiratory problems in asthma patients and reduce migraine attacks	High magnesium (Mg)
Reduces the overall consumption of food	High fiber content
Reduces the risk of gall bladder stone and production of excessive bile juice	High fiber content
Highly digestible and low allergic response (Reduces allergy in celiac patients)	Gluten-free starch

Note: The data was adapted from Malik (2015)

reducing powers (Saleh et al. 2013). Several antioxidants present in millets neutralize free radicals (reactive oxygen species) and boost overall immunity and human health. The free radicals can lead to oxidative stress, which in turn are associated with conditions like cancer, arthritis, respiratory, and compromised immunity. Thus, consumption of millets can improve human health by scavenging free radicals from the liver and kidney.

4.2 Antidiabetic

Diabetes mellitus causes several body disorders, characterized by high blood sugar levels with an imbalance in protein, carbohydrate, and lipid metabolism. Consumption of whole millet grains has been clinically proven to lower diabetic effects (Saleh et al. 2013). Rao et al. (2017) reported that regular consumption of millets helps prevent diabetes due to the higher level of magnesium in these small grains, which in turn enhances the efficiency of insulin and glucose receptors. Furthermore, millet-based diets have been reported for their antioxidant potential, nerve growth factor production, and wound healing properties (Rao et al. 2017).

4.3 Cardiovascular Diseases

Millets are abundant in magnesium, potassium, lignans, antioxidants, and fibers, which can reduce the risk of heart strokes, high blood pressure, low-density cholesterol, and atherosclerosis. Rao et al. (2017) reported that the addition of barnyard,

proso, and finger millets in the diet increased the blood plasma levels of adiponectin, high-density lipoprotein (HDL), and reduced triglycerides in hyperlipidemia. Therefore, millets, including proso, finger, barnyard, foxtail, and pearl millet, can significantly lower hyperlipidemia, hyperglycemia, triglycerides, and non-HDL and reduce the risk of cardiovascular diseases (Rao et al. 2017).

4.4 Anticancer

Cancer is characterized by changes at the cellular level due to uncontrolled cell growth and division. Millets generally have high levels of phenolic compounds such as tannins, fibers, and other phytonutrients than other cereals. These compounds improve health status and lower the risks of colon, breast, and esophageal cancers (Saleh et al. 2013). It is recommended that a daily ingestion of 30 g of fiber may reduce the risk of breast cancer chances by 50% (Rao et al. 2017).

4.5 Antiaging

Millets, including proso millet, are nutrient-rich functional food, enriched with high levels of micronutrients, vitamins, minerals, phenolic compounds, fibers, and antioxidants. These compounds are helpful in inhibiting glycation and cross-linking of collagen which is responsible for aging (Saleh et al. 2013).

4.6 Gluten Sensitivity

Celiac disease and gluten sensitivity are caused by gluten in organisms that are genetically susceptible to these conditions. The disease affects 0.6–1% of the population worldwide. Other food grains are amaranth, buckwheat, quinoa, corn, and sorghum functional and nutraceutical food. Millets have a lot of potential in the production of gluten-free food and beverages targeting people suffering from gluten sensitivity and celiac disease (Saleh et al. 2013).

5 Genetic Variation of Seed Components

Genetic variation is crucial for the adaptability and survivability of any species. From a breeding perspective, genetic variation ensures the selection of superior individuals (plants or animals) with improved characteristics from a population. A very limited number of studies have been conducted to assess the variation in seed composition in proso millet. Ravindran (1992) studied the amino acid composition and a few other traits of six proso millet varieties. He reported small differences in amino acid content among the varieties (Ravindran 1992). Kalinova and Moudry

(2006) assessed the crude protein and amino acid content in seven proso millet varieties. In contrast to Ravindran's findings, they observed significant varietal differences in seed content of the amino acid lysine, valine, isoleucine, phenylalanine, aspartate, glycine, tyrosine, histidine, and arginine (Kalinova and Moudry 2006). In another study, a varietal difference in phenolic compounds and antioxidant capacity in whole millet grains was reported (Chandrasekara and Shahidi 2011). Vetriventhan and Upadhyaya (2018) studied 200 proso millet accessions to assess the diversity of grain nutritional traits including seed protein, calcium (Ca), iron (Fe), and zinc (Zn). Large variations for all four grain-nutritional traits were observed in their study. More research on the genetic variation of seed components, including secondary metabolites, needs to be conducted for generating resources for genome-wide association studies (GWAS) and developing varieties with improved nutrient profiles (Vetriventhan and Upadhyaya 2018).

6 Breeding for Grain Quality Improvement

Plant breeding is the process of creating and selecting superior genotypes with enhanced yield, abiotic and biotic stress tolerance, and improved nutritional quality. Breeding programs dedicated to developing genetically improved varieties of proso millet were established in several countries. China, the USA, India, Russia, and Kenya are notable countries that have been instrumental in continuing efforts for the genetic improvement of proso millet (Gomashe 2017). Considerable progress has been made in generating high-yielding varieties with desirable maturity, seed color, plant height, and other yield-related morpho-agronomic traits. However, efforts to develop superior proso millet cultivars enriched with nutrients and health-promoting metabolites are very limited. With the growing demand for proso millet in the ever-expanding human healthy food market, it is imperative that breeding programs focused on improving nutrient and metabolite profiles of the high-yielding varieties are established to promote this crop as a functional food. Common breeding approaches and a couple of biotechnological tools to complement conventional breeding in accelerating variety development efforts are discussed further down.

6.1 Conventional and Wide Hybridization

The majority of proso millet varieties of North America were developed through conventional breeding methods (crossing followed by selection of progenies) using a limited pool of parental lines through conventional hybridization. The resulting narrow genetic base may lead to diminished performance of the varieties in terms of resistance to abiotic and biotic stresses over time. Besides, the variation of seed quality traits is not very large, which makes genetic improvement of seed composition through conventional breeding approaches even tougher. Nevertheless, the conventional method was still useful in developing specialty proso millet varieties

for human food uses. One such example was 'Plateau', the first and only waxy proso millet variety in North America (Santra et al. 2015). The variety was developed via artificial pollination between PI 436626 (Lung Shu 18), a Chinese waxy accession, and 'Huntsman', a high-yielding US variety. Similar market-driven strategies can be adopted to develop new high-yielding cultivars enriched with essential nutrients and healthy metabolites to market them as nutraceuticals.

The gene pool of wild relatives of proso millet can be a large repository of novel traits or genes that can be transferred via introgression into the existing cultivars (Santra et al. 2019). Wide hybridization is a promising prospect for improving grain nutritional quality by introducing genes from the wild relatives such as P. *sumatrense* and *P. repens* to improve the metabolic profile of the cultivars.

6.2 Mutation Breeding

Mutation breeding involves deliberate induction of mutation by artificial mutagenesis and breeding for genetic variations that do not exist in the gene pool. Mutation-inducing agents (mutagens) can be physical, ionizing (X-rays and γ-rays), and non-ionizing radiations (ultraviolet rays) or chemical agents such as ethylmethane sulfonate (EMS), methyl methane sulfonate (MMS), diethylsulfate (DES), and nitrosoguanidine (NS). EMS is the most widely used chemical mutagen due to its effectiveness and ease of use. Proso millet seeds treated with 0.2% EMS was found to improve panicle filling, grain shattering tolerance, and grain yield in the M2 progeny (Singode et al. 2018). Recently, Francis et al. (2022) used different doses of gamma radiation to develop phenotypic mutations for various traits, including plant height, panicle shape, compactness, seed color, and lodging resistance. They were able to isolate eight high-yielding mutant families with significantly improved grain yield (GY) and fodder yield (FY) (Francis et al. 2022). More research on artificial mutagenesis is absolutely required in proso millet. Mutation breeding is a viable technique to overcome poor combining ability and narrow genetic based for improving grain nutrient and metabolite profile (Santra et al. 2019).

6.3 Doubled Haploids and Transgenics

Doubled haploid (DH) and transgenic technologies are two commonly used tissue culture-based biotechnology tools for the genetic improvement of crops. The DH technology produces 100% homozygous genotypes using haploid gametes (pollen or egg). Transgenic technology uses genetic engineering to insert one or two specific genes from other plants. Conventional plant breeding via pure-line selection normally takes 11–13 years to develop a new variety as it usually involves 5–6 generations of inbreeding to generate homogeneous breeding lines with >98% homozygosity before multi-year yield assessment at multiple sites. The desirable 100% homozygosity can be achieved in a much shorter time by implementing doubled haploid technology (Khound et al. 2013; Santra et al. 2019). Only a few

reports on successful tissue regeneration have been reported in proso millet. In 1982, Heyser and Nobors reported successful callus induction and shoot regeneration from a variety of explants by manipulating auxin levels in Linsmaier and Skoog (L and S) medium (Heyser and Nabors 1982). Bobkov and Suvorova (2012) studied the efficiency of anther culture technique in proso millet for embryogenic callus induction and regeneration. Heat (32 °C) and cold (4 °C) were observed to successfully induce callus formation and regeneration of the explants (Bobkov and Suvorova 2012). For several decades, genetic engineering has been used to introduce foreign genes expressing novel traits into a host genome or to knock out genes with deleterious effects. Genetic improvement of crops through genetic engineering relies on the development of an efficient regeneration method and a robust transformation system (Kumar et al. 2016). There has been no report on the generation of transgenic proso millet via genetic transformation so far. The DH and genetic engineering technologies can be used for developing proso millet varieties enriched with health-promoting bioactive compounds and no or minimum antinutrients. Therefore, more studies on efficient tissue culture and transformation systems are warranted for facilitating genetic engineering-assisted genetic improvement of proso millet.

7 Omics for Improving Grain Nutritional Quality

Biology works as a "system" rather than as an individual part separately. All the parts of biology work together in harmony to manifest overall biological functions. Many biochemical compounds are involved in this intrinsic process. Similarly, all the nutrients and antinutrients in food work together in harmony to manifest their effect on human health and nutrition. Therefore, it is very important to study proso millet seed nutrients quality and quantity, genes, biosynthesis pathways, regulation, and interactions together rather than separately. That means all aspects of proso millet seed nutraceuticals must be studied following the "omics" approach. The term "neutrocetomics" is used to indicate the combined study of nutraceuticals and omics. Proso millet being a minor crop, its "omics" areas of research are not as rich as other major crops such as corn, wheat, rice, and soybean. However, in recent years a lot of omics research has been done in proso millet, and more is being conducted due to its increasing importance for human health. Details of proso millet "omics" research were published in a recent comprehensive review paper (Khound and Santra 2020). The following section summarizes various fields of "omics" in proso millet and their relevance to its "nutraceutomics" (Fig. 3).

7.1 Genomics

Genomics is the branch of omics that tackles large-scale studies on the structural and functional aspects of the genome to understand the genetic and molecular underpinning of various biological processes. Initial genomic studies were primarily focused on genome size and physical as well as genetic mapping of organisms. Next-

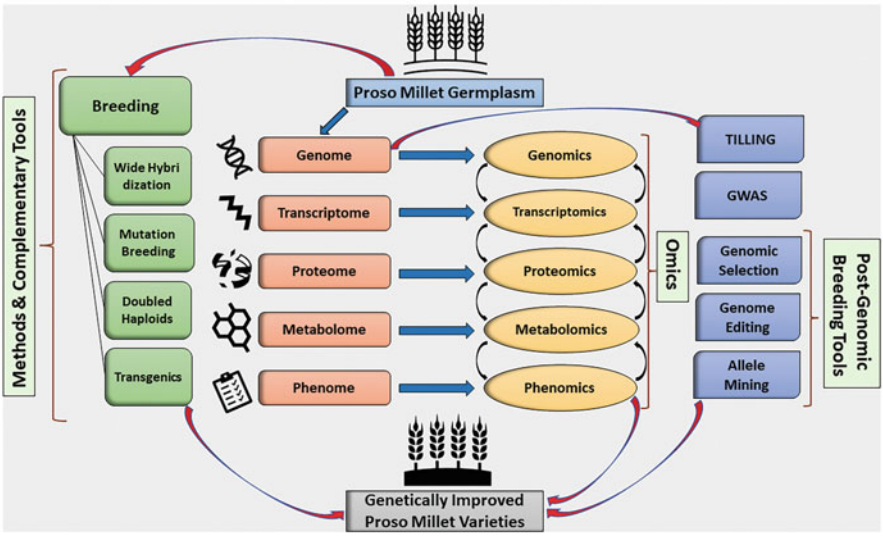

Fig. 3 Schematic representation of the applications of traditional breeding methods and tools, as well as omics-based and post-genomic breeding strategies to the genetic improvement of proso millet

generation sequencing (NGS) marked a new era of genomics by enabling researchers to sequence, assemble, and analyze the genomes of important crops at lower costs and in a shorter time (Khound and Santra 2020).

7.1.1 Molecular Markers

Molecular markers are important genomic resources that have been widely used in genetic mapping, genetic diversity, and taxonomic and population genetic studies of crops. A limited number of molecular markers were developed in proso millet as this crop is grossly under-researched. The molecular markers identified in proso millet so far include amplified fragment length polymorphism (AFLP), random amplified polymorphic DNA (RAPD), inter-simple sequence repeat (ISSR), cleaved amplified polymorphic DNA (CAP), simple sequence repeat (SSR), and single nucleotide polymorphism (SNP) markers. These molecular markers were primarily used for evaluating the genetic diversity of the proso millet germplasm (Santra et al. 2019).

SSRs are preferable for genetic studies as they are abundant, evenly distributed, multi-allelic, codominant, highly polymorphic, easy to score, and highly reproducible (Khound and Santra 2020). The earliest SSR-based genetic studies were conducted using SSRs from other species such as rice, wheat, oat, barley, and switchgrass. The first proso millet-specific SSRs were identified by Cho and coworkers (Cho et al. 2010). Twenty-five polymorphic SSRs were developed from the genomic DNA of 50 diverse proso millet genotypes. These SSRs were used to evaluate the genetic diversity of Chinese proso millet accessions (Liu et al. 2016).

SNP markers are ideal for genetic studies, genetic map constriction, and genomic selection as they occur abundantly in the genome (Khound and Santra 2020). These markers are especially well suited for constructing linkage maps as they are cost-effective, high-throughput, and more efficient compared to other DNA markers (Rajput et al. 2016). Several reports on SNP identification in proso millet have been published. Rajput et al. identified 833 high-quality biallelic genotype-by-sequencing (GBS)-SNPs from genotyping of 93 recombinant inbred lines (RILs). These GBS-SNPs were used for constructing the first proso millet linkage map (details later in the quantitative trait locus (QTL) mapping section) (Rajput et al. 2016). Wang and her coworkers evaluated the allelic diversity of two waxy genes, viz., Wx-L and Wx-S, in 132 proso millet accessions from 12 provinces of China. In their study, Wang et al. (2018) identified six SNPs at the *Wx-L* locus after sequencing the PCR amplicons of all the accessions. Johnson and his team used GBS to generate 1882 filtered SNPs to conduct genome-wide population genetic studies in proso millet. The SNP markers were found to accurately represent genetic variation within the population (Johnson et al. 2019). In 2021, Boukail et al. (2021) developed 2412 SNPs from 88 proso millet accessions with RAD-seq. The identified SNPs were used for conducting GWAS to detect marker-trait associations for several agronomic and seed morphology traits (more details are covered in Sect. 8) (Boukail et al. 2021). In another recently published report, 126,822 filtered SNPs were identified using specific-locus amplified fragment sequencing (SLAF-seq) of 106 accessions (Li et al. 2021). More recently, Khound et al. (2022) developed 972,863 high-quality biallelic SNPs from low-pass genome sequencing of 85diverse proso millet genotypes of the USDA gene bank. They employed those SNPs to study the population structure and phylogenetic relationships among the genotypes (Khound et al. 2022).

7.1.2 QTL Mapping

Quantitative trait locus (QTL) mapping is routinely used in many crops for detecting quantitative trait loci (QTLs) associated with key traits due to the abundance of versatile DNA markers and statistical models and methods. QTLs for a wide array of traits have been reported in many major and minor crops including wheat, rice, maize, sorghum, millet, amaranth, quinoa, oat, and rye (Yabe and Iwata 2020). Among millets, pearl millet and foxtail millet have the major share of published reports on QTL mapping. In proso millet, very little research has been done on genetic mapping of QTLs compared to major crops such as rice, wheat, maize, soybean, and sorghum. This is possibly because of the minor crop status and inadequate resources available to proso millet geneticists. The first-ever genetic linkage map of proso millet was published in 2016 by Rajput et al. They used 833 GBS-SNPs and 93 RILs. Several QTLs and linked SNP markers for a few morpho-agronomic traits were identified (Rajput et al. 2016). However, no QTLs for proso millet seed components such as starch, protein, minerals, vitamins, and other bioactive compounds have been identified in proso millet to date.

7.1.3 Whole-Genome Assembly

Developing a whole-genome assembly (WGA) is a crucial step in genome-wide molecular studies as this creates opportunities for exploring complex molecular structures and functions in an organism. Information on genome assembly is an invaluable resource for genomic-assisted breeding for crop improvement. Proso millet was the fourth millet to have a published whole-genome assembly after foxtail millet, pearl millet, and finger millet (Khound and Santra 2020). In 2019, Zou et al. developed the complete proso millet genome sequence using various NGS tools. They also identified 55,930 protein-coding and 339 microRNA genes (Zou et al. 2019). In the same year, Shi et al. reported a near-complete assembly of the proso millet genome. The authors generated 18 super scaffolds covering approximately 96% of the estimated genome. Moreover, they were able to annotate 63,671 protein-coding genes in the proso millet genome (Shi et al. 2019).

7.1.4 TILLING

Another modern approach that could be applied for improving grain nutritional quality of proso millet is the TILLING (targeted induced local lesions in genomes) method. This is an advanced method of detecting beneficial mutations or alleles that allows rapid identification of induced gene mutations within a mutagenized population via heteroduplex analysis. The initial step of TILLING involves creating a mutagenized population, which is subsequently assessed for detecting useful gene mutations that could be linked to important phenotypes. The mutations within the mutagenized population are usually detected by one of the three methods, viz., LI-COR method (uses CEL 1 enzyme), high-resolution melting (HRM) method, and NGS method. TILLING has been used for detecting useful mutations in a wide array of crops including wheat, rice, sorghum, and maize (Irshad et al. 2020). Tilling has been successfully employed to identify mutations in genes associated with starch synthesis, plant architecture, and disease resistance in several crop species. Another related method, namely, EcoTILLING, is used to detect naturally occurring polymorphisms within a population. The polymorphisms identified could be used to study the phylogenetic diversity within the population. This technique can also be used to detect novel allelic variations that can be exploited for genetic improvement. EcoTILLING has been utilized in different crops including Arabidopsis, chickpea (seed weight), wheat (disease susceptibility), rice (drought tolerance, starch synthesis), and soybean (seed protein) (Irshad et al. 2020).

7.1.5 Allele Mining

A large number of beneficial alleles are present in plant genetic resources, which remain unutilized as they were abandoned during evolution and domestication. Introgression of these natural genetic variations has the potential to improve the performance of available cultivars. The recent surge of genomic data accelerated the discovery and annotation of novel genes and loci linked to essential agronomic traits in many crop species. The idea of identifying alleles in the annotated genes led to the concept of allele mining in plants. Allele mining refers to the approach of dissecting

naturally occurring variations at candidate genes or loci associated with major agronomic traits with the help of modern genomic tools (Kumar et al. 2010). Two primary approaches for identifying alleles are EcoTILLING and sequence-based allele mining. As discussed in the previous section, EcoTILLING is used to identify naturally occurring allelic variants present in the primary and secondary gene pools. In a sequence-based approach, alleles of diverse genotypes are amplified by PCR and subsequently sequenced. Allele mining was used in identifying alleles for important seed quality traits including *Amy32b(*α-amylase gene) and *Gpc-B1* (gene for grain protein content) in barley, *wx* locus (waxy gene) in rice, and *Wx-A1* (waxy gene) in wheat (Kumar et al. 2010). The prospect of using allele mining for detecting novel alleles of genes is relatively unexplored in millets. The availability of whole-genome assemblies, high-quality molecular markers, and the gradually reducing cost of sequencing is expected to result in more studies for identifying novel genes and loci. That would encourage more efforts for the mining of candidate genes for some key agronomic and grain quality traits leading to the detection of useful alleles for application in molecular breeding.

7.2 Transcriptomics

A handful of reports on transcriptome studies investigating biological processes have been published in proso millet. Yue et al. (2016) used Illumina sequence reads from two proso millet accessions, viz., Yumi No.2 and Yumi No.3, to assemble a proso genome transcriptome. From the 113,643 unigenes assembled, 62,543 contigs were assigned to 315 gene ontology (GO) categories. Additionally, 15,514 unigenes could be mapped into 202 Kyoto Encyclopedia of Genes and Genomes (KEGG) clusters, and 51,020 unigenes were mapped to 25 clusters of orthologous groups (COG) categories. The most represented KEGG pathways included metabolic pathways (25.65%), biosynthesis of secondary metabolites (10.71%), and biosynthesis of amino acids (3.57%) (Yue et al. 2016). In 2017, Hou et al. developed a transcriptome assembly using Illumina sequence reads from a single genotype of proso millet named Neimenggu-Y1. They were able to identify 25,341 unigenes out of which 5170 (20.4%) could be mapped to 146 KEGG pathways. GO annotation with 2936 tissue-specific genes resulted in three subcategories- biological processes, molecular functions, and cellular components (Hou et al. 2017). Zhang et al. (2019) published a comparative analysis of transcriptome associated with drought tolerance in two genotypes, viz., Neimi 5 and Jinshu 6. Drought stress resulted in 833 and 2166 DEGs in Jinshu 6 and Neimi 5, respectively. Some of the DEGs could be mapped to some key KEGG pathways including carbon metabolism, phenylpropanoid biosynthesis, and amino acid biosynthesis (Zhang et al. 2019). The unigenes that were mapped to the key KEGG pathways in the above reports should be explored further to identify their roles in those pathways. This information could be useful in targeting specific genes for enriching proso millet with useful nutraceuticals or inhibiting the biosynthesis of antinutrients.

7.3 Proteomics

There is an abundance of reports on proteomics research for the major crops including rice, corn, soybean, wheat, and potato. However, like other omics disciplines, the number of published reports pertaining to proteomics in proso millet and other millet is very meager (Khound and Santra 2020). Perhaps the first proteomics analysis in proso millet was done on a 2500-year-old starch food in China. Comparative proteomics analysis between the ancient sour dough bread and a few other reference cereals identified proso millet and barley as the ingredients of the ancient bread (Shevchenko et al. 2014). In 2017, Roy and co-workers reported the seed protein analysis of four Korean proso millet varieties using two-dimensional (2-D) electrophoresis and mass fingerprinting to map the seed proteins and determine their functional properties. They detected 1152 differentially expressed proteins, out of which 26 reproducible proteins were further analyzed using matrix-assisted laser desorption/ionization time-of-flight/time-of-flight mass spectrometry (MALDI-TOF-TOF/MS). Two of the 26 proteins were found to be upregulated in all the cultivars, while 13 were upregulated and 11 were downregulated in 2 proso millet cultivars. The authors opined that the differential expression of the proteins in the four proso millet cultivars was possibly variety-specific (Roy et al. 2017).

7.4 Metabolomics

There are only a couple of available reports on the metabolomics of proso millet. The first published study on proso millet metabolomics used gas chromatography-time-of-flight mass spectrometry (GC-TOFMS) to evaluate gain quality. Kim et al. (2013) studied the primary metabolites and phenolic acids of the matured grains of three Korean proso millet varieties, viz., 'Joongback', 'Joongjuk', and 'Hwangguem'. They were able to identify 48 metabolites from the grains, which included 43 primary metabolites and 5 phenolic acids. The mature grains of the variety 'Joongjuk' contained significantly higher levels of phenolic acids than the other two varieties. This makes this variety a suitable candidate for further evaluations and genetic improvement as a nutraceutical (Kim et al. 2013).

In a relatively recent publication, 172 metabolites and 3 cooking quality traits were compared between conventionally and organically grown seeds of two proso millet varieties. There was no difference in the metabolite profiles between the conventionally and organically grown gains, except in the levels of some carbohydrates such as glucose and fructose, which were higher in the organically grown grain. The variations observed in the metabolite content could be primarily attributed to the variety (Liang et al. 2018a). These findings emphasize the importance of variety selection for developing proso millet varieties for nutraceutical use.

7.5 Phenomics

A phenome can be described as the complete set of phenotypic traits expressed by a cell, tissue, or organism, and the field of studies on the phenome is known as phenomics. Establishing the relationship between the genotypes and phenotypes is a major breeding objective of any crop improvement program. Traditional phenotyping approaches are usually laborious, time-consuming, expensive, and mostly destructive (Santra et al. 2019). It is important to determine more phenotype-to-genotype relationships to develop reliable predictive models for predicting a full array of phenotypes of a genotype (Gustin and Settles 2015). In recent years, high-throughput phenotyping techniques and tools including high-resolution imaging, spectroscopy, robotics, and powerful algorithms have been developed to push plant phenotyping to the next level. Different high-throughput phenotyping approaches have been used to study a variety of phenotypic traits such as plant growth, biomass, leaf morphology, maturity, and nutrient status (Santra et al. 2019). To the best of our knowledge, the first-ever report on high-throughput phenotyping in proso millet was reported by Zhao et al. who used UAV-based imaging for heading percentage detection in proso millet (Zhao et al. 2022).

A more niche area of phenomics, for example, "seed phenomics," could be developed in proso millet to specifically study various seed characteristics (Gustin and Settles 2015). This will require the integration of various imaging technologies, spectroscopy, and multiple omics such as genomics, transcriptomics, proteomics, and metabolomics. Various imaging techniques and rapid, nondestructive spectroscopic techniques, such as near-infrared (NIR) spectroscopy and nuclear magnetic resonance (NMR) spectroscopy, are routinely used to determine various seed traits such as shape, size, color, and chemical composition. To the best of our knowledge, there is no report or ongoing research on proso millet seed phenome, which is very important for genetic improvement of nutraceuticals values in proso millet.

8 Post-Genomic Approaches for Improving Seed Nutritional Quality

The following sections summarize the current status of proso millet "omics" resources available to the scientists working in the field of proso millet nutraceutomics. The following sections address post-genomic omics approaches for genetic manipulation of proso millet seed nutraceuticals.

8.1 Genome-Wide Association Studies (GWAS)

Genome-wide association study (GWAS) or association mapping (AM) involves the detection of an association between DNA marker(s) and a trait of interest based on the principle of linkage disequilibrium (LD). This is achieved through

large-scale genotyping of germplasm panels or breeding populations exhibiting contrasting phenotypes across different environments. Several GWAS have been conducted in millets to uncover the marker-trait association for some important traits. However, only a few reports of GWAS for seed nutritional traits are available. The only available report on GWAS in proso millet to date was published in 2021 by Boukail et al. They used a global collection of 88 varieties and landraces to identify marker trait associations (MTAs) for seed morphological traits. They identified 2412 high-quality SNPs using restriction site-associated DNA sequencing (RAD-seq). These SNPs were used for GWAS for seed traits, such as seed length (SL), seed width (SW), seed perimeter (SP), and seed color (RGB) as well as agronomical traits. They identified MTAs for the seed and agronomic traits (Boukail et al. 2021). The SNPs that were found to have a strong association with the agronomic and seed traits could be strong candidates for marker-assisted selection (MAS) in proso millet breeding programs. Having said that, no report on GWAS for nutraceutical traits is available in proso millet yet. This warrants the initiation of genome-scale studies to identify MTAs for some key seed quality traits to accelerate the development of proso millet varieties with impeccable agronomic qualities and healthy seed components.

8.2 Genomic Selection (GS)

Genomic selection (GS) is the breeding approach of using genome-wide high-density markers to facilitate rapid selection of suitable candidates for breeding (Srivastava et al. 2020). GS is still in the nascent stage in millets as very few GS studies have been conducted so far due to the limited availability of genomic resources. Varshney et al. (2017) utilized whole-genome resequencing (WGRS) data for performing GS to predict the grain yield of pearl millet under four different stress scenarios across environments. They used to analyze the grain yield of 64 hybrids with 302,110 SNPs to identify promising hybrid combinations for hybrid production (Varshney et al. 2017). In another study, Liang and his coauthors (2018b) evaluated four genomic selection schemes using two genotyping strategies, namely, RAD-seq and tunable genotyping by sequencing (tGBS) in pearl millet. The authors observed that for traits with significant mid-parent heterosis, the inbred phenotypic data moderately improved genomic predication of the hybrid genomic estimated breeding values when the trait values of the inbred and hybrid lines were scored relative to the mean trait values of the corresponding populations (Liang et al. 2018b). Similar GS studies can be conducted in proso millet for major morpho-agronomic and seed quality traits to accelerate genetic improvement of breeding populations in a time-efficient and cost-effective manner.

8.3 Genome Editing

Genome editing is a relatively newer technique adopted by plant breeders to develop new and improved varieties of crops. Rather than introducing transgene(s)

randomly into the host genome, genome editing used sequence-specific nucleases (SSNs) to induce targeted and precise nucleotide sequence changes to the genome (Santra et al. 2019). Genome editing tools have been successfully used to introduce genes into major cereals including rice, wheat, and maize (Ceasar 2022). The most commonly used genome editing tools are clustered regularly interspersed short palindromic repeats-CRISPR-associated nucleases (CRISPR-Cas) system, transcription activator-like effector nucleases (TALENs), and zinc-finger nucleases (ZFNs) (Santra et al. 2019; Ceasar 2022).

There are numerous reports on genome editing in major cereals, especially rice, wheat, maize, and barley. However, genome editing is still a relatively unexplored territory in millets. One example of the successful use of genome editing tools in improving grain quality is the knock-out of three key genes associated with phytic acid (PA) biosynthesis in maize. PA naturally occurs in the grains of many cereal crops, including proso millet. It is considered an antinutrient as it is largely indigestible and may cause environmental pollution. TALEN and CRISPR-Cas9 systems were used to induce mutations in the genes, viz., *ZmIPK*, *ZmIPK1A*, and *ZmMRP4*, encoding enzymes that catalyze three steps in PA biosynthesis (Liang et al. 2014). There are only two reports on successful CRISPR-Cas9-mediated genome modification in foxtail millet (Ceasar 2022). Similar strategies can be implemented in proso millet for improving grain quality by reducing the levels of antinutrients and enriching with health-promoting compounds such as carotenoids. However, reliable, reproducible, and robust micropropagation and transformation systems need to be developed for this crop in order to accomplish this.

9 Conclusion and Future Prospects

Compared to the major crops such as rice, wheat, corn, and soybean, there is a dearth of genomic resources available for the genetic improvement of proso millet. Especially, little to no progress has been made in exploring genes or QTLs linked to grain nutraceutical traits. Therefore, there is a need for devising strategies for developing and harnessing genomic resources in the identification of genes and QTLs associated with seed components in proso millet. This will facilitate omics-assisted breeding of this ancient crop thereby enabling rapid and precise genetic improvement for various agronomic and seed quality traits. Therefore, the global millet researchers must work together to take advantage of such technological advancement in the "omics" research to advance the field of "nutraceutomics" in proso millet. Interdisciplinary research, extension, and promotion are essential for using proso millet in the human food market.

The future prospects of proso millet along with other climate-resilient millets are vast for the food and nutritional security of the global population in the current century and future. The global climate is deteriorating exponentially with the acute pressure of population increase and farmland reduction. All seven millets have great

potential to address the mammoth global challenge. A strong collaboration among the millet geneticists and breeders across the globe will be mandatory for the successful implementation of the "omics" in proso millet "nutraceutomics" research and applications for human health and nutritional security in the changing climate, especially in the climate-fragile countries in the world.

Conflict of Interest The authors declare that they have no conflict of interest.

Funding Acknowledgment The project was supported by "Research State Aided" internal funds: 21-6243-1001.

Abstract

Soybean is a major protein feed and vegetable oil worldwide. Historically, soybean has been consumed in East and Southeast Asia, either as processed or fermented foods. Soybean also contains secondary metabolites such as isoflavones, saponins, and tocopherols (vitamin E) that are beneficial for human health. Studies have been conducted to understand the genetic basis of their biosynthesis and accumulation. Content and composition of most compounds change as response to environmental conditions during the plant growth and seed filling. This chapter will describe findings on oil, protein, isoflavones, saponins, and tocopherol biosynthesis and accumulation in soybean seeds. The availability of next-generation sequencing technologies has changed the way genetic analysis is done, and have accelerated the elucidation of genetic basis of the nutritional components. Moreover, the NGS affordability has provided us with reference genomes, large-scale sequencing data, and transcriptome data that are publicly available. Researchers can access and utilize this data to complement their findings. Lastly, this chapter will describe soy-based foods, the processing and nutritional values, and their potential as nutritional source and health component resources.

1 Introduction

Seeds of soybean (*Glycine max* (L.) Merrill) contain oil (20% of seed weight), protein (40% of seed weight), and secondary metabolites (isoflavones, saponins, and tocopherols). Having high protein and oil content, soybean became one of the major sources of protein and oil. During 2020/2021, soybean protein meal consumption as feed was 243.6 million metric tons, which contributed to 71% of the total protein meal consumed worldwide (Soystats 2022). Soybean oils contributed to 29% (58.7 million metric tons) of world oil consumption (Soystats 2022). Traditionally, soybean has been consumed in East Asia and Southeast Asia as various foods, which can be categorized into two, fermented and nonfermented foods. Nonfermented foods examples are tofu, bean sprout, soymilk, and yuba. Examples of fermented foods are natto, tempeh, miso, jang, and soy sauce. The fermentation process changes the nutritional components of soybean foods, reducing antinutrient components and increasing nutritional compounds. Natto and tempeh contain high vitamin K2 and B12, which are not detected in raw soybean seeds. The fermentation process also adds flavor through the catabolism of protein to amino acids and

reduces antinutritional components such as lipoxygenases, trypsin inhibitors, and phytic acid (Nout and Kiers 2005). In addition to traditional food, recent interest in plant-based diets also increased the attention to soy-based food. Furthermore, the potential of soybean as nutritious food for children, a new protein source in Africa and Europe, and the use of by-products as a new source of nutrients is being explored.

The domestication of soybean occurred about 6000–9000 years ago in Yellow River, Central China (Kofsky et al. 2018). The wild ancestor of soybean is *G. soja* (Siebold &Zucc.). Wild soybean naturally grows in diverse habitats in East Russia, Japan, China, and Korea (Kofsky et al. 2018). Wild soybean plants form vines, giving it the Japanese name "tsurumame," which means "bean (plants) with vines." The seeds are small and black. Soybean and wild soybean outcrossing produce fertile progenies. According to Kofsky et al. (2018), wild soybean has larger genetic diversity compared to soybean. Moreover, wild soybean possesses unique genes not available in soybean (Kofsky et al. 2018). Thus, wild soybean provides a huge genetic reservoir for current soybean cultivars' improvement. To tap this potential, screening natural variants of metabolites content and resequencing projects also include wild soybean in the analysis.

2 Nutritional Components: Biosynthesis and Regulation

2.1 Oil and Fatty Acids

Soybean oils contribute to 29% (58.7 million metric tons) of world oil consumption (Soystats 2022). Oil content per seed dry weight of soybean seeds is approximately 20%. It varies depending on varieties, as well as growth conditions (Clemente and Cahoon 2009). Soybean oil is composed by mainly five fatty acids, palmitic acid (C16:0), stearic acid (C18:0), oleic acid (C18:1), linoleic acid (C18:2), and linolenic acid (C18:3) (Clemente and Cahoon 2009). Generally, linoleic acid is the most abundant fatty acid in soybean oil, about 55% of the total fatty acid content (Clemente and Cahoon 2009). Among five fatty acids, oleic acid, linoleic acid, and linolenic acid are categorized as unsaturated fatty acids, because they have double bonds in their carbon chains. The other two, palmitic acid and stearic acid, are saturated fatty acids, having no double bonds in their carbon chains. Carbon chain length and the level of unsaturation are shown as numbers after "C." For example, oleic acid is described as C18:1, meaning it has 18 carbons and one double bond. Unsaturated fatty acids are more easily oxidized compared to saturated fatty acids, and if the fatty acids have higher number of double bonds, they are less stable. Therefore, linolenic acid is the most easily oxidized, followed by linoleic acid, and oleic acid. Oxidation makes oil becomes rancid and reduces its shelf life. Partial hydrogenation reduces the proportion of unsaturated fatty acids and creates trans-fatty acids, which are linked to cardiovascular diseases (Clemente and Cahoon 2009).

Linoleic (C18:2) and linolenic acids (C18:3) are essential dietary elements for humans and higher animals. They are also able to decrease the risk of coronary heart

diseases (Clemente and Cahoon 2009). Since human body cannot produce linoleic acid and linolenic acid, breeding cultivars with the optimum composition of unsaturated fatty acid and saturated fatty acid is one of the soybean breeding objectives. Quantitative trait locus (QTL) and genome-wide association study (GWAS) analyses have identified numerous quantitative trait loci (QTLs) associated with oil and fatty acid content in soybean seeds (Patil et al. 2017, 2018). Some of the oil content QTLs shared position with protein content but with contrasting effect.

2.1.1 Fatty Acids Biosynthesis and Its Regulation

Fatty acids are synthesized from acetyl-CoA in the plastid. Acetyl-CoA is carboxylated to produce malonyl-CoA. Fatty acid transferase adds two carbon atoms to the acyl chain on acyl carrier protein (ACP) repeatedly to create 16 carbon acyl-ACP (C16:0-ACP). Reduction, dehydration, and reduction processes also occur along with the elongation process. C16:0-ACP can be elongated further by ketoacyl-ACP synthase II (KASII) to produce C18:0-ACP. Stearoyl-ACP desaturase desaturases C18:0-ACP to produce C18:1-ACP. Free fatty acids (C16:0, C18:0, and C18:1) are released from ACP and transported to the endoplasmic reticulum (ER). In ER, C18:1 is further desaturated by fatty acid desaturases to C18:2, and lastly to C18:3. Fatty acids in soybean seeds are stored in the form of triacylglycerol (TAG). Free fatty acids from ER and plastid are incorporated into glycerol-3-phosphate and undergo a series of conversions to create diacylglycerol (DAG). DAG is converted to triacylglycerol (TAG) by acyl-CoA:DAG acyltransferase (DGAT). TAG in soybean seeds is mostly stored in oil bodies (oleosomes), within membranes containing phospholipids and oleosins.

Fatty acid desaturase-2 (FAD2) desaturases oleic acid (C18:1) to linoleic acid (C18:2). There are five *FAD2* genes in soybean. Mutations at either *GmFAD2-1A* or *GmFAD2-1B* increased oleic acid content to 80% and decreased linoleic acid content to 30% (Anai et al. 2008). Double mutations of *GmFAD2-1A* or *GmFAD2-1B* produced lines having 80% oleic acid whereas linoleic acid was reduced to less than 5% (Pham et al. 2012). Desaturation of linoleic acid (C18:2) to linolenic acid (C18:3) is catalyzed by FAD3. There are three genes encoding FAD3, namely *GmFAD3A*, *GmFAD3B,* and *GmFAD3C* (Pham et al. 2012). Combination of *GmFAD3A-GmFAD3B* or *GmFAD3A-GmFAD3C* mutations produced lines having linolenic acid about 3% of total oil content, whereas triple mutations of *GmFAD3* genes resulted in lines having 1% linolenic acid content (Pham et al. 2012). Pham et al. (2012) further combined *GmFAD2-1* double mutants with one *GmFAD3* mutant, producing mutants having less than 2% linolenic acid. Interestingly, growing locations affected the linolenic acid content of the mutants (Pham et al. 2012). Lines having triple mutants (*FAD2-1aabb FAD3aaCC* or *FAD2-1aabb FAD3AAcc*) had linolenic acid content less than 3% when they were grown in Portageville, Missouri, but quadruple mutants (*FAD2-1aabb FAD3aacc*) type is needed to achieve the same level of linolenic acid content for growing in Columbia (Missouri) which is located north of Portageville (Pham et al. 2012). Demorest et al. (2016) used transcription activator–like effector nucleases (TALEN), a gene editing method, to mutate

GmFAD3A in *fad2-1a- fad2-1b* mutants and produced lines with low linolenic acid (2.5%) and high oleic acid (82.2%).

2.2 Protein

Protein contributes to about 40% of seed dry weight in commercial cultivars, and varies based on genotype or growth environment. Multiple genes regulate protein content. More than 160 QTLs distributed across 20 chromosomes have been identified from 35 independent studies (Patil et al. 2017). Of these, QTLs located on chromosome 15 and 20 are strongly correlated with protein content. The result was also confirmed in large-scale GWAS analysis conducted on 12,000 soybean accessions (Bandillo et al. 2015). Candidate gene analysis on chromosome 15 and 20 both identified three candidate genes each, which need further investigation for their roles in protein content regulation (Bandillo et al. 2015). Both QTLs also regulated oil content (Bandillo et al. 2015), but total protein content is negatively correlated with oil content (Patil et al. 2017). Therefore, it is challenging to breed a soybean cultivar having both high protein and oil content. While genetic breeding remains focused on seed yield and soybean oil remains as the major consumption of global soybean production, there might be a very few cultivars developed for its ultrahigh protein content though soybean accessions with >50% protein content were reported (Patil et al. 2017).

Protein composition is also important for soybean nutritional value. About 70% of total storage proteins in soybean is composed by glycinin (11S globulin) and β-conglycinin (7S globulin) (Takahashi et al. 2003). β-conglycinin (7S globulin) is a heterotrimeric protein, and has three subunits: α, α′, and β-subunit. β-subunit has 420 amino acids (AA) that are shared with α and α′-subunit. The α and α′-subunits have additional 125 AA and 141 AA in the N-terminal, respectively. Glycinin (11S globulin) is a heterohexameric protein, consisting of five subunits A1aB1b, A1bB2, A2B1a, A3B4, and A5A4B3 (Adachi et al. 2003). Between two storage proteins, the amount of methionine and cysteine per unit protein is higher in 11S globulin (Kitamura 1995). Methionine is an essential amino acid that cannot be synthesized in human body but it is important to build proteins and molecules in human body. Sufficient intake of methionine is important for the proper function of cells. Moreover, high 11S to 7S globulin is preferred in tofu processing, as it forms harder curd in tofu production (Kitamura 1995).

Several breeding programs have aimed to increase the ratio of 11S globulin to 7S globulin using natural mutants in germplasm or mutants gained by γ-ray irradiation (Kitamura 1995). For example, 'Kebuli' lacking α'-subunit and 'Moshidou Gong 503' having low levels of α- and β-subunits have been used to breed lines with low α, β-subunits, and null α'-subunit (Kitamura 1995). The 7S-low lines had 50% lower 7S globulin and the 11S globulin was 15% higher compared to normal varieties without change in total protein content (Kitamura 1995). Gamma-ray irrradiation of 'Karikei 434' produced a mutant line lacking both α- and β-subunits and low level of α'-subunit without decrease in total protein content or defect in plant development

(Takahashi et al. 1994). The reduced 11S globulin content in soybean were compensated by increase in 7S globulin (Yang et al. 2016). Takahashi et al. (2003) produced a mutant line lacking both 7S and 11S globulin without any defect in growth and production by crossing a line lacking 7S globulin with a line lacking 11S globulin. Protein bodies in cotyledons of the mutant is underdeveloped but the nitrogen content did not change compared to wild-type cultivars (Takahashi et al. 2003). Interestingly, free amino acids (arginine, asparagine, glutamic acid, and histidine) increased in the mutant, contributing to 4.5–8% of seed nitrogen content, whereas the proportion in wild-type varieties is between 0.3% and 0.8% (Takahashi et al. 2003).

Soybean also has proteins which are allergens (Wilson et al. 2005). Subunits of 7S globulin also generate antibody response in mice fed with soy protein (Wilson et al. 2005). There are about 20 proteins identified as allergen in soybean. Three known major soybean allergens are *Gly m* Bd 60 K (α-subunit of β-conglycinin), *Gly m* Bd 30 K, and *Gly m* Bd 28 K (vicilin-like glycoprotein), respectively. P34 (Gly m Bd 30 K) shares 70% homology with peanut main allergen (Wilson et al. 2005). Due to this, most patients having allergy to peanuts also showed allergy to soybean (Wilson et al. 2005). Fermentation process hydrolyzes proteins and as the result, fermented soybean products such as miso, natto, tempeh, and soy sauce are potentially less allergenic than raw soybeans. For example, *Gly m* Bd 28 K content is reduced in fermented soybean products compared to raw soybean and nonfermented soy products (Ogawa et al. 2000; Bando et al. 1998). Another example of reducing soybean allergens is through breeding, such as low-P34 varieties having reduced P34 (Gly m Bd 30 K) content (Bilyeu et al. 2009). Analysis of soybean germplasm identified natural mutants such as PI 567476 and PI 603570A, which contain four base pairs insertion at P34 start codon resulting in translation initiation frameshift of the protein (Bilyeu et al. 2009). Molecular markers were developed to recognize this mutation and were used in marker-assisted selection for low P34 soybean cultivars (Watanabe et al. 2017).

2.3 Isoflavones

Isoflavones are metabolites derived from phenylalanine pathway. They are mainly found in legumes (Dhaubhadel et al. 2003, 2007). Soybean isoflavones can be categorized to three types based on their aglycone structure, daidzein, genistein, and glycitein. The aglycone forms are biologically active and are absorbed in the human intestine. Isoflavones have many human benefits, including reducing hormone-dependent cancers and cardiovascular disease risk alleviating postmenopausal symptoms, and preventing osteoporosis. In plants, it induces phytoalexin production as a response to pathogen attack, induces the expression of nodulation genes, and regulates the formation of nodules in soybean roots (Dhaubhadel et al. 2003).

Two major of soybean isoflavones are exist as malonylglycoside and glycoside forms (Tsukamoto et al. 1995). Isoflavones are synthesized starting at an early development stage and the accumulation rapidly increases at later stages of seed

development (Dhaubhadel et al. 2003, 2007). Seed isoflavone content is affected by the environment, particularly the temperature during plant growth and seed maturation (Chennupati et al. 2011). Seven soybean varieties were grown in Kyushu and six varieties were grown in Tsukuba in three sowing times: April, May, and June 1991 (Tsukamoto et al. 1995). Average temperatures in Tsukuba and Kyushu differed by 4 °C in July–August 1991, but the average temperatures differed only 1 °C in October 1991 (Tsukamoto et al. 1995). Four varieties ('Koganedaizu', 'Shirosaya I', 'Higomusume', and 'Kairyoshirome') belonged to the early maturity group (Group I and II) and were known as low isoflavone varieties, and the other three varieties grown as control belonged to maturity group IV and VI (Tsukamoto et al. 1995). Interestingly, regardless of the varieties, malonyldaidzin and malonylgenistin contents were higher in whole seeds of the plants sown in July 1991 compared to seeds of plants from earlier sowing dates (Kyushu only). Harvest dates of the early maturity group sown in July 1991 were late September 1991, when the average temperature was 24.7 °C, the maximum was 29.5 °C, and the minimum was 19.8 °C (Tsukamoto et al. 1995), which was lower compared to an average of 27.2 °C in August 1991 (Tsukamoto et al. 1995). Chennupati et al. (2011) also investigated the effect of high temperature on the isoflavone content of two cultivars, 'AC Proteina' (high isoflavone) and 'OAC Champion' (low isoflavone). Stress condition of 33 °C/25 °C (day/night temperature) and control condition of 23 °C/15 °C (day/night temperature) were imposed during all developmental stages, pre-emergence, vegetative stage, early seed filling (R1-R4 stages), and late seed filling stage (R5-R8 stages) (Chennupati et al. 2011). Both cultivars showed a reduction in total isoflavone content when stress was imposed during all development stages and late seed filling stages (Chennupati et al. 2011), which coincided with the rapid isoflavone accumulation during late seed filling stages.

2.3.1 Isoflavone Biosynthesis and Its Regulation

Isoflavone biosynthesis is a part of the phenylpropanoid pathway, which is also a precursor pathway for anthocyanins and lignin biosynthesis (Fig. 1). Phenylalanine ammonia lyase (PAL) catalyzes deamination of phenylalanine to cinnamic acid as the first enzyme of isoflavone biosynthesis process. Cinnamic acid is converted to p-coumaryol CoA through two steps catalyzed by cinnamate 4-hydroxylase (C4H) and 4-coumarate CoA ligase (4CL). P-coumaryol CoA and its precursor, p-coumaric acid, are a substrate for lignin biosynthesis. The next step is catalyzed by chalcone synthase (CHS). CHS converts p-coumaryol CoA to naringenin chalcone, and together with chalcone reductase converts p-coumaryol CoA to isoliquiritigenin. Naringenin chalcone and isoliquiritigenin are further converted to naringenin and liquiritigenin, respectively. This step is catalyzed by chalcone isomerase. Naringenin is converted to genistein by isoflavone synthase (IFS). IFS also catalyzes the conversion of liquiritigenin to daidzein. Glycitein is produced from liquiritigenin by a series of conversions involving flavonoid 6-hydroxylase (F6H) and IFS. Genistein, daidzein, and glycitein are further converted to their glucosides from (genistin, daidzin, and glycitin) by isoflavone 7-*O*-glucosyltransferase (IF7GT). Lastly, the malonylglucosides are synthesized from isoflavone glucosides, and the reaction is catalyzed by isoflavone 7-O-glucoside 6"-*O*-malonyltransferase

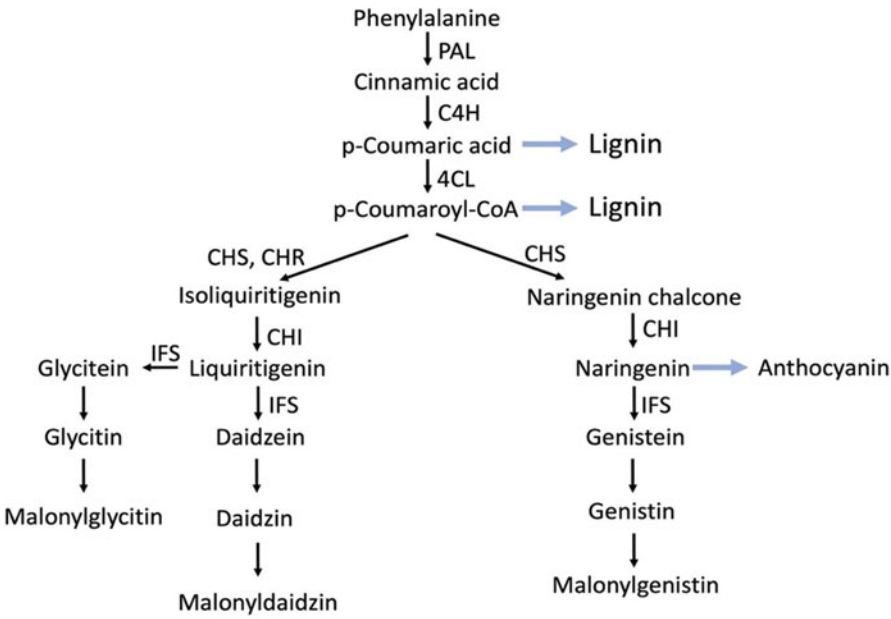

Fig. 1 Isoflavones biosynthesis pathway. Abbreviations for enzymes: *PAL* phenylalanine ammonia lyase, *C4H* cinnamate 4-hydroxylase, *C4L* 4-coumarate CoA ligase, *CHS* chalcone synthase, *CHR* chalcone reductase, *CHI* chalcone isomerase, and *IFS* isoflavone synthase

(IF7MaT) (Fig. 1). CHS and IFS are the most studied among enzymes in the isoflavone biosynthesis pathway.

Soybean contains multiple genes encoding for CHS. Dhaubhadel et al. (2007) performed transcriptome array analysis on two soybean cultivars, 'Harovinton' (low isoflavone) and 'RCAT Angora' (high isoflavone), to determine genes involved in isoflavone biosynthesis. The transcriptome analysis was conducted on five stages of seed development (Dhaubhadel et al. 2007). Compared to other copies, *CHS7* and *CHS8* are expressed in seeds and the expression level increased toward seed maturity (Dhaubhadel et al. 2007). The expression increases also coincided with the accumulation of seed isoflavones (Dhaubhadel et al. 2007).

There are two gene copies for IFS: *IFS1* and *IFS2*. Both copies are involved in isoflavone biosynthesis, but their transcription is regulated differently (Dhaubhadel et al. 2003). The genes are very similar, only *IFS1* is expressed in all tissues, but its expression is the highest in root and seed coats (Dhaubhadel et al. 2003). *IFS2* expression is low in stems, leaves, pods, and seed coats (Dhaubhadel et al. 2003). Its expression is high in embryos, developing seeds, and late-stage pods (Dhaubhadel et al. 2003). Interestingly, the expression level of *IFS2* in developing seeds increases toward maturity, whereas the *IFS1* expression is constant (Dhaubhadel et al. 2003). On the other hand, *IFS2* plays role in response to pathogen attack since its expression increased in hypocotyls and roots after pathogen attacks (Dhaubhadel et al. 2003; Subramanian et al. 2004).

Transcription levels of isoflavone biosynthesis genes are regulated by numerous transcription factors (TFs) such as MYB, bHLH, bZIP, WRKY, and MADS-boxand WD40 (Yi et al. 2010). There are more than 5000 genes putatively encoding TFs, and MYB TFs comprise about 14% of TFs. Based on the number of MYB domains, MYBs are classified into 1R, 2R (R2R3-type), 3R, and 4R MYBs. *GmMYB176* encoding R1-type MYB was identified as a regulator for *CHS8* (Yi et al. 2010). Cotransfection assay showed that *GmMYB176* transactivated the *CHS8* promoter (Yi et al. 2010). Hairy roots RNAi-mediated gene silencing of *GmMYB176* reduced isoflavone content, but the overexpression did not increase the transcript level of CHS8 (Yi et al. 2010). R2R3-type MYB TFs such as *GmMYB100*, *GmMYB39,* and *GmMYB29* were also identified as potential regulators for isoflavone biosynthesis (reviewed in Sohn et al. 2021).

Although genes encoding biosynthesis genes and transcription factors regulating isoflavone content have been identified, the regulation in natural germplasm is much more complex, since genotype × environment interaction effect is large, and flavonoids are also involved in biotic stress response. More than 200 QTLs distributed in 20 chromosomes have been reported from a GWAS and QTL analyses using 200 soybean cultivars and 150 RILs identified several SNPs and QTLs associated with isoflavone content (Wu et al. 2020).

2.4 Saponins

Soyasaponins are triterpenoid glycosides (Sundaramoorthy et al. 2018). In soybeans, there are two major types of saponins, group A saponins and DDMP saponins (Sundaramoorthy et al. 2018). Group A saponins are the major form of saponin in hypocotyl, whereas DDMP saponins is a predominant form in cotyledon (Sundaramoorthy et al. 2018). Group A saponins cause bitter and astringent taste in soy food products (Tsukamoto et al. 1995). On the other hand, DDMP saponin showed health benefits such as inhibition of HIV infection and activation of Epstein-Barr virus early antigen (Tsukamoto et al. 1995). Therefore, decreasing the amount of group A saponins and increasing DDMP saponins would contribute to the improvement of soy-based foods' quality (Tsukamoto et al. 1995).

Group A saponins and DDMP saponins differ in the C-21 position of their soyasapogenol structure. Group A saponins have a hydroxy group (-OH) at the C-21 position (Fig. 2). The aglycones are called soyasapogenol A orsoyasapogenol B (Fig. 3). DDMP saponins have a 2,3-dihydro-2,5-dihydroxy-6-methyl-4H-pyran-4-one (DDMP) moiety attached to the C-22 position of the soyasapogenol B (Fig. 3). During food processing, DDMP saponins are degraded to B saponin and E saponin (Fig. 3, Krishnamurthy and Min 2014). In addition, there are one or two sugar moieties attached to the C-3 position (R_1), and acetylxylose or acetylglucose attached to the C-22 position (R_2) resulting in saponin variations (Fig. 2). Saponins are derived from β-amyrin, which is a product of the mevalonate pathway (Sundaramoorthy et al. 2018). Genes involved in soybean saponin biosynthesis

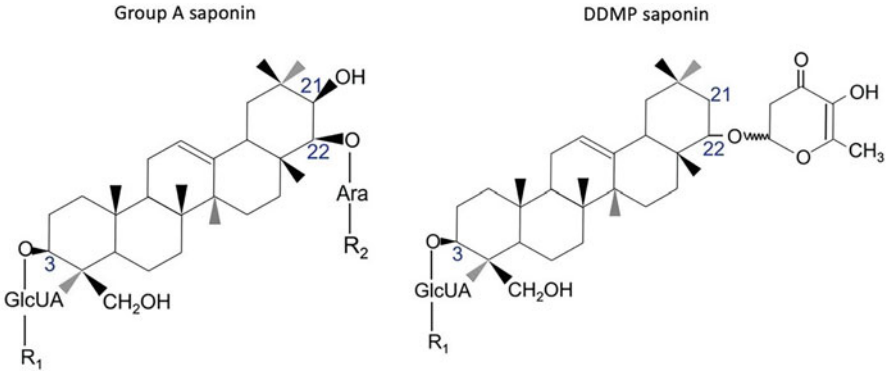

Fig. 2 Group A saponin and DDMP saponin structure. R_1 is either galactose (Gal), arabinose (Ara), combinations of glucose-galactose (Glc-Gal), rhamnose-galactose (Rha-Gal), Glc-Ara, or Rha-Ara. R_2 is either acetylglucose or acetylxylose

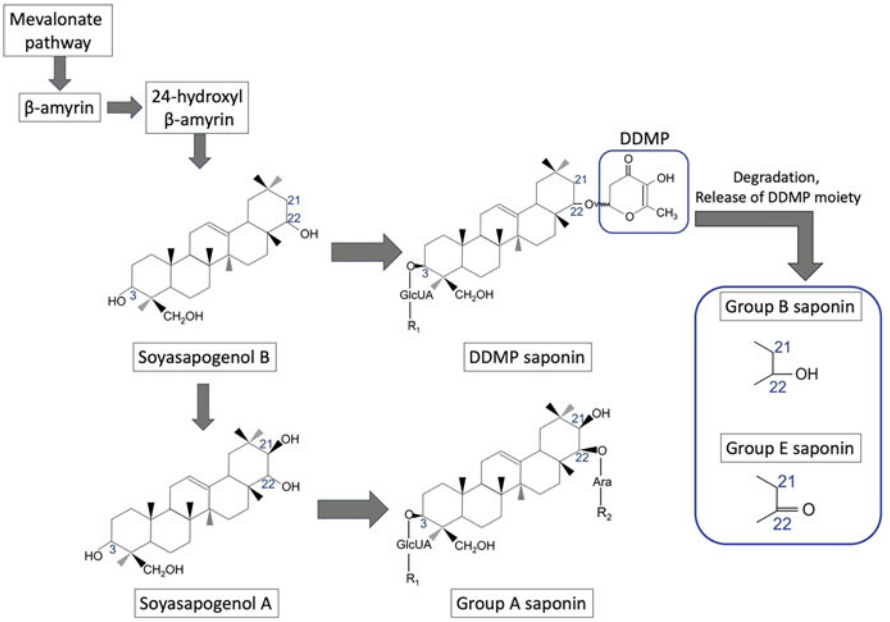

Fig. 3 Saponin biosynthesis pathway

pathway has not yet been fully elucidated, but several mutants having altered saponin composition have been identified (Fig. 3).

Two mutants, *Sg-1*^{a}and *Sg-1*^{b}, showed a mutation in Glyma.07G254600, encoding a glycosyltransferase (Sayama et al. 2012). The significant difference between them is the amino acid number 138; Sg-1^a and Sg-1^b proteins have serine and glycine, respectively (Sayama et al. 2012). This resulted in a difference in their

function. Sg-1^{a} adds xylose whereas Sg-1^{b}adds glucose to the aglycone (Sayama et al. 2012). Accessions with the *Sg-1^{a}*allele have acetylxylose, and accessions with the *Sg-1^{b}* allele have acetylglucose as the third sugar group at the C-22 position. Mutants having loss-of-function allele *sg-1^{0}* accumulated saponin A0-αg lacking acetylated terminal sugar at the C-22 position (Sayama et al. 2012). The *sg-1^{0}* mutant has been used to breed 'Kinusayaka', which has a less bitter taste and astringent flavor. The variety is suitable for soymilk and tofu production (Kato et al. 2007).

Sg-3 locus contains a glucosyltransferase UGT91H4 (Glyma.10G104700). The enzyme adds glucose as a third sugar at the C-3 position of group A saponin or DDMP saponin. *Sg-4* locus contains a glycosyltransferase UGT73P10 (Glyma.01-G046300). Homozygous recessive *sg-4* mutants lacked saponins that have arabinose as the second sugar group at the C-3 position (Takagi et al. 2018).

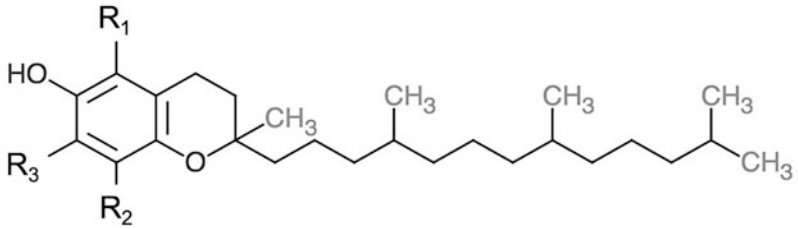
Sg-5 (Glyma.15g243300) encodes a cytochrome P450 enzyme (Yano et al. 2017). The natural *sg-5* mutant was first identified in wild soybean, and the mutant did not accumulate group A saponin but showed a high level of DDMP saponin (Yano et al. 2017). This mutant had a premature stop codon in Glyma.15g243300 (Yano et al. 2017). Since high DDMP-low group A saponin is desirable for food production, the *sg-5* allele has been introduced to 'Tohoku 152' (Yano et al. 2017). 'Tohoku 152' has low amount of group A saponins both in hypocotyl and cotyledon. Compared to cultivars carrying *Sg-5*, 'Tohoku 152' has higher DDMP saponin in the hypocotyl (Yano et al. 2017).

2.5 Tocopherols (Vitamin E)

Tocopherols are known as vitamin E. Tocopherol is consisted of a chromanol head and a saturated phytyl side chain. The number and position of the methyl groups on the chromanol head determine the isoforms as α-, β-, γ-, and δ- tocopherol (Fig. 4). Among four isoforms, α-tocopherol has high affinity with tocopherol transfer protein in the human liver, and kept at a high level in blood plasma. Thus, the vitamin E activity of α-tocopherol is the highest among four isoforms. The vitamin E activities of β-, γ-, and δ-tocopherol are 0.5, 0.1, and 0.03 when compared to vitamin E activity of α-tocopherol (equal to 1), respectively (Van Eenennaam et al. 2003).

Total tocopherol content of soybean seed oil is higher than other oils from canola, sunflower, or palm. The major isoform in seeds is γ-tocopherol (60–70%), followed by δ-tocopherol (20–30%), whereas α-tocopherol content is less than 10%. Increasing α-tocopherol content in soybean seeds may improve the vitamin E status of soybean. On the other hand, γ-tocopherol and its derivative showed an anti-inflammatory effect, which is a specific function that was not observed in α-tocopherol (Jiang et al. 2001). Altering the ratio of γ-tocopherol and α-tocopherol may be preferred instead of increasing only the α-tocopherol content.

Seed tocopherol content diversity of soybean germplasm has been surveyed in Japan (Ujiie et al. 2005; Dwiyanti et al. 2016), India (Rani et al. 2007), and Brazil (Carrão-Panizzi and Erhan 2007). From the screening of more than 1000 soybean and wild soybean accessions, three accessions containing high α-tocopherol



Compound	R1	R2	R3	Vitamin E Activity (ratio to α-tocopherol)
α-Tocopherol	CH_3	CH_3	CH_3	1
β-Tocopherol	CH_3	H	CH_3	0.5
γ-Tocopherol	H	CH_3	CH_3	0.1
δ-Tocopherol	H	H	CH_3	0.03

Fig. 4 Tocopherol structure and isoforms

(more than 20% of total tocopherol content) were identified: 'Keszthelyi Aproszemu Sarga', 'Dobrogeance', and 'Dobrudza 14 Pancevo' (Ujiie et al. 2005). The α-tocopherol content ranged from 58 μg/g oil to 794 μg/g oil (Rani et al. 2007). The highest α-tocopherol percentage (27%) was observed in the variety 'Ankur' (Rani et al. 2007). The α-tocopherol content 89 Brazil soybean accessions varied between 11 ppm ('Davis') and 191 ppm ('IPB-T') (Carrão-Panizzi and Erhan 2007). 'IPB-T' also showed high total tocopherol content (1386.29 ppm) (Carrão-Panizzi and Erhan 2007).

Tocopherols accumulate during the later stage of soybean seed development (R5–R8 stages). High temperature (28 °C) and mild drought during these stages increased seed α-tocopherol content approximately twofold compared to those grown at 23 °C (Britz and Kremer 2002). When the high temperature was imposed in different developmental stages, high temperature during whole growth stages or seed filling (R5–R8 stage) gave the largest effect on the increase in α-tocopherol content (Chennupati et al. 2011). In high temperatures, δ-tocopherol content decreased (Britz and Kremer 2002; Chennupati et al. 2011). Total tocopherol content and γ-tocopherol content change varied depending on studies and varieties (Britz and Kremer 2002; Chennupati et al. 2011).

2.5.1 Tocopherol Biosynthesis and Its Regulation

The tocopherol biosynthesis pathway in higher plants is already elucidated (Fig. 5). The first component in the tocopherol biosynthesis pathway is 2-methyl-6-phytyl-1,4-benzoquinone (MPBQ) which is synthesized by combining homogentisic acid (HGA) and phytyl-diphosphate (PDP). HGA is produced from the shikimate pathway, whereas PDP is produced from the MEP pathway or chlorophyll degradation

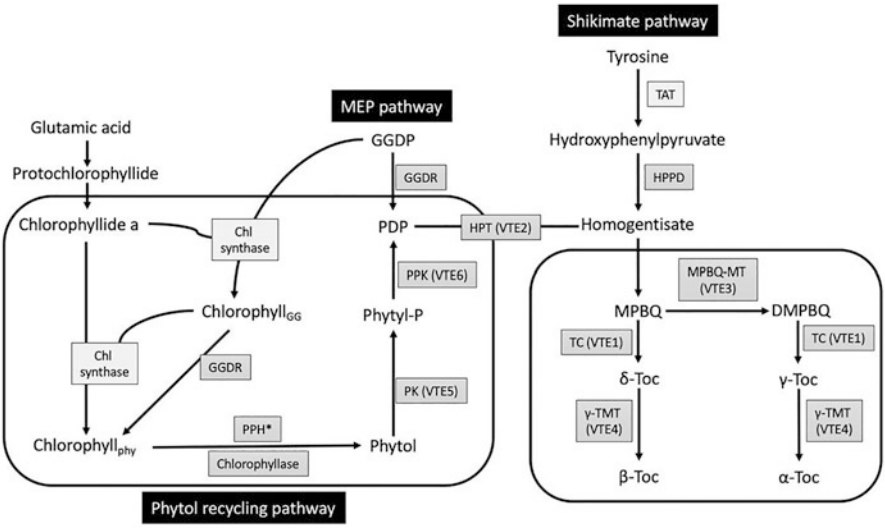


Fig. 5 Tocopherol biosynthesis and chlorophyll degradation/phytol recycling pathway. MEP: methylerythritol phosphate. Abbreviations for substrates: *GGDP,* geranylgeranyl diphosphate; *PDP,* phytyl diphosphate; *MPBQ,* methylphytylbenzoquinol; *DMPBQ,* dimethylphytylbenzoquinol; *Toc,* tocopherol. Abbreviations for enzymes: *GGDR,* geranylgeranyl diphosphate reductase; *PPK,* phytyl phosphate kinase; *PK,* phytyl kinase; *Chl synthase,* chlorophyll synthase; *PPH,* pheophytin pheophorbide hydrolase; *TAT,* tyrosine aminotransferase; *HPPD,* hydroxyphenylpyruvate dioxygenase; *HPT,* homogentisatephytyl transferase; *MPBQ-MT,* MPBQ methyltransferase; *TC,* tocopherol cyclase; *γ-TMT,* γ-tocopherol methyltransferase

pathway. MPBQ is subsequently methylated by MPBQ- methyltransferase enzyme (MPBQ-MT) and is converted to 2,3-dimethyl-5- phytyl-1,4-benzoquinone (DMPBQ). The δ-tocopherol and γ-tocopherol are produced from cyclization of the chromanol heads of MPBQ and DMPBQ, respectively. Tocopherol cyclase is involved in this process. Gamma-tocopherol methyltransferase (γ-TMT) adds a methyl group to the chromanol head of δ-tocopherol and γ-tocopherol, converting them to β-tocopherol and α-tocopherol, respectively. Most tocopherol biosynthesis genes were first identified in Arabidopsis. The names of the corresponding Arabidopsis genes (*VTE* genes) are annotated in Fig. 5. MPBQ-MT and γ-TMT enzymes play important role in determining tocopherol composition in soybean seeds (Van Eenennaam et al. 2003). Overexpression of Arabidopsis *VTE4* gene expressing γ-TMT (Van Eenennaam et al. 2003) could increase seed α-tocopherol percentage up to 50–75% of total tocopherol content, and reduced δ-tocopherol and γ-tocopherol percentage. Overexpression of Arabidopsis *VTE3* gene encoding the MPBQ-MT reduced δ-tocopherol and β-tocopherol, and increased γ-tocopherol and α-tocopherol 10% compared to wild type. Coexpression of both *VTE3* and *VTE4* expressing MPBQ-MT and γ-TMT further improved α-tocopherol up to 60.4–91%

of total tocopherol content, eliminated most of δ-tocopherol and β-tocopherol, and reduced γ-tocopherol (Van Eenennaam et al. 2003).

Overexpression of the Arabidopsis *VTE2* gene expressing homogentisate phytyltransferase (HPT) resulted in slight increase of total tocopherol content (Karunanandaa et al. 2005). Seed-specific overexpression of four genes encoding Arabidopsis HPPD, VTE2, GGDP dehydrogenase (GGH), and *Erwinia herbicola* prephenate dehydrogenase (*Eh-TYRA*) was conducted (Karunanandaa et al. 2005). TYRA catalyzes the synthesis of p-hydroxyphenylpyruvate, homogentisic acid precursor. The overexpression of four genes increased tocochromanols up to 15-fold in the best transgenic event (Karunanandaa et al. 2005). Surprisingly, up to 94% of tocochromanols in transgenic seeds were tocotrienols instead of tocopherols (Karunanandaa et al. 2005). How the combination of four genes led to conversion to tocotrienols is still unknown.

Based on the Williams82 gene annotation, soybean has multiple gene copies of each enzyme in tocopherol biosynthesis. The copies may show differentiation in function and response to the growth environment. For example, there are three gene copies for γ-TMT: Glyma.12G014200 (*γ-TMT1*), Glyma.12G014300 (*γ-TMT2*), and Glyma.09G222800 (*γ-TMT3*) (Dwiyanti et al. 2011). Based on public transcriptomics data, the three copies are expressed in leaves, flowers, and early-stage pods (Severin et al. 2010; Le et al. 2007). Since tocopherol also plays role as antioxidant in photosynthetic organs, the gene expression observed in leaves, flowers, and pods may relate to its function. Interestingly, in developing seeds, the difference in expression pattern was observed. The *γ-TMT1* is expressed higher in early stage of developing seeds and gradually decreased toward maturation. On the other hand, the seed *γ-TMT2* and *γ-TMT3* expression level increases toward seed maturation. Among three copies, only *γ-TMT2* expression level is elevated at high temperature, whereas *γ-TMT1* and *γ-TMT3* did not increase (Park et al. 2019).

Glyma.09G222800 (*γ-TMT3*) was identified as a candidate gene responsible for high α-tocopherol content in KAS. The candidate gene was identified based on QTL analysis on an F_5 population derived from 'Ichihime' × 'KAS' cross (Dwiyanti et al. 2011). Further confirmation using GUS-reporter assay in leaves of transgenic Arabidopsis transformed with 'KAS' *γ-TMT3* promoter-intron GUS and with 'Ichihime' *γ-TMT3* promoter-intron GUS showed that 'KAS' *γ-TMT3* promoter activity was higher than that of 'Ichihime' (Dwiyanti et al. 2011). Another QTL analysis using recombinant inbred lines (RILs) population derived from a Hokkaido cultivar 'TK780' and high α-Toc wild soybean ('B04009') identified several QTLs, including a QTL containing *γ-TMT3* and a QTL containing *γ-TMT1* and *γ-TMT2* (Park et al. 2019). Interestingly, both studies found *γ-TMT3* as the candidate gene and same single-nucleotide polymorphisms (SNPs) differentiating between high and low varieties (Dwiyanti et al. 2011; Park et al. 2019). One of these was located within CAAT-box, which is located 74-bp upstream the translation start codon (Dwiyanti et al. 2011). Compared to 'TK780' and 'Ichihime', the *γ-TMT3* expression level was elevated in 'KAS' and 'B04009', during seed maturation. This correlated to difference in α-tocopherol content (Dwiyanti et al. 2011; Park et al. 2019).

3 Genetic Marker Resources and Genotyping Technologies

3.1 RFLP, AFLP, and RAPD

Restriction fragment length polymorphism (RFLP) is a marker based on DNA variations within restriction enzyme sites. Restriction enzymes (REs) recognize RE sites and cut the DNA. If DNA variation occurs at the RE sites, RE cannot cut the DNA. RE then can be used to digest DNA, and the differences in fragment length are the source of RFLP markers. RFLP is a codominant marker and does not need reference genome information, therefore it is suitable for soybean genotyping before the whole genome sequence was available. The first soybean genetic linkage map consisted of 26 linkage groups and was constructed from 150 RFLP markers based on a F_2 population derived from a cross between a soybean cultivar A81-356022 and a wild soybean accession PI468916 (Song et al. 2004). After that several RFLP-based linkage maps were constructed (Song et al. 2004). However, RFLP has disadvantages: large amount of DNA needed for digestion and radioactive probe usage to detect polymorphism. In soybean, the polymorphism rate of RFLP markers is low. Also, since soybean is an ancient polyploid, RFLP probes map to more than one position in the genome, makes it difficult to compare the genotyping results across different studies.

Amplified fragment length polymorphism (AFLP) also utilizes variations within RE sites. The difference from RFLP is that, after the genomic DNA digestion with RE, the DNA fragments are ligated to adaptors that ligate to the restriction enzyme site. Primers complementary to adaptor sequences amplify a subset of ligated fragments. The amplified fragments are then electrophoresed, and the presence/absence of the fragments are visualized as variations for individuals. The advantage of AFLP is that it requires less amount of DNA compared to RFLP, and does not require radioactive probes. However, it is a dominant marker, so it is difficult to use as a marker in QTL analysis using segregating populations with a high rate of heterozygosity such as F_2 generation.

Random amplified polymorphic DNA (RAPD) markers are developed based on PCR amplification of random segments of genomic DNA with a single primer of the arbitrary nucleotide sequence. A disadvantage of RAPD markers is that it is a dominant marker, thus it cannot distinguish whether a locus is heterozygous or homozygous. Another disadvantage is that the amplification reproducibility is low because the amplification uses arbitrary primers that are not locus specific and the PCR result depends on genome DNA quality and PCR conditions.

3.2 Simple Sequence Repeats

Simple sequence repeats (SSR) markers or microsatellites are based on tandemly repeated 2–5 nucleotides, such as (CA)n, (AT)n, (ATT)n, and (ATG)n. Primers for SSR markers are designed using the conserved DNA sequences flanking these repeats. SSR is easy to use since it only requires PCR using the designated primers

to detect the repeat number variations between varieties. Repeat number variations can be observed as differences in fragment length using gel electrophoresis performed after PCR. SSR markers are abundant and easy to use, therefore they were the main markers used for QTL mapping prior to next-generation sequencing. Even now, SSR markers are still used to fill in the gaps in linkage maps produced from SNP genotyping, and it is useful for labs with limited budget and sometimes the genotyping using SSR is much faster and easy than SNP genotyping for a small-scale project or for fine-mapping a certain QTL locus.

A number of SSR markers for soybean has been developed since 1990s (Song et al. 2004). Song et al. (2004) evaluated the possibility of expressed sequence tag (EST) sequences as resource for SSR markers. The team screened 136,800 ESTs available in the GenBank to identify sequences containing SSRs. EST, however, contains low number of potential SSR markers having only low number of dinucleotide repeats of ten or more, and trinucleotide repeats of eight or more. Therefore, instead of EST, Song et al. (2004) looked into genomic libraries of 'Williams' soybean and bacterial artificial chromosome (BAC) clones. The number of SSR markers from genomic libraries and BAC clones was higher than that from EST. A total of 420 SSR markers developed: 24 from EST, and the remaining 396 markers were from BAC clones or genomic libraries. The SSR markers then were used to develop a genetic linkage map containing 20 linkage groups, with the number of markers per group varied between 12 and 29. After the release of Williams82 reference genome Glyma1, more than 210,000 potential SSR markers were identified from the reference genome (Song et al. 2010). After screening for locus specificity and perfect motif repeats, a BARCSOYSSR_01 database consisting of 21,206 SSR markers was published (Song et al. 2010). The database contains information on SSR marker ID, position in the chromosome, repeat motif, the physical position of flanking primers, estimated PCR product size, as well as the flanking primer sequences (Song et al. 2010).

3.3 Single-Nucleotide Polymorphism (SNP)

Single-nucleotide polymorphism (SNP) markers are abundant, biallelic, and their positions in the genome are known. In the GmHapMap dataset consisting of 1007 diverse accessions of soybean and wild soybean (Torkamaneh et al. 2021), there were 12.1 million SNPs across 1.1 Gb-length genomes. Biallelic means that at any SNP locus there will be only two nucleotides of four possible types (A, C, G, and T). The occurrence of the third allele is rare. The biallelic nature of SNPs also led to the development of automated and large-scale genotyping systems such as SNP chips or flexible array systems (Thomson 2014). Lastly, since the SNP position in the genome is known, it is possible to develop markers using primers based on the flanking sequences. These markers then can be used to compare genotyping results across different studies or populations and help the development of SNP databases compiled from different studies. In addition, the known position of SNPs makes it possible to predict the effect of SNPs on the phenotype. For example, SNPs located

in the exon may lead to an early stop codon, missense mutation, or induction of splicing variants. SNPs located in the promoter region may add or reduce cis-elements regulating the gene expression.

There are two types of SNP genotyping methods, fixed and flexible platforms (Thomson 2014). One example of a soybean fixed SNP genotyping platform is SoySNP50K BeadChip, which was developed based on DNA sequence analysis of six soybeans and two wild soybean accessions (Song et al. 2013). Initially, more than 200,000 SNPs were identified. After filtering for the distance between SNPs, unique flanking sequences indicating mapping to one locus, low rate of missing data, number of reads supporting each allele, and Illumina manufacturing phase, 52,041 SNPs distributed to 20 chromosomes were chosen as SoySNP50K content (Song et al. 2013). Genotype data of 12,116 soybean accessions has been used for genome-wide association mapping for oil and protein content (Bandillo et al. 2015). The GWAS study identified SNPs linked to oil and protein content on chromosomes 20 and 15, respectively (Bandillo et al. 2015). The advantages of a fixed SNP genotyping platform are high call rates because the SNPs included in the array already passed initial call rate filtering, fast turnaround time, cost-effectiveness per data point, the easiness to compare datasets resulting from different studies since the same set of SNPs are genotyped across samples, and, as a result, it is easier to create an SNP fingerprinting database (Thomson 2014). The main disadvantage of the SNP chip is the high cost to design a new SNP array. Therefore, a high-density SNP array is usually developed by company or institutions that are sure to use SNP array for a large number of samples. If the SNP array can be used as a "universal" array, meaning it can be used for genotyping a large number of samples, then the SNP chip will be cost-effective (Thomson 2014).

On the other hand, flexible SNP array platform examples are Douglas Array Tape, Fluidigm Dynamic Array, TaqMan, and KASP (Thomson 2014). The main characteristic of flexible array platforms is that these enable users to select markers for genotyping. Douglas Array Tape is a high-throughput platform having capacity to genotype more than 76,000 reactions per fun. Fluidigm Dynamic Array has less freedom in choosing number of markers and samples per run since it provides option either to genotype 96 SNPs × 96 samples or 24 SNPs × 192 samples. TaqMan and KASP can be run on a real-time PCR machine or fluorescence plate readers, thus the number of samples × markers in each run can be customized to fit in the 96-well or 384-well plate used in those machines. Region flanking target SNP is amplified using PCR and the SNP allele is detected using fluorescence tag attached to marker primers. If fixed array is more suitable for QTL mapping, GWAS, or genetic diversity analysis, flexible array is more suitable for marker-assisted selection (Thomson 2014).

Another type of a flexible SNP genotyping method is restriction enzyme (RE) sequence–based genotyping method. This method provides SNP data across the whole genome, thus it is suitable for QTL mapping or GWAS. There are several methods such as restriction site–associated DNA sequence (RAD-seq), double-digest RAD-seq (ddRAD-seq), and genotyping by sequencing (GBS). RE-sequence-based genotyping method does not require initial effort to develop SNP array but does require users to create barcoded adaptors to be linked to sample DNA fragments. In

addition, the sequencing cost is lower than normal deep whole genome sequencing because it combines multiple samples in one sequencing lane. Moreover, genomic library preparation can be performed in most labs equipped with molecular biology facilities. Therefore, users who do not have access to labs can do RE-sequence-based genotyping when they do not have SNP array. Disadvantages of RE-sequence-based genotyping is that it requires more computational resources for data analysis than fixed SNP array, the number and position of SNPs from genotyping can differ depending on the type of REs used in genomic library preparation, the SNP analysis pipeline.

As an example, GBS protocol will be described. The first step of the GBS protocol is the digestion of genomic DNA using two restriction enzymes (REs), a common-cutter RE and a rare-cutter RE (Poland et al. 2012). The digested DNA is ligated to adapters containing unique 4–6 bp nucleotides serving as a barcode sequence. A unique barcode sequence enables mixing samples between 96 and 384 samples into one sequencing tube (Poland et al. 2012). The sample mix is then sequenced using next-generation sequencing (NGS) machines. The resulting reads are then separated per sample based on barcode information, mapped to the reference genome, and called the variants. The tedious part of GBS is sequence read processing and data analysis, which needs computational skill for big data processing (Thomson 2014). Also, since multiple samples are mixed and sequenced in one sequencing reaction, the sequencing depth of each sample is shallow, which may produce a high missing rate in samples. Several bioinformatics tools are available for GBS data analysis and to impute (predict and filling-in) the missing SNP data, for example, TASSEL-GBS, IGST, Fast-GBS, UNEAK, or Stacks. The number of SNPs and accuracy of SNP calling can vary depending on the pipeline and parameters used.

3.4 Insertion-Deletion

Insertion-deletion (InDel) markers are developed based on small insertion-deletion (between 5 and 50 bp) when comparing two genome sequences. InDel can be detected using pipelines for SNP variant calling. Compared to SNP which is biallelic, insertion-deletion length can vary among individuals in diverse populations. Therefore, InDel marker genotype scoring cannot be easily automated and the markers are not commonly used for genome-wide association mapping. Nevertheless, the InDel marker is still useful in genotyping biparental segregating populations. In addition, InDel markers genotyping can be done in house, target fragments can be amplified by PCR, and variant detection can be done by gel electrophoresis – gel visualization.

4 QTL Mapping, GWAS, and Genomic Selection

4.1 QTL Mapping

Quantitative trait loci (QTL) analysis is a method to identify genomic regions associated with a quantitative trait by investigating phenotype-genotype association in a biparental segregating populations. Three types of populations are commonly

used in QTL mapping: F_2, recombinant inbred lines (RILs), and backcross inbred line (BIL) populations. F_2 population is derived from selfing the F_1 hybrid produced by crossing two parental lines having contrasting phenotype of target trait. The genome of F_2 lines is mostly heterozygous, therefore the F2 population is suitable for identifying major QTLs. RILs are developed by selfing F_2 individuals for 5–6 cycles, resulting in homozygous lines. Large number of seeds having identical genome composition can be produced from each RIL, therefore the RIL population is suitable for multi-years, multi-locations QTL analysis (Collard et al. 2005). Another type of population is BIL. BIL is developed by crossing back F_1 hybrids to one parental line (recurrent parent) for several cycles, followed by selfing until the genomes are fixed. BILs will have most of their genomes from the recurrent parent, and only a small part comes from the other parent. Since the genome is fixed, BILs can be used for multi-years and multi-locations studies. In addition, since the majority of the genome is from a recurrent parent, which is usually an improved line, promising BILs can be directly used in breeding programs.

The first step of QTL mapping is genotyping the population and constructing a linkage map or recombination bin map. Linkage map is constructed by calculating recombination frequency between markers, and the recombination frequency is translated to distance between markers (centiMorgan). One centiMorgan (cM) is defined as 1% chance of recombination between two markers. It means in a population of 100 individuals, there will be one recombination between two markers with 1 cM distance. In most of QTL analyses, marker distance calculation will involve more than two markers. There are two functions for marker distance calculation: Haldane mapping function, which assumes no interference between crossover, and Kosambi mapping function, which considers influence of recombination events to the adjacent recombination events (Collard et al. 2005). Recombination bin map approach is commonly used when genotyping is performed using GBS, RAD-seq, or SNP-chip. These genotyping methods produce high-density SNP map containing SNP markers that often are within the same haplotype, meaning they are closely located and segregated together. Using all SNPs in QTL mapping will require more computational resources and give redundant information. To reduce computational time and cost, only one SNP per bin is used in QTL mapping. This is already sufficient to represent the entire whole genome sequence (Patil et al. 2018). Representative SNPs are then used to create linkage map.

For QTL analysis, genotype, phenotype, and linkage map data are needed. There are several QTL mapping methods that are commonly used, such as single-marker analysis, interval mapping, or composite interval mapping (Collard et al. 2005). Single-marker analysis or single-marker association is finding association between one marker with phenotype. Single-marker analysis does not require linkage map data. Analysis of variance (ANOVA), linear regression, or *t*-tests are statistical methods used for single-marker analysis (Collard et al. 2005). Single-marker analysis can be performed without special QTL mapping software. However, QTL detection power will be less if the QTL is located far from the marker, due to recombination occurred between marker and QTL (Collard et al. 2005). Interval mapping incorporates marker distance information in QTL detection. While single-marker analysis only estimates correlation between QTL and one marker, interval

mapping can estimate QTL location between two markers (Collard et al. 2005). Composite interval mapping (CIM) is interval mapping method with linear regression and incorporates a subset of markers as covariates. By including covariates, the QTL analysis can account for linked QTLs and residual variation (Collard et al. 2005). CIM can detect QTLs with higher resolution but it requires more computational time.

After QTL is determined, the next step is fine mapping and candidate gene identification. This process largely changed after reference genomes and high-density SNP genotyping are available. First, the physical positions (position on genome) of flanking markers are determined. If the markers are generated by GBS or SNP chip, the marker physical position are already determined. Possible candidate genes are obtained by looking into reference genome sequence, for genes annotated within region between the flanking markers. Further selection can be done by checking whether the genes are expressed and the location or time of expression.

4.2 Genome-Wide Association Mapping (GWAS)

Genome-wide association mapping or genome-wide association studies (GWAS) utilize allelic diversity and recombination events in diverse populations to find genomic regions associated with certain trait (Chaudhary et al. 2015). One advantage of GWAS over QTL mapping is reduced time to create segregating populations needed for analysis. However, GWAS detection power relies on the frequency of minor allele in population and correct population structure (Chaudhary et al. 2015). Genotype data used for GWAS is usually filtered by removing SNPs having minor allele frequency less than 5% to avoid false positive, detect rare alleles (Chaudhary et al. 2015). GWAS studies have been conducted in soybean to identify SNPs associated with protein, oil, amino acid content, tocopherol, and isoflavones (Chaudhary et al. 2015; Wu et al. 2020; Bandillo et al. 2015; Sui et al. 2020). The challenge for GWAS analysis for nutritional components in soybean is the effect of environmental factors to the nutritional content. Diverse germplasm used in GWAS analysis may have different flowering time, thus temperature during seed filling period will differ for each accession. This may affect the phenotype and subsequently GWAS result.

4.3 Genomic Selection

Oil, protein, and isoflavone content are regulated by multiple and minor QTLs that interact with each other. Marker-assisted selection used a subset of markers linked to QTLs, therefore it may not correctly evaluate promising lines in breeding programs. Genomic selection term was introduced by Meuwissen et al. (2001). It utilizes all markers across the genome to predict phenotype, and this method is more affordable and efficient after the availability of NGS-based genotyping methods (Stewart-Brown et al. 2019). Genomic selection requires two populations, a training

population and test population. The training population will be genotyped and phenotyped, and both data are used to build a prediction model. Test population will be genotyped, and the genomic estimated breeding values (GEBV) will be estimated using prediction model built with training population. Possibility of using genomic selection in soybean was tested in Stewart-Brown et al. (2019), the protein and oil content were predicted using 483 elite breeding lines genotyped using BARCSoySNP6K iSelect BeadChips. The predictive ability for protein and oil was quite high, 0.81 and 0.71, respectively, compared with predictive ability for yield (0.26).

5 Genomic Resources and Other Bioinformatics Resources

5.1 Genome Assemblies and Reference Genomes

The estimated soybean genome size is 1.1-Gb, divided into 20 chromosomes (Schmutz et al. 2010). Approximately, 59 and 13 million years ago, genome duplications occurred twice, followed by several gene diversification and loss, as well as chromosome rearrangements (Schmutz et al. 2010). As a result, about 75% of soybean genes exist as multiple copies (Schmutz et al. 2010).

The first reference soybean genome was developed based on the Williams82 sequence (Schmutz et al. 2010), which was released as the Glyma1 version. The assembly was developed based on the whole-genome shotgun-sequencing method and it was one of the largest genomes to be assembled at that time (Schmutz et al. 2010). The assembly resulted in a total 950 Mbp length, grouped into 20 chromosomes and additional 1148 unanchored sequence scaffolds (Schmutz et al. 2010). The number of predicted protein-coding genes was 46,430 genes (Schmutz et al. 2010). About 78% of predicted genes were located in chromosome ends, where most all genetic recombination occurred (Schmutz et al. 2010). Genome sequence around centromeres is rich in repeats resulting in low recombination is this region (Schmutz et al. 2010).

The subsequent version (Wm82.a2.v1) replaced Glyma1 assembly by integrating a dense genetic linkage map produced from the RIL population of 'Williams 82' × wild soybean 'PI479752' and RIL population of 'Essex' × 'Williams82' (Song et al. 2016). This produced a genome assembly with a length of 949.2 Mbp for 20 pseudomolecules related to 20 chromosomes and additional 1170 unanchored scaffolds (Song et al. 2016), and 56,044 protein-coding genes (based on gene annotation file available in Phytozome.org). A major change in the Wm82.a2.v1 version is the change in the gene model name (Phytozome.org). Since some studies were conducted before the release of version 2.1, to know the relation between gene model in version 1 and version2.1, Soybase.org released a tool called Gene Model Correspondence Lookup where users can post the gene model either in version1 or version 2.1 and vice versa. As of June 2022, the current genome assembly of Williams82 has been improved to version Wm82.a4.v1. Wm82.a4.v1 was improved by incorporating the synteny of two other *Glycine* assemblies (Lee and Soja), and

also information based on PACBIO long reads. It has 961 Mbp of 20 pseudomolecules and 17 Mbp in unanchored scaffolds resulting in a total length of 282 scaffolds of 978.4 Mbp and the number of protein-coding genes is 52,872 genes (Valliyodan et al. 2019). The availability of multiple reference genomes for soybean will help identify genomic regions unique to certain varieties/species/regions.

5.2 Pangenomes

Pangenome represents the entire set of genes within a species, consisting of sequences that are shared among individuals or varieties in the species. The term pangenome was first defined in microbes (Tettelin et al. 2005). Core pangenome is entire genes shared by all strains within a clade (Tettelin et al. 2005). Shell pangenome is a gene set shared by several strains within a clade, whereas cloud pangenome is a gene set owned specifically by a strain within a clade. If the terms are translated to soybean, core pangenome can be defined as all genes shared by all varieties within soybean and wild soybean. Gene sets shared by several varieties in shell pangenome once were thought of as dispensable genes. However, recently it is thought that these genes may contribute to species diversity, encoding enzymes for a supplementary biochemical pathway that is not essential for growth but helps the species adaptation. Pangenome is getting attention instead of reference genome from one cultivar or variety because it can capture diversity present in the species.

The first pangenome study was published in 2014 (Li et al. 2014). Li et al. (2014) assembled de novo sequences of seven wild soybean accessions from Yellow River region, North and South China, Japan, Korea, Russia, and accession from the predicted domestication center in the China's northeast region. The de novo assemblies were compared to soybean reference genome Williams82 and identified 48.6% of the gene families as core genes (28,716 genes) (Li et al. 2014).

The second pangenome study included nine soybean landraces, 14 soybean, and three wild soybean accessions representing the diversity of 2898 deeply sequenced soybean and wild soybean accessions (Liu et al. 2020). De novo assembly of the 26 accessions produced genome assemblies with lengths varied from 992.3 Mb to 1059.8 Mb with average of 1011.6 Mb (Liu et al. 2020). The assemblies were then combined with Zhonghuang 13 as the primary reference genome into a graph-based pangenome (Liu et al. 2020). Orthologs analysis classified all genes from the 27 genomes into 57,492 families (Liu et al. 2020). Of these, 20,623 gene families were categorized as core genes since they were present in all 27 accessions (Liu et al. 2020). An addition of 8163 families were present in more than 90% of the collection (softcore genes), and the remaining 28,679 families were shell pangenome (Liu et al. 2020).

The third pangenome study (PanSoy) was published in 2021, involving de novo assemblies of 204 soybean accessions (Torkamaneh et al. 2021). The 204 accessions were selected as representative of the phylogenetic and geographical diversity of 1007 accessions from the GmHapMap dataset (Torkamaneh et al. 2021). PanSoy, sequence-based pangenome, was constructed by comparing each of 204 assemblies

to the 'Williams82' reference genome (Wm82.a4.v1; Valliyodan et al. 2019). PanSoy detected 54,531 gene families in the 204 accessions, 90.6% of which (49,431 genes) were identified as core genes (Torkamaneh et al. 2021). The PanSoy genome coverage was evaluated using 'Lee' reference genome (Valliyodan et al. 2019). About 99.9% of 'Lee' genome sequence could be mapped to the PanSoy genome, in comparison to 92% of the 'Lee' genome mapped to the Williams82 reference genome only (Torkamaneh et al. 2021). The fourth pangenome study was based on resequencing data of 1110 accessions from the USDA Soybean Germplasm Collection (Bayer et al. 2021). The analysis produced a pangenome with 1213 Mbp length and 51,414 predicted gene families (Bayer et al. 2021). Of more than 50,000 gene families, 86.8% of genes are core genes (Bayer et al. 2021).

5.3 Databases and Resources for Genetic Research

Online databases for reference genome sequences, gene annotation, resequencing data, SNPs, transposable elements, biosynthesis pathway, transcriptome, proteome, metabolomics, cyst nematode proteins, functional network, functional genomics, and root phenotype have been developed for soybean. These databases contain data that can help other researchers in furthering their research, however, unfortunately, many of these databases were not accessible anymore or were not easy to be found. Two databases, Soybase (www.soybase.org, last accessed April 5th, 2023) and Phytozome (www.phytozome.org, last accessed April 5th, 2023), will be introduced here.

Soybase (Grant et al. 2009) was developed by USDA-ARS. It provides a comprehensive repository of professionally curated genetics, genomics, and other related data for soybean analysis (Grant et al. 2009). Currently, it houses a large variety of data, from genetic marker data, genetic map, a compilation of QTLs and GWAS peaks identified in past, transcriptome data, SNP data from resequencing projects, whole-genome sequence data, and pangenomes to gene ontology, and tutorials on soybean development, disease, and pests. Transcriptome datasets from Severin et al. (2010) and Le et al. (2007) are also provided here.

Severin et al. (2010) provided transcriptome data from 14 soybean tissues (leaf, flower, one M-pod, 10 days after flowering (DAF), and 14-DAF pods, root, nodule, and seven stages of developing seeds). The data is in Glyma1, thus users need to convert the gene IDs to Wm82.a2.v1 version and vice versa. On the other hand, Gene Networks in Seed Development project (Le et al. 2007) is based on transcriptome profiling of soybean seed regions (seed coat, endosperm, and embryo subregions). It is also known as Goldberg/Harada dataset. It used laser capture microdissection (LCM) to isolate these subregions. A total of 40 soybean seed sections were analyzed. Detailed analysis using seed sections was performed at the following stages: globular stage, heart stage, cotyledon stage, and early maturation stage. In addition, data from the mid-maturation stage, late-maturation stage, dry seeds, trifoliate leaves, roots, stems, floral buds, and seedlings 6 days after imbibition are also provided to represent the soybean life cycle. The datasets provide

knowledge of genes active in different seed parts during development, transcription factors localized at specific seed regions and subregions, and biological processes important for seed differentiation. The dataset can be accessed from http://seedgenenetwork.net (last accessed July 7th, 2022) and from the Soybase Expression Explorer Database. There are also transcriptome datasets grouped by experiments and are provided under NCBI GEO Expression data.

Phytozome (Goodstein et al. 2012) is developed and is maintained by the Department of Energy, Joint Genome Institute. It serves as a plant comparative genome portal and the current version (Phytozome v13) houses 304 assembled and annotated genomes (last accessed 4th April 2023). Phytozome v13 hosts three soybean reference genomes, Williams82, Lee, Fiskeby III, and one wild soybean reference genome PI 483463. Users can perform BLAST analysis, search genes using keywords or gene ID, or retrieve sequences based on genomic position. For soybean and wild soybean, users can obtain the gene genomic sequence, transcript, coding sequence, and peptide sequence. Information about its function, organs where it is expressed, KEGG pathway annotation, gene homologs, and similarity to the homologs in other species are also available. Users can also perform gene comparative analysis across different species. Registered users can download whole-genome sequence (all softmasked, hardmasked, and repeat masked), transcript data, and gene annotation.

6 Soy-Based Food

Soy-based food has played an important contribution to the health, culture, and economy of Asian countries, especially China, Japan, Korea, and Indonesia. It is a high-protein food and contains essential fatty acids such as linoleic acid and linolenic acid. Soybean is known as “meat in the field” since it supplies high level of protein. It also provides nutritional components that provide health benefits beyond nutrients and other non-nutritional components with physiological function. There are currently three groups of Food for Specified Health Uses (FOSHU) soy-based products: cholesterol lowering, intestinal function regulation, and bone health (Yamamoto 2005). The versatility of soy for human consumption is shown in the rich varieties of soy-based food products.

The protein and oil in soybeans are the components that are mostly made use of. The protein content in soybeans is an important aspect to know because they are often the ones that will experience the most changes when being processed. During fermentation of several traditional soy-based products, such as tempeh and miso, the protein content is metabolized to amino acids which will result in higher nutritional value and also enhance its texture and taste (Handoyo and Morita 2006). Notable amino acids are the umami-inducing glutamate and arginine. Soybean and products made of soybeans with high glutamic acid content often tastes better and is more preferred. When the soybean is further processed, like in tempeh, for example, the glutamic acid content increases as fermentation progresses (Gunawan-Puteri et al. 2015). The glutamic acid content gives tempeh its umami taste. Arginine on the other

hand has an important function in metabolism reactions like, for example, in the urea cycle (Morris 2002). It helps in synthesis of larger protein molecules in the body. In the further processing of soybeans, arginine is one of the primary amino acids that could be used, for example, in fermentation.

Soybean is also a very promising ingredient for functional food products. Soybean contains significant amounts of bioactive components, mainly phenolic compounds like flavonoids and isoflavones, that have antioxidant activities which are found to be enhanced in soybean products. Alongside protein and other nutrients in soybean, the bioactive components give soybean its functional properties such as antidiabetic, anticancer, anti-inflammatory, estrogenic, and anti-hypercholesterolemic function.

Soy anti-nutrients, such as phytic acid, are eliminated with fermentation and soaking in processed soy foods such as tempeh, soy sauce, and tauco (Hui et al. 2004). Soybean could be processed using fermentation or without the fermentation process. Some of the soybean products that are fermented using *Lactobacillus bulgaricus* and *Mucor sufu* are soy yogurt and soy cheese, respectively. Well-known fermented products in Indonesia are tempeh, soy sauce, and tauco. Tempeh is fermented using a mould starter of *Rhizopus oligosporus*, soy sauce is made by inoculating with *Aspergillus sojae* mould, while miso is fermented using *Aspergillus oryzae* mould. Natto is another soybean fermented food with *Bacillus subtilis*. Examples of soy-based foods that do not undergo fermentation process are tofu or soymilk. Soymilk can be further processed into tofu. Nonfermented soy products processed with modern methods include oil, soy flour, and soy protein isolate. Soy protein could also be used as an ingredient to produce synthetic meat (TVP/textured vegetable protein). Learning about the soybean ingredient requirement for each food product might become the future in soybean cultivation development.

6.1 Vegetable Soybean

Vegetable soybeans are defined as those that are harvested after the R6, the immature green state, but before the R7, the beginning of maturity stage when pods located at the main stem start to change into brown or tanned color. Vegetable soybean has different names: edamame (Japan), poot kong (Korea), maodou (China), and tuarae (Thailand). Edamame – green pods attached to the stem – is a popular snack in Japan. It is generally sold in the pods as fresh or frozen beans, attached or detached from the stem, though canned and frozen shelled beans are also available in the market. For consumption, edamame is boiled for 5–7 min in highly salted water. However, it can also be shelled, removed from the pods for boiling, baking, steaming, or toasting over fire for making soup, salad, or vegetable dishes. And while it is logical that vegetable soybeans that have 9–10 times moisture content than the mature bean have lower other nutrient components, surprisingly vegetable soybeans are recorded to have higher vitamin A, vitamin C, sodium, and comparable niacin content. In the dry weight composition, vegetable soybean also contains more calcium, folate, and comparable protein, fat, ash, carbohydrate, and fiber content compared to the mature soybean seed.

The sensory quality of vegetable soybean owes to its sweetness and umami tastes along with the texture and aroma quality. Vegetable soybeans contain 1.28–7.12 g of sucrose, 0.37–1.51 aspartic acid, 0.64–2.82 glutamic acid, 0.17–0.72 glycine, and 0.11–0.51 g alanin per 100 g of bean (Kumar et al. 2011). The sodium content of vegetable soybean is higher than mature soybean (15 and 2 mg/100 bean), explaining the higher salty umami interaction of the sodium with umami inducing amino acid. It has significantly higher moisture content (67.5%) compared to mature soybean (8.54%) and was valued to have higher flavor quality compared to its mature soybean.

The morphological characteristics expected for a good quality vegetable soybean include pod size, number of beans per pod, and pod color (Shanmugasundaram and Yan 2010). Preferable traits for vegetable soybean are large seeds (>30 g per 100 g dry seeds), with two or more beans per pod, subsequently pod size (should be ≥5.0 cm and ≥1.4 cm) as well as number of pods (should be ≤175 pods per 500 g frozen pod packet) become a quality parameter in vegetable soybean. The preferable pod and bean color for vegetable soybean is dark green, however, the mature seed color can be diverse from yellow, green, brown/red, or black.

6.2 Tempeh

Soy tempeh is defined as a compact white cake that is prepared from dehulled, boiled, and acidified soybeans through solid-state fermentation with *Rhizopus* spp., originated from Indonesia. Tempeh uses the whole bean of mature soybean and thus creates a hearty and firm, meaty texture from mycelium with a grizzle of soft bean texture. It has savory, nutty, earthy, and mushroom flavors.

Tempeh is unique among major traditional soy foods because it did not originate from China or Japan. Variation occurs among tempeh artisans in the dehulling, boiling, and acidification processes prior tempeh starters inoculation. The acidification process can be conducted naturally by overnight soaking or chemically by soaking the bean in food-grade acidulants. Once the acidified soybean is inoculated with the mold, it is common to directly pack them into porous plastic bags or banana leaves and leave them to begin the solid-state fermentation. Tempeh can be consumed as it is, but the most popular preparation is to fry, stir-fry, or boil them with salt and spices and/or flour. The popularity of tempeh within the nation was never in question, as this relatively inexpensive meat replacement for protein source has been consumed by millions of Indonesian daily.

Tempeh has high socioeconomic importance in Indonesia as there are more than 115,000 micro-, small, and medium enterprises (MSMEs), which employ 285,000 workers and generate about 57 million EUR per year. The soybean tempeh industry alone absorbs more than 1.2 million tons of soybeans per year (Central of Indonesian Agricultural Data and Information System 2013), which is more than 70% of soybean consumption within the country. The importance of the tempeh industry in Indonesia has affected domestic soybean development as it also put importance on

the tempeh requirement such as the seed size, in addition to the yield, harvest time, and resistance to abiotic stress.

According to the standard quality of setup by National Standardization Agency of Indonesia, soy tempeh contains minimum 15% protein and 7% fat (National Standardization Agency of Indonesia 2015), while the USDA National Nutrient Database recorded that tempeh has approximately 20% protein and 10% fat. Several studies recorded that Indonesian domestic soybean in general is having higher protein and lower fat content compared to imported soybean, especially those from the USA. The main reason is that soybean is used in the USA for soybean oil production. Therefore, the soybean demand is more a derivative of animal product consumption rather than for direct human consumption, such as tempeh and tofu in Indonesia.

The first step in tempeh production is soybean hydration by soaking or boiling in water. This process also aims to loosen up the hull and facilitate the wet dehulling process. Traditionally, wet dehulling processes in tempeh are done manually by human feet as the workers get into the large pool of soybean and step on them. Nowadays, due to hygiene reasons and technological availability, dehulling machines have been employed for the process, and some more advanced tempeh industries are even employing dry dehulling techniques prior to water hydration. As tropical countries with high humidity and room temperature, microorganisms are naturally attracted during soaking which leads to natural lactic acid bacteria (LAB) acidification. The acidification is an important step in ensuring the success of mould inoculation as it wipes out other competitor microorganisms and provides an ideal condition for *Rhizopus* moulds to start the solid-state fermentation. In temperate countries where the humidity and temperature are much less, chemical acidification is often added to support this process.

After the acidification process, the bean is boiled, drained, and cooled prior to *Rhizopus* mold inoculation. Traditionally, the mold is introduced by mixing small amounts of tempeh from previous fermentation, but nowadays ready-to-use and optimized tempeh starters have been commercially available. Following the tempeh starter inoculation, the inoculated beans are wrapped with clean banana leaves or porous plastic bags and allowed to sit at room temperature for at least 24 h. By this time, mycelium hold the beans together, though the white mycelium might not be visually available yet. Tempeh producers usually have this stage of tempeh (tempepera) during distribution, allowing more fermentation to happen before it reaches the customers. The fresh ripe tempeh covered with white mycelium is usually consumed within 2 days, otherwise it goes into the next stage of overripe tempeh. While fresh ripe tempeh is often consumed as a whole meal, overripe tempeh has much stronger taste and aroma and is often used more as condiment.

Tempeh is a traditional Indonesian fermented food known for its high nutrients and superior digestibility (Hermana and Karyadi 1997). Tempeh fermentation increases sodium content that may contribute to salty taste and umami interaction with free amino acids. Tempeh also has a higher composition of manganese, niacin, and vitamin B-6 compared to soybean. Interestingly, tempeh contains vitamin B12 that commonly came from animal source food and was not available in raw mature soybean.

The protein and fat content per 100 g dry weight of tempeh is higher than per 100 g dry weight of soybean. Tempeh fermentation increases protein digestibility and free amino acid content, and the availability of other macronutrients through hydrolysis and reduction anti-nutrient such as phytate, saponin, and protease inhibitors, making it an even better plant-based protein source than soybean. The nutrient content and availability in the originated soybean remain important as it will support the microbial growth.

Tempeh consumption is associated with cholesterol reduction in blood and helps prevent cardiovascular diseases (Kris-Etherton et al. 1999; Mangkuwidjojo et al. 1985). It also shows diarrhea prevention effect, which improves its role in food safety area (Kiers et al. 2003). Tempeh has also found its way in the global market with the increasing findings of its benefits and the growing lifestyle toward plant-based food. At the current time, tempeh has been produced commercially in Japan, India, the USA, Canada, European countries, Australia, and New Zealand.

6.3 Natto

Natto is produced through fermentation of soybean by *Bacillus subtilis*. It originates and an important commodity in Japan. Natto is not the only soy-based *Bacillus* fermented product. In other countries, *Bacillus* fermented soy food has also been traditionally integrated into their national culture, such as chongkukjang in Korea, kinema in India, and thuanao in Thailand.

Natto has a dark color, pungent but pleasant aroma, and sticky viscous coating with cheese texture. It can be served as it is or used as a seasoning agent with raw or cooked seafood, meat, and vegetables. Natto contains higher vitamin C content than soybean seed and has approximately 43, 24, 12, and 10% dry weight of protein, fat, fiber, and sugar content, which is a higher proportion compared to soybean. The proportion (but not the content) of several minerals, such as calcium, iron, sodium, zinc, manganese, and selenium, in natto are also higher than those in soybean. The peptide, free amino acids, ammonia, saccharide hydrolysis products, and minerals produced during fermentation constitute the characteristic flavor of natto. The sticky substances covering the well-fermented natto are composed of polyglutamic acid and levan (fructan) (Claus 1986).

The *B. subtilis* fermentation also produces proteases and amylase that help with other food digestion processes inside the human body (Ferrari et al. 1993). Serine protease of subtilisin is shown to degrade Gly m Bd 28K (Ogawa 2000). Serine protease is also recorded to show fibrinolytic activity (Sumi et al. 1990), the formation of blood clots from platelets and blood-derived proteins (fibrin), which prevents extended bleeding and promote healing. Both catalase and subtilisin produced during natto fermentation exhibit a growth-promoting effect on fecal microflora (Terada et al. 1999), which adds more to its hypoallergenic character (Kalliomaki et al. 2001), as well as providing positive impact to gut health (Hosoi et al. 2000) and immune function (Pelto et al. 1998).

The natto quality is affected by the soybean quality and *B. subtilis* (natto) strains. Japanese domestic soybeans such as ‘Suzuhime’, ‘Suzumaru’, ‘Kosuzu’,

and 'Natto-shoryu' are preferred for natto production because of their small seeds (5.5–7.3 mm) or extra small (< 5.5 mm) in size, although there are natto produced from midsize or large-seeded soybeans. The seed size was reported to affect negatively with the activities of subtilisin alkaline protease that play roles in protein degradation and intensity of the taste and smell of natto. Therefore, natto made from larger seed soybean have weaker smell while those from extra small seed may have excess fermentation and stronger taste (Takahashi et al. 1996). Natto producers prefer soybean with yellow seed due to unappetizing appearance and lack of aroma character of brown and black soybean. It is just recently that black soybean natto is being on the shelf with highlights on the higher content of polyphenols.

Other than its morphological characters, the soybean contents also play an important role in producing high-quality natto. Higher sugar content is associated with better taste and flavor production as it also has a positive correlation with the bacteria growth as *B. subtilis* natto strain can utilize di- and oligosaccharides but not starch and fiber. Smaller seed size soybean varieties are also associated with higher sugar content and therefore preferable for natto production. The protein content and profile of the originated soybean also affect the natto quality as *B. subtilis* natto strain utilize protein, peptides, and amino acids for their growth. Soybeans with high protein content are preferred. Among Japanese domestic soybean used for natto production, 'Suzuhime' and 'Zizuka' cultivars are highly regarded starting ingredient as they have high protein content, bright color, and polished appearance (Hosoi and Kiuchi 2003).

In natto processing, soybeans are washed, soaked, and steamed prior to the *B. subtilis* (natto) spore inoculation. The inoculated beans are then packed and left for solid-state fermentation. Overnight soaking in cold water and steaming of the beans facilitates water hydration, bean swelling, and denature undesirable protein. Steaming also removes contaminant and pathogenic bacteria. Right after steaming, while the beans are still hot, *B. subtilis* (natto) spore suspension is sprayed onto the bean. The fermentation is set on 40 °C with 85–90% humidity whereas the humidity is reduced to 75 and 55% in the following 6 and 16 h after fermentation started. Traditionally the inoculated beans were packed in rice straw to maintain warmth and absorb emitted carbon dioxide during the initial stage of fermentation.

6.4 Miso

Miso is a traditional Japanese fermented soy paste with thick texture, salty taste, savory flavor and aroma, and white, red, or brown color. It has high protein and low-fat content. Miso is often used as a soup base though it may also be used for meat and seafood seasoning prior cooking, or as condiment in many traditional Japanese dishes.

There are two steps in miso production. First is koji production. In this process, *Aspergillus* fungi is inoculated to growth materials. The most common growth material is rice, although koji can also be produced using barley, or soybeans (Shurtleff and Aoyagi 2018). Second is the fermentation of boiled soybean by salt

and koji. In this step, koji interacts with salt and moisture to induce the yeast and bacteria growth of miso. Miso fermentation period is 1 week to 3 years, and the color and flavor intensity increase with longer fermentation time (Ogasawara et al. 2006). According to the amount of salt and length of fermentation, miso can be classified into white, red, or dark miso (Katz 2012). White miso uses more koji, less salt, and applies shorter fermentation time, while dark miso is the opposite, and red miso is in between the arrangement of white and dark miso.

Traditionally, miso was a homemade but commercial production is a major form since 1980. About 90% of miso produced in Japan came from factories (Shurtleff and Aoyagi 2018). The commercial miso production was boosted by mechanization, the availability and usage of commercial strains, standardization of processing methods, and the improvement of packaging and sterilization process (Shurtleff and Aoyagi 2018).

Not all soybean can meet the quality parameters of soybean suitable for miso production. And of them that are suitable, most of them are Japanese domestic soybeans. The requirements for soybean to be selected for miso production include white hilum color, light yellow color of cotyledon, a high water-absorbing capacity during soaking, softness, sucrose content, and protein content. Though the color requirements might slightly change due to the popularity of high polyphenol of the darker color soybean, in general light yellow soybeans were assumed to give a more appetizing end product in the miso production. As miso end product is in the form of paste, the soft structure and the high water absorbing capacity is important to ensure targeted tenderness after soybean cooking. The water absorbing capacity also correlates with higher carbohydrates that gives even more free sugars. Other than influencing the taste of the end product, free sugars along with free amino acids availability prior inoculation are known to support the microbial growth during miso fermentation.

Soy-fermented products similar to miso include tauco from Indonesia and also gochujang and doenjang from Korea. The tauco production differs from miso in terms of soybean form and the mold employed. The soybean preparation is similar without the mashing process. The soaked and cooked bean is fermented with salt and tempeh starter or combination of *Rhizopus oligosporus*, *R. oryzae*, and *A. oryzae*. Both gochujang and doenjang are fermented soybean paste that employ *Aspergillus* mold and brine fermentation. The soybean preparation is similar to miso with an additional process of square forming the mashed cooked soybean and drying them into large bricks. Inoculation of *Aspergillus* is done directly to the dried soybeans for 20–90 days resulting in fermented soybean bricks, called meju. Meju is the intermediate product that will be processed into either gochujang, or ganjang and doenjang, the trinity of Korean traditional condiments (Patra et al. 2016). In traditional production, Meju is broken down into small pieces and put into onggi, Korean traditional earthenware for storage or fermentation. To create gochujang, the meju is mixed with red chili powder, glutinous rice powder, salt, garlic, and onion, and then sweetened with a little sugar syrup and aged in onggi, a type of Korean earthenware (Song et al. 2021). To create ganjang and doenjang, brine is added to the broken meju and salt fermentation inside the onggi was performed for about 2 months creating the liquid part (kanjang) and the solid part (doenjang) (Patra et al. 2016).

6.5 Third-Generation Product from Soy Processing

In the first generation of soy processing, whole soybean is being used, for example, in the production of tempeh and natto. The second-generation soy products refer to those coming from part of the soybean such as soybean oil, soy milk, and soy sauce. The third-generation products are targeted compounds that are isolated or fractionated from soy. The third-generation products are commonly components with high benefits for specific health uses which are required in higher amounts than those that can be acquired by only consumption. The production commercially of third-generation products require solid scientific evidence of the component benefit, as well as advance investment in technology and therefore the products are commonly having a high economic value. Up to this book is being written the following third-generation products from soy processing have been commercialized either as supplement or food ingredients: isolate soy protein, soy peptides, soy isoflavone/phytoestrogen, soy lecithin, soy fiber, soy phytosterol, and soy oligosaccharides.

Protein and bioactive peptide contents of soybean contribute to its potential to prevent lifestyle-related diseases (Yoshikawa and Tsuruki 2005). Soy peptides have been reported to have hypocholesterolemic (Sugano et al. 1988), hypotriglyceridemic, hypotensive, anticancer, and immunomodulating activities while also having an impact on the regulation of food intake. While the roles of dietary peptide in nutrition have been well established, soy peptides have been used in the formulation of functional foods (Takamatsu 2005) to relieve sports fatigue and stress, overcoming obesity, lowering blood cholesterol, hypoallergenic food, and seemed to have a future in alleviating stress and improvement of brain function. Hypocholesterolemic nature of soy protein comes from its hydrophobic high-molecular-weight peptides left after digestion that binds to bile acids (Carroll 1991). The bile acid–binding ability of soy peptide increased fecal excretion of bile acids and reduced cholesterol level in serum and liver. Soy peptide was also reported to stimulate fat metabolism and suppress fatty acid synthesis, leading to its hypotriglyceridemic activity.

7 Conclusion

Numerous studies have been conducted on nutritional content and physiological benefits beyond nutrition of soybean seeds as well as the regulation of biosynthesis of these components. Knowledge on nutritional values and bioactive content of soybean seeds can be utilized to increase their content in current soybean varieties through breeding. The availability of next-generation sequencing technologies, high-density genotyping platforms, and soybean reference genomes have accelerated the elucidation of genetic basic of the biosynthesis of these compounds. The knowledge of genetic basis of these traits enables breeders to select potential breeding lines efficiently using DNA markers. The breeding lines then can be utilized to produce soybean-based food products that are not only nutritious but also meet the diverse needs of consumers and the food industry.

Nutraceutical Potential of Rapeseed: Breeding and Biotechnological Approaches

Mehak Gupta and Gurpreet Kaur

Contents

Abstract

Rapeseed (*Brassica napus* L.) is a prime oil crop of the world that also provides proteins for the livestock feeding. This crop has achieved remarkable success over the past few decades by development of canola types with low erucic acid

M. Gupta · G. Kaur (✉)
Department of Plant Breeding and Genetics, Punjab Agricultural University, Ludhiana, India

and glucosinolate contents. Considerable progress has also been made to enhance the oleic acid content of seed oil. In contrary, little attention has been paid to improve other health-promoting constituents such as phytosterols and tocopherols of the oil. Following oil extraction, rapeseed meal is an excellent source of vitamins, minerals, and high-quality proteins that can help to mitigate human malnutrition. However, poor digestibility, dark color, and bitter taste of rapeseed meal due to anti-nutritional factors like phenolics, phytates, and crude fiber make the meal unacceptable for human consumption. It is crucial to further improve the nutraceutical and commercial value of rapeseed by increasing the content of health-benefitting components while simultaneously minimizing the antinutritive components to the acceptable amounts. To achieve the objective, it is imperative to understand the consolidated genetic architecture of oil and meal quality traits in connection to each other. Recent advances in next-generation sequencing technologies, availability of pan-genome of *B. napus* together with improved bioinformatic and genome editing methodologies would be very useful to reveal the genetic networks and identify high-resolution sequence-based markers for marker-assisted breeding for quality traits in rapeseed.

Keywords

Rapeseed · Nutraceutical · Marker-assisted selection · Erucic acid · Glucosinolates

1 The Crop Rapeseed

Brassica napus L. (AACC, 2n = 38) is one of the six species comprising the well-known U's Triangle of *Brassica*, a genus that belongs to the plant family Brassicaceae. It is an allopolyploid crop species that possesses the full chromosome complements of two diploid species, known to be *B. rapa* and *B. oleracea* (Chalhoub et al. 2014). A few interspecific hybridization events followed by genome duplication are believed to occur in the recent past (<10,000 mya), when two progenitor species (*B. rapa* and *B. oleracea*) were growing in close geographical proximity in Mediterranean area to originate *B. napus* (Friedt and Snowdon 2010). *B. napus* encompasses two subspecies – *B. napus* ssp. *oleifera* (commonly known as rapeseed/oilseed rape) and *B. napus* ssp. *rapifera* (swede and rutabaga) cultivated for oil and fodder purposes, respectively. Of these two subspecies, *B. napus* ssp. *oleifera* carries abundant amount of oil (45–50%) in its mature seeds that has both nutritional and industrial applications depending upon fatty acid composition of oil (Nesi et al. 2008). Also, meal/cake, a by-product left after oil extraction, holds great promise as an excellent protein source (38–40%) for animal nutrition. Presently, rapeseed crop represents the third largest valuable source of vegetable oil (after soybean and oil palm) and the second largest source of protein rich extraction meal (after soybean) in the world (Tang et al. 2021). The crop is cultivated over a large geographical spread of around 33 million ha in Europe, America, China, and India. Different ecotypes of rapeseed, i.e., winter,

semi-winter, and spring types, are raised in diverse ecologies of the world (Song et al. 2020). Winter-type rapeseed with strong vernalization requirement is predominantly grown in Europe, parts of China, and eastern USA, whereas, very early flowering spring forms with no vernalization requirement are cultivated in Canada and Northern Europe. The rapeseed cultivation in Australia and China is largely based on semi-winter types that need mild vernalization (Friedt and Snowdon 2010). Winter cultivars give higher seed yield than spring types owing to advantage of lengthy crop season of over 300 days occupied by winter lines in contrast to only 120–190 days taken by spring cultivars. Historically, rapeseed oil was used widely as lamp oil for European domestic and railway coaches lighting or for some other technical purposes, i.e., to produce soaps, inks, candles, and lubricants. It was of limited value for edible use because of the presence of appreciable amount of two anti-nutritional components – erucic acid (EA) and glucosinolates (GSLs) in the seed, which have detrimental health effects on humans and animals, respectively. The huge success of rapeseed crop for edible oil and animal feed was achieved during just the past four decades after dramatic reduction of these two antinutritive components in the seeds. A trade name "Canola" or double zero/"00" was registered in Canada in 1979 that refers to the edible oil crop carrying low EA (<2%) in the oil and low level of GSLs in the extraction meal (<30 μmol/g of defatted meal). Tower was the first canola rapeseed cultivar, commercially released in Canada in 1974. Thereafter, canola forms largely replaced the traditional rapeseed in all rapeseed-producing areas in Australia, Canada, and Europe and to a very large extent in China (Friedt and Snowdon 2010). The cultivation of canola rapeseed has started in India from 2007 (Chauhan et al. 2010).

2 Nutraceutical Profile of Rapeseed Oil and Meal

Rapeseed oil and meal constitute excellent source of nutraceuticals that are crucial for human nutrition and health as discussed below.

2.1 Rapeseed Oil

In the rapeseed oil, there are triacylglycerols (fatty acids), representing the major component (98%) and non-glyceride fractions (phytosterols, tocopherols, pigments (carotenoids and chlorophylls), and waxes), that constitute the remaining minor fraction (2%) of oil.

2.1.1 Fatty Acids

The fatty acid composition which includes saturated fatty acids (palmitic (PA; C16:0) and stearic acids (SA; C18:0), monounsaturated fatty acid (MUFA) such as oleic acid (OA; C18:1), polyunsaturated fatty acids (PUFA) like linoleic (omega-6; LA; C18:2) and linolenic acids (omega-3; LiA; C18:3), and very long-chain fatty acids (VLCFA) like eicosenoic acid (C20:1) and erucic acid (EA; C22:1) determines the nutritional quality of rapeseed oil as seen in other vegetable oils. The rapeseed oil carries a healthy

lipid profile, fit for human consumption (Russo et al. 2021). The rapeseed oil is low in saturated fatty acids (<7%) and high in MUFA and PUFA, with OA accounting for 61%, LA for 21%, and LiA for 11%, that help in balancing cholesterol level. LA and LiA are two essential fatty acids as they are not synthesized by our body and need to be obtained from the diet. Rapeseed oil contains considerable amount of these two fatty acids with a nearly ideal ratio (5–10:1) to avert cancer, heart, and autoimmune-related diseases. High content of MUFA imparts stability to oil by making it resistant toward oxidation at high temperature and ambient storage. Earlier, rapeseed oil was not acceptable for edible purpose in many countries around the world due to the occurrence of high level of EA (>50%), which is believed harmful to health. EA has slow tendency to oxidize, thus, it accumulates in arterial lining resulting in fibrotic heart lesions. It was found responsible for body weight reduction and abnormal accumulation of fat in laboratory rats (Charlton et al. 1975). Although the negative effects of high EA have never been observed in human beings, it is still suggested to keep the level of EA low (<2%) in rapeseed oil for safe human consumption. Conventionally bred canola rapeseed cultivars lack this nutritionally undesirable long-chain fatty acid (<2% of C22:1), thus making the oil suitable for human consumption.

2.1.2 Phytosterols

Phytosterols in rapeseed occur as free sterols or combined in esters, glucosides, and esterified glucosides. Phytosterols comprise of 45–60% sitosterol, 29–43% campesterol, and 5–13% brassicasterol, with minor fractions of avenasterol (3–7%), stigmasterol (<1%), and cholesterol (<1%). Brassicasterol is a distinct type of phytosterol reported only in Brassicaceae family. Significant amount of phytosterols is present in oil of rapeseed cultivars (0.5–1.1%) (Piironen et al. 2000). Rapeseed oil is reported to contain highest phytosterol content just next to corn oil as revealed by biochemical analysis on ten different oil types (Gordon and Miller 1997). Phytosterols are known to reduce low-density lipoprotein cholesterol and total cholesterol (treatment of hypercholesterolemia) in humans, thus reducing the risk of heart diseases (Cabral and Klein 2017). They are proved to play a vital role as anticarcinogenic, anti-inflammatory, and anti-oxidation agents. They are also known to impart beneficial effects on dementia. Phytosterols are the essential membrane constituents. They protect the skin from UV rays by quenching singlet oxygen. Phytosterols need to be procured from the diet as they cannot be synthesized by our body.

2.1.3 Tocopherols

Rapeseed oil is one of the richest natural sources of tocopherols. The major form of tocopherol in rapeseed oil is γ-tocopherol followed by α- and δ-tocopherols. α-tocopherol is the biologically active form of vitamin E. Vitamin E has potential antioxidant properties and are helpful in avoiding aging-related diseases, Alzheimer's disease, and cardiovascular diseases (Gugliandolo et al. 2017). An adequate intake of vitamin E can also help to reduce chances of neurological disorders, cataracts, and cancer (Schneider 2005). γ-tocopherol is also important as it imparts oxidative stability to rapeseed oil at higher temperatures.

2.2 Rapeseed Meal

Hulls (seed coat) and embryos together constitute the de-oiled rapeseed meal with hull contributing nearly 30% of the total meal weight. Most of the carbohydrates including fiber and phenolic compounds are present in hull portion with tiny fraction of them in embryo part. On the other hand, embryo portion is mainly rich in protein which is less in hull part.

2.2.1 Proteins

The seeds of *B. napus* hold near 45% oil and 25% seed storage proteins. After oil extraction, the meal carries up to 40% of protein. Cruciferins-12S globulins (60%) and napins-2S albumins (20%) are the major proteins account for 80–83% of the total protein content (Swati et al. 2015). Other proteins such as oleosins and lipid transfer proteins constitute the minor proportion of total proteins. Rapeseed protein has a high biological value due to its nearly ideal amino acid composition, which is scarce in cereal proteins, making it an excellent addition to cereal-based diets. Slightly lower levels of essential sulfur containing amino acids (methionine and cystine in napin) have been reported in rapeseed protein as compared to soybean protein. Rapeseed meal protein shows amino acid composition comparable with milk protein casein. The cultivation of modern canola cultivars with low glucosinolate level decreased the amount of the desired napin in seeds (Malabat et al. 2003). The pathways of glucosinolate and amino acid biosynthesis are interconnected and share common enzymes, so manipulation of glucosinolate in canola cultivars could affect the content of napin (Nesi et al. 2008). Peptide mixtures of rapeseed are proved to show antidiabetic, anorexigenic, antiviral, anticancer, antioxidant, and bile acid binding properties (Alashi et al. 2014). Presently, the rapeseed meal is being used solely for livestock feeding. However, it can be served as a potential protein source for poultry and for human nutrition as well. To achieve this, there is need to decrease the content of most limiting anti-nutritional components (GSLs, fiber, sinapates, and phytic acid) responsible for unpleasant bitter taste, dark color, and reduced digestibility of rapeseed meal.

2.2.2 Vitamins and Minerals

Besides proteins, the rapeseed meal is also an abundant source of vitamins (A and C) and minerals. The calcium and phosphorus content of 0.64% and 1.03%, respectively, has been reported. These values are relatively higher than present in soybean meal.

2.2.3 Fiber

Rapeseed meal contains approximately 11–13% dietary fiber. Dietary fibers are of two types, soluble dietary fiber (SDF) and insoluble dietary fiber (IDF). IDF contains large amount of lignin and cellulose whereas SDF is comprised of mainly hemicelluloses. IDF can significantly reduce the digestibility of other essential nutrients, although SDF also have considerable ability to reduce the digestibility. The fiber negatively influences the seed oil and protein content, as the biosynthesis of fiber and oil/protein compete for same photosynthetic assimilates. The yellow-seeded genotypes of rapeseed contain less fiber and phenolics and more oil and protein contents

due to thinner and translucent seed coat resulting in a larger embryo and lower hull fraction. So, seed quality in rapeseed can be improved by breeding for yellow color seed coat.

2.2.4 Glucosinolates (GSLs)

GSLs are diverse glucose and amino acid derived secondary metabolites, specific to order Brassicales only. They are nitrogen and sulfur containing compounds comprising a thioglucose and a sulfonated oxime linked to the chain elongated amino acid. Over 130 diverse GSL types have been discovered from 16 dicot angiosperms, most of which are raised for edible purposes (Blažević et al. 2020). Based upon precursor amino acid, GSLs can be aliphatic (derived mainly from methionine), aromatic (phenylalanine or tyrosine derived), and indolic (tryptophan derived) (Halkier and Gershenzon 2006). However, this classification has little significance. Later, Blažević et al. (2020) gave classification based on three criteria, i.e., amino acid precursor, degradation product, and presence or absence of an aromatic moiety. Using these criteria, 130 GSL types were divided into 9 panels from A to I. Fifteen main GSL types are recorded in rapeseed, achieving content ranging from 60 to 100 μmol/g dry weight in seeds. Aliphatic GSLs are the predominant ones, comprising up to 92% of whole GSL types. The GSL biosynthetic pathway can be divided into three steps: (1) chain elongation, i.e., addition of a methylene group into the chain elongated amino acids, (2) formation of core structure of GSL, i.e., addition of the sulfur group and S-glucosylation, and (3) modification of the core structure (i.e., secondary side chain modifications) – benzoylation, desaturation, hydroxylation, methoxylation, and oxidation depending upon GSL type. Intact GSLs are chemically stable and relatively biologically inactive. However, the enzymatic hydrolysis of GSLs by endogenous myrosinase upon physical injury or tissue damage (cutting, chewing, and mixing) releases biologically active compounds such as isothiocyanates (ITC), oxazolidine-2-thiones, thiocyanates (SCN), nitriles (NI), and epithionitriles (Blažević et al. 2020). Isothiocyanates and its derivatives are known for their therapeutic properties such as biocidal, chemopreventive, antioxidant, and antimutagenic effects (Grundemann and Huber 2018). GSLs and their hydrolysis products also known to protect the plants against bacterial and fungal pathogens and generalist herbivores. Some GSL types such as sulforaphane and indole-3-carbinol possess potential anticarcinogenic properties. However, hydrolysis of other GSLs such as progoitrin and epiprogoitrin gives goitrogenic products. Numerous adverse metabolic effects such as reduced appetite, retarded growth, and liver and kidney damage have been recorded in poultry, fish, and pigs (Kaiser et al. 2021). Studies proving the harmful effects of GSLs in humans are limited. Traditional rapeseed carries high level of GSLs (>50 μmol/g of defatted meal). However, canola forms of rapeseed have a much reduced content of GSLs (<30 micromoles/gm of defatted meal), thus making the meal fit for animal nutrition.

2.2.5 Phenolic Compounds

The main phenolics accumulate in rapeseed are phenolic acids along with soluble and insoluble forms of condensed tannins. The phenolic acids exist in the three forms – free, esterified, and insoluble-bound form. Free phenolic acids comprise about 15% of the total phenolic acid content, whereas nearly 80% of total phenolic acids occur in the

esterified form. Sinapic acid is the prime phenolic acid that constitutes around 90% of the total present free phenolic acids and 70.9–96.7% of esterified phenolic acids (Naczk et al. 1998). Tannins are widely distributed complex polyphenolic compounds showing molecular weights ranging from 500 to 6000 Da. They can be classified into insoluble and soluble forms as per their structure and reactivity response to hydrolytic agents. Majority of the tannins in oilseed rape are proanthocyanidins, also known by the name of condensed tannins. They are formed by polymerization of flavan-3-ols or flavan-3,4-diols. The content of tannins in rapeseed meal varies from 0.2% to 3% of defatted meal (Naczk et al. 1998). Rapeseed meal accumulates more phenolic compounds than any other oilseed (Nowak et al. 1992). Phenolic components contribute to astringency, off-flavor, and dark color of meal. Sinapine, an unpalatable phenolic compound, is reported to impart adverse effects on feed intake and body weight gain with diets containing rapeseed meal (Tangtaweewipat et al. 2004). Egg tainting has been observed when tannin-rich rapeseed meal is fed to laying hen (Shahidi and Naczk 1992). Phenolics are known to affect overall protein digestibility and amino acid availability. However, phenolic compounds are also known to possess antioxidant properties and work as radical scavengers and quenchers. They exhibit protection against heart diseases. Rapeseed extracts with sinapine showed excellent antioxidant activities towards liposomes oxidation and low-density particles. Nowak et al. (1992) have reported phenolic compounds to carry antimicrobial properties, effective against gram-negative bacteria (*E. coli* and *Enterobacter aerogenes*) and gram-positive bacteria (*Bacillus subtilis* and *Streptococcus lactis*).

2.2.6 Phytates

In rapeseed, majority of organic phosphorus (up to 90%) is stored in embryo contained phytic acid. The content of phytic acid ranged from 2% to 4% in seeds, 2–5% in the oil-extracted meal, and 5–7% for the protein concentrates of rapeseed (Lickfett et al. 1999). It is biosynthesized through two distinct metabolic pathways that involve seven enzymes – *MIPS*, *MIK*, *IMP*, *ITPK*, *IPK2*, *2-PGK*, *IPK1*, and *MRP5*, a multidrug resistance-associated protein. Phytic acid is believed to act as an anti-nutritional component but also has anticancer and antioxidant activities. Phytates have a high tendency to bind to metal ions, such as calcium, phosphorus, magnesium, iron, and zinc, owing to their strong chelating properties, which ultimately reduce the bioavailability of essential minerals. Phytates are poorly metabolized by humans and non-ruminant chicken and pigs. Thus, phytases are added externally to rapeseed meal to improve the digestibility of phytates and availability of free phosphorus. Genetically eliminating or reducing the phytic acid content in the rapeseed would be an effective approach to make rapeseed meal nutritious for human consumption.

3 Growing Importance of Rapeseed Nutraceuticals in Face of Chronic Diseases and Malnutrition

Inadequate intake of vitamins and minerals, often known as micronutrient malnutrition or hidden hunger, has a negative impact on human health. Even mild level of micronutrient deficiency may promote disease development and affect cognitive

ability. Hidden hunger affects around two billion people worldwide, with the African continent and South Asia having the highest frequency. Micronutrient malnutrition often leads to stunted growth in children (starting from fetal development to 4 years of age), as already observed in developing countries (Branca and Ferrari 2002). Chronic conditions/diseases arising as a result of malnutrition can be effectively treated with the healthy plant-based diets and via biofortification of the important staple crops. Biofortification is the method of breeding food crops that are naturally enriched with micronutrients/macronutrients in the adequate quantity in their edible parts (in a bioavailable form) to mitigate the hidden hunger. Now, the focus of agricultural sector has been inclined towards developing nutrient supplement food crops rather than just increasing the supply of food crops. Biofortification approach targets on enhancing the nutritional value of the food crops that people already consume rather than attempting to add some health-promoting components to the diet. This approach is certainly the most sustainable and cost-effective approach as it is a one-time investment and gives long-term results to alleviate nutrient deficiency. The rapeseed crop has gained substantial importance over the years owing to the health-promoting effects of various bioactive compounds present in it as already mentioned above. Great efforts have been done in the past to improve the composition of rapeseed oil and meal to meet the dietary requirements of the consumers. Levels of anti-nutritional compounds such as EA and GSLs have been reduced to acceptable amounts. However, further interventions are required to convert this crop species into a high-quality food-grade crop in which desirable components should be high enough to support human and animal health but at the same time should not be too high that they become toxic. The prime objectives to enhance the nutraceutical value of rapeseed are to improve the content and composition of the seed oil and meal for food and feed purposes.

4 Attempts to Enhance Seed Oil Content in Rapeseed

Increase in oil content has been one of the most important goals of rapeseed breeding. Variation for seed oil content has been reported in *B. napus* germplasm. It varies from 26% to 50% (Xiao et al. 2019). The trait is under the control of complex regulatory mechanisms that is still not completely understood. Genetic studies have revealed the polygenic inheritance of the trait, which is frequently influenced by the environment.

4.1 Mapping for Oil Content

Numerous QTLs (quantitative trait loci) ranging from 3 to 27, each with small effect of $<10\%$, have been detected to control the variation for oil content in *B. napus* in many biparental QTL mapping studies (Zhao et al. 2012; Jiang et al. 2014). These have been visualized on all 19 chromosomes of *B. napus*. However, many QTLs,

i.e., 67, including a few QTLs with more than 20% phenotypic variation explained, were identified in a doubled haploid (DH) population generated from the cross between KenC-8 and N53-2 varieties of *B. napus* (Chao et al. 2017). The study also found some common QTLs that affected both oil and protein contents but in an opposite manner. Four QTLs on chromosomes A08, A09, C03, and C06, explaining >10% effects for oil content consistently over more than four trails, were further screened to detect candidate genes controlling oil content by integrating genome resequencing and transcriptomic analysis of parental genotypes (Yan et al. 2022). More recently, genome-wide association studies (GWAS), which exploit historical recombination events and provide high mapping resolution, have been attempted to reveal the genetic basis and identify candidate genes for seed lipid content in *B. napus.* A patatin-like lipase (*PTL*) gene on C07 was found to be associated with oil content using GWAS in a collection of 290 rapeseed germplasm accessions (Wang et al. 2021). Another major QTL (*qA07.SOC*) on A07 has been detected for seed oil content based on the GWAS and RIL population (derived from *B. napus* and *Sinapis alba*) based mapping (Zhao et al. 2022). Tang et al. (2021) also provided a deeper understanding of oil accumulation in rapeseed by associating genome variants and transcriptomes (of developing seeds) of a large natural *B. napus* population (505 inbred lines) with multiyear, multilocation seed oil content data. Previously reported 27 QTLs and some novel QTLs for seed oil content were detected in the study. QTL regions under breeding selection were also underpinned based on selection intensity of identified QTLs. A pair of homologous genes, *BnPMT6s* encoding a S-adenosyl-L-methionine-dependent methyltransferase, was demonstrated to negatively affect the oil content.

4.2 Characterization of Genes Involved in Oil Biosynthesis

A few genes regulating oil content have been cloned in *B. napus* (Liu et al. 2019). *ORF188*, a novel chimeric mitochondrial gene cloned using comparative genomics and transcriptome analysis, increased oil content by 8% in *B. napus* (Liu et al. 2019). Ding et al. (2019) used RNA interference (RNAi) technology to elucidate *BnLACS2* to be the key element for seed oil production. *BnLACS2* is a long-chain acyl-CoA synthetase, whose overexpression increased the oil content, whereas its silencing lowered oil content in rapeseed plants. Transgenic oilseed rape lines showed a near 10% increase in oil content by overexpression of a lysophosphatidate acyltransferase (*LPAT*) gene from yeast (*Saccharomyces cerevisiae*) (Zou et al. 1997; Taylor et al. 2002). About 40% surge in oil content has been recorded by an increase in Gly3P content upon overexpression of a yeast *Gly3P* dehydrogenase gene in rapeseed (Vigeolas et al. 2007). Seed-specific overexpression of the *BnLEC1* and *BnL1L* genes at an appropriate level under the control of the two truncated canola storage protein 2S-1 promoters, also known as the *napA* promoters, significantly promoted the seed oil content in rapeseed with no detectable negative effects on other major agronomic traits, including protein content (Tan et al. 2011). The CRISPR-CAS9 has emerged as a powerful technology to study gene function and produce desired traits

by efficient mutagenesis of targeted genes (Zhang et al. 2021). The technology has been used recently for functional characterization of genes involved in oil biosynthesis. Knocking out many *BnSFAR4* and *BnSFAR5* genes at the same time improved seed oil content of *B. napus* without affecting seed germination or vigor (Karunarathna et al. 2020). Silencing of the *BnLPAT2* and *BnLPAT5* genes caused decreased oil content and enlarged oil bodies (Zhang et al. 2019).

5 Improvement in Fatty Acid Composition of Rapeseed Oil

5.1 Reduction in Erucic Acid (EA)

EA is synthesized from OA by elongation process catalyzed by a rate-limiting enzyme *β*-ketoacyl-CoA synthase (KCS) encoded by the gene *FAE1*. Mutants for FAE1 led to decreased content of longer chain fatty acids (Lassner et al.1996). A mutant identified from German spring rapeseed cultivar 'Liho' is regarded as the only donor source for low EA to all canola quality rapeseed cultivated today. 'Oro' and 'Zephyr' were the first low EA rapeseed cultivars, followed by many, that were developed through conventional breeding efforts and released first in Canada. Content was found to regulate by two loci with additive effect as F_1 seeds from cross between low and high EA genotypes depicted intermediate EA content between corresponding parents and segregation ratios in F_2 and F_3 seeds were in accordance to expected ratios under control of two genes (Fourmann et al. 1998).

5.1.1 Mapping for EA Content

Various molecular markers have been used for mapping the EA content. Two additive loci (E^A and E^C on A and C genomes of *B. napus,* respectively) were identified that on collective basis explained 90% of whole EA variation in *B. napus*, while contributing unequally to the final EA content (Jourdren et al.1996). The two genes *BnFAE1.1* on A08 and *BnFAE1.2* on C03*,* encoding *β*-ketoacyl-CoA synthases, were cloned and revealed to co-segregate with E^A and E^C, respectively (Fourmann et al. 1998). GWAS studies have also been carried out to identify loci for EA content of rapeseed oil. Candidate genes *BnaA08g11130D* and *BnaC03g65980D*, orthologous to Arabidopsis *FAE1*, and *BnaA08g11140D* and B*naC03g66040D*, orthologous to *KCS17*, were identified through GWAS (Zhu et al. 2019).

5.1.2 Characterization of *FAE* Genes

There are six gene copies encoding *FAE1* proteins in *B. napus* (Wu et al. 2008; Cao et al. 2010). Of these, *BnaA8.FAE1* and *BnaC3.FAE1* are the major ones that control erucic acid synthesis in seeds. Comparison of *FAE1* sequences between HEA (high erucic acid) and LEA (low erucic acid) genotypes of *B. napus* indicated nucleotide variations. Functional activity of *FAE1* was lost *via* deletion of two to four bases in C genome homolog (Fourmann et al. 1998; Wu et al. 2008) or substituting C/T in A genome homolog (Han et al. 2001). Single SNP substitution causing amino acid change from serine to phenylalanine led to the

development of LEA *B. napus* cv. Oro (Katavic et al. 2002). Nineteen mutants for the *BnFAE1* fragment were detected through the targeting induced local lesions in genomes (TILLING) approach during the screening of 1344 M_2 plants. Of these, three M_3 plants showed reduced EA (Wang et al. 2010). The low level of EA content in *B. napus* was achieved by inhibiting the gene expression of *FAE1* genes through RNAi (Peng et al. 2010; Shi et al. 2017) and CRISPR/Cas9 technologies (Liu et al. 2022a).

5.2 Progress to Increase Oleic acid (OA) or/and Reduce Linolenic Acid (LiA) in Rapeseed: HOLL (High Oleic and Low Linolenic) Varieties

Increased levels of MUFA (OA) and reduced content of PUFA (LiA) in rapeseed oil are vital to impart thermal stability to the oil so that it can be utilized for food applications that need high cooking and frying temperatures and for salad dressings. Presently, canola quality rapeseed cultivars contain approximately 55–65% OA. There is a necessity to further increase the OA content in rapeseed oil. Thus, breeding rapeseed cultivars with high oleic acid (HOA) and low linolenic acid (LLiA) content is an important objective. The objective can be achieved by developing high OA germplasm combined with improved understanding of genetic control of trait. In the fatty acid biosynthesis pathway, activity of fatty acid desaturases (*FADs*) regulates the amount of OA, LA, and LiA. The OA is desaturated to LA by inserting double bond at delta 12 position mediated by an enzyme oleoyl-PC D12-desaturase encoded by gene *FAD2* (Hu et al. 2006; Peng et al. 2010; Yang et al. 2012), whereas LA is further desaturated to LiA by inserting double bond at the delta 15 position mediated by another enzyme, delta-15 desaturase encoded by gene *FAD3* (Yang et al. 2012; Lee et al. 2016). HOA and LLiA rapeseed mutants were identified in the physically and chemically mutagenized populations of rapeseed (Bai et al. 2019; Fu et al. 2021). Mutants harboring >80% OA were demonstrated to display reduced agronomic potential (lower seedling vigor, delayed flowering, and reduced plant height) and oil content (Bai et al. 2019). Depending on mutants, one or two major loci for *FAD2* controlling OA (Falentin et al. 2007), while two loci for *FAD3* genes for LiA were revealed (Barret et al. 1999). The first LLiA *B. napus* cultivar, Stellar, was identified in 1987 (Scarth et al. 1988) followed by Scarth with very LLiA (Scarth et al. 1995).

5.2.1 Mapping for OA and LiA Content

Both linkage and association studies have been used to map QTLs for OA in *B. napus* (Hu et al. 2006; Yang et al. 2012; Wen et al. 2015; Qu et al. 2017; Bao et al. 2018; Fu et al. 2021). The QTLs detected through linkage analysis were mapped on chromosomes A01, A05, C01, and C05 of *B. napus*. GWAS for fatty acid composition in a set of 520 genetically diverse rapeseed accessions identified a total of 62 MTAs distributed over 18 chromosomes which explained 2.31–14.48% of the phenotypic variance for seven fatty acids: PA, SA, OA, LA, LiA, EiA, and EA (Qu et al. 2017). However, only five genomic regions present on chromosomes, A02, A08, A09, C01, and C03,

were common in the two years. Six haplotype regions on chromosomes A02, A07, A08, C01, C02, and C03 were identified as significantly associated with OA through GWAS of haplotype blocks (Yao et al. 2019). Further, whole-genome sequencing of 50 rapeseed accessions revealed three genes: *BnmtACP2, BnABCI13*, and *BnECI1* in the haplotype region of A02 and two genes, *BnFAD8* and *BnSDP1* in the C02 responsible for variation in OA content. Association studies in a diversity set comprising 435 rapeseed accessions identified 149 quantitative trait nucleotides (QTNs) for fatty acid content and composition, of which 34 QTNs were overlapped with previously reported loci (Guan et al. 2019). Candidate genes *BnaA08g08280D* and *BnaC03g60080D* for OA indicated genome sequences differences between HOA and LOA genotypes. A novel QTL for *FAD2* explaining 6.2–11.7% of phenotypic variation over three crop seasons was revealed on A09 through GWAS analysis using 375 low EA *B. napus* genotypes. Transfer of this region together with previously mapped QTLs could facilitate increase in OA to 80%. Additionally, fine mapping of identified QTL unraveled three promising candidate genes that could also be validated via gene expression studies. Closely linked marker, *BnA129,* was also designed to enable marker-aided selection for OA (Zhao et al. 2019). Candidate gene-based association study in 324 rapeseed accessions identified three candidate genes present on chromosomes A07, A08, and C03 to be associated with oleic acid (Zafar et al. 2020). In the abovementioned studies, two major QTLs located on chromosomes A05 (Hu et al. 2006; Yang et al. 2012) and C01 (Hu et al. 2006) were found to harbor homologs to *AtFAD2* gene of Arabidopsis, that catalyze OA into LA acid and hence plays crucial role in controlling OA content in seed oil.

5.2.2 Characterization of *FAD* Genes

Four *AtFAD2* orthologs (the major effect *BnFAD2.C01* and *BnFAD2.A05,* plus their homeologous copies *BnFAD2.A01* and *BnFAD2.C05*) have been identified in allotetraploid *B. napus* (Yang et al. 2012; Gacek et al. 2017). Three copies of *BnFAD2* (*BnFAD2.C01*, *BnFAD2.A05*, and *BnFAD2.C05*) are functional while one copy *BnFAD2.A01* seems to be a pseudogene. Mutations in the *BnFAD2* copies have been revealed to influence OA quantity. A single nucleotide polymorphism (SNP) in the coding region of copy *BnFAD2.C01* caused surge in OA content up to 77%, whereas for *BnFAD2.A05* copy, a single-nucleotide substitution or a 4-bp insertion (Hu et al. 2006; Yang et al. 2012) in the coding region caused increase in OA quantity up to 75%. Fu et al. 2021 also confirmed the role of *BnFAD2* copies to control OA by revealing SNPs in *BnFAD2.A05* and *BnFAD2.C05* copies. Loss of function of *BnFAD2* copies in *B. napus* via RNAi (Peng et al. 2010), gene knockouts (Wells et al. 2014), and CRISPR/Cas9-mediated genome editing (Okuzaki et al. 2018; Huang et al. 2020; Liu et al. 2022b) again confirmed the significance of *FAD2* genes in increasing OA amount up to 84–85%. CAPS markers (Falentin et al. 2007), Illumina qPCR-based assay (Hu et al. 2006), SNP markers (Yang et al. 2012), and KASP (Fu et al. 2021) markers have been developed for marker-assisted selection of desirable *FAD2* alleles for high OA. Gene sequence comparison of *FAD3*copies also indicated single nucleotide mutations. For direct selection of *FAD3* allele, restriction site generating–polymerase chain reaction (RG-PCR) (Barret et al. 1999) and SNaPshot (Spasibionek et al. 2020)

have been developed. These markers have been successfully employed for selection of high OA and LLiA content in winter rapeseed.

5.3 Increase in Eicosapentaenoic Acid (EPA) and Docosahexaenoic Fatty Acid Levels

Long-chain unsaturated fatty acids (i.e., EPA and DHA) rich oil is in high demand because of its numerous health benefits. These fatty acids were once acquired exclusively from fish oil. Attempts were made to obtain EPA and DHA from rapeseed oil through transgenic approach. Using six different gene constructs from *Thraustochytrium* sp., *Pythium irregular*, and *Calendula officinalis*, levels of arachidonic acid (AA) and EPA were increased up to 25% and 15% of total seed fatty acids in rapeseed, respectively (Wu et al. 2005). Similarly, transgenic *B. napus* expressing microalgal PUFA synthases (*OrfA*, *OrfB*, and hybrid *OrfC*) from *Schizochytrium* sp. ATCC 20888 showed 2.87–3.43% average DHA content in T2 seeds of inbred lines of selected transformation events (Walsh et al. 2016). The total DHA and EPA content was around 4.4% in the field-produced canola oil (Walsh et al. 2016). In the latest transgenic DHA canola variety, seven fatty acid biosynthesis genes from yeast and microalgae were used as single fragment of around 19 Kb to transform *B. napus*, which increased the DHA levels from 9% to 11% like those obtained from fish (Petrie et al. 2020).

6 Minor Oil Components

In addition to total oil content and fatty acids composition, some minor oil components, such as phytosterols (Amar et al. 2008) and tocopherols (Fritsche et al. 2012; Gugliandolo et al. 2017), have also recently drawn the interest among rapeseed researchers to study and improve their content and composition owing to numerous health-benefitting potentials associated with them. The studies executed on phytosterols and tocopherols are discussed below.

6.1 Phytosterols

Abidi et al. (1999) recorded phytosterol content varying from 7659 to 14,023 mg/kg oil in 12 different spring canola varieties. In another study, a twofold variation was observed in the phytosterol content, varying from 4475 to 9380 mg/kg oil among the lines of three winter-type rapeseed DH populations (Amar 2007). Canola cultivars have been observed to contain higher (3565–4800 mg/kg) phytosterol content than traditional non-canola (2079–4329 mg/kg) cultivars (Amar et al. 2009). In a winter rapeseed DH population segregating for EA, QTL mapping results depicted colocalization of two of the three QTL identified for total phytosterol content and two of the four QTL detected for sinapate ester content with two EA genes on A08

and C03 (Amar et al. 2008). A close negative association of phytosterol and sinapate ester content with EA content was found. The study suggested the pleiotropic effect of the two EA genes on phytosterol and total sinapate ester content in seeds of rapeseed. This was supported by the fact that common cytoplasmic acetyl-CoA precursor is required for the synthesis of both EA and phytosterols. To further understand the genetics of phytosterols and their association with other important seed quality traits (oil content, fatty acids content, protein content of the defatted meal, and seed weight), a DH population constructed from the two-canola quality winter rapeseed cultivars, Sansibar and Oase, was used for QTL mapping (Teh and Mollers 2016). The parental genotypes were differed with respect to both oil and phytosterol content. Variable number of QTLs ranging from one to six were identified for the evaluated traits. QTLs governing large effects ($R^2 \geq 25\%$) were all identified on the A genome. QTLs identified for one trait often found to colocalize with QTLs for other traits.

6.2 Tocopherols

Rapeseed germplasm has been investigated for variation in tocopherol content and composition in some instances. Significant variation in alpha, gamma, and total tocopherol content that varied from 63 to 157 ppm, 114–211 ppm, and 182–367 ppm, respectively, has been revealed in a diverse panel comprising 87 winter rapeseed genotypes in a study by Goffman and Becker (2002). Alpha−/gamma tocopherol content ratio found to be varied from 0.36 to 1.23. However, groups with different seed quality types (double zero, single zero, and conventional) showed no significant differences for tocopherol content and composition. The study showed lack of correlation between alpha and gamma tocopherol contents. However, a positive correlation of 0.34 was observed between gamma-tocopherol content and oil content. In another study, a broader range of variation (197.5–460.1 ppm) was reported for total tocopherol in a worldwide germplasm collection of 299 rapeseed accessions (Fritsche et al. 2012). A candidate gene-based association mapping study performed on 96 accessions of this wide set identified between 26 and 12 SNPs within tocopherol biosynthesis genes (*BnaX.VTE3.a* and *BnaA.PDS1.c*) that explained 16.93% of total genetic variance for tocopherol composition and up to 10.48% for total tocopherol content. Gene-based markers were also designed and validated on the remaining accessions of the set to facilitate the selection of rapeseed genotypes with enhanced tocopherol qualities. Endrigkeit et al. (2009) cloned the first gene *BnaA.VTE4,* involved in tocopherol biosynthesis pathway in rapeseed using sequence information of Arabidopsis *VTE4* orthologs. The function of gene was also verified by an *A. thaliana* transgenic approach leading to 50-fold increase of α-tocopherol in seeds of *BnaA.VTE4.a1* overexpressing plants. A marker assay was developed for the gene and mapped to the position of two QTLs on chromosome A02 of Tapidor X Ningyou7 genetic map to facilitate marker-assisted selection for increased tocopherol content. Wang et al. in 2012 used Tapidor X Ningyou7 derived DHs and its reconstructed F_2 population and a panel of 142 rapeseed accessions to

decipher the genetic control of seed tocopherol amount and composition. They found 33 unique QTLs contributing towards phenotypic variation in tocopherol content and composition in biparental populations. Furthermore, they shortlisted 7 QTLs that colocalized with potential candidate sequences in association with tocopherol biosynthesis based on in silico and linkage mapping studies. GWAS performed on diverse panel of 142 rapeseed accessions revealed 61 loci linked with tocopherol content and composition out of which 11 were located within the regions of QTLs detected in biparental populations. The relative abundance of individual tocochromanol species in the seed oil has been modified by overexpression of chimeric TC gene constructs in developing seeds of transgenic rapeseed plants (Kumar et al. 2005). Co-overexpression of *PDS1*and *VTE2* genes have also been attempted in *B. napus* to augment total tocopherol content (Raclaru et al. 2006).

7 Progress to Improve Rapeseed Meal Value

At present, the use of rapeseed meal is restricted to feed of ruminants only, but it can be used as a high-quality protein source for poultry and hog nutrition and even for human consumption by reducing the content of most limiting anti-nutritional factors such as GSLs, fiber, phytic acid, sinapates, and non-starch polysaccharides (NSP) (Wanasundara et al. 2016). Therefore, the present objective in rapeseed meal improvement is to decrease these undesirable components in the seed. Concurrently, there is a great interest to elevate the total seed protein content and manipulating the protein composition by altering napins and cruciferins ratio.

7.1 Reduction of GSLs

Rapeseed meals with high GSLs are not considered good for animal health. So, rapeseed breeding programs are always aimed at reducing GSL content in the seeds. Breeding for low GSL content was initiated after the discovery of Bronowski, a Polish cultivar of *B. napus* (Finlayson et al. 1973). The low GSL content of Bronowski was successfully incorporated into elite zero EA germplasm of summer and winter rapeseed through conventional cross-breeding and pedigree selection (Kondra and Stefansson 1970; Wittkop et al. 2009). The reduction in GSL content occurred due to decrease in aliphatic type of GSLs (Kondra and Stefansson 1970). Today all cultivated rapeseed depicts low EA (<2%) and GSL (<15 μmoles/g of defatted meal) levels in the oil and meal, respectively. The lower level of GSLs in seeds has also raised the concern regarding increased susceptibility of cultivars to pests, pathogens, and birds owing to simultaneous decrease of GSL content in leaves. Thus, it would be desirable to improve the protective effects of *B. napus* by genetic manipulation of the leaf GSL profile without affecting seed quality. A few investigations have suggested the lack of correlation between GSLs of seeds and leaves and proposed the possibility of tissue specific manipulation of GSL profiles (Fieldsen and Milford 1994). Although GSLs can be traced in all parts of the plant,

their concentration varies throughout the plant body, i.e., unequal amount is present in different parts of plant that may also differ with respect to plant development stages and in response to various biotic and abiotic factors (Wittstock and Burow 2010). For instance, the GSL content was found higher in seeds as compared to leaves in *B. napus*. GSL content of leaves varied between 0.6 and 6.9, whereas in seed, it varied from 10.8 to 57.9 μmol/g of dry material (Baaij et al. 2018). Moreover, profile of GSL also varies in different plant tissues. Aliphatic GSLs predominates both in leaves as well as in seeds, whereas indole GSLs are found more abundantly in leaves than in seeds (Velasco et al. 2008). The differences of GSL content and profile may be attributed to diverse functions of different parts of plants. Total GSL content show quantitative inheritance. Profiling of GSLs in *B. napus* indicated three main types: gluconapin, glucobrassicanapin, and progoitrin. The content of these GSLs was found to be determined by the genotype of the mother parent. Three, four, and five loci were reported to control gluconapin, glucobrassicanapin, and progoitrin, respectively. Higher content of gluconapin and glucobrassicanapin showed partial and overdominance over low content of GSL, whereas partial dominance was indicated for high content of progoitrin over absence of progoitrin (Kondra and Stefansson 1970).

7.1.1 Mapping for Glucosinolate Content and Composition

To reveal the genetic control of GSL synthesis and accumulation in vegetative tissues or/and seeds of rapeseed, several studies have been carried out using biparental linkage mapping and GWAS approaches. Available reports indicate that four major genomic regions present on chromosomes A02, C02, A09, and C09 to be the most likely regions to control seed GSL content variation in *B. napus*. Two loci have been revealed to control side chain elongation and hydroxylation in leaves or seeds of populations derived from natural and resynthesized *B. napus* genotypes (Magrath et al. 1994; Parkin et al. 1994). Uzunova et al. (1995) identified four QTLs on rapeseed linkage groups 2, 9, 16, and 18, which together accounted for 61.7% of observed phenotypic variation for seed GSLs in a DH population. Similarly, four QTLs were revealed by Howell et al. (2003) in linkage groups 2, 7, 9, and 19 that together explained 76% variation for seed GSL content in two backcross populations. A total of 39 QTLs governing variation for seed GSL content were detected, 28 of those were mainly found on 4 chromosomes (A02, A09, C02, and C09), that explained 10.2–35.3% of phenotypic variation on individual basis in the TNDH population (Feng et al. 2012). A major effect QTL, *qGSL-C2*, explaining 30.88–72.87% of the phenotypic variation was identified on chromosome C02 in a DH mapping population developed from cross of two *B. napus* accessions that differed in their seed GSL contents (Liu et al. 2020a). The gene, *BnaC2.MYB28/HAG1*, orthologous to the *AtMYB28,* responsible for aliphatic GSL synthesis, was also suggested as promising candidate gene for the detected QTL.

Three loci on chromosomes A09, C02, and C09 were found to be in association with seed GSL content by Harper et al. (2012) in a small set of 53 *B. napus* lines using associative transcriptomics. They also revealed that deletions of orthologs of the gene *AtMYB28* on chromosomes A09 and C02 led to low seed GSL content

(Harper et al. 2012). Two *MYB28* copies on chromosomes A09 and C02 were identified as key regulators for aliphatic GSL variation in rapeseed leaves though associative transcriptomic analysis on 288 accessions of *B. napus* (Kittipol et al. 2019). Additionally, *Bna.HAG3/MYB29.A3*, was revealed to control root aromatic GSL variation. A candidate gene *Bna.MAM3.A3* was also proposed to have a role in phenylalanine chain elongation for aromatic GSL biosynthesis based on root expression data. Lu et al. (2014) inferred 26 candidate genes including orthologs of gene *AtMYB28*, i.e., *BnaA.GTR2a* and *BnaC.HAG3b*, for low seed GSL content in a larger set of 101 *B. napus* lines. Further, Li et al. (2014) also suggested that different copies of *AtMYB28* on chromosomes A09, C02, C07, and C09 responsible for the seed GSL content using a Brassica 60 K SNP array on a set of 472 rapeseed genotypes. Wang et al. (2018) identified 49 loci and 27 candidate genes for association with seed GSL content using GWAS in a diversity set. Further, 5 common and 11 tissue-specific loci were associated to total leaf and seed GSL content using GWAS analysis in 366 accessions of *B. napus* (Liu et al. 2020b). A candidate gene *BnaA03g40190D (BnaA3.MYB28)* responsible for high leaf and low seed GSL content was also validated by gene sequence polymorphism and expression assays.

7.1.2 Characterization of GSL genes

Specific gene regulatory mechanisms combined with environmental influences control GSL biosynthesis, transport, and accumulation, resulting in varying content and distinct GSL profile in different tissues of Brassica species (Mitreiter and Gigolashvili 2021). The glucosinolate biosynthetic pathway has been well characterized in the model species *A. thaliana.* Almost all genes involved in three biosynthesis stages, i.e., side chain elongation of amino acids, core structure formation, and modification of secondary side chain, have been revealed (Sonderby et al. 2010). An intricate network of TFs together with biotic and abiotic stimuli and hormonal and epigenetic factors governs the spatiotemporal synthesis of GSLs (Hirai et al. 2007). The three types of GSLs (aliphatic, indolic, and aromatic) are independently regulated by different group of genes (Sonderby et al. 2010). Three TFs, *MYB28, MYB76*, and *MYB29*, belonging to the *R2R3-MYB* family, regulate biosynthesis of aliphatic GSLs (Gigolashvili et al. 2007, 2008a, b). They are also denoted as *HIGH ALIPHATIC GLUCOSINOLATE (HAG) 1, 2,* and *3,* respectively. Of these, TF*MYB28 (HAG1)* is the prime transcriptional regulator that upregulate most of the genes involved in aliphatic GSLs biosynthesis, including side chain elongation (*MAM1* and *MAM3*) and core structure development (*CYP79F1*, *CYP79F2*, *CYP83A1, ST5b*, and *ST5c*) (Gigolashvili et al. 2008a, b; Baskar and Park 2015). Owing to closest evolutionary relationship of *A. thaliana* with Brassica crops, many *MYB28*orthologues have been identified in Brassica species, including four in *B. rapa* (Kim et al. 2013), three in *B. oleracea* (Augustine et al. 2013), five in *B. juncea* (Yin et al. 2017), and six in *B. napus* (Long et al. 2016). The DNA sequences of *MYB28* members in Brassica crops are found to be highly conserved. The coding region varies from 1350 to 1630 bp in length. The inferred *BnMYB28* protein sequences of *B. napus* share percent identity ranging from 59% to 78% with *AtMYB28* and from 59% to 98% with each other (Long et al. 2016). Many genes explaining variation for GSL content in *B. napus* have been identified via

QTL mapping, genome-wide association, and associative transcriptomic studies as already described above. These studies indicated the significant role of *MYB28* homologs in aliphatic glycoside biosynthesis. Aliphatic as well as total GSL content were also reduced by silencing of *MAM* gene family through RNAi (Liu et al. 2011). Independent knockout mutants of genes *MYB28* and *CYP79F1* have been verified to carry decreased aliphatic GSL content by 55.3% and 32.4%, respectively, compared to control plants in *B. napus* (Jhingan et al. 2023). Genes encoding TFs *MYB34/ATR1 (altered tryptophan regulation 1)*, *MYB51 (HIG1)*, *MYB122 (HIG2)*, and cytochrome P450 enzymes, *CYP79B2, CYP79B3*, and *CYP83B1*, are associated with biosynthesis of indolic GSLs (Celenza et al. 2005; Gigolashvili et al. 2007; Frerigmann and Gigolashvili 2014). Overexpression of allele, *atr1D,* altered the expression of *CYP79B2, CYP79B3*, and *CYP83B1*, which led to increased levels of indolic GSLs, whereas, loss of function mutants resulted in decreased levels of indolic GSLs (Celenza et al. 2005). Redirection of tryptophan into tyramine transformed rapeseed with *TDC* (*tryptophan decarboxylase*) gene resulted in lower levels of indolic GSLs (Chavadej et al. 1994). Limited information is available for synthesis of aromatic type of GSLs. It is obvious that GSLs biosynthesis pathway in Brassica crops is extremely complicated than *A. thaliana* due to presence of polyploidization and multiple genomic rearrangements events. Spatial-temporal transcriptional regulation of different *MYB28* homologues has been commonly observed in Brassica, suggesting the occurrence of functional divergence of *MYB28* copies after genome polyploidization (Kim et al. 2013). Genetically, removal of GSLs in seeds while maintaining them in leaves could be achieved in *A. thaliana* through manipulation of two transporters, *GTR1* and *GTR2*, that control GSL accumulation in seeds (Nour-Eldin et al. 2012). GSLs are primarily synthesized in leaves and silique walls (source tissues) and then translocated to embryos via phloem by two transporters, *GTR1* and *GTR2* (Nour-Eldin and Halkier 2009). The *gtr1 gtr2* double mutant of *A. thaliana* failed to accrue GSLs in its seeds; however, it over-accumulated GSLs higher than tenfold in the source tissues, leaves, and silique walls (Nour-Eldin et al. 2012). In the similar way, low level of GSLs has been achieved through gene editing of transporter genes, *GTR 2* gene in *B. napus* (He et al. 2022). Overexpression of STM gene caused reduction in seed GSL levels (Elhiti et al. 2012). Modified GSL content was also achieved by engineering leaf cotyledon 1 gene (Elahi et al. 2016).

7.2 Reduction of Other Antinutritive Compounds

Breeding of rapeseed cultivars with reduced phenolic compounds (sinapates, tannins, and proanthocyanidins), fiber, and phytates in seeds is important as these components limit the usage of rapeseed meal as a quality grade protein source for human and animal consumption. Interestingly, seed coat color is found to be associated with some of these antinutritive seed constituents in Brassica species. Proanthocyanidins and tannins are the prime components responsible for seed coat pigmentation. Black/brown-seeded genotypes have more proanthocyanidins, tannins, and fiber deposited in their seed coats. In contrast,

yellow-seeded lines with thinner seed coats display improved quality of the seed (higher proportions of oil (also more transparent) and protein) and derived meal (lower quantities of tannins, proanthocyanidins, and fiber). Much attempts have been carried out for the development of yellow-seeded genotypes in oilseed rape. There is no naturally occurring germplasm with yellow seed color in *B. napus.* Most of the yellow-seeded *B. napus* has been derived from interspecific/intergeneric crosses of *B. napus* with related species *B. rapa, B. juncea, B. carinata, B. oleracea* spp. *Alboglabra*, and wild crucifers (*Sinapis alba* and *Descurainia sophia*) (Wen et al. 2012). Although seed coat color/seed pigmentation is a morphological marker, it is difficult to select owing to its low heritability, polygenic inheritance, and maternal and environmental effects (temperature and light) controlling the trait (Stein et al. 2013). So, molecular markers linked to seed coat color were also established in rapeseed (Rahman et al. 2010). Transparent testa mutants (TT), including early (EBGs) and late (LBGs) biosynthesis genes, are known to mainly regulate variation in seed coat color (Appelhagen et al. 2014). The EBGs include *TT4, 5, 6*, and *7,* and LBGs include *TT3, 12, 18, 19, BAN*, and *AHA10.* A few seed coat color genes *TT1TT2, TT10, F3'H, PAL, BAN*, and *TTG1* have also been cloned and revealed to be involved in flavonoid biosynthesis pathways in *B. napus* (Zhang et al. 2013; Lian et al. 2016). Concurrently, genetic mechanisms of seed fiber (Behnke et al. 2018; Miao et al. 2019; Gacek et al. 2021) and condensed tannins (Lipsa et al. 2012) have also been studied together with seed color, oil, protein, and glucosinolate content in order to improve oil content and meal value of rapeseed. QTLs of one trait were repeatedly found to be colocalized with other traits because of interlinked biochemical pathways involved in the synthesis of these components from common substrates/precursors. A lignin biosynthesis gene, *BnCCR1*, on A09 was reported to affect both seed color and lignin content (Liu et al. 2012). More recently, a QTL cqSC-A09 has been detected which simultaneously explained variation for seed color, fiber, and oil content with a large effect (Chao et al. 2022). Most of the studies revealed one major locus on chromosome A09 that explained most of the variation for seed color and meal quality traits (Rahman and McVetty 2011; Liu et al. 2012; Kebede et al. 2012).

Significant genetic variation for phytate content has been reported across 505 genotypes of rapeseed. It ranged from 0.41 to 0.97 mg/5 seeds (Liu et al. 2021). A multidrug resistance-associated protein 5 (*BnaA9.MRP5*) gene was also identified as a candidate gene, with eight distinct haplotypes in association with both seed phytate content and concentration using GWAS in 505 accessions. RNAi-mediated downregulation of *MIPS* genes has been known to decrease phytate amount in a patent (Georges et al. 2006). Phytic acid mutants with knockout mutations in the six genes *BnMIPS, BnMIK, Bn2-PGK*, *BnIPK1, BnIPK2*, and *BnMRP5* were identified in an EMS (ethyl methane sulfonate) mutagenized population of rapeseed after implementation of high-throughput NGS screening protocol (Sashidhar et al. 2020). The study also identified double mutants of *Bn.2-PGK2*, which revealed substantial decrease in phytic acid content. In order to decrease the phytic acid content in rapeseed, three functional paralogs of an important enzyme

BnITPK (inositol tetrakisphosphate kinase) were knocked out using CRISPR-Cas9 mutagenesis in spring rapeseed cultivar Haydn. The mutants with low phytic acid and presence of free phosphorous were obtained.

7.3 Seed Storage Protein (SSP) Content and Composition

Substantial genetic variation for protein content and quality has been observed in rapeseed germplasm (Schatzki et al. 2014; Stolte et al. 2022). The content of cruciferin and napin ranged from 25.5 to 34.7 μg/sample and from 20.0 to 26.4 μg/sample, respectively, across 30 winter rapeseed hybrids of canola quality (Stolte et al. 2022). However, a few genomic studies have been carried out to reveal the molecular regulation of seed storage protein content and its composition. The outcomes of those studies revealed common or closely linked QTLs for seed oil and protein content but controlling the traits in an opposite manner. This is usually expected as both oil and protein compete for common substrates in the metabolic pathway, thus must be partly regulated by the same genes. Also, seed oil is significantly negatively correlated to protein quantity (Gül et al. 2003). *BnFus3* mutant seeds of *B. napus* depicted declined level of oil proportion with increased protein content. Decreased expression of sucrose photo-assimilation and glycolysis pathway related genes was observed in the seeds. This might have affected the synthesis of both oil and protein to alter their content in the seeds (Elahi et al. 2015). To identify the unique/separate QTLs for oil and protein content, Zhao et al. (2006) used a conditional mapping approach. The study detected five QTLs localized on chromosome A07, A09, C01, C08, and C09 for protein synthesis uncommon to QTLs for oil content (Zhao et al. 2006). Three QTLs for napin were envisioned on chromosomes A02, C06, and C09, and two QTLs for cruciferin content were observed on A02 and C19 (Schatzki et al. 2014). Four QTLs for protein content of defatted meal were found on chromosomes A01, A07, and C03. Of these, QTL located on chromosome A01 was associated to five traits, i.e., PA, OA, LA, oil content, and protein content. The variation in the region resulted in decreased PA, LA, and protein content in the defatted meal and increased oil content in the seed (Teh and Mollers 2016). Potential candidate genes encoding seed storage 2S, caleosin, oleosin, and cruciferin were identified for 38 QTLs regulating seed protein content in *B. napus* by Chao et al. (2017). Some promising attempts have also been undertaken to engineer rapeseed with more desirable levels of napin through introducing a Brazil nut (*Bertholletia excelsa*) 2S gene (Guerche et al. 1990, Altenbach et al. 1992) or expression of an antisense gene for cruciferin (Kohno-Murase et al. 1994; Hannoufa et al. 2014). In these cases, transgenic plants showed increased levels of lysine, cysteine, and methionine essential amino acids which led to more napins in their seeds. Also, the increase in napin content was counterbalanced by a decrease in cruciferins, thus suggesting that the 12S/2S ratio is tightly regulated. The lysine content of canola meal protein has also been improved by disrupting the feedback regulation of lysine during biosynthesis (Falco et al. 1995).

Abstract

Sunflower is an important oilseed crop. Worldwide, it ranks fifth in cultivation among oilseed crops. Sunflower oil is preferred for domestic consumption as well as for cooking due to its nutritional quality. The sunflower oil quality is decided based on the proportion of various fatty acids and tocopherols. Recent breeding efforts in sunflower require a special focus on altering the oil quality. Breeding of new sunflower genotypes for food and nonfood industries assures a bright future for sunflower. Recent developments in molecular techniques helped to understand the genetic architecture of sunflower traits and the changes that happened during domestication. The availability of the sunflower genome sequence made a real breakthrough in sunflower molecular biology. This sequence could be effectively used to locate QTLs associated with various traits. It may help to understand the metabolic pathways of various quality traits. It may also help to replace SSR markers with SNPs. The valorization of the nutritional aspects of sunflower would throw the limelight in the realization of oil sustainability and enhance the circular economy in the global oilseed market.

Sunflower · Genetic architecture · Oil quality · Fatty acid · Molecular biology · Genome sequence

1 Introduction

Sunflower (*Helianthus annuus* L.) is a diploid (2n = 34) annual plant. It belongs to the subtribe Helianthineae, tribe Helianthea, subfamily Asteroideae, and family Compositae (Asteraceae). The botanical name *Helianthus* comes from the Greek words *helios* (sun) and *anthos* (flower). The genus *Helianthus* is native to temperate North America. It has 14 annual and 37 perennial species. As per archaeological reports, the sunflower was cultivated by American Indians during 4625 BC (Jocic et al. 2015). Sunflower is used in many ways. It is used in the diet as nuts and flour. It is used as oil to decorate the hair and to protect the skin from the sun. It is also used to obtain colors (yellow and red). Sunflower is used for medical purposes and also as an ornamental plant.

Sunflower is an important oilseed crop. Globally, it ranked fifth among edible oilseed crop area with 22.9 million hectares. The nutritional value of vegetable oils is based on the proportion of various fatty acids (Fig. 1). The most important fatty acids of sunflower oil are linoleic acid (45–65%) (PUFA or poly unsaturated fatty acid) and oleic acid (20–30%) (MUFA or mono unsaturated fatty acid). In addition, palmitic and stearic acids are also available. Sunflower oils are categorized as high linoleic, high oleic, and mid-oleic. Mid-oleic sunflower oil has a minimum of 50–60% oleic acid. High oleic sunflower oil has 80–85% oleic acid. Oleic acid (18:1) only reduces cholesterol's atherogenic fraction. Therefore, oleic acid is

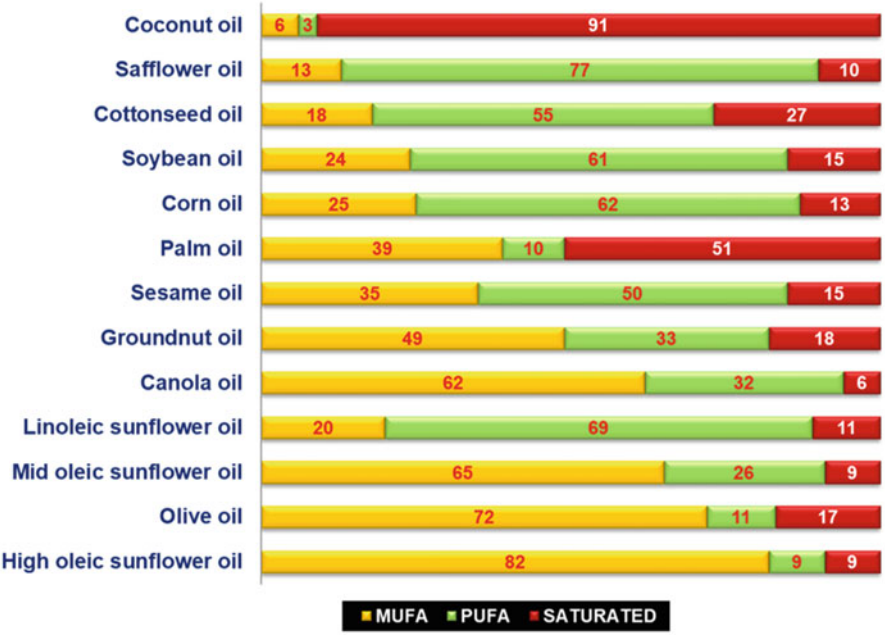

Fig. 1 Fatty acid profile of different vegetable oils

beneficial for cardiovascular disease prevention (Delplanque 2000). Dietary recommendations are the higher proportion of MUFA and reduction of saturated fats. Hence, the food manufacturing industry has more interest in high oleic sunflower oil. The qualitative manipulation of oils involves the changes in fatty acid composition. It decides the chemical properties of the oil and its use. Breeders exploit various breeding techniques to modify the proportion of the fatty acids.

Vegetable oils and fat are the third most important components in the human diet. Oil is the main cooking medium for majority of dishes. It increases the taste of those dishes. The suggested per capita oils and fat are 30 g per day. Hence, there is a need to enhance the oil quality to reduce the levels of bad (low density lipoprotein, "LDL") cholesterol.

2 Nutritional Composition of Sunflower

The common sunflower seed supplies many nutritious components like protein, unsaturated fats, fiber, vitamins (especially E), selenium, copper, zinc, folate, iron, and more. It can be used as cooking oil, enjoyed as a roasted or salted snack, dehulled, and included as a confectionary nut. Since sunflower seed is high in sulfuric amino acids, its meal is widely used as both livestock and pet feed. Sunflower oil quality is related to seed oil content and fatty acid composition and defines the oil's value for the industry. Sunflower seed contains 35–42% oil and is

naturally rich in linoleic acid (55–70%) and consequently poor in oleic acid (20–25%) (Premnath et al. 2016). Oleic acid is a mono unsaturated omega-9 fatty acid. It is capable of lowering triacyl glycerides and low density lipoprotein (LDL) cholesterol levels, increasing high density lipoprotein (HDL) cholesterol. Hence, it reduces the risk of heart attack (Guo et al. 2017).

Oleic and linoleic acids contribute almost 90% of the total fatty acid content in sunflower oil. High oleic sunflower oil is generally with more than 80% oleic acid. Linoleic sunflower oil has at least 65% linoleic acid. High oleic sunflower oil has a very neutral taste. It offers great stability without hydrogenation. Linoleic sunflower oil has susceptibility for oxidation, particularly during frying. The patents for high oleic seed (patent # 4627192) and high oleic oil (patent # 4743402) were issued on December 9, 1986, and May 10, 1988, respectively. These patents subsequently expired on December 9, 2003, and May 10, 2005, respectively, for high oleic seed and oil. Hence, the research work on high oleic oil has been started in the public research institutions as the expiry of the patent expired. The total tocopherol content in standard sunflower oil is 700–1000 mg/kg. Natural tocopherols are present in four isomers: α (5,7,8-trimethyltocol), β (5,8-dimethyltocol), γ (7,8-dimethyltocol), and δ (8-methyltocol). Standard sunflower oil contains mostly α-tocopherol (95%) and lower quantities of β-tocopherol (3%) and γ-tocopherol (2%) (Skoric et al. 2008). Tocopherols are considered to be natural antioxidants but have different *in vivo* and *in vitro* antioxidative activities. α-Tocopherol expresses maximum *in vivo* activity, also known as vitamin E activity, but low *in vitro* protection of extracted oil. γ-, δ-, and β-ocopherols are very important antioxidants, but with low vitamin E values (Packer and Jevic 2002).

Sunflower sprouts accumulate high amounts of caffeoylquinic acids (CQAs) including chlorogenic acid (5-CQA) and 1,5-diCQA. HaHQT2 was found to be the major isoform, which could be responsible for CQA biosynthesis during germination in both hypocotyls and cotyledons. Therefore, manipulation of this gene could be applied to biofortify sunflower sprouts as functional foods (Cheevarungnapakul et al. 2019).

Sunflowers have been employed in the preparation of various delicacies. Sunflower seeds can be processed into different forms, such as flour or roasted, baked, or boiled as composite functional foods. Sunflower remains a source of nutritional food for humans. Studies have revealed that sunflower seeds are rich in nutrients and certain different phytochemicals such as antioxidants, flavonols, phenolic acids, procyanidins, phytosterols, amino acids, dietary fiber, potassium, arginine monounsaturated, and polyunsaturated fatty acids which contribute to the improvement of human health (Adeleke and Babalola 2020). Ye et al. (2015) reported caffeic acid hexose I, caffeic acid hexose II, p-coumaric acid hexose, chlorogenic acid, isoquercitrin, 3,4-Di-*O*-caffeoylquinic acid, 1,5-Di-*O*-caffeoylquinic acid, 3,5-Di-*O*-caffeoylquinic acid, and 4,5-Di-*O*-caffeoylquinic acid as principal phenolic contents in sunflower florets. The presence of some essential amino acids such as aspartic acid, glutamic acid, serine, histidine, glycine, threonine, arginine, alanine, tyrosine, cysteine, valine, methionine, phenylalanine, isoleucine, leucine, lysine, and proline in sunflower products has also been reported (Karangwa et al. 2015). Sunflower seeds contain high amounts of vitamins like vitamin E, B, folate, and niacin and

minerals like calcium, copper, iron, magnesium, manganese, selenium, phosphorous, potassium, sodium, and zinc. By and large, the therapeutic potential of sunflower seeds has been proven to be medically curative for colds and coughs, as a substitute for quinine, exhibiting anti-malaria efficacy, and as a diuretic and expectorant (Islam et al. 2016). As a promising protein source, sunflower seeds in food preparation can be made as a substitute for soybean (Oliveira et al. 2019).

3 Genetic Resources of Health-Related (HR) Genes in Sunflower

A sustainable agricultural system and the security of global food supply are based on the maintenance of essential crop species and crop wild relatives (CWR). Gene banks' goals consist of encouraging the usage of CWR for crop improvement. It serves as the primary repository for the preservation of accessions and associated data and for distributing seeds for germplasm associated studies. Resources for germplasm can be categorized as *ex situ* or *in situ*. *In situ* resources are preserved in their natural settings in which they continue to change because of their surroundings. This is the best approach to keep populations alive, but in contrast to populations kept in gene banks, natural populations are frequently threatened by human activity. *Ex situ* conservation's most significant benefit is that it offers equal weight to resource availability and preservation.

3.1 Gene Pool Classification in Sunflower

The primary gene pool of sunflower contains cultivated and wild species of *H. annuus* and winter sunflower (*H. winteri* J. C. Stebbins). All these species are readily crossable (Stebbins et al. 2013). The secondary gene pool (e.g., *H. anomalus* S. F. Blake, *H. paradoxus* Heiser, *H. petiolaris*, and *H. deserticola* Heiser) consists of species that have undergone some degree of differentiation to the genome of cultivated species. These species have potential meiotic difficulties during hybridization. The tertiary germplasm pool (e.g., *H. hirsutus* Raf., *H. tuberosus*, and *H. divaricatus* L.) has a high degree of differentiation. Hence, it requires specialized techniques such as embryo rescue for the recovery of interspecific hybrids. Differentiation among the species can be measured through molecular, cytological, and morphological bases. The extent of wild species uses decreases from primary through tertiary pools due to differences in ploidy level and growth habit, as well as reproductive barriers (Warburton et al. 2017).

3.2 Crop Wild Relatives (CWRs) in Sunflower

Cultivated sunflower is a new crop when compared to the other major temperate crops. Although its genetic basis was restricted by a domestication bottleneck, the

huge number of sunflower CWR allows for the mining of a sizable genetic pool for crop improvement. Collection and preservation are made possible with little difficulty because North America is the principal region of origin for the genus *Helianthus*. There are 53 species in this genus. Of this, 14 and 39 are annuals and perennials, respectively (Stebbins et al. 2013). These species can be found from Canada to Mexico and alongside the Pacific and Atlantic coasts. Wild species constitute an important source of resistance genes due to the coevolution of sunflower CWR, their pathogens, and insect pests (Terzic et al. 2020). Information on wild species is highly useful to identify sources of tolerance genes in ecotypes (Seiler et al. 2017).

Sunflower CWR has high variation for tolerance to abiotic stresses. Salinity tolerance available in *Helianthus paradoxus* was incorporated into cultivated sunflower (Miller 1995). Hajjar and Hodgkin (2007) suggested that these saline tolerant genotypes could produce higher yield under salinity. CWR additionally offers the possibility of studying physiological processes of the survival mechanisms of species available under desert situation (Bowsher et al. 2016). *Helianthus argophyllus* has been significantly used for drought tolerance breeding. Baldini and Vannozzi (1998) stated that interspecific derivatives were obtained involving *H. argophyllus.* These derivatives were selected through divergent selection for physiological traits of *H. argophyllus.* These derivatives had better drought tolerant traits under drought situation than *H. annuus* lines. Resistance genes for rust, downy mildew, *Verticillium* wilt, *Alternaria* leaf spot, powdery mildew, *Phomopsis* stem canker and *Sclerotinia* wilt/rot, and broomrape were incorporated into cultivated sunflower from CWR (Seiler et al. 2017).

3.3 CWRs for Fatty Acid Composition in Sunflower

Two annual desert species, *Helianthus anomalus* Blake and *H. deserticola* Heiser, are excellent candidates for increasing oil concentration and enhancing quality based on their adaptation to desert environments. *H. anomalus* (sand sunflower) is a rare endemic species adapted to sand dune and swale habitats in Utah and northern Arizona (Heiser et al. 1969). Sand sunflower is a diploid annual species of hybrid origin that is endemic to active sand dunes, an extreme environment from its parents, *H. annuus* and *H. petiolaris* (Ludwig et al. 2004). *H. deserticola* (desert sunflower) is a xerophytic annual species found in sandy soils on the floor of the Great Basin Desert in small populations in western Nevada, in west central Utah, and along the border of Utah and Arizona (Heiser et al. 1969). *H. anomalus* has a larger seed and higher oil concentration than any other wild sunflower species. It also has the same chromosome number as cultivated sunflower. This will facilitate the introgression of agronomic traits from wild germplasm into cultivated sunflower. The lower saturated fatty acid profile in *H. anomalus* has the potential to reduce saturated fatty acids in cultivated sunflower. There appears to be sufficient variability in *H. anomalus* to introduce and select for high linoleic acid concentration and reduced saturated fatty acid concentrations in cultivated sunflower oil (Seiler 2007).

Reduced concentrations of saturated palmitic and stearic fatty acids have been observed in a population of wild *H. annuus* that had a combined concentration of 58 g kg^{-1}, and 65 g kg^{-1} was observed in a wild perennial species, *H. giganteus* (Seiler et al. 2017). These values are 50% lower than in the oil of cultivated sunflower (120 g kg^{-1}), providing new potential sources for reducing saturated fats in the oil.

The CWR of sunflower has played a vital role in the sunflower crop improvement. It will continue as one of the primary sources of genetic diversity for the sunflower crop. Traditional breeding technologies have established a basis for utilizing CWR in the improvement of cultivated sunflower. Incorporating CMS from wild sunflower facilitated the development of the globally valued sunflower crop. The incorporation of disease resistance and other biotic and abiotic traits has protected the investment in hybrid sunflower. Future developments are expected to take advantage of emerging technologies to increase the efficiencies of the breeding process of mining the genes from existing sunflower CWR.

4 Mode of Gene Action for High Oleic Acid Content in Sunflower

Genetic control of a high oleic mutation had been reported as one dominant gene *Ol* (Fick 1984; Urie 1985); major gene *Ol* and gene-modifier *ml* (Miller et al. 1987); recessive gene *ol* and dominant *Ml* (Martinez et al. 1999); three complementary genes *Ol1*, *Ol2*, and *Ol3* (Martinez et al. 1989); five genes *Ol1*, *Ol2*, *Ol3*, *Ol4*, and *Ol5* (Velasco et al. 2000); gene *Ol* with incomplete penetrance determined by genotypic epistatic factors of reversion (Demurin 2003); and high oleic locus *oleHOS* and suppressor locus *Su* (Lacombe et al. 2001; Berville 2010). Since the high oleic trait is such a complex one, these authors expressed the need for conducting further research with various crosses, locations, temperature, etc. to get a clear idea of the genetic system of oleic acid content (Dimitrijevic et al. 2017). The details on the genetics of high OAC in sunflower were presented in Table 1.

Genes responsible for tocopherol content of the seed were first reported in sunflower. Two independent genes, viz., *Tph1* and *Tph2*, were identified (Popov et al. 1988). *Tph1* controls the relationship among α- and β-tocopherol. *Tph2* gene controls the relationship among α- and γ-tocopherol. Both *Tph1* and *Tph2* genes under recessive homozygous condition have an epistatic effect. It leads to the production of δ-tocopherol (Demurin 1993). Velasco et al. (2004) reported that one recessive gene is responsible for β- and γ-tocopherol content. Demurin et al. (2004) and Vera-Ruiz et al. (2005) identified tph1 recessive gene in both T589 and LG15 lines. Demurin et al. (2004) identified *tph2* gene in lines T2100 and LG-17. Using these lines, the first sunflower hybrids with higher tocopherol composition were developed. The hybrid Krasnodarskiy 917 has 50% of β-tocopherol content. Another hybrid Oxy has 60% of γ- and 40% of β-tocopherol content with high oleic acid (Demurin 2012).

Table 1 Variations in gene action for high oleic acid in sunflower

Dominant/recessive/ intermediary	Major gene + modifiers	References
Partially dominant	1 major gene	Fick (1984)
Dominant	1 major gene + modifiers	Urie (1985)
Intermediate	1 major gene + modifiers	Miller et al. (1987)
Dominant	1 major gene	Schmidt et al. (1989)
Dominant	3 major genes additive + modifiers	Martinez et al. (1989)
Dominant/partially dominant	No conclusion	Nikolova et al. (1991)
Dominant, sometimes recessive	3 hypotheses as to increasing gene numbers	Demurin and Skoric (1996)
Dominant, sometimes recessive	1 major gene + modifiers not clear	Dehmer and Friedt (1998)
Partially dominant	2 interacting major genes	Martinez et al. (1999)
Dominant	Not addressed	Vares et al. (2000)
Dominant	Major QTL (85% EV)	Perezvich et al. (2000)
Complex, some maybe dominant	Five major genes + modifiers	Velasco et al. (2000)
Dominant	1 M locus = Δ 12-RFLP	Lacombe et al. (2001)
Dominant	One or more genes with modifier effect	Berville (2010)
Dominant	At least three loci	Ferfuia and Vannozzi (2015)
Dominant	Three QTLs	Premnath et al. (2016)

5 Genetic Diversity Analysis for Oil Quality Traits in Sunflower

Cultivated accessions of the sunflower have useful genes that encode various phenotypic traits that could be used to speculate on the origin of sunflower oil. These genes may later be employed in breeding initiatives to produce sunflower oil of higher quality. Sunflower oil has the potential for enhanced nutritional properties. Breeders have a variety of approaches for increasing oil content, including using genetic variation from several sunflower germplasms and wild populations. The traits can be introduced into grown sunflowers by gathering, researching, and choosing the best populations (Seiler 2007). Although wild accessions of sunflowers have less seed oil than cultivated sunflowers, backcrossing can increase the oil content to a desirable level (Seiler and Gulya 2010).

5.1 Phenotype Based Diversity Analysis for Quality Traits in Sunflower

The major objective of sunflower breeding is to develop hybrids or varieties with high yield, oil content, and oil quality along with disease resistance. To achieve these

objectives, the breeder needs to select genetically diverse parents. Therefore, knowledge of the existing genetic diversity in the germplasm is important to plan for recombination breeding.

Ahmadian et al. (2019) assessed the genetic diversity of 107 cultivated accessions of sunflower. A significant negative relationship between oleic acid, stearic acid, and saturated fatty acids (SFA) with oil content was observed. The correlation coefficient of the ratio between unsaturated fatty acids to saturated fatty acids (UFA/SFA ratio) with oil content was positive and significant. In the PCA analysis, four major principal components (PCs) were identified. These PCs account for 87.19% of the total variation. The accessions were grouped into seven distinct clusters, and the accessions in clusters 4 and 7 contained high UFA and low SFA values.

Dudhe et al. (2019) evaluated 2149 sunflower germplasm accessions. Significant differences among genotypes for almost all characters were observed. The first PC accounted for 29.20% of the total variation in the population with more contribution from oil content. The second PC contributed 57.6% to days to maturity and 50% flowering contributed maximum. DUS characters such as pigmentation of seedlings, leaf petiole, disc, and stem can be considered as morphological markers to differentiate the germplasm. Ray floret coloration, plant branching, type of branching, and pollen color characters can help the breeder to identify the specific germplasm. The identified trait-specific accessions will help in the effective utilization of promising accessions in the breeding.

5.2 Marker Based Diversity Analysis in Sunflower

Molecular markers play a major role in identifying variation in genomic DNA sequences. Polymorphism at the molecular level in different species has played a major role in the analysis of genetic diversity, identification of phylogenetic relationships, and also transfer of target traits to elite germplasm. Different molecular markers have been used in mapping genes leading to the development of sunflower linkage maps resulting in studies revealing genetic diversity in the genus *Helianthus* (Mwangi et al. 2019).

Mandel et al. (2011) studied an association panel of sunflower. It consists of 433 cultivated and 24 wild accessions. A set of 34 expressed sequence tag (EST)-simple sequence repeats (SSRs) were used. Gene diversity was 0.47 and 0.70 in cultivated and wild accessions, respectively. The results showed that cultivated accessions had less genetic diversity than wild accessions. Further wild accessions were grouped in four clusters. The cultivated accessions were grouped into two clusters. The maximum likelihood method indicated that the diversity in cultivated accessions was sourced from two wild sunflower populations. These are from the east-central USA. It is the same region where sunflower domestication is presumed to have occurred. A nested subset of accessions captured more allelic diversity in the cultivated accessions. A core set of 288 accessions captured about 90% of alleles of full set. Another core set of just 12 captured about 50% of alleles in cultivated accessions.

Filippi et al. (2015) studied the association mapping population. This population consisted of various accessions. It had 137 genotypes of National Institute of

Agricultural Technology, Argentina. A set of 33 open-pollinated and composite populations were also included. Two types of markers, viz., 42 SSR markers and single-nucleotide polymorphism (SNP) markers, were used. Clustering was compared for the two marker types. The population structure was dominated by the maintainer/restorer trait.

The molecular diversity in a set of 114 cultivated sunflower populations was studied by single-nucleotide polymorphism genotyping (Mangin et al. 2017a). The mean allele number varied from 1.07 to 1.90. Intrapopulation variability was slightly reduced according to the number of multiplications since entry, but some populations were probably largely homozygous when received. A principal component analysis was used to study interpopulation variability. The first three axes accounted for 17% of total intrapopulation variability. The first axis was significantly correlated with seed oil content, more closely than just the distinction between oil and confectionary types. The second axis was related to the presence or absence of restorer genes, and the third axis was to flowering date and possibly to adaptation to different climates. Propositions are made to improve sunflower population maintenance procedures to keep maximum genetic variability for future breeding (Mangin et al. 2017a).

Chernova et al. (2021) performed high-throughput lipidomic profiling in sunflower by genotyping 601 inbred sunflower lines and analyzed their lipid and fatty acid composition. The genome-wide association analysis based on genotypes for 15,483 SNPs and the concentrations of 23 fatty acids, including minor fatty acids, revealed significant genetic associations for 11 of them. The identified genomic regions included the loci involved in rare fatty acid variation on chromosomes 3 and 14, explaining up to 34.5% of the total variation of docosanoic acid (22:0) in sunflower oil.

6 Mutation Breeding for Altered Oil Quality in Sunflower

A substantial change in the quality of sunflower was created through mutation breeding. In contrast with other oil crops, modifications in oil quality are considerably more in sunflower. This was possible through many factors. These factors are induced mutations with both physical and chemical means, precise phenotyping techniques to fix mutants, nondestructive analyses, etc. Mutants have various levels of saturated fatty acids, oleic acid content, β-, γ- and δ-tocopherols. It helped to create more oil profiles in sunflower. For example, sunflower oil contains the above 90% oleic acid. It is higher than any other vegetable oils in the world market (Cjevic et al. 2014). Fatty acid and tocopherol content had higher stability over environments. These traits are controlled by a few genes. Hence, it can easily be utilized to develop hybrids with different oil quality.

6.1 Mutation Breeding for Altered Fatty Acid Composition in Sunflower

The outcome of mutation breeding for modified fatty acid content composition is the changes in their proportion. Mutation with DMS resulted in high oleic

acid content (>80%). EMS and sodium azide (NaN_3) mutagens provided increased stearic acid content (over 25%). Likewise higher proportion of palmitic acid content was obtained with the usage of physical mutagens (X-rays and γ-rays). The high oleic acid content donor was developed by Soldatov (1976). He used DMS to obtain mutants from VNIMK 8931 variety. His studies resulted in the identification of the high oleic (80–90%) Pervenet variety. Pervenet has been widely used as a high oleic donor in sunflower improvement programs.

6.2 Mutation Breeding for Altered Tocopherol Content in Sunflower

Kurnik (1966) identified a mutant with modified tocopherol composition. He reported the absence of α-tocopherol and presence of β- and γ-tocopherols in two samples of Peredovik variety. Demurin (1986) reported a spontaneous mutation with 50% increase in β-tocopherol content. It was identified with the use of half-seed technique and TLC (Popov and Aspiotis 1991). The line LG15 with higher β-tocopherol content was identified in this material. Another spontaneous mutant LG17 was identified in the USA with modified tocopherol. It had 5% of α- and 95% of γ-tocopherol (Popov and Demurin 1987).

7 Molecular Mapping of Fatty Acid Related Genes in Sunflower

Genotype of female parent influences the oleic acid content (OAC) (Ferfuia et al. 2015). Increased OAC was obtained through silencing the *FAD2-1* gene. The gene encoding *FAD2* enzyme was obtained through mutation (Schuppert et al. 2006). It controls the pathway of oleic-linoleic conversion. The Pervenet variety is the main donor for higher OAC in sunflower improvement programs (Allman-Farinelli et al. 2005). The OAC was controlled by one dominant to many genes (Urie 1985; Lacombe et al. 2004; Joksimovic et al. 2006; Berville 2010; Ferfuia and Vannozzi 2015; Premnath et al. 2016; Dimitrijevic et al. 2017).

Various markers were used to map *Ol* mutation in sunflower. Dehmer and Friedt (1998) mapped *Ol1* gene with random amplified polymorphic DNA (RAPD) markers F15-690 and AC10-765 with flanking distance of 7.0 and 7.2 cM. Perez-Vich et al. (2002) and Schuppert et al. (2006) mapped *Ol1* on linkage group (LG)14. Perez-Vich et al. (2002) mapped major quantitative trait locus (QTL) for OAC with 84.5% as R^2. Schuppert et al. (2006) reported 49 SNPs and 5 insertion/deletions (INDELs) to identify Ol mutation. Tightly linked codominant and dominant SSR markers were reported by Lacombe et al. (2009). Premnath et al. (2016) reported three quantitative trait loci (QTLs) at LG8, LG9, and LG14. The QTLs on LG14 and LG8 had more than 60% as R^2 for OAC. Dimitrijevic et al. (2017) reported that marker F4-R1 was effective for selection of high OAC.

8 Marker-Assisted Breeding for Oil Quality Traits in Sunflower

Molecular markers were efficiently used in sunflower improvement (Dimitrijevic and Horn 2018). These markers are highly polymorphic and mostly codominant. It has linkage with the trait of interest. These markers can be used at all growth stages and phenotypically neutral. QTL analysis helps to identify potential markers for yield and component traits (Abdi et al. 2012), high OAC (Schuppert et al. 2006; Dimitrijevic et al. 2017), β-tocopherol content (Vera-Ruiz et al. 2006), and γ-tocopherol content (Moreno et al. 2006).

8.1 MAS for High Oleic Acid Content in Sunflower

Breeding for high OAC is an essential objective in sunflower. Normally sunflower has 18–25% OAC (Rauf et al. 2017). As OAC has beneficial effect on human health, this trait was incorporated into hybrids. The dominant mutation in Pervenet variety increases OAC to >89%. Commercial varieties with high OAC have a premium in price (Rauf et al. 2017). At present, these varieties occupy up to 4% of the total sunflower oil production. Phenotypic selection for high OAC is expensive and slow. It involves the laborious gas chromatography protocols. Molecular markers facilitate the selection in early generations. Markers like NI-3F/N2-IR help to identify genotypes in segregating material (Rauf et al. 2020).

8.2 MAS for Tocopherol Content in Sunflower

Tocopherols are highly abundant in sunflower oil (Rauf et al. 2017). This fat-soluble tocopherol has vitamin E activity. These tocopherols protect cells and oil from oxidative damage (Rauf et al. 2017). Sunflower seed is predominantly comprised of α-tocopherol. Substitution of α- with γ-tocopherol helps to improve the shelf life of the oil (Moreno et al. 2012). The selection for tocopherol content is expensive and laborious. Moreover, this trait has complex genetics due to interaction of loci for tocopherol derivatives (Moreno et al. 2012).

Molecular markers help to select plants with desired composition of fatty acids in oil with low cost. *Tph1* gene controls the β-tocopherol content. A QTL with flanking markers ORS-1093, ORS-222, and ORS-598 on LG1 is associated with *Tph1*. Allelic pattern of ORS-716 was useful to identify the low β-tocopherol and high β-tocopherol genotypes (Vera-Ruiz et al. 2006). Moreno et al. (2006) developed inbred lines with high γ-tocopherol content (85%). They also reported that *Tph2* controls the levels of γ-tocopherol. The flanking region of markers ORS-312 and ORS-599 on LG8 had association with γ-tocopherol content (Moreno et al. 2006).

9 Association Mapping Studies in Sunflower

Association mapping (also known as linkage disequilibrium (LD) mapping) has emerged as an alternative to QTL mapping for investigating the genetic basis of quantitative traits. Because it involves the analysis of a diverse collection of more or less unrelated individuals, association mapping allows for the simultaneous evaluation of the effects of multiple haplotypes across diverse genetic backgrounds. Moreover, because association populations typically capture numerous generations of historical recombination, this approach provides much higher resolution than is possible with a family-based mapping population. Nambeesan et al. (2015) reported the results of a detailed analysis of variation in branching in an association mapping population that captures nearly 90% of the allelic diversity present within the cultivated sunflower gene pool (Mandel et al. 2011, 2013).

Two approaches have been followed in association mapping. They are genome-wide association studies (GWAS) and candidate gene approaches. High-throughput marker systems nowadays give full genome coverage. It helps studies like GWAS, QTL Seq, and genomic selection possible. Fusari et al. (2008) reported that the linkage disequilibrium in sunflower rapidly decays. Hence, association studies may help to detect QTLs. However, assessment of population structure should be checked to avoid false positives. So far, Mandel et al. (2013) alone reported one association mapping. All other reports were on candidate gene approach (Fusari et al. 2012; Cadic et al. 2013; Talukder et al. 2014; Nambeesan et al. 2015; McAssey et al. 2016).

Mandel et al. (2011) studied an association population for GWAS with SNP markers. Traits, viz., flowering time, branching, and heterotic groups were studied. LD showed significant association between marker and trait. They reported that selection for disease resistance and domestication were the factors for the genome-wide variations. Nambeesan et al. (2015) carried out an association mapping study based on candidate genes for branching. A total of 39 genes for branching were detected. Up to eight of the highest BLAST hit for each gene were included in the analyses due to the recent triplication of the sunflower genome (Badouin et al. 2017). SNPs associated with 13 candidate genes for branching were identified (Nambeesan et al. 2015). Most of these were found on LG10. Earlier QTL studies also mapped the B-locus for branching on LG10 (Tang et al. 2006; Bachlava et al. 2009). McAssey et al. (2016) reported a SNP linked with flowering time QTL.

Both association and linkage mapping were used to identify QTL for flowering time (Cadic et al. 2013). Associations with flowering time could be demonstrated for 11 regions distributed over 10 LGs. In addition, QTLs for flowering time were detected on 11 LGs in a RIL population by linkage mapping. This large number of QTL is consistent with the polygenic pattern of inheritance of flowering time reported earlier (Leon et al. 2000). SNPs detected by association mapping were then investigated about positional overlaps with QTL identified in the RIL population. The remaining eight regions contained five candidate genes linked with

flowering time in other species that showed SNPs in sunflower, and one of the genes was the gibberellin receptor GID1B (Cadic et al. 2013). Thirty genes, including this gene, had before been investigated as candidate genes for flowering time concerning domestication and improvement in sunflower (Blackman et al. 2011). Kiani et al. (2009) reported a major QTL through linkage mapping. However, it was not found by association mapping (Cadic et al. 2013). It may be due to the lower proportion of alleles in the association population.

10 Genomic Selection for Oil Quality Traits in Sunflower

Individuals were selected using genomic breeding values in genomic selection (GS). The concept of GS is to use genome-wide molecular information to identify QTLs. Many markers were developed by genotyping-by-sequencing. New 25 K SNP genotyping arrays (Livaja et al. 2016) and sequencing of parental lines (Mangin et al. 2017b) were also helped to develop more markers. The hybrid performance was predicted with 572 AFLP markers (Reif et al. 2013). GS helps to accurately predict the hybrid performances when the parents were closely related (Reif et al. 2013). However, prediction based on GCA was not improved by GS.

Prediction accuracy of GS and GCA modeling was compared with 36 CMS lines and 36 restorer lines (Mangin et al. 2017b). Multi-environmental field trials were carried out with 452 hybrids for oil content. All parents were sequenced to obtain SNP markers (Mangin et al. 2017b). Mangin et al. (2017b) reported that GS had more efficiency than GCA modeling.

11 Recent Concepts and Strategies Developed in Sunflower

Advances in molecular research and the availability of vast amounts of genomic data offer opportunities to overcome breeding challenges and ensure the advancement of sunflower, as an important source of edible oil. In recent years, dense genetic maps, largely based on SNPs, have become available; hence, markers can be found for major genes or QTL. The availability of this reference genome and companion resources will not only strengthen interest in the sunflower as a model for ecological and evolutionary studies but will also accelerate breeding programs (Badouin et al. 2017).

11.1 Whole-Genome Sequence Information of Sunflower

The domesticated sunflower is an important oilseed crop. It has promise for climate change adaptation. It can maintain stable yields across a wide variety of environmental conditions. Even more resilience is obtainable via the mining of resistance alleles from crossable wild accessions. Badouin et al. (2017) provided a high-quality reference for the sunflower genome (3.6 gigabases), together with enormous

transcriptomic data from vegetative and floral organs. The genome mostly consists of highly similar, related sequences and required single-molecule real time sequencing technologies for successful assembly. Genome analyses enabled the reconstruction of the evolutionary history of the Asterids. Further, it established the existence of a whole-genome triplication at the base of the Asterids II clade and sunflower specific whole-genome duplication around 29 million years ago (Barker et al. 2016). An integrative approach combining quantitative genetics, expression, and diversity data permitted the development of comprehensive gene networks for flowering time and oil metabolism. It also revealed new candidate genes in these networks. The sunflower genome represents a cornerstone for future research programs. It may help to exploit genetic diversity to improve biotic and abiotic stress resistance and oil production.

11.2 Integrated Omics Approaches in Sunflower

Omics technologies offer novel possibilities for deciphering the complex pathways and molecular profiling through the level of systems biology and can provide important answers that can be utilized for more efficient breeding of sunflower. The development of sunflower as a significant source of edible oil can be ensured due to developments in genetic research and the accessibility of enormous amounts of genomic data. A thorough description of genotypic and phenotypic variation is crucial for gaining a greater understanding of research that has been done into the variations of critical features that can be used to enhance sunflower genetics. Using an integrated strategy involving proteomics, metabolomics, phenomics, transcriptomics, epigenomics, and genomics in an integrated manner termed as systems biology provides fresh opportunities to understand intricate networks and molecules profiling for significant and intricate agronomic features and deliver solutions that can improve sunflower (Jockovic et al. 2021).

11.3 Initiation of Genome Editing in Sunflower

Over the recent years, clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated (Cas) systems have been widely leveraged to edit the genomic DNA in many organisms. The prevailing CRISPR-based genome editing systems, for instance, CRISPR/Cas9, CRISPR/Cpf1, base editing system, and prime editing system, have brought promises to highly effective improvement of crop genetics with elite traits since they are born (Zhu et al. 2020). Compared to the zinc finger nuclease system (ZFN system) and transcription activator-like effector nuclease system (TALEN system), CRISPR-based genome editing technology has unparalleled advantages in easy manipulation. Indeed, theoretically, we can mutate almost every gene of interest only by rationally designing the target sequence and expressing the editing systems in targeted crops. Accounting for the unprecedented merits and the easy access to genome sequences of ever-increasing plant species,

CRISPR-based genome editing systems have broad applications in fundamental biological research and crop breeding. There are very few reports on the applications of CRISPR-based genome editing technology in sunflower, mainly due to its complicated genomes and recalcitrance to transformation (He et al. 2021).

12 Conclusion and Future Prospects

Sunflower genome database allows access to transcriptome data. These were effectively used to address flowering time and oil metabolism (Badouin et al. 2017). GWAS and GS with large amounts of markers are useful to address complex traits in sunflower. Considering the ever-increasing newly developed and diverse CRISPR/Cas systems and their derivative editors, with the continuous development of CRISPR/Cas reagent delivery methods such as carbon nanomaterial mediated genetic elements delivery (Demirer et al. 2019), genome editing in sunflower would flourish soon. The new genomic tools may help to understand the genetic variation in sunflower. These techniques may help to evolve a variety with combination of several quality traits. This will enable tailoring speciality oils for food and nonfood industry. These developments help to achieve a promising future for sunflower in the world market.

Next-Generation Breeding for Nutritional Traits in Peanut

Priya Shah, Manish Pandey, Spurthi N. Nayak, Charles Chen, Sandip Bera, Chittaranjan Kole, and Naveen Puppala

Contents

Abstract

Peanut, an important oilseed legume, is largely grown in Asia, Africa, and the Americas. It is a source of vital nutrients and amino acids for optimal health. In addition to its health advantages, further enhancing the vitamin and protein content may aid in alleviating the issue of hidden hunger, particularly in Asian and African countries. Due to the availability of high-oleic peanut oil, consumers now have access to another inexpensive cooking oil that offers similar advantages to olive oil in terms of quality. Hence, there is a need to put immense focus on generating varieties of peanuts that are high in nutrients along with the yield, oil

content, and disease resistance. Development of nutrient-rich peanuts can be accelerated through marker-assisted selection and genomics-assisted breeding, followed by functional characterization of the candidate genes. In addition to current research on breeding, genetics, and genomics studies, this review also deliberates on the possible application of genetic engineering and genome editing to improve nutritional traits.

Peanut · Functional compounds · Allergens · Marker-assisted selection · Genomic-assisted breeding · Genetic engineering · Genome editing

1 Introduction

Peanut (*Arachis hypogaea*, Family Fabaceae) is a valuable source of nutrition, most notably for those with a poor socio-economic conditions, as it is inexpensive. It is a rich source of amino acids comprised of protein, lipids like unsaturated fatty acids (UFA), and other components like dietary fibers and polysaccharides. According to a recent analysis, the approximate nutritional makeup of peanuts was 31–46% fat, 20.7–25.3% protein, and 21–37% carbohydrates. Peanut is also referred as "Poor man's almond" with its dietary properties not only as food but also for its functional components augmenting health benefits (Nayak et al. 2021).

Molecular markers have been used to improve peanut oil and oleic acid content (Sarvamangala et al. 2011; Shasidhar et al. 2020). Recent developments in genomics have paved the way to better understand the molecular mechanisms that are involved in improving the nutritional properties of peanut. In this regard, the reference genomes for diploid (Bertioli et al. 2016; Chen et al. 2016) and tetraploid (Bertioli et al. 2019; Chen et al. 2019; Zhuang et al. 2019) progenitors have made genome-wide single nucleotide polymorphism (SNP), variant genetic mapping, and genome-wide association studies (GWAS) in peanuts much easier. In a GWAS analysis of 120 genotypes from the US mini core collection, 24 quantitative trait loci (QTLs) for boron (B), two QTLs for copper (Cu), six QTLs for sodium (Na), three QTLs for sulfur (S), and one quantitative trait locus (QTL) for zinc (Zn) with 18.35–27.56% phenotypic variance expression (PVE) explained by each QTLs (PVE) were identified. Furthermore, mining genomic regions yielded 110 unrelated candidate genes. Interestingly, the key elemental/metal transporter gene *arahy.KQD4NT* (position5,413,913-5,417,353) was discovered on chromosome B04 (Zhang et al. 2019). Peanut germplasm has many genotypes in terms of oil content, which makes it possible to use GWAS to find genetic areas linked to health related (HR) traits in peanuts (Yol et al. 2017). In terms of oil content, several QTLs have been identified that regulate grain oil content, fatty acid composition, and protein content (Pandey et al. 2014b; Shasidhar et al. 2017; Wilson et al. 2017; Liu et al. 2020a). In the Tifrunner × GT-C20 recombinant inbred line (RIL) population, six QTLs were detected for oil content accounting for 3.0–10.2% PVE and nine QTLs for oil content accounting for 3.9–14.0% PVE percent using an RIL population (Sun Oleic

97R × NC94022) (Pandey et al. 2014b). On chromosome B03, a significant QTL (*qOCB3*) for oil content was discovered with 14.36% PVE and 3.9 logarithm of odds (LOD) (Huang et al. 2015). Later on three main QTLs for oil content were discovered in an advanced backcross population with 18.0–25.0% PVE (Wilson et al. 2017), and eight QTLs for oil content were identified in an RIL population (ICGV07368 × ICGV06420) with 5.67–22.11% PVE (Shasidhar et al. 2017). According to several studies, oil content has additive inheritance, which allows for the pyramiding of linked loci in the peanut breeding program (Fu et al. 2017; Shasidhar et al. 2017; Zhaoming et al. 2017). In an RIL population (TG 26 × GPBD 4), three QTLs explaining 1.5–10.2% PVE were detected (Sarvamangala et al. 2011).

Seven QTLs have been identified on five chromosomes (A04, A05, A08, B05, B06), accounting for 6.07–27.19% PVE (Xuhua 13 × Zhonghua 6), with one large and stable QTL (*qOCA08.1*) on A08 accounting for 10.14–27.19% PVE (Liu et al. 2020a). Similarly, 27 QTLs for oil content were discovered using a whole-genome resequencing technique, including a major and stable *qA05.1* QTL with a LOD range of 13.62–26.94 and 9.62–22.74% PVE. In an RIL population Zhonghua10×ICG12625, two major and stable QTLs *qOCB06* with 22.59% PVE and *qOCB10.1* with a PVE range 9.18–12.55% were observed across three environments (Guo et al. 2021).

Besides oil content, fatty acid components are other key quality factors linked to shelf-life of peanut products and has health benefits. A previous study revealed two mutations of the *fatty acid desaturase* (*FAD*) gene *FAD2A* and *FAD2B* from the A- and B-subgenomes, respectively, from high O/L (oleic/linoleic acid) genotypes. The *FAD* gene encodes enzymes that allow the transformation of oleic acid into linoleic acid in peanuts (Lopez et al. 2000; Chu et al. 2011). In addition, QTL analysis was performed using two RIL populations (SunOleic 97R × NC94022 and Tifrunner × GT-C20) to determine the proportional contribution of *FAD2* alleles to oil quality (Pandey et al. 2014b). This study found 21 QTLs with 1.04–42.33% PVE for oleic acid, linoleic acid, and oleic/linoleic acid ratio in the SunOleic 97R × NC94022 population and 23 (M-QTLs) with 3.63–28.98% PVE in the Tifrunner × GT-C20 population for oleic acid, linoleic acid, and O/L ratio. The influence of *FAD2* alleles on oleic and linoleic acid concentration was recently explored and identified QTLs for oleic acid (C18:1), linoleic acid (C18:2), and the ratio of oleic acid to linoleic acid (O/L) were positioned on linkage groups A03, A04, A09, B09, and B10. This study was based on phenotyping in seven environments, and it was found that Marker2575339 and Marker2379598 in B09 were associated with C18:1, C18:2, and O/L in all seven environments, whereas Marker4463600 and Marker4391589 in A09 were associated with C18:1, C18:2, and O/L in six environments. The results were verified in multiple genetic backgrounds using a high-density genetic map (Hu et al. 2018).

Four QTLs linked with oleic acid, linoleic acid, and the O/L ratio were discovered in the RIL population (TG 26 × GPBD 4), accounting for 1.4–9.7% PVE (Sarvamangala et al. 2011). In the RIL population (Zhonghua 10 × ICG12625), 10 QTLs (seven significant) accounting for 1.72–20.20% PVE were detected for six fatty acids (Huang et al. 2015). Another 20 significant QTLs with 10.3–78.6% PVE

with LOD values ranging from 3.7 to 191 have recently been discovered in the F_2 population (ICGV 06420 × SunOleic 95R) (Shasidhar et al. 2017). Another study reported a significant QTL on chromosome A09 in an RIL population TMV 2 × TMV 2-NLM that explains a 15.1% PVE for oleic acid (Hake et al. 2017). In a more recent study, four QTL clusters for saturated fatty acids were identified (palmitic, stearic, arachidic, behenic, and lignoceric acid) (Liu et al. 2019). On chromosome B04, 20 significant QTLs were detected on three QTL clusters (CLB04–1, CLB04–2, and CLB04–3), accounting for 10.77–41.89% PVE. Six QTLs for stearic, arachidic, and behenic acid were found in another QTL cluster (CLB06) on chromosome B06, with up to 20.32% PVE. Further investigation into these QTL clusters will aid in understanding fatty acid metabolism and discovering diagnostic markers that may be utilized in marker-assisted selection (MAS) to improve peanut cultivars.

Protein content is another significant characteristic that improves peanuts' nutritional quality as food and feed. Six QTLs for protein content have been found in an RIL population with 1.50–10.70% PVE and 2.87–3.63 LOD, while a recent study found one main QTL flanked by AhTE0003-AhTE0332 markers, associated with protein content on chromosome A10 with 26.4% PVE and 11.2 LOD (Sarvamangala et al. 2011; Hake et al. 2017). In a RIL population (Zhonghua 6 × Xuhua 13, 186 progenies), a recent study discovered nine additive QTLs for resveratrol content with 5.07–8.19% PVE and LOD 2.50–3.64 across four environments (Luo et al. 2021). Further research is needed using high-density genotyping and sequencing-based mapping, which will lead to fine mapping of genomic areas and candidate gene discovery, allowing for faster and more precise breeding of nutrition-rich peanut types. Apart from oil, the by-products of peanut contain many other functional compounds like proteins, fibers, polyphenols, antioxidants, vitamins, minerals, which can be added as a functional ingredient into many processed foods (Arya et al. 2016). Studies have indicated that peanuts are an excellent source of compounds like flavonoids, phenolic acids, resveratrol, and phytosterols in the kernels and shells (Nepote et al. 2002; Adhikari et al. 2019).

Peanuts have also been termed as functional food with numerous functional components like Coenzyme Q10, which protects the heart during the hypoxia conditions. Peanuts are also a good source of dietary fiber and provide a wide range of essential nutrients, including several B group vitamins, vitamin E, minerals such as iron, zinc, potassium and magnesium, antioxidant minerals (selenium, manganese and copper), plus other antioxidant compounds (such as flavonoids and resveratrol) (Gülçin 2010). There are attempts to profile the nutraceutical properties especially total antioxidant activity and total polyphenolic compounds in 60 groundnut genotypes varying in skin color, i.e., from pure white to purple (Nayak et al. 2020). The study indicated that peanut skin color has positive correlation with antioxidant activity as well as the total polyphenol content. Transposable marker based association analysis indicated 24 marker-trait association related to nutritional traits like fat, crude protein, ash, crude fiber, carbohydrate, total polyphenol content, and antioxidant activity and had QTL with PVE more than 10% (Nayak et al. 2020). In another study, the total flavonoid content was linked with four expressed sequence

tag – simple sequence repeat (EST-SSR) markers in a Chinese peanut germplasm of 57 accessions. The EST-SSRs were derived from ESTs coding for HSFs (GM2284), TiC20 (GM2156), agglutinin (GM2067) and mitochondrial outer membrane porin protein (GM1878) (Hou et al. 2017). Genetic variability for total phenolics, flavonoids, and antioxidant activity of testaless seeds in a RIL population VG 9514 × TAG 24 was used to identify QTLs (Mondal et al. 2015). The results indicated five QTLs for total flavonoid content, four QTLs for DPPH radical scavenging activity, and a single QTL for total phenolic content in six linkage groups. Of these 10 QTLs, six were clustered in the linkage group A02 and A03 (Mondal et al. 2015).

The major problem associated with peanut is the presence of antinutritional compounds and toxin contamination. The incidence of toxin contamination caused by fungus along the food chain significantly impacts the availability of healthy and safe food. From standing in the field through postharvest processing and storage, mycotoxin has been reported to harm one-fourth of the world's food crops (Wu 2007). This fungal toxin is mostly associated with three genera: *Aspergillus*, *Fusarium*, and *Penicillium* (Reddy et al. 2010). Aflatoxin produced by the genus *Aspergillus* can be found in various foods, including maize, peanuts, dried fruits, spices, milk, and its derivatives (Pandey et al. 2019c; Soni et al. 2020). Aflatoxin-contaminated food has significantly but negatively influenced human health (Atherstone et al. 2016). As a result, several countries have enacted stringent safety regulations and precise instructions to limit aflatoxin exposure to human health and welfare.

The European Union (EU) has imposed a rigorous guideline for aflatoxin-affected food consumption of 4 g/kg (European Commission-EC 2010). Similarly, the allowable limit for aflatoxin contamination in the United States is 20 g/kg (Wu 2007). Nonetheless, the EU's criteria are not practical to implement globally because many nations with lower GDPs and poor economies, particularly those in Africa and Asia, cannot comply with these regulations due to the higher expense of cultivation required to reach those standards. As a result, alternatives are required to keep aflatoxin levels below the safe limit, taking into account human health and wealth. Understanding the *Aspergillus* biology and the toxin it produces is one step toward improving crops with low aflatoxin contamination. New strategies to breed peanut cultivars with low aflatoxin contamination are required to ensure advantageous exports and healthy life.

Another problem with this crop is peanut allergy, a serious food allergy that affects 1–2% of the world's population and is the most common cause of anaphylaxis or death (Pandey et al. 2019b). It has been found that Australia, United States, Canada, Denmark, United Kingdom, and France are among the several other countries that are most affected by peanut allergens. Until recently, there was no accessible allergy vaccination or strategy for lowering allergenicity from peanut foods. There are 32 types of seed storage proteins in the peanut kernel, and 18 are allergenic proteins (Pele 2010).

Peanut allergens are divided into two categories: major and minor based on their lethal reactions detected with IgE, among this Ara h1, Ara h2, Ara h3, and Ara h6 are

classified as major allergens. These reactions can result in anaphylaxis or death. Around 617 kb from the cultivated peanut genome (cv. Florunner UF-439-16-1003-2) and 215 kb from a wild relative (*Arachis duranensis*; A genome) were sequenced in a previous study using the technique of bacterial artificial chromosome sequencing, and three Ara h 1, one Ara h 2, eight Ara h 3, and two Ara h 6 allergen coding genes were identified (Ratnaparkhe et al. 2014).

In addition, the A genome has 21 allergen-coding genes. Nine of these have already been detected in peanuts, with the remaining were homologous of the other crops (Chen et al. 2016). Recently, a monoclonal antibody-based sandwich ELISA approach has been effectively standardized on diverse peanut accessions, and significant allergens such as Ara h 1, Ara h 2, Ara h 3, Ara h 6, and Ara h 8 have been screened (Pandey et al. 2019b). Developing lower allergen-containing lines or cultivars is proclaimed to be a future breeding strategy (Pandey et al. 2019a).

Recently, studies conducted by the US FDA (Food and Drug Administration) revealed that peanut consumption in infants between the ages of 4 and 10 months, has reduced the fear of developing a severe peanut allergy, as it is stated that early peanut consumption is one of the paths to reducing severe peanut allergy (https://www.fda.gov/food/cfsan-constituentupdates/fda-acknowledges-qualified-health-claim-linking-ear). According to a health claim regarding allergic reactions to peanuts, the FDA has established the connection between the use of food sources containing powdered peanuts and a reduced risk of developing an allergy, with the logical proof that is acceptable and has advised realizing offices to provide accurate data for nourishments to avoid deceiving consumers. Furthermore, the FDA will examine peanut-containing foods and issue a qualified health certificate to reduce the concern of peanut allergy (https://www.fda.gov/media/107357/download). Peanut lines with low allergen concentrations can generate vaccines or therapeutic medicines, reducing the risk of peanut allergies.

2 Molecular Breeding and Biotechnology for Nutritional Traits

The genome-wide association studies (GWAS) allow us to unravel the trait of interest in a diverse panel with high precision; therefore, this approach can be useful for studying the genetics of nutritional traits in peanuts. This strategy can be effective for exploring the genetics of HR characteristics in peanuts because association studies allow us to unravel the trait of interest in a broad panel with high precision. A panel of 292 lines was used to identify 12 linked oil content markers, including one highly stable connection (AGGS1014_2) with 9.94% PVE (Liu et al. 2020b). Similarly, GWAS was used to investigate the genetic basis of HR traits in a reference set of 300 diverse global peanut collections, resulting in the discovery of 24 marker-trait associations (MTAs), including two MTAs for oleic acid content (16.42–20.8% PVE), 22 MTAs for O/L ratio (13.7–47.45% PVE), 25 MTAs for oil content (5.84% (gnPt-714,399) to 40.37% (TC4G10) PVE,

11 MTAs for protein content with 11.63–36.1% PVE, and 1 MTA for zinc content with 15.63% PVE (Pandey et al. 2014a).

Molecular breeding has been successfully utilized to improve crops' nutritional content and improve nutritional traits. Peanut oil has a higher unsaturated fatty acid (UFA) to saturated fatty acid (SFA) ratio than palm and coconut oil, making it a healthier cooking oil. Peanut oil's high oleic acid (HOA) content aids in the reduction of low-density lipoprotein cholesterol (LDLC) levels and the risk of cardiovascular disease (CVD). To improve peanut lines with HOA, a healthier choice for eradicating malnutrition in rural and tribal communities, breeding for improved peanut lines with HOA is required.

Florida Agricultural Experiment Station in the United States released SunOleic 97R, a multiline cultivar with 81.8% oleic acid content (Gorbet and Knauft 2000). It is made up of three breeding lines descended from a cross between F435–2-2-E-2-l-b4-E-b2-b3-l-E (high oleic) and "Sunrunner" (F519–9), with the latter serving as the recurrent parent (Norden et al. 1985; Gorbet and Knauft 2000). With the discovery of diagnostic markers for HOA, peanut breeding techniques, including marker-assisted selection (MAS) and marker-assisted backcrossing (MABC) have emerged as viable options for crop improvement. As a result, two simultaneous backcross procedures were employed to increase oleic acid levels in Tifguard (nematode-resistant cultivar), utilizing linked markers for HOA and nematode resistance, with Florida-07 and Georgia-02C as HOA donors (Chu et al. 2011). Phenotyping was done on progenies of BC_3F_2 that demonstrated homozygosity for HOA and nematode resistance alleles to supplement the precision of MAS. SunOleic 95R (HOA line) mutant alleles of *FAD2A* and *FAD2B* were transferred into ICGV 06420, ICGV 06142, and ICGV 06110 using MABC and MAS (Janila et al. 2016).

Consequently, 27 lines with 53–58% oil content and 80% oleic acid were improved, while 28 lines with 42–50% oil content and 80% oleic acid were enhanced. Backcross lines with HOA were created, and multilocation yield studies were conducted. As a result, the varieties "Girnar 4" and "Girnar 5" were identified and launched in India in 2020 as the best-performing varieties with HOA content (Nawade et al. 2016; Bera et al. 2019). To increase the oleic acid content of four Chinese peanut cultivars (Yuanza 9102, Yuhua 9326, Yuhua 9327, and Yuhua 15), competitive allele-specific PCR (KASP) assay-based MABC was used to detect *FAD2A* mutations (Huang et al. 2019). Consequently, 24 HOA lines with similar agro-morphological traits to recurrent parents (with 79.49–92.31% genome recovery) have been produced and are undergoing multilocation experiments in preparation for possible release. The MABC technique was used to deploy GJGHPS 1, GJG 9, and 20 to boost HOA content and foliar disease resistance (FDR) (Shasidhar et al. 2020).

As a result, in the BC_3F_7 generation, >50 FDR ILs (introgression lines) and > 80 high oleic ILs were produced and carried forward for seed multiplication. For HOA and FDR, Kadiri 6, Dh86, ICGV 00351, and ICGV 87846 were used to generate >200 ILs (BC_3F_4) (ICRISAT unpublished). More than 200 pyramided lines were created using the above ILs by incorporating HOA and FDR into all six kinds and are being tested, evaluated, and released. In addition, more than 300 HOA breeding lines (F_3-F_7 and BC_3F_3-BC_3F_7) have been produced in the background of high-yielding varieties such

as GG22, GG20, GJG32, Kadiri-6, DH86, DH256, DH257, KadiriLepakshi, TG37A, TKG19A, TG51, TG81, JL 501, Girnar 2, NRCGCS268, and NRCGCS257. They are in different stages of testing (ICAR-Directorate of Groundnut Research, India).

Mutation breeding is also used in improving peanut cultivars to develop cultivars with high oil content. The genotypes Minhua 8 and Minhua 6 were exposed to gamma-ray and EMS-based mutagenesis, respectively, to develop new high oleate lines in peanuts (Zhuang et al. 2019). Until then all the HOA lines were developed by the natural mutation at *ahFAD2A* and *ahFAD2B*loci. As a result, three Minhua 8 varieties and four Minhua 6 cultivars were developed with HOA and improved agronomic performance. Two of them are reportedly undergoing multilocation trials in preparation for further testing. MABC was recently used to increase the oleic acid content of two elite genotypes, GPBD 4 and G-252, which have high productivity, oil content, and resistance to late leaf spot (LLS) and rust diseases. Only the mutant allele at *AhFAD2B* was transferred from the donor SunOleic 95R because both the recurrent parents already had the mutant allele at *AhFAD2A* (80.6%). In $BCnF_2$ generations, three rounds of backcrossing with foreground selection using allele-specific PCR and the KASP assay revealed a substantial number of plants homozygous for the mutant allele at *AhFAD2B*.

Targeted mutations can be created to address human needs shortly, thanks to the advances in genome-editing technology. The peanut crop has a significant potential to provide customers with extremely nutritious items that will not only assist in addressing the issue of malnutrition but will also help to provide high energy and nutrition while consuming fewer food products. For breeding more nutritious peanut cultivars, next-generation genetic improvement technologies such as genomic selection and genome editing should be investigated. Most importantly, gaining a better understanding of nutritional traits through precision phenotyping and sequencing will aid in identifying the causal genes that make this crop so nutrient-dense. The promotion and acceptance of nutrition-dense peanut cultivars should also be prioritized to guarantee that the benefits reach the farmers, industry, and consumers.

3 Genetic Transformation and Gene Editing in Peanut

Increasing food production by cultivating high-yielding, high-quality crops is critical to ensure food security. Various genetic transformation and gene-editing tools have recently been developed. These strategies have been used in various scientific sectors, and their development has improved nutritional quality (Yuan et al. 2019; Biswas et al. 2022). Plant breeders use diverse gene transformation strategies to impart biologically essential features and produce high-yielding crops with good nutritional quality and other traits for various reasons. Two genetic transformation approaches, *Agrobacterium*-mediated and biolistic strategies, are essential to develop commercially relevant traits and alter plant genetic resources. In a particle bombardment approach, immature peanut cotyledons were used as explants (Deng et al. 2001). Exogenous DNA segments are freed in the nucleus and can be integrated into chromosomal DNA by illegitimate or homologous recombination

processes, which depend solely on cellular components. Micro-projectile bombardment of peanut tissue has been reported in several publications, including bombarding leaflets from mature embryos (Clemente et al. 1992) and the somatic embryogenesis regeneration system (Deng et al. 2001).

Peanut is thought to be difficult to culture and genetically modify. Many species either resist or have limited effectiveness with this gene transformation technique (Estrada-Navarrete et al. 2006). Successful genetic transformation by *Agrobacterium*-mediated technique has been described in peanut research employing various explant sources such as de-embryonated cotyledons (Sharma and Anjaiah 2000), embryo axes (Grabiele et al. 2012), and cotyledons (Bhatnagar et al. 2010). Cotyledonary nodes (CNs) are more able to regenerate than other explant sources. *Agrobacterium*-mediated transformation in peanuts has been reported using a variety of explant sources, including a cotyledonary node, de-embryonated cotyledon, leaflet, immature leaves (Mehta et al. 2013; Marka and Nanna 2018).

Genetic transformation is useful for studying plant gene function, although restricted transformation capability limits its influence in some systems. *Agrobacterium tumefaciens*-mediated transformation has been used to research gene function in legumes. Furthermore, increased availability and cost-effectiveness are two benefits that can be obtained using this gene transfer technology. Genome-editing technologies are very new and widely used in plant research to modify genes linked to nutritional quality, yield, disease resistance, and drought resilience (Kaniganti et al. 2022).

Zinc-finger nucleases (ZFNS), transcription activator-like effector nucleases (TALEN), and clustered regularly interspaced short palindromic repeats system (CRISPR/Cas9), for example, are currently used widely by researchers and are helping to boost productivity and production. CRISPR/Cas9, a gene-editing tool that is simple and inexpensive, is frequently used in plant breeding programs. Peanuts are an important oil-producing allotetraploid crop. As a result, peanut gene editing technology could boost the amount of oleic acid in edible peanut oil.

Genome-editing methods based on site-directed endonucleases capable of causing chromosomal double-strand breaks (Kim et al. 1996; Christian et al. 2010; Jinek et al. 2012) can assist overcome the limits of traditional breeding and speed up the production of better crops. Double-stranded breaks (DSBs) can deliver targeted disease resistance and genome alterations to improve agronomic parameters such as yield and nutritional content by harnessing the natural cellular DNA repair process. The most promising approach for developing an improved genotype has been genome editing technology. Peanut genome editing techniques targeted HR characteristics such as high oleic acid content and allergens(Yuan et al. 2019; Biswas et al. 2022).

It is anticipated that using the revolutionary biotechnological tool as genome editing will enhance crops' nutritive and practical quality. Rapidly developing genome editing technology might make it possible to create grain legumes with increased protein levels without inserting foreign genes. The development of crop plants with enhanced and novel traits of economic and nutritional importance has been made possible by genome editing technologies. Various crop plants have

improved quality traits, such as increased fragrance and low gluten, starch, or oleic acid contents (Ku and Ha 2020). Genetic engineering is applied to improve the nutritional quality of plants, and increase stability during processing and storage, among others (Tien Lea et al. 2016). In this context, a significant amount of work is needed to pinpoint the genes involved in fatty acid composition metabolism and create a system of gene-specific markers to enhance crop nutrition. The use of molecular markers can greatly aid breeding operations by revealing the precise position of the genomic region/quantitative trait locus (QTL) that controls the nutrient content trait. The markers that are associated with QTL have the potential to be used across breeding material for identification and introgression (Gaikwad et al. 2020).

Plant breeders have identified crops with commercially important features through germplasm screening. Beans, particularly peanuts, were recognized as having a high oleic acid concentration. F435, a high oleate spontaneous mutant line, contains 80% oleic acid and 2% linoleic acids (Norden et al. 1987). Two types of mutations were found in this mutant line: "G" to "A" substitution occur at 448 base pair (bp) in the *ahFAD2A* gene that result in a missense mutation whereas there occur an "A" insertion between 441 and 442 bp (441442insA) in the *ahFAD2B* gene (Jung et al. 2000). Using this mutant line (F435) as one of the parents in normal peanut breeding helps to improve essential traits and since then, many cultivars with high oleic acid to linoleic acid ratio (O/L) have been created (Chu et al. 2009). Increasing the amount of oleic acid in the peanut genome improves shelf-life and provides health benefits.

Peanut oil includes roughly 12 fatty acids, with oleic acid, a monounsaturated fatty acid (36–67%), and linoleic acid, a polyunsaturated fatty acid, accounting for nearly 80% of the total (15–43%). Furthermore, palmitic acid, a saturated fatty acid, accounts for roughly 10% of the total, with the remaining 10% made up of up to nine additional fatty acids; (Janila et al. 2016). The presence of various fatty acids, such as saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids, in peanut oil, determines the nutritional quality, flavor, and shelf-life of peanut seeds and products. Due to consumer and commercial benefits such as antioxidation and long shelf-life, increasing the concentration of oleic acid in peanut seeds is one of the key goals in peanut breeding.

The fatty acid desaturases encoded by the homologous *ahFAD2A* and *ahFAD2B* genes are the primary enzymes for converting oleic acid to linoleic acid, easily oxidized. So far, all high oleic acid peanut variants have resulted from spontaneous mutations in both genes. Inducing mutations in the DNA of other superior cultivars could help speed up the introduction of this desirable characteristic. Using peanut protoplasts and hairy root cultures as models, a gene-editing strategy based on CRISPR/Cas9 technology has been used to create de novo mutations in the *ahFAD2* genes.

There have been reports of a novel G451T mutation in the coding area of the *Arachis hypogaea FAD2B* gene in the peanut caused by CRISPR/Cas9-based gene editing (Yuan et al. 2019). Using freshly established gene-editing technology, peanut breeders will increase the oleic acid to linoleic acid ratio (O/L) ratio. Several

high-oleate (HO) peanut cultivars have been developed in China, and nations such as Argentina, Australia, Brazil, Israel, Japan, and South Africa are also developing high-oleate peanut products for human consumption (Janila et al. 2016). The target region was a hotspot of a natural mutation in these genes. Suitable sgRNAs were created and cloned into a CRISPR/Cas9 expression plasmid.

Three mutations were discovered due to CRISPR/Cas9 activity: G448A in *ahFAD2A*, 441442insA, and G451T in *ahFAD2B*. The G448A and 441442insA mutations are in current high oleate types, but the G451T mutation is new. Because natural mutations in the *ahFAD2A* gene are more common than in the *ahFAD2B* gene in *A. hypogaea* var. *hypogaea*, the mutations induced in *ahFAD2B* by gene editing may be useful in developing high oleate lines with a variety of genetic backgrounds after validation of oleic acid content in transformed lines. The G448A mutation in *ahFAD2A* is another advantage of high oleic acid oil content. The CRISPR-based genome editing generated mutations in peanuts, and this CRISPR/Cas9 technology could be valuable in peanut breeding efforts. The desaturase enzyme encodes the *ahFAD2A* and *ahFAD2B* genes (Jung et al. 2000). This enzyme is extremely important in converting oleic acid to linoleic acid. Hence, gene editing to lower linoleic acid and boost oleic acid in the peanut genome significantly impacts future breeding programs (Yuan et al. 2019).

Similarly, the protoplast culture has been used to disrupt the *Ara h2* gene, a major allergen gene, with the help of an endogenous tRNA-processing system. Here, multiplex CRISPR/Cas9 genome editing was performed in peanut protoplasts. Finally, several edits were identified in the target gene after polyethylene glycol (PEG)-mediated transformation in protoplasts with a Cas9 and sgRNA-containing vector through deep-sequencing analysis. This strategy provides an efficient pipeline to develop gene-editing constructs for various genes or peanut transformation. These findings demonstrated that PEG-mediated protoplast transformation system could serve as a rapid and effective tool for transient expression assays and sgRNA validation in peanuts. Once optimized, stable transformants can be developed using *Agrobacterium*-mediated transformation or alternative delivery systems. However, an efficient gene-editing platform in peanuts needs to be established to assist in basic research in understanding gene functions and molecular pathways and to help speed up breeding programs in developing peanuts with improved yield, quality, and tolerance to various abiotic and biotic stresses. Indeed, further optimization of the CRISPR/Cas9 system in peanuts can be explored using other editing techniques, including allele replacement, to widen the target traits and speed up the breeding progress (Biswas et al. 2022).

4 Conclusions

Peanuts are cultivated in the continents of Asia and Africa, primarily in the semi-arid zones where malnutrition is worrisome. Numerous high-oleic peanut genotypes have been developed worldwide using conventional breeding techniques, but little attention has been given to other nutritional components. The peanut crop has enormous

potential to provide consumers with highly nutrient-rich products that will not only help solve the problem of malnutrition but also provide high energy and nutrition by consuming fewer food products. Next-generation genetic improvement techniques, including genomic selection and genome editing, will prove immensely promising for developing more nutrient-dense peanut cultivars. These techniques are highly applicable for functional validation and are widely used in plant research to modify genes linked to nutritional quality, yield, disease resistance, and drought resilience. The most critical step will be identifying the causal genes that make this crop so nutrient-rich by developing a greater understanding of nutritional features through precision phenotyping and sequencing. Additionally, it is important to prioritize adopting and promoting nutrient-dense peanut cultivars to guarantee that farmers, businesses, and consumers reap the rewards.

Abstract

Mustard (*Brassica juncea*) is an important crop of the Indian subcontinent and has been used as oilseed and as a condiment for a long time. Its importance as a nutraceutical crop is growing rapidly as it is a rich source of polyunsaturated fatty acids that have long been associated with cardioprotective activities, while mustard extract has been reported to harbor anticancerous properties. Mustard leaves and oil cake that is left after oil extraction are also excellent sources of antioxidants, minerals, and vitamins. However, mustard oil also contains glucosinolates and erucic acid in large amounts that are considered antinutritional as they have been implicated in goiter and cardiac lesions. The major objectives for the mustard breeding programs across the world therefore focus on enhancing the nutritional and functional properties with a concomitant overall increase in the seed oil percentage. As the nutraceutical properties of mustard are being recognized and are supported by many research studies based on QTL mapping, GWAS, genomic selection, etc., the breeding programs now also include the traits with potential nutraceutical applications. However, limited germplasm lines

with high therapeutic values, genetic bottleneck due to continuous selection for oil and yield, along with a low preference for varieties with possible nutraceutical applications by farmers, are some of the major hurdles in the development of mustard varieties with high nutritional and pharmaceutical values. Modern technologies like high-throughput genotyping, sequencing, and genome editing through the novel CRISPAR/CAS9 system hold a great promise in overcoming these impediments to achieving the targets of genetic improvement of nutraceutical properties of *B. juncea*.

1 Introduction

1.1 Agricultural Importance of Indian Mustard

Brassica juncea (AABB, 2n = 36) or Indian mustard is an oilseed crop majorly cultivated in South Asia, and India ranks fourth in its production worldwide. It is an amphidiploid species derived from the natural hybridization of diploid progenitor species *B. rapa* (AA, n = 10) and *B. nigra* (BB, n = 8). Based on cytological and molecular evidence, it is considered to have originated about 4000 years ago. It is an annual herb, adapted to diverse climatic conditions, and grows on varying soil types. Mustard is a crop of temperate region that prefers moderate temperature and is largely grown in the rabi season. The crop is mainly self-pollinated; however, cross-pollination to the extent of about 15–30% has also been reported (Rakow and Woods 1987).

Considerable variation exists in *B. juncea* for different important agro-morphological traits (Singh et al. 1980; Khulbe et al. 2000; Pant and Singh 2001) in collections from different agro-climatic zones. The gene pools of *B. juncea* can be divided into the East European and the Indian gene pools (Srivastava et al. 2001; Pradhan and Pental 2011). The germplasm of *B. juncea* has been utilized extensively in different breeding programs to develop high-yielding varieties with favorable agronomic values and better seed oil and meal quality.

1.2 Nutritional Composition

Cultivars of *B. juncea* are grown mainly for the extraction of edible oil from the seeds. Besides, they are used as spice and condiments, salad crop, and as green vegetables. *B. juncea* is also now being used as green manure or as fodder crop, and for industrial purposes due to its high erucic content in the oil (Thomas et al. 2012). Through its different edible parts, the mustard plant carries a whole range of nutraceuticals (Fig. 1). According to the USDA (USDA 2019), the seeds of Indian

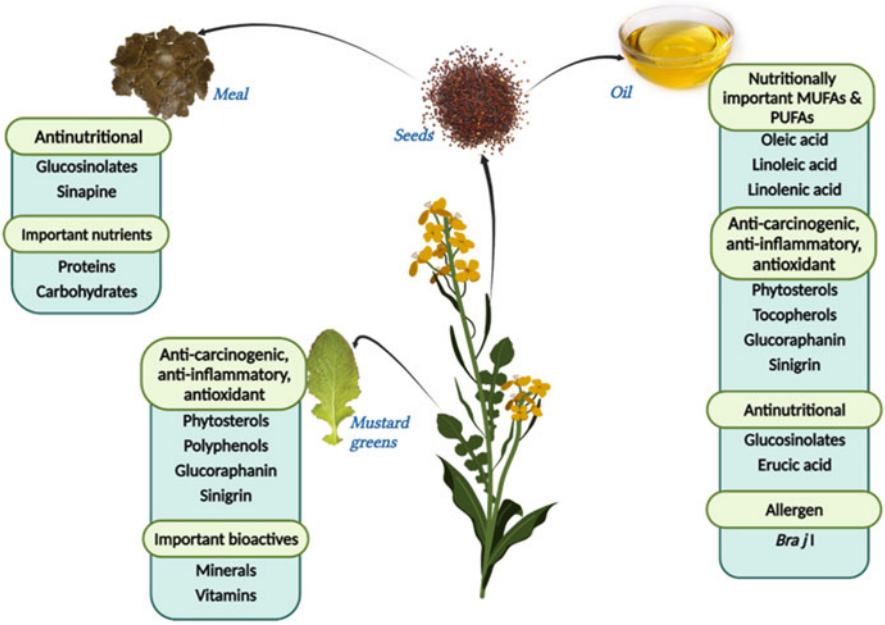

Fig. 1 Different nutraceutically important compounds present in *B. juncea*

mustard are a rich source of nutritionally vital minerals like potassium, calcium, phosphorus, and magnesium, vitamins, and dietary folate.

The calorific value of the oil of brown mustard seeds is estimated to be 541, which, although considered high, does not reduce the importance of mustard oil as a heart-healthy oil because it contains omega 3 fatty acids. *B. juncea* oil is a source of many important fatty acids like oleic acid, linoleic acid, linolenic acid, and erucic acid. However, high erucic in mustard oil is considered to be harmful and can impair myocardial conductance, cause myocardial fibrosis, and increase the blood cholesterol level (Gopalan et al. 1974; Ackman et al. 1977). *B. juncea* seeds are also rich in volatile oil (2.9%), which is optically inactive with the major constituent being allyl isothiocyanate (93–99%) formed by the hydrolysis of glucosinolate (GSL) called sinigrin an antinutritional compound.

Mustard greens, or mustard plant leaves, are a rich source of minerals, vitamins, dietary fibers, and different types of GSLs, including sinigrin and others. There are also various other types of bioactive compounds present in mustard like phenolic acids (caffeic and ferulic acid), and flavonoids (isorhamnetin, quercetin, and kaempferol). Seed meal or oil cake has a high protein, fiber, and glucosinolate content and is used mainly for feeding poultry or as a cattle feed, but also has a potential to be used as manure.

1.3 Growing Importance in the Face of Chronic Diseases and Malnutrition

Due to the presence of important fatty acids and various biologically active compounds in different plant parts of mustard, it is considered a good dietary inclusion and has been extensively used as a medicinal plant in diverse cultures since ancient times (Lietzow 2021). Major portion of mustard seeds is composed of saturated and unsaturated (monounsaturated [MUFA] and polyunsaturated [PUFA]) fatty acids. The essential fatty acids that are not synthesized in the body include oleic acid and linolenic acid (Sharafi et al. 2015), which therefore must be ingested via dietary sources (Chauhan et al. 2012). Linoleic acid has been reported to reduce the blood cholesterol level and prevent atherosclerosis (Ghafoorunissa 1994) and decrease the risk of ischemic heart disease (Rastogi et al. 2004). Introducing mustard oil in diet is therefore a good way to fulfill the body's requirement of these essential fatty acids and other important phytochemicals. In these times of growing malnutrition and prevailing diseases, introducing dietary supplements in the staple food or oil crops is an efficient approach.

Mustard has been in use in the alternative forms of medicine by different cultures around the world since early times. The ancient Greeks used mustard to cure scorpion or snakebites and to stimulate blood circulation and in the treatment of arthritis and rheumatism (Thomas et al. 2012). Mustard seeds and leaves have been used in the preparation of Indian *Ayurveda* medicine (Kapoor 1990; Khare 2004), *Yunani* medicine, and traditional Chinese (Small 2006) medicine. Prescriptions for using brown mustard seeds to treat internal and external diseases (liver and spleen enlargement) have been found in texts from Ayurveda (Rohilla et al. 2017). Skin diseases, inflammations, or rheumatism have been reportedly treated by applying mustard seeds externally (Khare 2004; Sharma and Prajapati 2016).

With the increase in focus on nutraceutical importance of spices and other food items, Indian mustard has gained further importance for its therapeutic and medicinal values in Europe and North America also. The compound isothiocyanate, which is found in abundant quantity in mustard, has emerged as a very important cancer chemopreventive phytochemical (Shin et al. 2021; Zhang 2010).

Kaplan (1989) studied the association between two major metabolic disorders, diabetes and hyperlipidemia, for their association with obesity. Based on the information available on the pharmacological activities of mustard products, they suggested their therapeutic potential against these disorders. Since Indian mustard is an easily cultivable plant and enough preclinical information is available about its medicinal uses, it can be used in breeding and germplasm improvement programs as a sustainable and affordable source of nutraceuticals that could help mitigate the malnutrition issues and also help prevent certain noncommunicable diseases and metabolic disorders.

1.4 Limitations of Conventional Breeding and Rationale for Next-Generation Breeding

The objectives of conventional *B. juncea* breeding programs have mainly focused on increasing the seed yield, oil content, and improving the quality/nutritional components of oil and meal. Although a considerable success through conventional breeding methods such as phenotypic selection, backcross breeding, and hybridization has been achieved, the presence of low variability for the oil and seed meal quality traits in the gene pool limits the success of conventional breeding programs. According to Chauhan and Singh (2004), only a few common ancestors have been used for the derivation of pure lines that were the source of most mustard varieties, and the number of donors used by the breeders was also limited. This has resulted in a narrowing of the genetic base of mustard. Various methods for genetic manipulation like mutagenesis using physical and chemical agents, hybridization, and genetic engineering are currently being used routinely to generate new variants and widen the genetic base in *Brassica* crops.

Further, the advent of molecular markers and advancements in the high-throughput omics methods have facilitated the sequencing of transcriptomes and whole genome of *B. juncea* (Yang et al. 2016; Khattak et al. 2019; Paritosh et al. 2021; Shen et al. 2021; Gao et al. 2022; Mathur et al. 2022). This has led to the identification and development of a large number of markers that can be used to dissect the genetic loci associated with various economically important traits that can now be used in precision breeding programs to improve the nutritional value of mustard oil and meal by mustard breeders.

2 Nutraceutically Important Compounds in *B. juncea*

B. juncea contains important saturated and unsaturated fatty acids, various phytosterols that are suggested to have cholesterol-decreasing properties (Duke 2002), and important secondary metabolites. The proportions of saturated and unsaturated fatty acids (MUFA and PUFA) and concentration of secondary metabolites determine the quality of mustard oil. In the seed oil, the amount of erucic acid is found to be relatively high, while the amount of glucosinolates is moderate to high.

Seed meal or oil cake left after oil extraction contains a moderate to high amounts of erucic acid and proteins (Downey and Röbbelen 1989). It also contains carbohydrates (14–15%) and fibers (10–12%) and is also an important source of phytic acid (3–6%), glucosinolates (2–3%), minerals and vitamins (1.0–1.5%), tannins (1.6–3.1%), and sinapine (1.0–1.5%). However, the presence of fibers, tannins, phytic acid, glucosinolate, and sinapine is undesirable in the seed meal, all of which lower its feed value (Chauhan et al. 2002).

Mustard greens are known to have high vitamin content, which have many health benefits (Jahangir et al. 2009; Czarnowska and Gujska 2012), fiber and mineral content (calcium, potassium), and various important bioactive compounds (Sanlier and Guler 2018).

2.1 Fatty Acids

Fatty acids are organic acids that occur in an ester or free form and contain a long-chain single carboxyl group (Chauhan et al. 2012). Saturated fatty acids do not contain a carbon–carbon double bond, for example, stearic acid (C18:0) and palmitic acid (C16:0), while unsaturated fatty acids have double bonds in their aliphatic chain, for example, erucic acid (C22:1), eicosenoic acid (C20:1), oleic acid (C18:1), linoleic acid (C18:2), and linolenic acid (C18:3). Monounsaturated fatty acids (MUFAs) contain one double bond (erucic acid and oleic acid) while polyunsaturated fatty acids (PUFAs) (linoleic and linolenic acids) contain more than one double bond in their aliphatic chain.

Two separate, genetically independent biosynthetic pathways are known for fatty acid synthesis in rapeseed-mustard (Krzymanski and Downey 1969). In one pathway, oleic acid undergoes successive desaturation and produces linoleic and then linolenic acid (Cherif et al. 1975), while, in the second pathway, oleic acid undergoes chain-lengthening process to produce eicosenoic and subsequently erucic acid (Agrawal and Stumpf 1985).

Erucic acid, with antinutritional properties, forms a major fraction (~50%) of the mustard oil (Ackman et al. 1977). Therefore, the development of *B. juncea* lines with "0" erucic acid (ZE) or <2% fraction of the seed oil has been a major objective in mustard breeding programs. Most of the *B. napus* varieties, whether pure line or hybrids, are ZE. However, ZE mustard varieties are found to have a lower seed oil content (Rout et al. 2018) than that of the normal high erucic lines (HE). Therefore, even though *B. juncea* lines with "0" erucic acid content (zero erucic mustard [ZEM]) are available for use in breeding programs (Kirk and Oram 1978), till now breeders are less successful in the development of high-oil-content-productive ZE mustard lines or varieties.

2.2 Glucosinolates (GSL)

Glucosinolates are a very important constituent of mustard plant parts, and along with erucic acid, greatly influence the quality of oil. The amount and composition of glucosinolates are different in different plant organs with the highest concentration being found in the reproductive tissues (florets, flowers, and seeds). Sinigrin, the most important glucosinolate in mustard oil, is an aliphatic compound and yields a pungent chemical called allyl isothiocyanate on hydrolysis by β-thioglucosidase enzyme (myrosinase) at the time of processing of seed for oil extraction (Yu et al. 2003). Along with allyl isothiocyanate (0.25–1.4%), glucose, potassium bisulfate, and minor amount of other volatile components are also released during hydrolysis (Thomas et al. 2012). Allyl isothiocyanate ($CH_2{=}CHCH_2N{=}C{=}S$) is a colorless liquid having a boiling point of 152 °C and acts as an antimicrobial agent (Luciano and Holley 2009). It has been shown recently as being an important phytochemical with cancer-preventive properties that also exhibits other potential health benefits (Okulicz 2010; Zhang 2010).

Some other types of glucosinolates and their breakdown products, however, may cause damage or physiological disorders. One of the harmful glucosinolates is progoitrin (2R-2-hydroxy-3-butenyl), which is a toxic indole glucosinolate and yields goitrin on breakdown (van Doorn et al. 1998). It may cause goiter or growth retardation by inhibiting the key enzyme called thyroperoxidase involved in the synthesis of thyroid hormone and is considered to be unfit for consumption by humans and animals (Rosa et al. 1997). Amongst the edible cruciferous vegetables, the highest amount of glucosinolates is reported in *B. juncea* leaves (McNaughton and Marks 2003). Cartea and Velasco (2008) have reported that goitrin can get absorbed in the human stomach by nitrosation if the water has high nitrate levels (Lüthy et al. 1984).

2.3 Vitamins and Minerals

Mustard greens are reported to be a rich source of vitamins and their precursors (vitamins A, K, C, E, folate, and carotenoids) and various important minerals (Sanlier and Guler 2018; Jahangir et al. 2009; Kim and Park 2009). According to Czarnowska and Gujska (2012), high amounts of folate in mustard may prevent cancer, vascular diseases, and neural tube defects. They are also rich in minerals important for human health like calcium (Ca), magnesium (Mg), potassium (K), chromium (Cr), iron (Fe), and phosphorus (P). Although the calcium concentration in mustard greens is relatively lower (22 mg to 150 mg/100g), a low concentration of calcium-binding compounds like oxalic and phytic acids ensures a higher bioavailability of calcium (Cartea et al. 2011) Potassium has been shown to participate in various metabolic processes (Cartea et al. 2011). *B. juncea* also has the potential to accumulate heavy metals (Del Río et al. 2004), and it thus becomes rich in important minerals like iron (Fe), zinc (Zn), and chromium (Cr), which are required in human diet.

2.4 Phenolic Compounds

Phenolic compounds present in mustard are among one of the several beneficial bioactive compounds (Sanlier and Guler 2018) that inhibit the carcinogen activity and facilitate faster detoxification of reactive oxygen species (ROS) (Morales-Lopez et al. 2017). These compounds are classified into different types according to their molecular structure: (1) simple, low molecular weight compounds, (2) single aromatic cyclic compounds, (3) tannins of large and complex nature, and (4) polyphenols derived from other sources. These compounds, based on the number and arrangement of carbon atoms, are also divided into two categories: (i) flavonoids, for example, flavonols, anthocyanidins, flavones, and flavanones; and (ii) nonflavonoids, for example, phenolic acids and stilbenes.

2.5 Agronomic and Postharvest Techniques to Improve Nutraceutical Composition

Various agronomic practices have been adopted to improve the nutrient content of food or oil crops (Kumar et al. 2020). The success of these practices depends mainly on the type and nature of crop, local environment, and the geographical location. Agronomic practices exploit the available genetic variation within the crop variety and make use of the plant's response to various types of fertilizers to improve the nutritional quality of the crop. A disadvantage of this method is the effect of chemical fertilizers on the soil and local fauna and flora.

Zinc (Zn), boron (B), potassium (K), phosphorus (P), and iron (Fe) are important minerals that have been shown to accumulate in *Brassica* plants by providing fertilizers rich in these minerals. Zn fertilizers are reported to increase the seed yield of rapeseed mustard (Grewal and Graham 1999). Nelson et al. (2016) reported that the flowering time is the crucial stage at which sufficient nutrient supply is very important to produce maximum yield.

Although glucosinolates and their derivatives are considered to be antinutritional, there are studies that have also identified the anticancerous properties of these compounds and suggested their use in crop protection and as biofumigants. Sulfur is an important constituent of glucosinolates, and in a study by Hassan et al. (2007), sulfur levels were shown to have a linear correlation with glucosinolate levels in plants. Studies in rocket salad (*Eruca sativa*) have demonstrated that seed glucosinolate levels increased on the application of fertilizers rich in sulfur and nitrogen (Singh et al. 1999). Environmental stresses have also been shown to increase the concentration of certain important compounds (l-ascorbic acid, glucosinolates, and phenolic compounds) in *Brassica* plants (Antonious et al. 2009).

Nitrogen (N) fertilizers have been shown to affect the oil quality and quantity of Indian mustard seeds. One of the objectives of oil quality improvement is to increase the concentration of oleic acid, and essential fatty acids – linoleic (ω6) and linolenic acids (ω3) – and to decrease the erucic acid concentration. According to Gao et al. (2010), high level of N increases the concentration of total saturated fatty acids and erucic acid, resulting in a decrease in oil quality.

Digestibility of seed meal is also affected by nitrogen. Plants treated with higher concentration of N show reduction in fiber content and soluble sugar levels. However, total soluble proteins do not show any significant change in N treatment (Mawlong et al. 2017). Oil pigments like β-carotene, pheophytin, and chlorophyll also showed change when the plants were treated with nitrogen (Mawlong et al. 2018).

Selenium (Se) is a micronutrient that is required in human and animal diet. Se-rich fertilizers can therefore be used to fortify mustard oil or cake to supplement the requirement of this micronutrient (White and Brown 2010). Application of Se in the form of fertilizer has also been reported to enhance the productivity of Indian mustard (Singh et al. 1980).

Some studies have shown that the fatty acid profile of *Brassicas* is also affected by the planting density and shading, wherein the erucic acid concentration was found to be reduced at high-density planting (Khan et al. 2018). Since these agronomic and postharvest methods are highly influenced by the geographical and environmental conditions of a particular crop season and are dependent upon the variability available within the species, there is a dire need to develop better and more efficient methods to improve the quality of oil and meal of *B. juncea*. Also, chemical fertilizers are harmful to the environment as they get washed away with irrigation water and contaminate the waterbodies.

Biotechnological methods are therefore a better alternative to improve oil quality traits and biofortification of mustard. These methods also allow production of new varieties and increase the overall variability within the species. Mutation breeding is another very important method to increase variability and has been used for a long time in breeding programs. Genetic modification techniques are highly effective in developing fortified food crops with high levels of health beneficial bioactive compounds. For example, the glucosinolate called glucoraphanin has many health benefits, but is not found in *B. juncea*. It will be beneficial to fortify *B. juncea* with glucoraphanin and reduce other harmful glucosinolate contents (Augustine and Bisht 2015). Using biotechnological methods, Augustine and Bisht (2015) successfully developed a *B. juncea* line (Varuna) with high glucoraphanin content.

3 Genetic Resources of Health-Related Genes

Although *B. juncea* being an amphidiploid species consists of the whole genomes of both the diploid parents (*B. rapa* and *B. nigra*), it has remained mostly unchanged since the hybridization event (Axelsson et al. 2000). Various human or natural phenomena have helped in the evolution of *B. juncea* genome and increasing the genetic variability. While natural hybridization events facilitated the genome evolution of *Brassica* species (Sharma et al. 2022), the diversity of the *B. juncea* cultivars was enriched during the domestication process by divergent selection. There are several reports using cytogenetic, genomic, and molecular marker-based investigations that facilitated the identification of basic *Brassica* crop genomes and the mode of evolution of *Brassica* and its related genera (Prakash and Hinata 1980; Hosaka et al. 1990; Song et al. 1990; Branca and Cartea 2011).

Wild races of the crop species are a very important source of genes for desirable traits and have been exploited by breeders for introgression of these genes, cytoplasmic substitutions, and construction of chromosome maps for a long time. The domestication and selection processes, although important from the plant breeding perspective, have left the gene pool of crop species very diminished over the years. Besides other factors, such as the production of F_1 hybrids, environmental disasters, agricultural practices, deforestation, and migration of population from rural to urban areas, have also added to the genetic drift. This reduction of genetic variability has resulted toward not only in the loss of wild germplasm but also in the loss of evolved landraces.

Brassica germplasm collections are mainly maintained in the form of seeds under long-term storage conditions so that the seeds could maintain viability for many years. There are many germplasm collections maintained at different places to ensure the availability of accessions for use by plant breeders and researchers. Universidad Polite´cnica of Madrid (UPM), Spain, has the one such largest repository of wild *Brassica* accessions and related genera. The National Gene Bank (NGB) in India has a diverse collection of *Brassica* germplasm (13,239) acquired from various agro-climatic zones of the country. Ninety-eight percent of the total *Brassica* collection are cultivated species while the rest are wild relatives of important *Brassica* species, out of which over 57% (7756) of all *Brassica* accessions in NGB are reported to be of *B. juncea*.

There are two important gene pools of *B. juncea* in cultivation, Indian and East European. Maximum heterosis has been recorded between the Indian × East European crosses because of the high genetic diversity between them. This variation was exploited in the development of the first commercial hybrid, DMH1, in *B. juncea* by crossing Pusa Bold and EH-2, lines from the Indian and East European gene pools, respectively (Sodhi et al. 2006).

According to two authors, Harlan and de Wet (1971), who were pioneers of the crop diversity conservation movement, the gene pool is categorized into three types (primary, secondary, and tertiary gene pools).

3.1 Primary Gene Pool

Primary gene pool is a collection of germplasm, members of which can be easily crossed, resulting in a successful sexual reproduction and fertile offspring. It includes true biological species that can be easily crossed, there is no abnormal chromosome pairing during meiosis, and genes are segregated normally. The biological species include all the spontaneously evolved wild varieties of the crop species as well as their cultivated forms (Harlan and de Wet 1971).

Each cultivated *Brassica* species, including *B. juncea* (AABB), is characterized by its own primary gene pool with several subspecies and morphological varieties, East European and Indian gene pools of *B. juncea* are one of such examples.

3.2 Secondary Gene Pool

This is a group of germplasm where crossing between the members is difficult and requires methods to overcome some biological barriers before crossing. The hybrids produced are either weak or partially sterile, and the chromosome pairing is poor. This gene pool includes non-conspecific wild relatives of the crop species and other cultivated species from the same genus, for example, *B. nigra, B. napus,* and *B. rapa*. When the genetic variability within the species is not sufficient to produce desired results, introgression from members belonging to the secondary gene pool becomes very important.

3.3 Tertiary Gene Pool

Crossing a crop variety with the members of tertiary gene pool produces anomalous, nonviable, or completely sterile hybrids. It is difficult to transfer genes for the trait of interest from a plant belonging to the tertiary gene pool to the desired crop species. Gene transfer either does not occur or requires advanced breeding or biotechnological techniques, like embryo rescue, tissue culture, etc.

The tertiary gene pool is made up of the distant wild relatives of the species, including those from different genera, for example, *Arabidopsis*. This group includes the related genera of *Brassica* species, like *Eruca, Hirschfeldia, Sinapis, Trachystoma, Enarthrocarpus,* and *Raphanus* (Hu et al. 2009; Hammer et al. 2013). Some of these genera have been used to introgress various traits of interest using somatic hybridization (Kirti et al. 1992; Müller et al. 2001; Hu et al. 2009; Hammer et al. 2013; Kumar et al. 2020).

While the variation within *B. juncea* species is limited, there are several wild relatives belonging to different genera that are considered a reservoir and a good source of novel genes of importance that can be introgressed into the cultivated varieties to improve various traits. *Crambe abyssinica* is such a source of high erucic acid genes, which is important for industrial application of the oil, while *Sinapis incana* and *Diplotaxis tenuifolia* are sources of cytoplasmic male sterility genes (Katche et al. 2019).

4 Breeding *B. juncea* Using Classical Genetics and Traditional Breeding Methods

4.1 Genetics of the Health-Related Genes

The gene controlling linolenic acid was reported as dominant by Kondra and Thomas (1975). Woods et al. (1999) found in a study that low oleic acid (C18:1) and high linoleic acid (C18:2) contents were affected by a single gene, which was observed to be under embryonic control and not the maternal parent. The gene was reported to be dominant with a small additive effect. Several authors have reported that there are two genes controlling the amount of erucic acid (C22:1) in mustard oil and both have additive effect (Tiwari 1995; Potts and Males 1999; Bhat et al. 2002; Singh and Singh 2015). The candidate gene for oleic to erucic acid elongation was reported to be *Fatty Acid Elongase 1* (*FAE1*) gene (James and Dooner 1991). Later Gupta et al. (2004) cloned and sequenced the *FAE1* gene in high as well as low erucic acid lines and identified two *FAE1* genes (*FAE1.1* and *FAE1.2*). Pandey et al. (2013) studied the erucic acid content of hybrids and their reciprocal lines and observed that the content of erucic acid in both types of hybrids was intermediate between the two parents, which suggested that maternal effect on the erucic content was absent, and it was rather under the genetic control of the developing embryo.

In case of glucosinolates, many different genes have been reported in different germplasms. In Indian gene pool lines, 6–8 genes controlling glucosinolate content

have been reported (Stringam and Thiagarajah 1995; Sodhi et al. 2002), while in case of East European gene pool, digenic control was reported (Love et al. 1990). Variety of roles played by glucosinolates in the plant system is possible due to variety of structural configurations of glucosinolates and their concentration. This variation is controlled by four major loci, *GSL-AOP*, *-ELONG*, *-OH,* and *-OX* (Kumar et al. 2020). These four loci have been shown to have epistatic effects, resulting in the generation of 14 different structural profiles of glucosinolates in plants.

4.2 Breeding Objectives: Positive and Negative Selection

Nutraceutical improvement of oilseed crops has now become an important part of research objectives. The *Brassica* breeding programs have mainly provided emphasis on increasing seed and oil yield, and improving the quality of oil (low erucic acid, high oleic acid, linoleic acid, and tocopherols) and seed meal (low glucosinolate). Since oil quality in *B. juncea* depends upon the concentration of unsaturated and saturated fatty acids, nutritional (vitamins, minerals, etc.) and antinutritional components (glucosinolate, erucic acid) present in the oil, selection for these traits is undertaken to produce biofortified mustard oil.

Positive selection for a desired trait selects for the presence or increase in the trait, like oleic acid, linoleic acid, vitamins, etc., while negative selection results in the removal or reduction of the trait phenotypes that are not desirable in the oil, like glucosinolates and erucic acid. Over 120 variants of glucosinolates are known, out of which Brassicaceae members contain one or more types in their seed or meal or greens (Fenewick et al. 1983). Thus, it is imperative to reduce glucosinolate in Indian mustard cultivars from their present high levels.

Visual selection for quality traits is ineffective, and for which marker-assisted selection becomes a useful solution. Several types of molecular markers have been identified over the years, and with the advancements in sequencing technologies, their development has become easier. This has helped tremendously in the construction of dense linkage maps and identification of quantitative trait loci (QTLs) to be used for the marker-assisted selection (MAS) of the traits of interest.

4.3 Classical Breeding Achievements: Composition and Contents

Although *B. juncea* is a mostly self-pollinated crop, cross-pollination instances of around 18% have also been recorded (Labana and Banga 1984; Bhajan et al. 1991; Abraham 1994).

The research work for the improvement of rapeseed mustard in India started at Pusa (Bihar) at the start of the twentieth century, which involved collection of different landraces and their purification (Chauhan et al. 2012). Until 1970, the only breeding methods in use were pure line and mass selection that had been used to develop several varieties, the first of which was released in 1936. In

B. juncea, the most common method used for cultivar development was pedigree selection that was responsible for the yield improvement in conventional *Brassica* breeding (Downey and Rimmer 1993). But the method is not very efficient as the environmental influence on yield components modulates the response to selection (Thurling and Depittayanan 1992).

After Sun (1943) reported the presence of heterosis in rapeseed-mustard and Ogura (1968) produced *B. juncea* lines with cytoplasmic male sterility developed by introgressing genes from *R. sativus*, hybrid production to exploit heterosis became a very important method of mustard plant breeding. The number of hybrid varieties produced therefore increased consistently after 1980. Simultaneously, mutation breeding was also pursued and has since been used successfully to improve quantitative as well as qualitative traits in *Brassicas* (Röbbelen 1990; Bhatia et al. 1999). Over 31 varieties of *B. juncea* developed by mutation breeding have been released all over the world, out of which 8 were contributed by India. A somaclone (Bio-902 or Pusa Jai Kisan) of the *B. juncea* line Varuna developed through tissue culture has also been released as a variety (Katiyar 1997).

Breeding mustard varieties with low glucosinolate content and/or low or zero erucic acid content to meet the internationally acceptable standard of oil and seed meal quality is a very important objective of mustard breeding programs in India. The first low erucic acid variety (Pusa Karishma) of Indian mustard was released in 2004, and the first double low variety (GSC 5 of gobhi sarson) that is characterized by low glucosinolate as well as low erucic acid was released in 2005. Remarkable success has been achieved in improving the oil quality by manipulating its fatty acid composition. Single mutation using ethyl methane sulfonate (EMS) for high oleic acid (70%) has also been reported in *B. juncea* (Ripley et al. 2014).

4.4 Limitations of Traditional Breeding and Rationale for Molecular Breeding

Traditional breeding methods utilize already existing genetic variation within a species. Pedigree selection, recurrent selection, backcross breeding, and hybridization, all require the presence of naturally occurring variation, which is, however, limited. Production of hybrid varieties to exploit heterosis is a very important contribution of genetics to the plant breeding programs around the world. Heterosis is generally observed to be higher in hybrids produced by crossing geographically diverse lines in comparison with the hybrids of closely related lines (Pradhan et al. 1993). However, limited variability exists within the species for oil and seed meal quality traits.

Mutagenesis has been used to introduce variations to the *B. juncea* germplasm. As the global demand of edible oil is rising and there is a need to combat malnutrition and metabolic disorders, molecular breeding has become a good alternative to traditional breeding. It allows introduction of novel genes in the mustard plant, which is not possible by traditional breeding due to biological barriers or low variability. Yao et al. (2003) transformed the *B. juncea* plants with *ADS1* gene from *Arabidopsis*, which resulted in a significant decrease in undesirable saturated fatty acids in seeds.

5 Genetic Diversity Analysis

5.1 Phenotype-Based Diversity Analysis

Phenotyping for diversity analysis is the simplest way of quantifying genetic variation and to assess the performance of the genotypes. However, phenotype-based evaluation of genetic diversity has very limited success as the relatively fewer number of traits showing polymorphism across different genotypes pose a major roadblock, while low heritability and environmental effects on the phenotypic performance are some other hurdles.

Considerable variation has been reported for various important agro-morphological traits (Khulbe et al. 2000; Pant and Singh 2001; Singh and Chowdhury 1983) among different accessions collected from various agro-climatic regions of India. Variability among different accessions can be studied by various methods; however, the first step in this process is to provide morphological characterization of germplasm for their description and classification (Smith and Smith 1989). There have been numerous studies using morphological, physiological, and molecular markers for diversity analysis in mustard (Ghosh et al. 2019; Verma et al. 2021; Chaturvedi et al. 2021).

Seeds of 20 accessions belonging to the six *Brassica* species (*B. napus*, *B. juncea*, *B. carinata*, *B. oleracea*, *B. nigra,* and *B. rapa*) including five wild relatives were utilized for analyzing oil and fatty acid composition (Sharafi et al. 2015). The fatty acids that were analyzed included palmitic, stearic, oleic, linoleic, linolenic, and erucic acid. The study observed that these fatty acids were present in the range of 89–94% for the total fatty acids in all the six species. Highest oleic acid (61%) and lowest erucic acid (1%) content were observed in *B. napus,* while in *B. juncea* the highest linolenic (20.22%) and linoleic (19.92%) acid contents were observed. Other fatty acids like oleic acid ranged from 12.46 to 16.69%, and linoleic acid content varied from 17.46 to 22.39% in the *B. juncea* varieties, while the linolenic acid content varied from 18.35 to 22.80%. Erucic acid content was also observed to be higher in *B. juncea* accessions and varied from 23.75 to 38.19%. These results clearly indicate the presence of high genetic variation in *B. juncea* for oil content and fatty acids composition.

Yadav et al. (2017) evaluated 148 accessions of *B. juncea* representing nine different agro-ecological zones of India for 15 quantitative traits. These accessions showed large variation for the trait values, wherein maximum variation was observed in case of leaf petiole length, leaf width and number, 1000 seed weight, primary branches per plant and beak length.

5.2 Molecular Markers-Assisted Assessment

The use of phenotypic markers for genetic diversity studies always has a constraint as phenotypic traits may express in one environment while may not express in another. DNA-based markers, also referred to as molecular markers, have better potential in diversity analysis as they can be utilized without any influence of the environment or plant's growth phase. Genetic diversity is measured on the basis of the genetic distance and gives us an idea about the genetic changes that could have

taken place over the time (Ravi et al. 2003). Initial attempts to use DNA-based molecular marker in *B. juncea* were taken by Jain et al. (1994) by using 500 polymorphic RAPD markers assayed among 12 Indian and 11 East European accessions of *B. juncea*. By utilizing RAPD markers, Rabbani et al. (1998) conducted genetic diversity analysis on germplasm that included accessions from Pakistan and Japan comprising of oilseed cultivars/lines as well as vegetable types. Oilseed accessions obtained from Pakistan had a low polymorphism rate, indicating these accessions had undergone selection for the same agronomic traits over time. In another study using molecular markers, AFLP loci were used by Srivastava et al. (2001) to estimate genetic diversity in 9 synthesized and 21 natural accessions of *B. juncea*. As the advancements in the field of molecular biology continued, next-generation markers like SSR, SRAP, and other marker systems were progressively used for genetic diversity analyses in *B. juncea* (Singh et al. 2021; Wu et al. 2009); however, SSR markers were the most preferred compared to other marker systems.

5.3 Relationship with Other Cultivated Species and Wild Relatives

Genetic bottleneck has occurred in *B. juncea* mainly because of domestication and polyploidy. Intensive plant breeding efforts to select desired plant particularly for low glucosinolate and low erucic acid contents has further eroded the genetic base in *B. juncea*. The breeding strategy that can be utilized to expand genetic base is through resynthesis of *B. juncea* from cultivated or wildtype diploid progenitors as the variation present in diploid species can be used to mobilize into synthetic varieties. Introgression of variation available in wild germplasm or related species can be another option. UN (1935) was the first to report resynthesis of *B. juncea* by utilizing genomic relationship triangle of *Brassica* species. In case of *B. juncea*, the genetic diversity that is present in the wild germplasm is very extensive for nuclear as well as for the cytoplasmic genes. If the alien genetic diversity can be utilized, it can be a path-breaking step in terms of widening the germplasm base of *B. juncea*. This can be achieved by facilitating the hybridization between wild relatives of *B. juncea*. However, this process is quite cumbersome due to several hybridization barriers that first need to be overcome by various means. Although different hybridization and compatibility barriers exist, still a large number of hybrids have been developed that utilize interspecific and intergeneric crossing between *B. juncea* and wild crucifers (Prakash et al. 2009). However, to get desirable results for the introgression of nuclear-encoded genes only limited attempts have been made, and that too with limited success only.

5.4 Relationship with Geographical Distribution

Vavilov (1949) suggested that the primary center of origin of *B. juncea* of the species is in Afghanistan and surrounding regions while secondary centers of origin were in

China and eastern India. These conclusions were drawn from the diversity analysis of different lines and the relationship between them. Since then, many investigations have been conducted to study diversity among collections from different geographical centers and understand the relationship between them (Gupta et al. 1991). Both morphological and molecular markers are good tools to study divergence between the varieties having different or same centers of origin. It has been shown that the extent of heterosis is maximum in the hybrids of genotypes belonging to two geographically separate gene pools (Indian and East European gene pools) (Vaughan et al. 1963; Vaughan 1977; Sodhi et al. 2006). To establish the correlations between heterosis and genetic diversity, several attempts have been made (Gupta et al. 1991; Krishna and Ghose 1992).

5.5 Extent of Genetic Diversity

Presence of genetic diversity in the germplasm is a prerequisite for many types of breeding programs. A lot of research involving diversity analyses has been conducted using cytological, phenotypic, and molecular markers. Diversity analysis has led to the identification of two distinct gene pools in Indian mustard, Indian gene pool, and East European gene pool (Vaughan et al. 1963; Vaughan 1977). These two gene pools show many trait differences as in oil content, erucic acid content, plant height, branching, flowering time, seed color, etc. (Pradhan et al. 1993). The lines belonging to these gene pools show excellent heterosis when crossed to produce hybrids, and which has already been utilized to produce commercial hybrid varieties (Sodhi et al. 2006). Other studies using molecular markers have further confirmed the availability of two gene pools in Indian mustard (Jain et al. 1994; Srivastava et al. 2001; Burton et al. 2004). Srivastava et al. (2001) used amplification fragment length polymorphism (AFLP) markers to conduct diversity analysis and found that Indian and Chinese lines formed one cluster while East European, Russian, Canadian, and Australian accessions formed another cluster.

In a study using 60 germplasm lines (27 Indian, 25 Australian, and 8 Chinese genotypes), Meena et al. (2014) investigated the extent of variability among the accessions of *B. juncea*. They used morphophysiological and quality characters to study the differences. They found that all the three types of genotypes differed from each other in either the quality traits or physiological traits. Indian genotypes had higher erucic acid content, lower oleic acid content, and higher glucosinolate content than Australian genotypes, while Chinese lines failed to set seed in Indian conditions.

6 Molecular Mapping of Health-Related Genes and QTLs

In countries like India, the major objective of various *Brassica* breeding programs is to develop cultivars with higher seed yield and high oil content, whereas in countries like Canada and members of the European Union there is a preference for oil and

meal quality (Gupta 2016). However, in India also, the focus on improving oil quality has increased in recent years and various molecular markers have been used to construct linkage maps that are then utilized to dissect QTL for the various nutraceuticals and other agronomically important traits (Pradhan et al. 2003; Ramchiary et al. 2007; Punjabi et al. 2008; Yadava et al. 2012; Dhaka et al. 2017; Panjabi et al. 2019).

6.1 Molecular Markers

Genetic markers are tools to identify genetic differences between individual organisms or species. A genetic map indicates the linear arrangement of genes on a chromosome and is developed using meiotic recombination data of a segregating population. Molecular studies using a wide array of DNA markers have been used to assemble linkage maps in many Brassica species. Various low-throughput PCR-based markers have been used over the years for linkage and QTL analysis, for example, random amplified polymorphic DNA (RAPD) (Sharma et al. 2002), restriction fragment length polymorphisms (RFLP) (Sharma et al. 1994), amplified fragment length polymorphism (AFLP), and simple sequence repeats (SSR) (Pradhan et al. 2003). Recently, advances in high-throughput sequencing and genotyping have led to the construction of very high-density maps in *B. juncea*. Next-generation sequencing technology-based platforms like genotyping by sequencing (GBS) and Illumina Infinium Brassica 90K SNP array have also been used in the map construction using doubled haploid (DH) populations (Bhayana et al. 2020; Aakanksha et al. 2021).

6.2 Mapping of QTLs for Nutraceutical Traits

Different marker systems and mapping populations have been used to map QTLs associated with fatty acids, glucosinolates, as well as tocopherols in various studies (Table 1). Cheung et al. (1998) undertook molecular mapping of seed quality traits in *B. juncea* using an F_1DH mapping population. Glucosinolate traits mapping was undertaken using DH population using AFLP markers (Mahmood et al. 2003a), in which two and three major QTLs were identified for the 3-butenyl and 2-propenyl glucosinolates, respectively. QTL mapping with F_1DH population and advanced generations (BC_4DH) using AFLP markers led to the identification of true QTL-controlling glucosinolates based on mapping and validation in DH lines (Ramchiary et al. 2007). Based on genome survey sequences (GSS) a comparative genomics approach between *B. juncea* and *B. rapa* helped in the identification of nonsynonymous single-nucleotide polymorphisms (SNPs) that were associated with the glucosinolate trait (Yang et al. 2014). Rout et al. (2015) undertook QTL mapping in DH population using AFLP, RFLP, SSR, IP, and genic SNP markers to identify glucosinolates QTLs in *B. juncea.* Ramchiary et al. (2007) used an AFLP map for the identification of loci controlling glucosinolates in F_1DH and advanced DH lines.

Table 1 Summary of QTL studies undertaken for nutraceutical traits in Indian mustard

Trait	Markers used for mapping	Mapping population	Number of QTLs	QTL/flanking markers	LOD	PVE (%)	Linkage group/ chromosome	Reference(s)

Marwede et al. (2005) detected QTLs for tocopherols in a DH population using linkage map based on RFLP markers.

Using DH population(s) and RFLP markers, Cheung et al. (1998) and Mahmood et al. (2003b) detected QTLs that control the fatty acid profile. Lionneton et al. (2002) used a DH population and AFLP markers to map QTLs for seven constituent fatty acids of mustard oil including erucic acid. Sharma et al. (2002) used the RAPD linkage map in a RIL population to identify two QTLs for oleic acid on two different linkage groups (LGs) of *B. juncea*. Linkage map with AFLP, RFLP, SSR, IP, and genic SNP markers was also used to identify oil content QTL in two sets of populations – one segregating for erucic acid and another with zero erucic acid lines, in their oil content (Rout et al. 2018).

In *B. juncea*, the inheritance of high linoleic acid and low oleic has been found to be controlled by a single gene with dominant gene action along with minor additive effects (Potts and Males 1999; Woods et al. 1999). Kondra and Thomas (1975) investigated the fatty acid composition of *B. napus* and reported a dominant gene effect for low linolenic acid content, additive gene action for oleic and linoleic acid in one of the three crosses studied. In the other two crosses, they discovered partial dominance effect for high oleic acid and low linoleic acid content.

6.3 Association Mapping

Several SNP markers are now available with the advent of technologies in the field of genomics, and the high-throughput next-generation sequencing (NGS) platforms like Illumina, PacBio, Nanopore, etc., have further accelerated the speed of resource generation. Genome-wide association studies (GWAS) and candidate gene-based association mapping (CG-AM) are now the ideal choices to find out novel genes and marker–trait associations for health-related traits in *B. juncea* as they overcome several limitations posed by tradition mapping methods (Brachi et al. 2011). However, association mapping for health traits in *B. juncea* is mainly confined to glucosinolate traits only (Yang et al. 2021; Akhatar et al. 2020; Tandayu et al. 2022).

7 Marker-Assisted Breeding for Nutraceutical Traits

7.1 Germplasm Characterization

The role of diverse germplasm is very crucial for utilizing genetic diversity in various breeding programs. In *B. juncea*, natural variation exists for glucosinolates (Sodhi et al. 2002), erucic acid, antioxidants, and oleic acid (Sivaraman et al. 2004; Jagannath et al. 2011). However, several efforts were also made to induce variation through tissue culture (Shyam et al. 2021), ethyl methyl sulfonate (EMS)-induced mutations (Nour-Eldin et al. 2017), and using currently available technologies like CRISPR-Cas9 system (Huang et al. 2020; Assou et al. 2022). Once the germplasm

having variation for the traits are developed, they can be utilized for deriving improved varieties through marker-assisted selection and conventional breeding approaches.

7.2 Marker-Assisted Gene Introgression

The genetic loci/QTL identified in research programs need to be transferred into elite varieties having better adaptability and higher yield. Transferring the gene/QTLs based on phenotypes in a conventional breeding program is a tedious process and often involves linkage drag. Marker-assisted gene introgression is more efficient and considered more effective compared to conventional breeding as it helps in selection at early stages and can also be used for traits where phenotyping is not possible (Collard et al. 2005).

In *B. juncea*, diverse molecular markers have been deployed to map health-related (HR) genes. For example, the fatty acid elongase (*FAE*) having two homologs *FAE1.1* and *FAE1.2* that are present on the LGs A08 and B07, respectively, were tagged after sequencing and cloning the gene (Gupta et al. 2004). Gill et al. (2021) used Kompetitive allele-specific PCR (KASPar) method for tagging *FAE* gene by employing SNPs at 735 and 1476 positions in the two homologs *FAE1.1* and *FAE1.2*, respectively. Tagging of genes will assist in transferring low erucic acid trait to *B. juncea* cultivars with the objective of developing low erucic acid lines.

For glucosinolates traits in *B. juncea*, QTL studies were performed to identify molecular markers that showed close association with the regions controlling the synthesis of glucosinolates (Mahmood et al. 2003a; Ramchiary et al. 2007; Bisht et al. 2009). Pushpa et al. (2016) further used the molecular markers to validate them on a larger set of recombinant inbred lines (RIL) and showed that the markers and germplasm developed can potentially be used for marker-assisted selection of lines in *B. juncea* with low glucosinolate content. For increasing oleic acid content in *B. juncea*, Kaur et al. (2004) introgressed the desaturase suppressor genes from *B. napus* to *B. juncea* through interspecific crosses.

7.3 Gene Pyramiding

Gene pyramiding is a method to accumulate loci identified in different parents into one genotype to get the desirable trait phenotype. Gene pyramiding is possible with two approaches – through conventional breeding and by the application of biotechnological methods like recombinant DNA technology. Conventional breeding is usually time-taking; however, it can be accelerated using molecular markers. In case of wide crosses or interspecific crosses, conventional breeding approach is not possible for gene pyramiding and in such cases biotechnological means of gene pyramiding is the ideal tool although it requires great technological expertise and infrastructure.

Currently, there are no reports on gene pyramiding of health-related genes using conventional breeding methods in *B. juncea*. However, Kumar et al. (2022) have reported the pyramiding of *glyoxalase I* (*gly I*) and *γ-tocopherol methyltransferase* (*γ-TMT*) involved in tocopherol biosynthesis, which resulted in 35–51% increase in total tocopherol content in transgenic lines. α-Tocopherol, which is an active form of vitamin E and is synthesized from γ-tocopherol, has been described to reduce the risk of different forms of cancers, heart diseases, and a number of other human diseases (Bramley et al. 2000).

7.4 Limitations and Prospects of MAS and MABCB

Marker-assisted selection (MAS) and marker-assisted back cross-breeding (MABCB), besides providing a speedy introgression of genes/QTLs into related or elite germplasm, have a few inherent limitations. The biggest hurdle that limits the wide application of MAS and MABCB is the limited availability of molecular markers as markers associated with a trait identified in one germplasm have to be confirmed and validated in the unrelated germplasm before applying MAS. Also, the QTL regions identified with genome mapping are usually large and show variable expression in different backgrounds (Singh and Singh 2015). With the advancement of sequencing technologies, all six *Brassicas* have been sequenced and it has consequently resolved the issue of inadequacy of molecular markers as a large number of SNP markers are now available for different traits. However, the use and identification of SNP markers are very low in *B. juncea* mainly because of homologous sequences that are present in different subgenomes (Yang et al. 2021).

As the sequence information of all the *Brassica* species are now available, technologies like genotype by sequencing (GBS) can generate a large number of SNPs quickly and at low cost. Besides these, the recently developed 90K SNP genotyping chip has been also used in *B. juncea* that can generate a plenty of markers distributed over entire genome in one experiment (Aakanksha et al. 2021). These advancements can help in the rapid detection of markers tightly linked to the traits of interest that will accelerate speed and accuracy of MAS and MABCB.

8 Map-Based Cloning of Health-Related Genes/QTLs

Map-based cloning, also referred to as positional cloning, utilizes the association of trait to a marker whose position is known on the chromosome. Map-based cloning is an assumption-free approach as no prior information about the gene is required. The earliest attempt to clone health-related genes in *B. juncea* was made by Venkateswari et al. (1999). The study described cloning and characterization of *FATTY ACID ELONGATION1* (*BjFAE1*) gene using PCR-amplified sequences of *A. thaliana FAE* gene.

In *B. juncea*, the gene *CYP79F1*, which is an ortholog of *A. thaliana* gene *At1g16410* involved in the biosynthesis of sinigrin (an aliphatic glucosinolate),

was isolated and characterized (Sharma et al. 2016). Sinigrin on degradation produces allyl isothiocyanate, a bacteriocide with antimicrobial activities and anticancerous properties against liver and bladder invading cancers (Wang et al. 2012; Jie et al. 2014). Functional validation of *CYP79F1* was performed genetically using 95 F_2 lines along with the development of transgenic plants using a QTL-NIL J16Gsl4 line that was lacking for sinigrin content. After genetic transformation with *CYP79F1,* sinigrin biosynthesis was observed in QTL-NIL J16Gsl4.

9 Genomics-Aided Breeding for Health-Related Traits

9.1 Structural and Functional Genomics Resources Developed

Development of genetic resources is fundamental to any genomics-based breeding effort as the availability of genomic resources helps in the efficient use of molecular markers for functional characterization of genes and QTLs. In any plant species, availability of genomic resources such as DNA-based markers, genetic maps, and genome sequencing data are essential for genetic assessment and marker-assisted breeding (Srivastava et al. 2020).

The Arabidopsis Information Resource (TAIR) (Rhee et al. 2003) was initially the sole database for Brassicaceae members. As technological advancements in the sequencing methods progressed, it led to the development of more and more information in the form of EST sequences, genome sequences, and expression data on different species. Currently, vast information on structural genomics is available in the form of Brassica Database (BRAD V3.0, http://brassicadb.cn). BRAD hosts sequencing information of 26 *Brassica* species, and along with the information on syntenic loci, it also provides information on genomic variation across the different species.

Another database, "brassica.Info," was established by the Multinational Brassica Genome Project (MBGP) in 2002 and includes information of genomes, phenomes, metabolomes, transcriptomes, and proteomes. Brassica EDB is another repository that provides information on the expression of 1,01,040 genes based on RNA-seq analysis (Chao et al. 2020). These available resources have assisted in the development of molecular markers for trait improvement. However, a single comprehensive database that integrates genomics, transcriptomics, proteomics, metabolomics, and phenomics is presently not available for *Brassica* crops.

9.2 GWAS and Genomic Selection (GS)

Genome-wide association studies (GWAS) utilize linkage disequilibrium (LD), the nonrandom association of alleles of different loci present on different chromosomes or different regions of the same chromosome. Unlike biparental QTL mapping studies, GWAS utilizes variation present in a natural population and thus reduces the time that is required to develop a segregating population for linkage mapping

studies. With the availability of more and more of structural genomics resources, GWAS has emerged as the most popular option because it can utilize a wide amount of genetic variation from populations that have undergone domestication and selection.

In *B. juncea*, Yang et al. (2021) undertook GWAS to identify loci controlling glucosinolates content and reported loci on chromosomes A02 and A09 that both contain, *BjuVA09G07110.1, BjuVA02G46870.1,* and *HAG1 (MYB28)*, the major regulatory genes controlling the glucosinolates. In another study, GWAS analysis of 92 genotypes under different nitrogen conditions identified genes involved in the biosynthesis of glucosinolates, oil, and proteins (Akhatar et al. 2020). GWAS analysis by Yan et al. (2020) recognized a large number of QTLs controlling various glucosinolates and oil and protein contents under two different nitrogen (N) regimes. The candidate genes involved in the metabolism of glucosinolates, including *QGsl.ig01.1, QGsl.atg09.1,* and *QGsl.atg11.1,* were *GSH1, GSL-ALK,* and *MYB28*, which were also identified in this study. In a recent study, 158 *B. juncea* lines were used for GWAS analysis, and it identified seven loci for total GSL content, along with 8 and 19 loci for sinigrin and gluconapin, respectively (Tandayu et al. 2022). The key genes included homologs of *MYB34, MYB28, HY5, SDI2,* and *LSU2* that were located in the regions showing strong associations with the GSL traits.

Genomic selection (GS) is a promising and novel but hitherto unexplored breeding tool that has been derived as an application of GWAS analysis. GS can be used to introgress polygenic traits that are difficult to transfer through MAS or MABCB (Pant et al. 2022). GS uses a "training population" of individuals with both phenotypes and genotypes to train the prediction model to compute genomic estimated breeding values (GEBVs). Consequently, using this trained model, the GEBVs can be estimated for the untested individuals from the "candidate population" and can be used to identify selection candidates for initiating a crossing scheme or for enhanced productivity tests (Varshney et al. 2017). As the number of GWAS studies on various traits in *B. juncea* is continuously increasing, GS can serve as an efficient tool to transfer polygenic traits or QTLs to elite varieties for the improvement of nutritional and pharmaceutical characters. It is only until recently that high-density genome-wide SNP arrays have been available in *Brassica* species, allowing every individual that is phenotyped in a breeding program that could also be genotyped using SNP arrays (Clarke et al. 2016; Mason et al. 2017).

10 Recent Concepts and Strategies Developed

10.1 Gene Editing

The crop improvement practices have progressed from conventional breeding technologies like mutation, selection, and backcross breeding to the use of modern technologies like zinc finger nuclease (ZFN), transcription activator-like effector nuclease (TALEN), and clustered regularly interspaced short palindromic repeats (CRISPR)-CRISPR-associated protein (Cas) system (CRISPR/Cas9). These new

technologies have revolutionized the crop improvement methods as the limitations posed by the conventional breeding methods can be overcome with these technologies (Nagamine and Hiroshi 2022). CRISPR/Cas9 system combined with the SNP technologies has resulted in a surge in the genome-editing practices for crop improvement. The products obtained through CRISPR/Cas9 editing or by other nucleases are classified as site-directed nuclease systems (SDN), which are further classified into SDN-1, SDN-2, and SDN-3. Recently, the Indian government has relaxed the SDN-1 and SDN-2 categories of genome-edited plants from the stringent regulatory process, and therefore these methods can now be used in the development of *B. juncea* lines with better nutritional profiles by employing methods like CRISPR/Cas9 system.

Gene editing has not been utilized extensively for improving health-related traits. There are only a few successful examples of genome editing in *B. juncea*. In *B. juncea*, Augustine et al. (2013b) used an RNAi-based suppression method to silence the transcription factor *MYB28* to develop a low GSL mustard line. Targeted modification of glucosinolate transporters (GTRs) to reduce glucosinolates in *B. juncea* by targeting induced local lesions in genome (TILLING) method has been successfully tried (Nour-Eldin et al. 2017). Kajla et al. (2017) targeted UDP-glucose:sinapate glucosyltransferase (*SGT*) and Sinapoylglucose:cholinesinapoyltransferase (*SCT*), the two enzymes involved in the synthesis of sinapine, an antinutritive compound present in *B. juncea* seeds. The study described the use of RNAi technology to silence *SGT* and *SCT* in order to reduce sinapine content in the seeds. For the modification of allergenic *Bra j I*, a seed storage protein of the 2S albumin class, gene editing using the CRISPR/Cas9-based method was used to mutate the two homologs of *Bra j I* gene (Assou et al. 2022). Apart from these few studies, there still exists a vast scope for using gene editing methods for the improvement of *B. juncea* to develop lines that are rich sources of antioxidant molecules but also have minimal levels of antinutritional compounds.

10.2 Nanotechnology

Nanotechnology is the science of studying materials at a scale of 1–100 nanometers (nm). It has emerged as a new arena of scientific research with a very broad range of applications ranging from semiconductors, textile, space industry, healthcare, and medicine to agriculture. Nanotechnology utilizes particles of the range 1–100 nm called nanoparticles and is being considered to hold promise for increasing crop productivity in the future at a large scale (King 2017). As agriculture is a traditional industry where the economic margin of profit is subtle, and the advancements and innovations in technologies using nanoparticles, the demand for increased food supplies can be attained in a sustainable manner (Kah et al. 2019). Besides increasing productivity, plant-based edible nanoparticles can be used in the health industry to treat diseases (Zhang et al. 2016). Use of mustard extract in silver nanoparticles has been shown to be hepatoprotective and can be used in acute liver injury (Hassan et al. 2020).

B. juncea being a good source of many antioxidants and health-related compounds thus has a great potential to be used in nanoparticles-based therapeutics.

11 Genetic Engineering of Nutraceutical Traits in Mustard

Mustard is highly amenable to the techniques of genetic engineering; however, the in vitro plant regeneration frequencies of different genotypes are highly variable with the Indian gene pool lines being more responsive than those belonging to the East European and Chinese groups (Fazekas et al. 1986; Yadav et al. 1991; Pental et al. 1993; Assou et al. 2022). Agrobacterium-mediated genetic transformation of hypocotyl explants is the predominantly used method for developing transgenics in *B. juncea* (Barfield and Pua 1991; Pental et al. 1993). A number of genes regulating the nutraceutical traits have been identified and functionally validated in *B. juncea* using the transgenic approach (Table 2). Recent studies have also reported the use of CRISPR/Cas9-mediated gene editing in mustard (Wang et al. 2021; Assou et al. 2022).

11.1 Fatty Acids

The nutritional quality of mustard oil is ascertained by the relative proportions of the saturated and unsaturated fatty acids. Several attempts have been made to minimize the saturated fatty acid fractions via transgenic approaches in *B. juncea*. For example, the transfer of *ADS1* gene from *Arabidopsis* to *B. juncea* resulted in a significant decrease in the concentrations of palmitic and stearic acids, along with an enhancement in the oleic acid fraction (Yao et al. 2003). *B. juncea* lines contain a high amount of erucic acid (~50%), which is a long-chain fatty acid and an antinutritional component (Ackman et al. 1977). *FAE1* gene encodes the first enzyme in the erucic acid biosynthesis pathway, β-ketoacyl-CoA synthase (KCS) (James et al. 1995). The knockdown of *FAE1* gene in *B. juncea* causes a significant reduction in the erucic acid fractions (Kanrar et al. 2006). Sinha et al. (2007) overexpressed *FatB* from *Diploknema (Madhuca) butyracea* in *B. juncea,* which was accompanied with the silencing of endogenous *FAE1* gene using hairpin-RNA. This resulted in a 64–82% reduction in erucic acid in transgenic lines with a 4–13% enhancement in the oil content. A suppression of *FAD2*, which encodes a crucial enzyme in the biosynthesis of PUFA, has been shown to reduce α-linolenic acid content accompanied with an increase in the oleic acid content (Stoutjesdijk et al. 2000; Sivaraman et al. 2004). The PUFA (linoleic and linolenic acids) do not pose a direct heath risk to humans; however, oils with high concentrations of C18:2 and C18:3 oxidize and deteriorate rapidly, which lends them unfit for consumption (Röbbelen and Nitsch 1975). Another PUFA – γ-linolenic acid (GLA) – has been shown to possess therapeutic properties and is used as a dietary supplement (Horrobin 1992). Mustard oil lacks GLA due to the absence of *Δ6-desaturase (d6D)*, and therefore the transgenic lines of mustard with high levels of GLA and enhanced nutritional quality were engineered via the transfer of *d6D* from heterologous systems (Hong et al. 2002; Das et al. 2006).

Table 2 A summary of genetic engineering of nutraceutical traits in mustard

Trait	Added nutraceutical value	Gene	*B. juncea* genotype	Approach for genetic engineering	Reference(s)
Fatty acids	Low saturated fatty acids and high oleic acid	*ADS1* from *Arabidopsis*	J96D-4830	Transgene expression	Yao et al. (2003)
	High oleic acid	*FAD2*	815-1-6-2	Co-suppression	Stoutjesdijk et al. (2000)
	High oleic acid and low linolenic acid	*FAD2*	VH486	Antisense RNA	Sivaraman et al. (2004)
	Improved oil content	*DGAT1*	RLM198	Transgene expression	Savadi et al. (2015)
	Increase in γ-linolenic acid	*d6D* from *Pythium irregulare*	1424	Transgene expression	Hong et al. (2002)
	Increase in γ-linolenic acid	*d6D* from *Synechocystis* PCC6803	B85	Transgene expression	Das et al. (2006)
	High oleic, PUFA, and low erucic acid	*ACP* from *Azospirillum brasilense*	PCR7	Transgene expression	Jha et al. (2007)
	High oleic, PUFA, and low erucic acid	*FatB* from *Diploknema (Madhuca) butyracea* and *FAE1* from *B. juncea*	PCR7	*FatB* overexpression; silencing of endogenous *FAE1*	Sinha et al. (2007)
	Low erucic acid	*BjFAE1*	RLM-198	Knockdown	Kanrar et al. (2006)
Glucosinolates	Low aliphatic glucosinolates	*BjuMYB28*	Varuna	RNAi and Antisense RNA	Augustine et al. (2013b), Augustine and Bisht (2019)
	High glucoraphanin	GSL-ALK	Varuna	Gene silencing	Augustine and Bisht (2015)
	High sinigrin	*CYP79F1*	QTL-NIL *J16Gsl4*	Transgene expression	Sharma et al. (2016)
Others	Low sinapine	SGT and SCT	Varuna	Gene silencing	Kajla et al. (2017)

(continued)

Table 2 (continued)

Trait	Added nutraceutical value	Gene	*B. juncea* genotype	Approach for genetic engineering	Reference(s)
	High α-tocopherol (vitamin E)	*γ-TMT*	Varuna	Transgene overexpression	Yusuf and Sarin (2007)
	Reduced allergen Bra j I	*Bra j IA* and *Bra j IB*	Terratop and CR2664	Gene editing (CRISPR/Cas9)	Assou et al. (2022)
	Immunity against anthrax	PA gene from *Bacillus anthracis*	Varuna	Transgene expression	Gorantala et al. (2014)

11.2 Glucosinolates

Glucosinolates are secondary metabolites and a characteristic of the family Brassicaceae. The hydrolytic products of some glucosinolates impart nutraceutical value to mustard whereas some of them have antinutritional properties. Therefore, the reduction of nonbeneficial glucosinolates and improvement of those with therapeutic potential are the key targets of breeding programs for the genetic improvement of oilseed mustard. Transgenic approaches have used RNAi to target *BjMYB28*, a key transcription factor controlling the biosynthesis of aliphatic glucosinolates (Augustine et al. 2013a, b; Augustine and Bisht 2019). The transgenic line with the most significant suppression of the gene showed a striking 89% reduction in aliphatic fraction of seed glucosinolates without altering the levels of desirable nonaliphatic glucosinolates (Augustine et al. 2013b). However, it also showed an 80–90% decrease in leaf glucosinolate content. The leaf glucosinolates play an important role in plant defense responses (Hopkins et al. 2009). In another study, Augustine and Bisht (2019) used seed-specific *FAE1* and napin promoters in RNAi and antisense constructs to knockdown *BjMYB28*. They observed no reduction in total glucosinolates in the transgenic lines driven by napin promoters. The transgenic lines with the *FAE1* promoter showed reduction in total glucosinolates but also presented altered levels of other seed quality traits. The study concluded that the use of RNAi constructs with the native promoter could be the strategy of choice for the silencing of *BjMYB28*. Nour-Eldin et al. (2017) reported a seed-specific reduction of aliphatic glucosinolates in *B. juncea* by mutagenesis (TILLING) of 4 of the 12 *GTR* orthologs in *B. juncea* and observed a 60–70% reduction in the seed glucosinolate levels.

Glucoraphanin is another major nutraceutical compound in mustard. Its hydrolytic derivative, sulphoraphane, has anticancer properties (Fahey et al. 1997). Therefore, the biofortification of glucoraphanin is a major objective for the nutritional enhancement of oilseed mustard. The knockdown of *GSL-ALK* by Augustine and Bisht (2015) resulted in an enhancement in the amount of glucoraphanin (up to 43.11 μmol g^{-1} of dry weight) in *B. juncea*. The transgenic lines also showed reduced concentrations of gluconapin, sinigrin, and total glucosinolates. Sinigrin, which is the final product of 3C glucosinolate pathway, upon degradation produces allyl isothiocyanate that has been reported to have antimicrobial and anticancer activities (Okulicz 2010; Bhattacharya et al. 2010; Jie et al. 2014). Therefore, an increase in the levels of sinigrin is desirable for improvement of nutraceutical properties of mustard seed. Sharma et al. (2016) identified *CYP79F1* as a candidate gene for the regulation of sinigrin biosynthesis. The study showed that the transformation of wildtype *CYP79F1* gene in *B. juncea* QTL-NIL *J16Gsl4* line lacking sinigrin resulted in the biosynthesis of sinigrin in the transgenic lines.

11.3 Other Nutraceutical Compounds

The mustard seeds also contain an antinutritive phenolic compound – sinapine – which accumulates in the embryo during seed filling stages and reduces the

digestibility of *Brassica* seed meal (Huang et al. 2008). The RNAi-mediated knockdown of *SGT* and *SCT* genes, encoding enzymes crucial for final steps of sinapine biosynthetic pathway, resulted in up to 67% decrease in sinapine levels in the transgenic mustard lines (Kajla et al. 2017). These results are crucial for the improvement of *B. juncea* seed meal. Transgenic approaches have also been used for the biofortification of mustard with the components imparting high nutritive value. Yusuf and Sarin (2007) overexpressed the *Arabidopsis γ-TMT* gene in *B. juncea*. This resulted in an enhancement in the α-tocopherol levels in the seeds of the transgenic lines. α-Tocopherol/vitamin E is an essential fat-soluble vitamin with antioxidant and therapeutic properties (Bramley et al. 2000).

Another objective of mustard improvement programs is the reduction of allergens. The brown mustard seeds contain an allergen compound, Bra j I, which is a major storage protein. In a recent study, Assou et al. (2022) inactivated the *Bra j I* gene in brown mustard using CRISPR/Cas9 system and developed Bra j I-free *B. juncea* lines. The study is a big move toward the development of allergen-free mustard; however, extensive efforts are still needed to identify and characterize other compounds with allergenic properties in mustard.

Oilseed crops are preferred for the development of edible vaccines as they involve only a few processing steps (Daniell et al. 2001). Gorantala et al. (2014) expressed an antigenic protein from *Bacillus anthracis* – protective antigen (PA) to develop oral anthrax vaccine in *B. juncea*. The study demonstrated the development of systemic and mucosal immune response in mice on oral ingestion of purified PA and highlighted the scope of use of oilseed mustard for the production of biopharmaceuticals.

12 Resources for Translational Genomics in *B. juncea*

The model plant system *Arabidopsis* is the most extensively studied member of the family Brassicaceae and was also the first plant genome to be sequenced (The Arabidopsis Genome Initiative 2000). The TAIR database (https://www.arabidopsis.org/) provides extensive information on the genetics and genomics of *Arabidopsis* (Rhee et al. 2003). Cytological and genetic mapping evidence showed the presence of syntenic regions defined by gene collinearity between *A. thaliana* and the diploid *Brassica* species – *B. rapa* (AA), *B. nigra* (BB), and *B. oleracea* (CC) (Lysak et al. 2005; Parkin et al. 2005). The genome triplication was followed by a reduction in chromosome numbers and genome reshuffling in the three paleohexaploid genomes A, B, and C (Schranz et al. 2006; Mun et al. 2009). The genome assemblies of *B. rapa* (Wang et al. 2011) and *B. oleracea* (Liu et al. 2014) have provided further credence to these hypotheses and have revealed that the three diploid genomes underwent gene fractionation. Subsequent hybridization between the three diploid species led to the evolution of the three allopolyploid species of U's triangle (UN 1935).

The genomes of all the species of the U's triangle have now been sequenced, and the resulting data on genomic and genic sequences is freely available in public databases, including NCBI, *Brassica*DB (http://brassica.nbi.ac.uk/BrassicaDB/),

Brassica.info (http://www.brassica.info/), and the *Brassica* database (BRAD; http://brassicadb.cn). BRAD also includes the genome assembly of *B. juncea* var. Tumida (Yang et al. 2016) along with 25 other species of Brassicaceae and provides their syntenic relationships to the genes in *Arabidopsis* (Chen et al. 2022). Since there is a close phylogenetic relationship between the species of Brassicaceae, these resources could be useful for the identification of candidate genes for different agronomic and nutritional traits using comparative genomics. The recently published, highly contiguous genome assembly of an Indian oleiferous line – Varuna (Paritosh et al. 2021) – would be of immense value to dissect the QTL for different agronomic and nutritional traits mapped previously in *B. juncea* (Ramchiary et al. 2007; Panjabi-Massand et al. 2010; Yadava et al. 2012; Padmaja et al. 2014; Dhaka et al. 2017; Rout et al. 2018). Recently, Kang et al. (2021) have also published a contiguous assembly of a yellow-seeded *B. juncea* var. Sichuan Yellow (SY) and also resequenced 480 global accessions of *B. juncea,* which included accessions from previously defined Indian and East European gene pools (Pradhan et al. 1993; Srivastava et al. 2001) and exotic accessions predominantly from East Asia. These studies provide scope for the use of a wider germplasm to study allelic diversity and would considerably accelerate the translational research in mustard.

Seed is the economically most important product and is the primary source of nutraceutical compounds in oilseed mustard. Recently, Gao et al. (2022) reported a spatiotemporal transcriptome atlas of seed coat and embryo development of six *Brassica* species of U's triangle, including *B. juncea* (AC Vulcan-J). The study revealed differences in the accumulation of storage reserves and fatty acid metabolism among these species, and is of immense value toward understanding the transcriptional dynamics underlying different seed traits. A number of studies have also undertaken a comparative transcriptome profiling of seeds from diverse *B. juncea* lines (Khattak et al. 2019; Shen et al. 2021; Mathur et al. 2022) and provided detailed insights into understanding the biology of these traits.

Additionally, the biosynthesis and degradation pathways of most nutraceutical compounds like fatty acids, glucosinolates, flavonoids, and phenolic compounds have been well characterized in the model plant systems and are freely accessible in databases, including KEGG (Moriya et al. 2007), AraCyc (Mueller et al. 2003), PlantCyc (Grafahrend-Belau et al. 2012), and ARALIP (Li-Beisson et al. 2013), among others, and will be useful in the translational research directed at the improvement of these traits.

13 Social, Political, and Regulatory Issues in the Improvement of Nutraceutical Traits

The transgenic approaches have been successful in the genetic engineering of a number of nutraceutical traits (Table 1), especially for traits for which very low/no variability is reported in the *B. juncea* germplasm limiting the use of conventional breeding approaches, for example, enhancement of GLA and glucoraphanins (Hong et al. 2002; Das et al. 2006; Augustine and Bisht 2015). Additionally, the transgenic

approaches are more efficient, faster, and most importantly avoid the problem of linkage drag. However, their use in edible crops involves a number of ethical, socioeconomic, and regulatory concerns. The technique has been opposed by environmentalists across the world on the grounds of biosafety issues. The genetically modified crops are subjected to regulated field trials and strict biosafety checks before their commercial release. This limits the scope of improvement of nutraceutical compounds in mustard using these approaches. However, a number of countries including India have relaxed the regulatory norms for crops developed using gene-editing approaches like the novel CRISPR/Cas9 system. This would prove to be beneficial for the improvement of traits where gene knockout/allelic conversions/expression changes by modification of promoter sequences result in an altered phenotype. Recent reports have successfully used CRISPR/Cas9 approach to improve nutraceutical (Assou et al. 2022) and yield traits (Wang et al. 2021) in *B. juncea,* which should be seen as a major development in the genetic improvement of mustard.

14 Conclusions and Future Outlook

The enhancement of oil quality and nutritional composition are the major breeding objectives for the improvement of oilseed mustard. Since mustard is the predominant source of edible oil in India, more research initiatives are directed toward the improvement of nutritional value of oil in the Indian mustard lines by the reduction of antinutritive components – erucic acid, linoleic acid, α-linolenic acid, aliphatic seed glucosinolates, and sinapine, accompanied with the biofortification of nutraceuticals – oleic acid, glucoraphanin, sinigrin, GLA, tocopherols, among others, to enhance the nutritive value of mustard oil. Extensive research has been undertaken for molecular mapping of these traits in mustard; however, the QTL mapping studies have predominantly exploited the genetic diversity between the Indian and East European gene pools only. The availability of genome sequence information of a large number of global accessions of *B. juncea* could now be exploited in conjunction with the high-throughput genotyping platforms and large-scale phenotyping experiments can be undertaken for studying the extent of allelic diversity and identification of novel variants for these traits in a wider germplasm. Furthermore, the availability of genome sequences of the East European and Indian gene pool lines of *B. juncea* could also be used to identify the genes underlying the QTL identified for these traits using candidate gene approaches. Moreover, the availability of genome and comparative seed transcriptome data of all the species of U's triangle will tremendously aid the translation of information available in these crops to enhance the nutraceutical traits in *B. juncea* using comparative genomics. Further, the recent advancements in the optimization of the protocols for gene editing using CRISPR/Cas9 in both East European and Indian *B. juncea* lines appear promising in expediting the targeted improvement of quality traits in mustard with relatively fewer biosafety concerns. Therefore, there is a constant need to identify suitable target genes to leverage the immense potential of these resources for the

improvement of *B. juncea*. Finally, studies need to be undertaken to identify and characterize other compounds with a potential nutraceutical value in *B. juncea* to enhance its food and seed meal quality.

minerals, and natural antioxidants, such as sesamin, sesamolin, and tocopherols. Sesame is consumed directly as the edible seed and oil and applied for nutrition and medicine industry as the functional food and nutraceuticals because of its anti-oxidative, anti-inflammatory, hypolipidemic, cardioprotective, neuroprotective, and anticarcinogenic effects. In the past four decades, a great deal of new sesame varieties with high-yield potential and elite agronomic traits including the high resistance to biotic and abiotic stresses and the high content of seed nutrients were bred through high-efficient breeding techniques and released for sesame industry. Achievement of the Sesame Genome Project with huge amount of sesame genomic data impedes the rapid development of genomics and molecular genetics research in sesame. As a result, a list of invaluable genetic resources, including molecular makers, genetic maps, quantitative trait loci (QTLs), and functional genes, were detected to decipher the genetic basis of the especially nutrition-related traits and improve the molecular breeding strategies for sesame. We herein summarize the available information about sesame nutraceutomics and molecular breeding research. We systematically introduced the technological progresses mainly in new germplasm creation, highly efficient marker-assisted breeding, and genetic transformation for sesame and forecasted the development of sesame nutrition mechanism studies so as to meet the consumer's demands.

1 Introduction

Sesame (*Sesamum indicum* L., 2n = 26) belongs to the *Sesamum* genus of the Pedaliaceae family and is the sole cultivated species in *Sesamum*. Sesame is an ancient oilseed crop with high oil quality. Its domestication and cultivation history could be traced back to the Harappa and Anatolian eras on the Indian subcontinent 5000 years ago (Bedigian 2003). At present, sesame is widely planted in the tropical and subtropical regions of Africa, Asia, and Southern America (Pathak et al. 2017). In 2020, the total harvest area of the world sesame reached 13.97 million hectares. The total product was 6.8 million tons, while the average yield was low at 487.2 kg per hectare for the low production technology in the main production countries (Table 1) (FAOSTAT, 2020). During the past decade, the total production of the world sesame was consistently rising mainly due to the contribution of harvest area increase especially in Africa (FAOSTAT, 2011–2020).

Sesame is a traditional and manually produced crop, but meets the continuous global demand for high-quality vegetable oils during the past decades. On the other hand, sesame plays an important role as a cash crop in the development of local economy and cultivation structure (Zhang et al. 2021a) as the major production countries, including Sudan, Myanmar, Tanzania, India, Nigeria, and China are developing countries (Table 1). In 2020, 7 of the top 10 sesame production countries

Table 1 Sesame production statistics of the world and the top 10 production countries in 2020

Country	Area harvested (ha)	Production (tons)	Yield (kg/ha)
World	13,965,844	6,803,824	487.2
Sudan	5,173,521	1,525,104	294.8
Myanmar	1,500,000	740,000	493.3
Tanzania	960,000	710,000	739.6
India	1,520,000	658,000	432.9
Nigeria	621,413	490,000	788.5
China	278,652	449,452	1613.0
Burkina Faso	450,000	270,000	600.0
Ethiopia	369,897	260,258	703.6
Chad	392,241	202,074	515.2
South Sudan	608,159	189,721	312.0
Others	2,091,961	1,309,215	625.8

The data are cited from FAO dataset (www.fao.org/statistics/en/)

were from Africa. Sudan was the biggest sesame producer, while China presented the highest yield level in the world.

Sesame is traditionally produced for edible seed production and oil crash. Sesame seeds contain high oil content (~55%), and the monounsaturated and polyunsaturated fatty acid compose more than 80% of the oil. Besides plenty of fatty acids, abundant proteins and dietary fibers, various vitamins and minerals and natural antioxidants, such as sesamin, sesamol, sesamolin, and tocopherol derivatives improve the quality of sesame seeds and oil (Anilakumar et al. 2010; Pathak et al. 2017). Sesame seeds have been regarded as "the queen of oilseed crop seeds" as possessing the abundance of nutrients. Many reports have demonstrated that the specific unsaturated fatty acids with lignans in sesame seeds have the health-promoting effects on preventing cardiovascular diseases, suppressing age-related neurodegenerative diseases, reducing the incidence of cancer, and improving wound healing, because of their antiatherogenic, antithrombotic, anti-inflammatory, hypolipidemic, cardioprotective, neuroprotective, antiaging effects, and antioxidative activity (Shenoy et al. 2011; Ray and Katyal 2016; Pathak et al. 2017; Andargie et al. 2021; Langyan et al. 2022). Thus, sesame is being used as the functional food and nutraceuticals on account of the specific health-related properties. In addition, main chemical composition of sesame is also applied as pharmaceutical substances, antifungal, insecticides antiseptics, disinfectants, and cosmetics, even as biofuel in pharmaceutic and industrial areas (Pathak et al. 2017; Zhang et al. 2021a).

Sesame originated in Africa as most of the wild relatives of cultivated sesame are found in the African continent (Nimmakayala et al. 2011; Zhang et al. 2021b). An Indian wild species *S. malabaricum* (2n = 26) has been regarded as the closest species to *S. indicum* and might be the direct progenitor of sesame (Bedigian 2003; Andargie et al. 2021; Zhang et al. 2021a). In the past decades, sesame is regarded as an orphan crop (Dossa et al. 2017). One reason is that the belonged small Pedaliaceae family of sesame is remote from other big families with oilseed crops,

such as Cruciferae (oilseed rape), Asteraceae (sunflower), and Fabaceaae family (soybean and peanut) in the plant phylogenetic relationship (Zhang et al. 2013). Few related species could be directly used as references for sesame genetics and breeding research. The second is that the genetic basis of sesame is relatively narrow as sesame is the sole cultivated species in the *Sesamum* genus. Increasing the yield potential with high resistance to biotic and abiotic stresses seems too difficult for sesame in the near future. At present, sesame contributes only about 1% of the global oilseed production and the competition capability with other major oilseed crops including rapeseed, soybean, peanut, and sunflower is still low. However, elite agronomic traits and the specific species characteristics determine the important academic position of sesame. Long cultivation history indicated the specific phylogenetic position of sesame in plants. The small genome size (~369 Mb) (Zhang et al. 2013) close to rice and relatively simple genome structure facilitates the genomics analysis of sesame and the wild *Sesamum* species. Moreover, high oil content and seed quality, rapid growth, and abundant seeds of a progeny also help to perform genetics and breeding research in sesame. Thus, sesame is regarded as a model of oilseed crop for its academic importance (Zhang et al. 2019).

In recent years, numerous studies have been implemented to improve agronomic traits and production through traditional and modern breeding methods in sesame. Especially, with the complete genome sequencing and the release of enormous genomic resources, sesame research has been led into the "Omics" era since 2013 (Dossa et al. 2017; Wang et al. 2014; Wei et al. 2015; Zhang et al. 2013; Zhang et al. 2021a). So much invaluable molecular resources, including omics data, genome information, molecular markers, and functional genes, are being applied to decipher the genetic basis of the seed yield and quality traits and to speed up sesame variety improvement. Thus, in this chapter, we give a systematical account of sesame nutritional compounds and their related genetic bases and regulation mechanisms. We summarize the main theoretical and technological achievements in sesame seed quality breeding. Some updated data and unpublished information obtained in the past a few years are shown in the chapter so as to facilitate readers understanding the key topic points.

2 Nutrient Components in Sesame

Sesame is the highest oil content in annual herbs. In sesame seed, the main nutrients include oil, protein, edible fibers, vitamins, antioxidants, and other components for providing energy and health-related nutrient (Prakash and Naik 2014). For the diverse sesame germplasm under different cultivation conditions, the oil and protein contents vary from 29.5–62.7% and 12.9–31%, respectively (Anilakumar et al. 2010; Zhang et al. 2021). The contents of lignans, mainly including sesamin and sesamolin, range from 0.517 to 15.832 mg/g, which can keep sesame oil stable and high quality (Zhang et al. 2021a). In addition, the carbohydrates also present in sesame seeds with the highest content of 17.4%. The digestible fiber content is high at 9.8% and exists mainly in sesame seed hull. Noticeably, the polysaccharide takes

up the total seed weight of 6.5%, which are mainly composed of galacturonic acid, glucuronic acid, rhamnose and glucose, and possesses the antioxidant activity (Zhang et al. 2022). Moreover, sesame seed contains abundant vitamins, such as pantothenic acid, vitamin E, folic acid, lactochrome (B2), niacin, thiamine (B1), and vitamin C. Sesame seeds and leaves also are excellent sources of minerals, such as magnesium, potassium, calcium, copper, iron, zinc, and selenium (Zhang et al. 2021a).

With the above beneficial nutritional composition, sesame seeds are widely used to produce raw or roasted sesame seeds, sesame oil, sesame paste, sesame flour, confectionery, and bakery ingredient for food production. In specific regions, sesame products also exhibit the local food culture. In China, sesame oil is even used as a substitute for olive oil. Sesame meal with the high protein content is consumed as an important food in India. Tahini, a paste made from roasted hulled sesame seeds, is used as a traditional sugar ingredient in Eastern Asia.

2.1 Sesame Oil Composition

Sesame oil is composed of more than 95% triacylglycerols and a small amount of diacylglycerols, free fatty acids, phospholipid, and unsaponifiables (Tzen 2021). Of the sesame oil, oleic acid (C18:1) (~40%) and linoleic acid (C18:2) (~46%) are the two main unsaturated fatty acids and reach up to 85%. The other polyunsaturated fatty acid linolenic acid (C18:3) (~0.4%) and saturated fatty acids including palmitic acid (C16:0) (~8%), stearic acid (C18:0) (~6%), arachidic acid (C20:0) (~0.4%), and behenic acid (C22:0) (~0.6%), comprise about 15% (Anilakumar et al. 2010; Zhang et al. 2019; Langyan et al. 2022). Accorded with the recommendation for low saturated fatty acid level for human health by the World Health Organization (WHO), sesame oil could be regarded as an ideal vegetable oil. The rich unsaturated fatty acids in sesame oil can help prevent cardiovascular diseases, such as arteriosclerosis, by lowering cholesterol and elevating the level of high-density lipoprotein in human blood (Langyan et al. 2022). Of the unsaturated fatty acids, linoleic acid (C18:2) and α-linolenic acid (C18:3) are the essential fatty acids for human body, but cannot be synthesized by itself. Linoleic acid (C18:2) has been proved to inhibit malignant melanoma growth (Smith and Salemo 1992), while α-linolenic acid (C18:3) and its metabolites play vital roles in the visual and brain development in infants and have beneficial effects on suppressing Alzheimer's disease in the aged (Hashimoto and Hossain 2011). In addition, oleic acid (C18:1) with the presence of natural antioxidants in sesame seeds characterized high oxidative stability of the oil. In recent years, breeding new varieties with the high oleic acid (C18:1) content have been a key objective for sesame.

2.2 Sesame Seed Protein and Amino Acid Composition

Sesame seed protein mainly comprises insoluble 11S globulin (α-globulin) (60–70%) and soluble 2S albumin (β-globulin), as well as minor 7S globulin.

The top two protein fractions account for 80–90% of the total protein. In sesame, 11S globulin is the most abundant seed storage protein and presents as a hexamer (300–350 kDa) formed by random assembly of several 11S globulin isoforms (Plietz et al. 1986). Compared with that of soybean, 11S globulin of sesame has the similar subunit structure, but shows more hydrophobic properties. Thus, the solubility, gelation properties, and emulsification capacities of sesame protein are diverse from other crops during food processing (Tzen 2021).

Sesame protein contains 18 types of amino acids, and glutamic acid (4.21%) and arginine (2.79%) are the two main amino acids (Zhang et al. 2021a). Of these, the essential amino acids for human health comprise 31.4% content of total amino acids. Except for lysine, the content of other amino acids in sesame is close to or exceeds the values of high-quality protein from beef and milk recommended for dietary requirement by the Food and Agriculture Organization (FAO) and WHO. Particularly, sesame contains high content of sulfur-containing amino acids, methionine, and cysteine, all of which are attributed mainly to 2S albumin and partly to 11S globulin (Tzen 2021). Thus, the nutritive compositions of sesame protein exhibit the wide usage as food additives for increasing the nutritional quality and food product price. However, the intrinsic property of sesame protein, mainly high hydrophobicity of 11S globulin, does not favor fluid and beverage processing (Anilakumar et al. 2010). After oil crushing, most sesame proteins and cakes are directly processed as animal food or agricultural fertilizer. New more processing techniques should be innovated to increase the nutritional value of sesame protein source.

2.3 Antioxidants

As a specific oilseed crop, sesame is not only used traditionally as a health food, but also as a medicine to prevent diseases. In ancient Chinese pharmacopeia, black sesame seeds were recorded as the medicine and tonic. In Ayurvedic of India, sesame oil was used for external administrations to provide health benefits and treat specific indications (Lahorkar et al. 2009). Current studies point out that the health-promoting properties of sesame are mainly attributed to the antioxidant activity of several bioactive components such as tocopherols and lignans (Andargie et al. 2021; Zhang et al. 2021a).

Tocopherol is one of the important lipid-soluble antioxidants and is mainly present in vegetable oils. Since its discovery as an essential nutrient for reproduction in rats in 1922, tocopherol has been demonstrated to have the effects on scavenging free radicals generated during lipid peroxidation and other radiation-induced oxidation, and thus play a role in preventing chronic diseases such as cardiovascular disease, arteriosclerosis, and cancer (Brigelius-Flohé and Traber 1999; Herrera and Barbas 2001). Tocopherol has four derivative forms, that is, α, β, γ, and δ. Of these, α-tocopherol is the predominant form in nature and presents the highest biological activity by fetal resorption assays (Brigelius-Flohé and Traber 1999). In sesame oil, the content of tocopherol reaches 0.45 mg/g, with 90.5% γ-tocopherol and traces of α-tocopherol and δ-tocopherol (Langyan et al. 2022). In contrast to α-tocopherol

with the oxygen radical scavenging, γ-tocopherol may prevent peroxynitrite-dependent lipid, protein, and DNA damage in the cell (Brigelius-Flohé and Traber 1999). Further reports also showed that γ-tocopherol possesses anti-inflammatory effect by inhibiting cyclooxygenase activity but independent of oxidative activity (Jiang et al. 2000). Moreover, γ-tocopherol and lignans have been found to act synergistically by the intake of sesame seeds to enhance vitamin E activity, which is related to its potential protective effect against cardiovascular disease and cancer (Yamashita et al. 1992).

Lignans are plant phenolic metabolites formed from two molecules of phenylpropanoids. In sesame, lignans are comprised of sesamin, sesamolin, sesaminol, sesamolinol, pinoresinol, sesamol, lariciresinol, matairesinol, piperitol, episesamin, episesaminone, and samin (Andargie et al. 2021). Sesamin and sesamolin are the major lignan components. The contents of that in sesame seeds vary significantly among varieties of sesame accessions (Andargie et al. 2021; Zhang et al. 2021a; Langyan et al. 2022) (Table 2). Sesamin and sesamolin belong to the furofuran family and present in sesame oil, while other minor lignans are grouped into furofuran, tetrahydrofuran, and butyrolactone class. Pinoresinol and sesaminol are mainly present in mono-, di-, and triglycosylated forms. Mono glycosylated lignans are oil-soluble, while diglucoside and triglucoside isoforms are water-soluble.3.

In sesame, the biosynthesis process of lignans, including (+)-sesamin, (+)-sesamolin, and (+)-sesaminol, has been well studied (Fig. 1). Two molecules of coniferyl alcohol from phenylpropanoid metabolism pathway are initially converted to (+)-pinoresinol (a central precursor of lignans) by stereo-selective radical coupling reaction. (+)-sesamin is subsequently formed through sequential oxygenation of (+)-pinoresinol by a cytochrome P450 monooxygenase CYP81Q1 (Ono et al. 2006). Further, CYP92B14, another P450 enzyme, converts (+)-sesamin into (+)-sesamolin and (+)-sesaminol through oxidative rearrangement of α-oxy-substituted aryl groups (Murata et al. 2017). In contrast to the native lignans in sesame seeds, several specific lignans form during seed roasting and sesame oil refining and bleaching. For instance, sesamol is produced from sesamolin by hydrolysis under heating and bleaching with acidic clay, thus is found to have a relatively high content in roasted seed oil but not in unroasted seeds and raw oil (Andargie et al. 2021). The bleaching process converts sesamolin into sesaminol, and also catalyzes the epimerization of sesamin to form episesamin (Fukuda et al. 1986). Differing from sesamin and sesamolin with no or weak antioxidative activity, the converted sesaminol and sesamol are potent antioxidants due to their free phenolic groups (Wan et al. 2015). Therefore, it is considered that the content of antioxidative lignans in sesame products could be raised by the processing such as roasting.

Numerous reports have demonstrated that lignan-rich sesame products as functional nutrients play important roles in preventing diseases. Apart from fatty acids and tocopherols, the sesame lignans, mainly sesamin, sesaminol, sesamol, and sesaminol, attract the most interest of nutritionists, health professionals, even pharmacologists due to their in vitro and in vivo biological activities and therapeutic benefits, including antioxidative, anticancer, anti-inflammatory, anti-hypercholesterolemic, neuroprotective, hepatoprotective, and cardioprotective effects (Table 2).

Table 2 Physical characteristics, content, and main biological functions of sesame lignans, sesamin, sesamolin, sesamol, and sesaminol

Sesame lignan	Molecular formula	Molecule size	Content in seeds (mg/100 g)	Biological function
Sesamin	$C_{20}H_{18}O_6$	354.35	20–1060	Antioxidative and radical scavenging activity in vivo Increasing γ-tocopherol levels in plasma and liver Decreasing blood glucose level and improving body weight and blood pressure Attenuated endothelial dysfunction correlated with cardiovascular diseases Lowering the serum lipid Acting with α-tocopherol synergistically to lower cholesterol level Exerting the antinociceptive and anti-inflammatory effects Protecting kidney against lipid peroxidation and prevent inflammation Protecting liver against ethanol- and carbon tetrachloride-induced damage Suppressing inflammation-induced neurodegeneration Preventing apoptotic cell death and microglial activation Alleviating depression-like behavior and memory deficits, and suppressing age-related cognitive decline Preventing ischemic stroke Extending the mean lifespan Suppressing age-related disorders of kidney Presenting anticancer activity and inhibiting the proliferation of cancer cells
Sesamolin	$C_{20}H_{18}O_7$	370.35	2.4–752	Antioxidative activity in vivo Alleviating the effect of cerebral ischemia by a mixture of sesamin and sesamolin Prolonging median and mean lifespan, and preventing Alzheimer's disease (sesamin, sesamolin, and sesamol synergistically acting) Inducing apoptosis in lymphoid leukemia cells and colorectal cancer cells, and inhibiting growth of leukemia cells Inhibiting premalignant lesions of colon

(continued)

Table 2 (continued)

Sesame lignan	Molecular formula	Molecule size	Content in seeds (mg/100 g)	Biological function
Sesamol	$C_7H_6O_3$	138.12	0–30	Antioxidative activity both in vivo and in vitro Inhibiting lipid peroxidation and mutagenicity of reactive oxygen species Inhibiting myeloperoxidase Reducing blood pressure, preventing vascular dysfunction and exerting both cardioprotective and hepatoprotective effects Accelerating wound healing, and exerting the antinociceptive and anti-inflammatory effects Protecting kidney against lipid peroxidation and prevent inflammation Presenting neuroprotective and myoprotective effect Improving depression and memory deficits Antiaging effects Presenting anticancer activity and inhibiting the proliferation of cancer cells
Sesaminol	$C_{20}H_{18}O_7$	370.40	0–1.4	Antioxidative activity both in vivo and in vitro Stimulating elastin and collagen production in the skin, and accelerating wound healing Protecting against neuronal apoptosis Protecting skin against photodamage caused by chronic UV exposure Stimulating collagen and elastin production and migration of keratinocytes Inhibited cancer cells in vitro

Source: Andargie et al. (2021), Zhang et al. (2021a), and Langyan et al. (2022)

Major sesame lignans possess both or either in vitro and in vivo antioxidant activity, which accounts for a large part of the health benefits of sesame consumption (Ray and Katyal 2016). For example, sesamin has been reported to protect liver from oxidative damage in vivo, which results from its metabolites with the catechol moieties presenting radical scavenging and antioxidant activities (Nakai et al. 2003). Similar to sesamin, sesamolin has no antioxidant activity in vitro, but presents high superoxide scavenging effects in vivo. After converted from sesamolin, sesamol possesses both in vitro and in vivo antioxidant activity, thus has the effects in inhibiting lipid peroxidation, and mutagenicity of reactive oxygen species and hydroxyl radical-induced DNA damage (Joshi et al. 2005). In addition, sesamin

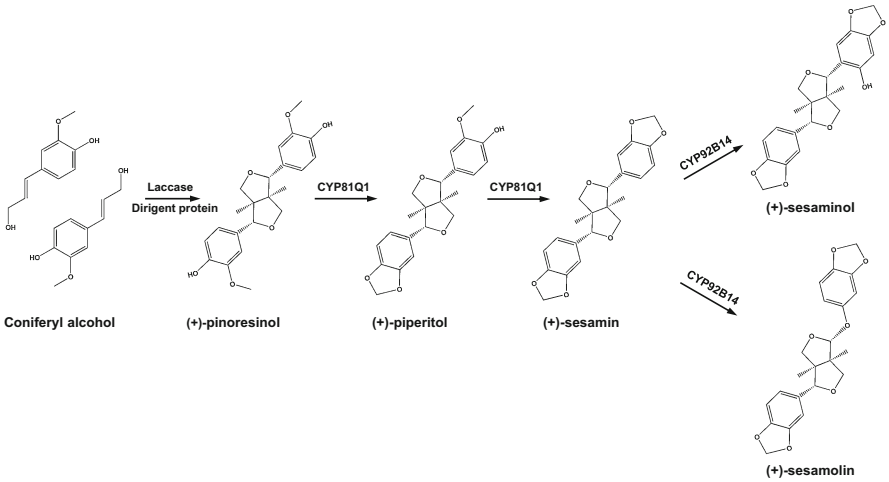

Fig. 1 The biosynthesis pathway of lignans in sesame from (+)-pinoresinol to (+)-sesamolin and (+)-sesaminol

exerts indirectly antioxidant effects via the inhibition of the catabolism of tocopherol (Parker et al. 2000). The effect of the intake of sesamin actually increases the level of tocopherol in vivo, which is the physiological antioxidant mentioned above.

Some reports indicated that sesame lignans were likely responsible for prevention and treatment of neurodegenerative diseases such as Parkinson's and Alzheimer's disease and multiple sclerosis (Ray and Katyal 2016), which were in part attributed to oxidative damage. Amelioration of oxidative stress by supplying sesame lignans was demonstrated to delay the aging of aerobic organisms (Zuo et al. 2013). Sesame lignans also have the effects on prevention of cardiovascular diseases by lowering the levels of lipogenesis, blood pressure, and cholesterol (Andargie et al. 2021). In addition, sesame seed and sesame oil were found to possess wound-healing activity, while sesamin and sesamol were accounted for a part of the effect (Shenoy et al. 2011; Monteiro et al., 2014). Remarkably, the anticancer activity of sesame lignans, mainly sesamin and sesamol, has been extensively tested in tumor cell lines and animals, and the positive effects were acted to inhibit the proliferation of lung, prostate, breast, cervical, colon, liver cancer, skin papillomas, and leukemia cells (Langyan et al. 2022). Recently, the therapeutic benefits of sesame lignans have been comprehensively reviewed in detail (Andargie et al. 2021; Langyan et al. 2022). We expect sesame lignans to be applied for further pharmacological and clinical studies with regard to their physicochemical properties and biological activities.

3 Genetic Resources and Nutrition-Related Traits

According to data statistics, about 20,000 sesame germplasm resources from the world are collected and reserved in sesame germplasm reservoirs mainly in South Korea, India, China, the United States, and some African countries now. Substantial

evidence indicated that the content range of oil, protein, and other nutrients in sesame seeds is evidently huge among the diverse germplasm accessions and exhibits the contribution of both genotype and environment (Tashiro et al. 1990; Li et al. 2014). For hundreds of the world sesame germplasm, the content of oil and protein ranges from 27.9% to 59.8% and 16.7% to 31%, respectively (Li et al. 2014).

To rapidly and concisely evaluate the content of sesame nutrients in seeds, the near-infrared reflectance spectroscopy (NIRS) method has been applied to establish evaluation standard curves and evaluate the contents of oil, protein, fatty acid components, lignan, edible fiber, and polysaccharide, respectively, in sesame seeds (Yuan et al. 2022). With the aid of evaluation platform, Sesame Research Center, Henan Academy of Agricultural Sciences (HRSC, HAAS) evaluated the content of oil, protein, the main fatty acid components of the 857 sesame germplasm planted in Hainan, Henan, and Yuanmou of China in 2019 (Table 3) (unpublished data). Evident variation is presented in oil and protein content. Meanwhile, the contents of palmitic acid (C16:0), palmitoleic acid (C16:1), stearic acid (C18:0), oleic acid (C18:1), linoleic acid (C18:2), and linolenic acid (C18:3) also fluctuated with genotypes and environments. The assayed results of 126 sesame germplasm by the NIRS method showed that their content of oleic acid, linoleic acid, palmitic acid, and stearic acid ranged from 35.1–51.8%, 31.6–47.8%, 7.2–11.3%, and 4.4–7.7%, respectively (Yuan et al. 2022).

As regards the contents of antioxidant, Tashiro et al. (1990) analyzed the 42 sesame accessions from Japan and detected that the contents of sesamin and sesamolin varied from 0.07 to 0.61 mg/g oil and 0.02 to 0.48 mg/g oil, respectively. Rangkadilok et al. (2010) investigated the sesame accessions from Thailand and found that the mean content of sesamin and sesamolin was 1.55 mg/g and 0.62 mg/g seed, respectively, and the total tocopherols was 50.9–211 μg/g seed. While the ranges of sesamin, sesamolin, and tocopherol contents were 0.93–2.89 mg/g, 0.30–0.74 mg/g, and 0.30–0.65 mg/g in commercial sesame oils. The extensive variability in sesamin, sesamolin, and tocopherol contents demonstrated the nutrition variation of different sesame products. Wang et al. (2013) analyzed sesamin and sesamolin contents of the 62 sesame cultivars from China using high-performance liquid chromatography (HPLC), which showed the sesamin and sesamolin contents ranged from 0.82 to11.05 mg/g and 1.35 to 6.96 mg/g, respectively, and the total sum of sesamin and sesamolin among about 60.0% of the assayed Chinese cultivars varied from 6.0 to 9.0 mg/g. Moreover, some Chinese landraces possessed significantly higher sesamin and sesamolin contents than those of cultivars. The concise phenotypes of sesame nutrients with highly efficient evaluation techniques supply the basis for genetic mechanism analysis of sesame nutrients and application in sesame production.

4 Genetic Diversity Assessment of Sesame Germplasm with Nutrition-Related Traits

Genetic diversity indicates the gene or genome sequence variation of the individuals of a species, which is believed as a key aspect to reflect the evolution of a species and the adaption to environmental stresses. Most of the biological diversity studies in plants focus on both phenotypes and genome variation.

Table 3 Variation of nutrition components of the 857 sesame germplasm under different environments

Seed nutrition	Cultivated location	Maximum content (%)	Minimum content (%)	Average value (%)
Oil	Sanya	61.60	39.73	51.37
	Yuanmou	58.53	40.72	49.47
	Yuanyang	56.84	42.59	50.62
	Average	58.99	41.01	50.49
Protein	Sanya	27.79	15.48	22.21
	Yuanmou	26.73	16.47	23.55
	Yuanyang	27.48	16.43	22.26
	Average	27.33	16.13	22.67
Palmitic acid (C16:0)	Sanya	10.68	2.81	8.03
	Yuanmou	10.09	3.28	7.83
	Yuanyang	15.23	4.66	7.79
	Average	12.00	3.58	7.88
Palmitoleic acid (C16:1)	Sanya	0.16	0.01	0.11
	Yuanmou	0.18	0.01	0.11
	Yuanyang	0.30	0.04	0.12
	Average	0.21	0.01	0.11
Stearic acid (C18:0)	Sanya	7.09	4.33	5.57
	Yuanmou	8.71	4.08	6.35
	Yuanyang	7.86	4.16	5.86
	Average	7.89	4.19	5.93
Oleic acid (C18:1)	Sanya	62.98	32.33	44.20
	Yuanmou	65.45	40.13	49.83
	Yuanyang	57.17	24.24	44.88
	Average	61.87	32.23	46.30
Linoleic acid (C18:2)	Sanya	53.09	32.77	41.40
	Yuanmou	43.86	22.86	35.05
	Yuanyang	51.57	29.70	41.01
	Average	49.51	28.44	39.15
Linolenic acid (C18:3)	Sanya	0.45	0.15	0.28
	Yuanmou	0.52	0.16	0.31
	Yuanyang	0.49	0.18	0.29
	Average	0.49	0.16	0.29
Arachidic acid (C20:0)	Sanya	0.88	0.37	0.63
	Yuanmou	0.93	0.33	0.65
	Yuanyang	0.89	0.38	0.60
	Average	0.90	0.36	0.63

Up to now, extensive studies on the genetic diversity of sesame germplasm have been performed using various molecular markers, such as AFLP, SRAP, ISSR, SSR, EST-SSR, SNPs, and InDels (Wei et al. 2008; Zhang et al. 2010; Zhang et al. 2012; Wu et al. 2014; Wei et al. 2015; Cui et al. 2017; Yadav et al. 2022). Using SSR markers, a genetic diversity survey was conducted in sesame germplasm panel consisting of 545 accessions, including 390 lines from China, 149 lines from 19 other countries, and 6 sesame wild relatives (Yue et al. 2012). As a result, a total of 106 alleles were detected in the germplasm lines. The three major clusters were grouped in an UPGMA tree. The first cluster included 4 sesame wild relatives, and the second cluster consisted of 28 lines that were mainly from Ethiopia, while the third cluster contained the rest of 513 lines. In addition, the genetic diversity study was also conducted with the 366 elite germplasm lines using specific-locus amplified fragment sequencing (SLAF-seq) data (Cui et al. 2017). Of these, 329 lines were from 18 provinces in China, and the rest 37 lines were from 11 other countries. Based on the population structure analysis through STRUCTURE program, 144 and 111 germplasm lines were assigned to the two subgroups, respectively, and the rest 111 lines were in a mixed subgroup. For all of the lines, the sequence diversity (π) of the panel was estimated as 1.1×10^{-3}. The estimates of sequence diversity were 1.0×10^{-4}, 2.7×10^{-4}, and 3.6×10^{-4} for subgroups 1, 2, and the mixed, respectively (Cui et al. 2017).

The large genetic diversity of germplasm means the diversity of various nutrition-related traits in sesame. In fact, nutrition-related traits such as the contents of oil, protein, and lignans vary significantly in sesame germplasm, which provides a foundation for subsequent genetic research on sesame nutrition-related traits. On the other hand, the diversity studies of sesame germplasm with nutrition-related traits showed that the diversity of nutrition-related traits from the same germplasm subgroup could not be clearly distinguished from other subgroups, that is, the germplasm from the same subgroup also contain highly variable nutrition-related traits. For example, in a panel containing the 369 core sesame germplasm, both oil and protein contents significantly varied among the germplasm, reflecting a broad phenotypic diversity and showing no significant correlation with the group structure of germplasm (Li et al. 2014). Thus, further fully exploring genetic variation should be indispensable for applying germplasm and conducting breeding programs.

5 Classical Genetics of Nutrition-Related Traits

Sesame is the sole cultivated species in *Sesamum*. Digging new germplasm and creating new materials with elite traits and genotypes are urgent for improving the sesame genetics and breeding research (Ju et al. 2021). Most nutrition-related traits belong to complex quantitative traits in sesame and other oilseed crops, being affected by both genotype (G) and environment (E). Li et al. (2014) systematically investigated the phenotype variation in a panel of the 369 sesame germplasm and indicated that the oil and protein contents were affected by G and G $\times$ E, and the oil content is negatively correlated with protein content (Wei et al. 2013; Li et al. 2014).

Moreover, the broad-sense heritability value (H^2) of oil content trait was higher than that of protein content, which suggested that the variation of oil content is mainly affected by genotype. For sesame oil content trait, many researchers conduct the classic genetics analysis to explain its genetic variance, and gene actions of the additive, nonadditive types or both interaction were found in different crossing populations (Wei et al. 2021). It meant that the advanced generation selection could not be efficient to improve oil content in sesame variety breeding. Besides, the specific combining ability variance of sesame oil and protein contents was respectively in moderate and high proportions. Especially, there is almost no heterosis in oil content, while protein content showed significant negative heterosis (Murty 1975; Sumathi and Muralidharan 2014).

As regards the fatty acid components, few genetic studies have been performed on sesame because of deficiency of specific germplasm and phenotype data in the early stage. Recently, the genetic character analysis of oleic acid content was performed with the aid of a mutant with a high oleic acid content. The first mutant with a high oleic acid content, named HO995, was created using EMS mutagenesis by HRSC, HAAS in 2017. Its oleic acid content increases up to more than 75% and is significantly higher than the average value of control samples (40%). Genetic background analysis indicated that the oleic acid content for the mutant HO995 is controlled by one incomplete gene pair (unpublished data). Based on the mutant and hybrid breeding technique, Yuzhi HO995, the first sesame variety with a high oleic acid content in the world, was released in China in 2022.

Sesamin and sesamolin contents were significantly and positively correlated with each other (Xu et al. 2020). Their contents are quantitative traits in sesame germplasm accessions and are controlled by a common polygenic system (Usman et al. 2020). However, the classic genetic analysis determined that the sesamin and sesamolin contents fit to an additive-dominant model, and the additive variance exceeded the dominance variance in both contents (Ogata and Kato 2016). In addition, by analyzing the sesamin and sesamolin contents in the 18 sesame cross-combinations, the heterosis of the sesamin and sesamolin contents was found to be mainly mid-parent and mostly negative, while only 5 of 18 combinations present over-high parent heterosis (Xu et al. 2020). Thus, the selection and combination of elite parents should be critical to breed new sesame varieties with high sesamin and sesamolin contents.

Not only significant correlation was determined between lignan contents, but also between lignan contents and other nutrition-related traits. Wu et al. (2017) found the significant positive correlation between the oil and sesamin contents in sesame seeds ($r = 0.608$, $P < 1\%$), but no correlation between the oil and sesamolin contents. In addition, the protein content was considered to be negatively correlated with the sesamin content as the oil content was negatively correlated with protein content. Positive correlation among multiple nutrition-related traits is usually beneficial for breeding high-quality sesame varieties, but the adverse effects of negative correlation should also be carefully considered during the breeding process.

6 QTL/QTN Mapping of Nutrition-Related Traits

To decipher the genetic basis of the seed quality traits in sesame, so many studies of molecular markers discovery, genetic map construction, population association analysis, and quantitative trait locus (QTL) mapping have been performed in the past two decades (Table 4). Wei et al. (2013) analyzed the oil, protein, oleic acid, and linoleic acid content variation of the 216 Chinese sesame accessions using 79 molecular markers. Only marker M15E10–3 was confirmed to associate with the oil

Table 4 Genetic and association mapping of nutrition-related components in sesame seeds

Traits	Marker type	Marker number	Population	Major result	Reference
Oil, protein, oleic acid, and linoleic acid	SRAPs, SSR, AFLP	79	216 germplasm lines from China	Ten markers associated with oil, protein, oleic acid, and linoleic acid concentration were identified	Wei et al. 2013
Oil and protein	SSR	112	369 worldwide germplasm lines	A total of 19 and 24 SSR markers associated with oil and protein contents, respectively, were detected	Li et al. 2014
Mineral-nutrients	SNP, InDel	19,309	149 F_2 lines	A bunch of QTLs significantly associated with Zn, Fe, Cu, Mn, Ca, Mg, K, P, and S concentration were detected	Teboul et al. 2020
Sesamin and sesamolin	SSR	424	548 RILs (F_8)	Sixteen and 10 QTLs associated with sesamin and sesamolin contents, respectively, were detected	Xu et al. 2021
Vitamin E	SNP, InDel	5962	96 core germplasm accessions	LG08_6621957 associated with γ-tocopherol significantly; SLG03_13104062 weakly associated with β-tocotrienol	He et al. 2019
Oil, protein, sesamin, sesamolin, fatty acid, and unsaturated fatty acid	SNP	1,805,413	705 worldwide germplasm lines	Total of 549 associated loci for 56 agronomic traits	Wei et al. 2015

content under two environments. Li et al. (2014) performed an association analysis of oil and protein contents of the 369 worldwide sesame lines using 112 polymorphic SSR markers under multienvironments. A total of 19 and 24 SSR markers were found significantly associated with oil and protein content with the R^2 values of 4–29% and 3–29%, respectively.

In order to mine QTLs associated with the content of mineral-nutrient elements, Teboul et al. (2020) conducted genetic mapping of micronutrient (zinc, Zn; iron, Fe; copper, Cu; and manganese, Mn) and macronutrient (calcium, Ca; magnesium, Mg; potassium, K; phosphorus, P; and sulfur, S) contents with the 149 lines of an F_2 population. Of the mineral elements, Fe concentration was positively correlated with those of Zn, Cu, and Mg. P content was positively correlated with those of Zn, Fe, Cu, Mg, and S, rather than with those of Mn, Ca, and K. A bunch of QTLs significantly associated with Zn, Fe, Cu, Mn, Ca, Mg, K, P, and S were detected, with the explanation of the variance of 7.2–45.7%, 6.1–21.6%, 6.3–30.4%, 7.1–22.2%, 6.1–21.4%, 6.8–12.0%, 7.5–10.7%, 5.9–7.8%, and 7.2–12.5%, respectively.

The sesamin and sesamolin contents vary broadly in sesame germplasm. Some reports reflected that sesamin and sesamolin contents are quantitative traits controlled by polygenes in sesame (Wei et al., 2015; Xu et al., 2021). In order to dig the candidate genes and the potential networks regulated the sesamin and sesamolin content in sesame, Xu et al. (2021) firstly constructed a genetic map with the 548 recombinant inbred lines (RILs, F_8) derived from a cross between ZZM2748 (male parent) and Zhongzhi 13 (female parent). A total of 424 SSR markers distributed in the 13 linkage groups of the genetic map with a total length of 1869.78 cM. As a result, 16 and 10 QTLs associated with sesamin and sesamolin contents, respectively, were detected, with the phenotypic variation explanation (PVE) of 1.15–67.69% and 1.87–46.05%, respectively. Of these, qSmin_3.1, qSmin_9.2, qSmin_11.1, and qSmol_11.1 were detected in the two environments. The loci of qSmin11–1 and qSmol11–1 were detected in the same region, explaining 67.69% and 46.05% of the phenotype variation of sesamin and sesamolin, respectively. Further fine mapping of the loci qSmin11–1 and qSmol11–1 to the reference genome determined that two genes, *SIN_1005755* and *SIN_1005756*, were proposed as the candidate gene involved in sesamin and sesamolin biosynthesis. Meanwhile, He et al. (2019) conducted a GWAS for vitamin E content, composed of β-tocopherol, γ-tocopherol, and β-tocotrienol, using 5962 genome-wide markers acquired from 96 core sesame accessions. Locus LG08_6621957 detected was significantly associated with γ-tocopherol content. The allelic variation of base "G" to "A" resulted in the increase of the average γ-tocopherol content in sesame seeds.

Remarkably, a comprehensive GWAS was executed to reveal the variants associated with the nutrient components, including oil, protein, sesamin, sesamolin, fatty acid, unsaturated fatty acid, and the ratio fatty acid/unsaturated fatty acid among the 705 sesame accessions (Wei et al. 2015). The validation of quantitative trait nucleotides (QTNs) indicated six candidate genes were for seed oil content (SIN_1003248, SIN_1013005, SIN_1019167, SIN_1009923, *SiPPO*/SIN_1016759 and *SiNST1*/SIN_1005755), while

one candidate gene was associated with protein content (*SiPPO*/SIN_1016759). Meanwhile, eight candidate genes (i.e., *SiKASI*/SIN_1001803, *SiKASII*/SIN_1024652, *SiACNA*/SIN_1005440, *SiDGAT2*/SIN_1019256, *SiFATA*/SIN_1024296, *SiFATB*/SIN_1022133, *SiSAD*/SIN_1008977 and *SiFAD2*/SIN_1009785) were for the fatty acid compositions, and one gene *SiNST1*/SIN_1005755 for sesamin and sesamolin content. All the above information provides useful molecular markers and candidate genes for further genetics and breeding research of sesame seed quality.

7 Discovery of Nutrition-Related Genes

The key genes regulating the fatty acid biosynthesis and metabolism in sesame and other oilseed crops always attract more attention. For sesame, cDNA library screening, homolog gene cloning, fine linkage mapping, genome-wide association studies, and comparative genomic and transcriptomic analysis have been applied to dig functional genes-related nutrient traits (Table 5). With the aid of genomic resources, more than a dozen functional genes related to the oil content and antioxidant biosynthesis have been identified in sesame. To reveal its genetic basis of high oil content, the FA gene families and comparative genomic analysis were executed between sesame and other oilseed crops (Miao et al. 2021b). Sesame has unexpectedly lower gene copy numbers (708) of the lipid-related genes compared to soybean (1298), five lipid-related gene families were found to significantly expand and two lipid degradation-related families were contracted in sesame (Wang et al., 2014). Among these families, the transfer protein type 1 (LTP1) genes had the functional activities in lipid biosynthesis according to transcriptome analyses, which suggested their potential role in high oil accumulation in sesame seeds (Wang et al., 2014). Furthermore, genome-wide sequence analysis indicated that two genes *SiLTPI.23* and *SiLTP1.28* integrated the *SiLTPs* expression profiles and were related to the variation of oil content in sesame varieties. Ectopic expression of *SiLTP1.23* in *Arabidopsis thaliana* proved that the gene played the important role in significant increase of oil content and regulation of the ratio of fatty acid compositions in developing seeds (Song et al. 2021). In addition, three genes, SINPZ1100015 (NAC domain-containing protein 43), SINPZ1201700 (trehalose-phosphate synthase I, *SiTPS1*), and SINPZ1201748 (3-oxoacyl-[acyl-carrier-protein] synthase I, *SiKAS1*), were significantly associated with the oil and fatty acid contents under all three environments by GWAS (Zhou et al. 2022). For SINPZ1100015, an allele variation of "C" to "A" resulted in the significant increase of the palmitic acid (C16:0) and linolenic acid (C18:3) contents, but decrease of the oil content in sesame seeds. For *SiTPS1* and *SiKAS1*, the allelic SNP variations from the reference base "A" to "T" and "C" to "A," respectively, were related to the reduction in the palmitic acid (C16:0) content. The above three genes were significantly and highly expressed during the seed development in sesame varieties with high oil content. Overexpression of *SiTPS1*in *Arabidopsis* also exhibited a significant increase in the oil, palmitic acid (C16:0) and oleic acid (C18:1) contents, and the reduction in the

Table 5 Genes related to the oil content and lignan biosynthesis in sesame

Gene	Protein	Function	Trait	References
SiLTP1.23	Nonspecific lipid-transfer protein	Increasing the oil content and regulating fatty acid composition metabolism	Oil biosynthesis	Song et al. 2021
SiLTP1.28	Nonspecific lipid-transfer protein	Involved in fatty acid metabolism	Oil biosynthesis	
SINPZ1100015	NAC domain-containing protein 43	Involved in the fatty acid metabolism	Oil biosynthesis	Zhou et al. 2022
SINPZ1201700/ *SiTPS1*	Trehalose-phosphate synthase I	Maintains fatty acid composition through palmitic acid, oleic acid, and linoleic acid metabolism	Oil biosynthesis	
SINPZ1201748/ *SiKAS1*	3-Oxoacyl-[acyl-carrier-protein] synthase I	Maintaining fatty acid composition through palmitic acid biosynthesis	Oil biosynthesis	
SeFAD2	Oleic acid desaturase	Catalyzing desaturation of oleic acid to linoleic acid	Fatty acid biosynthesis	Jin et al. 2001
CYP81Q1	Cytochrome P450 monooxygenase/ piperitol/sesamin synthase	Converting (+)-pinoresinol to (+)-sesamin through two consecutive oxygenation	Sesamin biosynthesis	Ono et al. 2006
CYP92B14	Cytochrome P450 monooxygenase	Converting (+)-sesamin to (+)-sesamolin and (+)-sesaminol	Sesamolin biosynthesis	Murata et al. 2017

UGT71A9	UDP-sugar-dependent glucosyltransferases	Glucosylating at the 2-hydroxyl group of (+)-sesaminol to produce sesaminol monoglucoside	Sesaminol glucosylation	Noguchi et al. 2008
UGT94D1	UDP-sugar-dependent glucosyltransferases	Catalyzing β1 → 6-O-glucosylation of sesaminol glucosides and preferring sesaminol monoglucoside as a substrate	Sesaminol glucosylation	
UGT94AG1	UDP-sugar-dependent glucosyltransferases	Catalyzing the β1 → 2-O-glucosylation of sesaminol glucosides to form sesaminol triglucoside	Sesaminol glucosylation	Ono et al. 2020
UGT94AA2	UDP-sugar-dependent glucosyltransferases	Catalyzing β1 → 6-O-glucosylation of sesaminol glucosides and preferring (+)-sesaminol 2-O-β-d-glucosyl-(1 → 2)-O-β-d-glucoside as a substrate	Sesaminol glucosylation	
LOC105172736/ *SinPRL2*	Bifunctional pinoresinol-lariciresinol reductase	Converting pinoresinol to lariciresinol and subsequently lariciresinol to secoisolariciresinol	Lariciresinol and secoisolariciresinol biosynthesis	Andargie et al. 2021
SiWRKY67	WRKY transcription factor	Regulating melatonin content	Melatonin biosynthesis	Wang et al. 2022

linoleic acid (C18:2) content. Thus, *SiTPS1* was considered a key regulator of fatty acid biosynthesis and triacylglycerols formation in sesame (Zhou et al. 2022).

In plants, *FAD2* and *FAD6* function respectively for endoplasmic reticulum- and plastid-derived ω-6 fatty acid desaturases (FAD), which catalyze desaturation of oleic acid to linoleic acid (C18:2). The sesame *SeFAD2/FAD2*, essential for the biosynthesis of polyunsaturated fatty acids, was obtained from the cDNA library by the homolog sequence alignment and synthesized in developing seeds using RT-PCR (Jin et al. 2001). *SeFAD2* transcripts were regulated by an intron-mediated regulatory mechanism. Some reports showed that the other two genes *SebHLH* and *SeCKI* enhanced the expression of *SeFAD2* via the *SeCKI-SebHLH-SeFAD2* pathway, in which *SeCKI* phosphorylated *SebHLH* transcription factor, and phosphorylated *SebHLH* subsequently mediated trans-activation of the *SeFAD2* promoter (Kim et al. 2007; Kim et al. 2010). These lipid-related genes are the essential resources for genetic improvement of high oil content and suitable fatty acid composition in sesame.

Besides the oil content, the variation of antioxidants content in sesame attracts more attention for the contribution to oil quality and health-promoting properties. Till now, the biosynthesis pathways of sesame lignan have been comprehensively reviewed (Andargie et al. 2021). Several genes, including *CYP81Q1*, *CYP92B14,* and UDP-sugar-dependent glucosyltransferases (UGT), have been identified to involve in the metabolic pathway of sesame lignans (Table 5). *CYP81Q1* encoding a cytochrome P450 monooxygenase was screened from a sesame seed cDNA library with probe mixtures of cytochrome P450 genes. The consistent expression patterns were correlated with the accumulation pattern of (+)-sesamin during seed development. Further studies demonstrated that *CYP81Q1* played a role as a piperitol/sesamin synthase in the conversion of (+)-pinoresinol to (+)-sesamin through two consecutive oxygenation processes (Ono et al. 2006). Another P450 monooxygenase gene *CYP92B14* was located in a RAD-seq genetic map with a sesame RIL lines (F_6 generation) derived from the cross of a (+)-sesamolin-deficient accession #4294 and a high (+)-sesamolin content cultivar ITCFA2002 (Murata et al. 2017). The results proved that CYP92B14 was responsible for the conversion of (+)-sesamin to (+)-sesamolin and (+)-sesaminol through oxidative rearrangement of α-oxy-substituted aryl groups. In the allele of *CYP92B14* from #4294, the insertion of "T" resulted in the lack of four C-terminal amino acids and finally led to the deficiency of (+)-sesamolin. Differing from the function of *CYP92B14* and *CPR1*, co-expression of *CYP81Q1* with *CYP92B14* and *CPR1* in yeast increased the amount of (+)-sesaminol and (+)-sesamolin. The results suggested there exists functional cooperation between *CYP81Q1* and *CYP92B14* (Murata et al. 2017).

In addition, two UGT genes, *UGT71A9* and *UGT94D1*, were identified and screened from a cDNA library according to the lignan glucosylating activity (Noguchi et al. 2008). The other two distinct UGT genes, *UGT94AG1* and *UGT94AA2,* were obtained based on the transcriptomic co-expression and enzymatic characters (Ono et al. 2020). *UGT71A9* glucosylated at the 2-hydroxyl group of (+)-sesaminol to produce sesaminol monoglucoside, while UGT94AG1 catalyzed the β1 → 2-O-glucosylation of sesaminol glucosides to form finally sesaminol

triglucoside. In sesame seeds, *UGT94D1* and *UGT94AA2* showed coordinated spatio-temporal expression pattern and possessed the redundant function in displaying β1 → 6-O-glucosylation activity toward sesaminol glucosides during sesaminol triglucoside biosynthesis. More studies showed that UGT94AA2 might prefer (+)-sesaminol 2-O-β-d-glucosyl-(1 → 2)-O-β-d-glucoside as a substrate, while UGT94D1 preferentially glucosylated sesaminol monoglucoside (Ono et al. 2020). The results further suggested that the β-O-glucosylation of sesaminol triglucoside biosynthesis is involved in β1 → 2-O-glucosylation of sesaminol monoglucoside induced by UGT94AG1 and the subsequent β1 → 6-O-glucosylation by UGT94AA2 or β1 → 6-O-glucosylation of sesaminol monoglucoside by UGT94D1, followed by UGT94AG1-mediated β1 → 2-O-glucosylation (Ono et al. 2020).

Melatonin (N-acetyl-5-methoxytryptamine) is another kind of important antioxidant with health-promoting effects and always ubiquitously exists in plants, mammals, and human beings. Among sesame germplasm resources, the content of melatonin varied significantly from 0.04 to 298.62 ng/g (Wang et al. 2022). Through GWAS analysis, a WRKY transcription factor *SiWRKY67* was screened and associated with melatonin content trait in sesame. The transient expression of *SiWRKY67* was correlated with the melatonin accumulation in *Agrobacterium rhizogenes*-mediated sesame hairy roots (Wang et al. 2022). Gene sequence analysis indicated that there was a nucleotide polymorphism of *SiWRKY67* in various sesame accessions. The molecular marker could be applied for high melatonin variety improvement in sesame.

8 Available Genome Resources and Databases

So far, hundreds of sesame varieties have been bred and released in the major production countries by mainly using the traditional breeding techniques (Zhang et al. 2021c). However, the relatively narrow genetic variation basis of germplasm accessions limits the genetics and breeding for sesame. Improving the sesame varieties with more elite agronomic traits seems more difficult. Impelling the molecular genetics and genomics research becomes the necessary solution to expand the genetic basis of key agronomic traits in sesame. With the development of genome sequencing technologies, the sesame genome project was implemented since 2010 (Zhang et al. 2013). Till now invaluable genomic resources were generated and stimulated the progress of sesame genomics and molecular breeding (Zhang et al. 2013; Wang et al. 2014). Particularly, the release of several genome drafts of sesame leads to sesame breeding into a new era.

The genome size of sesame is estimated at about 369 Mb by the flow cytometry data (Zhang et al. 2013). Sesame is considered a potential model of oilseed crop for genetic studies due to the small genome size with other characters including high production, short life cycle, and high adaptability for harsh environments (Wang et al. 2014; Zhang et al. 2019, 2021a). The first draft genome with 293.7 Mb of size for sesame cultivar 'Yuzhi 11' was sequenced by Solexa platform (Zhang et al. 2013). Subsequently, the draft genome was optimized by assembling "ABI3730xL+

Roche/454+ Illumina/Solexa + PacBio SMRT" sequencing data and assisting with the "SNP genetic map + BAC-FISH physical map + Hi-C library data." The final genome draft of 'Yuzhi 11' (version 3) reached 335.2 Mb in size with the 13 pseudo-chromosomes and contained the estimated 31,462 genes (Miao et al. 2021a). In parallel, another genome draft for sesame cultivar 'Zhongzhi 13' was released with 274 Mb in size, encompassing estimated 27,148 genes distributed on 16 linkage groups (LGs) (Wang et al. 2014). Both genome drafts are being applied as reference sesame genomes for the world researchers for genomics and comparative genomics analysis nowadays. Moreover, the other three genome assemblies from two sesame landraces (Baizhima and Mishuozhima) and a cultivar Swetha were also sequenced for sesame genome assembly, which provided more valuable resources for structural, functional, and comparative genomic analyses for sesame (Wei et al. 2016) (Table 6). Based on the above de novo genome assemblies, sesame pan-genome and comparative genomics analysis indicated that there were 12 genes involved in lipid biosynthesis and metabolism were under positive selection, which might contribute to the high oil content in sesame (Yu et al. 2019). Integrating comparative genomic and transcriptomic data indicated that the high genetic diversity of lipid-related genes might be related to the wide variation of sesame oil content (Wang et al. 2014). In addition, the chromosome-scaled genomes of the six wild *Sesamum* relatives, that is, *S. alatum* ($2n = 2x = 26$, 3651), *S. angustifolium* ($2n = 2x = 32$, G01), *S. angolense* ($2n = 2x = 32$, K16), *S. latifollum* ($2n = 2x = 32$, KEN1), *S. calycinum* ($2n = 2x = 32$, KEN8), and *S. radiatum* ($2n = 4x = 64$, G02), were de novo assembled, respectively (Zhang et al. 2021b). Genomes of the key *Sesamum* species supply the precious genome information for sesame genetics and breeding research in the world (Table 6).

Besides the genome sequence resources, massive genome resequencing data for more than 2000 sesame accessions and population lines were obtained and released in the past decade (Wei et al. 2015; Zhang et al. 2016; unpublished data). Based on the released multitude genome sequencing and resequencing data and transcriptomes data, five comprehensive online databases have been set for sesame and referred to the Sesame Genome Project (http://www.sesamegenome.org), Sinbase 2.0 (updated version of Sinbase, http://www.sesame-bioinfo.org/Sinbase2.0), SesameHapMap (http://202.127.18.228/SesameHapMap), SesameFG (http://www.ncgr.ac.cn/SesameFG), and SisatBase (http://www.sesame-bioinfo.org/SisatBase). The four public databases, viz., NCBI (http://www.ncbi.nlm.nih.gov/genome/?term=sesame), ocsESTdb (http://www.ocri-genomics.org/ocsESTdb/index.html), PTGBase (http://www.ocri-genomics.org/PTGBase/index.html), and PMDBase (http://www.sesame-bioinfo.org/PMDBase), include sesame genomic resources at the same time.

With the aid of sesame genome databases, studies of molecular marker development, genetic diversity and variation analysis, gene fine-mapping, and genome-wide association studies (GWAS) are being developed accordingly (Wei et al. 2015; Dossa et al. 2017; Murata et al. 2017; Zhang et al. 2016). For example, Sinbase 2.0, a versatile web-based database, including genome, comparative genomes, genetic and phenotype information, supplies an important source to study agronomic

[a]Two versions of genome assemblies for sesame cultivar 'Yuzhi 11' have been released in NCBI

traits regulation in sesame in detail (Wang et al. 2021). A fatty acid biosynthesis and metabolism-related gene database of *Sesamum* species has been locally constructed to reveal the genetic nature of lipid biosynthesis in *Sesamum* (Miao et al. 2021b). The completion of the sesame genome project covering sesame and the six wild species has greatly promoted the progress of molecular genetics and breeding in sesame.

9 Molecular Breeding Strategy for the Development of Nutrition-Related Traits in Sesame

In the past decade, the discovery of so many functional QTLs and genes related to important traits in major crops, such as rice, wheat, corn, and soybean, presents progress in molecular genetics and functional genomics analysis and molecular breeding. For the modern breeding strategy, obtaining appropriate breeding elements including QTLs, genes, and molecular markers associated with the key agronomic traits are the predetermined objective (Zhang et al. 2019). Being an orphan crop, the progress in sesame molecular breeding and -omics research gives more expectation for sesame breeding. Breeding superior sesame varieties with high seed quality is a key goal for sesame breeders. Based on the genomics-assisted breeding in sesame, the Sesame Genome Working Group proposed the scheme of the molecular design breeding for sesame (Zhang et al. 2019; Zhang et al. 2021d). Five major steps are involved in (1) screening and creating elite breeding materials, (2) determining breeding objectives and hybrid crosses, (3) making breeding pipeline and selection strategy, (4) selecting elite progeny with highly efficient marker selection techniques, and (5) breeding superior elite sesame varieties. Thus, improving sesame varieties on nutrition-related traits should be performed according to the above strategy.

9.1 Marker-Assisted Breeding in Sesame

Genetic polymorphism analysis of nutrition-related traits among sesame accessions was initiated from molecular marker screening. In the past two decades, a variety of molecular markers, such as RAPD, AFLP, SCAR, SRAP, ISSR, SSR, EST-SSR, and SNP, have been developed for genetic diversity analysis, QTL mapping, and genetic dissection of key traits (Wei et al. 2013; Li et al. 2014; Wei et al. 2015; Yadav et al. 2022). The high variation explanation of these markers such as SSRs and SNPs presented the availability of marker-assisted breeding strategy. SSR markers have been demonstrated to play an important role in crossbreeding of major crops. While the SNP and InDel variants with the allelic nucleotide polymorphism of functional genes exhibit the genome variation character and can be more widely applied for sesame seed quality breeding (Murata et al. 2017; Zhou et al. 2022). Even though there are few reports on improving sesame varieties with high seed quality by the marker-assisted breeding approach now. Two SNP markers *SiDt27–1* and

SiSNPdwf1 for *SiDt* and *Sidwf1* gene, respectively, give the successful examples for new materials creation and molecular marker application in ideal variety breeding in sesame (Zhang et al. 2016; Miao et al. 2020).

9.2 Modern Breeding Technology of Sesame

In the past decade, HRSC, HAAS established the highly efficient germplasm creation and breeding platform for sesame, including EMS mutagenesis, distant hybridization, and genetic transformation. The mutant libraries, containing thousands of EMS mutants, transgenic lines, and interspecific progeny had been established. Of the above key techniques, genetic transformation was considered a cost-effective and powerful technology for the genetic improvement in sesame (Miao et al. 2021c). A great deal of effort has been devoted to establishing an efficient genetic transformation system for sesame. However, sesame is recalcitrant to regeneration in vitro (Bhaskaran and Jayabalan 2006). Application of genetic transformation technology lags behind. So many methods, including microparticle bombardment, and *Agrobacterium*-mediated and pollen tube channel methods, have been tried in the past decades. Except for pollen tube channel methods, the others depend on the tissue culture and shoot regeneration techniques (Miao et al. 2021c). Recent studies on tissue culture in sesame showed that adventitious shoots could be induced from the explants such as seed, shoot tip, stem, cotyledon, and young leaf via direct organogenesis way or indirect somatic embryogenesis way, which is dependent on the induction and differentiation of callus tissue (Miao et al. 2012; Miao et al. 2021c). Moreover, the regenerated sesame plants with suitable genotypes were induced from the adventitious buds producing in somatic embryogenesis way (Li et al. 1996; Miao et al. 2012). However, it is difficult to induce the adventitious shoots and the regenerated plants by callus induction and differentiation in sesame (Taskin and Turgut 1997). Two successful examples are that the regenerated plants respectively produce from adventitious shoots by direct explant induction for the hypocotyl and cotyledon of *S. radiatum* accession (Miao et al. 2012) and indirect callus differentiation for the de-embryonated cotyledon of an *S. indicum* variety TMV7 (Muthulakshmi et al. 2021).

Compared with other genetic transformation methods, *Agrobacterium*-mediated genetic transformation is more comprehensively studied in sesame. Taskin et al. (1999) discovered that sesame was susceptible to *A. tumefaciens*, but no transformed shoot was induced by *Agrobacterium*-mediated transformation in this study. Yadav et al. (2010) successfully induced cotyledon explants of sesame to produce transgenic plants carrying the neomycin phosphotransferase gene (*nptII*) and β-glucuronidase (*GUS*) gene for the first time, with a transformation frequency of 1.01%. Furthermore, Chowdhury et al. (2014) carried out a high-frequency *Agrobacterium*-mediated transformation by inducing the de-embryonated cotyledons at somatic embryogenic stages and presented the regeneration frequency of 57.33% and transformation efficiency of 42.66%. More recently, the transgenic sesame plants have been produced to introduce several functional genes related to key agronomic traits using the above method

(Muthulakshmi et al. 2021). Of these genes, acylCoA: diacylglycerol acyltransferase (*DGAT*) and phospholipid diacylglycerol acyltransferase (*PDAT*) play important roles in TAG biosynthesis, and *FAD3* are involved in polyunsaturated fatty acid biosynthesis. Overexpression of the *DGAT1* and *FAD3* and *PDAT1* and *FAD3* gene combinations showed to increase 9.0% and 11.5% TAG content in transgenic sesame leaves, respectively (Muthulakshmi et al. 2021). The study presents the modification potential of sesame plants as a biodiesel resource, even though whether the TAG content and fatty acid composition could be altered in the transgenic sesame seeds is still unclear. More attempts would be made to manipulate the functional genes by genetic transformation in sesame, so as to improve the nutrition-related traits in sesame. Predictably, with the abundance of functional gene resources, genetic transformation would show a huge function, especially in sesame nutrition improvement.

Recently, the metabolic engineering strategies were proposed to develop nutritionally optimized sesame oil by enhancing stearic acid (C18:0), oleic acid (C18:1), linolenic acid (C18:3), and total oil content (Bhunia et al. 2016). In the strategies, overexpression of acyl-ACP thioesterase gene or downregulation of stearoyl-acyl-carrier protein D9 FA desaturase (*SAD1*) gene were intended to enhance stearic acid (C18:0) content. Silence of *FAD2* would increase the oleic acid (C18:1) content. Moreover, overexpression of the heterologous *FAD3* and *FAD7* genes enhanced the accumulation of linolenic acid (C18:3) and manipulated the expression of the transcription factors Wrinkled 1 (*WRI1*), leafy cotyledon (*LEC1* and *LEC2*), and *DGAT* and *SiLTP1* genes and finally increased the content of total fatty acids in sesame. Definitely, more functional genes, especially transcription factors controlling the fatty acids and antioxidants metabolism, should be identified using the above techniques.

10 Conclusion and Future Prospects

In this chapter, we provided a summary of the progresses in sesame genetics and breeding research related to nutrition traits, as well as the achievement of key breeding materials and techniques. All the achievements reveal the importance of both the elite breeding materials and the molecular breeding elements for constructing the high-efficient molecular design breeding technology for sesame (Zhang et al. 2019; Zhang et al. 2021d). We also believe that sesame molecular breeding strategy would contribute to sesame seed quality breeding in the near future. Predictably, the superior sesame varieties introducing nutrition-related genes would be developed through the genetic engineering approach. Moreover, gene-editing system should be created for sesame based on the high-efficient transgene system.

Sesame is an ancient oilseed crop with high-quality nutrition, including abundant unsaturated fatty acids, proteins, tocopherol, and lignans. Of the main health-related components, the contents of oil, protein, fatty acid compositions, and lignans are hot research topics for sesame scientists around the world. In the past four decades, traditional breeding methods, including cross-breeding and mutagenesis breeding,

have achieved success in developing a series of sesame varieties with high yield and quality. With the development of the Sesame Genome Project and omics research, rich genome resources and tools have been obtained through continuous efforts. A list of molecular makers, QTLs, and functional genes related to key agronomic traits has been discovered in sesame and is available for molecular breeding programs (Zhang et al. 2021d). Even though the genetic dissection of oil and lignan contents and fatty acid compositions in sesame should be further developed, the designed molecular breeding strategies for sesame are going to play a key role in sesame genetics and breeding in the future. As regards the breeding techniques, the clustered regularly interspaced short palindromic repeats/associated protein 9 (CRISPR/Cas9) gene-editing system has been constructed for sesame with the *Agrobacterium*-mediated transformation recently (unpublished data, Zhang Haiyang). Differing from the transient expression validation of CRISPR/Cas9 vectors in hairy sesame root tissues reported by You et al. (2022), the stable transformation of CRISPR/Cas9 vectors proved the feasibility of gene edition and transgene system (Miao et al. 2021c) (unpublished data, Zhang Haiyang). In the future, the genetic modification approach will be employed to create mutants related to antinutritional genes and modify metabolic pathways of fatty acids and bioactive compounds to improve sesame varieties with low contents of free fatty acids and antinutritional factors such as phytic and oxalic acids, and high accumulation of antioxidant such as sesamin, sesamolin, and tocopherol (Langyan et al. 2022). In addition, the gene–metabolite relationships should be further investigated so as to uncover the regulation factors of the nutriment biosynthesis and accumulation in sesame. At present, only one metabolomics analysis was performed to reveal differences in metabolite accumulation between different sesame tissues (Dossou et al. 2021). Future exploration should develop comprehensive proteomics and metabolomics resources to understand fully the metabolic network of nutrient metabolites.

pharmacological activity, and ethnomedicinal usage of castor. Castor contains various chemical components, which includes flavonoids, phenolic compounds, fatty acids, amino acids, terpenoids, phytosterol, etc. According to studies, these substances have anticonception, antidiabetic, antifertility, anti-inflammatory, antibacterial, antioxidant, hepatoprotective, insecticidal, and wound-healing properties. Additionally, the castor has demonstrated Hg and free radical scavenging activities as well as repellent qualities. Due to their use as medicines, castor plants have gained significant importance. The stem can be used to treat cancer and hypoglycemia, while the leaves can treat biliousness, antiviral, burns, ear and headache problems, night blindness, and malaria. You can apply the flowers to ease glandular and vaginal pain. In addition to cancer, piles, liver, and spleen diseases are all treated with fruits. In the treatment of rheumatoid arthritis, ascites, leprosy, rectal aches, hypoglycemia, asthma, and bronchitis, root can be used as a purgative. The castor oil plant has also shown negative effects since it contains the proteins ricin and ricinine which are highly poisonous. However, there is still a need for additional study to be done in relation to its medicinal significance and the active chemicals responsible for a variety of functions.

Keywords

Castor · *Ricinus communis* · Nutraceutical properties · Pharmacological properties

1 Introduction

Castor (*Ricinus communis* L.) belongs to the spurge (Euphorbiaceae) family. It is believed that it came from India and Ethiopia. Ricinus is a single species and *R. communis* is the only species. *Ricinus* and *Communis* are Latin words; "ricinus" is a tick, a specific synonym of the Mediterranean sheep tick (*Ixodes ricinus*), and is the common name for this tick's common species. The name Ricinus was invented by Caroleus Linnaeus, father of the taxonomy, because the seeds of the castor bean resemble "ticks" that inflict blood (a body that is mutilated by certain ticks), especially large ticks that are expanded with blood. Although plants and seeds are often referred to as Castor beans, they are not legumes. Castor is a member of the monotypic subtribe Ricininae of the genus Ricinus. It is one of the oldest plants and is becoming increasingly important as a crop for tropical and subtropical nations worldwide. Castor is a robust plant that yields 350–900 kg of oil per hectare, needs little maintenance, tolerates marginal soils, is simple to start in the field, and is drought-resistant. Castor oil exhibits excellent functional value in the pharmaceutical, industrial, and energy sectors. It has seen an increase in demand in recent years on the global market for its more than 700 applications, which range from biodiesel, plastic, and lubricants to medicine and cosmetics. Due to its high and low temperature tolerance capabilities, the oil is important for many industrial uses in comparison to other oils derived from plants. The majority of castor is grown in dry and semi-arid climates. It is grown

commercially in 30 nations, with India, China, Brazil, Russia, Thailand, Ethiopia, and the Philippines being the top producers of castor seeds, accounting for over 88% of global output. Castor seeds are extremely valuable and contain between 48% and 52% of the oil. Other plant components, including leaves, branches, flowers, fruits, and roots, can be utilized separately or in conjunction with other items for a variety of medical applications. Since at least 5000 years, India has used numerous plants in its traditional medical practices (Ayurvedic, Unani, and Siddha). More than 8000 herbal medicines have been documented in Ayurveda. Indian traditional medicines, folk medicines, and herbal remedies have utilized almost 6000 plants (Huxley 1984) for the treatment of different diseases. In most medical treatments, various parts of castor plants and the oil have been used as the base material. For example, leaves can be used to treat antivirals, bile ducts, burns, ear and head pain, malaria, and night blindness, stems are used to cure cancer and hypoglycemia. Flowers are effective for treating glandular and vaginal pain. Malignant diseases, liver and spleen ailments, and piles are all treated with fruits. Rheumatoid arthritis, ascites, asthma, bronchitis, diarrhea (gas from the stomach and intestines), hypoglycemia, and leprosy are all treated with the root bark as a cleanser (Neogi et al. 1989).

2 Nutraceutical Application of Castor Oil

The eyeball is covered and shielded by the conjunctiva, a delicate and thin membrane. An inflammation of the conjunctiva known as conjunctivitis is characterized by redness and typically ends with an ocular discharge of water. When eyes are exposed frequently or constantly to environmental factors and microorganisms that could cause infections or allergic reactions, it is a common eye ailment. Depending on the type of organism or agent involved and the intensity of the symptoms, it might be acute or chronic. Close physical contact is the most straightforward way to transfer conjunctivitis to others, especially among children (Pewitt 2004). The leaf decoction of *Achyranthes aspire*, mixed with castor oil, can be applied to the head and body 1 hour before bathing to overcome the problem of conjunctivitis.

A type of chronic skin inflammation characterized by weeping vesicular lesions, redness, and itching is called eczema. Other symptoms of eczema include skin edema/swelling, dryness, itchiness, crusting, peeling, blistering, breaking, leaking, or bleeding (Johannes et al. 2006; Williamson 2002). To treat eczema, castor oil is combined with powdered Indian birthwort (*Aristolochia indica*), and the oil is made by boiling *Datura stramonium* leaf juice, which is then applied to the skin.

When combined with copper sulfate, castor oil is used to treat a variety of skin conditions. Castor oil is combined with crushed *Alangium salvifolium* leaves, which are then applied to the area of inflammation. The scalp, ears, genitalia, and skin are the most typical areas of the body affected by the chronic skin disorder psoriasis. It is characterized by dry, red areas that are coated in scales. Cow urine in combination with the rhizome of *Curcuma domestica*, the seed of *Piper nigrum*, and the leaf of *Aristalochia bracteata* is combined to make a paste that is then fried in castor oil. The area with psoriasis should receive regular applications of this mixture for its treatment.

Sexually transmitted diseases (STDs) are also known as sexually transmitted infections (STIs) and are transmitted by human sexual behavior. Some are transmitted through childbirth or breastfeeding and through the re-use of medical needles which have been used by the infected people. STDs reduce the white and red blood cell counts (WBC and RBC), which leads to a weaker immune system. Castor oil packs improve WBC and RBC counts within 2 weeks, which strengthens the immune system of the body. To treat syphilis and gonorrhea, castor oil is used along with arsenic and copper sulfate. Although several drugs can increase lymph flow, castor oil can be applied topically to achieve the same goal. The number of lymphocytes in the blood increases when castor oil is absorbed by the skin. This results in a positive effect on the thyroid gland and/or lymphatic tissues. Increased lymph flow throughout the body accelerates toxins' removal, reduces swelling lymph node size, and improves overall organ function.

Castor oil is a widely used drug used to treat painful diarrhea and is often referred for constipation. In rural areas, children with diarrhea receive a small amount of castor oil that promotes gastrointestinal movements.

3 Nutraceutical Application of Castor Leaf

The condition known as yellow fever is caused by the excess bilirubin in the body, causing yellow skin and eyes. When the liver decomposes dead red cells, yellow pigments called bilirubin are formed. Jaundice is a sign of liver, gall bladder, or pancreas dysfunction. Tender castor leaf paste and coconut water are administered orally to patients with jaundice.

A fine paste of mature leaves is prepared to which a small amount of salt is added and then warmed up. This material is applied to the swollen muscles. In addition to calming the swelling, this also eases the pain, backache, and constipation.

Sesame oil is applied to the entire castor leaf and warmed on the metal plate. This is used on the gouty arthritis-affected joints. If the process is repeated every day for a week, it reduces pain and edema.

4 Nutraceutical Application of Castor Seed

Filariasis is a tropical parasitic and infectious disease caused by filariasis nematode worms and transmitted by the bite of a mosquito. Elephant edema with skin and subcutaneous tissue thickening is the most striking symptom. It affects mainly the lower extremities, with less frequent cases of the ear, mucous membranes, and amputation of skin. To treat filariasis, castor seed paste is given to the affected area.

5 Nutraceutical Application of Castor Root

Roots are used to treat swelling, fever, abdominal disease, arthritis, rheumatoid arthritis, pain in the back region, and similar diseases. A decoction of the dried roots is created using 20–25 grams. Alternatively, medicinal milk can also be made

from the roots. A dose of 40 ml of the decoction is given twice daily. This aids in easing the discomfort brought on by conditions like sciatica and backaches, among others. Additionally, it also soothes constipation.

6 Role of Castor in Cancer Research

The medicinal potential of ricin is considerable, and it is even being researched in the context of nanoparticle formulations for tumor therapy as an anticancer medication, in bone marrow transplantation, or in cell-based research. Based on the description of ricin's chemical structure and mode of action, the cytotoxic effects of ricin on tumor cells have already been seen in numerous investigations.

Lin and coworkers expanded on the first findings in rat sarcomas by describing the longer life of mice with Ehrlich ascites tumors after ricin treatment (Lin et al. 1973), as well as in a mouse model using human xenografts (FODSTAD and OLSNES 1977). Cancer cells have been found to be more sensitive to ricin, which may be due to their higher rate of protein synthesis, which makes them more susceptible to ricin's ability to inhibit this process, or to the presence of more ricin (B-chain) receptors on the surface of tumor cells, which facilitates better uptake. A preliminary phase of research in 54 patients with advanced cancer showed some therapeutic results in a small number of individuals (Fodstad et al. 1984). However, it was shown that ricin binds to almost with all cell types, making this binding specificity insufficient (Audi et al. 2005). Additionally, it was discovered that the ricin B chain played a part in the membrane-bound A chain's intracellular movement and translocation as well as its own pro-apoptotic actions (Timar et al. 1991). As a result, it was discovered that immunotoxins based on the conjugation of the entire ricin molecule, as opposed to only its A chain, were more effective (Olsnes 2004) Aside from the castor applications listed in the preceding paragraphs, Table 1 and Fig. 1 list a few of the other pharmacological features of the castor plant.

7 Nutraceutical Improvement in Castor: Molecular Basis

Many nations consider castor beans to be a significant crop. Castor oil, which is widely used in many industries, is the principal usage for it. After the oil is extracted, meals and cakes high in protein are what are left. They show promise for usage as protein supplements in the creation of feed. The presence of poisons, however, places restrictions on it. These are ricinine alkaloid and ricin protein. Genomic editing with the CRISPR/Cas9 system is one such technique. The technique entails using a small guide RNA fragment to help the Cas9 enzyme cut the target region of intact DNA. The delivery of Cas9 and the guide RNA genes to the cells of the edited plant is often carried out by plasmid vectors. Promoting sequences with intact USE and TATA boxmotifs have been used in the construction of CRISPR/Cas9 vectors that can be used to effectively edit the castor bean genes involved in the synthesis of ricin and ricinine (Alexandrov and Karlov 2021).

Table 1 Pharmacological properties of different parts of castor

S. No	Pharmacological activities	Part used	Mode/Reaction	Reference
1	Abortifacient effect	Castor oil	Anti-implantation and anti-ovulation effects due to ricin-A	Salhab et al. (1999)
2	Analgesic activity	Root bark extract	Saponin, steroids, and alkaloids	Rajeshkumar et al. (2013)
3	Acid phosphatase stimulation	Castor oil	The intraluminal acid phosphatase increase	Ross (2003)
4	Anti-fertility activity	Seed extract	Anti-fertility effects due to steroids and alkaloids	Jena and Gupta (2012)
5	Antiasthmatic activity	Root extract	Saponin and flavonoids have a property to stabilize and relax smooth muscle	Jena and Gupta (2012)
6	Anticonceptive effect	Seed extract	Direct effect on the uterus	Okwusasaba et al. (1997)
7	Anti-amoebic activity	Root/stem extract		Ross (2003)
8	Antimicrobial activity	Root extract	Activity against pathogenic fungi	Jena and Gupta (2012)
9	Antidiabetic activity	Root extract	Antihyperglycemic activity in one of the root fractions	Shokeen et al. (2008)
10	Antibacterial activity	Leaf extracts	Activity against pathogenic bacteria	Islam et al. (2010), Jombo and Enenebeaku (2007)
11	Anticancer effects	Seed and stem extract	In vitro anticancer effects against cancer cell lines: Colon cancer cell line, liver cancer cell line, breast cancer cell line, cervix cancer cell line	Prakash and Gupta (2014)
12	Anti-inflammatory activity	Root extract	Anti-inflammatory and free radical scavenging activities of the root extract of *R. communis* in Wistar albino rats	Nath et al. (2011)
13	Antioxidant activity	Root extract	The phytochemicals constituents responsible for antioxidant activity may be methyl ricinoleate, Ricinoleic acid, 12 octadecadienoic acid and methyl ester	Jena and Gupta (2012)
14	Central nervous system (CNS) stimulant	Seed coat extract	Ricinine is responsible for central nervous system stimulant	Williamson (2002)

Genetic markers including agromorphological traits, biochemical markers, and cytological markers were commonly utilized to characterize genetic variation in the germplasm from India, Nigeria, Turkey, China, Brazil, Iran, and Ethiopia. Depending on the markers and genotypes examined, these markers suggested a low-to-high

Fig. 1 Pharmacological usage of different parts of castor

amount of variability in the castor bean germplasm. Castor bean genetic diversity was assessed using both dominant and codominant molecular markers, such as expressed sequence tag-simple sequence repeats (EST-SSR), start codon targeted, inter-simple sequence repeats, random microsatellite amplified polymorphic DNA (RMAPD), amplified fragment length polymorphism (AFLP), and simple sequence repeats (SSR). Utilizing molecular markers to characterize the genetic diversity in germplasm from countries like India, China, Brazil, Mexico, and the worldwide collection, castor bean exhibits a low-moderate level of genetic variability. The availability of the castor bean genome has accelerated the creation of straightforward, rapid, and trustworthy DNA markers for the evaluation of genetic variation in the plant. Additionally, these markers will be an important tool for determining genetic diversity and supporting projects for marker-assisted breeding to improve crops.

Castor organelle genomics revealed that single nucleotide polymorphism markers and phylogenetic analysis allowed the identification of two significant clades that were not visible in earlier population genetic research utilizing genetic markers obtained from nuclear DNA. Within each major clade, two separate subclades could be identified, and extensive genotyping of castor bean populations around the world verified the previously noted low levels of genetic variation and revealed that each sub-clade was widely distributed geographically (Rivarola et al. 2011).

It has been determined that the accessions from East Africa are the extant wild progenitors of castor bean and that domestication took place around 3200 years ago using a de novo chromosome-level genome assembly approach of the wild progenitor of castor bean with resequencing and analyzing 505 worldwide accessions. This study

also demonstrated a link between the Turkana depression's previous temperature variability and the large genetic divergence between wild populations in Ethiopia and Kenya. The present work, in conjunction with quantitative trait locus analysis, has discovered significant candidate genes linked to plant architecture and seed size (Xu et al. 2021). Whereas the castor bean's draft genome sequencing revealed critical genes for significant oil synthesis, unexpectedly, there are more members of the ricin gene family. According to comparative genomics research, the dicotyledonous lineage has been preserved through an ancient hexaploidization event (Chan et al. 2010).

8 Other Uses of Castor

8.1 Acid Phosphatase Stimulation

Rats were administered 2 ml/animal of castor seed oil intragastrically, which increased intraluminal acid phosphatase liberation in the duodenum and jejunum but not in the stomach (Ross 2003).

8.2 Analgesic Activity

While the common medication diclofenac was utilized at a dose of 50 mg/kg for analgesic action, the aqueous extract of the root bark of *R. communis* was examined at doses of 100 mg/kg and 200 mg/kg. Six albino mice of each sex were used in each group for the evaluation study using the hot plate method and tail immersion method. The findings showed that the extract had notable anti-nociceptive action against the two mouse pain models. Saponin, steroids, and other phytochemical substances may be responsible for the same.

8.3 Antidiabetic Activity

The anti-diabetic potential of *R. communis* root extract (RCRE) was investigated. The diabetic rats received RCRE (500 mg/kg b.w.) for 20 days in order to achieve this goal. The outcome showed beneficial effects on liver and kidney functions as well as the total lipid profile and fasting blood glucose. Of the total fractions studied, only one (R-18) showed a significant amount of anti-hyperglycemic activity. *R. communis* can therefore be a crucial component of an efficient phytomedicine against diabetes (Shokeen et al. 2008).

8.4 Antimicrobial Activity

The antibacterial properties of several solvent extracts of *R. communis* roots (200 mg/ml) were examined. In this regard, the pathogens such as *Aspergillus*

niger, *Bacillus subtilis*, *Candida albicans, E. coli*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, *S. aureus*, and *Salmonella typhimurium* that cause different disorders were studied using the well-known diffusion method. Maximum antibacterial activity was demonstrated by the hexane and methanol extracts, but the aqueous extracts displayed reduced antimicrobial characteristics (Jena and Gupta 2012).

8.5 Anticancer Effects

The ethanolic extract of *R. communis* was tested against seven human cancer cell lines for its in vitro anticancer properties. Colon cancer cell lines (Colon HT-29, SW-20, SiHa), liver cancer cell lines (Hep-2), breast cancer cell lines (T-47D), cervical cancer cell lines (OVCAR-5), and prostate cancer cell lines were the seven cell lines (PC-3). The test substance was tested for cytotoxicity against all cell lines at a concentration of 100 g/ml using the sulforhodamine B (SRB) assay. The greatest activity was shown by the stem component of *Ricinus communis* against SiHa (47%), whereas the ethanolic extract of the seed showed 41% activity against Colon 502713 (Prakash and Gupta 2014).

8.6 Anti-inflammatory Activity

A test was done on Wistar albino rats to see how well *R. communis* root extract reduced inflammation and scavenged free radicals. The study found that the aforementioned extract was effective for the activities examined. The flavonoids, alkaloids, and tannins contained in the plant may be the chemical components that triggered the aforementioned behaviors (Nath et al. 2011).

8.7 Bone Regeneration Activity

The purpose of the study was to assess the biocompatibility and potential of the Ricinus communis polyurethane to stimulate bone regeneration. The findings showed that RCP is a biocompatible substance that can promote matrix mineralization when mixed with calcium carbonate or calcium phosphate. Alkaline phosphatase addition and subsequent incubation of RCP in synthetic bodily fluid may enhance its biological characteristics. RCP has the benefit over demineralized bone in that the latter's reabsorption process is slower (Rana et al. 2012).

8.8 Repellent Properties

Castor oil has been used as a spray to deter moles, despite its unpleasant taste. Castor plants have also been utilized as a repellant by being grown around areas where

moles are a problem because of their foul odor. Care should be taken that children and pets have no access to the poisonous seeds (Baker and Grant 2018).

9 Important Composition of Castor Oilseed

9.1 Phospholipids

Phospholipids are one type of lipid that creates lipid bilayers in the cell membrane. Tocopherols and phospholipids may work together to postpone the onset of lipid oxidation (Chew and Nyam 2019). The pharmaceutical and food sectors can benefit from knowing more about phospholipids, especially when used as emulsifiers.

Castor oilseed's phospholipid makeup has long been researched. Castor has less than 1% total polar lipids, with phosphatidylcholine, phosphatidylinositol, and phosphatidylethanolamine being the main constituents, according to Moreau et al. (Moreau et al. 1980). Phosphatidylcholine, which made up 30% of them, was the most common. Donaldson also noted that 2-day-old castor oilseed contained 2% phospholipid, and that the values for the various phospholipid classes were comparable (Donaldson 1976). The phospholipid values recorded for castor are low when compared to other oilseed crops, such as chufa nuts, which have a 5.4% phospholipid content (Oderinde and Tairu 1992). Dark-colored oils typically have high phospholipid concentrations as a result. Because of the low concentration of phospholipids in the oils, castor oil has a clear, pale yellow tint.

9.2 Phenolic Components

Secondary metabolites from several categories are present in phenolic substances. This substance has one or more hydroxyl groups that can attach to aromatic molecules directly (Rampadarath et al. 2014). The three main categories of dietary phenolic substances are tannins, phenolic acids, and flavonoids. The two principal subclasses of phenolic acids are hydroxycinnamic acid and hydroxybenzoic acid (Chew and Nyam 2019). Gallic, syringic, and vanillic acids are byproducts of hydroxybenzoic acids, which primarily have aromatic rings with C1-C6 structure (Boualem et al. 2017). Having regard to hydroxycinnamic acids, their derivatives with a C3-C6 structure include caffeic, ferulic, and p-coumaric acids. Varied oils have different phenolic component types and contents. The flavor and antioxidant properties of oils are influenced by phenolic substances.

9.3 Fatty Acids

Vegetable oils contain linolenic and oleic acids, which are very good for human health and have been used to cure a number of ailments like diabetes, skin cancer,

renal illness, heart attacks, lupus, high blood pressure, and high cholesterol levels (Ganesan et al. 2018). Because it resists oxidation, oleic acid can be employed to enhance the activities of antioxidants and as agents that prevent polymerization (Anjani 2012). It can be blended with other oils to stop oxidation when paired with antioxidants (such as tocopherols). Because they have certain beneficial effects for the skin, linoleic, palmitic, and stearic acids are utilized widely in the beauty industry (Ganesan et al. 2018). Cosmetic items or pharmaceuticals are made using stearic acid esters such as glycol distearate, glycol stearate, and ethylene glycol. Glycol distearate, glycol stearate, and ethylene glycol are stearic acid esters that are used to make cosmetic items or to enhance the pearly look of shampoos (Gunstone 2009). The presence of these fatty acids in castor oil suggests that this plant has nutritional and industrial benefits.

9.4 Insecticidal and Pesticidal Activity of Castor

Castor oil was compared against cottonseed, linseed, rosin, and petroleum spray oils for the treatment of many citrus pests, particularly red scale (*Chrysomphalus aurantii*) with a deadly immersion duration of 1400 min. Out of all the vegetable oils, castor oil outperformed the light petroleum distillate in terms of managing the scale. However, the vegetable oils were also more phytotoxic (De Ong et al. 1927).

Castor oil prevented the hatching of sweet potato whitefly eggs better than cottonseed, peanut, soybean, and sunflower oils, with only 19% of the eggs surviving (Fenigstein et al. 2001). The outcome was comparable to peanut oil and much superior to cottonseed, soybean, and sunflower oils. The same study showed that a 3% solution of castor oil was successful in lowering the survival rates of larvae, with survival rates for the first instar being 7.9%, the second instar being 4.1%, the third instar being 14.0%, and the fourth instar being 19.0%. A 3% mortality rate after 2 hours, but a 75% mortality rate after 24 hours, indicated that 3% castor oil was only slightly effective against humans.

Another research suggested that *B. tabaci* larvae fed with castor oil had marginally greater survival rates than those treated with cottonseed oil; however there was no statistically significant difference between the two treatments (Butler Jr et al. 1991). The stakes were made of wood from the *Acacia nilotica* tree and were treated with castor oil using vacuum pressure, surface application, and dipping at concentrations of 10%, 15%, and 20% using each of the three techniques. After being sun- and oven-dried, the stakes were buried in a pit with *Odontotermes obesus* termites. For all three application types, all rates, and all types of drying techniques, castor oil significantly reduced wood loss from termite damage compared to the untreated control (Ahmed et al. 2014). The 20% rate offered marginally but significantly greater control than the lower rates. The 20% concentration by the dipping process resulted in the minimum percent loss, with 8.91% loss in sap wood and 7.62% loss in heart wood. Losses in the control were over 40% for heart wood and over 50% for sap wood.

9.4.1 Improvement of Pharmacological Quality of Castor Oil Through Biotechnological Approaches

Plant biotechnologists have been interested in the metabolism of castor, since it can accumulate significant amounts of ricinoleic acid. The primary extra plastidial alteration of fatty acids in castor oil plants is the hydroxylation of oleate, which is catalyzed by the membrane-bound enzyme FAH12 hydroxylase, which is closely linked to FAD2 and FAD3 (Van De Loo et al. 1995). This enzyme can add a hydroxyl group to oleate at the delta 12 position, which is where the endosperm of castor oil seeds develops. Nevertheless, the activity of this enzyme by itself is unable to account for the fatty acid content of castor oil (Fig. 2).

Various experimental studies have shown that the castor seed's synthetic machinery is specifically designed to improve ricinoleic acid into TAGs, involving the entire route rather than just specific enzymes (Hu et al. 2012). The castor plant is a very interesting manufacturing platform for uncommon fatty acids, particularly hydroxylated fatty acids of economic significance, because of this biochemical

Fig. 2 Different techniques to improve castor neutraceuticals

characteristic. The castor plant, which can be grown as an annual crop and is feasible with both productive and low-maintenance, is of particular scientific interest (Baldwin and Cossar 2009).

Significant strides in the use of castor oil plants as biofactories were accomplished once the toxicity of the seeds was removed (Sousa et al. 2017). Additionally, a draft version of the plant genome has been released, exposing the genetic makeup of the plant (Chan et al. 2010). The synthesis of other specialized fatty acids in this plant may one day be based on castor oil mutants with changed fatty acid compositions, such as the OLE1 mutant with up to 80% oleic acid and decreased ricinoleic acid content (Venegas-Calerón et al. 2016).

A methodology based on the transformation of seed dissected embryos, followed by selection and plant regeneration, has also been used to produce transgenic castor oil plants (Ahn et al. 2007; Sujatha and Sailaja 2005). However, very little transformation efficiency (0.04%) was seen using meristem-based methods in this plant. Transient gene expression studies are frequently used to enhance plant physiology, biochemistry, and biotechnology research of some plants because permanent transformation of those plants is typically a difficult process with numerous drawbacks.

10 Conclusion

For at least 5000 years, numerous plants have been used in traditional medicine in India. In traditional Indian medicine, folk medicine, and herbal medicine, nearly 6000 plants have been used to treat various diseases. In most of the medical treatments, different parts of castor plants and oil were used as raw materials. The leaf decoction of *Achyranthes* aspire mixed with castor oil can be applied to the head and body one hour before bathing to solve the problem of conjunctivitis. For the treatment of eczema, castor oil can be applied to the skin in combination with powdered Indian birthwort. In combination with copper sulfate, castor oil is used to treat a variety of skin diseases. Castor oil is combined with crushed leaves of *Alangium salvifolium*, which are then applied to inflamed areas. Castor oil packs improve the number of white and red blood cells within two weeks, which strengthens the body's immune system. The number of lymphocytes in the blood increases when castor oil is absorbed by the skin. In rural areas, children with diarrhea are given a small amount of castor oil, which promotes gastrointestinal movements. Tender castor leaf paste and coconut water are given orally to patients with jaundice. This not only has a soothing effect on swelling but also relieves pain, back pain, and constipation. The medical potential of ricin is considerable, and it is even being explored in nanoparticle formulations for tumor therapy as an anticancer drug, in bone marrow transplantation, or in cell-based research. Based on the description of the chemical structure and mode of action of ricin, numerous studies have already established the cytotoxic effect of ricin on tumor cells. Immunotoxins based on conjugation of the entire ricin molecule, not just the A-chain, were found to be more effective. Because of their use as medicines, castor plants have become very important. However, more studies are needed on their medicinal importance and the active compounds responsible for a variety of functions.

Genetic Enhancement of Nutraceuticals in Linseed: Breeding and Molecular Strategies

C. Manimurugan, A. Zanwar, and M. Sujatha

Contents

Abstract

Linseed (or flax) is an important industrial oilseed crop mainly grown in temperate climates for its oil and fiber properties. Linseed fiber separated from stalks is a bast fiber which possesses high mechanical properties. The textile "linen" made from this fiber is popularly used in the textile industry. Seeds of linseed contain 33–47% of oil, with excellent drying property, and its oil is mainly used in the manufacturing of paints, varnishes, linoleum, oil cloths, and printing inks. In the recent past, linseed has gained attention and considered as "superfood" because it is one of the richest sources of omega-3 fatty acid or alpha-linolenic acid (ALA), a nutritionally important fatty acid, phytochemical compounds, vitamins, and minerals. Genetic

enhancement in linseed through conventional and biotechnological tools was focused mainly on increased productivity, enhancing oil content and quality, increasing seed size, early maturity, lodging resistance, plant height, and resistance to major diseases. Limited efforts were made toward improvement of the nutraceutical properties of the crop concerning the omega-3 fatty acid content, oil quality modification, essential lignan (secoisolariciresinol diglucoside – SDG), and mucilage which have proven value of linseed as a functional food. Attempts were made to assess variation for these components among the linseed accessions and to study the genotype and environment interaction based on quantitative traits and molecular markers. A noteworthy achievement was made in the development of solin flax (edible oil) through mutagenesis with a point mutation in the *LuFAD3A* and *LuFAD3B* genes encoding microsomal desaturases and expanding the utility of linseed oil for edible purposes. During the past two decades, efforts of different research groups have led to the enrichment of genomic resources in terms of mapping populations, construction of linkage maps, development of molecular markers, and identification of quantitative trait loci (QTLs) and quantitative trait nucleotides (QTNs) for traits of agronomic importance. Genetic engineering studies in flax were encouraging and modifications with regard to SDG content, fiber quality, tolerance to herbicides, and resistance to *Fusarium* were successfully demonstrated. Use of nanoparticles of linseed oil in assessing antitumor activity and as a source of omega-3 in various food preparations and hydrogel derived from mucilage for drug delivery in skin care products is receiving special attention as they are found to be safe with guaranteed delivery and maximum benefit. Despite the promise the crop holds and the research advancements made in this crop, there is a long way to go to exploit the full potential of the crop for diverse nutraceutical and pharmaceutical uses.

1 Introduction

Linseed is one of the important self-pollinated oilseed crops, which is mainly grown for its oil and fiber properties. Linseed with a chromosome number of $2n = 30$ is belonging to the family Linaceae and the genus *Linum*. The name "Linum" is originated from the Celtic word lin or "thread," and the name "usitatissimum" is Latin for "most useful." There is a lot of disagreement regarding the origin of linseed. Vavilov (1935) proposed "Mediterranean region" as the origin of cultivated annual linseed. Linseed was introduced in North America by colonists and cultivated in a larger area mainly for its fiber. It was a major cultivated fiber crop in ancient Egypt, and linen was considered as a symbol of purity in Egypt. The drying property of linseed oil was extensively utilized in paint industries. Globally, linseed is

cultivated under 3.54 million ha with production of 3.37 million tons and average productivity of 951 kg/ha. The countries including Kazakhstan, Russia, Canada, China, India, the United States, Ethiopia, the United Kingdom, Argentina, Germany, Afghanistan, and France are the major linseed growers in the world. Kazakhstan with 31.4% contribution is the leading producer followed by Russian Federation (23.4%) and Canada (17.2%) (FAOSTAT 2020) (Table 1). During 2020, the top exporters of linseed were Canada, Russia, Kazakhstan, Belgium, and Poland, while the top importers were China, Belgium, Germany, the United States, and Poland. Top linseed-consuming countries are China, Belgium, the United States, Turkey, and Germany. The highest levels of linseed oil per capita consumption were registered in Belgium, followed by Turkey, Germany, the United States, and China (https://www.indexbox.io/blog/which-country-consumes-the-most-linseed-oil-in-the-world/).

Nowadays nutritional aspects of linseed are gaining more attention from nutraceutical and pharmaceutical industries. The phytochemical components present in seeds of flaxseed are α-linolenic acid (ALA) or omega-3 fatty acid, linoleic acid, oleic acid, digestible proteins, carbohydrates, lignans (phytoestrogen), soluble mucilage, and dietary fiber and an array of antioxidants. Approximately, 21% and 34% of proteins are found in flaxseed grain and ground flaxseed paste, respectively (Chung et al. 2005).

Flaxseeds are a good source of sulfur-containing (methionine and cysteine) and branched-chain (isoleucine, leucine, and valine) amino acids. It also comprises limiting amino acids like lysine, threonine, and tyrosine. Additionally, flaxseed is a good source of various kinds of phenolic acids such as ferulic acid (10.9 mg/g), chlorogenic acid (7.5 mg/g), and gallic acid (2.8 mg/g) along with some minor phenolic acids such as ρ-coumaric acid glucosides, hydroxycinnamic acid glucosides, and 4-hydroxybenzoic acid. Flaxseeds also constitute a rich source of minerals like calcium (236 mg/100 g), magnesium (431 mg/100 g), phosphorus (622 mg/100 g), and potassium (831 mg/100 g) and vitamins like γ-tocopherol (522 mg/100 g),

Table 1 Area, production and productivity of linseed in major producing countries

Country	Area (ha)	Production (tons)	Productivity (kg/ha)	Contribution to world production (%)
Kazakhstan	1,342,518	1,058,247	788	31.4
Russian Federation	973,411	787,923	809	23.4
Canada	371,000	578,000	1558	17.2
China	250,000	330,000	1320	9.8
India	200,000	121,000	605	3.6
United States of America	119,790	144,940	1210	4.3
Ethiopia	78,921	80,457	1019	2.4
Total world	3,540,139	3,367,331	951.2	–

Source: FAOSTAT (2020) (https://www.fao.org/faostat/en/#data/QCL)

α-tocopherol (7 mg/100 g), δ-tocopherol (10 mg/100 g), and niacin (3.2 mg/100 g) (Bernacchia et al. 2014). The seeds possess a pleasant nutty taste with a crisp and chewy texture (Carter 1993). Generally, consumption of one tablespoon (7 g) of ground flaxseed is recommended per day for a healthy person (Meacham et al. 2022). The bioavailability of nutrients is improved only after processing flax seeds. About 20 to 25% of daily fiber needs can be fulfilled by consuming half an ounce of dry whole flax seeds, and 30 g of flaxseeds contain 7 to 30% of the Recommended Dietary Allowances of calcium, magnesium, and phosphorus (Singh et al. 2011). The above nutritional components present in the seeds of linseed have a vital role in human diet and health maintenance.

Human diseases are caused by genetic, environmental, pathogenic, nutritional, food habits, and lifestyle reasons. Adding functional foods like nutrient-rich vegetables, fruits, seeds, grains, and nuts to the food will improve human health. Researchers proved that consumption of linseed have a potentially positive effect on health beyond basic nutrition and can prevent, postpone and besides being supportive in management of several kinds of diseases like cardiovascular complications, cancer, kidney disease, dry eye disease, polycystic ovary syndrome (PCOS), gout, diabetes mellitus, liver disorders, neurodegenerative disorders, stomach ulcers, constipation, etc. (Gaber and Badawy 2019; Rezaei et al. 2020; Saivarshine et al. 2020).

To harness the potential of linseed, there is a need to develop the varieties/hybrids with higher seed yield and resistance to pests and diseases along with environmental stress tolerance and higher nutritional values. Focus of conventional breeding is mostly on agronomic traits related with yield and fiber quality along with pest and disease resistance. There is an immense need to understand and improve the nutritional aspects of linseed cultivars. In this context, utilization of advancements in molecular and biotechnological strategies will pave the way for successful linseed breeding and its effective utilization in nutraceutical and pharmaceutical industries.

2 Nutritional Compounds

The linseed oil is the richest vegetarian source of α-linolenic acid (ALA; ω3-C18: $3^{9,12,15}$), which is also known as omega-3 fatty acid. Human body cannot synthesize omega-3 fatty acids by utilizing any other substrates and, hence, must be supplied through food. These kinds of fatty acids are known as essential fatty acids. ALA is the parent fatty acid of the ω3 family which includes stearidonic acid (SDA; ω3–18: $4^{6,9,12,15}$), eicosapentaenoic (EPA; ω3–20:$5^{5,8,11,14,17}$), and docosahexaenoic acid (DHA; ω3 22:$6^{4,7,10,13,16,19}$) (Fig. 1). These omega-3 fatty acids are crucial for optimal development of the human brain, circulating cells (red blood cells (RBCs), leukocytes, etc.), and skin (Ratnayake and Galli 2009). When flaxseeds are consumed, ALA may alter plasma oxylipin concentration which produces antihypertensive effects in patients suffering from peripheral arterial disease (Caligiuri et al. 2014).

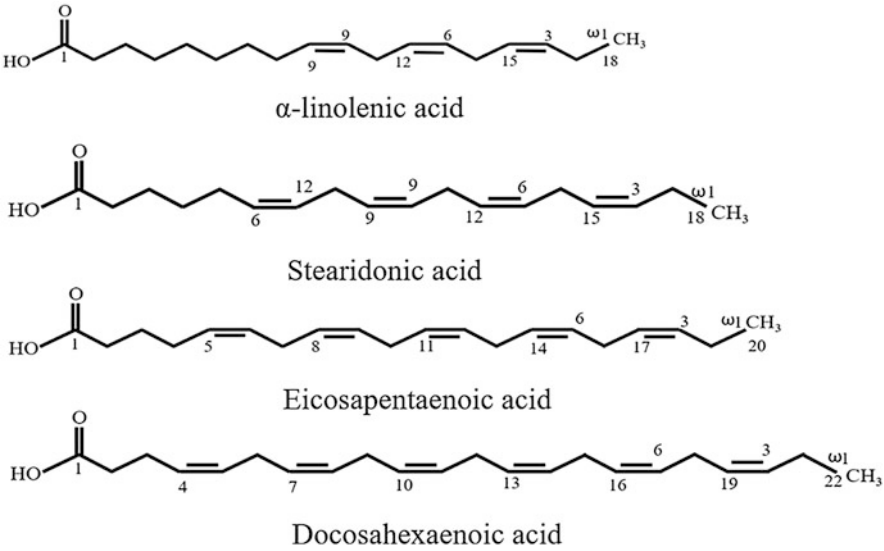

Fig. 1 Structures of omega-3 fatty acids

Flaxseed is one of the richest plant sources of lignans [secoisolariciresinol diglucoside (SDG- 294–700 mg/100 g), pinoresinol (3.32 mg/100 g), matairesinol (0.55 mg/100 g), and lariciresinol (3.04 mg/100 g)], providing 800 times more lignans than most other foods. When flaxseed is consumed, SDG lignans are metabolized in the intestinal region by gastrointestinal bacteria to enterolactone (the major active mammalian lignan that is found in body tissues) and also enterodiol (also a mammalian lignan). The enterolignans, enterolactone, and enterodiol are known to possess weak estrogenic activity. Because of this, SDG is classified as phytoestrogen. Weak hormonal action of flaxseed lignan competes with the same receptor for estrogen. This may decrease the hormonal signaling involved at the beginning of tumor development in the breast (Dyer 2014).

Intake of flaxseed lignans reduces the risk of polycystic ovary syndrome (PCOS) in susceptible women as lignan binds with free circulating testosterone and excluded the biliary system. Studies with flaxseed supplementation (30 g/day) for 4 months in a 31-year-old PCOS woman showed a reduction in total testosterone (from150 ng/dL to 45 ng/dL) and free testosterone (from 4.7 ng/dL to 0.5 ng/dL) along with reduced hirsutism (a condition of unwanted male-pattern hair growth in female) (Nowak et al. 2007).

Flaxseed has very low levels of carbohydrates (1 g/100 g). Due to high dietary fiber, higher levels of micronutrients, and lower levels of carbohydrate, flaxseed cake has low glycemic index. In a recent study, incorporation of flaxseed as 10 g in three servings to a daily diet in the form of muffins lowered glucose profile over 24 h

compared to the control (0 g of flaxseed) (Almehmadi et al. 2021). This study highlights the key role of flaxseed cake/flour for control and prevention of diabetes. Consumption of flaxseed protein hydrolysate prevents the production of potent blood vessel constrictor octapeptide angiotensin II by inhibiting the angiotensin-I-converting enzyme and thus reduces the blood pressure (Marambe et al. 2008). Among many reasons, nitric oxide an endogenously synthesized free radical within human body causes neuroinflammation and progress in Alzheimer's disease. Synthesis of nitric oxide requires transport of electrons from the carboxyl-terminal domain to the amino-terminal domain of nitric oxide synthase by calmodulin. Omoni and Aluko (2006) observed that flaxseed protein hydrolysate induced a change in secondary and tertiary structures of calmodulin which presumably decreases the production of nitric oxide and thus reduce the risk of neurodegenerative disorders.

Linseed mucilage is obtained from the seed coat. Aqueous extract of mucilage from seed by precipitation process (soaking in water for 24 hours) gives high viscosity solution that forms a white friable, fibrous mass when fully dry. Its functional properties are equivalent to gum Arabic, and its composition includes polysaccharides like xylose, glucose, galactose, galacturonic acid, arabinose, and rhamnose. Linseed mucilage is utilized as an emulsifier and thickener in food products, inflammation or irritation reliever in pharmaceutical industries, and a base material for eye ointment (Das and Naik 2017).

Utilization of nutritional compounds of linseed in nutraceutical and pharmaceutical industries is gaining momentum along with research findings in human health improvement by linseed products (Fig. 2). Flax seed lignan extract is available in the market as 40 mg capsules and recommended as a support for menopausal and postmenopausal women. Flax lignan SDG 156 mg of 60 capsules available in the market is used as a dietary supplement which is having strong antioxidant activity; promotes prostate, breast, circulatory, and bone health; and helps alleviate discomforts associated with menopause. Concentrated linseed SDG lignan 35 mg capsules are commercially available in the market and are mainly used for treating liver and hormonal problems in the dog.

Fortification of α-linolenic acid in meat, eggs, bakery, dairy, and infant formula is effective and an economical way to deliver omega-3 fatty acid among health-conscious consumers (Patel et al. 2022). Nanotechnology delivery system can be effectively used for fortification of food with bioactive lipids (fat-soluble vitamins, omega-3 fatty acids) to improve nutritional quality and the bioavailability of the products. Novel nano-emulsion for fortification of dairy beverages with α-linolenic acid and essential micronutrients, production of omega-3 yogurt using flaxseed oil, vegetarian omega-3 fatty acid enriched cake, linseed oil-based nano-encapsulation using chia seed mucilage, and ice cream using microencapsulated flaxseed oil are some of outcomes from nanotechnological approach (Gowda et al. 2018; Stefani et al. 2019; Jagtap et al. 2020; Almasi et al. 2021; Murugkar et al. 2021). It was found that microencapsulation not only improved antioxidant activity of food but also improved shelf life and sensory attributes (Eric-Parfait Kouamé et al. 2021).

- **Flaxseed (*Linum usitatissimum* L.)**
- **Major constituents:**
  - ❖ Flaxseed oil (Alpha-linolenic acid)
  - ❖ Dietary Fibre
  - ❖ Lignan - Secoisolariciresinol diglucoside (SDG)
  - ❖ Proteins
  - ❖ Carbohydrate
  - ❖ Amino acids
  - ❖ Vitamins
  - ❖ Minor micronutrients
  - ❖ Antioxidants

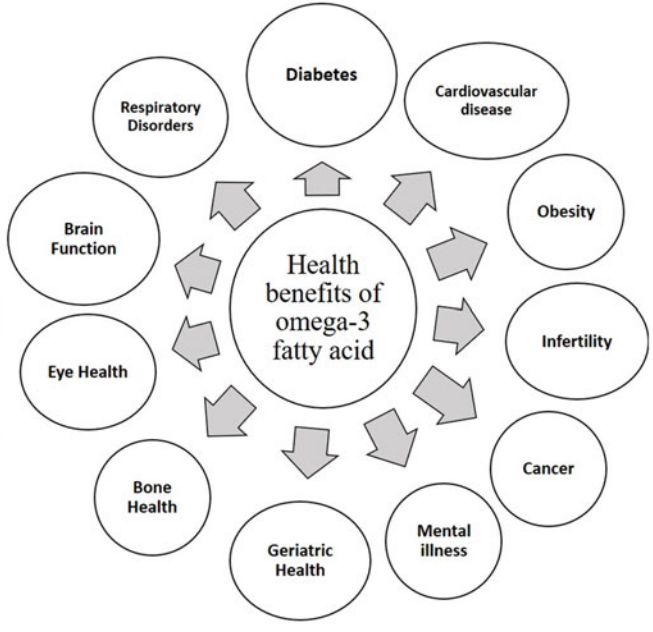

Fig. 2 Major constituents, health benefits, and diversified products of linseed

3 Genetic Resources of Health-Related (HR) Genes

Plant genetic resources (PGR) with a wider genetic base are the most important and essential basic materials to meet the current and future requirements of crop improvement programs. Wild relatives, breeding lines, elite cultivars, native landraces, local selections, mutants, polyploids, and hybrids of crop plants are essential components of PGR. The diversity in PGR is systematically collected and conserved by PGR institutes/centers. Around 48,000 linseed germplasm accessions are conserved in gene banks all over the world. Approximately 3500 accessions of world cultivated flax collection are being maintained at Plant Gene Resources of Canada (PGRC 2018). Approximately, 2900 linseed accessions are stored under a long-term storage facility of the National Bureau of Plant Genetic Resources (NBPGR) in India. The crop gene pool concept was first developed by Harlan and de Wet (1971). Further, they classified the germplasm resources into primary, secondary, and tertiary gene pools. Cultivated flax (*L. usitatissimum*) and its progenitor pale flax (*L. bienne*) are together considered as primary gene pool. Both are diploid species with $2n = 30$ chromosomes. They are cross compatible with each other in both directions and yield fertile progeny. Those closely related flax species which can be crossed with cultivated flax and can give partially fertile progeny are kept under secondary gene pool. Wild flax species like *L. nervosum*, *L. pallescens*, *L. africanum*, *L. corymbiferum*, *L. decumbens*, *L. hirsutum*, *L. floccosum*, and *L. tenue* produced successful cross progeny with cultivated flax, and these can be considered as the secondary gene pool. Those species which are distantly related to flax and cross incompatible with cultivated flax but could be exploited using advanced biotechnological tools like genetic engineering (Fu 2019) are classified as tertiary gene pool. Quaternary gene pool was introduced by Gepts and Papa (2003) which includes genetically engineered flax like CDC Triffid. This classification helps to assist the access of genetic resources of the crop for plant breeding and to assess the extent of gene flow among populations of a crop and related taxa. Genetic resources in different gene pools need to be expanded and evaluated to identify the germplasm with useful traits like pest and disease resistance, high oil content, high or low omega-3 acid and high or low seed mucilage content, higher thousand seed weight, higher seed yield, etc. Two similar types of linseed are commonly traded, brown and yellow (golden) seeds which are closely related in terms of oil content, but the brown seeds contain more alpha-linolenic fatty acids (59%) when compared to the yellow seeds (51%). Therefore, brown linseed can be considered as nutritionally richer than yellow seeds. Both types of linseed are used for human consumption. Mostly yellow linseed is considered for cooking purposes because it blends well with various dishes due to its golden color. Among the many traits, seed mucilage content and omega-3 fatty acid are important traits with huge nutraceutical values. Diederichsen et al. (2006) reported a wide variation of seed coat mucilage content in 1689 flax accessions from 61 countries based on mucilage indicator values (MIVs) ranging from 22.1 to 343.4 centistokes (cSt) mL g^{-1}. These accessions can be utilized for mapping quantitative trait loci (QTL) and genes that are associated with mucilage content by linkage analysis and association mapping.

4 Classical Genetics and Traditional Breeding

The genus *Linum* consists of approximately 230 species and separated into 5 sections, *Cathartolinum*, *Dasylinum*, *Linum*, *Linastrum*, and *Syllinum*, based on floral morphology, chromosome number, and interspecific compatibility. Cultivated flax, *L. usitatissimum*, and its suggested progenitors *L. angustifolium* (also known as pale flax) and *L. bienne* are placed under section *Linum*.

Improvement in flax has lagged behind other oilseeds because it occupies a smaller niche as an oilseed and, consequently, received limited resources for research and developmental efforts. Exploitable genetic diversity is also very low within the crop and cannot be readily supplemented by intraspecific hybridization. Hence, breeding strategies in flax involve creating additional genetic variability, selecting the best recombinants, and fixing the genes by making them homozygous. Inheritance of crop characteristics can be controlled by one major gene not influenced by the environment (qualitative traits) to many genes, much influenced by the environment (quantitative traits). Since flax is an autogamous crop, many important traits in flax including days to flowering, days to maturity, plant height, branching and seed yield are quantitative in nature and demonstrate additive gene effects (Mohammadi et al. 2010).

The traditional breeding methods of flax are mainly concentrated on increasing and stabilizing seed yield, enhancing oil content and quality, increasing seed size, and discovering resistance sources to major diseases, early maturity, lodging resistance, plant height, etc. (Dhirhi et al. 2018; Terfa and Gurmu 2020). The selection of genetically diverse parental material in flax breeding depends on the interested trait(s), the crossing purpose, characters which are relatively important other than yield, the pedigree of the pure lines, and the resources and time available. The parental lines can be from many different sources including existing cultivars, adapted elite breeding lines, or new introductions from global flax collection. Flax breeding methods based on inbreeding selection and line evaluation include pure line method, pedigree method, bulk population method, single-seed descent, backcross breeding, recurrent selection, and early-generation testing. Other methods like male sterility, mutation breeding, molecular marker-assisted selection, haploid culture, anther culture, and genetic engineering have much greater potential to enhance and accelerate the flax breeding programs. Commercially cultivated flax cultivars are pure lines which are developed through hybridization of inbred lines along with pedigree selection of recombinant lines from segregating populations (Hall et al. 2016). Consequently, cultivated flax programs continue to rely on a narrow genetic base.

Wang et al. (2017) evaluated six different cultivars of oil and fiber types and evaluated phytochemical compounds, namely, caffeic acid, ρ-coumaric acid, and ferulic acid, and secoisolariciresinol diglucoside (SDG) along with total phenolics, flavonoid contents, and total antioxidant activities. Phytochemical profile of oil- and fiber-type cultivars was non-significantly altered, while cellular antioxidant activity was more in fiber-type cultivars. This study indicated fiber-type cultivars can also be suitable option as that of oil-type cultivars for functional products and dietary supplement production.

Recently, Zhang et al. (2022) studied the effects of environment and genotype along with their interactions on lignan (SDG) content of flaxseed. In this study, six genotypes, namely, Zhangya 2, Longya 8, Linxiabai, Gaolanbai, Shandanbai, and DYMS, were evaluated at eight different locations in China. The lignan (SDG) content in flaxseed ranged between 4.71 and 7.27 mg/g, and this study revealed that among the total recorded variation, 51.38% was due to genotypes and 44.40% due to environments. Further altitude had positively affected lignan content. The study concluded SDG content is mainly genetically controlled and essentially affected by environmental conditions.

Mutation-based breeding, using radiation or chemical mutagenesis, is useful to upgrade elite lines by altering one or two production-limiting or quality traits. Modification of fatty acid profiles, reduction of bast fiber content (McKenzie 2011), and development of new flax type with edible flaxseed oil by eliminating α-linolenic acid (ALA) (18:3cis$\Delta^{9,12,15}$) is also possible through mutation breeding. Mutation breeding has the possibility to remove undesirable compounds from flaxseed, such as linatine and cyanogenic glycosides (Green et al. 2008). Most interesting low and medium linolenic acid linseed lines were obtained through use of ethyl methanesulfonate (EMS) (Ntiamoah and Rowland 1997). Time-consuming procedures, the lack of creation of variability, and narrow genetic base of developed varieties are considered as limitations in conventional breeding. However, molecular methods are being developed to support and speed up the conventional breeding programs.

5 Genetic Diversity Analysis

Important utilizations of genetic diversity analysis (GDA) are an examination of evolutionary relationships of wild species, development of the genetic-linkage and physical mapping, QTL mapping, association mapping, estimation of genetic distance between different accessions, identification of novel trait-specific alleles and discovering microsatellite markers, fingerprinting and cultivar identification, etc. GDA provides an option for the selection of new breeding lines in sustainable plant breeding program. Morphological parameters and isozyme markers were first used for the determination of genetic diversity in linseed. Two distinct morphological types, namely, flax and linseed, were recognized in cultivated linseed species. The flax-type cultivars are mainly grown for the extraction of fiber and are tall-growing with straight stems and few numbers of secondary branches. The linseed types were shorter with lots of branches and grown for seeds, and those predominantly grown in India are meant for extraction of the oil. Diversity analysis based on morphology in flax includes characteristics like plant height (cm), petal color, days to flowering, days to maturity, capsules per plant, seeds per capsule, seed color, seed yield per plant, thousand seed weight (g), oil content (%), oil yield per plot, etc. Adequate variability among the genotypes was identified by GDA, and available genotypes were classified into different groups based on cluster analysis. Genotypes under different clusters with maximum distance can be exploited in the linseed improvement programs (Patial et al. 2019; Kumar and Kumar 2021). However, morphological characteristics are highly

affected by the environment and require labor-intensive field evaluation over an extended period. In addition, biochemical markers are affected by plant developmental stages. Hence, these limitations with morphological and biochemical markers led to the utilization of DNA-based markers for GDA.

Oh et al. (2000) first reported DNA-based markers utilization in linseed for assessing the genetic diversity study. Molecular markers are a specific fragment of DNA sequences found at particular locations on the genome which shows polymorphism between dissimilar individuals and are transmitted from one generation to the next by the standard laws of inheritance. Molecular markers identify insertions, deletions, point mutations, or inversions that occur in allelic DNA sequences, which can distinguish every individual in the same species (Prabha et al. 2017). Various types of molecular marker systems including random amplified polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), inter-simple sequence repeat (ISSR), inter-retrotransposon amplified polymorphism (IRAP), expressed sequence tag (EST), and simple sequence repeat (SSR) have been utilized for GDA of flax germplasm. DNA-based molecular characterization has numerous advantages like abundance, non-tissue-specific traits, early and rapid assessment, and environment independence and can be effectively utilized in GDA (Nag et al. 2015).

The genetic diversity available for mucilage content in flax germplasm makes it feasible to create breeding approaches for high seed mucilage (SM) flax for human consumption and low SM flax for animals and fish. Soto-Cerda et al. (2012) used 150 microsatellite loci to evaluate the linkage disequilibrium (LD), population structure, and genetic diversity of 60 linseed cultivars/accessions covering the breadth of seed mucilage variation in linseed germplasm. Similarity-based methods and STRUCTURE analysis showed the presence of populations expressing particular their geographic origins (North America, South America, and South Asia) and the influence of germplasm exchange among North American flax breeding programs. The spatial distribution of the accessions in the principal coordinate analysis (PCoA) diagram revealed the occurrence of higher genetic distance among the South Asian population and more similarity within the genetic composition of the South American and North American populations. The genetic diversity for each population showed the presence of higher polymorphism information content (PIC) values, allele numbers, and alleles per locus in the North American and South American populations than in the South Asian population. Thirty accessions, covering the allele richness of 99.5% and a comparable range of mucilage variation that exists in the sixty accessions were identified as the ideal core set, which helps to optimize the detection of significant associations between SSR alleles and mucilage-related genes/QTLs in flax. The results conclude that the collection of flax accessions could be effectively utilized in association mapping (AM) studies targeting the discovery of alleles/genes involved in seed mucilage. However, there is a need for greater diversity to improve the AM resolution in flax.

Maximization of genetic gain in linseed needs increasing of genetic diversity of linseed parental stocks by including diverse genotypes. For this purpose, Hoque et al. (2020) analyzed the population substructure, linkage disequilibrium, and genetic diversity of 350 linseed genotypes distributed globally by utilizing 6200 single

nucleotide polymorphism (SNP) markers. The average marker density of SNP markers across the 15 chromosomes was 1 per 51.17 kb. The presence of more transitions and less transversions SNPs in linseed indicates more tolerable nature of transition SNPs in natural selection (Luo et al. 2017). Structure analysis using the PCoA, delta K approach, and neighbor joining tree analysis categorized the whole linseed genotype collections into seven sub-populations (P1 to P7). The genotypes that originated from Asia (India, Pakistan), Europe (Hungary), and Turkey were grouped under P6, P1, and P7, respectively, whereas North Dakota State University (NDSU) along with other American genotypes were categorized under P5 sub-population. P2, P3, and P4 consisted of a mixture of linseed genotypes from different origins. Oil-type genotypes were observed in all the sub-populations except P2, which included mostly the fiber-type linseed genotypes. Among oil types, P1 and P7 sub-populations belonged to winter type. Spring-type seed flax belonged to P5, Indian seed flax with short large seed belonged to P6, the Argentine or Mediterranean seed flax belonged to P3 and forage type, and seed flax of Ethiopia belonged to P4 sub-population. The identified SNP markers revealed only moderate diversity in different sub-populations. Negative Tajima's D value of sub-population P6 indicated occurrence of more rare alleles in P6 group, and positive Tajima's D values of remaining six sub-populations indicated less rare alleles in groups other than P6. This concluded P6 as a group with recent expansion and remaining as groups of recent population contraction. Hybridization between Asian individuals (P6) and NDSU stock (P5) is possibly the best choice to increase genetic gain. Dual-purpose varieties could be developed by crossing P2 and P5 because of their low genetic differentiation and possibilities for accumulation of desired alleles for oil and fiber content.

Though cultivation of linseed has been practiced over a period of 1000 years or more as an oil and fiber crop, it was unclear about the changes in agronomic traits at the genetic level during linseed cultivation. Zhang et al. (2020) performed whole-genome shotgun sequencing on multiple accessions of oil-use, fiber-use, landraces, and pale flax to identify the genomic variations during flax cultivation. The findings of this study revealed that the genes pertinent to plant architecture, flowering, dehiscence, and oil production were favorably selected during linseed domestication. Furthermore, regardless of the origin, the advancement in modern oil-use flax is more compared to fiber-use flax, although the selection for both oil and fiber flax occurred simultaneously during the early period of flax domestication. They also found that the spread of *MYB46/MYB83* sister genes in flax may cause the biosynthesis of unique secondary cell wall in flax stem. The directional selections of *MYB46/MYB83* may have provided a shape to morphological profile of the present oil and fiber flax.

It is well identified that genes of fatty acid desaturase (*FAD*) and stearoyl-ACP desaturase (*SAD*) families play an important role in fatty acid synthesis, and few alleles of these genes are inked with flax oil synthesis. Genetic polymorphism of *FAD* and *SAD* genes was assessed in the representative accessions of 84 linseed cultivars and lines showing different levels of palmitic (5–7.6%), stearic (2.7–6.4%), oleic (12.9–24%), linoleic (11.9–72.4%), and linolenic (2.7–65.3%) acids. The highest level of genetic diversity was observed for *FAD3A* and *FAD3B* genes. The polymorphisms identified in this study could be effectively utilized for the marker-assisted selection in flax breeding (Dmitriev et al. 2020).

6 Molecular Mapping of HR Genes and QTLs

Association mapping (AM) approach is effectively applied for identification of QTLs by examining the marker-trait associations across the set of diverse germplasm/population. Identification of alleles and new genes as well as dissection of complex characters is possible by AM. Genome-wide association studies (GWAS) and candidate genes are important components of AM. The selection of germplasm, phenotypic and genotypic data quality, and use of suitable statistical analysis for detection and verification of marker-phenotype associations are critical to association analysis. AM provides a high-resolution than the linkage map to determine the importance of various loci or segment of the genome on the expression of single or multiple traits, because AM utilizes an extensive range of germplasm including natural populations and collections of varieties and breeding lines to map traits by linkage disequilibrium (LD). Population structure, population and sample sizes, and marker density are few critical factors which should be considered in application of AM (Ibrahim et al. 2020). Cloutier et al. (2009) reported the development of 275 polymorphic EST-SSRs in flax which could be used to develop physical maps, QTL mapping, and potential to reduce the time for cultivar development. Following the development of these markers, a consensus genetic and physical map using DNA markers in combination with the flax genome sequencing was reported (Cloutier et al. 2012). Three dissimilar mapping populations (CDC Bethune/MacBeth, E1474/Viking, and SP2047/UGG5–5) were used to generate this map. The consensus map has 670 DNA markers anchored to 204 of the 416 fingerprinted contigs of the physical map, and the overall map density is 2.0 cM for markers arranged on 15 linkage groups.

Linseed oil is used for its food and non-food applications. Modification in oil content along with fatty acid profiles of linseed to fulfill the needs of the market promptly requires a clear understanding of their QTL architectures, which have received poor attention to date. Soto-Cerda et al. (2014) assayed a flax core collection of 390 accessions with 460 microsatellite markers for the quantitative nature of seed quality traits including oil content (OIL), palmitic acid, stearic acid, oleic acid, linoleic acid (LIO), linolenic acid (LIN), and iodine value. After growing the core collection in a modified augmented design at two locations over 3 years, phenotypic data for all the seven traits were obtained from six environments. Substantial phenotypic diversity was noticed for each trait along with moderate to higher heritability. Most of the stable candidate QTLs were identified by multivariate analyses. Co-localizations of candidate QTLs for LIO and LIN were observed with previously identified QTL of bi-parental populations. Some QTLs were mapped with the genes which are considered to be responsible for fatty acid biosynthesis. Canadian cultivars showed absence of 58 percent of QTL alleles when compared to core collections which indicated potential usefulness of core collection in improvement of seed quality traits. The candidate QTLs identified in the particular study laid the foundation for marker-assisted breeding studies in linseed.

Kumar et al. (2015) constructed a genetic map based on selected 329 SNPs and 362 SSR markers using a recombinant inbred line population of 243 individuals from a cross between the Canadian varieties CDC Bethune and Macbeth. The

genetic map comprised of 15 linkage groups including 691 markers where one marker in every 1.9 cM was the average marker density. Total number of QTLs identified in this study with respect to 14 traits was 20. Among them, two QTLs for linoleic acid, one QTL each for linolenic acid, palmitic acid, and oil content, and three QTLs each for stearic acid and oleic acid were identified. Proteins synthesized by candidate gene regions linked with QTLs were involved in yield component traits along with fatty acid biosynthesis and their metabolism. This study provided a base for map-based QTL cloning and marker-assisted selection (MAS) in linseed.

Soto-Cerda et al. (2012) assessed 62 flax cultivar/accessions to understand the LD, population structure, and genetic diversity of linseed germplasm showing variation in mucilage content. It is crucial for the recognition of QTLs and genes related to mucilage by association mapping.

GWAS of flaxseed was conducted by Soto-Cerda et al. (2018) for mucilage content and hull content. A total of 200 diverse linseed accessions were genotyped by using 1.7 million SNP markers. The data revealed a wide range of phenotypic variation along with high (~70%) and an average (~49%) narrow-sense heritability for mucilage content and hull content, respectively. Seven QTLs for MC and four QTLs for HC were also identified. Promising candidate genes such as *TRANSPARENT TESTA 8*, *GALACTUROSYL TRANSFERASE-LIKE 5*, *SUBTILISIN-LIKE SERINE PROTEASE*, *MUCILAGE-MODIFIED 4*, *AGAMOUS-LIKE MADS-BOX PROTEIN AGL62*, *GLYCOSYL HYDROLASE FAMILY 17*, and *UDP-GLUCOSE FLAVONOL 3-O-GLUCOSYLTRANSFERASE* were identified which are *Arabidopsis thaliana* gene orthologs to *L. usitatissimum*. These genes play a significant role in seed coat development, synthesis, and release of mucilage and biosynthesis of anthocyanins in *A. thaliana*.

Several software/statistical packages have been utilized in AM studies. These include Trait Analysis by Association, Evolution and Linkage (TASSEL), STRUCTURE, R package, EINGENSTRAT, Statistical Analysis System (SAS), Spatial Pattern Analysis of Genetic Diversity (SPAGeDi), Multiple Trait Derivative-Free Restricted Maximum Likelihood (MTDFREML), Residual Maximum Likelihood (ASREML), STRAT, Bimbam, and GEN STAT 11 (Álvarez et al. 2014). Heterogeneity in dependent instruments (HEIDI) and Summary-data-based Mendelian randomization (SMR) tools are utilized to test pleiotropic interaction between gene expression level and complex traits using expression quantitative trait loci (eQTL) and GWAS data (Zhu et al. 2016).

7 Marker-Assisted Breeding for HR Traits

Marker-assisted breeding (MAB) combines classical plant breeding with the tools and discoveries of molecular biology and genetics, most specifically the utilization of molecular markers to develop new varieties/hybrids in cultivated crops. Utilizing molecular markers in linseed improvement started in the late 1990s. Initially RAPD and RFLP markers were developed along with isozymes and morphological markers for construction of genetic maps. The discovery of PCR-based marker system

provided new opportunities to identify several DNA polymorphisms within linseed genomes. Among many PCR-based markers, SSRs/microsatellite markers based on genomic structural variation became popular because of their highly polymorphic and robust nature and relatively simple and inexpensive analysis. In earlier study, Cloutier et al. (2009) developed 275 EST-SSR loci and studied the genetic relationships of 23 linseed accessions. Two microsatellite-enriched linseed genomic libraries were constructed by Deng et al. (2011) for trinucleotide ATC and TTC motifs. They also characterized and evaluated 38 polymorphic microsatellite markers in 8 linseed cultivars from different regions of the world. These research findings are useful in identification and classification of germplasm, construction of genetic linkage map, QTL mapping along with gene identification, and marker-assisted breeding of linseed. Wu et al. (2017) screened 1574 microsatellites from linseed obtained using reduced representation genome sequencing (RRGS) to systematically identify SSR markers that would be immediately suitable for use in flax breeding. The identified SSR markers were immediately utilized to distinguish oil and fiber types of flax among the 48 varieties screened. 'NEW1' and 'Venus' exhibited distinct genetic backgrounds from the other fiber cultivars. Similarly, cultivar 'A0529' showed a different genetic composition than the other oilseed cultivar. Therefore, it was concluded that these three cultivars, 'NEW1', 'Venus', and 'A0529', have the huge potential to use in flax improvement programs.

SNPs which are highly abundant and known to be present in high frequency in the genome gained attention during the past decade. Kumar et al. (2012) discovered 55,465 SNPs using reduced representation libraries of 8 linseed genotypes and validated 4706 SNPs using genotyping-by-sequencing of 96 F_6 individuals from a population of recombinant inbred lines derived from a cross of CDC Bethune and Macbeth. The authors recommended SNP marker developed in this work for construction of high-density maps of linseed, association mapping, phylogenetic analyses, QTL discovery, MAS, and whole genome shotgun sequencing. Advancements in molecular marker development resulted in their effective utilization in construction of high-density linkage map (Yi et al. 2017), genomic variations and association study (Xie et al. 2018), and identification of powdery mildew resistance source (Speck et al. 2022) in linseed through marker-assisted breeding.

8 Genomics-Aided Breeding for HR Traits

Breeders can select suitable parents with novel combinations for different crossing programs by genomics-assisted breeding (GAB) which ultimately helps to develop the elite breeding lines. Adequate genomic resources coupled with broad genetic base in cultivated gene pool are a prerequisite for GAB. Several research groups are engaged in developing genomic resources during the last few years in linseed.

Advancement in molecular genetic methods led to development of numerous molecular markers allowing breeders to use the markers to aid breeding. Though MAS was proposed to improve the linseed traits that are governed by QTLs or genes with relatively large effects, most of the economically important traits of crops are

controlled by polygenes, each with a smaller effect (Riedelsheimer et al. 2012). This is a limitation of MAS in linseed breeding. Therefore, an advanced method, i.e., genomic selection (GS) which enables to evaluate breeding values (BVs) of the segregating individuals of crosses, was introduced. GS is considered as an advancement of MAS. In GS, a statistical prediction model is built to predict breeding values (BVs) called genomic estimated breeding values (GEBVs) of unphenotyped individuals by using genome-wide markers in a genotyped and phenotyped training population (Meuwissen et al. 2001). This is highly useful in breeding to predict GEBVs of individuals and thus identify superior genotypes among selection candidates according to their genomic information.

In another advancement, the integration of GS and computer simulation resulted in an improved genomic tool known as genomic cross prediction. Genomic cross prediction uses the available information of genome-wide molecular markers and consensus genetic maps and integrates computer simulation and GS to simulate virtual crosses, generate segregation populations, and estimate the expected genetic performance of the virtual crosses to assist breeders in selecting parents and crosses in plant breeding effectively.

You et al. (2022) extracted a total of 290 linseed accessions from the flax core collection as a training population. These accessions are possible parents in flax breeding, including 13 landraces, 193 cultivars, 59 breeding lines, and 25 unknown lines collected from 34 countries. A set of 258,708 SNPs in 290 flax accessions were selected (He et al. 2019) for further analyses. Five important linseed traits including days to maturity (DTM), seed yield (YLD), linolenic acid (LIN), oil (OIL), and powdery mildew resistance (PM) were chosen as breeding targets in flax breeding selection. Genomic selection models were constructed, virtual crosses and simulation of progeny populations, evaluation of virtual crosses were carried out. A total of 317, 450, 313, 496, and 235 nonredundant QTNs were identified using six multi-locus models for DTM, YLD, LIN, OIL, and PM, respectively. The predictive abilities for all five traits were greater than 0.90, being 0.95, 0.90, 0.95, 0.92, and 0.89 for YLD, DTM, OIL, LIN, and PM, respectively. GCAs of 290 parents were calculated for all 41,905 single crosses. A consistently high linear relationship, i.e., close to 1, was observed between GCAs and GEBVs of the parents, suggesting that GEBVs of parents estimated using GS models with QTN markers can effectively predict the GCAs of the parents. In linseed breeding programs, early maturing, disease-resistant individuals with high YLD, OIL, and LIN were selected. The top 10% accessions (29 out of 290 accessions) with the highest GCAs for each trait, which have the best potential to improve traits in linseed cross breeding, were identified.

9 Cloning of HR Genes

Industrial oil flax and edible oil or solin flax differ mainly in seed linolenic acid levels. Seed oil of flax contains high level of linolenic acid, generally around 45% to 65%. Rowland (1991) observed an M_2 seed with mutations that contain less than 2% linolenic acid by using chemical (EMS) mutagenesis. Two genes, *LuFAD3A* and *LuFAD3B*, are responsible for high linolenic acid in wild flax. Microsomal

desaturases encoded by these two genes are capable of desaturating linoleic acid. Vrinten et al. (2005) reported that cloning of two members of the FATTY ACID DESATURASE (FAD3) family of microsomal Δ15-FADs, designated *LuFAD3A* and *LuFAD3B*, reveals the molecular mechanism behind this trait. The expression of these two genes in *Saccharomyces cerevisiae* revealed point mutations in both the genes which result synthesis of premature stop codons and production of truncated inactive proteins in the low-linolenic-acid solin line.

A project on the Total Utilization Flax GENomics (TUFGEN; http://www.tufgen.ca) was started in Canada during 2009 to create genomics resources for linseed and to develop an inclusive knowledge of its unique genome with specific goals in applied genomics targeting flax improvement. In this study, genome-wide physical map for flax was constructed first time by using 43,776 bacterial artificial chromosome (BAC) clones from the library of the flax cultivar CDC Bethune. It provides a framework for accessing target loci with economic importance for marker development and positional cloning (Ragupathy et al. 2011).

Enzymes of *FAD2* and *FAD3* are responsible for the Δ12 [converted oleic acid (OLE) to linoleic acid (LIO)] and Δ15 desaturation [converted LIO to α-linolenic acid (LIN)] in planta. Three alleles of *FAD2A*, four of *FAD2B*, six of *FAD3A*, and seven of *FAD3B* were cloned in to a pYES vector (yeast expression vector), and all the 20 constructs were transformed in yeast along with an empty construct. The transformants were activated in the presence of substrates like OLE acid and LIO acid for FAD2 and FAD3, respectively. Fivefold increase of FAD3A-C activity and fourfold increase of FAD3A-F activity were identified. Utilization of such isoforms in breeding line development could enhance the relative amount of LIN acid in flax (Radovanovic et al. 2014).

Lysophosphatidic acid acyltransferases are an emerging family of enzymes that catalyze the synthesis of phosphatidic acid (PA) using lysophosphatidic acid (LPA) and acyl-CoA (Korbes et al. 2016). The product of this enzymatic reaction, PA, is precursor for the biosynthesis of all glycerophospholipids and triacylglycerol (TAG). Fahs et al. (2019) investigated the contribution of 2-lysophosphatidic acid acyltransferase (LPAAT) enzymes from flax in the accumulation of α-linolenic acid into the oil fraction of flax seed. cDNAs encoding three class A microsomal LPAAT2 isoforms were isolated from developing seeds of flax, and their specific activity was assayed. LPAAT2A showed high selectivity for linolenic and linoleic acids when compared to saturated fatty acids. Increased accumulation of linolenic and linoleic acids was observed in Arabidopsis seeds because of heterologous expression of LPAAT2A in two transgenic Arabidopsis lines. These findings suggest the incorporation of LPAAT2 isoform in linseed breeding program for developing cultivars with higher α-linolenic acid.

10 Genetic Engineering for HR Traits

Genetic engineering is considered as an excellent technology to enrich the gene pool of linseed/flax with genes of interest which are not naturally present in the linseed genome. The first genetically engineered flax cells were created in 1983 by

recombinant DNA technologies. Different methods to deliver genes into flax genome have been developed and utilized over the years. The most used procedure in the flax has been *Agrobacterium*-mediated hypocotyl transformation. Gene transfer using protoplast transformation, particle gun (biolistic) method (University of Saskatchewan, Saskatoon, Canada), *Agrobacterium* transformation of flax via floral dip (Dutta et al. 2021), and apical meristem-targeted in planta transformation protocol (Kesiraju et al. 2021) are also other successful methods to obtain transgenic flax. The fatty acid content and composition, the lignan (especially secoisolariciresinol diglucoside – SDG) content, flax fiber quality (improved elastic properties, reduction of pectin content, higher retting efficiency, improved mechanical properties, biodegradable polymers), tolerance to herbicides (sulfonylurea, glyphosate, and glufosinate-ammonium), and diseases resistance (*Fusarium*) have already been altered or improved by genetic engineering in flax (Rui-López et al. 2009; Ludvíková and Griga 2015). In 1996, the transgenic linseed cultivar CDC Triffid (sulfonylurea resistance) was officially registered in Canada, and it was deregistered in 2001 due to problems in its export to European countries. *Solanum sogarandinum* glycosyltransferase (SsGT1) gene was introduced into the flax genome to overproduce SsGT1 which is responsible for higher resistance to *Fusarium* infection in transgenic flax than wild-type plants. Overproduction of glycosyltransferase in transgenic flax also resulted in the accumulation of ferulic acid, ρ-coumaric acid, and caffeic acid and their glucoside derivatives, kaempferol, quercetin, and secoisolariciresinol diglucoside (SDG) in flax seeds (Czemplik et al. 2012). This transgenic flax seedcake extract showed a superior effect on fibroblast migration after a 24-hour treatment and inhibitory properties toward two bacterial strains: *Staphylococcus aureus* and *Escherichia coli*. This flax seedcake extract is good for skin health of human and can be considered an alternative treatment for infected wounds (Czemplik et al. 2012). Lorenc-Kukuła et al. (2005) aimed at generating flax plants with increased antioxidant capacity to increase the yield and resistance to *Fusarium culmorum* and *Fusarium oxysporum* via the expression of genes encoding chalcone isomerase, chalcone synthase, and dihydroflavonol reductase. Along with increase in antioxidant properties, pathogen resistance, and seed yield, increased content of SDG was also observed in transgenic lines. Introduction of *crtB*, a bacterial phytoene synthase gene, into flax by *Agrobacterium*-mediated transformation increased phytoene, α-carotene, and β-carotene content in seeds. The flow of phytoene production from geranylgeranyl diphosphate was first stimulated by the expressed *crtB* gene product in flax seeds. Then phytoene was further decomposed to α-carotene, β-carotene, and lutein, as catalyzed by the enzyme which biosynthesize endogenous carotenoid in seeds. These transgenic seeds expressed 65.4 to156.3 μg/g of carotenoid on fresh weight basis. A 7.8- to 18.6-fold enhancement of carotenoid content was observed in transformed seeds than in untransformed controls. These carotenoid-enriched transgenic seeds were considered as nutritional sources for human health (Fujisawa et al. 2008). Transformation of genes encoding acyl-desaturases and acyl-elongases in linseed from *Phaeodactylum tricornutum* (algae) and *Physcomitrella patens* (mosses) resulted in higher accumulation of 20C PUFAs including arachidonic acid (ARA) and eicosapentaenoic acid (EPA) in seeds of

transgenic flax (Abbadi et al. 2004). Introduction of the omega-3-specific D6-desaturase gene from *Primula vialii* in linseed by *Agrobacterium*-mediated transformation accumulates stearidonic acid (SDA) in flax seed. SDA is a metabolic intermediate on the biosynthetic pathway of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), generated by the D6-desaturation of omega-3 fatty acid. Evidence suggests that SDA provides similar health benefits like EPA and DHA (Rui-López et al. 2009). The suppression of the chalcone synthase gene in transformed linseed plants resulted in the increased antioxidant status of seeds. Consequently, 20–45% of higher polyunsaturated fatty acid (mainly α-linolenic acid) accumulation was observed in transgenic seeds than in the control (Zuk et al. 2012). Pinoresinol lariciresinol reductase (PLR) is a key enzyme for SDG formation in the seed coat of flax seeds (Hano et al. 2006). RNAi phenomenon was successfully used to downregulate *LuPLR1* gene expression which leads to failed accumulation of SDG in plants. Synthesis of 8–5'linked neolignans dehydrodiconiferyl alcohol glucoside (DCG) and dihydro-dehydrodiconiferyl alcohol glucoside (DDCG) deviate the monolignol flux in linseed. These PLR devoid transgenic lines were utilized for the comparison of their behavior in the domain of insect resistance (Renouard et al. 2014). High oleic oil is a trait preferred by industries because of its stability and multiple applications. Two isoforms encoded by two *FAD2* genes in flaxseed, desaturate monounsaturated oleic acid to polyunsaturated linoleic acid. High content of oleic acid in flax, up to 80%, was realized in RNAi-mediated gene silenced lines by simultaneous silencing of both the FAD2 genes (Chen et al. 2015).

In general, plant oils do not contain very-long-chain polyunsaturated fatty acids (VLCPUFA). VLCPUFA play a major role in human physiology, either as elements of membrane phospholipids in specialized tissues or as precursors to produce the different groups of eicosanoid effectors. The nutritionally most essential VLCPUFA like arachidonic acid (ARA; ω6–20:$4^{5,8,11,14}$), EPA, and DHA are mostly available in fish oil. Synthesis of VLCPUFA in plant seed is possible by genetic engineering strategies. Seed-specific expression of cDNAs encoding fatty acyl-desaturases and elongases in transgenic linseed resulted in the very high accumulation of Δ6-desaturated C18 fatty acids and up to 5% of C20 polyunsaturated fatty acids (Abbadi et al. 2004). These results encourage biotechnological intervention on nutritional enchantment in linseed crop.

11 Social, Political, and Regulatory Issues

Nowadays food fortification with omega-3 fatty acid is gaining commercial importance. Any fortified food generally offers prophylactic effect and not therapeutic effect, and hence, a lot of time is required to understand the health benefits of any fortified products including omega-3 fortified products. Although health benefits of omega-3 fatty acids are well established, there is no fixed recommended daily allowance for omega-3 fatty acid. Further technological and regulatory issues

relating to food fortification are yet not fully clear with special reference to the appropriate levels of such ingredients in various foods (Panse and Phalke 2016).

Cadmium, cyanogenic compounds, and protease inhibitors present in seeds of linseed are toxic to human health. These are eliminated or reduced when linseed seeds are subjected to thermal treatments like frying in a pan, cooking in microwaves, autoclaving, and boiling (Austria et al. 2008). Some studies showed that flaxseed antinutrients have lesser effects when compared to soybean and canola. The consumption of flaxseed is not advisable in pregnancy, lactation, bleeding disorder, low blood pressure, bipolar disorder, food allergy, gastric obstructions, etc. (Ganorkar and Jain 2013). Daily consumption of three muffins (a total of 32.7 g of flaxseed) for 4 weeks didn't show any toxic or deleterious effect on the hemopoietic system or renal and hepatic function. However, serum triglyceride level was elevated (Stuglin and Prasad 2005). Though transgenic approaches showed lot of potential, strict legislative/political measures of European Union prevent the access of transgenic flax to the EU countries (Ludvíková and Griga 2015).

12 Future Prospects

Linseed improvement requires wider genetic variability, and it can be created with the aid of advanced molecular techniques. Application of marker-assisted breeding and genomic-aided breeding is the need of the hour to harness the nutraceutical and pharmaceutical potential of linseed crop. Flax has a long history of traditional use both as an oil and fiber source. Nowadays, there has been an emerging interest toward the nutraceutical and pharmaceutical properties of flax seed and its health benefits to human population. Though flax oil is the richest source of ALA, it is highly susceptible to oxidation and therefore has a very poor shelf life. Flax oil is generally cold-pressed and enriched by adding vitamin A and E or stored in dark glass jars to avoid faster rancidity. Since none of these protection methods are fully satisfactory, there is a necessity of appropriate breeding strategies, biotechnological interventions, and genetic engineering approaches for overproduction of various natural antioxidants within flax grains. Though conventional breeding and advancements in breeding approaches gave attention on agronomic traits and nutritional factors of linseed, there is a huge need to focus on reduction of toxic substance present in flax seeds. Genetic engineering approaches through transgenic route to create additional variability for targeted traits are available. In view of the regulatory concern, genome editing techniques like transcription activator-like effector nucleases (TALENs), zinc finger nucleases (ZFNs), and clustered regularly interspaced short palindromic repeats/CRISPR-associated (CRISPR/Cas) application have to be explored for linseed improvement. With about 48,000 cultivar accessions including 230 species belonging to primary, secondary, and tertiary gene pools, characterization of the entire set for exploitable variability for nutraceutical traits is yet to be accomplished. Unlike several other crops where the development is through research consortia with huge investments, linseed crop received very less attention and resources. Efforts need to be intensified to accelerate the breeding programs as

linseed with varied uses as food, fiber, and oil has great potential and a huge impact on human health, industry, and economy.

13 Conclusion

Linseed is getting huge demand considering its nutritional and medicinal properties. In order to fully exploit the nutritional potential of the linseed crop, technological advancements both in pre- and post-harvest is need of the hour. In this context, for crop improvement various crop-oriented technologies such as marker-assisted breeding and genomic-aided breeding, genome editing techniques followed by biotechnological interventions, and genetic engineering approaches for improved nutritional content and reduction of anti-nutrients in the crop for improving the edible use of flaxseed should be the right approach. Further, to utilize the medicinal and therapeutic potential of the crop, value addition using various post-harvest technologies for developing linseed-based fortified food products for improved human health and exploring its potential for food and pharmaceutical industries is of prime importance.

Increasing Nutraceutical and Pharmaceutical Applications of Safflower: Genetic and Genomic Approaches

Megha Sharma, Varun Bhardwaj, Poulami Goswami, Anmol Kalra, Kadirvel Palchamy, Arun Jagannath, and Shailendra Goel

Contents

Abstract

Nutraceuticals are functional foods that are produced in nature and show medicinal, health-promoting, and disease-preventing properties. One of the important sources of dietary and herb-based nutraceuticals is safflower. Safflower is an oil seed crop cultivated globally in ~23 countries. Being a source of unsaturated fatty acids such as linoleic and oleic acid, safflower oil confers several health benefits. Besides seed oil, petals and leaves of the safflower have been used widely in the pharmaceutical industry due to their richness in flavonoids and alkaloids. Crude floral extracts are known to possess anti-inflammatory and analgesic properties and bring wide health-related benefits in cardiovascular and diabetic patients. Although safflower oil is healthier, it is not a popular crop due to its lower oil content and economical value. Various efforts have been made by plant scientists

Megha Sharma, Varun Bhardwaj and Poulami Goswami contributed equally to this study.

to increase oil content as well as oil composition in the safflower. Over the past few decades, various breeding strategies including conventional breeding, molecular breeding, and genetic engineering approaches resulted in improved cultivars with better oil composition and content. Thus, with its high nutrition value, safflower has great potential to play an important role in the nutraceutical and pharmaceutical industry.

1 Introduction

With the emergence of the new world and increased life expectancy, the risk of lifestyle diseases has also increased significantly. Epidemiological studies show that dietary habits play a critical role in human health. These studies increased the popularity of plant-based compounds commonly called "nutraceuticals." The combined efforts of the food industry, pharmaceutical, and newly merged nutritional conglomerates led to the development of nutraceuticals to cater to demands of the herbal and dietary supplements market. Nutraceuticals are often referred as functional foods or phytochemicals. These are natural, bioactive, chemical compounds with medicinal, health-promoting, and disease-preventing properties (Dureja et al. 2003). They can be classified as Nutrients, Herbal, or Dietary based compounds. Herbal or botanical products are concentrated or extracts whereas Dietary products are the reagents derived from other sources which include pyruvate, sulphate. These products serve functions of sports nutrients and meal replacement. In the present era, Aloe Vera, Echinacea, Evening primrose oil, Garlic, and Ginger Plantago have been used commonly in herbal and phytochemical products (Dureja et al. 2003).

The human staple diet includes fruits, vegetables, whole grains, herbs, nuts, and seeds and is often supplemented with fats and edible oil which are rich in energy. Based on the saturation levels, edible oil rich in unsaturated fatty acids are healthier as compared to oils rich in saturated fatty acids. Safflower oil is characterized by higher levels of unsaturated fatty acids, and the plant is also a rich source of secondary metabolites. Hence, safflower has immense potential as a nutraceutical crop and can be an important source of herbal as well as dietary supplements (Fig. 1).

Safflower (*Carthamus tinctorius* L.*)* is a member of the Asteraceae. It is grown in ~23 countries with 6.2 million tons of seed production (FAOSTAT 2019). Kazakhstan, United States of America (USA), Russia, Mexico, China, and India are the major producers of safflower and contribute to ~81% of the global production. Along with oil, it has been used as coloring dye, food flavoring agent, and for pharmaceutical purposes (Carlsson et al. 2014). More than 200 compounds can be extracted from safflower including fatty acids, flavonoids, and steroids.

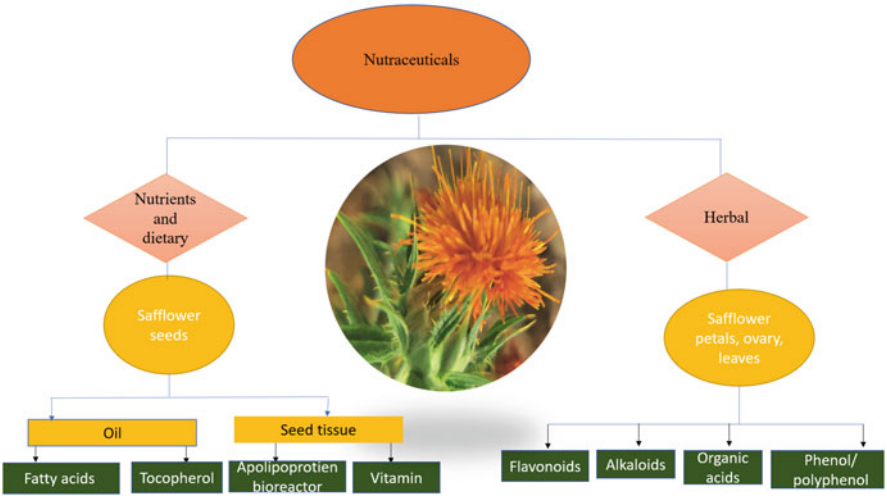

Fig. 1 Scope of nutraceuticals in safflower *(Carthamus tinctorius)*

Safflower promises diverse roles in human nutrition and health. The nutritionally beneficial compounds are mainly extracted from its seeds and flowers. Based on the plant part used, safflower products can be categorized into seed-based and non-seed based products. Safflower seeds are the source of edible oil along with protein, β-carotene (vitamin A), and riboflavin (vitamin B_2). The richness of safflower oil in unsaturated fatty acids such as OA and LA along with low levels of low-density lipoprotein makes it highly effective in managing cardiovascular diseases. It contributes to artery dilation, lowering of blood pressure, blood flow enhancement as well as tissue oxygenation. Due to the high levels of LA, it is also effective in controlling osteoporosis. It possesses anti-inflammatory properties, corrects bone loss, and increases intestinal calcium absorption (Bae et al. 2002). The seed has active α-glucosidase inhibitors in derivative form of serotonin and is used in traditional medicine for treatment of diabetes (Takahashi and Miyazawa. 2012). The non-seed based plant parts such as petals are the source of the flavonoid glycosides, carthamin, kaempferol, quercetin, chalcones including hydroxysafflor yellow A (Shirwaikar et al. 2010). Safflower yellow A showed inhibition of formaldehyde-induced swelling, formation of ball granuloma, and histamine-stimulated capillary permeability and thus exhibits anti-inflammatory effects (Huang et al. 1984). Petals of safflower possess analgesic activity and can be considered a potential drug equivalent to morphine without the side effects (Almeida et al. 2001). Being rich in hypolipidemic agents, safflower petals have antidiabetic effects. The flowers of safflower elevate insulin level by enhancing insulin secretion from islets of Langerhans as well as regeneration, restores protein breakdown, and promotes glycogenesis (Asgary et al. 2012). Being the source of the fatty acids, tocopherols, vitamins, and antioxidants, safflower oil is a potential bioactive food ingredient.

Safflower exhibits a high level of geographical diversity (Ashri and Knowles 1960), phenotypic diversity (Ashri et al. 1974; as well as molecular diversity (Hassani et al. 2020; Ambreen et al. 2015; Amini et al. 2008). Safflower is characterized by a rich germplasm, consisting of cultivars, landraces, and wild-species. A germplasm directory of safflower documented details of germplasm collected from 18 different collection sites across 14 countries (Zhang and Johnson 1999) (http://safflower.wsu.edu/). Currently, a large collection of safflower germplasm is available at USDA, USA and has a repository of ~2400 accessions representing germplasm from 50 countries. A large collection of germplasm and the associated genetic diversity provide an opportunity to exploit safflower for its nutraceutical as well as pharmaceutical properties through genetic improvement programs. The focus of such breeding efforts has largely been on improvement of seed-based products while other non-seed based compounds are yet to be targeted in research programs. Thus, this review on safflower provides a detailed study of the composition, utility, and genetic improvement of seed-based products of safflower, along with a brief account on non-seed based products.

2 Seed-Based Compounds in Safflower

2.1 Description of Compounds

Safflower is well supplied with compounds such as fatty acids (including OA and LA), vitamins such as tocopherols, and antioxidants such as flavonoids and alkaloids (Table 1). Although flavonoids and alkaloids could be extracted from seeds, they are major constituents of petals and are described in later sections.

2.1.1 Fatty Acids and Oils

Oilseed crops are major sources of vegetable oil. Based on seed oil content and fatty acid composition, they can be utilized for dietary, industrial, or pharmacological purposes. Oil content in safflower germplasm ranges from 20% to 45%. The crop germplasm can be broadly divided into two categories (High Oleate and High Linoleate varieties) based on composition of seed oil, which is principally composed of two unsaturated fatty acids: Oleic acid (C18:1) (OA) and Linoleic acid (C18:2) (LA). These account for approximately 90% of total fatty acid content in safflower oil. The remaining 10% is contributed by saturated fatty acids such as Palmitate (6–8%) and Stearate (2–3%), with traces of other fatty acids not exceeding 0.81% (Porokhovinova et al. 2022). In a study conducted by Fernández-Martinez et al. (1993), fatty acid compositions of 200 safflower accessions were analyzed and both OA and LA demonstrated significant levels of variation, from 3.1% to 90.60% and from 3.9% to 88.8%, respectively.

Safflower seed oil has also been used for treating cardiac and hepatic disorders (Dajue and Mündel 1996). Recent reports have suggested that, when other vegetable oils were blended with safflower oil it enhanced their nutritional value/quality. It has been shown to improve various physiological systems and is used for treatment of

Table 1 Compounds isolated and characterized from safflower seeds (Adapted and modified from Zhang et al. 2016)

S. No	Classification of compound	Name of compound	Reference
1.	Organic acids	Oleic acid	
		Linoleic acid	
		Palmitic acid	Gecgel et al. (2007), Fernandez-Martinez et al. (1993)
		Stearic acid	
		Myristic acid	
		Palmitoleic acid	Ghareghani et al. (2017)
		Linolenic acid	
		Caffeic acid	Vieira et al. (2021)
		Ferulic acid	Zhang et al. (1997)
2	Flavonoids	Kaempferol 7-O-β-D-glucopyranoside	
		Acacetin–glucuronide pentoside	Chakradhari et al. (2020)
		Acacetin-7-O-D-glucuronide	
3	Alkaloids	N-feruloyl serotonin	Koyama et al. (2006)
		N-(p-coumaroyl) serotonin	Takii et al. (1999)
		N-(p-coumaroyl)serotonin-O-β-D-glucopyranoside	Sakamura et al. (1978)
		N-[2-(5-hydroxy-1H-indol-3-yl)ethyl] ferulamide	Zhang et al. (1997)
4	Other compounds	Coniferyl alcohol	Peng et al. (2017)
		Sinapyl alcohol	Peng et al. (2017)

arteriosclerosis, hyperlipidaemia, and coronary heart disease (Abidi 2001). The polyunsaturated fatty acids (PUFA) in safflower oil suppress the accumulation of low-density lipoproteins (LDL or bad cholesterol) (Cho 2001). Consumption of safflower phospholipids was shown to have desirable effects on human health such as reduction of lipids in liver and higher levels of high density lipoprotein (Iwata et al. 1992). Significant reduction was observed in levels of total cholesterol, blood glucose, triglyceride LDL, alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase in alloxan-induced diabetic rats after their diet was supplemented with 200 mg/kg safflower seed oil, demonstrating the protective effects of safflower oil on liver (Rahimi et al. 2014). In the same study, it was concluded that safflower oil had hypoglycemic and hypolipidemic effect in hyperglycemic rats under the same set of dietary conditions, adding to the growing evidence on its antidiabetic and anti-obesity properties. Zhang et al. (2010) showed that diet supplemented with safflower oil can change gene expression pertaining to fat deposition resulting in mitigation of diet-induced obesity. Safflower oil can stabilize storage of lipophilic compounds showing potential as a functional food or for usage as vector in drug delivery. Cod liver oil encapsulated in safflower oil has increased oxidative stability of PUFAs.

2.1.2 Tocopherols

Tocopherols ($C_{28}H_{48}O_2$), commonly known as vitamin E, is a group of closely related lipids with substitutions on 2H-1-benzopyran-6-ol nucleus along with isoprenoid units. The oilseeds have different types of tocopherols, viz. α-, β-, γ-and δ-tocopherols which protect PUFA against oxidation (Vosoughkia et al. 2011). Three types of tocopherols (α-tocopherol, β-tocopherol, and γ-tocopherol) were found in safflower oil in various amounts ranging from 460.5 to 709.3 mg/kg, 8.5 to 21.6 mg/kg, and 4.5 mg/kg of oil, respectively (Mani et al. 2020). In a separate study, cold pressed safflower seed oil was found to contain α-tocopherol at 376.6 mg/kg, as the main component along with β-tocopherol (4.4 mg/kg), γ-tocopherol (25.9 mg/kg), and δ-tocopherol (1.0 mg/kg) (Topkafa 2016). Safflower oil has high α-tocopherol content making it an excellent source of vitamin E, although low thermostability makes it less suitable for deep frying (Cuesta et al. 2014). Tocopherols have also been used for feed, food, resins, pharmaceuticals, and cosmetics.

2.2 Genetic Improvement Efforts in Safflower

With an ever-increasing demand for healthier foods and plant-based nutraceutical products, research groups around the world are exploring the natural diversity of compounds found in safflower. This entails elucidation of molecular mechanisms governing the biosynthetic and regulatory pathways to modify the biochemical machinery for production of desired products. With continuous efforts in safflower breeding, nutraceutical profile of safflower seeds has been enhanced, especially for oleic acid. However, to keep pace with current market demands further improvement along the same lines is required. Evaluation of safflower germplasm and identification of lines with differing fatty acid profiles could serve as basis for development of lines with higher oil and tocopherol content. Modifying amino acid composition of seed meal as well as purging of harmful content like matairesinol monoglucoside and lignin glucoside can further enhance the nutritional quality of safflower seeds.

2.2.1 Conventional Breeding

The initiation of breeding programmes for crop improvement require germplasm possessing high genetic variability for quantitative traits. Many institutions across the world have curated germplasm collections from major centres of safflower diversity including national collections at China, India, and USA. Detailed information about safflower germplasm collections can be found in a review by Vollman and Istvan (2010).

Oil content and composition are complex traits and are significantly influenced by genotype X environment interactions. Therefore, breeders have relied on simple traits with high heritability for identification of superior genotypes. The direct attributes for oil content and oil composition are total yield of the plant, whereas the indirect attributes for seed yield are head (capitulum) number, head diameter, and grains per head (Arslan 2007). For oil composition, head weight, number of heads, and hull (pericarp) content was used for indirect selection. Seed structure is also an

important determinant of oil content. The percentage of oil in seed shows inverse correlation with hull size. The percentage of oil increases in the very thin hull types (Bergman et al. 1985). Other factors which affect the yield and oil content are crop phenology which is related to genotype and environmental condition.

Biometric analyses have been performed to estimate the effect of genes on morphological traits. Number of branches and plant height are under the influence of additive gene action whereas head diameter (Golkar et al. 2012) shows low broad-sense heritability. The white hull is dominant over the striped hull (Urie 1986). The striped seed and reduced pericarp were shown to be controlled by recessive genes (*Th* and *Stp*) (Ebert and Knowles 1966) and had monogenic inheritance (Ashri and Efron 1964. The seed protein content is governed by additive dominance model (Golkar et al. 2012). Besides oil content, major attention has been given to oil composition for safflower improvement as it makes safflower oil a healthier alternative to others plant-based oils available in the market. Safflower oil is rich in the OA, LA, Palmatic acid (PA) and Stearic acid (SA). For fatty acid composition, both narrow and broad-sense heritabilities have been reported (Golkar et al. 2011). All the fatty acids follow additive gene effect [OA (Hamdan et al. 2009b), LA (Hamdan et al. 2008), PA & SA (Hamdan et al. 2009a)]. LA and SA in safflower are influenced by maternal factors (Golkar et al. 2011) whereas high OA is under the influence of recessive alleles (Fernandez–Martinez et al. 1993).

Unlike fatty acids, safflower germplasm shows little variability for tocopherol profiles. Johnson et al. 1999 reported no variability in the tocopherol profiles whereas Velasco and Fernández-Martínez (2001) found variation in γ-tocopherol profiles. Velasco et al. (2005) identified a natural mutant of *C. oxycantha* which is rich in high gamma-tocopherol instead of standard high alpha-tocopherol content. Mutant allele from *C. oxycantha* was then introgressed in C. tinctorius followed by selection, resulting in a line with 90% gamma-tocopherol content (Velasco et al. 2005).

Conventional breeding methods, however, have had limited success in improving quantitatively inherited characters listed above. Crossing and record keeping procedures are laborious and slow, compounded with limitations such as low genetic base in varieties, loss of genes in the successive generations due to segregation and genetic drag. These limitations can be mitigated to some extent by applying recent genomic tools.

2.2.2 Molecular Breeding

Modern tools such as expression profiling and genetic engineering have been effectively used to address limitations of classical breeding efforts. Linkage maps are used to identify chromosomal regions that control qualitative and quantitative traits (Collard et al. 2005); DNA markers associated with genes are subsequently used for marker-assisted selection (MAS). Breeding objectives so far have been primarily focused on increasing seed yield and oil yield and acquisition of resistance against biotic and abiotic stresses. Little has been done on the positional cloning of genes/QTLs involved in the production of nutraceutical compounds. Information on trait mapping in safflower is limited and is described below.

Construction of Linkage Maps

Linkage maps for safflower were initially constructed by Mayerhofer et al. (2010), using RFLP and PCR-based (SSR and cDNA) markers on an intraspecific F2 mapping population of *C. tinctorius* and an interspecific BC population generated through a cross between *C. tinctorius* X *C. oxycantha.* The resulting linkage maps were compared for synteny and showed significant collinearity of markers in several regions. Since then, several groups have attempted the construction of linkage maps (Table 2).

Linkage maps constructed by various groups in safflower over the last two decades suffer low resolution (with a few exceptions) as the number of markers utilized is limited. Mapping of traits in most cases was done using F2 populations which suffer from greater heterozygosity compared to RILs. It is therefore crucial that efforts be made for development of high-density linkage maps using SNP markers.

Mapping of Genes

Linoleic Acid

Inheritance of high LA content in safflower was first reported by Hamdan et al. (2008). Results from their study showed 5 RAPD bands linked to the LA content controlling *Li* locus. The fragments were sequenced to design SCAR markers and a linkage map was constructed to include 5 SCAR markers along with *Li* and *Ms* gene loci. The SCAR markers flanked *Li* and *Ms* loci at 15.7 cM and 3.7 cM respectively.

Table 2 Linkage maps constructed in safflower

References	Marker number and type	Population	No. of linkage groups	Length of map (cM)
Mayerhofer et al. (2010)	1412 SSR and 75 RFLP	F_2: *Carthamus tinctorius*	11	954
Mayerhofer et al. (2010)	1412 SSR and 75 RFLP	BC1: *C. tinctorius* X *C.oxycantha*	13	580
Hamdan et al. (2012)	47 RAPD, 60 SSR, and 4 SCAR	F_2: *Carthamus tinctorius*	15	816
Pearl et al. (2015)	244 SNP	F_2: *C. tinctorius X C. palestinius*	12	858

Wu et al. (2021)	248 SSR	F_2: AH04 X YH04 (both *C. tinctorius*)	12	1136.46

Adapted and modified from Golkar and Karimi (2019)

Oleic Acid

Most safflower germplasm lines are rich in linoleic acid (~70% of total oil content). Knowles (1989) identified safflower germplasm that produced high levels of oleic acid. When compared to oils with higher levels of polyunsaturation, oils high in oleic acid have been reported to have a hypocholesterolemic effect on human health and a higher oxidative stability (Mensink and Katan 1989). High oleic acid content is under the genetic control of partially recessive alleles at the *Ol* locus (Fernandez-Martinez et al. 1993). Efforts have been made for mapping major and modifying genes responsible for high oleic acid content (Hamdan et al. 2012). A genetic linkage map was constructed spanning 816.4 cM, comprising 15 linkage groups by using RAPD (47), SSR (60), and SCAR (4) marker loci using an F_2 population. This population was generated through a cross consisting of CL-1(male sterile) × CR-9 (>84% oleic acid) (Hamdan et al. 2012). The *Ol* locus was located on linkage group T3 between the SSR marker ct365 and the SCAR marker IASCA-73, respectively, with genetic distances of 0.4 and 39.1 cM.

Tocopherols

Tocopherols are the principal naturally occurring antioxidants in oilseed crops with protective action in biological systems and in oils or products derived from oils. Molecular tagging was used to decipher the genetic control of high gamma-tocopherol, leading to identification of markers for high gamma-tocopherol. A mutant line IASC-1 with high γ-tocopherol was crossed with CL-1 with high α-tocopherol. The resultant F2 population was analyzed for segregation of the partially recessive *Tph2* gene. Bulked segregant analysis revealed that *Tph2* gene was linked to eight RAPD and one SSR marker, leading to construction of a *Tph2* linkage map. RAPD fragments closest to the *Tph2* gene were converted into SCAR markers. Later, a γ-tocopherol methyltransferase locus was shown to co-segregate with *Tph2* (Garcia-Moreno et al. 2011).

Association Mapping in Safflower

Conventional methods are the time-consuming method for discovering genomic regions governing simple and/or complex traits, such as linkage analysis and/or QTL mapping, involves establishment of biparental mapping populations. Since fewer recombination events are evaluated in biparental population, the allelic variation obtained in QTL mapping is limited, resulting in poor mapping resolution. However, association mapping (AM) provides a faster and efficient method for evaluating complex traits at high resolution, offering a promising way to overcome the constraints of linkage mapping (Abdurakhmonov and Abdukarimov 2008). AM uses naturally occurring recombination events to identify correlations between phenotypes and genetic polymorphisms in a heterogeneous collection of unrelated accessions/genotypes, allowing for fine-scale mapping of attributes. It has proven to be an effective method for discovering marker-trait relationships for a variety of agronomic traits in several crop species (Zhang et al. 2014; Abdurakhmonov and Abdukarimov 2008). Small, operational core collections of safflowers have been constructed to assist genetic deconstruction of complex characteristics (Kumar et al. 2016). These core

collections can be the basis for AM if they represent substantial genetic variation and a weak population structure (Pritchard et al. 2000).

Ambreen et al. (2018) performed AM on a set of 124 safflower accessions (CartAP), resourced collectively from two core collections. Significant correlation ($R^2 > 10\%$, $P < 0.05$) was seen between 96 marker-traits associations (MTA). Consistent associations were represented in both General Linear and Mixed Linear models among two growing seasons for traits such as oil content, oil composition, and number of primary branches. Many MTAs were also found between parameters with positive or negative phenotypic correlations (e.g., plant height; days to 50% flowering; OA/LA concentration; number of primary branches/numbers of capitula per plant). Such associations will complement marker-assisted breeding and will assist in deciphering genetic basis of trait variability.

2.2.3 Marker Assisted Breeding and Gene Introgression

In the twenty-first century, molecular breeding has emerged as an indispensable tool for crop improvement crucial for meeting the continuous demand to increase the production of the crop A PCR based multiplex marker assay for selection of high OA allele *'ol'* based on mutation in *CtFAD2-1* gene was reported by Liu et al. (2013). Kadirvel et al. (2020) designed and used SNP genotyping assays such as KASP (Kompetitive Allele Specific PCR) and the Amplifluor™ SNPs genotyping systems for prediction of *"ol"* allele. Using these assays, the "*ol*" allele from Montola-2000 was introgressed into the Bhima using assisted backcrossing resulting in the development of promising high oleic lines with OA content ranging from 75.2% to 81.8%.

2.2.4 Genetic Engineering

Genetic engineering uses biotechnological tools to manipulate DNA, resulting in the transfer of genes within/between organisms to produce improved or novel organisms. When applied to crop improvement, transgenesis has yielded genetically modified (GM) crops having novel genes and desirable characteristics. It also overcomes the limitations of reproductive incompatibility encountered in conventional breeding methods. This allows for transfer of traits from any organism into the target crop. The following section describes studies in safflower pertaining to genetic engineering for improvement of health-related traits.

The nutraceutical, γ-linolenic acid (GLA) is a precursor for long-chain polyunsaturated fatty acids. It is synthesized from linoleic acid in endoplasmic reticulum by the activity of Δ-6 desaturase. Δ6-desaturase gene from *Saprleginadeclina* was transformed into a high LA variety of safflower resulting in accumulation of high levels of GLA (70% v/v). The transgenic line was eventually granted approval from US Food and Drug Administration and commercialized for nutraceutical purposes as Sonova 400 (Nykiforuk et al. 2012).

Safflower was also used as a bioreactor to produce Italian version of Apolipoprotein AI called $ApoAI_{Milano}$, which is a major component of circulating HDL and has therapeutic applications against atherosclerosis. In Atherosclerosis, plaque accumulates along the inner lining of an artery, causing hemorrhage or thrombosis (blood clot formation). $ApoAI_{Milano}$ was expressed in transgenic safflower as a fusion

protein specifically targeted to seed tissue. Results showed that selected lines accumulated 14.5% fusion protein as a fraction of total seed protein (TSP) (Nykiforuk et al. 2011). Similarly, recombinant human fibroblast growth factor 10 (rhFGF10) was expressed in safflower seeds using oil body-oleosin technology (Huang et al. 2017). Oleosin-rhFGF10 was introduced and expressed in safflower seed. The trait inheritance was checked till T3 generation.

Decades of plant breeding efforts have raised the oleic content in safflower to ~90%, but costed in terms of low field performance accompanied with poor yields. Wood et al. (2018) engineered super high oleic (SHO) safflower producing seed oil with 93% oleic acid. Safflower was transformed with hairpin-based vectors. Transgenic plants produced seed oil with low PUFA (<1.5%) and only 4% saturate fatty acids. There was no effect on lipid composition of leaves and roots. The seed yield of transgenics was also comparable to non-GM safflower even under different environments and varied sites.

2.2.5 Genomics-Aided Breeding

Genomics is a branch of biology primarily concerned with structure and function of genomes. Functional genomics, a subset of genomics, is concerned primarily with assigning functions to unknown genes. Various technological platforms such as transcriptomics, proteomics, metabolomics, and phenomics are used to analyze gene function. Numerous transcriptomic studies have been conducted to improve our knowledge and understanding of the molecular functions of the genomic components of various organisms. Such studies are expected to increase with the availability of genome sequences.

Partial cDNA clones were generated based on two protein sequences with thioesterase activity (molecular masses: 34 and 40 KDa). Similarly, cDNA clone (CTOS1) was generated based on a new protein putatively involved in accumulation of high levels of oleic acid in seeds (Mizukami et al. 2000) from an accession of safflower with high oleic acid in seeds. In recent years, sequencing of cDNA libraries using next generation sequencing (NGS) has emerged as a novel method for whole transcriptome analysis. De novo transcriptome analysis was performed by Li et al. (2012) using three different tissues, viz., leaves, petals, and seeds leading to identification of differentially expressed unigenes among these tissue. The analysis identified oleosins which were specifically expressed in the seeds. An enzyme, *FAD2* (microsomal oleoyl phosphatidylcholine desaturase) is known to introduce a double bond at Δ12 position of OA, thereby converting it to LA (Cao et al. 2013). They cloned 11 *ctFAD2* genes, each with a divergent functionality, the largest number of FAD2clones in any species. The temporal transcriptome profile of safflower for *FAD2* and other genes involved in oil accumulation was investigated by Li et al. (2021). Their study identified changes in expression of stearoyl-[acyl-carrier-protein] 9-desaturase gene (*SAD*) from 10 to 14 days after fertilization (DAF) and oleate desaturase (*FAD2–1*) from 14 to 18 DAF. They also identified 13 putative transcription factors (TFs) involved in regulating the expression levels of the *FAD2–1*gene.The study found a link between fatty acid biosynthesis and gene expression during seed development.

Safflower seeds (also known as *Carthami semen*) hold a wide array of nutritionally beneficial compounds with a greater part of compound diversity yet to be explored. The recent shift in consumer preferences towards healthier foods and plant-based pharma alternatives has reinvigorated research in improvement of nutritional aspects of seeds. Conventional breeding efforts have led to improvement in overall oil content while molecular breeding has led to the development of high oleic acid lines, many of which have been released for cultivation. With the publication of safflower genome and use of molecular breeding tools becoming commonplace, exploration into other classes of compounds such as seed flavonoids and alkaloids is to be expected.

3 Non-seed Based Compounds in Safflower

Safflower is cultivated primarily for its seeds and oil which could be exploited as nutraceuticals. However, since ancient times, safflower has been used in traditional medicines using/derived from flowers and leaves of the plant. Due to adverse effects of chemical medications, the pharmaceutical industry is exploring alternatives and Safflower has emerged as a promising option. This section describes pharmaceutical compounds obtained from safflower.

Flowers and leaves of safflower contribute medicinal as well as nutritional compounds. Safflower petals are consumed as herbal tea and have medicinal uses for menstrual problems, cardiovascular diseases, hypertension, arthritis, spondylosis, diabetes, pain, and swelling associated with trauma. They also have purgative, antioxidant, anti-inflammatory, analgesic, and anticonvulsant properties (Zhou et al. 2014). Flowers of the plant also possess central analgesic activity and can be considered as potential drugs equivalent to morphine-like substances. Thus, these can be beneficial to surpass the side effects caused by morphine (Almeida et al. 2001).

3.1 Description of Compounds

The major constituents of safflower flowers are flavonoids, glycosides, carthamin, and safflower yellow. Other components, viz., quercetin, carthamidin, kaempferol, isocarthamidin, glycosides of hydroxykaempferol, chalcones such as hydroxysafflor yellow A, safflomin-A, and acetylenic glucosides (carthamosides) have also been found (Table 3) (Jiang et al. 2005). The leaves of safflower are rich in Luteolin and its glucopyranosides (Lee et al. 2002).

3.1.1 Flavonoids

Flavonoids are polyphenolic secondary metabolites synthesized via phenylpropanoid pathway, with naringenin chalcone acting as precursor for a majority of them. In safflower, bioactive flavonoids are primarily concentrated in petals and seeds and exhibit a broad range of pharmacological activities. Flavonoids are broadly divided

into two groups: quinochalcones and flavonols. The quinochalcones comprises of hydrosafflower yellow A, tinctorimine, carthamin, and cartorimine while the flavons include kaempferol, quercetin, and their glucosides (Guo et al. 2017).

Glycosides derived from flavonols such as quercetin and shannesol, have been extensively studied and were shown to possess antioxidative activity. Safflower extract containing flavonoids is also protective to the cardiac system, stabilizing

the oxygen supply to the heart and the heart rate (Guo et al. 2018). Flavonoids can induce aggregation of the platelets and depolymerization of ADP in platelets). The hypotensive effect of safflower flavones has been shown in animals (Mani et al. 2020). The major component of yellow pigment, Hydroxysafflor yellow A (HSYA) have a strong antagonistic effect on the receptors of platelet activating factor. In the in vitro experiments carried out by Zhang et al. 2002, varying concentrations of HSYA was found to inhibit both aggregation of polymorphonuclear leukocytes and platelet induced by platelet activating factor. HSYA also helps to improve the condition of acute myocardial inflammation (Zhou et al. 2013) by inhibiting the process causing it. HSYA also act as neuroprotector against cerebral injury and ischemia-reperfusion conditions by antioxidation, reducing neurological-deficit scores and decreasing superoxide-dismutase activity.

Diabetes is an important cause of vascular complications because it can activate dysfunctional biochemical pathways. One such example is the increased glycation of the proteins by methylglyoxal. Under in vitro conditions, HSYA was seen to inhibit protein glycation by reducing the production of advanced glycated end products, by reducing the protein modifications that were methylglyoxal-mediated and their cross-linking (Yue et al. 2013). The extract derived from the flowers of safflower also elevates insulin level by regenerating Langerhans islets and further induces the beta cells to secrete insulin. It is also capable of restoring breakdown of protein and promoting glycogenesis.

Quinochalcones are the primary yellow and red pigments in safflower. Structurally, most quinochalcones isolated from this plant have a unique C-glycosylated cyclohexanonedienol moiety. Up to 18 quinochalcone C-glycosides have been isolated from safflower till date. Carthamin is composed of two C-glucosylquinochalcone moieties (Zhang et al. 2016). Quinochalcone C-glycosides has an array of bioactivities like anticoagulation, anti-inflammation, antioxidation along with antihypertensive, and antitumor activity.

3.1.2 Alkaloids

Alkaloids are a group of small cyclic organic compounds, containing a nitrogen atom usually within the carbon ring, which gives them a slightly basic property. They are classified on the basis of precursors from which they are synthesized. Tryptophan, Tyrosine, Lysine, and Ornithine are amino acid precursors, which undergo enzymatic reactions giving rise to indole, tetrahydroisoquinoline, piperidine, and pyrrolizidine alkaloids, respectively). In addition to nitrogenous bases, serotonin derivatives like N-feruloyl serotonin and N-(p-coumaroyl) serotonin, and spermidines have also been isolated from safflower. Based on their inhibitory action against melanin production, it was suggested that they can be potential inhibitors of melanogenesis (Zhou et al. 2014). Protective effects of the serotonin derivatives against cardiovascular diseases were investigated in ischemic and reperfused heart of guinea-pig. The study showed that there was improvement in relevant biological markers after administration of the two alkaloids and played important antioxidant roles for such conditions (Al-Snafi 2015).

3.2 Genetic Improvement of Non-seed Based Products from Safflower

Although safflower is used widely in Chinese medicine, the major attention for the breeder has been the safflower oil due to its health-related and commercial benefits. Thus, in contrast to seed-based products, very few genetic studies have been done for non-seed based products. However, some work has been done on flavonoids through genomics-aided breeding.

Transcriptomic studies including full-length transcriptome sequence analysis for the major flavonoid – HYSA, has shown that *CtC4H2, CtCHS3, CtCHI3, CtF3H3*, and *CtF3H1* are the major genes that are involved in flavonoid production (Chen et al. 2018). These known putative flavonoid genes can be the basis for biotechnological improvement of safflower. In a study by Yang et al. (2007), cDNA-AFLP was used in combination with bulked segregant analysis to mine differentially expressed genes associated with high HSYA content. Transcript derived fragments (TDFs) which showed significant association with HSYA content were retained for construction of linkage maps. Genetic linkage analysis showed that TDF-2, TDF-3, and TDF-9 were tightly linked to the HSYA genomic region. Another key regulatory enzyme of the flavonoid pathway is Chalcone isomerase (CHI). Guo et al. (2019) successfully obtained transgenic *Arabidopsis* and Safflower lines overexpressing *Ct*CHI1 gene. The overexpressed *Ct*CHI1 genes caused the 3.9 fold upregulation of*Ct*PAL3 and *Ct*C4H1 genes and downregulation/inhibition of *Ct*4CL3, *Ct*F3H, and *Ct*DFR2. Also, the comparison of transgenic and control groups revealed that there were 788 different metabolites marked and mostly were upregulated. Wang (2015) achieved overexpression of *CtAK* (key regulator of Aspartate metabolism) in transgenic safflower using CaMV35S promoter. Exogenous applications of ethylene and 1-aminocyclopropane carboxylic acid oxidase (ACO) were shown to affect the accumulation of flavonoids in safflower (Tu et al. 2019). Two of the ACO genes were cloned from safflower (*CtACO1* and *CtACO2*) and transgenic plants were developed through *Agrobacterium*-mediated floral dip method. In overexpressed lines of *CtACO1*, metabolite analysis showed the accumulation of quercetin and its glycosylated derivatives like rutin, while the amount of quinochalcones, kaempferol derivatives, apigenin, and luteolin were reduced.

Genetic studies were also done for the domestication-related traits in safflower. Sixty-one Quantitative Trait Loci (QTL) in various linkage groups were identified including a large-effect QTL corresponding to the flower colour (Pearl et al. 2014). A 3:1 segregation pattern was observed for flower colour in the F2 mapping population consisting of 276 individuals. This indicated that the changes in carthamin (the quinochalcone pigment responsible for the red-colored florets) synthesis are influenced by a single locus. These findings differed from other studies (Pahlavani et al. 2004) that showed the impact of multiple genes on flower color and the presence of at least two interacting genes that distinguishes the orange and the yellow-colored florets. These contrasting results are obtained probably due to selection of high carthamine-producing parents than any other compounds controlling the flower coloration to develop the mapping population by Pearl et al. (2014).

4 Social, Economic, and Political Impact of Nutraceutical and Pharmaceuticals

Healthy diet and lifestyle are key factors that influence prevention of diseases and promote betterment of human health. In recent years, there is a strong and increasing demand for development of functional food markets that mainly focus on increased production of nutraceuticals using organic and natural ingredients that are high on nutrition (Daliri and Lee 2015).

Safflower offers good raw material for several economic sectors. It is widely cultivated because of its ability to survive under varying edaphoclimatic conditions (Menegaes and Nunes 2020). Safflower oil is rich in linoleic acid containing tocopherols that act as antioxidants. It is recommended to patients suffering from diabetes and cardiovascular diseases, as it helps in reducing the level of cholesterol in blood similar to olive oil (Menegaes and Nunes 2020).

Due to advances in agricultural biotechnology, it is now possible to produce food crops which have enhanced nutritional content and can contribute towards overall human health. Biofortification practices are generally employed in order to enhance the nutritional value of food crops either by conventional breeding or through the use of biotechnology. Through these practices vitamins and minerals have been added to crops in order to produce a diet that has well balanced nutrition and supplements to address the issues of a malnourished population successfully. Nutraceuticals include bioactive components such as polyunsaturated fatty acids (PUFA), antioxidants, phytochemicals that are found in plants. Genetic engineering is generally employed to improve natural and therapeutic values of natural foods (Prabavathy et al. 2022).

Nutraceutical sector includes three main divisions which include herbal/natural products, dietary supplements, and functional foods (Asif 2019). Globally, of these three, dietary supplements and herbal/natural products were the most rapidly growing divisions with 19.5 % and 11.6% of growth per year, respectively (Asif 2019). It has been observed that the use of genetically modified products, increased income of farmers by $92 million between 1996 and 2011 because the overall production cost got decreased, and there was reduction in crop loss because GM crops were insect and pest resistant (Karalis et al. 2020). The Nutraceutical market has grown exponentially from the last decade in developed and developing nations all over the world. Globally, USA and Japan have well established nutraceutical markets and their income from this sector is showing a consistent increase. Among developing nations, India, China, and Brazil are taking the lead in the field of nutraceuticals. India and China are now providing the raw sources for development of natural products. Nutraceutical foods were the major market section with worth of 39.9 billion USD in year 2007 and increased up to 56.7 billion USD by 2013 (Singh et al. 2019). Beverages included under nutraceuticals had worth of 38.4 billion USD in 2007 and 71.3 billion USD in 2013. The nutraceutical markets grew by around 250 billion USD in 2018, and it has been observed that the evolution of nutraceuticals within these years has helped to improve the average lifespan of adult people specially belonging to age of more than 60 years (Bhowmik et al. 2013). In 2015, the estimated value of the nutraceuticals market in India was 4 billion

USD however, it is expected to increase to 10 billion USD by 2022. Ministry of AYUSH and companies like Dabur, Patanjali, etc., have played a significant role in expanding the nutraceutical market in recent years (Singh et al. 2019).

Under the Food Safety and Standards Act, 2006, a regulatory body has been established which was named as Food Safety and Standards Authority of India (FSSAI). Through combining the various acts and orders under different governmental bodies, it manages the food related issue in India. FSSAI functions to ensure that safe and wholesome food is available for human consumption and regulates import, distribution, manufacture, storage, and sale of nutraceuticals and dietary supplements (Verma and Popli 2018). In USA, nutraceuticals and functional foods are tightly monitored by the Federal Food, Drug, and Cosmetic Act by the Food and Drugs Authority (FDA), USA. Safety and labelling of dietary supplements is also under the control of FDA to ensure that they are able to fulfil the needs of FDA and Dietary Supplement Health and Education (DSHE) regulations before being marketed (Daliri and Lee 2015). Before releasing new supplements into the markets, manufacturers are required to inform FDA and provide information indicating that their product qualifies as a new dietary supplement and is safe to use as specified in labelling. The Nutraceutical industry has to face a lot of challenges including adherence to country-specific regulations, less innovation by food industries (Daliri and Lee 2015). When a company obtains the petition for health claim and receives the acceptance, other competitors can also use their claim since majority of companies use products containing "easily available" ingredients which can be copied, unless and until the nutraceutical products contain exclusive ingredients that may be patented. The Nutraceutical sector can achieve more milestones when food companies become more innovative. Currently, they are functionalizing conventional products by adding more vitamins, herbal extracts, and minerals rather than inventing new products.

5 Future Prospects

Being rich in nutra and pharmaceutical compounds, safflower has a scientific and economic rationale for its use in the nutraceutical industry. Its rich nutritional value can also provide food security and improve the economy of developing countries. Many countries have adopted safflower as a mainstream crop and are now among the top producers in terms of production and acreage. Due to its richness of oleic acid and linoleic acid, Safflower has been used widely for its oil. Being a semi-arid crop, it can grow in the area where irrigation is limited. Safflower is also known for various important medicinal and nutritional benefits, which makes it an ideal candidate for use as a nutraceutical as well as pharmaceutical. However, the knowledge accumulation has been slow as safflower is a marginal crop, but it promises much more due to the benefits it brings along. With the availability of genome sequence data and sufficient genetic variability, the crop requires concentrated efforts to boost its status as a mainstream crop in nutraceutical and pharmaceutical industry.

Contents

Abstract

Edible palm oil products are free from trans fats, making them healthier and safe for application in food industry. Palm oil contains valuable vitamins and phytonutrients that exhibit cardioprotective mechanisms, immune system enhancement, neurodegeneration protection, and antioxidative as well as anti-carcinogenic properties. Red palm oil (RPO), a component of crude palm oil, is beneficial as a vitamin A supplement for treating vitamin A deficiency and its related diseases. The nutritional value of palm oil can be further enhanced via conventional breeding, using, for instance, palms exhibiting high carotene and

vitamin E contents that are available in the oil palm germplasm collection. Genes for key enzymes involved in carotene synthesis in palm oil have been isolated and characterized. These, together with the oil palm genome builds and its associated databases, provide resources for developing marker-assisted selection (MAS) programs and support genetic engineering technologies toward improving the nutritional values of oil palm and palm oil.

Keywords

Palm oil · Phytonutrients · Red palm oil · Vitamin E · Nutritional genomics

1 Agricultural Importance of the Oil Palm Crop

Oil palm is a perennial tree crop that produces two types of oils, namely, palm oil which is extracted from the fleshy mesocarp and palm kernel oil which is obtained from the oil palm kernel. The former has vast applications in the food industry, while the latter is mostly used in the oleochemical industry. Oil palm is a monocotyledon classified under the genus *Elaeis*. This genus consists of two species, *Elaeis guineensis* and *Elaeis oleifera*. *Elaeis guineensis* originates from Central and West Africa and is presently the main oil palm planting material planted commercially. *E. oleifera* has a South and Central America origin and possesses interesting features such as high carotene content (Mohd Din et al. 2002), low height increment rate, high oil unsaturation (Hardon 1969), and tolerance to diseases (Turner 1981), which are pertinent to oil palm improvement.

The oil palm has the highest productivity among oil-producing plants, producing approximately 3.7 tons of oil hectare^{-1} year^{-1}. With 11 and 10 times the yield capacity of soybean and rapeseed, respectively (Khosla and Sundram 2010), oil palm produces 75 million tons of oil from only ~24 million hectares of planted area. This output is obtained from less than 5% of the total area planted with oil crops. For many years, palm oil has contributed approximately 30% of the total oils and fats produced worldwide (Oil World 2022). Palm oil recorded a 53.4% market share of the major global oil and fat exports in 2021 (Oil World 2022). The main producers of palm oil are Indonesia (58.8%), Malaysia (23.8%), and South and Central America (6.9%). Palm oil is a rich source of vitamins and phytonutrients. The abundance of worldwide supplies and vast applications in the food industry make palm oil a prospective source of vitamins and phytonutrients that could meet the micronutrient requirements across the globe.

2 Chemical Composition of Palm Oil and Oil Palm

Palm oil and palm kernel oil differ in terms of their fatty acid compositions, particularly in the proportions of saturated fatty acids (SFA) and unsaturated fatty acids (UFA). Palm kernel oil has properties similar to coconut oil, with 82% SFA and

18% UFA. The 82% SFA is mainly composed of lauric (~50%), myristic (~16%), and palmitic acids (~8%), while the 18% UFA includes oleic acid (15%) and linoleic acid (~3%) (Ibrahim 2013). On the other hand, palm oil contains balanced amounts of SFA and UFA. The main SFAs in palm oil are palmitic acid (45%) and stearic acid (5%). Oleic acid and linoleic acid are the UFA present in palm oil at 40% and 10%, respectively. Besides fatty acids, palm oil also contains a wide range of health-benefiting phytonutrients such as tocopherols, tocotrienols, carotenoids, polyphenols, phytosterols, squalene, phospholipids, and coenzyme Q_{10} or ubiquinone-10 (Choo and Nesaretnam 2014). The detailed fatty acid composition of palm oil and palm kernel oil is listed in Table 1.

There are also active research and development (R&D) programs to improve and innovate the milling and processing of palm oil to preserve the natural phytonutrients. The phytonutrients in red or cold-pressed palm oil, for instance, are extracted for food, cosmetic, and pharmaceutical applications (Hassan et al. 2021; Abd Rashid et al. 2021). Red palm oil (RPO) contains vitamin E (α-, β-, and γ-tocotrienols), carotenoids (xanthophylls, α- and β-carotenes), phytosterols, ubiquinone, and squalene and is a competitive and better alternative to other consumer oils due to its nutritional content (Loganathan et al. 2017). Oil palm-based products and by-products from the fruit bunches, kernel shells, trunk, fronds, and pressed fruits also contain phenolic compounds, terpenes, lignin, lignans, vitamins, sugar, and minerals (Ofori-Boateng and Lee 2013). The aqueous waste from the palm fruit milling and processing has been extensively studied and valued for its high content of phenolic compounds (Syarifah-Noratiqah et al. 2019).

Table 1 Palm oil and palm kernel oil fatty acid composition

Fatty acid	Lipid number, carbon/double bond (C:D)	Saturation	Palm oil (%)	Palm kernel oil (%)
Palmitic acid	16:0	Saturated	39.2–45.8	7.5–9.3
Oleic acid	18:1	Unsaturated	37.4–44.1	13.7–17.0
Linoleic acid	18:2	Unsaturated	8.7–12.5	2.1–2.9
Stearic acid	18:0	Saturated	3.7–5.4	1.8–2.4
Myristic acid	14:0	Saturated	0.9–1.5	15.4–17.2
Arachidic acid	20:0	Saturated	0.0–0.5	0.0–0.1
Linolenic acid	18:3	Unsaturated	0.0–0.6	–
Lauric acid	12:0	Saturated	0.0–0.5	45.4–49.8
Palmitoleic acid	16:1	Unsaturated	0.0–0.4	
Capric acid	10:0	Saturated	–	2.9–3.7
Caprylic acid	8:0	Saturated	–	3.2–4.7
Caproic acid	6:0	Saturated	–	0.2–0.4

3 Oil Palm Phytochemicals

The natural chemical components of plants are known as phytochemicals. The term "phyto" comes from a Greek word that means plant (Liu 2004). Phytochemicals are of fundamental biological importance to plants; they provide protection against pathogens, herbivores, and solar radiation and function as signaling molecules and regulators (Csepregi and Hideg 2017; Winkel 2004). Phytochemicals are known to be bioactive and antioxidative against free radicals, cancerous cells, bacteria, and viruses and have various therapeutic functions comprising anti-inflammatory, antimutagenic, and antitumor effects on human health (Ciucure and Geană 2019; Naithani et al. 2008). They are also the source of fine products for dyes, drugs, fragrances, and flavors which are important to the commercial industry (Shilpa et al. 2010).

Apart from the prized palm oil, the palm fruit contains phospholipids which are initially part of the cell membrane. Phospholipids are amphiphilic and are a source of lecithin and an important releasing agent in food products (Choo et al. 2004). Crude palm oil contains very low amounts of phospholipids due to the milling process, and, therefore, phospholipids are better extracted from the palm fruit fiber and calyx (Gold et al. 2016; Choo et al. 2004). The primary phospholipids in palm oil are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylglycerol (PG) with a small amount of phosphatidic acid (PA), diphosphatidylglycerol (DPG), lysophosphatidylethanolamine (LPE), lysophosphatidylcholine (LPC), and phosphatidylserine (PS) (Goh et al. 1982). The fibrous by-products retained after oil extraction from the oil palm fruit, also known as oil palm fruit fiber, predominantly contain PC, PE, PG, and PA (Choo et al. 2004). Galactolipids of monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG), which are also part of palm fruit cell membranes, were profiled from palm oil (Cheong et al. 2014). These glycolipids are reported to show health-promoting effects (Christensen 2009).

Terpenes are natural unsaturated hydrocarbons that form the largest class of plant secondary metabolites. They are made up of five carbon isoprene units assembled into multiple pairs of isoprene pairs and various additions of side chains and functional groups (Perveen 2018). Terpenes can take linear or cyclic forms and are categorized according to their isoprene units and structural variations. Terpenoids are terpenes with additional, removal, or substitution of functional groups, for example, oxygen, methylene groups, or hydrogen atoms (Masyita et al. 2022). Terpenes include squalene, sterol, saponin, and carotenoid, while the terpene isoprene unit is the side chain of tocotrienols (Ahsan et al. 2015). Squalene is found in palm oil and palm oil milling waste. It is a biochemical intermediate in the synthesis of phytosterols in plants and hormones in humans. Squalene acts as an antioxidant and is an important ingredient especially in the cosmetic industry (Gonzalez-Diaz and García-Núñez 2021). Crude palm oil and its by-products contain phytosterols of β-sitosterol, campesterol, and stigmasterol (Jalani et al. 2021; Choo and Nesaretnam 2014). These plant sterols modulate membrane-bound enzyme activities and demonstrate cholesterol-lowering activity (De Smet et al. 2012).

Derived from tetraterpenes, carotenoids can be classified into xanthophylls and carotenes based on their oxygen content (Cazzaniga et al. 2016). Xanthophylls of

lutein and carotene epoxides and at least 11 other types of carotenes were profiled in palm oil, namely, phytoene, phytofluene, α-carotene, β-carotene, ξ-carotene, γ-carotene, δ-carotene, lycopene, α-zeacarotene, β-zeacarotene, and neurosporene (Ping and Gwendoline 2006; Ng and Choo 2016). Tocopherols and tocotrienols are collectively identified as vitamin E and are important palm oil constituents. Crude palm oil, palm olein, and red palm olein were all reported to retain α-tocopherol (α-T), α-tocotrienol (α-T3), γ-tocotrienol (γ-T3), and δ-tocotrienol (δ-T3).

Lignans are water-soluble polyphenols formed from monolignols of coumaryl, coniferyl alcohol, or sinapyl alcohols. On the other hand, lignin is synthesized from similar monolignols but is linked differently by dirigent proteins resulting in hydrophobic natural polymers in the plant cell wall (Davin and Lewis 2000). Isolariciresinol, lariciresinol, and pinoresinol are examples of lignans detected in palm oil (Tardugno et al. 2022). These lignans exert beneficial effects on human health (Rodríguez-García et al. 2019). Other secondary metabolites such as phenolic compounds are detected in the by-products of the milling process due to their low lipophilic nature. The term "phenolic" includes metabolites with hydroxyl-substituted benzene ring synthesized by the phenylpropanoid biosynthetic pathway. Flavonoids, the largest group of phenolics, are composed of a diphenyl-propane (C6-C3-C6) backbone in which two aromatic rings are connected via a three-carbon chain (Alseekh et al. 2020). Flavonoids occur naturally as aglycone or as conjugates with sugars, organic acids, and other molecules and are present in the oil palm fruit and leaf (Hazir et al. 2012; Tahir et al. 2013).

Organic acids in plants typically form alkaline salt, ester, and glycoside that are very important in human nutrition as biochemical pathway intermediaries (Gundogdu et al. 2014), while amino acids are the building blocks for tissue proteins and are substrates for the synthesis of numerous substances of physiological importance in the human body (Wu 2013). Table 2 explains each class of the nutritive phytochemicals characterized in palm oil and oil palm tissues and their biosynthesis pathway references from the Kyoto Encyclopedia of Genes and Genomes (KEGG) (Kanehisa and Goto 2000).

Other oil palm plant parts such as the leaves, fruits, and cabbages (palm heart) are mostly edible by humans and ruminants (Reddy et al. 2019; Ebrahimi et al. 2015). Alkaloids are bitter to the taste and can be found in plants in small quantities (Muñoz et al. 2020). A qualitative investigation revealed that alkaloids are the least phytochemical component found in oil palm leaves (Yin et al. 2013) and were not identified exhaustively except for β-phenylethylamine derivatives of tyramine and catecholamines in environment and disease studies (Tahir et al. 2022; Rodrigues-Neto et al. 2018). Catechins are a well-studied group of flavonoids found at high levels in tea and are also recorded in oil palm leaf and root (Tahir et al. 2013, 2022). Procyanidin B, the oligomer of catechin, is also found in oil palm root (Nurazah et al. 2013). Ferulic, sinapic, coumaric, and caffeic acids are among the hydroxycinnamic phenolic acids found in oil palm fruits (Sambanthamurthi et al. 2011). Dietary fibers and sugars derived from cellulosic and hemicellulosic components from oil palm biomass are also valuable and gaining attention from food and fuel industries (Mazlan et al. 2021; Palamae et al. 2017).

4 Significance of Palm Oil and Its Phytonutrients in Human Diseases and Health

Palm oil is semisolid in a tropical environment and can be fractionated to separate the liquid component, known as palm olein, from its solid component called palm stearin. Palm olein can be used directly as cooking oil, whereas palm stearin is employed to produce fats such as margarine, shortening, and ghee. Unlike other vegetable oils that require the hydrogenation step to make them solid, more stable, and less reactive for food manufacturing, palm olein can be made more solid by adding the natural palm stearin, resulting in oils that are trans fat-free. The hydrogenation process converts the geometrically cis ("same side") structure of fatty acid molecules into the trans ("opposite side") which causes changes in physical and biological properties (Goh 2006). Consuming food that contains trans fats results in increased low-density lipoprotein (LDL), or "bad" cholesterol, and decreased "good" cholesterol (high-density lipoprotein – HDL) in blood serum and interference of many cellular signaling pathways in humans (Mensink and Katan 1990; Judd et al. 1994). Elevated levels of LDL contribute to accumulation of plaque along artery walls, also known as atherosclerosis. This subsequently causes inflammation and increases the risk of heart disease. Long-term consumption of foods blended with hydrogenated vegetable oils has also been reported to cause other major diseases such as diabetes, cancer, cystic fibrosis, diabetes, inflammatory diseases, macular degeneration, and Parkinson's and Alzheimer's diseases (Goh 2006). Studies have shown that replacing hydrogenated oils with palm olein could decrease heart disease risk by 30% (Mozaffarian and Clarke 2009). Palm olein also demonstrates anticarcinogenic and antioxidant attributes and a wide range of protective properties against diseases (Abdullah et al. 2018). Palm olein appears to be a healthier and better alternative for hydrogenated oils in the food industry as far as health effects are concerned.

RPO is trans- and cholesterol-free and has pro-vitamin A activity. Children fed with red palm oil and confectionaries containing red palm oil recorded increased blood retinol levels (Manorama et al. 1996; van Stuijvenberg et al. 2000), which significantly reduced night blindness and Bitot's spots occurrences due to vitamin A deficiency (Sivan et al. 2002). Several other studies also supported the safety and efficacy of using RPO for fighting vitamin A deficiency (Hedrén et al. 2002, Zagré et al. 2003, Canfield et al. 2001, Radhika et al. 2003,Lietz et al. 2001). RPO also potentially confers anticancer properties (Boateng et al. 2006; Yamanushi et al. 2001) and plays an important role in tumor suppression by increasing natural killer cells and B-lymphocyte populations which enhances the immune system (Nesaretnam et al. 2002).

In general, phytonutrients exhibit bioactive properties, i.e., inhibition or initiation of gene expression and enzyme activity and suppression of receptors. Phytonutrients are directly beneficial to humans as a nutraceutical or supplemental product or indirectly through use as a livestock feed (Tahir et al. 2013). Tocotrienol is the major vitamin E component extracted from palm oil. In fact, palm oil is one of the plant species offering the highest source of tocotrienols, apart from rice bran. Several

in vitro and animal studies showed that palm oil tocotrienols have anticarcinogenic potential (Komiyama et al. 1989; Sundram et al. 1989; Wada 2009; Samant et al. 2010; Shah et al. 2003; Sylvester and Shah 2005; Nesaretnam et al. 2004) and neurodegeneration protection (Nesaretnam et al. 2004; Shah et al. 2003; Sen et al. 2007; Khanna et al. 2005; Park et al. 2011). Tocotrienols could also prevent heart disease through their ability to reverse arterial blockage (Nafeeza et al. 2001; Black et al. 2000) and are involved in other cardioprotective mechanisms (Li et al. 2010; Budin et al. 2009; Das et al. 2005).

Phenolics are another phytonutrient extracted from the vegetative liquor of palm oil mill (Sambanthamurthi et al. 2011). Based on animal studies, oil palm phenolics (OPP) are beneficial for heart health and neurons (brain) and are bioactive against free radical damage and atherosclerosis (Leow et al. 2013; Sambanthamurthi et al. 2011). Palm oil and palm products with phenolics and phytosterols are strong inhibitors of peroxidation, and the dietary intake of lignan-rich foods such as oil palm products is known to prevent certain types of cancers and cardiovascular diseases. Figure 1 illustrates the human health-promoting properties of palm oil and oil palm products. Other phytonutrients such as phytosterols, squalene,

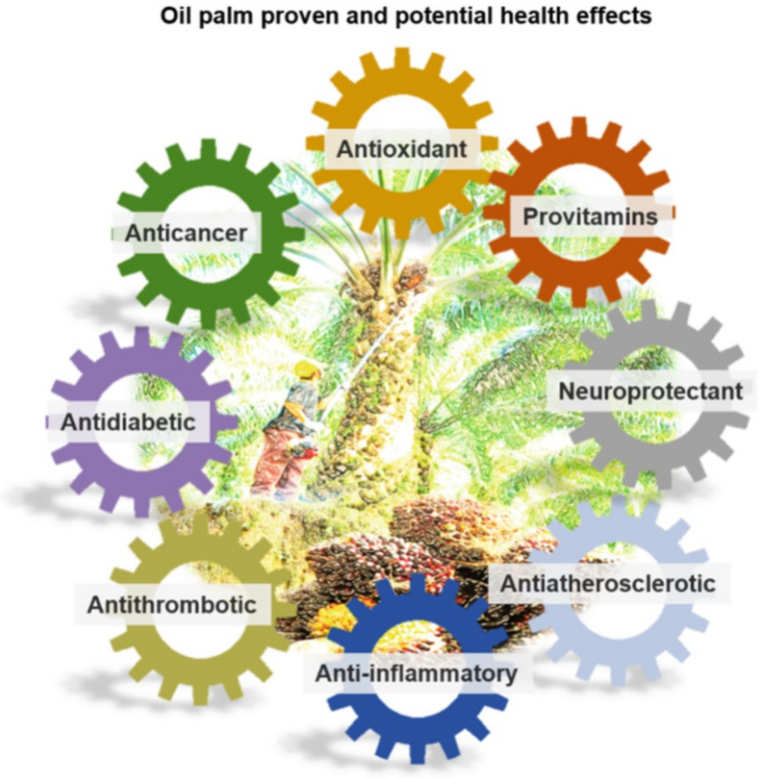

Fig. 1 Oil palm and its health-promoting properties

coenzyme Q10, phospholipids, and polyphenols play a crucial role in the stability and quality of the oil. In addition, these phytonutrients have antioxidant properties, and some exhibit nutritional and health benefits beyond their antioxidant functions (Choo and Nesaretnam 2014).

Oil palm leaves contain bioactive agents such as antioxidants and are anti-hyperglycemic with organ-protective effects against hypertension (Tahir et al. 2022). The leaf extracts also possess pharmacological activities of wound healing, hypoglycemic, vascular relaxation, hypocholesterolemic, neurogenesis, phytoestrogenic, osteogenic, fungicidal, and antimicrobial properties (Tow et al. 2021).

5 Oil Palm Genetic Diversity

The assessment of genetic diversity in any crop species helps to identify genotypes for crossing, generating hybrids with increased heterosis and variability (Adon et al. 1998). In oil palm, the diversity of germplasm populations is determined to evaluate their value for increasing diversity of the present genetically narrow breeding populations as well as identifying accessions carrying economically important genes or traits. Such efforts would benefit the oil palm industry by developing new planting materials that produce diversified products and are more sustainable against extreme climate changes as well as fatal diseases.

The genetic diversity among oil palm populations and genotypes has been evaluated by means of phenotypes and molecular markers. Phenotypic characteristics have conventionally been used to select individual plants for genetic improvement programs. Phenotypic evaluation of oil palm populations for improvement programs in Malaysia started in the 1920s. For selection and incorporation into breeding programs, oil palm breeders initially focused on evaluating oil yield and bunch quality components contributing to yield. Thus, parameters such as fresh fruit bunch (FFB), oil-to-bunch (OTB), mesocarp-to-fruit (MTF), and kernel-to-fruit (KTF) ratios are emphasized in selecting oil palms to be included in crossing programs. However, despite good progress in improving oil yield via conventional breeding, the average yield in commercial fields is 3.7 tons per hectare per year which is far below the potential yield of about 8 tons per hectare per year (Woittiez et al. 2017).

The Malaysian Palm Oil Board houses the largest oil palm genetic resource, covering both *Elaeis guineensis* and *E. oleifera*. These resources, which were collected from the species' center of distribution, are maintained as *ex situ* living collections. Field evaluation of the oil palm germplasm identified oil palms exhibiting other traits contributing to oil yield, namely, large fruit and thin-shelled (Kushairi et al. 2003) and high bunch index (Junaidah et al. 2004). Selected oil palms originating from Nigeria exhibited high oil yield (Rajanaidu et al. 2006). Incorporating these palms into breeding schemes resulted in offsprings with higher FFB, OTB, and oil yield than commercial planting materials (Marhalil et al. 2013). Besides yield, further evaluation of the oil palm germplasm populations revealed other secondary traits such as slow height increment (Rajanaidu et al. 2006), high carotene content (Mohd Din et al. 2002; Mohd Din et al. 2006), high iodine value (IV), high kernel content (Rajanaidu et al. 2006), longer stalk

(Noh et al. 2005), and high vitamin E (Kushairi et al. 2011) which gained interest among breeders. Several *Elaeis guineensis* palms, which originated from Nigeria, Cameroon, Zaire, Angola, and Tanzania, recorded high vitamin E content of between 1300 and 2496 ppm as compared to commercial varieties (800 ppm) (Kushairi et al. 2011). Carotene content ranging from 2000 to 3000 ppm, higher than the 500–700 ppm from commercial planting materials, was recorded in *E. guineensis* from Tanzania and *E. oleifera* palms from Panama and Costa Rica (Mohd Din et al. 2002, 2006). The selected palms are presently being selfed and intercrossed for introgression into oil palm genetic improvement programs to develop planting materials that produce palm oil with increased nutritional value. Apart from the simple and straightforward method of introgressing new traits from *E. guineensis*, oil palm breeders also adopted the inter-specific hybrid breeding program to integrate the fascinating traits observed in the pure *E. oleifera* into the commercial oil palm variety. This is due to the extremely low yield attained in *E. oleifera*; thus, direct commercialization of this species is not possible.

Besides phenotypic measurements, oil palm populations have been characterized using molecular marker tools. The randomly amplified polymorphic DNA (RAPD) and restriction fragment length polymorphism (RFLP) markers were initially used to study genetic diversity among Nigeria, Tanzania, Cameroon, and Zaire oil palm accessions (Shah et al. 1994; Mayes et al. 2000). Furthermore, 48 parental populations were analyzed for genetic diversity using amplified fragment length polymorphism (AFLP) markers (Purba et al. 2000). Several genetic diversity studies of *E. guineensis* and *E. oleifera* accessions originating from different collection sites were reported for pre-breeding programs using RAPD, RFLP, and AFLP markers (Moretzsohn et al. 2002; Ithnin et al. 2006). Bakoumé et al. (2015) analyzed 494 accessions representing 49 oil palm populations using simple sequence repeat (SSR) markers. This study revealed an average genetic distance value of 0.796 among accessions, indicating variability for future exploitation. The presence of rare alleles in populations from countries located within low rainfall and dry weather regions revealed their possible association with adaptive traits. The development of next-generation sequencing (NGS) techniques and expressed sequence tag-based SSRs (EST-SSRs or eSSRs) allow for assessment of the diversity of candidate genes of interest. A total of 19,243 EST sequences were mined from an oil palm EST database (http://palmoilis.mpob.gov.my/palmgenes.html) (Ting et al. 2010). Of these, 722 SSRs were designed, and polymorphisms were observed in MADS-box transcription factors, bZIP zinc finger proteins, and NAC-like transcription factors. Many more reports on applying molecular markers to analyze the genetic diversity of oil palm were recently published (Babu et al. 2019a, b, c, 2020; Bhagya et al. 2020; Sowmya et al. 2017; Venu et al. 2018; Ithnin et al. 2017; Ithnin et al. 2021).

6 Linkage and GWAS Mapping of Oil Palm

In oil palm, the relatively long generation times have promoted interest in MAS to accelerate conventional breeding through early selection. Marker trait association for oil palm was initially conducted by exploiting the genetic mapping approach

whereby a RFLP marker associated with shell thickness was identified (Mayes et al. 1997). Rance et al. (2001) and later Billotte et al. (2005) reported evidence on the linkage between SSR markers and quantitative trait loci (QTLs) for FFB yield, OTB, bunch number, oil-to-mesocarp (OTM), and vegetative components. *E. oleifera* exhibited high polyunsaturated fatty acids (PUFAs) and iodine value (IV) but low SFA compared to *E. guineensis*. Using interspecific OxG mapping populations genotyped with SSR, AFLP, and RFLP markers, Singh et al. (2009) identified QTLs influencing oleic acid, linoleic acid, palmitic acid, and iodine value. Montoya et al. (2013) studied the candidate gene mechanism involved in fatty acyl thioesterase A (FATA) and stearoyl-ACP desaturase (SAD) genes of the oleic acid pathway. Fatty acid candidate genes such as β-ketoacyl-ACP synthases (KAS) I and II were discovered within their associated QTL region on linkage group 15. It was anticipated that other candidate genes influencing other related fatty acids could also be found in the same genomic region. Pootakham et al. (2015) constructed a genetic map from 1086 single-nucleotide polymorphism (SNP) markers (Fig. 2) and identified several QTLs associated with height and fruit bunch weight in linkage groups 3, 14, and 15. Another group reported a separate QTL on a different linkage group linked to oil palm stem height (Lee et al. 2015). Palm oil quality is determined by its free fatty acid (FFA) content which is used as its quality index (Tan et al. 2009). High FFA indicates poor palm oil quality. The levels of FFAs are influenced by endogenous lipase activity which is initiated after the oil palm bunches are harvested. High lipase activity results in accumulation of FFAs and causes rancidity of palm oil. Domonhédo et al. (2018) identified the genetic loci influencing lipase activity in oil palm. This major genetic loci for lipase explained 84–92% of the variation for endogenous lipase content in oil palm. They also validated its acidification by the most common gene, viz., FLL1 (fruit lipase-like 1) and two lipase genes.

Other than genetic mapping, researchers also applied the association mapping (AM) procedure to identify loci influencing oil palm economic traits. Teh et al. (2016) employed a 200,000 SNP array to genotype over 2,000 palms and identified significant QTLs on chromosome 5 that are linked to oil-to-dry-mesocarp (OTDM) ratio, one of the key components of yield trait. It was shown that the progeny exhibiting the homozygous favorable allele for the significant SNP marker had an elevated amount of OTDM. Using the same SNP array across 312 palms, Kwong et al. (2016) detected several SNP markers on linkage groups 4, 12, and 15 influencing the shell-to-fruit (STF) ratio, also an important component influencing mesocarp content and subsequently oil content. Using over a million SNPs, Xia et al. (2019) discovered 26 significant SNPs associated with high palmitic acid and major candidate genes (acyl-ACP thioesterase B genes) within the QTL region in oil palm. Likewise, several SNP- and SSR-based molecular markers were associated with oil yield, vegetative traits, height increment, and bunch quality parameters in oil palm (Ithnin et al. 2017; Babu et al. 2019b, c, 2020; Bhagya et al. 2020; Bai et al. 2017). Bai et al. (2017) performed genotyping by sequencing across 153 oil palm DxP population and identified significant QTLs for OTB and OTDM ratios on linkage groups 1, 8, and 10. These associations were detected based on *E. guineensis*

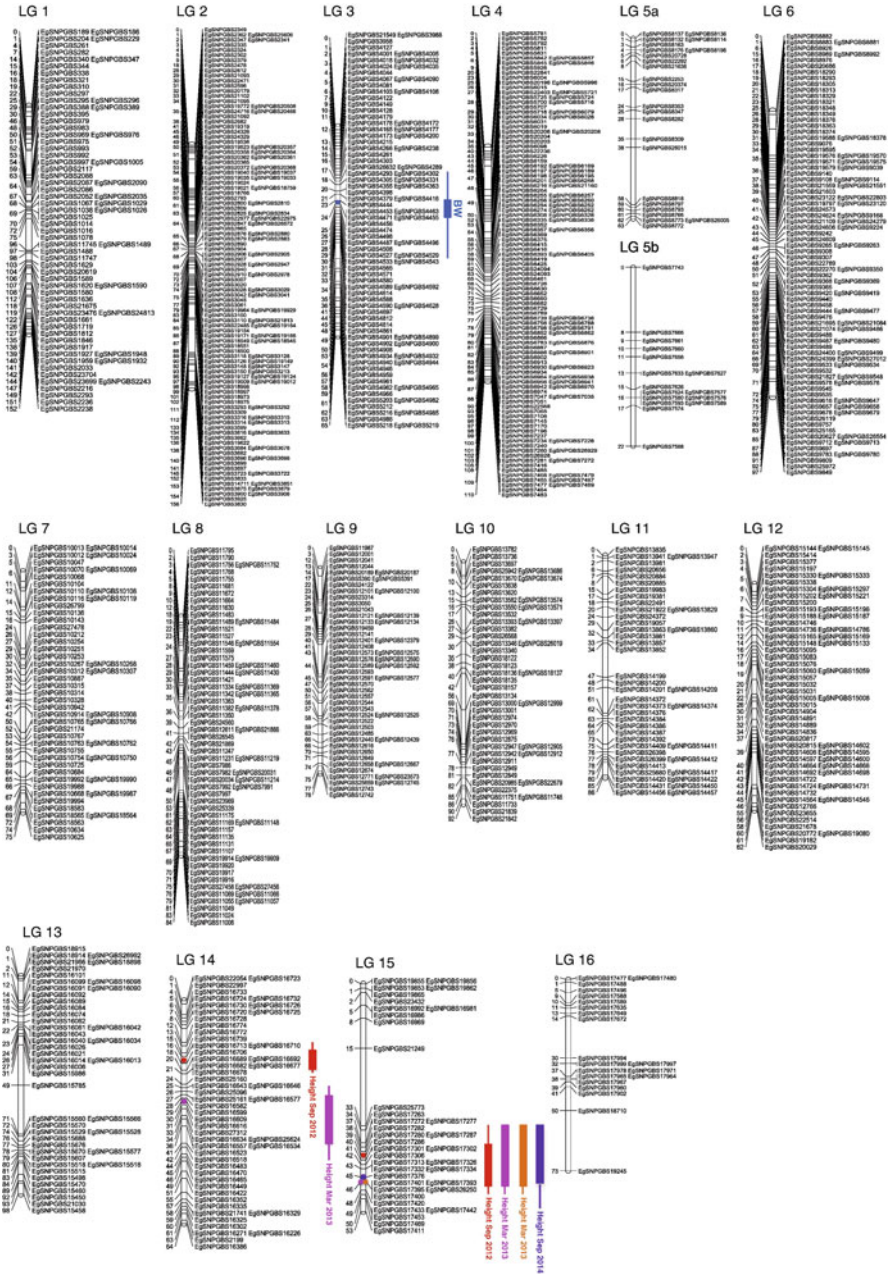

Fig. 2 Oil palm linkage map constructed using SNP markers published by Pootakham et al. (2015). QTLs associated with height and bunch weight (BW) are detected on linkage groups 3, 14, and 15

populations. Ithnin et al. (2021) described QTLs associated with fatty acid composition together with vegetative and yield-related traits from an analysis involving *E. oleifera* natural populations. The group also identified several pleiotropic SNPs linked to multiple correlated traits suggesting that the traits concerned are influenced by common genes and/or involved in the same biological pathways. Similarly, QTLs influencing fatty acid composition were detected in an interspecific (OxG) hybrid population (Shin et al. 2021). In this research, machine learning algorithms were applied to predict the values of the associated traits when different combinations of significant QTLs are used in breeding and selection programs. These outcomes provided the basis for developing MAS tools applicable for breeding programs to improve oil palm productivity and quality.

7 Oil Palm Gene and Genome Databases

Improvements in sequencing technologies and bioinformatic analyses, together with the reduced costs, have contributed to the increased number of crop genomes being sequenced each year. Although many published genomes are incomplete with variable quality, the sequences are a remarkable resource that can be exploited in various ways. The genome sequences have been used to generate high-density molecular markers to map agronomically important traits and subsequently identify candidate genes within a genomic region of interest. These traits can be characterized and bred into commercial varieties. A high-density genetic map also helps in the identification of molecular markers tightly linked to the traits of interest for MAS development. Genome sequences can be annotated with gene models to depict exons, introns, gene names, gene functions, gene regulatory sequences, and protein products, among others, allowing further research toward understanding the genetic control of gene or traits of interest. These inspired oil palm researchers to sequence the oil palm genome (Singh et al. 2013a). The oil palm genome sequence was assembled, published, and stored in Genomsawit (http://genomsawit.mpob.gov.my) (Singh et al. 2013a; Rosli et al. 2014). The database also houses the transcriptome and hypomethylated sequences useful for gene prediction and curation (Amiruddin et al. 2022; Masura et al. 2022; Amiruddin et al. 2020; Rosli et al. 2018a; Rosli et al. 2018b; Chan et al. 2017; Singh et al. 2014; Jayanthi et al. 2013; Singh et al. 2013b) and development of molecular markers (Ting et al. 2014, 2016, 2021; Yaakub et al. 2020). The transcriptome sequences are useful for the identification and analysis of expressed genes (mRNAs). Transcriptome sequencing has enabled researchers to identify differentially expressed genes between tissues, time points, and individuals with contrasting phenotypes. Transcriptomic analyses also play a part in discovering the interactions between biochemical pathways.

The Genomsawit database was integrated into a web-based interface known as MYPalmViewer (http://gbrowse.mpob.gov.my) (Low et al. 2015) for comprehensive search and interactive browsing of the data, to enable direct visualization and exploration of the oil palm genome. A total of 15 tracks were mapped to the EG5.1 genome build including oil palm genomic sequences, GenBank sequences, predicted

genes, genomic markers, other plant genomes, GC content, scaffold gaps, and enzyme restriction sites. Several biological databases were further established to store the results from advanced analysis of oil palm genomic sequences. One of them is PalmXplore-DB which consists of 26,059 EG5.1 predicted genes and their annotation (Sanusi et al. 2018). PalmXplore-DB (http://palmxplore.mpob.gov.my) is useful for the identification of new genes and gene families for biological research in oil palm. Coupled with the transcriptome sequences, research can then be initiated to further understand the biological and molecular role of individual genes and their involvement in regulatory networks. The association of gene expression data from a variety of tissues and developmental stages with gene models creates a new layer of information that contributes to the understanding of gene interactions and regulation. These are essential particularly in developing strategies using genetic engineering technology for oil palm improvement.

From the EG5.1 build, a total of 1714 SSR markers were mined and stored in the Oil Palm SSR Resource Interface (OPSRI-DB), where the primer sequences and their genome locations are available that would help link to phenotypes of interest. The OPSRI (http://opsri.mpob.gov.my) enables browsing of SSR markers together with bioinformatic tools such as Open Reading Frame Search, SSR Search, and BLAST (Rosli et al. 2022). The number of databases from the EG5.1 genome build advance analysis will be expanded in the nearest future.

The information available in Genomsawit could also facilitate researchers in their efforts to improve palm oil nutrition through marker-assisted conventional breeding techniques. Karim et al. (2021) observed an SNP conversion from TAAT to form the CAAT box which could be a promoter activity-enhancing factor leading to an increase in tocotrienol content in palm oil. Using the genomic information in Genomsawit, candidate genes associated with tocotrienol can be identified within the genomic region of the significant SNPs, for instance. New markers can be developed using the candidate gene sequences and then applied to further saturate the associated QTL regions. This will result in the identification of molecular markers tightly linked with tocotrienol in oil palm. The tightly linked QTLs can be applied in MAS to increase selection efficiency and reduce the time needed to produce oil palm with improved tocotrienol content.

8 Biofortification of Oil Palm and Palm Oil

Biofortification is the process of enhancing the nutritional quality of food crops through transgenic, conventional, and agronomic approaches, which involve modern biotechnology techniques, crop breeding, and fertilization, respectively (Garg et al. 2018). In view of the dependency of human nutritional health on plant food and agricultural products, developing different crop varieties with improved nutritional quality is of great importance. Most of the staple crops and some legumes, oilseed crops, vegetables, and fruits, such as rice, wheat, maize, barley, sorghum, soybean, pea, chickpea, canola, mustard, carrot, sweet potato, potato, lettuce, and tomato, have been nutritionally enhanced using micronutrient biofortification through

agronomic practices. Biofortification of crops by foliar spray of iron, zinc, and selenium and fortifying germinating rice plantlets with ferrous sulfate were among the effective ways to promote micronutrient concentrations in plant grains (He et al. 2013; Yuan et al. 2013; Zhang et al. 2013; Poblaciones et al. 2013). A foliar spray of selenium and iodine was favored as the most dynamic and economical method in cereals compared to soil application of the microminerals (Lyons 2018). Other than chemical and organic fertilizers, biofertilizers containing plant growth-promoting soil microorganisms, such as *Bacillus*, *Pseudomonas*, *Rhizobium*, and *Azotobacter* species, have also been applied for crop biofortification (Nooria et al. 2014; Ramzani et al. 2016; Dhawi et al. 2015; Sathya et al. 2013; Nosheen et al. 2011; Hameed et al. 2018). However, these methods are less cost-effective, labor-intensive, and non-sustainable in some cases and therefore cannot be generally applied as a strategy to improve the nutritional quality of most crops. In addition, it is not always feasible to target biofortification of micronutrient into edible plant parts. Thus, the desired nutrients may accumulate in leaves or other non-edible portions of the plants.

Crop biofortification through conventional breeding is the most preferred method on account of its success rate, sustainability, and cost-effectiveness. This approach is useful to enhance and improve the levels of micronutrient content in crops when sufficient diversity of the trait of interest is available in the gene pool of the targeted crop (Garcia-Oliveira et al. 2018). In the scenario where genetic diversity is limited or unavailable for the targeted component, genetic engineering or transformation provides another alternative for developing biofortified crops with the desired nutritional composition (Bouis and Saltzman 2017).

The improvement of oilseed nutritional quality has been targeted in some oilseed crops including oil palm, rapeseed, soybean, and sunflower (Kishore and Shewmaker 1999). Apart from increased oil palm productivity and palm oil yield, efforts are also being made to develop a nutritionally enhanced high-yielding biofortified oil palm. The improvement of fat quality traits in palm oil can be executed through biofortification of fatty acids in palm oil, where the SFA level can be controlled to an optimum level while increasing the level of bioactive components such as carotenoids and tocotrienols. Hence, more value-added palm oil can be generated in new emerging markets. This can be feasibly accomplished by identifying candidate genes and transcription factors affecting iodine value and fatty acid composition in palm oil (Singh et al. 2009). This type of oils can lead to wider dietary acceptance and weaken the link between cardiovascular disease risk and palm oil.

9 Oil Palm Genetic Engineering

Genetic engineering involves modifying and manipulating the genome to change the characteristics of an organism. It is believed to be more specific and could accelerate conventional breeding methods. Genetic engineering technique was applied to achieve sustainability in oil palm growth and development particularly improving palm oil quality, productivity, and tolerance to pests and diseases. Successful transformation strategies and regeneration methods play significant roles in the success of genetic

engineering in any crop including oil palm. The oil palm genetic engineering program started more than two decades ago, much later than other oil-bearing plants, mainly targeting to modify the fatty acid composition in the oil, specifically to increase oleic content for industrial purposes. The objectives were expanded to achieve transgenic palms that can produce palm oil with high stearate, palmitoleic, and ricinoleic acids and high lycopene as well as other products including biodegradable plastics (Parveez et al. 2015; Sambanthamurthi et al. 2002). Three methods to deliver genes into oil palm tissues have been reported, namely, particle bombardment (Parveez and Christou 1998), *Agrobacterium*-mediated transformation (Masli et al. 2009), and novel DNA microinjection (Masani et al. 2014).

Modifying the fatty acid composition in palm oil requires a change in the regulation of the genes involved in oil palm fatty acid synthesis. Some of the key genes concerned have been isolated and characterized, including acetyl-CoA carboxylase (Omar et al. 2008), 3-keto-acyl-ACP synthase II (KAS-II) (Ramli and Sambanthamurthi 1996), palmitoyl-acyl carrier protein thioesterase (Abrizah et al. 1999; Parveez et al. 2010), stearoyl-ACP desaturase (Shah et al. 2000), oleoyl-ACP thioesterase (Asemota et al. 2004), oleoyl-ACP desaturase (Syahanim et al. 2007), and lysophosphatidic acid acyltransferase (Manaf et al. 2005). In addition, a handful of genes involved in the carotenoid synthesis including phytoene synthase (Rasid et al. 2008), phytoene desaturase (Rasid et al. 2014), lycopene cyclases (Rasid et al. 2009), and 1-deoxy-D-xylulose-5-phosphate synthase (Khemvong and Suvachittanont 2005) have also been isolated. Analysis of gene expression using RT-PCR revealed that phytoene desaturase and lycopene cyclase convert lycopene to β-carotene (Römer et al. 2000). Thus, genes for both enzymes are important for the genetic engineering of oil palm targeting palm oil with higher β-carotene content.

Regulatory sequences, also known as promoters, which are capable of increasing or decreasing the expression of specific genes in various oil palm tissues, are available. Oil palm promoters that have been identified include the mesocarp-specific (MT3-A) (Zubaidah et al. 2017) and FLL1 (Nurniwalis et al. 2015), kernel-specific (pOP-KT21) (Siti Nor Akmar et al. 2014), root-specific (MT3-B) (Zubaidah and Abdullah 2010), and leaf-specific (LS01) (Chan et al. 2008; Hanin et al. 2016) promoters. With the availability of these genetic materials and establishment of the transformation technique, positive transformants carrying the respective genes have been produced. Palmitoyl acyl carrier protein thioesterase (PATE) that regulates the accumulation of palmitic acid in palm oil was successfully transformed into *E. oleifera* immature zygotic embryos using the bombardment transformation method (Bhore and Shah 2012). Downregulation of this gene will result in improved palm oil quality with reduced palmitic acid content.

The *Cry* genes isolated from *Bacillus thuringiensis*, which are effective in conferring insect resistance in other crops, were introduced into oil palm immature embryos via the biolistic method (Lee et al. 2006). Further analysis revealed successful expression of the transgene in the transformed tissues. In addition, the transformation method to deliver glufosinate-ammonium resistant genes into oil palm tissues using the alternative *Agrobacterium* system was reported by Masli et al. (2009). Although the transformation rate attained was lower than that achieved

using the biolistic method in oil palm, the *Agrobacterium*-mediated technique offers a stable integration of the transgene at a low copy number.

Yeap et al. (2021) recently reported their success in establishing a gene editing method, namely, clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9) mutagenesis system for the oil palm. A mutation frequency between 62.5% and 83.33% was recorded when CRISPR was applied to phytoene desaturase (EgPDS), a gene involved in carotenoid biosynthesis. Mutation of this gene resulted in albino phenotypes among the transgenic oil palm shoots. Furthermore, application of CRISPR/Cas9 on EgBRI1 gene, coding for a major receptor of the plant hormone brassinosteroid, resulted in a stunted phenotype of oil palm transgenic shoots due to nucleotide substitutions. The CRISPR/Cas9 method was also employed to knock out the OsFAD2-1 gene in rice as a model system (Bahariah et al. 2021). The goal is to subsequently repeat this highly effective approach in knocking out fatty acid desaturase genes in oil palm, to produce higher oleic acid in palm oil. These achievements lay the foundation for adopting gene editing techniques for nutrition-enhancement programs in oil palm.

10 Conclusion

The enormous amounts of vitamins and phytonutrients present in palm oil have opened up substantial opportunities in research leading to significant discoveries of their health and nutritional benefits. The available germplasm collection and genomic sequences of oil palm provide great opportunities in developing new planting materials to produce palm oil with enhanced nutritional values. Using novel genomic, genetic, and molecular techniques, relevant biochemical pathways can be investigated which leads to an understanding of the genetic control mechanisms underlying the synthesis and accumulation of essential vitamins and phytonutrients. Such knowledge is useful in formulating a more efficient and rapid improvement process through MAS for conventional breeding and/or development of transgenic lines aimed at increasing vitamins and phytonutrient levels in palm oil. While improvement efforts via conventional breeding are rather straightforward, implementing genetic engineering approaches faces a complex legal framework. Nevertheless, such efforts are worthy, particularly when implemented in a highly productive crop like the oil palm. Moreover, palm oil has a wide range of applications in the food industry. Thus, improving palm oil's nutritional value could intensify efforts toward delivering more nutritious food in addressing the malnutrition issues faced globally.

Pulse Crops

Nutritional Traits of Beans (*Phaseolus vulgaris*): Nutraceutical Characterization and Genomics

M. W. Blair, H. Li, L. Nekkalapudi, V. Becerra, and M. Paredes

Contents

Abstract

Common bean is among the top three edible legumes on the planet and is very diverse in seed size and shape constituting two genepools (Andean and Mesoamerican) and many commercial seed types within each of these. The seed structure of common bean provides a basis for defining some of the nutraceutical

properties of the crop: The seed coat while less than a tenth of the seed weight is packed with secondary metabolites that can have health benefits ranging from anti-cancer effects to diabetes control. Since the seed coat is maternal tissue, it is important that fixed lines be considered so that the hybrid internal tissues match the outside genotype. The cotyledonary tissue is a powerhouse of macronutrients, predominantly storage proteins, fiber, and complex starches that can control obesity and contribute to reduction in heart disease. Minerals and vitamins make up micronutrients that are found in the embryonic axis and other tissues of common beans providing health benefits especially to women and infants having iron deficiency anemia and other hidden hunger effects. Regular consumption of beans can have multiple nutritional benefits, for example, phytosterols can reduce blood cholesterol levels and hypertension. High calcium and magnesium are important for bone strength and cardiovascular function. The genetics behind nutraceutical properties of common bean are not well studied and require a detailed analysis of seed physiology, growth, and development and genotypic differences for each trait described above. Transcriptomics can be as useful as genomics in this analysis. Therefore, we propose a tissue-specific, gene expression-based analysis for improvement of certain nutraceutical properties using as examples the well-known flavonoid pathway that leads to many beneficial molecules found in the different tissues of common beans, as well as starch, phytate, and protein pathways. Since this pulse is mostly consumed directly after boiling, common beans do not require the extensive processing that some other grain legumes or pulses undergo, making their analysis for health benefits easier to evaluate. However, given many seed types, colors, and origins, researchers should use multiple carefully selected genotypes to make conclusions about specific commercial classes of beans or nutritional traits.

Commercial bean classes · Cotyledon storage proteins · Dry grain pulse · Embryo axis · *Phaseolus* genus · Seed coat colors

1 Introduction

Nutraceuticals are those plant compounds that have a beneficial effect on human health. They contribute to overall food security but also determine the food quality of plant products such as grains. They include macronutrients, micronutrients, and secondary metabolites unique to each group of plants. High-quality, nutritious pulses (grain legumes) are one key to food security in the world's human population (Carbonaro et al. 2015). The legumes are on par in importance with calorie-supplying cereals but are the major source of protein among income-limited groups and vegetarian/vegan consumers. Pulses are major suppliers of higher protein levels in grain-based diets along with essential amino acids such as lysine and tryptophan that are low in cassava, maize, potatoes, or rice, the main crops for carbohydrate supply in the world.

Among legumes, the common bean (*Phaseolus vulgaris* L.) is considered the most important for direct human consumption in terms of total area of production, amounts consumed, and contribution to nutritional quality of various diets across many nations (Hayat et al. 2014) with various reviews written on their potential for biofortification and essential nutritional compounds (Blair 2013; Nyau 2014). Given their diversity, it is important to know that common beans were domesticated in two sections of the New World, Central/North America and South America, and thus have two major genepools. Common beans are therefore a very diverse crop with many different seed types depending on the environmental zone in which the crop is grown and the consumers supplied with beans of various commercial classes.

Small and medium seeded beans from Central/North America are termed Mesoamerican, while those from South America are more specifically called Andean based on their origin along the Andes Mountains. Among the Andean genepool are the commercial classes of kidney beans (pink and red), popping beans (nuna), red mottled (Cargamanto rojo, Pompadour, and Rosecoco), sugar beans (Borlotto, Cargamanto blanco, Coco, and cranberry types), and yellow beans (Canario and Jalo) plus others used on more local levels, such as Liborino a yellow Cargamanto bean (Peláez et al. 2022) found only in one region of Colombia. Andean beans became prevalent in Eastern and Southern Africa to which they are not native but where production and consumption levels are very high.

Among the Mesoamerican genepool are the commercial classes of black beans, navy beans, pintos, small reds, all major classes across various countries, and some yellows or tans. Carioca and Jalinho are also small seeded and Mesoamerican beans found originally in Brazil, with some expansion into Africa. Various specialty types are found only in Guatemala and Mexico such as shiny black seeded or Flor de Mayo/Junio types, respectively. Great Northern beans are medium-sized white beans from the Plains region of the United States. Figure 1 shows a range of these bean types with variation of seed color and size.

As a major export crop, common beans are traded globally and regionally from country to country and zone to zone. At the national level, local trading from rural to urban areas is very important and ensures fresh harvested beans. Exported beans tend to be less fresh and require months in transit from a producer region often in the northern hemisphere (Canada, China, and the United States) to the tropics and sub-tropics where consumption is higher than in countries of origin. For example, US beans arrive in Central America from ports in the upper Mississippi basin, while Canadian beans reach Cuba from the Atlantic Ocean. Chinese beans are shipped worldwide, and some arrive in Latin America or the Middle East. North American beans are prevalent in European markets. Exports/imports between neighboring countries of Argentina/Bolivia and Brazil are also important in terms of trade volume. Total worldwide production is between 25 and 30 million (M) metric tons grown on up to 35M hectares according to data available for the past decade (www.fao.org/faostat). A greater amount of Mesoamerican genepool beans than Andean genepool beans are produced when considering all production regions but the latter tend to be produced more locally and are less a part of the export, although exceptions to this are found for certain growing regions and consumer markets.

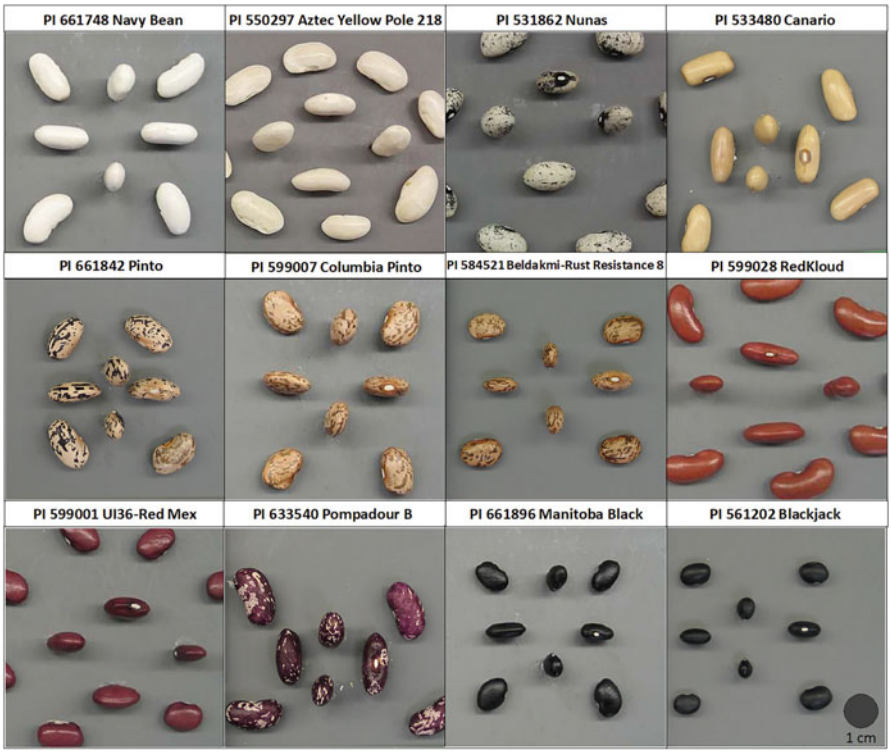

Fig. 1 Pictures of the colors of common beans based on plant introductions (PIs) shown to scale from the Genetic Resources Information Network (GRIN) of the USDA

Some inaccuracy in data for Asia may reflect confusion between *Phaseolus* beans and some *Vigna* species, although we only discuss the former genus. This chapter covers nutraceuticals in the common bean per se with highlighting overall characteristics of their contribution to diets.

2 Races/Subraces of Common Bean

Commercial classes of common bean align with genotypically and phenotypically defined races and subraces of the species (Blair et al. 2006). For example, race Durango-Jalisco, joined as races by some authors but somewhat distinct in plant morphology, include almost all the medium-sized beans originating mostly in Mexico. Race Mesoamerica includes most small seeded beans of different colors (Díaz and Blair 2006). Subraces have been proposed for this race with small red beans proposed as subrace Honduras, black beans grouping as subrace Veracruz, and various light-colored beans as subraces Carioca and Jalinho (Blair et al. 2013a, b).

Andean beans are divided into two major races (Nueva Granada and Peru) with a third subgroup (Chile) and have large diversity in seed colors making it difficult to distinguish commercial classes and with substantial overlaps in races as well. The importance of commercial classes and races/subraces of common bean lies in their association with some nutraceutical and plant morphology characteristics as well as each having a limited number of alleles for genes of interest. Common bean is among the most diverse in terms of number of seed types with colors ranging from white to yellow, tan, brown, pink, red, purple, and black with varying sizes. Seed size varies with the genepools, and races as discussed above determine the variability in many plant organs within the seed or those organs derived form it in seedling stages. For example, the sizes of cotyledon, embryo axis, and cotyledonary/primary leaves are all correlated with seed size and vice versa are influenced by these factors.

Proportion of seed coat as maternal tissue to non-seed coat as filial tissue is also related to seed size as we will discuss below. These relationships have implication on the nutraceutical properties of common bean genotypes, as different chemistries are stored in each part of the grain that we consume and even though the grain is consumed whole for the most part, the proportion of each organ influences where primary and secondary metabolites or vitamins and minerals accumulate.

3 Seed Organs and Nutritional Quality

The seed of grain legumes like common beans, being dicotyledonous, are made up of embryo and two cotyledons which are enlarged parallel storage organs that replace leaves from the growing hybrid plant as nutrient-rich tissues (Gomes et al. 2018). Figure 2 summarizes the relationship of the seed organs with nutraceutical properties as discussed in the next section using red to indicate anti-nutritional properties and green beneficial properties. The embryo is a small proportion of the total seed weight occupying a space in between the large cotyledons that make up the majority of the seed concentration. The embryo is a powerhouse of nutraceutical vitamins, hormones, and minerals with benefits listed in the niche squares above and to the upper left of the bean in the figure below. Cotyledons have both anti-nutritional (lower left, red) and beneficial (lower right, green) nutraceutical characteristics.

The seed coat is a maternal tissue derived from the mother plant that produced the seed. In an inbreeding crop like beans, this differentiation is only important if two genotypes are hybridized or if a plant happens to outcross, but it does indicate distinctions of the pulses compared to the grains of monocotyledonous cereals and have significant implications on the accumulation of nutrients, secondary metabolites, and nutraceuticals across the seed itself. Below we will discuss various macronutrients, micronutrients, and health-promoting factors in relationship to where they occur in the seed, so we refer the reader to the next figures summarizing the health effects found in each part of the seed (Figs. 3 and 4). Since common bean is generally consumed whole and not decorticated, the different locations of nutrients and nutraceuticals have implications on plant physiology, gene expression within the

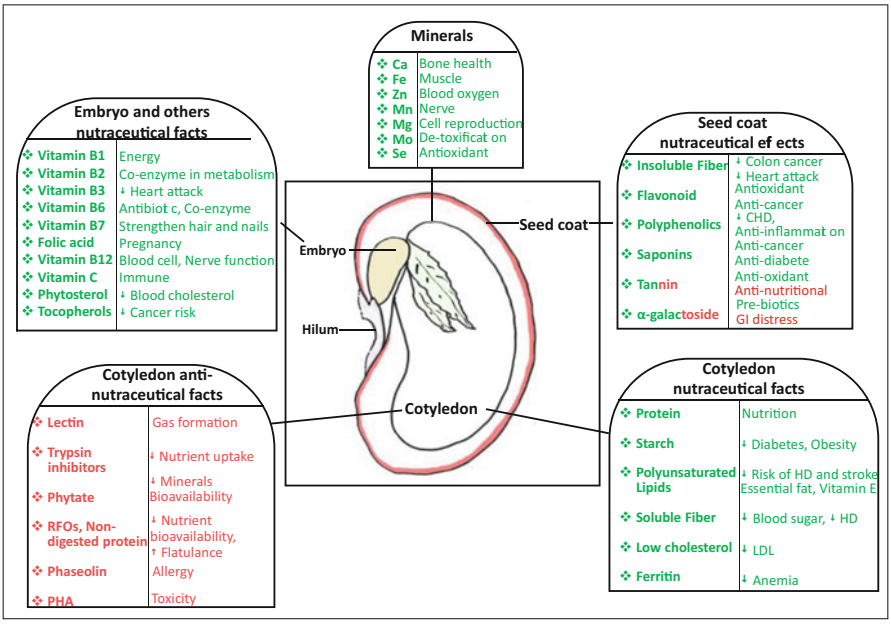

Fig. 2 Distribution of nutraceutical properties among common bean seed organs

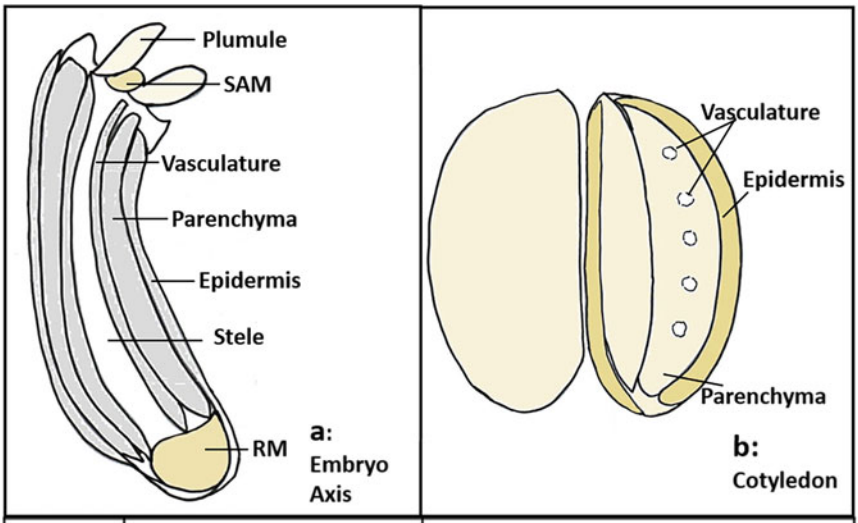
seed, and bioavailability to the human diet, more than to methods of preparation or potential processing of this pulse crop.

4 Macronutrients: Proteins, Carbohydrates, and Lipids

As pulse legumes, common beans are complementary to non-legume grains because they provide high amounts of proteins and specific amino acids that cereals are low in. According to OECD (2019), common beans of different commercial classes range from around 23% protein (in Navy and pink Mesoamericans) to over 26% (in Cranberry and kidney Andean types).

Specific authors have estimated a range in protein concentration from as low as 18% to as high as 30% for common beans (Rodiño et al. 2003). While this is often related to the variety involved, genotype x environmental effects are significant (Florez et al. 2009). Low yield environments can produce common beans of higher protein concentration, but so can higher yield environments; and nitrogen fixation may be one component of protein accumulation in common bean as a pulse grain. The types of seed storage proteins and their relative abundance can also influence overall protein quantity and quality in terms of digestibility (Osborn et al. 2003; Emani and Hall 2008).

Phaseolin, a type of globulin, is usually most of the protein in the cotyledon (40 to 60%), but the embryo axis can be filled with many other types of polypeptides (Carbonaro 2006). Albumins, with 10–20%, are the next most common seed protein. Prolamins are much smaller portions of total proteins, representing 2% or less.



Proteins	✓ High quality diverse proteins ✓ Balanced amino acid profile ✓ High sulfur containing amino acid ✓ Ferritin/ Fe in axis	✓ Storage proteins predominant ✓ Globulins / Phaseolin ✓ Ferritin/ Fe in vasculature
Carb	✓ Low Fiber ✓ Digestible sugars	✓ High Fiber ✓ Resistant starches ✓ Sugar (Glucose, raffinose, stachyos)
Phytate	Phytate lower	Phytate concentration high
Minerals	Zinc containing enzymes and Potassium	Zinc and Iron bioavailability are reduced by phytate

Fig. 3 Structures of (**a**) embryo axis and (**b**) cotyledons as seed tissues and their nutrient traits

However, both these proteins are important sources of essential sulfur-containing amino acids for common beans, which are considered low in these. Related to mineral content, ferritin is an iron-storing protein that is found mainly in the vascular tissues of cotyledons and the embryo axis within the seed (Cvitanich et al. 2010). It is determinative in how much iron is in the seed and where it is located. Anti-digestive proteins include lectins, phytohemagglutinins, and protease inhibitors, but these are often broken down by cooking of common beans (De Mejía et al. 2003).

Common beans are also high in carbohydrate concentration as this is the principal nutritional component of this type of pulse being up to 70% of the dry grain (OECD 2019). Bean carbohydrates can be divided into sugars and starches (Rivera et al. 2018). The simple sugars are glucose that is easily digestible, while

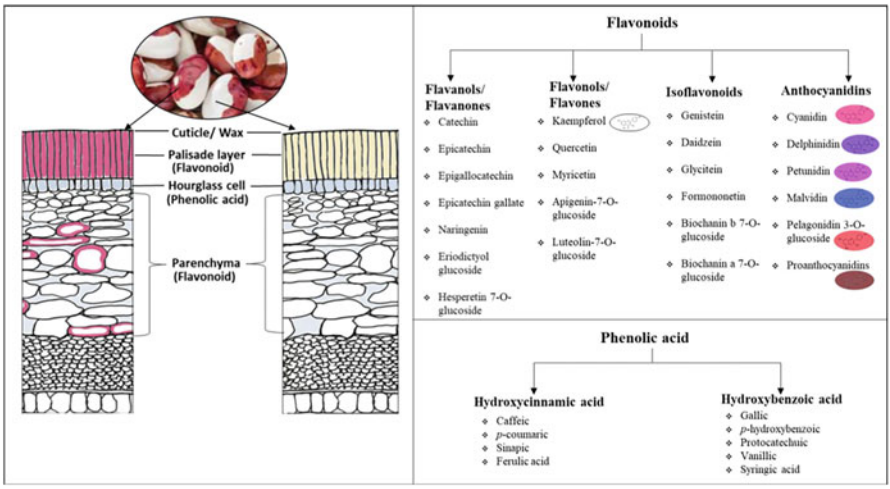


Fig. 4 Diagram of seed coat structure and the color containing portions (to the left) and uncolored portions (to the right) of this seed tissue. Seed coat flavonoids and phenolic acid component in common beans

complex sugars such as raffinose, stachyose, and verbascose are not (Sathe et al. 1984). They are considered flatulence causing factors in common bean as they are not digested in the stomach but in the lower intestine where they cause discomfort! The starches in common bean include amylose and amylopectin (Rivera et al. 2018) which are found in the two cotyledons usually in starch crystals inside specialized accumulator cells (Uebersax et al. 2022). Common beans are high in fiber, which is found mainly in the seed coat (Dhital et al. 2016; Ma et al. 2017). Fiber in beans is mostly not digestible because it is locked inside the hardened cell walls of seed coat tissue cells.

In contrast to proteins and carbohydrates, common beans are very low in lipid content. They are never pressed for oil, unlike peanuts or soybeans, two other pulses that are used for extracting oils. The small amount of fats is of high quality though being mostly polyunsaturated. Overall concentration of lipids is 1–2% among major commercial classes tested by OECD (2019) or in Spain (Rivera et al. 2018). Common bean lipids are from cell membranes and vesicles of cotyledon and embryo tissues. Like proteins, lipids are not common in the seed coat, but waxes occur on that tissue and determine if the grain type is shiny (low wax) or matte (high wax).

5 Micronutrients: Minerals and Vitamins

Common bean is a superstar crop in terms of certain essential minerals and vitamins. Since these are required by human diets but in small (micro) amounts, they are often called essential micronutrients. Among the minerals are Fe, iron; S, sulfur; Se,

selenium; and Zn, zinc all targets of biofortification or breeding for enhanced concentration above the normal or average amount found in common bean seed (Blair 2013). Soil effects are significant on the accumulation of Zn and Se, while homeostasis is active to prevent over-accumulation of Fe beyond what is needed for photosynthesis and other enzymatic processes. The amount of S usually depends on sulfur-containing amino acids and the proportion of different proteins, while the amount of Se is highly dependent on the soils on which the beans grow.

Meanwhile Fe and Zn have been studied well for inheritance and are genotype-dependent with factors of partitioning and environmental interactions coming into play to determine whether a variety is biofortified or not. Both elements can be enhanced by micro-fertilization, especially Zn which tends to be deficient in soils used to grow common beans but can easily be absorbed from foliar or seed treatments. In addition, common beans contain small amounts of other microelements such as B, boron, and Cu, copper.

The macroelements, N, nitrogen, and P, phosphorus, are related to limited supply in unfertilized soil or the amount provided as fertilizer. While N is proportional to the protein content of seed, P is often closely related to an antinutrient to the human diet which is phytate. The availability of these two elements for common bean depends on soil fertility conditions such as organic matter concentration as well as on biological/symbiotic nitrogen fixation (SNF) which in turn is highly dependent on the supply of organic/inorganic P cycles in the soil. The amount of Ca, calcium; K, potassium; Mg, magnesium; and Mn, manganese are related to soil conditions and plant uptake plus homeostasis, as is the case for Fe as well but less so for Zn. Genomics regions based on quantitative trait locus (QTL) studies for all these minerals have been detected providing a selection method to reach desired value of mineral concentration, except where correlations inhibit selection for opposing factors (Blair et al. 2016; Izquierdo et al. 2018).

The division of micro- and micronutrient between different seed organs varies based on the mineral or element. For example, Ca along with Mg are most abundant in the seed coat, with up to 85% found there. Phytates are abundant in the cotyledons (Moraghan and Grafton 2002) and a portion of the Fe of the seed, especially that portion found as ferritin. Zn and K are found principally in the embryo axis, as is another portion of Fe (Moraghan and Grafton 2002). In turn, the amount of S is related to the prevalence of phaseolin and lectins which are low in this microelement versus other proteins generally found in the embryo axis which are high in it. Many of the microelements are found as part of the embryo where there is a greater diversity of enzymes that use them as co-factors.

Common bean grains are rich sources of certain vitamins mainly those in the vitamin B family including folates (a.k.a vitamin B9), niacins (vitamin B3), thiamine (vitamin B1), riboflavins (vitamin B2), pantothenic acid (vitamin B5), and vitamin B6 (OECD 2019). Niacins are of the highest concentration in parts per million (ppm) of dry seed (mg/Kg) being 5.4–26.8 ppm. Thiamine are next being 4.9–11.4 ppm. Pantothenic acid follows with 3.5–12.3 ppm. Others are vitamin B6 (3.2–5.7 ppm), vitamin B9 (1.2–5.8 ppm), and vitamin B2 (1.4–2.9 ppm). In contrast, common bean grains are low in vitamin A or C. These vitamins are only found in leaves of the crop

that are sometimes cooked as a vegetable dish, primarily in sub-Saharan Africa. The low lipid content of the pulse means that the latter vitamins are not highly available, so it is common for beans to be eaten with other sources of vitamins such as pumpkin, carrots, and tomatoes which increase absorption of certain minerals such as Fe and Zn.

6 Other Health-Promoting Factors

The health benefits of a diet rich in pulses have long been known to scientists and some consumers but are better studied for European species such as chickpeas compared to those grain legumes popular in Africa or the Americas such as common bean (Nyau 2014). Various factors of bean seeds are health promoting, but we will limit this review to those that have been studied for common bean.

The health benefits of common beans address some of the major diseases of developed and developing countries including diabetes, certain cancers, iron deficiency anemia, micronutrient deficiencies, and heart disease/stroke risk (Anderson and Major 2002). Obesity is of growing concern around the world and can be partially controlled by pulse-rich diets as these give a feeling of satiety that reduces overall calorie intake in some cases. Interactions of various conditions means that lower blood pressure and lower obesity translate into lower risk of cardiac disease, heart attacks, and strokes.

Diabetics can benefit from eating common beans mainly because they are low in available sugars and therefore are of low glycemic index. The low glycemic index associated with beans may also be due to their complex starches or high amounts of fiber ranging from 8% to 28% of seed (Singh et al. 2017). Complex starches have been discussed and refer to non-storage carbohydrates in seeds. They include disaccharides and oligosaccharides that are difficult to digest in the stomach and intestine but which are digested by bacteria in the lower gut leading to flatulence. They play a role in gut health as they reach the colon intact and encourage beneficial bacteria to grow.

Fiber contents often depend on commercial class (OECD 2019) with this fraction consisting of cellulose, hemicellulose, mucilage, and pectins along with digestion-resistant starch making beans healthy and useful to control diabetes (Mojica et al. 2017). Insoluble fibers are generally found in the seed coat, while fiber from the cotyledons have various characteristics of water solubility (Wang and Toews 2011). A smaller component of fiber-derived products is digestion-resistant starches or complex sugar such as beta-glucans and inulin (Rebello et al. 2014). Inulin has been postulated to be a promoter of gut health and micronutrient uptake. Fiber amount in the seed coat depends on the seed coat thickness which appears to vary in different genepools and different varieties. This fiber fraction can correlate with longer cooking time making it a balancing act among consumer preferences for fast cooking and health benefits of higher fiber. However, consumption is encouraged for diabetics and those at heart attack risk, despite the longer cooking time that can modify other components of the final cooked bean product.

Another health benefit of beans is their postulated reduction in certain cancer prevalence. Most studies have concentrated on breast and colon cancers and are in mouse and rat models for these diseases rather than in human clinical studies (Reynoso Camacho et al. 2007). The beneficial effect of common bean on human health depends on their rate of consumption, with healthy diets usually including 20 Kg or more of pulses per year. High consumption is also needed for common bean biofortification of diets to be effective (Blair 2013). However, the absorption of Fe and Zn can be influenced by phytate concentration so that in addition to being a macronutrient, amount of P is surrogate for micronutrient availability.

Anti-cancer affects have also been ascribed to the flavonoids and other phenolics such as tannins in common beans. Suggestive of this is the lower incidence of colon cancer in Guatemala where black beans are commonly consumed. However, low tannin/low flavonoid beans that are white in seed coat color are often among the best beans for in vitro anti-cancer assays for other cancer types such as breast and prostate cancers. Therefore, the food components and exact metabolic compounds behind the anti-cancer effects of common beans are still a mystery. In this review, we look at the components in the seed coat and which are associated with seed color as shown in Fig. 4. This may explain the diversity of seed types selected by consumers over many locations and many generations.

Quercetin, a component of tannins and part of the flavonoid synthesis pathway (to be discussed later), has been suggested to have anti-inflammatory characteristics that blocks cyclooxygenase pathway and protects against heart disease and attacks (Nijveldt et al. 2001). Other secondary metabolites from common bean seed coats such as pro-anthocyanins can act as antioxidants reducing effects of detrimental cholesterol. Again, these are concentrated in the seed coat, specifically in palisade layer and certain parenchyma cells that show color. A layer of hourglass cells below the palisade layer has no color components but can accumulate tannins that lead to darkening of the seed coat with time and exposure to UV light. This darkening is well understood to be controlled by a few major genes and to involve enzymatic reactions that combine phenolics into complex tannins.

Common beans also contain phytosterols that are similar in structure to cholesterol but as they are plant derived have health benefits of reducing serum LDL levels and help manage blood cholesterol levels in human beings. They do this in the intestine where the phytosterols mix with bile salts displacing animal-derived cholesterols, inhibiting their absorption or retention by the intestinal lining and allowing these to be excreted into the eventual waste stream. Tannins, phytosterols, and flavonoids may act in conjunction with the high fiber of whole grains such as common bean as well as associated factors from a healthy diet to reduce heart attack risk (Jeon et al. 2012). A variety of bean types are eaten in Mediterranean diets that correlate with slow aging foods, low rates of diabetes, cancers, and obesity. Other bioactive carbohydrates apart from fiber and starch may also play a role in reducing diabetes, coronary disease, or cancer risk either directly or through the gut bioflora that common bean consumption encourages with non-starch poly-, oligo-, and monosaccharides. Slow digestion of some of the polysaccharides found in common bean can control blood glucose levels compared to rapidly digested starches found in

most cereal products. Resistant starches and fiber pass through the large intestine where they can control colon pH levels, increase fecal matter, and affect any further digestion processes along the way.

Slow digest starches can account for 25% of all polysaccharides and are principally found in the cotyledonary portion of the seed (Yadav et al. 2010; Ma et al. 2017). Another mechanism for heart health can be the lowering of cholesterol and other heart damaging lipids. Overall the benefits of common bean start with reduction in the onset of obesity which helps with heart health and minimizing type II diabetes. In countries where common bean consumption was traditional but is declining, such as Puerto Rico, Mexico, Guatemala, and Colombia, we see higher rates of this diabetes and people being overweight. Consumption rates in the United States are too low to see beneficial effects of bean-based diets except with certain communities that are vegan or vegetarian, such as Adventists, who have longer life spans than others. Previous research found that people who consume legumes at least four times per week have 22% reduced risk of heart diseases.

7 Antinutrients: Lectins, Phytates, Phytohemagglutinins, Tannins, Trypsin Inhibitors

A fraction of protein in common bean is associated with anti-herbivory and as such is anti-nutritional, reducing amino acid absorption or dietary efficiency in human foods, especially if the seed is raw or undercooked. The proteins known to be problematic include lectins and trypsin inhibitors. Lectins are a class of glycoproteins that include alpha-amylases (AIs), arcelins (ARC), and phytohemagglutinin (PHA) that are useful in an evolutionary sense because they protect against insects and some abiotic stresses (drought, salinity); however they also inhibit food digestion of the globulins that make up the majority of seed protein (Mojica and de Mejía 2015). Trypsin inhibitors (TIs) are also known as serpins (serine protease inhibitors) that also inhibit the digestion of proteins.

Various protease inhibitors exist, but TIs form the largest and most diverse family of these potent anti-herbivory agents and are found in larger concentrations in wild accessions than in cultivated common beans (de Mejía et al. 2003). Fortunately, most of these problems can be overcome by cooking beans well past softness and eliminating the water used for soaking or cooking (Batista et al. 2010; Champ 2002). Eating raw beans or flours derived from them are never a good idea especially where dosage is not controlled. It is notable that unlike mung bean and other Asian legumes, few processed foods are made from common beans or their extracts and flours.

Phytates are also considered antinutrients by reducing the bioavailability of some proteins (Ariza-Nieto et al. 2007) and micronutrients to the human body (Huber 2016), although they are necessary for health and viability of the seedling common bean. As such, phytates are found principally in the cotyledon and embryo axis where they are immediately available to the growing plantlet that germinates from the common bean seed (Schlemmer et al. 2009). Total concentration of phytates can

be up to 3% of dry weight of common bean seeds (Blair et al. 2012). Phytates interact with some proteases to inhibit protein utilization in the plant or during digestion, so complex interactions of these factors must be considered when modifying phytate levels in common beans.

Phosphorus as a nutrient that makes up the bulk of the phytate molecules is needed at every growing stage of the plant and therefore is provided in abundance within legume seeds by the mother plants. Phytate concentration in seeds varies with the genotype selected for analysis, their efficiency at P use and mobilization, and the growing environment. Genotype x environmental effects are significant when experiments are done in the field before measuring phytate levels in common bean seeds. Phytates are usually higher in raw beans than in cooked ones so phytic acid can be reduced by cooking. Germinating or soaking the seed can also reduce phytates as these processes activate phytases. Breeding for lower phytates while considered a goal of some programs should be approached with caution as some low phytate mutants are less vigorous in production environments. In addition, some health benefits have been ascribed to phytates, and they play a role in slowing down amylase digest of starches.

Another aspect of phytates is that they are made up of various inositol types (IPs) with varying levels of phosphate groups, from IP1 to IP6. These different phytates vary in their ability to complex with Fe and Zn as micronutrients or Ca as an intermediate constitute of seeds (Rousseau et al. 2020a, 2020b). This influences the utility of common bean as a source of these minerals as well as P to the human diet. Mutants with low phytate production (*lpa*), especially for IP6 amounts, have been found in common bean by a program in Italy, and they have suggested that using this mutation may be a way to increase the bioavailability of Fe in biofortification of common bean (Campion et al. 2009; Cominelli et al. 2020).

Other potential antinutrients that also have roles as a nutraceutical is the complex group of flavonoids and tannins found in common bean seeds, primarily in the seed coat. Tannins are polyphenolics that can be condensed or uncondensed (Caldas and Blair 2009; Yang et al. 2018). As antinutrients, tannins inhibit absorption of various microelements (e.g., Fe) and also many proteins. They are generally rather heat stable and therefore remain after cooking affecting the color of the bean dish produced and how rapidly it oxidizes. Within the seed coat, tannins can also lead to darkening of the seed color so that light-colored beans such as cream mottled, cranberries, pinks, and pintos are often selected to be slow-darkening (Junk-Knievel et al. 2008). Flavonoids can be bioactive components and are found in many of the light-colored beans but not in white beans, while anthocyanins are found in black beans in particular (Moreno-Jiménez et al. 2019). These are water-soluble, and so in some common bean, cooking preparations can be reduced especially during long boiling. Cooking time can depend on seed hardness, seed coat thickness, and waxy seed coats that slow water absorption. Wax on the cuticle determine if the seed is shiny (now wax) or buff (wax present). Common bean tannins and flavonoids are probably less important in controlling disease compared to these components found in wine, where resveratrol is known to be a beneficial compound. The following table describes studies that have related common beans to health factors with an example given for each of the major human diseases affected by this pulse (Table 1).

Table 1 Research into common beans and human health for the discovery of nutraceuticals

Human health	Journal	Authors, year	Nutraceutical values
Coronary heart disease	*The American Journal of Clinical Nutrition, 74(4), 418–425.*	Nijveldt et al. (2001)	Quercetin has anti-inflammatory characteristics that blocks cyclooxygenase pathway and protects against coronary heart disease
	Official Journal of the Korean Physiological Society and the Korean Society of Pharmacology, 16(4), 249–253.	Jeon et al. (2012)	The Health Professionals Follow-Up Study found that males who followed a more sensible diet, which included more whole grains, legumes, fish, and chicken, had a 30% lower chance of developing heart disease
Antioxidant activity in common beans	*African Journal of Food, Agriculture, Nutrition and Development, 14(7), 9483–9496.*	Nyau (2014)	Methanol extract in the seed coat can stop oxidative chain reactions. Common beans have greatest antioxidant activity than 100 food items using in oxygen radical absorbance capacity (ORAC) assay
Cancer and Beans	*Agricultura técnicaen México, 33(1), 43–52*	Reynoso Camacho et al. (2007)	Dietary fiber may be protective against colorectal cancer. Pinto, black and white fed rats had four times less tumors than non-fed
Blood glucose level	*Legume Science, e155.*	Uebersax et al. (2022)	Legumes have moderate glycemic reactions
	Phytotherapy Research 16(7), 662–664.	Pari and Venkateswaran (2002)	*P. vulgaris* extracts have lower postprandial glycemia similar to metformin
Weight management	*Nutrition today, 39(1), 10–17*	Jones et al. (2004)	Diet with low glycemic index prevents onset of obesity

8 QTLs Discovered for Nutraceutical Breeding

Protein is the most cited nutritional component due to its often-cited high concentration of up to 22% in common bean (e.g., Jannat et al. 2019). The inheritance of protein content in common bean has been dominated by the dissection of the *Phs* locus for phaseolin type since this makes up over half the polypeptides in the seed (Viscarra-Torrico et al. 2021). This megalocus on chromosome Pv07 encodes the storage proteins, made up of many tandem copies of orthologous genes, which show up as the major QTL for protein concentration and protein quality (Joshi and Rao 2017;

Pandurangan and Marsolais 2017). Phaseolin is a type of globulin as mentioned earlier and is used for storing protein as the seed is developing and once it is fully grown (Fig. 5). Mutations that reduce the amount of the storage proteins increase the concentration of cysteine and methionine since these are not major components of the wild-type phaseolins (Taylor et al. 2008). Lectins follow phaseolins in abundance as seed proteins but are only 5–10 times as common. These proteins are also encoded at a megalocus that includes sequences for arcelin/phytohemagglutinin/α-amylase inhibitor (APA) on chromosome Pv04 (Viscarra-Torrico et al. 2021). QTLs for amino acid content are understudied except in the context of reduced phaseolin or lectin where cysteine and methionine contents increase, perhaps due to replacement of the two most common storage proteins by more unique proteins. This would be variable depending on the population studied (Table 2).

While carbohydrates are more abundant than protein at 60% or more of seed weight and of obvious organoleptic importance, it has been assumed to be quite static, which is unlikely given the large number of commercial classes of common bean and their variability in seed type. In addition, this is the portion of the seed most likely to change upon cooking. Pujolà et al. (2007) studied raw, soaked, and cooked states of eight Spanish beans versus a control Navy bean for amylose, amylopectin, digestible starch, and resistant starches finding that the latter two tend to increase in concentration with cooking if soaking water is removed. Of the other carbohydrate components, fiber and digest-resistant oligonucleotides have been the best studied. In the case of seed fiber, a pioneering study in the mapping of QTLs for fiber content in common bean was

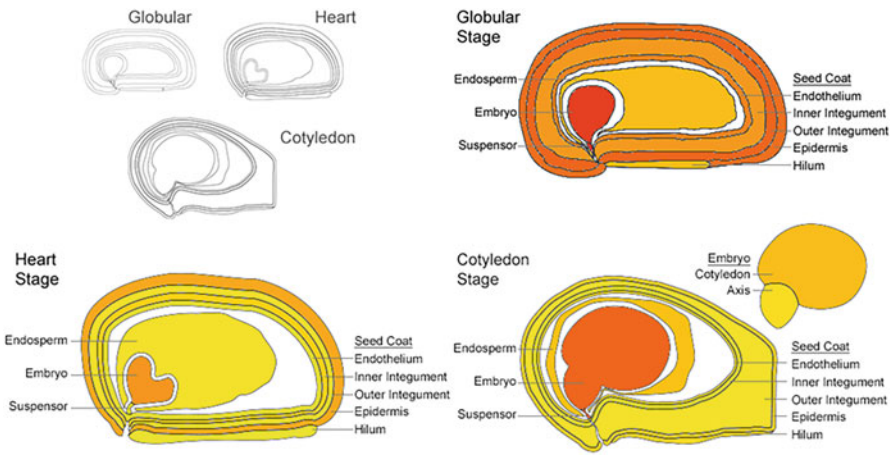

Fig. 5 Seed expression pattern for a phaseolin homolog globulin protein GLYMA03G399–40 in developing seed through three stages (heart, globular, and cotyledon) to show the intensity of tissue-specific levels of prevalence from low (yellow color) to medium (orange colors) to high (red). Subfigure at top left shows relative size of the developing seed at the three stages. Gene expression pattern for common bean is inferred from soybean as found in the eFP Browser (bar.utoronto.ca/efpsoybean/cgibin/efpWeb.cgi?dataSource=soybean_heart_cotyledon_globular) in which the protein is found early on in the seed coat, then in both seed coat and embryo and finally only in the embryo of *Glycine max*

Table 2 Germplasm and quantitative trait loci studies in common bean for nutritional components, a sampling

Title	Author	Journal	Population	Genotypes	Summary
Trypsin inhibitors, tannin, lectins	De Mejía et al. (2003)	*Journal of Agricultural and Food Chemistry, 51(20), 5962–5966*	5 bean cultivars	TI: 6.3–14.5 TUI/mg for 5 cultivars. Tannins:10.1–44.2 mg CE/g. Lectins: No significant diff.	The contribution of location to lectin of common bean was 13 times greater than cultivar and site interaction, implying that breeding for this feature may be difficult owing to a shortage of genetic resources For using beans as nutraceuticals, cultivars with high TI and tannin are promising because of their simple genetic control
Flavonoids	de Lima et al. (2014)	*Journal of Agricultural and Food Chemistry, 62(40), 9699–9704.*	16 genotypes	Kaempferol – highest in light color seed coat. Quercetin: 1.09–15.85 mg/g Myricetin: 26.15–78.94 mg/g	Significant quantities of flavonoids were found in common bean germplasm produced under the same environmental circumstances, with substantial diversity among groups with various seed coat colors
Proteins	Jannat et al. (2019)	*International Food Research Journal, 43(2), 595–601*	35 landraces from Pakistan +1 reference collection	Protein percent ranges from 18% to 22%	The common bean is the primary source of inexpensive protein for the people of many nations throughout the world. The protein profile revealed that the tested local bean ecotypes are effective protein sources for mountain dwellers
Minerals	Blair and Izquierdo (2012)	*International Journal of Plant Breeding Research, 62(40), 9699–9704*	7 pop's; 5 previously produced (2 Andean, 2 Middle American, 3 inter-genepool)	87 QTL (except QTL on chromosome 11) MQTL: 72 41 Andean, 25 Middle American, 6 wild Middle American	These findings demonstrated stronger consolidation than a maize meta-QTL study for grain Fe and Zn, which consolidated 28 unique QTL into 10 meta-QTL
Iron and zinc	Blair et al. (2010)	*Theoretical and Applied genetics, 121(6), 1059–1070.*	110 RILs in F_{10} generation developed by crossing G14519 × G4825	13 QTLs were identified for iron (5) and zinc (8)	A stable cross section QTL was found for seed mineral concentration associated with zinc and iron

Iron, zinc, phosphorous	Cichy et al. (2009)	*Crop Breeding & Genetic,49(5), 1742–1750*	77 RILs; AND696	Variation in seed Fe (40.8 mg/k) concentration in RIL was higher than Zn (16.5 mg/k). 46 QTLs are identified: 26% on linkage group B1 and more than1 trait affected; 28% linkage group B6 and multiple traits affected	Because there is substantial natural variety in seed Fe and Zn in common bean, such a goal is possible through plant breeding. Fe levels in the AND696/G19833 RIL population varied from 38 to 79 mg kg1, and Zn levels ranged from 16 to 33 mg kg1, all of which are within the predicted range based on bean germplasm screening
Anthocyanin	Díaz et al. (2010)	*Food Research International, 43(2), 595–601*	87 RILs	Anthocyanins: 0.013–0.21%. Most of the individuals did not pass 0.1%	Anthocyanins or polyphenolics are strong antioxidants that are thought to contribute to the health properties of beans
Macrominerals	Ribeiro et al. (2019)	*Genetics and Molecular Research, 18(2)*	100 RILs	Significant treatment effect is shown in potassium, calcium, and magnesium in F5:6 and F5:7 generations	Potassium-rich diets can lower blood pressure, especially in hypertensive people, and minimize the risk of diabetes. Calcium is required for the creation and maintenance of bones and skeletal structures. Magnesium is essential in the prevention of diabetes, osteoporosis, migraines, and cardiovascular disease
Folates	Khanal et al. (2013)	*International Journal of Agronomy, 1–9*	4 dry beans, 6F1 and 6F2	Total folate content: 217–345 in first injected solution; 167–231 mg/100 g in second injected solutions. g1268 (7.7%) and g2498 (7.8%) on Pv09 in first injection and g457_B in second injection shows significant dominant effect	The findings of this investigation indicated that, despite the prominent levels of folate concentration in dry beans, genetic diversity occurs between genotypes

carried out by Casanas et al. (2013) using a recombinant inbred line (RIL) population from the cross of a Spanish Alubia type Andean bean named Xana with a small black disease-resistant Mesoamerican bean named Cornell 49,242. They found a major QTLs associated with dietary fiber named DF7XC on chromosome Pv07, near the *p* locus involved in the genetic control of seed coat color.

Dietary fiber was also studied in a genome-wide association study (GWAS) panel of 280 cultivars from the Mesoamerican group of edible dry beans with 100 race Mesoamerica and 180 race Durango–Jalisco representatives by Moghaddam et al. (2018) who found a few more QTL for this trait. The same group also evaluated complex starches and found two candidate genes – *Phvul.001G214300* and *Phvul.001G215300* – for raffinose production that were homologous to Arabidopsis Stachyose Synthase (Sts)/Raffinose Synthase 4 (Rs4) and Galactinol Synthase 1 (GolS1), respectively.

Lipid content may vary between genotypes, but as this component is a small component of common bean, no current studies have looked at the inheritance of this trait. Some fat-soluble and insoluble vitamins have been evaluated. For example, Khanal et al. (2013) determined total folate content in four varieties of dry beans and their F_1 and $6F_2$ progeny finding that concentration could vary from 217 to 345 mg/100 g of seed in the first injected solution and from 167 to 231 mg/100 g in the second injected solutions with QTLs identified on chromosome Pv09 associated with markers g1268 (7.7% of variation explained) and g2498 (7.8%) for first injection and g457_B for second injection showing significant dominant effect. The findings of this investigation indicated that genetic diversity occurs between genotypes, despite the overall high levels of folate concentration in dry beans.

The seed coat is extremely important in the analysis of nutraceuticals as it is home to many of the health-benefiting minerals and secondary metabolites (Beninger and Hosfield 2003). Minerals are often bound to the tannins that accumulate in bean seed coats (Caldas and Blair 2009). Ca and to a lesser extent Mg are enriched in the seed coat (Aparicio-Fernandez et al. 2005).

Component of cell walls are compact in the hourglass and palisade layers that are external and internal facing cells. Two thirds to four fifths or more of seed Ca is found in the seed coat of common bean which contrast with soybean (Moraghan and Grafton 2001) and perhaps helps to explain differences in cooking time (Bassett et al. 2021). Tannins or polyphenolics accumulate at the seed coat cells that may also bind up $Fe^{2+/3+}$ and Zn^{2+} as well as Mg^{2+} as positively charged ions explaining their higher concentration.

Caldas and Blair (2009) analyzed three inter-genepool populations of RILs for condensed tannins from seeds and associated 12 QTLs with major genes for seed coat color. QTL explaining from 10% to 64% of the phenotypic variation for condensed tannin were found on linkage group B3, B7, and B10 associated with the Mendelian genes *Z*, *P*, and *Bip*, respectively. Most phenolics have strong antioxidant properties (Wang et al. 2016). Other than tannins, chief among the organic compounds found in seed coats are the flavonoids, flavones, flavonols, and isoflavonoids which include a range of polyphenolics from the flavonoid and isoflavonoid pathways (Fig. 6).

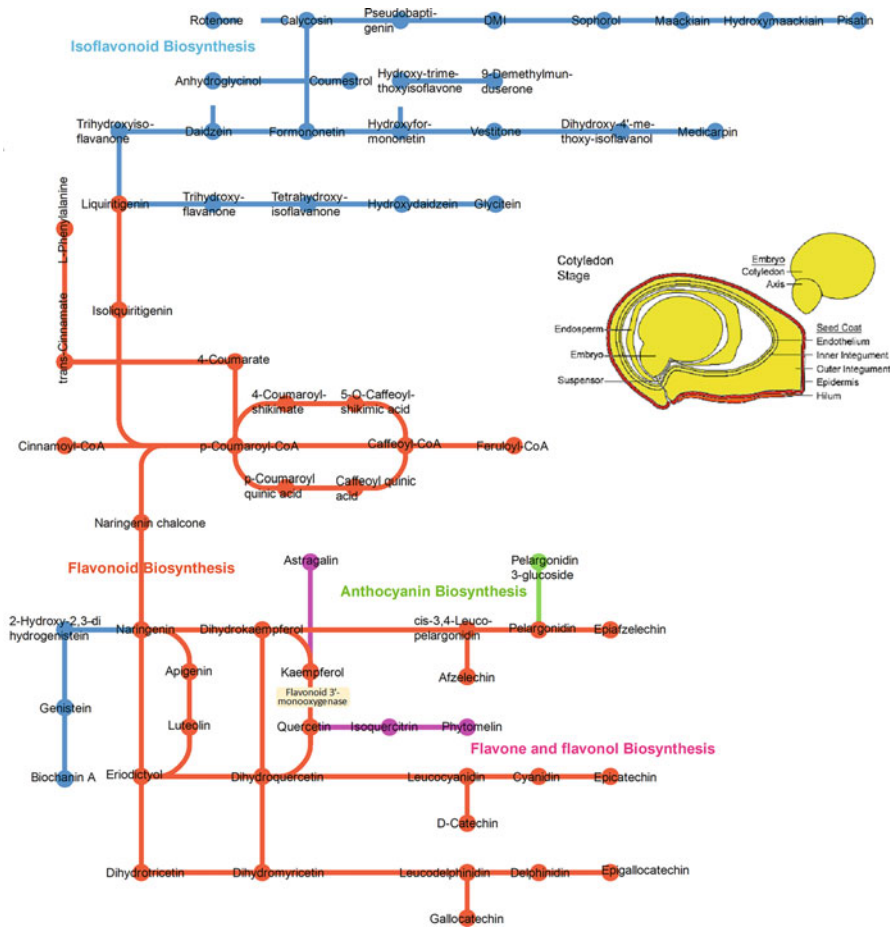

Fig. 6 A common bean specific drawing of the flavonoid (red), flavone/flavonol (pink), isoflavonoid (blue), and part of the anthocyanin (green) pathways with steps involved in intermediate and final products such as D-catechin, cyanidin, delphinidin, gallocatechin, kaempferol, pelargonidin, quercetin, etc. Subfigure to the right shows gene expression pattern for the highlighted gene flavonoid 3′ monooxygenase which converts kaempferol to quercetin. Gene expression pattern for common bean is inferred from soybean as found in the eFP Browser (bar.utoronto.ca/efpsoybean/cgibin/efpWeb.cgi?dataSource=soybean_heart_cotyledon_globular) in which the enzyme is produced only the epidermis of seed coat tissues both around the seed and in hilum areas of *Glycine max*. Pathway based on KEGG (http://www.genome.jp/kegg/) for genes expressed in *Phaseolus vulgaris* (pvu) using iPath v3.0 (https://pathways.embl.de/)

Authors have analyzed the flavonoids influencing seed color (Rocha-Guzmán et al. 2007). As a further example, de Lima et al. (2014) found that kaempferol was highest in light color seed coat among 16 genotypes evaluated. Quercetin ranged from 1.09 to 15.85 μg/g and myricetin from 26.15 to 78.94 μg/g. They concluded that significant quantities of flavonoids were found in common bean germplasm

produced under the same environmental circumstances, with substantial diversity among groups with various seed coat colors. Anthocyanins are an offshoot of the flavonoid pathway leading to pelargonidin and other dark colored red and purple tones, which are found mostly in dark red or small black beans. Díaz et al. (2010) used 87 RIL's from a combination of G19833 (sequenced genome) × DOR364 to find a range in anthocyanins of 0.013–0.21% skewed toward lower content. They suggested evaluation of anthocyanins and other polyphenolics as strong antioxidants that are thought to contribute to the health properties of beans.

The figure above highlights a key enzyme involved in metabolite synthesis for flavonoids, namely, the flavonoid 3′ monooxygenase for quercetin synthesis from kaempferol. This gene in *Glycine max* (soybean) was found with major expression in epidermis and hilum cells when KEGG and iPath were used to build a model of the metabolite profiles in the flavonoid pathway. It is important to consider that any of these phenolic derivatives have roles not only in seed coat color but also in anti-herbivory by insects or protection and camouflage from birds.

For phytates, another nutraceutical that has physiological roles in seed development and subsequent seedling growth, mutants have been analyzed to reduce the amount of phytates. Low phytic acid (*lpa*) mutants for the most part have abnormal plant phenotypes since phytic acid is a signaling molecular as well as phytates being a source of P for cell development. Blair et al. (2012) found QTL for phytate concentration in a central DOR364 × G19833 population that aligned with markers for the genes myo-inositol (3)P1 synthase (MIPS), myo-inositol kinase, and various inositol kinases. A phytate concentration QTL was found associated with one of two paralogs of the myo-inositol (3)P1 synthase gene family, located on linkage group Pv01 and expressed in common bean seed rather than in vegetative tissues. They concluded that natural variability in phytate levels was controlled by variation for MIPS activity as well as other loci that underlie the oligogenic inheritance in common bean. In Fig. 7, we show the primary enzymes and substrates/products in the inositol phosphate pathway, through the steps to phytates. One of the key enzymes is ATP1-myo-inositol 3′-phosphotransferase shown by KEGG mapping of annotated metabolites onto the pathway map from studies in many legumes (Darzi et al. 2018).

9 Current and Future Foci of Nutraceutical Research in Common Bean

To date, the best studied nutraceutical features of common bean have been protein, phytates, and several minerals considered important for biofortification, a process of improving legumes and other basic grains or starch sources for micronutrients (Blair 2013). Breeding for protein levels has had minimal success as most legumes already maximize their seed protein levels, and in common bean only a few mutants exist to change the makeup of those proteins that accumulate.

Meanwhile, phytates are important to biofortification with minerals because of chelation of iron, zinc, calcium, and other charged ions. Cominelli et al. (2020)

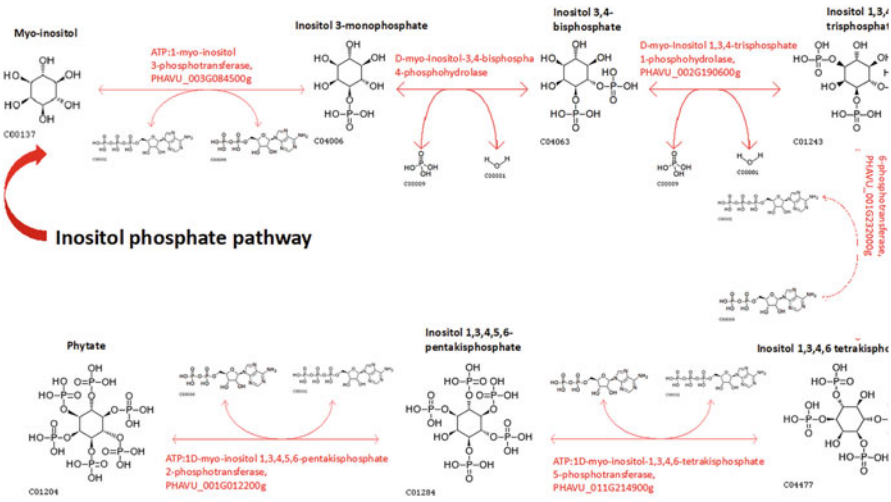

Fig. 7 The inositol phosphate pathway with enzymes (and gene accession IDin *Phaseolus vulgaris*) confirmed for common bean based on KEGG (http://www.genome.jp/kegg/) database

postulated that biofortification and plant adaptation may be at odds because of the inverse relationship between phytates and mineral bioavailability. Petry et al. (2010) found that this has real-world implications in feeding trials with common bean as a main source of iron for young women. Fiber also plays a complex role. Interactions during digestion including fermentation by microbes of fiber in the gut can affect human health. Butyrate, for example, is a product of fiber digestion that has anti-tumor and anti-inflammatory properties thus reducing cancer risk (Lanza et al. 2006; Chen et al. 2017).

Despite the interaction with tannins and phytates, the inheritance of mineral concentration has been a major focus of biofortification with the approach of "more is better" especially for iron and zinc which generally are deficient in grain-based or vegetarian diets (Blair 2013). The studies have been conducted in inter-genepool and within genepool populations. The former kind includes the pioneering study of Cichy et al. (2009) who found QTL for each of the two biofortification target mineral in the DOR364 × G19833 (Mesoamerican × Andean, $n = 87$) and AND696 × G19833 (Andean × Andean, $n = 77$) populations, respectively.

In the latter study, variation in seed Fe (40.8 mg/kg) concentration in RILs was higher than variation in Zn (16.5 mg/kg) with phytate also varying significantly resulting in a total of 46 QTLs found for iron, zinc, and phosphorus, the latter as a stand-in for phytates. In a third population, G14519 × G4825 (Mesoamerican × Mesoamerican) only 13 QTLs were found in total, 5 identified for Fe and 8 for Zn, but the population size was bigger ($n = 110$). A meta-analysis by Blair and Izquierdo (2012) looked at all previously produced populations and two new ones to identify 87 QTLs on every chromosome except Pv11. In more recent studies a greater number of minerals have been analyzed for QTL associations (Blair et al. 2016;

Ribeiro et al. 2019). While most of these studies looked at whole seed and did not attempt to breed lines with confirmed QTL, the studies by Blair et al. (2013a, b) were unique in using advanced backcrossing and seed coat analysis of minerals to do so. Advanced backcrossing was also used by Blair and Izquierdo (2012). Variability in national and international collections for biofortification traits has been confirmed by many authors (Celmeli et al. 2018; Delfini et al. 2021; Jan et al. 2021; Murube et al. 2021). Inheritance for all these micronutrients is mainly controlled as quantitative traits.

A more holistic approach is needed for true nutraceutical improvement of common bean. This should include analysis of nutrient levels as has been done with most studies conducted so far but also analysis of the genes involved in nutraceutical quality and physiological mechanisms leading to their expression. As an example of this, which admittedly is only an initial attempt to define some nutraceutical candidate genes, the KEGG pathway was used to target key enzymes in starch, protein storage, phytate synthesis, and flavonoid (anthocyanidin) synthesis pathway and find where in seed tissue the genes are expressed in an orthologous system.

To this end, we prepared a figure showing gene expression level in different seed compartments (Pelletier et al. 2017) for nine selected nutraceutical candidate genes (Fig. 8). In each case, the orthologous genes in soybean (*Glycine max*) were used to predict expression for common beans, as the eFP database does not yet include *Phaseolus vulgaris*. The 1,4-alpha-glucan branching enzyme (PHAVU_009G011000g), beta-amylase (PHAVU_011G107700g), and isoamylase (PHAVU_001G148700g) gene expression at globular seed stage indicate that alpha-

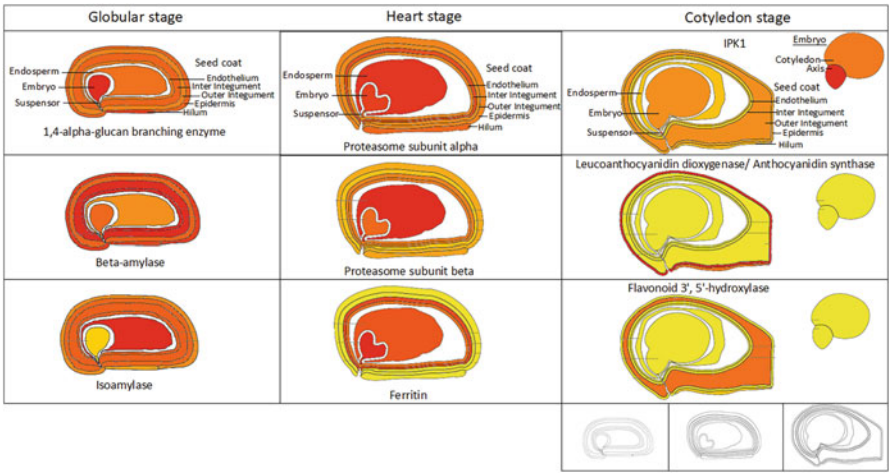

Fig. 8 Seed expression pattern for orthologs of nutrition candidate genes for common bean (*Phaseolus vulgaris*) based on RNA analysis of soybean (*Glycine max*) seeds where the intensity of tissue-specific levels of prevalence range from low (yellow color) to medium (orange colors) to high (red) based on the eFP Browser (bar.utoronto.ca/efpsoybean/). Subfigure at bottom in black and white shows relative size of the developing seed at the three stages

glucan enzyme has higher expressed level in the embryo. Isoamylase for starch degradation was mainly cotyledon expressed. Proteasome subunit alpha (PHAVU_008G093300g) and subunit beta (PHAVU_009G103400g) for protein degradation were highly expressed in heart stage cotyledons indicating places where phaseolin is accumulating and when.

Continuing with three more nutraceutical candidate genes: the enzyme highlighted for phytate accumulation. IPK1 (PHAVU_001G012200g) was observed to be highly expressed in the embryo axis at late stages. Finally, anthocyanidin synthase (PHAVU_002G152700g), an enzyme for anthocyanidin synthesis, was mainly expressed in seed coat epidermis. Similarly, flavonoid 3′,5′-hydroxylase (PHAVU_006G015400g) that converts quercetin to myricetin was mainly expressed in the seed coat outer integument but only at late stages of seed development. All these genes help researchers define where to look for nutraceutically important metabolites.

10 Conclusion

In conclusion, the common bean has been most often associated with diets of lower classes in developing countries, where it is known as "meat of the poor." This has created a bias toward studying only its basic proximate analysis of protein and starch contents for amino acid and caloric uptake or to evaluate its potential in biofortification for minerals such as Fe and Zn deficient in diets that are based on cereals. This reductionist attitude as exemplified in Pfeiffer and McClafferty (2007) does not holistically consider the full benefits that common beans can have on the human diet of both developed and developing countries.

Therefore, to reap the benefits of the entire suite of nutraceutical compounds in common beans, there is a need to evaluate the whole set of metabolites, their locations in the seed, and their interactions. This approach is practical for the proximate or reductionist researcher too. For example, during the biofortification project, phytates and tannins were not considered while breeding for higher minerals. And as a result, bioavailability has been ignored compared to total mineral accumulation, and the results have been mediocre advances in micronutrients that can be absorbed, in addition to problems with homeostasis of mineral content in the seed, considering where these are deposited. More reviews of all components of nutritional quality is needed since the biofortification aspect of common bean has been well reviewed (Blair 2013; Dwivedi et al. 2012) but other aspects have not. Here we have attempted to show the full benefits of common bean to human health through their nutraceutical properties. We have found that a lack of biochemical and functional studies stymies the advancement of common bean research in the legume nutraceutical space.

Acknowledgments The authors would like to thank the USDA Evans Allen program (TEN-X07) for funding this project as well as input from previous Bill and Melinda Gates Foundation projects. Useful discussions with previous and current students of the Blair Lab: Aura Diaz, Carolina

Astudillo, Daniel Ambachew, Gina Caldas, Karen Cichy, Josh Relyea, Max Miller, Maia Payne, Paulo Izquierdo, Tito Sandoval, and Tatiana Zabaleta, are also acknowledged. We also thank the USDA Nutrition laboratory in Ithaca New York under Dr. Ray Glahn for hosting many visits over the years, the ECABREN leadership under Dr. Paul Kimani, and the 1890s Capacity Building Program faculty development program for providing contexts in which to write this chapter.

Genetic Improvement of Nutraceutical Traits in Chickpea (*Cicer arietinum* L.)

Alok Das, Biswajit Mondol, Prateek Singh, and Shallu Thakur

Contents

Abstract

Chickpea is a rich source of essential dietary nutrients and is considered as a functional food that offers various health benefits, including maintaining healthy gut, reduce obesity, aid in weight management, etc. Chickpea plays a vital role in ensuring nutritional food security and is considered as chief source of protein, carbohydrate, fats, fibers, folate, beta carotene, and different elements. Beside nutritional significance chickpea has the therapeutic properties and is claimed to inhibit cancer and is involved in maintaining normal blood pressure and assists in regulating type-2 diabetes and various cardiac disease. Apart from these nutritional benefits, chickpeas have been reported for the presence of some antinutritional factors (ANFs) that can be minimized employing various processing techniques. Efforts are in progress to identify QTLs linked to enhanced nutritional content and

genome wide association of protein, beta-carotene, Fe, Zn, Cu, P, and K in a panel of chickpea genotypes. Biotechnological interventions for biofortification of chickpea included combination of chickpea nicotianamine synthase 2 (*CaNAS2*) and soybean ferritin (*GmFER*) genes that have reported to enhance iron content from the transgenic seeds, however, further study is required in this area. Chickpea is widely adopted in various cuisines and forms across populations, and its nutritional enrichment should be the priority area of research.

Protein-rich legumes · Nutraceutical duality · Nutritional diversity · Mapping · QTLs · Genome wide association studies (GWAS) · Genetic engineering

1 Introduction

Chickpea is a grain legume belonging to the *Leguminosae* family that are prominently cultivated in Asia, Africa, the Middle East, Mediterranean Europe, Canada, Australia, and some parts of South America. The genus *Cicer* comprises of one cultivated species (*Cicer arietinum* L.) and 42 wild species. Chickpea originated from South East Turkey in the Fertile Crescent belt near Syria. Four centers of diversity were identified, viz., Mediterranean, Central Asia, the Near East, and India, besides, the secondary center of origin in Ethiopia (Vavilov 1951). Van der Maesen (1972) reported that the species originated in the southern Caucasus and northern Persia. Later, Ladizinsky (1975) reported southeastern Turkey as the center of origin. Based on the presence of the closely related annual *Cicer* species, *C. reticulatum,* and *C. echinospermum*, P.H. Davis, Van der Maesen (1987) opined the southeastern part of Turkey adjoining Syria as the possible center of origin. Wild *C. reticulatum* is intercrossable with the cultivated species *C. arietinum* and resembles morphologically as well. It was regarded as the wild progenitor of cultivated species, *C. arietinum* (Ladizinsky 1975). Duke 1981 also reported chickpeas were first domesticated in the Middle East and were widely cultivated in India, Mediterranean area, the Middle East, and Ethiopia. Wild *Cicer* species were reported to be abundant in Turkey, Iran, Afghanistan, and Central Asia (Duke 1981). The crop subsequently spread with human migration toward the West and South via the Silk Route (Singh et al. 1997). Chickpea is diploid and primarily self-pollinated (occasional cross-pollination by insects up to 1%). Thirty-six of the wild relatives are perennials and the ten are annual (Toker et al. 2021). It is the world's second largest legume crop based on the annual production and India being the largest producer accounting for the two-third of the total production (FAOSTAT 2020). Chickpea are broadly classified into two major classes: *Desi* and *Kabuli* based on the seed morphology. The *Desi* variety have relatively smaller seeds with dark colored thick seed coat whereas, the *Kabuli* variety have pale cream-colored thinner seed coat.

Chickpea plays a vital role in the diet of humans and animals and also helps to maintaining soil fertility, especially in arid areas. The ability of chickpea to fix

nitrogen in the soil makes it an important choice in farming systems. Under favorable environmental condition, chickpea can fix up to 60–80 kg/ha of atmospheric nitrogen. The symbiosis process in *Rhizobia* is governed by mainly two classes of genes involved in the nodulation process and other employed in nitrogen fixation. The nodulation genes are important component of the rhizobium-legume pairing that are involved in the production of enzymes that play key role in the biosynthesis and secretion of Nod factors that interact with plant flavonoids for initiating nodulation (Via et al. 2016). The genes responsible for nitrogen fixation include nitrogenase enzyme genes that are involved in conversion of free atmospheric nitrogen into ammonia. Chickpea are vulnerable to climate change, both drought and heat can significantly reduce its productivity. Temperatures and drought tolerance are the key traits in chickpea breeding for maintaining the production of chickpea in adverse areas.

In the contemporary era, with the change in lifestyle and food habits, nutritional quality has been a matter of consideration. Pulses together share only 5% of total protein consumption globally (Joshi and Parthasarathy Rao 2016), but it is significantly higher in India (6–24%) (NNMB 2006). Legumes have been scored >100 along with animal-based proteins for amino acid score based on lysine content (WHO 2007), which were conventionally grouped as *second-class* proteins by dieticians with respect to the animal-based protein (classified as *first-class* protein). Animal protein-based food contains cholesterol which is not advantageous for the human compared to plant-based protein foods. Chickpea is the major food legume or pulse crop in South Asia and it figures in the dietary habits of people in Africa, Mediterranean Europe, South and North America as well. Owing to its nutritional quality, chickpeas are currently being tested in space programs.

2 Nutritional Composition

Chickpea, also known as *garbanzo beans*, has been part of human diet since ancient times. Its leaves and seeds are globally consumed in several different forms and preparations based on the ethnic and regional factors. Chickpea has been the part of staple diet among the population living in the Middle East, India, Israel, Spain, and North Africa. The soaked chickpea seed salad is a healthy alternative for weight management, the dehusked split seeds are consumed as *dal,* and the whole seeds are consumed in boiled, roasted, and fermented forms in the Indian subcontinent.

Chickpea seeds contains carbohydrates (50–58%), protein (15–22%), moisture (7–8%), fat (3.8–10.20%), and micronutrients (<1%) (USDA 2021). They are also rich in globulin (42%), albumin (16%), and glutens (10%). They contain all essential dietary amino acids except the sulphur-containing amino acids that can be complemented from cereals to form a balanced diet when consumed together. Chickpeas are rich in carbohydrates containing both simple sugars (glucose, fructose, and ribose) and complex sugars (raffinose, ciceritol, and starch). Besides nutritional benefits, chickpea also contains prebiotics that have been claimed to provide several health benefits including maintaining healthy gut, reduce obesity,

and aid in weight management. Furthermore, prebiotic carbohydrates assists in lipid metabolism producing short chain fatty acids that are linked with various health benefits including reducing obesity, reduces insulin dependency, and prevents colorectal cancer. Prebiotics carbohydrates are complex sugars that include simple sugars, fructo-oligosaccharides (ketose and nystose), inulin, resistant starch, sugar alcohols (sorbitol and mannitol), and raffinose oligosaccharides (raffinose, stachyose, and verbacose). Chickpea contains various carotenoids and vitamins including β-carotenoids, canthaxanthin, xanthophyll, tocopherols, and vitamin B complex (B2, B5, B6, and B9).

Chickpea being a nonoil seed crop has low fat content (3–10%) but is higher compared to other pulses. Major classes of fatty acids found in chickpea originated from storage lipids (triacylglycerols) (Jukanti et al. 2012). Sterols and phytosterols and various classes of polyunsaturated fatty acids (66%) including essential fatty acids (ω-6 and ω-3), monounsaturated fatty acids (19%), and saturated fatty acids (15%) are present in chickpea. In general, chickpea seeds have higher fat content than most of the pulses and cereals consumed globally. Although chickpea has low lipid content, but the two prominent polyunsaturated fatty acids (PUFAs) include linoleic and oleic acids that constitute more than 50% of total chickpea lipid reserve. PUFAs belong to the class of good cholesterols, an essential element that is required to regulate the level of bad cholesterol in humans.

Chickpea seeds and sprouts are rich source flavonoids, especially isoflavones. Carotenoids are brightly colored lipid-soluble pigments that exhibit antioxidants activity. Carotenoids are of two types: oxygenated type (xanthophylls that includes lutein, violaxanthin, and neoxanthin), and the nonoxygenated type (carotenes that includes β-carotene and lycopene). The major classes of carotenoids present in chickpea include α-carotene, β-carotene, lutein, zeaxanthin, lycopene, and β-crypto xanthin. Interestingly, average concentration of carotenoids present in the wild accessions of chickpea is higher than the cultivated varieties. Among all the carotenoids found in plants, the β-carotene is the most widely distributed carotenoid that can be converted into vitamin A efficiently (Abbo et al. 2005).

Chickpeas are rich source of dietary minerals like calcium, zinc, phosphorus, magnesium, and folate. Furthermore, it is a chief source of other vitamins including riboflavin, niacin, thiamin, and folate. Chickpea serves as a major source of protein and carbohydrate among the vegetarian population living in the semi-arid tropics. They are cheap source of dietary protein and also sometimes referred as “poor man’s meat.”

3 Medicinal and Physiological Properties

Isoflavones, linoleic acid, saponin, and β-sitosterol found in chickpea exhibit therapeutic significance as they are associated with anticancerous properties and assist in cholesterol management and promote cardiac health. Isoflavones found in chickpea have been reported to inhibit development of breast cancer cells by initiating apoptosis of the MCF-7 cells at a concentration of 32.8 μg/ml. Inhibition of cell

proliferation is governed by up-regulation of apoptosis signaling pathway and down-regulation of genes involved in mRNA splicing pathway. The modified expression of 11 hub genes of PPI (protein-protein interaction) networks under the effect of isoflavones enhances the survival time and is potential anticancer agent in breast cancer patients (Wang et al. 2020). Chickpea consumption had been associated with a reduction in the incidence of HDL cholesterol, type-2 diabetes, and heart disease. Linoleic acid, a dominant PUFA which is involved in maintaining normal blood pressure and its involvement in production of prostaglandins had been reported in chickpea. Saponin rich foods have been reported to reduce plasma cholesterol significantly (Singh et al. 2017). Saponin binds with the dietary cholesterol, thereby promoting their egestion through faeces. Saponins have also been reported with strong cytotoxic effects against cancer cell lines. β-sitosterol (dominant phytosterol in chickpea) have been reported effective in reducing serum cholesterol levels and incidence of coronary heart disease. Recommended intake of folic acid had been reported to lower the serum homocysteine concentrations, a risk factor for chronic heart disease. It is found that people with recommended fibre intakes (26 g/day) had a 27% lower risk of cardiovascular diseases compared to those with low intakes (12 g/day). Deposition of visceral and ecotopic fats, resulting in hypolipidaemia and insulin-sensitizing effects in the rats were reduced by inclusion of chickpea in high-fat rodent feed.

Chickpea and yellow pea hydrolysates produced by gastrointestinal enzymes had high ACE inhibitory activity which was comparable to milk protein hydrolysates. Furthermore, peptides derived from garden pea, cowpea, and chickpea exhibits antioxidant, hypo-cholesterolemic, anticancer, and antimicrobial properties. The chickpea derived peptides had been reported to inhibit the growth of Caco-2 and THP-1 cell lines. The cancerous cell lines Caco-2 responsible for tumors in the colon and THP-1 cells grow in basal space. The antioxidant and free radical scavenging activities of chickpea protein hydrolysates (CPH). The CPHs were assayed based on reducing power, inhibition of linoleic acid autoxidation, and 1,1-diphenyl-2-picrylhydrazyl (DPPH)/ superoxide/ hydroxyl radical scavenging assays. The authors reported antioxidant activity of lowest molecular weight fraction as 81.13%, which was closer to that of α-tocopherol (83.66%) in the linoleic acid oxidation system.

4 Nutraceutical Duality

Food legumes contain several antinutritional factors (ANFs) like protease inhibitors, amylase inhibitors, lectins, saponins, phytic acid, and long chain oligosaccharides (raffinose family)/ polysaccharides. Biochemistry research of 1980s and 1990s concentrated majorly on quantification and characterization of those ANFs in food legume crops. Singh (1988) reported various antinutritional factors present in chickpea, viz., protease inhibitors, amylase inhibitors, phytolectins, polyphenols, and oligosaccarides that can be significantly reduced through processing practices as cooking, germination, and fermentation. Mittal et al. (2012) studied different processing treatments, namely,

germination, boiling, pressure cooking, and roasting for reduction of various antinutritional factors like phytic acid, polyphenols, tannins, saponins, oxalates, and trypsin inhibitor activity in chickpea. The authors reported pressure cooking as maximum effective methods in reduction of all types of antinutritional factors. Pressure cooking reduced tannins by 93.97% and polyphenols by 87.71% which were maxima. Protein fraction, fatty acid profile, and mineral content of chickpea were affected by processing treatments. Notably, the albumin fraction was least affected on processing. However, germination increased the linolenic acid to 48.42%, Fe to 56.89%, and K to 28.6% respectively. Cooking treatments observed to be causing significant reduction in fat, total ash, carbohydrate fractions, antinutritional factors (trypsin inhibitor, haemagglutinin activity, tannins, saponins, and phytic acid), minerals, and water-soluble B-vitamins. Significant reduction was observed after cooking treatment for reducing sugars, sucrose, trisaccharides (raffinose and stachyose); whereas verbascose was completely eliminated. Authors reported cooking treatments affect protein profile by reducing the concentrations of lysine, tryptophan, and total aromatic amino acids. However, after the reduction in concentration, cooked chickpeas were still higher in lysine, isoleucine, and total aromatic amino acid contents with respect to the standard (FAO and WHO). The authors reported lesser reduction in B-vitamins and minerals in chickpeas cooked by microwaving than those cooked by boiling and autoclaving. Chickpeas subjected to the various cooking treatments varied considerably, depending on the type of treatment. Based on the chemical score and limiting amino acid, the authors recommended microwave cooking for chickpea preparation, which not only improved nutritional quality (by reducing the level of antinutritional and flatulence factors, increasing in-vitro protein digestibility and retention rates of both B-vitamins and minerals) but also reduced the cooking time. Singh et al. (2017) reviewed illustratively regarding saponins in chickpea, where processing and cooking have been reported to reduce them. The effect of soaking, sprouting, and cooking on the stability and bioavailability of saponins has been studied to limited extent.

The duality regarding the ANFs is interesting and intriguing. ANF like raffinose family of oligosaccharides (RFO) which consist of oligosaccharides like raffinose, stachyose, verbascose are commonly found in pulse crops and often associated with flatulence. However, recent researches suggest RFOs reduce the risk of intestinal cancer and promote bowel clearance. During germination, RFOs serve as a carbon source. The long chain oligosaccharides or polysaccharides help in reducing the glycemic index by reducing the rate of digestion. It reduces hankering for carbohydrates and is utilized by dieticians for weight management diets. Another ANF, haemagglutinogen exhibit beneficial role in arresting metastasis and killing cancerous cells, activation of body defense mechanisms along with obesity reduction. Saponins are another group of ANF present in legume crops which has been reported to trigger RBC hemolysis in higher concentration. Recent researches report saponins to decrease the serum lipid and glucose level and also lower cancer risk. Diets rich in saponin have been reported to prevent dental carries as well. Amylose inhibitors have potential to be used in treatment strategy to control diabetes for its property to reduce the digestion of starch and altar response of sugar to insulin. Hemolytic disorder causing ANFs from fababean, viz., vicine and convicine have also been

reported to reduce cholesterol. The beneficial attributes of protease inhibitor (ANFs), viz., trypsin and chymotrypsin inhibitors include their anticancerous, anti-inflammatory properties. The authors also reported ANF Angiotensin I-converting enzyme (ACE) inhibitor to be associated with control of hypertension. Replacement of animal protein foods with legume proteins limited the intake of saturated fats and increased the intake of dietary fibers, which helped lowering the risk of cardiovascular disorders. WHO in its 2008 report has stated that adoption of pulse-based diets prevents up to 80% of heart disease, stroke, type 2 diabetes, and some cancers.

Pulses are being considered as food of future based on the contemporary lifestyle of sedentary behavior and less physical activity. They have low glycemic index and have been reported to indirectly control the blood glucose level thereby preventing risk of diabetes (Lunde et al. 2011). The indirect control of blood glucose level is achieved through the feeling of satiety (feeling of full stomach), thereby reducing the hunger and increasing the food intake gap (Lunde et al. 2011). The ANFs can be reduced through processing, those are either thermo-labile or water soluble. Soaking the seeds before cooking and draining the water (for water soluble ANFs) or stirring the seeds in dry heat (for thermo-labile ANFs) before cooking makes pulses/ grain legumes ready for consumption.

For the genetic enhancement of chickpea with respect to nutraceutical parameters, target traits should be well defined. Nutraceutical parameters essentially include the nutrition quality and grain quality parameters which determine the consumer preference. Nutrition quality parameter include the concentration of proximate (protein, lipid, carbohydrate) and protective (macro and micronutrients like Fe, Zn, etc.) principles of food. The grain quality traits in chickpea include the grain phenotypical characteristics per se, for example, testa color, cotyledon color, 100 seed weight, seed shape, testa texture, raphae, ribbing, etc. Traits like cooking quality and milling attributes are directly associated with those parameters. The pigments imparting color are essentially antioxidants and their role in health is well documented. Besides, the so-called antinutrition factors with therapeutic properties also come in consideration here. Finally, all those traits have to be combined with high yield and stress (biotic/ abiotic) tolerance so that the concerned nutraceutical enhanced genotype or variety is accepted by the farming community.

5 Importance in Alleviating Chronic Diseases and Malnutrition

Chickpea have been classified as "functional food" that has numerous health benefits like reducing blood glucose, promotes bone health, assist in blood pressure management, promotes cardiac health, helps in reducing cholesterol, promotes mental health, promotes digestive health, and promotes weight management. Chickpea also serves as a cheap source of vitamins, mineral, and numerous bioactive compounds (carotenoids, isoflavones, enzyme inhibitors, etc.) that are essential for healthy living. Chickpeas seeds are rich source of calcium, phosphorus, and iron that

promote bone health and prevents osteoporosis. Chickpea contains choline and selenium two essential nutrients that promote brain and nervous system health.

Chickpea diet has been reported to combat several chronic diseases including type II diabetes, cardiovascular diseases (CVD), and cancers. Chickpea have low glycemic index (GI) and rich in dietary fiber, PUFA, and bioactive compounds (Isoflavones, saponins, and β-Carotene) that lower the risk of CVD and maintains cardiac health. Furthermore, consuming chickpea helps in management of type II diabetes. Its seeds are rich in complex sugar (starch and amylose) that are slowly digested in the small intestine, ensuing low bioavailability of glucose and lowering the demand for insulin. Consumption of complex sugar diet has been proven to enhance glucose tolerance and insulin sensitivity in humans.

Research has indicated that consuming chickpea promote butyrate production. Butyrate belongs to a group of short-chain fatty acids (SCFAs) that has been reported to inhibit cell division and induces apoptosis, thereby preventing development of colorectal cancer. Furthermore, butyrate initiates an irreversible pathway of maturation causing cell death. Lycopene, a bright red colored oxygenated carotenoid is found in chickpea (Jukanti et al. 2012), inhibits development of prostate cancer, lung, and other forms of cancer.

6 Gene Pools

Gene pools of chickpea have been proposed by various authors based on crossability between different species. On the basis of the results derived in wide hybridization, different authors had proposed the gene pool structure of chickpea which are broadly similar. Gene pool structure classifies the annual *Cicer* species and forms the basis on which further wide hybridization breeding program is decided. Harlan and Wet (1971) first proposed the gene pool classes of chickpea which has been validated and contrasted by various authors. Smartt (1984) reviewed the gene pools of legumes and referring to the studies of Ladizinsky and Adler (1976) proposed division of the primary gene pool into GP 1a. and GP 1b., housing *C. arietinum* and *C. reticulatum* respectively. Secondary gene pool (GP 2) was proposed to be comprising of *C. echinospermum*. The tertiary gene pool (GP3) was proposed to be comprising of *C. bijugum, C. pinnatifidum, C. judaicum, C cuneatum, C. yamashitae,* and other annual and perennial species. The gene pool structure proposed by Harlan and Wet (1971) has been validated by Van der Maesen et al. (2007). Here, *C. echinospermum* was placed in primary gene pool. Six annual species have been grouped within the crossable limit. The gene pool structure comprises of *C. arietinum* in the primary gene pool (GP 1a.); *Cicer reticulatum* and *C echinospermum* in GP 1b.; *C. bijugum, C. pinnatifidum,* and *C. judaicum* in GP 2; whereas rest *Cicer* species belong to GP 3. Gene pool structure concluded in the report of by Van der Maesen et al. (2007) is as follows: GP1a: *Cicer arietinum;* GP1b: *Cicer reticulatum* and *C. echinospermum;* GP2: *C. bijugum, C. pinnatifidum, C. judaicum;* GP3: other *Cicer* Species (annual and perennial). An equivalent system was proposed by Redden and Berger (2007), who included *C. arietinum* and *C. reticulatum* in the primary gene pool, *C. echinospermum* in the secondary gene

pool, whereas rest of the annual and perennial species in the tertiary gene pool. Mallikarjuna et al. (2011) modified the above gene pool structure placing *C. arietinum* in primary gene pool (GP 1); *C. reticulatum* and *C. echinospermum* in secondary gene pool (GP 2) and all the rest annual and perennial species in tertiary gene pool (GP 3). Gene pools of *Cicer* proposed by Mallikarjuna et al. (2011) are as following: Primary gene pool: *C arietinum* (Land races and cultivars); Secondary gene pool: *C. reticulatum, C. echinospermum*; Tertiary gene pool: *C. bijugum, C. judaicum, C. pinnatifidum, C. chorassanicum, C. yamashitae, C. cuneatum, C. atlanticum, C. incisum, C. incisum* ssp. serpentinica, C. *floribundum, C. floribundum* var. amanicola*, C. graecum, C. heterophyllum, C. heterophyllum* var. kassianum, *C. uludereensis, C. isauricum, C. montbretii, C. acanthophyllum, C. anatolicum, C. balcaricum, C. baldshuanicum, C. fedtschenkoi, C. flexuosum, C. grande, C. incanum, C. korshinskyi, C. laetum, C. luteum, C. macracanthum, C. microphyllum, C. multijugum, C. nuristanicum, C. paucijugum, C. pungens, C. rassuloviae, C. rechingeri, C. songaricum, C. stapfianum, C. subaphyllum, C. tragacanthoides, C. kermanense, C. mogoltavicum, C. oxyodon, C. spiroceras, C. canariense.*

Out of all the gene pool structures proposed in chickpea, it can be concluded that three annual species, namely, *C. arietinum, C. reticulatum,* and *C. echinospermum* are readily crossable and trait transfer can be attempted through conventional hybridization. In case of wide hybridization involving any other annual or perennial species, interventions like hormonal treatment of the peduncle to prevent abscission, embryo rescue, etc., are essential. Strategic locations often help wide hybridization activities, particularly locations with prolonged congenial temperature window (<25 °C) with normal relative humidity and less wind. It has been observed in the Wide Hybridization Garden Facility at the ICAR-Indian Institute of Pulses Research, Kanpur, that congenial conditions prevailing after pollination enhances the chances for fertilization and further development. Zygotic embryogenesis through embryo culture is a cornerstone of wide hybridization activities. Pod and seed setting in wide hybridization have been long standing issue. Besides, development of the chlorotic mutants like green, partially green, albino, etc., plants from the rescued embryo limits the embryo rescue technique to considerable extent in chickpea. Limited literature and reports are available in embryo rescue in this crop.

7 Diversity Analysis

Jukanti et al. (2012) reviewed the nutritional profile of 100 grams of raw chickpea seeds which approximately provide about 5.0 mg of iron, 4.1 mg of zinc, 138 mg of magnesium, and 160 mg of calcium. Grain protein content of chickpea has been reported to range from 17–22% (Jukanti et al. 2012). Genetic variation for total protein content in grains do exist in the germplasm of chickpea, the maxima being reported >28% in indigenous accessions like T39-1 and T1-A (Singh 1983). Till date, there are limited reports of genetic enhancement of seed protein content in chickpea through conventional breeding or marker assisted interventions. Among

food legumes, protein content has been characterized and genetically enhanced to some extent in soybean, groundnut, pea, etc., (reviewed by Burstin et al. 2011). The amino acid composition of chickpea protein is balanced and is rich in lysine, however concentration of tryptophan and sulphur containing amino acids (methionine, cysteine) is low. The average content of lysine, methionine, and tryptophan in chickpea seed is 7.2 mg, 1.1 mg, and 0.9 mg per gram of protein, respectively. Kaur et al. (2014) reported seed protein content among 30 Indian chickpea cultivars ranged from 16.9% to 29.0% with a mean of 22.6%. Singh (1983), gave a detail account of the work done in ICRISAT and partner institutes between 1976 and 1982 on protein content in chickpea. Protein content of chickpea germplasm panel of 150 lines was estimated following the Kjeldahl method, Technicon auto analyzer method, Dye binding capacity method, and Biuret method over the years and across several locations in India. A comparative study of different methods of protein estimation in chickpea showed equivalent expression across the protocols. Influence of environment on seed protein content was also studied. The lines were found to be stable in protein content over the years. Location had pronounced effect on the protein content of the seeds. Chickpea lines T-1-A, P-3318, and T-39-1 were found to be highest protein containing lines, with a range of 29–32%. The panel had a range of 15–32% in total seed protein content.

Serrano et al. (2017) screened a representative panel of the European chickpea germplasm collection comprising of 79 accessions and observed protein ranging from 14.6% to 23.2%, fibre 3.43–11.11%, fat 3.92–6.98%, and ash ranging from 2.99% to 5.18% respectively. Concentration of resistant starch was comparatively less in the panel (0.13–4.56%). Vitamin E (tochopherol) profile was developed for the germplasm accessions in which α-Tocopherol ranged from 13.42–216.75 mg/g fat, β-Tocopherol was not detected, γ-Tocopherol ranged from 300.86–1078.76 mg/g fat, and δ-Tocopherol ranged from 16.86–57.35 mg/g fat. The concentration of lutein was of a wide range 2.13–28.32 mg g–1 flour. Pigment components like Zeaxanthin also varied significantly, i.e., from 0.13–8.62 mg/g flour and β-Cryptoxanthin was not detected at all. Several accessions were identified with higher concentrations of α-Tocopherol (>200 mg/g). Genotype LEGCA728, with green seed coat and cotyledons, was identified with high lutein concentration (28.32 mg/g). European chickpea accessions were observed to be nutritionally promising and had variability regarding different quality and nutrition parameters, which is the prerequisite of a breeding program. Özer et al. (2010) screened Turkish Kabuli landraces for nutritional quality parameters. Variability pattern observed in the landraces of the place of center of origin of the crop gives an idea of the breeding potential of the traits for which diverse alleles are available. Significant variability was observed for nutrition quality traits like protein (17.55–23.31%), fat (4.45–6.11%), ash (2.54–3.41%), fiber (2.03–4.18%), starch (41.76–49.07%), and 100-seed weight (25.03–51.67 g). Grain quality traits, namely, hydration capacity (0.2585–0.6169 g/ml), swelling index (0.7207–1.1859), swelling capacity (0.15–0.32 ml/seed), cooking time (33–72 min) and seed density (0.8450–1.4800 g/ml) also exhibited considerable variation. Significant correlation was observed between the seed quality and cooking parameters, which has potential for indirect selection for enhancement of cooking quality.

Tripathi et al. (2012) studied the diversity and interrelationships of phenological, physicochemical, and cooking quality parameters in 86 chickpea (*Cicer arietinum* L.) genotypes, including 44 Kabuli and 42 Desi genotypes (varieties and advanced breeding lines). Considerable variation was observed for the grain quality traits, namely, hydration capacity (0.11–0.68 g water/seed), hydration index (0.80–1.21), swelling capacity (0.11–0.7 ml/seed), seed volume (0.1–0.52 ml/seed), and cooking time (38–125 min). Except for hydration index, swelling index and cooking time, Desi and Kabuli types differed significantly in all phonological and quality parameters. Traits like 100-seed weight, hydration capacity, swelling capacity, and seed volume were recorded with high heritability and genetic advance, thereby can be taken as selection parameters. Test weight and seed volume traits were positively correlated with hydration capacity and swelling capacity. This study contrasted the study of Özer et al. (2010) in terms of cooking time trait, for which no correlations were observed, indicating some other factor/loci controlling this trait. This observation may be attributed to the genotype composition of the panel, where on one side Turkish landraces (kabuli type) were studied by Özer et al. (2010) and on the other hand a composite panel of genetically enhanced Desi and Kabuli genotypes were studied. This observation also indicates that cooking properties of Desi and Kabuli grains are different, this may be due to the higher fiber content in the grains of Kabuli genotypes which leads to higher water imbibition, a basic determiner trait for cooking time.

Bhagyawant et al. (2015) carried out biochemical characterization of chickpea accessions for total protein, proline, and antioxidant activity. Significant variation in biochemical composition of chickpea was noted for total protein (100–266 mg/g.), proline (12.2–19.4 mg/100 g), and antioxidant activity. Concentration of Zn and Fe ranged from 0.37 to 0.91 mg/g in the panel. *Cicer reticulatum* accession ILWC-257 was identified with highest Zn (0.66 mg/g) and Fe (2.76 mg/g) and may be used as a potential donor to improve the Fe and Zn content.

8 Mapping of Health-Related Genes

Nutritional quality traits like protein, beta carotene, Fe, and Zn content in seeds of chickpea has been addressed through molecular marker interventions. Molecular marker interventions include association mapping, quantitative trait locus (QTL) mapping, and development of trait specific markers. Abbo et al. (2005) mapped quantitative trait loci (QTLs) for beta carotene and lutein in an interspecific cross with *Cicer reticulatum* accession Cr205 originating from Turkey as donor (0.48 μg/gm). In the inter specific (*Cicer arietinum*/ *Cicer reticulatum*) F_2 population, Abbo et al. (2005) mapped 4 QTLs for beta carotene and single QTL for lutein. The most significant QTL of LOD (Logarithm of odds) >3 was located in an unlinked locus with marker TS 19. Two of three other QTLs reported for beta carotene were located on linkage groups 3B and 1B (B denotes associated linkage group along with the main linkage group 3 and 1). The last QTL for beta carotene was also mapped in an unlinked locus. SSR markers like TA 64, STMS 28, GA11, TA122, and TR 26 were observed to be linked with the beta carotene QTLS and can be utilized for future

marker assisted interventions. Single QTL for lutein concentration was reported on linkage group 8 with LOD 2.4.

Jadhav et al. (2015) carried out association mapping for seed protein content in a varying germplasm panel of 187 chickpea genotypes (comprising of both *Desi* and *Kabuli* types). Nine significant marker-trait associations (MTA) representing four QTLs were identified by the authors considering the entire population. Sub-population analyses identified ten significant MTAs representing five QTLs, however, four of those QTLs were common with the previously identified QTLs in the entire population. Two most significant QTLs were present on LG3 and LG5 and linked with markers TR26 (205 cM) and CaM1068 (195 cM). Twenty-nine candidate genes were identified (gene ontology search) in the region of significant MTAs on LG3. LG3 and LG5 were suggested as possible targets for identification of closely linked markers for protein content in chickpea and for their use in marker assisted genetic enhancement for nutritional quality.

Upadhyaya et al. (2016) carried out genome wide association mapping (GWAS) for Fe and Zn concentration in a diverse panel of 92 chickpea accessions comprising of the Desi and Kabuli genotypes. QTLs for Fe and Zn content in developing seeds were identified in an interspecific mapping population developed from the cross ICC 4958/ICC 8261 (F_7 RIL population with 277 individuals). Eight major genomic regions (for two seasons) governing Fe and Zn concentrations in seed explaining 39.4% combined phenotypic variation on six chromosomes through SNP-based high-resolution QTL mapping in the F_7 RIL population ICC 4958/ICC 826. One QTL was identified each on chromosome 1, 2, , and 7 respectively. Two QTLs were identified on chromosome 3 and 4 respectively. LoD of those QTLs ranged from 6–8.8, identified QTLs explained 16–23% phenotypic variation and the additive component ranged from 4.1 to 8.7. Sixteen genomic loci/genes associated (29% combined phenotypic variance) with seed-Fe and Zn concentrations were identified through GWAS. One genomic region was identified in chromosome 2; two on chromosome 1 and 7; three on chromosome 4 and 5; five genomic regions on chromosome 3. Eleven trait-associated SNPs linked tightly with eight QTLs were validated by QTL mapping and differential expression profiling as well. Rapid integrated genomic strategy led to delineation of novel functional nonsynonymous and regulatory SNP allelic-variants from 16 known/candidate genes. Those included three strong trait-associated genes (encoding late embryogenesis abundant and yellow stripe-like 1 protein and vacuolar protein sorting-associated protein) and eight major QTLs regulating seed-Fe and Zn concentrations.

Ozkuru et al. (2019) reported association mapping for seed Copper, Phosphorus, and Potassium concentrations in a population consisting of 107 *Cicer reticulatum* and 73 *Cicer arietinum* accessions raised at two locations for two seasons. Through genome-based selection, 121,840 SNPs were genotyped across the 180 genotypes. The authors identified eight SNPs which were significantly associated with variations in three nutrient elements (Cu, P and K) in more than two environments.

Wang et al. (2019) mapped QTLs for seed protein content in chickpea in a recombinant inbred line (RILs) population developed from the cross ICC 995 (medium protein)/ICC 5912 (high protein donor). On the basis of multi

environment analysis, one QTL was mapped in each of LG 1 and 6; whereas 2 QTLs were mapped on LG 3, respectively. Significant effect was observed in a QTL identified on LG 3 which explained 52.5% of the phenotypic variances for 100 seed weight, 44.3% for protein content in seeds, and 14.6% for seed shape. Flower color (95.2% phenotypic variance explained) was also observed to be associated with this locus. Alleles of this QTL on LG 3 might be inherited from the high protein donor parent ICC 5912 with blue flower in the RILS which conferred the blue flower color and produced small, round seeds with relatively high protein concentration. The QTL was also observed to be linked with starch accumulation; however, it explained the phenotypic variation for starch content to a lower extent (4%). Protein and starch accumulation being antagonistic to each other, identification of a QTL associated to both protein and starch accumulation is quite intriguing. The study concluded that the genes affecting seed filling at QTL in LG 1 and seed coat development at QTL mapped in LG 3 were responsible for the differences in seed composition and morphology observed in the RIL population.

Fayaz et al. (2022) carried out a GWAS (Genome Wide Association Study) in a diverse core set of 147 chickpea genotypes. The accessions were phenotyped for content of four micro nutrients, namely, Cu, Fe, Mn, and Zn in seeds for two consecutive seasons. The panel was genotyped with 50 K Cicer SNP array. Significant variation was observed for all the parameters in the association panel. During the first season, Zn concentration in seeds ranged 14.56 204.39 ppm (mean 45.31 ppm), Cu concentration ranged 4.23 185.47 ppm (mean 60.99 ppm), Fe concentration ranged from 79.36 to 198.26 ppm (mean 143.24 ppm), and Mn content ranged 9.07 54.29 ppm (mean 25.62 ppm). In the consecutive season, Zn concentration ranged 9.36 205.86 ppm (mean 46.58 ppm), Cu concentration 3.66 190.36 ppm (mean 66.81 ppm), Fe content ranged 100.36 127.36 ppm (mean 132.29 ppm), and Mn content ranged 4.86–122.86 ppm (mean 28.68 ppm) in seeds. However, the authors reported significant differences for all the four micronutrient concentrations ($P \leq 0.05$) across both seasons which posed a challenge in future breeding programs regarding stable donor for respective traits. The mean concentrations of Fe, Zn, Cu, and Mn pooled over two-year data were 146.1 ppm, 45.9 ppm, 63.8 ppm, and 27.0 ppm respectively in seeds. Thirty-five SNPs were identified that are significantly associated with seed Zn, Cu, Fe, and Mn concentration. Five stable MTAs (consistently identified in consecutive seasons) were identified. Six major MTAs identified which explained more than 15% phenotypic variation of respective trait and three MTAs, both major and stable in nature were reported.

9 Breeding Strategies and Genetics

Smartt et al. (1975) outlined the thrust areas for a breeding program targeting for enhancement of seed protein content. The three thrust areas included improvement of the overall protein content, improvement of the amino acid profile of the seed storage proteins, and improvement of the digestibility. Attempts to mobilize the genes for high protein content from the improved landrace background of T39-1

(ICC 5912) or T1-A to the high yielding backgrounds of chickpea by hybridization and consequent handling of the segregating generations are currently in progress. Smartt et al. (1975) also outlined the selection approaches for enhancing protein parameters, those were, selection for a specific desirable amino acid profile, selection for total protein content, and negative selection against any particular amino acid profile. Selection for quality parameters needs handling of large populations and developing the SDS-PAGE profiles of seed tissue of breeding lines of a large population is a cumbersome process. Vijayalakshmi et al. (2001) carried out primary work to study the inheritance pattern of the seed protein content trait in chickpea. T39-1, a high protein containing line was crossed with moderate and low protein parental lines P9623 and RS11. Low protein content was been reported to be dominant over high protein content trait. Oligogenic inheritance was observed in F_2 and transgressive segregant were also observed in advanced generations.

The genotype × environment interaction studies with protein content in chickpea are interesting and provide various ways to conceptualize the approaches for genetic enhancement of the trait. Singh et al. (1993) studied the genotype × environment interaction of the trait protein content in chickpea seeds in five set of trials evaluated in three locations for two winter seasons of the Mediterranean region. Effects of genotype × location and genotype × season were observed to be small on the seed protein content indicating genetic component for the trait. The genotypes were observed to be stable across the environment and season for protein content (season to season variation was 0.1–1%) and had negligible effect of sowing date in the Mediterranean region.

In another report, the performance of chickpea genotypes for protein content at eleven locations across India for two seasons was studied Singh et al. (1983). Pronounced effect of location was observed for variance of protein content, whereas effect due to genotypes on the variance was low. Insignificant effect of cultivars × location on variance of protein content was observed suggesting breeding potential of the seed protein content trait in chickpea. The study suggested breeding material adapted to the location for genetic enhancement for protein content in chickpea. Frimpong et al. (2009) reported significant genotype × environment interaction effects on starch, amylose, and protein concentrations in chickpea. The correlations identified in this study were interesting, in both *Desi* and *Kabuli* genotypes, starch concentration was negatively correlated with the protein content in the seed (r Kabuli $= -0.25$, $P < 0.05$; r Desi $= -0.16$, $P < 0.05$). Though not universal, but this finding gives a direction to understand the protein accumulation physiology in chickpea. The authors reported negative correlation of yield and protein content. The chickpea landrace with high protein T39-1 (ICC 5912) which was identified by Singh (1983) had considerable heat susceptibility. It is evident from those findings that linkage drag may exist while selecting for protein content in chickpea. Such donors need to be crossed with diverse recipient parents (check varieties, high in yield and biotic/ abiotic stress resistance/tolerance), and large F_2 populations need to be grown to address the linkage drags and identify the desirable recombinants.

Wang et al. (2017) reported genotype × environment interaction for different grain quality parameters like seed weight, total starch, amylose, and crude protein in

237 chickpea genotypes (180 *Desi*, 49 *Kabuli,* and 8 *pea* shaped) for two seasons grown under field conditions and greenhouse. Kabuli genotypes showed higher total starch (34.1–63.2%) and crude protein (15.7–28.0%) concentrations; whereas, amylose concentration (27.1–41.6% of total starch) was higher in *Desi* genotypes. Intriguing inter trait associations were observed in this diverse panel, on which correlated selection strategies can be worked out. Significant negative association of seed weight with amylose and crude protein was observed. Seed weight was positively associated with total starch. Amylose content was significantly negatively correlated to starch. Crude protein was positively correlated to amylose content and negatively correlated with starch content. Broad sense heritability (H^2) was observed for seed weight (0.70), whereas low to moderate H^2 was observed for starch (0.12–0.51), crude protein (0.15–0.37), and amylose (0.10–0.14) content. This finding is very important and a major factor for working out selection indices for genetic enhancement of protein content. Based on accumulation of amylose (early podding-seed setting stage) and its conversion to starch (late podding – grain filling stage) phenological traits may be targeted for association and indirect selection for high seed protein content. However, this finding needs to be tested in different germplasm panels and to be tested in diverse locations for their universality because such findings are often result off type genotypes.

Wang et al. (2017) validated the findings of Frimpong et al. (2009) and recommended chickpea genotypes with high crude protein and amylose content can be utilized in breeding programs. Cobos et al. (2016) studied genotype × environment interaction in chickpea genotypes grown in winter and spring sowings in four different locations in the Mediterranean region and reported high oil, acid detergent fiber (ADF) but low protein with respect to the spring harvest. The authors reported pronounced genotype effect on oil, acid detergent fiber (ADF), and protein content. Environmental effect was more in amylose and amylopectin concentration. Cobos et al. (2016) advocated for indirect selection for the grain nutritional parameters and suggested selection of lines on the basis of sensory/ nutritional/ grain quality traits in advanced generations only. No approach to handle the segregating populations in early generation has been reported in the limited literature surveyed, which authors consider a major research gap. No multitrait selection model was identified in the literature for genetic enhancement of nutritional and quality parameters in pulse crops where segregation in seed traits up to late generation poses a problem for varietal release.

Gaur et al. (2016) reported multiple gene control of protein content and its association with other traits. Contrasting cross was developed utilizing high protein donor ICC 5912 (29.2% protein) which had small seed, grey seed coat, and blue flower with a *Kabuli* line ICC 17109 (20.5% protein) having contrasting traits. Seed protein content and other contrasting traits were controlled by multiple genes and had normal F_2 distribution. Flower color and testa color traits showed recessive epistasis (9:3:4) in F_2. Pleiotropy was reported for flower color and testa color traits as well. High protein trait was associated with blue flower trait in the segregating lines of F_2 population. Authors reported negative correlation with seed size and yield. This may be attributed to the heat susceptibility of ICC 5912. Notably, ICC

8397 (T1-A, landrace), ICC 5912 (T39-1, landrace) have been confirmed for high protein content in seeds (~29%, Kjeldahl's method), and ILWC 237 (wild germplasm accession, *Cicer reticulatum*) has been confirmed for high Fe, Zn concentration. Those donors are being utilized in crossing program for generation of breeding materials.

10 Next-Generation Breeding

Around 3 billion people in world suffer from malnutrition caused due to nutritional deficiencies of iron or zinc. Chickpea being rich in iron (Fe), zinc (Zn), and selenium (Se) can be an alternative diet supplement in order to counter malnutrition. Since last decades several attempts have been made to counter "hidden hunger" (deficiency of mineral nutrients and micro nutrients) and biofortified chickpea varieties have been developed expressing higher levels of these minerals (Vandemark et al. 2018). Developing biofortified cultivars that stably over-express selected minerals requires genetic information, environmental interaction, and its effect on mineral concentrations (Ray et al. 2014). Biofortification of chickpea employing next-generation breeding to enhance nutritional value is vital for combating these issues associated with global hunger and malnutrition. The introduction of new breeding technologies is expected to contribute significant improvements in crop production. Although, conventional breeding methods have developed more than 200 improved varieties of chickpeas, there is still scope for better productivity. Conventional breeding is time consuming and laborious process that requires substantial amount of space for crossing of desirable crops. The long duration of cropping season and seed to seed cycle are the major limitation in the conventional breeding method. Integrated uses of modern genomic resources and speed breeding methods can produce the desired varieties efficiently. With the advancement of modern genomic tools and analysis of high-resolution phenotypic and genetic data has assisted in trait associated gene identification. Genomic tools have been developed for marker identification employed in marker-assisted back-crossing for the production of improved chickpea varieties.

QTLs associated with carotenoid components (violaxanthin, lutein, zeaxanthin, β-cryptoxanthin, and β-carotene) in chickpea was derived from crosses between cultivars with green and yellow cotyledon colors using high-performance liquid chromatography (HPLC). The result indicated a total of 1068 bin markers that were derived from the 50 K Axiom CicerSNP array (mapped onto eight linkage groups (LGs)). A total of eight QTLs in the "CDC Jade" × "CDC Frontier" population, including two each for β-carotene and zeaxanthin and single QTLs for total carotenoids, β-carotene, violaxanthin, and β-cryptoxanthin were identified. Similarly, 694 bin markers were mapped onto eight LGs and one partial LG in the "CDC Cory" × "CDC Jade" population. Various carotenoids including β-cryptoxanthin, β-carotene, violaxanthin, lutein, and total carotenoids were identified on linkage group 8. In another "ICC4475" × "CDC Jade" derived population indicated presence of 581 bin markers in the third population. Total five QTL one for β-carotene

and four others, one each of β-carotene, lutein, β-cryptoxanthin, and total carotenoids, were identified in this population. Interestingly, highest phenotypic variation was observed in the β-carotene QTLs, ranging from 58% to 70% in all the three crossed populations.

The total isoflavone content (TIC) in chickpea is reported to vary 153 to 340 mg/100 g of chickpea (Singh et al. 2017). Formononetin and biochanin A are the major isoflavones present in chickpea while biochanin A-7-O-β-D-glucoside, genistein, calycosin, trifolirhizin, sissotrin, and ononin are present in smaller proportion (Kashiwagi et al. 2015). Isoflavones promotes uterine growth and prevent bone loss. Furthermore, isoflavones induces estrogen responsive element (ERE)-promoter that promotes estrogenic activity in cells.

Chickpea has numerous nutritional and health benefits along with some associated processing issues, like the presence of antinutrients, prolonged cooking time, and poor digestibility. These antinutritional elements include tannin, phytic acid, trypsin inhibitor, chymotrypsin inhibitors, and alpha amylase inhibitors that inhibit the nutritional availability. Bioavailability of the nutrient present in chickpea is the function of the interaction between antinutrients and nutrients. These antinutritional factors usually form complexes with the nutritional elements and inhibit their absorption. Among the various antinutritional factors found in chickpea, tannins and phytate are the most prevalent. Tannins are polyphenols that have been reported to interact with proteins and enzymes to form tannin-protein complexes, that severely diminishes nutritional bioavailability. Phytate is an inositol hexa-phosphate that interacts with minerals resulting in their reduced absorption. Minerals like, zinc, calcium, magnesium, and iron found in chickpea are present in traces, and the phytic acid found in chickpea interact with these minerals and inhibits their absorption. Similarly, trypsin and chymotrypsin inhibitors interact with hydrolytic enzymes and obstruct their activity. The alpha-amylase inhibitors impede the activity of amylase enzyme and obstruct digestion and absorption of starch. Hence, it is essential to reduce the antinutritional factors for biofortification of chickpeas. Major biofortification efforts are significantly focused on micronutrients, however these techniques can be applied to other nutritional traits Roorkiwal et al. (2021). Similarly, Chickpea is rich in linoleic acid (LA; ω-6), compared to the α-linolenic acid (ALA; ω-3), the other essential fatty acid. Thus, breeding efforts to enrich these essential fatty acids is important aspect; however, these traits are governed by multiple genes families making the process complicated.

11 Biotechnological Interventions

Genetic engineering (GE) approach for biofortification with Iron (Fe) in chickpea employing combination of the chickpea nicotianamine synthase 2 (*CaNAS2*) and soybean ferritin (*GmFER*) genes was reported (Tan et al. 2018). The *CaNAS2* gene is responsible for Fe transportation while the soybean derived gene *FER* help in storage of iron. The experiment was conducted using three commercial Kabuli cultivars (Genesis090™, Kalkee™, and PBA Monarch) and three commercial Desi cultivars

(PBA Boundary, CICA0912, and PBA HatTrick). Similar Fe levels were reported among all the tested cultivars and lower Fe levels were obtained where soil Fe bioavailability was low. Analysis of transformants indicated doubled levels of nicotianamine (NA) compared to the control while the Fe levels remained unchanged. Higher NA level is linked with high Fe bioavailability that can play an active role in overcoming the issues associated with the bioavailability of Fe in the presence of inhibitors found in chickpea; however, further study was required for confirmation. In another report, transgenic chickpea expressing CaWRKY31: CaCKKX6 were found to have increased root mass, resulting in increased nutrient content in seeds of the transgenic lines: Zn (27–62%), Cu (26–61%), and Fe (22–48%) (Khandal et al. 2020).

Genome editing by targeting gene for cytokinin dehydrogenase was also suggested for biofortification (Mahto et al. 2022), owing to its linkage with stress regulation (Cortleven et al. 2019) and plant mineral concentration (Gao et al. 2019).

12 Conclusion

Chickpeas are very important for nutritional security, and its characterization and enrichment are immediate priority. However, accomplishments in quality breeding in chickpea are limited and yet to head to a product delivery phase. Nutritional profiles based on data generated for protein, fats/oils, carbohydrate, fibers, folate, beta carotene, and different elements in different chickpea genotypes are available in the literature. Majority of such reports have taken very limited number of genotypes and has worked on the quality of the protein (amino acid profile). The methods adopted in those reports are the conventional biochemical protocols. Few studies on diversity available in the germplasm for quality parameters like protein, iron, and zinc content are available in pulse crops which will be the foundation for future plant breeding. Research status of the protein aspect in chickpea is largely confined to the amino acid profiling or protein fraction characterization in the germplasms. Nutrition quality breeding is a team work of breeders, biochemists, physiologists, engineers, and food technologists to scale up the present research to product delivery.

Abstract

Being nutritionally dense legume crop, pea holds great promise toward nutritional security of resource poor folks. Among the legume crops, pea is well recognized to be rich in easily digestible protein coupled with an admirable amount of macro- and micronutrients. It offers a wide range of health advantages due to excellent quality of starch, dietary fiber and reasonable source of flavonoids and phenolic compounds. In this chapter, authors deliberated about the nutritional configuration of peas and its nutraceutical enhancement accomplished through various agronomic and genetic biofortification strategies. In addition the chapter also elaborated about the arsenal of genetic resources; trait specific genotypes for nutritional traits and their genetics mechanism; status of markers and molecular mapping of health-related (HR) genes and QTLs; map-based cloning of HR genes/QTLs; omics approaches in relation to HR genes: genomics-aided breeding for HR traits; genome editing; gene stacking; TILLING; future strategies for modulating HR genes in pea: current status and future possibilities for genetic engineering application for HR traits and role of bioinformatics. Overall very limited efforts so far have been made toward the exploitation of existing variability for nutritional traits. Hence, there is an urgent need of large-scale high-throughput phenotyping to unveil the existing genetic variability and their subsequent utilization in regular breeding program to develop nutrient-enriched pea. However, in the case of pea, genomic resources have not been well developed and exploited for nutritional traits, therefore, recent omics-based approaches need to be embraced to facilitate the identification of genes/QTLs to develop the robust markers' platform to accelerate marker-assisted breeding program. Fortunately, the recently accomplished pea reference genome assembly offered several contigs, transcripts, markers, and GBS platforms for their further annotation. The transcriptomics, proteomics, and metabolomics analysis have not been used considerably for nutrition-related genes. However, few valuable transcripts' atlas has been generated recently that would further boost reverse genetic studies, fine mapping, allele mining, and identification of candidate genes. To further accelerate nutraceutical improvement in pea induced mutagenesis; genome

editing; gene silencing, bioinformatics, and transgenic approaches need to be adopted in regular breeding programs. The advent of affordable genomic tools and their access will speed up the creation of novel pea cultivars with refined HR genes for the benefit of resource poor mankind.

1 Introduction

Pea (*Pisum sativum* L.) is a nutritionally dense annual herbaceous post rainy season legume crop grown around the world for food, fodder, and feed (Parihar et al. 2020, 2022c; Lamichaney et al. 2021a, b). Fresh green seeds and pods are consumed as vegetables whereas mature dry seeds are used in diverse forms, i.e., whole, split, and flour (Parihar et al. 2023). Moreover, it is considered an integral part of plenty of cuisine and confectioneries, for example, *chat, soup, dal, chhola,* vegetables, *snacks, stew,* and flour (Parihar et al. 2014a, b). Being an admirable source of protein, starch and fibre, it is extensively used as an important constituent in several food products-based industries (Dixit et al. 2014; Gupta and Parihar 2015). Pea seeds are nutritionally enriched and have 15–35% protein along with essential amino acids like lysine and tryptophan. Being a legume crop it is an important component of crop rotation as it disturbs the disease and pest life cycle, offers nitrogen, proliferate the level and performance of soil microorganism, enhances soil aggregation and improves soil water holding capacity. Pea is the fourth most important legume crop at global level occupying around 9.80 Mha areas with a production of about 34 Mt. The recent trend of area and production worldwide is illustrated in Fig. 1.

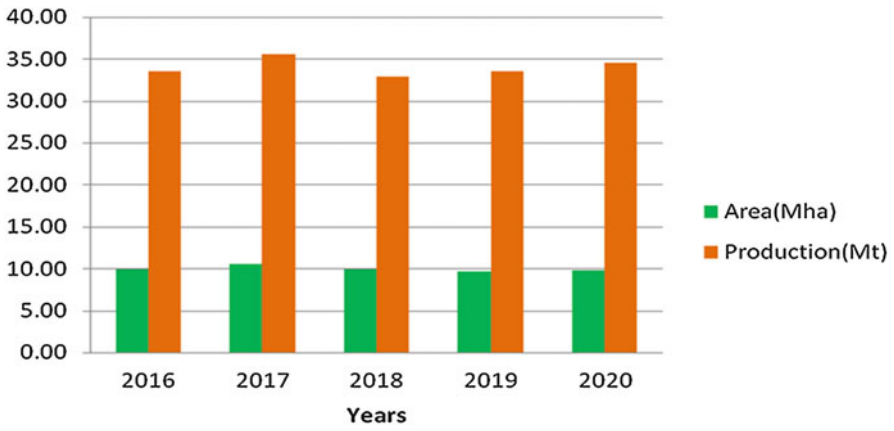

Fig. 1 Recent trends of area and production of peas at global level

In general, food legumes are enriched with various nutrients and deliver a greater amount of essential nutrients relative to cereals and tuber crops (Harmankaya et al. 2010; Blair et al. 2011). Among the legume crops, pea seeds have been well recognized to be rich in easily digestible protein coupled with an admirable amount of macro and micronutrients. Approximately 21–32% of dry seeds are composed of proteins that predominantly contained storage proteins, i.e., globulin and albumin (Tzitzikas et al. 2006). Besides protein, it is a decent source of essential amino acids like methionine, arginine, and valine. It is an excellent source of carbohydrates which ranges from 56% to 74% and is rich in amylase content which leads to slow digestion of starch. The seed coat and cotyledon are rich in dietary fibre, i.e., water unsolvable and solvable fibre (Tosh and Yada 2010). The most dominating macronutrient in pea is potassium followed by phosphorus, magnesium, and calcium. It has also been acknowledged as an excellent source of other micro-nutrients for instance iron, zinc, selenium, and molybdenum. Furthermore, it has an appreciable amount of vitamin B9 (folate), vitamin C (Ascorbic acid), vitamin B1 (thiamin), B6 (pyridoxine), B3 (Niacin), and B2 (riboflavin). Corresponding to other legumes, it is also containing several phytochemicals such as carotenoids, chlorophyll, flavonoids, saponins, and oxalates (Parihar et al. 2016).

Malnutrition has become a severe problem owing to the insufficient supply of nutritionally balanced diet to the resource-poor folks of developing countries. Nutritionally, the pea is a precious food, which can cater the nutritious dietary requirements of about 80–90 crores of malnourished folks globally. In the case of developing countries, approximately 2 billion people are facing malnourishment, whereas above 3 billion folks are deprived of essential micronutrients worldwide. Micronutrient scarcity causes numerous health-related issues, viz., anemia, intellectual debilities, poor immunity, respiratory diseases, and recedes work efficiency. In general, rural habitats of developing nations are mainly having shortages of iron, zinc, selenium and iodine, and globally around 60, 33, and 15% of inhabitants are malnourished for Fe, Zn, and Se, respectively (Hotz and Brown 2004). Besides, vitamin A, Zn, Fe, and/or I deficiencies all together cause approximately 20% mortality in kids of less than 5 years. Deficiency for these micronutrients mostly exists in the folks who are dependent on plant-based diets to cater to their nutritional needs in which bioavailability of iron is less as compared to nonvegetarian diets. Fortunately, the pea is enriched with iron and zinc and therefore, could tackle the prevailing deficiencies for these micronutrients (Demirbas 2018).

This crop offers a wide range of health advantages owing to its excellent quality of starch and dietary fibre which makes it a low glycemic index (GI) food and plays a crucial role in type 2 diabetes inhibition and administration. Besides, consumption of intact peas, flour, and its byproduct checks the arbitrary mounting of blood sugar level. The solvable dietary fibre, niacin, and saponin compounds also reduce the threat of cardiovascular disease by plummeting and stabilizing the blood cholesterol levels (Ekvall et al. 2006). Interestingly, flavonoids also play an instrumental role in heart disease management by inhibiting blood platelet aggregation and providing antioxidant shelter to bad cholesterol. Being a reasonable source of flavonoids and phenolic compounds it has cancer combating and antioxidant properties. The insoluble fibers of peas also improve bowel movement which is vital in the avoidance of

constipation and other gastrointestinal diseases including bowel cancer. The raffinose and other galactose-encompassing oligosaccharides may play the role of prebiotic in the intestine which improves the overall gastrointestinal functions (Fernando et al. 2010). The aforesaid attributes collectively designated pea as an important food article, which can fulfill the dietary needs of people of developing and underdeveloped nations.

2 Nutritional Profile of Pea

The nutritional configuration of peas proved it as an admirable source of carbohydrates, proteins, macro and micronutrients, vitamins, and essential amino acids (Parihar et al. 2022a, b). The existing variability for various nutritional elements is presented in Table 1. Cotyledon is the reservoir of nutrients in pea, while embryo and seed coat contributed to less than 10% of the total nutritive value. The carbohydrates are an integral part of pea seeds and are present in sizable amounts accounting for about 56–74% of the dry matter which is made up of oligosaccharides, monosaccharides, polysaccharides, and disaccharides (Dahl et al. 2012). The starch content accounted for 27.6–57.23% of the pea seed dry matter (Tzitzikas et al. 2006). Starch is grouped into three classes, i.e., slowly digestible starch (SDS), rapidly digestible starch (RDS), and resistant starch (RS) considering the digestion ability of glucose and its absorption efficiency into the gastrointestinal territory (Singh et al. 2017). Starch is made up of amylose and amylopectin and their proportion plays an important character in starch digestibility and after-meal glucose response. In general, pea contains 20.7–38.0% amylase which reduces digestion ability with the release of glucose making it a low GI food (Dahl et al. 2012). Pea comprises of extensive quantity of RFOs and other oligosaccharides, of them, stachyose, total a-D-galactosides, verbascose, raffinose, and sucrose content oscillated from

0.7–4.1%, 22.6–63.4 g/kg, 0.0–26.7 g/kg, 4.1–10.3 g/kg, and 11.6–25.4 g/kg, respectively (Tosh and Yada 2010).

Peas are enriched with protein, therefore, used as an essential component in many food product-based businesses. In general protein content in peas varied from 20% to 22%, however, it is reported to vary from 13% to as high as 35% (Irzykowska and Wolko 2004; Tzitzikas et al. 2006). Pea protein has been recognized as a nonallergic foodstuff with excellent nutritional status (Ge et al. 2020). Pea protein is distributed into four distinct classes: globulin, albumin, prolamin, and glutelin, of them, globulin and albumin are the key storage protein that accounts for 55–65% and 18–25%, respectively. Globulin is further differentiated into legumin and vicilin. The other proteins (prolamin and glutelin) are available in very small quantities (3–5%) (Lu et al. 2020). The crude protein of pea comprises of 10–15% of nonprotein nitrogenous stuff and the remaining crude protein (70–80%) is composed of enzymes, hormones, enzyme inhibitors, and nonstorage and storage proteins (He et al. 2020). The pea protein is rich in lysine, leucine, and phenylalanine and poor in sulphur-containing amino acids, i.e., methionine and cysteine (Lu et al. 2020).

Peas are vitamin and mineral-rich legume crops, and their consumption has numerous health paybacks. Amongst the minerals, potassium is the most noticeable mineral with about 1.0% of dry weight, followed by phosphorus (0.39%), magnesium (0.10%), and calcium (0.08%). The occurrence of other minerals such as Fe (97 ppm), Se (42 ppm), Zn (41 ppm), Mo (12 ppm), Mn (11 ppm), Cu (9 ppm), and B (4 ppm) have been reported in pea. The yellow pea seeds possess higher content of Fe, Mg, and Mn, as compared to green peas but are low in K. A substantial amount of variation was reported for Fe, Zn, and Mg which ranged between 46–54, 39–63, and 1350–1427 mg kg^{-1}, respectively. Furthermore, peas have also been considered as an excellent supplement of folate which is higher in green seeded than a yellow seeded pea (Han and Tyler 2003; Jha et al. 2015a). In pea, fat content is low and seeds are an appreciable source of vitamins namely vitamin C, thiamine, pyridoxine, niacin, and riboflavin.

Corresponding to other pulse crops, peas are an excellent source of various phytochemicals namely carotenoids, chlorophyll, β-carotene, and phenolic compounds. The seed coat and cotyledon of colored seeds are enriched with phenolic compounds (Duenas et al. 2004). On a similar note, dark seed coat peas are rich in tannin content, which is having high antioxidant properties. In addition, a subgroup of flavonoids namely Isoflavones also exists in peas in a noticeable amount. The testa and cotyledon of pea seeds are the primary reservoirs of dietary fibre, of them, cellulose (2.4%) predominant in testa while the cotyledon harbored hemicelluloses (1.0%), pectin (1.2–1.7%), and lignin (2.5%) (Tosh and Yada 2010).

3 Nutraceutical Improvement: Cultural and Genetic Biofortification

In addition to the nutritional advantages, the pea is also having certain antinutritional elements like trypsin inhibitors, lectins, oligosaccharides, gallic acid, and other phenolic substances with phytoestrogenic properties. The given compounds could

be either toxic for example lectins, glycosides, alkaloids, indigestible like tannins, saponins, oligosaccharides, or antinutritive like phytates. Such an antinutritional substance diminishes the bioavailability of nutrients in the course of ingestion in the human intestine. The nutritional profiling of staple crops can be uplifted by shrinking the magnitude of antinutritional elements and increasing the concentration of nutritional components by adopting various strategies. The application of orthodox and contemporary breeding procedures to design nutritionally compact varieties is an effective and viable approach to upsurge the bioavailability of minerals. Identification of particular nutritional character(s) is a prerequisite to set objectives to elevate or downsize their level by biofortification. The insufficiencies of Fe, Zn, and Se have been globally noticed particularly among the citizens of underdeveloped nations and approximately 60, 33, and 15% population are experiencing deficiency, respectively (Hotz and Brown 2004). During the last two decades, concentrated efforts were dedicated to conquering the malnutrition problems by employing various tactics such as dietary value addition, food fortification, and biofortification. In biofortification, the nutritive amelioration of the food crops is performed by implication of agronomical techniques and plant breeding/genetics strategies to ensure the supply of adequate essential micronutrients and vitamins in the daily diet of resource-poor populations and vegetarian folks.

3.1 Postharvest Techniques

In the form of dietary supplements beta-carotene has been microencapsulated in pea protein isolate with and without maltodextrin and can be utilized as a worthy component in various food materials, health supplements, and drugs microencapsulation. It can be considered a transitory arrangement to improve the nutritional status of resource-rich people, but it is not sustainable at a large scale. Many food processing/postharvest procedures, viz., dehulling, soaking, germination, autoclaving, fermentation, micronization, and roasting can uplift the lusciousness of pea byproduct along with increment in bioavailability of nutrients by eliminating antinutritional compounds (Ma et al. 2015). Significant changes in physicochemical properties in seeds occur like gelatinization, puffiness of starch, breakdown of protein structure, solubilization of polysaccharides, and softening of structure which transforms the functional properties as well as the deliciousness (Ma et al. 2011). Most interestingly, boiling of frozen peas surges β-carotene level, as cooling and boiling practices break down cell configuration and release the element which was confined with other components in raw peas. Urbano et al. (2006) reported that the sprouting of peas enhanced the bioavailability of Zn and Mg in peas. On the contrary, seed drenching and sprouting for 18 and 48 h decline the level of polyphenols up to 52% and 88%, respectively. Remarkably, seed drenching coupled with the removal of the hull from seed and pressure cooking trickled down the polyphenols by 76% (Bishnoi et al. 1994). Milling and boiling reduce Se content in grains, while improving Zn bioavailability by reducing phytate (Thavarajah et al. 2008). The intake of 100 g of cooked peas biofortified by Se (0.06) and Zn (0.5) is sufficient to meet 50 and 45% of the daily suggested requirement of zinc and

selenium, respectively (Fairweather-Tait et al. 2011). Most recently, different processing methods were employed in pea and a significant increase in the level of protein and starch digestion ability coupled with a decrease in the activity of trypsin inhibitor and level of tannin was observed (Ma et al. 2017). Given reports could be considered as elementary information to explore the opportunities of peas as ingredients, particularly in the agri-food business to boost the competency of peas in terms of augmented nutritional and techno-functional potentials.

3.2 Agronomic Biofortification

In pulse crops very limited efforts have been made toward agronomic bio-fortification. It could be an efficient tactic to intensify the level of Zn and Se in the eatable portions of crops cultivated in Zn and Se deficit fields (Parihar et al. 2021). In agronomic biofortification, seed priming, seed coating, and soil / foliar fertilization are the imperative approaches that can enhance the micronutrient level in the grain without compromising the yield potential. Foliar application of iron and zinc has increased the Fe content in grains under Fe and Zn dearth soils. Interestingly, it has been noticed that blossoming is the appropriate stage for the foliar spray of iron to boost its concentration in grains (Khamparia et al. 2010). Pea has been considered most pertinent to supply Se in the diet due to its selenium accumulation ability in seeds. Foliar spray of 10 g Se per hectare is adequate to upsurge Se levels near to daily recommendation. On a similar note, the foliar application of zinc alone or with soil zinc application enhanced the grain zinc content. The use of zinc sulfate ($ZnSO_4$), zinc oxide (ZnO), ferrous sulphate ($FeSO_4$), and other micronutrient encompassing fertilizers in soil possess excellent promise to escalate crop grain yield and nutrient profile in mature seeds (Shivay et al. 2016). Spraying of Se (0.06) and Zn (0.5) improves the grain nutrient profile in such a way that intake of cooked grains (100 g) could furnish 5%, 35%, and 90% of the daily recommendation of Ca, Mg, and Fe, respectively. Therefore, biofortified peas with iron, zinc, and selenium through the aerial spray of respective nutrients can be the most efficient agro-fortification tactics to combat prevailing malnourishment. To improve the micronutrient level in grains rigorous efforts have to be dedicated to ascertain the potential of a variety of fertifortification tactics. There are several vital components that influence nutrient enrichment of grains including crop, genotype, environment, soil condition, etc., which may also need to be taken into consideration before any agro-fortification recommendation.

3.3 Genetic Biofortification Though Traditional Breeding

Genetic biofortification is offering a more sustainable and economic approach as compared to agronomic biofortification to cater to the requirement of essential micronutrients of developed and developing nations vegetarian folks. Conventional breeding is well acknowledged as the most sustainable and beneficial substitute for

transgenic and agronomic-based strategies to stride against the malnutrition problem across the countries. Unlike cereals, very limited efforts towards biofortification have been made in pulse crops. In the HarvestPlus program ICARDA has released numerous high-yielding varieties of lentil with high iron and zinc suitable for different ecologies. On a similar note, using conventional breeding four cowpea improved cultivars namely PL-1, PL-2, PL-3, and PL-4 have been released with high iron content under the HarvestPlus program. In the case of common beans, to date, 10 varieties with improved Fe and Zn content are developed in Rwanda and Congo in association with the HarvetPlus platform. Unfortunately, in peas very limited efforts are dedicated toward bio-fortification. Nevertheless, it is inherently well-off in Fe, Zn, Mg which oscillated from 46–54, 39–63, and 1350–1427 mg kg^{-1}, respectively. In another report the Fe, Zn, Ca, Mg, and Se levels oscillated between 45.2–48.9, 32.3–35.0, 786–802, 1210–1270, and 0.413–429 mg/kg, respectively, in Canadian conditions. Protein is one of the vital compounds present predominantly in pea seeds in addition to starch and fibers. Some of the investigation findings have illustrated ample variability of protein content in pea that fluctuates between 14% and 38% (Tzitzikas et al. 2006). To quantify protein various tools and techniques, i.e., Kjeldahl, Calorimetric, NIR, Dumas, and amino acid analysis have been adopted that showed substantial variation for protein content among the studies. In a report comprising of 1146 pea accessions, the protein content ranged from 13.2% to 30.9% with a mean of 24.4% in the Genetic Resource Information Network (GRIN) program (USDA 2020). Some improved cultivars, viz., Cameor, VavD265, and CDC Striker were evaluated for protein content in different studies, and these cultivars demonstrated high protein content (>26%). However, in addition to genetic factors, environmental conditions also play a major role in the variation of protein content. Besides, enrichment of grain micronutrient status, the bioavailability of nutrients needs to be increased through conventional breeding by reducing anti-nutritional elements and escalating compounds that encourage iron assimilation. For example, phytate declines the bioavailability of micro-nutrients; therefore, the reduction in phytate level is the utmost tactic toward the biofortification of pea. The biochemical pathway of phytate was modified by mutagenesis followed by conventional breeding. In pea, two low phytate mutants, viz., 1-150-81 and 1-2347-144 were developed employing chemical mutagenesis in base parent CDC Bronco (Warkentin et al. 2012). To understand the effects of environmental conditions on phytate level, multilocation testing was performed and results revealed that inorganic phosphorus, phytate phosphorus, and level of iron were significantly changed over the locations (Warkentin et al. 2012). In another study, it has been found that the reduced phytate in pea is operated through a recessive single gene (Rehman et al. 2012). The carotenoid enriched peas seeds are part of a biofortification approach and recently reported that the green-colored cotyledon pea cultivar possesses twice the total carotenoids as yellow cotyledon cultivar. Notably, the genotypic effect influences carotenoid content to a greater extent than the environment. The association analysis revealed that iron content has a positive correlation with iron bioavailability, while phytate content has a negative correlation with iron bioavailability. In addition, lutein content has a positive correlation with iron bioavailability.

The conventional breeding approach has been well accepted as it is cost effective, free of synthetic inputs, eco-friendly, and sustainable practice. In spite of the several benefits of employing traditional breeding to bio fortify foods, certain limitations are also there; the first one is dependency on the existing genetic diversity for the trait of interest in targeted crop gene pools, i.e., primary, secondary, tertiary. If substantial diversity is not available then biofortification through conventional breeding in the targeted crop is not possible. For instance, biofortification in oilseed could be possible only through transgenic approach owing to its narrow genetic base, low heritability, and linkage drag with targeted traits. Furthermore, nutritional profiling of contemporary crops and crop wild relatives (CWR) has demonstrated that some of the crops are poor in nutritional worth than their wild colleagues. Though, the exploitation of CWR in biofortification could be a difficult task in owing to their cross incompatibility, tight linkage with undesirable traits with targeted traits and least representation of CWR in world gene bank. Another important drawback of conventional breeding is that it takes years to develop a cultivar because incorporation of a trait into an elite cultivar has to go through an exhaustive selection procedure at least till sixth generation. Conversely, many approaches are there like high-throughput phenomics platforms, seed chipping technology, molecular markers, genomic selection, genome editing, and speed breeding that can hasten the varietal improvement process. Of which, some of the methods are expensive than traditional breeding methods, therefore, not used extensively in public breeding institutes albeit they are more efficient. Last but not least, in conventional breeding before releasing, the cultivar must be tested in different environments because genotype-by-environment relationship can considerably affect cultivars phenotypic and nutritional performance. Consequently, a biofortified variety may lose its improved nutritive trait owing to the genetic-by-environment interactions.

Laborious and time-consuming nature of conventional breeding and availability of genomic tools prompted plant breeders to go for marker assisted selection. Biotechnological approaches have played an instrumental role in crop improvement and could be helpful in designing food crops with targeted nutritional profile. The amalgamation of conventional breeding with biotechnological intervention has resultant improved cultivars with high nutritional profile. The most important activity for the detection and development of molecular markers associated with micronutrient is précised phenotyping of available germplasm accessions and successive discovery of contrast genotypes for trait of interest, which will be used to develop appropriate experimental populations. Mapping populations will be exploited to identify molecular markers related with the trait of interest. Ultimately, the identified genetic variants accountable for an amplified level of the targeted nutrient should be introgressed in targeted genotype to emanate the nutrient rich cultivar, either by traditional breeding or by current biotechnological tools. Genomic resources let breeders to take advantage of the existing genetic variability more precisely; hence, duration and expenses could be reduced significantly. In traditional plant breeding, the selection is carried out just considering phenotype, however, by applying genetic and genomic apparatus, allelic variants can be allied with phenotypic variation, which allow early selection of the plant. In the recent past, efforts

were dedicated in pea towards development of genomic resources (Krajewski et al., 2012). Unlike other legume crops, in pea genomic resources have not been exploited judiciously in order to identify genes or quantitative trait loci (QTLs) for nutritional traits. However, some of the researchers revealed the genetic mechanism of iron content in seeds and successfully obtained markers and quantitative trait loci to facilitate breeding programmes (Gali et al. 2018). Most recently, SNPs markers associated with iron and zinc were identified using a group of genotypes of pea (Diapari et al. 2015). On a similar note, SNPs marker allied with Ca, Mg, carbohydrates, and inositol were found in pea (Cheng et al. 2015). Besides, QTLs were also identified on LG3, LG4, and LG7 for Fe status in a RIL population derivative of Carrera/CDC Striker. By employing genome wide association approach in a recombinant inbred line (RIL) population of Kiflica/ Aragorn, many QTLs have been discovered for seed weight and mineral concentration (Ma et al. 2017). Biotechnological approaches have been utilized to support breeding programs, such as marker-assisted selection (MAS) which dramatically accelerated the achievement of breeding for biofortification program. Unfortunately, pea being oldest domesticated crop is still lagging behind in the case of genomic resources. To accelerate genomics enabled biofortification there is urgent need of creation of more genomic resources and their judicious utilization towards identification of genes/QTLs that will be an important asset in MAS. The brief description of markers and molecular mapping of nutrient related genes and QTLs is presented in Sect. 6 of this chapter.

If genetic variability is inadequate for trait of interest then the desired variability may be created by adopting induced mutagenesis or modern techniques like genome editing (i.e., clustered regularly interspaced short palindromic repeats (CRISPR) – associated system (CRISPR/Cas). The beauty of genetic engineering is that it can utilize indefinite group of genes for the targeted transfer and expression of desirable characters from one organism to another without any taxonomic constraints. Besides, if a targeted nutrient is not synthesized in a particular crop, to biofortify such crops for that specific nutrient transgenic is the best option. Using transgenic approach genes were integrated in the genome of the targeted crop to manufacture the micronutrient, for instance, golden rice. Initially, transgenic technique involves considerable duration, labor, and expense, but in a long term, it is lucrative and sustainable unlike other biofortification approaches. On this line biofortification efforts are underway in several crops including pea and brief account of transgenic and genome editing is elaborated in respective section of this chapter.

4 Pea Genetic Resources

4.1 Current Germplasm Holding

Pea is considered as the world's oldest domesticated crop and is cultivated globally in temperate climates. It has been cultivated from Neolithic period as a food and vegetable crop. Pea is the fourth largest pulse crop cultivated mainly for a pulse,

fodder, and vegetable. As per the information in the GENESYS portal, total collections of pea amounted to 33,023 accessions, conserved in different genebanks in the various parts of the world (Genesys portal, accessed on August 30, 2022). United Kingdom has the highest holding of germplasm collections followed by Australia, India, and Lebanon. The list of major genebanks holding pea germplasms are given in Table 2.

4.2 Primary Genepool

The genepool concept was given by Harlan and De wet to categorize the hybridization relationship of a species with other species and grouped into three categories, primary, secondary, and tertiary genepool. However, advancement in plant genomics has led to another set of category defined by Hammer and Gepts and Papa as a fourth genepool (quaternary genepool), and it could include any synthetic strain revealed in nucleic acid sequence, DNA or RNA that do not exist in nature. According to this concept, the species which are in the primary genepool of a crop can be easily crossable and develop fertile progenies during hybridization. It includes plants of the same species or closely related species wherein genes tradeoff can be done between the species by simple crosses, and it is considered as the précised material in term breeding importance. It is believed that *P. sativum* was domesticated in the Near East about 11,000 years ago, likely from *P humile* (also known as *Pisum sativum* subsp. *elatius*). In the *Pisum* genus, the species which are in the primary genepool are *Pisum sativum* subsp. *elatius*, *Pisum sativum* subsp. *elatius* var. *brevipedunculatum*, *Pisum sativum* subsp. *elatius* var. *elatius*, *Pisum sativum* subsp. *elatius* var. *pumilio.*

4.3 Secondary Genepool

The species in the secondary genepool results partial fertile hybrids on crossing with primary genepool. It includes plants related to the species. The introgression of gene from such material to primary genepool is feasible but difficult. The *Pisum* species which comes under this category are *Pisum abyssinicum* and *Pisum fulvum.*

4.4 Tertiary Genepool

The species in this category will lead to the synthesis of sterile hybrids on crossing with primary genepool, and the transfer of genes between the species is possible only with the help of exceptional techniques like bridge crossing, genetic recombination, etc. The species of peas which are under tertiary genepool are *Vavilovia formosa.*

4.5 Sources of Donor Genes

The proper utilization of genetic resources in any breeding program mainly relies on a valorization of genetic resources for targeted traits. In case of evaluation of existing germplasm, accessions for quality traits pea is still lagging behind other legume crops. During last 3–4 decades, concerted efforts have been made to characterize the pea germplasm for various nutritional traits, i.e., protein, iron, zinc, RFOs, and antinutritional traits (Tzitzikas et al. 2006; Tosh and Yada 2010; Harmankaya et al. 2010; Dahl et al. 2012; Demirbas 2018). Most importantly, the landraces and CWR could serve as arsenal of genetic resources to breed new crop varieties suitable for

changing environmental and demographic conditions. Legume crop holds an exceptional status in world agriculture being protein rich and inbuilt ability of environmental nitrogen fixation, but bioavailability of protein is a major concern, because, the protease inhibitors decreases protein digestibility and are operated by two genes (TI1 and TI2) in pea. Recently, a wild pea (*P. elatius*) accession got mutated within the aforesaid both genes and considerably decreased the scale of protease inhibitor activity improving the bioavailability of amino acid (Clemente et al. 2015). Gawłowska et al. (2017) evaluated about 248 accessions belonging to *P. abyssinicum*, *P. elatius*, *P. fulvum*, *P. syriacum*, *P. sativum* subsp. *asiaticum, P. sativum* subsp. *transcaucasicum, P. sativum* subsp. *sativum* convar. *Axiphium*, convar. *Medullosaccharatum* and *medullare*, convar. *Vulgare* and convar. *Speciosum* for RFOs. The results revealed that highest content of total soluble carbohydrates and total RFOs were noticed in accessions with wrinkled seeds and the lowest content in the wild species *P. fulvum*. Therefore, *P. fulvum* could be used as valuable source in conventional breeding to further decrease RFOs. Most recently, in another study Ethiopian pea (*Pisum sativum* var. *abyssinicum)* landraces were examined to estimate the nutritional composition, and results demonstrated abundant variation for nutrients and mineral content. The protein content varied from 21.63% to 28.13%. Furthermore, all the landraces had high potassium (41.43–74.21 μg/g) and low sodium (0.93–27.65 μg/g) content (Gebreegziabher and Tsegay 2020). These finding clearly indicated that Ethiopian pea is an excellent source of protein, and other minerals and could be utilized in regular breeding to develop cultivars with enhanced nutritional status. In addition, *P. fulvum, P. sativum* subsp. *elatius* var. *pumilio*, *P. abyssinicum,* and *P. sativum* subsp. *elatius* also provide resistance against many biotic and abiotic stresses like rust, pea weevil, powdery mildew, ascochyta blight, broomrape and bruchid, bacterial blight, frost tolerance. *P. sativum* subsp. *sativum* var. *arvense* has potential to be utilized as feed and fodder for livestock. The given genotypes could be used in conventional and molecular breeding to develop high yielding and nutritionally enriched cultivars, experimental populations and established marker trait association to identify genes/QTLs. Henceforth, intensive efforts should be made toward the evaluation of available germplasm accessions for various nutritionally important traits, which could be used in breeding program to develop nutrient dense cultivars that would be helpful in the improvement of the overall health status of resource poor and vegetarian population of developed and developing countries.

5 Genetic Mechanism of Nutritionally Important Traits

Pea protein is complicated genetically because of various multigenes families encrypting protein composition and content. Pea seed protein composition is operated genetically; however, environmental factors and postharvest processing circumstances also influences protein magnitude (Bourgeois et al. 2009; Bourgeois et al. 2011). An earlier report identified that three QTLs accounting for 45% of the total variation of protein (Tar'an et al. 2004). On a similar note, 14 QTLs were identified

across the environment affecting the development of genes controlling pea seed protein concentration (Burstin et al. 2007). Another report in which a RIL population was used and detected significant QTLs on linkage group V for total protein content (Irzykowska and Wolko 2004). Similarly, in two populations synthesized by hybridization between a small-seeded and protein rich line and two diverse large-seeded and high-yield potential cultivars detected QTLs for seed protein content located on LG V (Krajewski et al. 2012). Recently, a QTL on LG VI was detected that demonstrated 45% of the seed protein content variation. In addition, single-nucleotide polymorphism (SNP) within *O_2like* gene in pea was identified having a significant consequence on seed protein content. *O_2like* genes in pea have resemblance to *Opaque2* (*O2*) of maize, a bZIP transcription regulating factor that influences starch and protein content (Jha et al. 2015b).

The pea seed protein largely comprises of globulins legumin and vicilin storage proteins, where its synthesis is operated by at least 40 genes and 10 different genetic loci (Casey et al. 2001). Nevertheless, as mentioned above pea seed protein content as quantitative trait, therefore, single gene mutations may be less efficient to influence total protein concentration if not the mutation is at a locus which encrypt substantial part of phenotypic variation (Bourgeois et al. 2009; Rayner et al. 2018). For legumin biosynthesis up to four genes which are defined by distinct loci have been reported and approximately there are 10–15 genes which produce protein (Casey et al. 2001). Interestingly, the loci control starch synthesis can also influence the legumin synthesis due to mutant alleles at loci (*r* and *rb* controlling starch synthesis and synthesis of large subunit of ADP-glucose pyrophosphorylase, respectively) influence the expression of legumin genes and ultimately manipulates the ratio of legumin/vicilin in the overall seed protein (Casey et al. 2001).

Another important storage protein is vicilin that is a poor source of sulphur-containing amino acids in comparison to legumins. Consequently, these amino acids designated as negative factor in pea, and increment in their level is considered as a prime objective toward the nutritional upgrading. In cotyledon, vicilin produces amyloids which are protein aggregates having unique physiochemical attribute like resistance to alimentary tract digestion (Antonets et al. 2020). Using proteomics technique, 24 genes were found controlling vicilin synthesis in pea and also develop a reference map of pea seed proteome (Bourgeois et al. 2009). Interestingly, Domoney et al. (2013) demonstrated how the fast-neutron mutagenesis at single loci knocks out multiple genes which could influence synthesis of vicilin and some other proteins. On a similar note, a mutant allele at *Vc*-2 position influenced the manufacture of vicilin polypeptides and that subsequently impacted seed protein concentration (Chinoy et al. 2011). In a QTL analysis, genes operating legumin, convicilin and vicilin have been identified (Bourgeois et al. 2011). In another investigation, wherein characterize loss of function of *abi*5 mutant in pea and noticed that vicilin content reduces in mutant, and genes encrypting other major protein were upregulated (Le Signor et al. 2017). The gel permeation chromatography demonstrated the proportion of legumin and vicilin in total protein predominantly remains under genetic control, however, agronomic components also influences (Mertens et al. 2012). Most recently, reference genome of pea has been available which offer great opportunity for seed protein

annotation. The genome assembly was explored, and DNA sequences programming proteins counting legumin, vicilin, and convicilin have been recognized. In the pea reference genome alleged RY motifs (CATGCATG) up regulated three storage protein genes by regulating their expression (Kreplak et al. 2019).

There are two proteins, i.e., lectin and albumin which are undesirable due to poor digestibility and allergic effects (Le Gall et al. 2007). In earlier reports it is mentioned that, the lectin is determined by *LecA* gene that control symbiotic interactions of roots with rhizobium (Díaz et al. 1989). Most recent study illustrated the nodulation competence of the *LecA* mutant and observed that it is similar to that of wild-type pea, advocating that absence of lectin is not affecting the symbiotic interaction (Rayner et al. 2018). For pea albumin 2 (PA2) and PA1 coding nine and eight gene sequences, respectively, could identify using the reference genome (Kreplak et al. 2019). In another study, the null mutant for PA2 was hybridized with cultivar (Birte), and a RIL population was synthesized. The examination of RIL exhibited that the lines deficient to PA2 were higher in seed nitrogen content probably owing to a surprising upsurge in the production of other seed proteins (Vigeolas et al. 2008). Backcrossing with cv. Birte has also revealed the PA2 function in plant growth and response to stresses (Vigeolas et al. 2008). This was further validated in a report wherein it is explained that the polyamine and spermine can unite to the homolog of PA2 in grasspea (Gaur et al. 2010).

Two major Lipoxygenases (LOX) polypeptides are present in pea seeds, viz., LOX-2 and LOX-3, of which, one catalyze the creation of compounds which are not preferred by customers (Forster et al. 1999). Both polypeptides are programmed by two or three genes at the *lox* locus situated on LG IV (North et al. 1989). However, a null mutant for LOX2 has been identified from *P. fulvum* collection at the John Innes Centre. Further analysis of this locus in this particular accession portrayed that the decrease in LOX-2 mRNA was not the outcome of a loss of LOX genes, but it happened owing to the one or multiple insertions, deletions, or substitutions into the LOX-2 promoter of the null mutant (Forster et al. 1999). Being rich in sulphur-containing amino acids, pea albumins are vital component for human, and questions are often raised over low level of these amino acids in legumes. Hence, pea albumins can offer a nutritional advantage in respect to amino acid configuration, notwithstanding, apprehension are also there regarding its allergic properties and resistance to ingestion of these proteins in human guts.

Starch, being a most dominating storage carbohydrate in pea seeds accounts for about 50% of dry seed weight. It is composed of various segments considering their configuration and digestibility (Lockyer and Nugent 2017). In his experiment Mendel used seven external characteristics of pea, including variation in mature seed shape, i.e., round or wrinkled to established laws of inheritance (Bateson 1901). Initially, this trait or locus was named as *rugosus* (gene symbol "r") by white (1917) derived from Latin for wrinkled or shriveled shape and is located on chromosome 7 (Bhattacharyya et al. 1990). Later on, another locus named *rb* produces wrinkled shape seeds was recognized (Kooistra 1962). The *r* locus conferred a prominent visible effect on seed appearance that resulted due to the dominant effect of this locus on the configuration of pea seed. There is an unambiguous variation in starch

metastasis of round and wrinkled seeds of peas (Bhattacharyya et al. 1993). In addition, round seeded pea contain more starch than wrinkled seeded and elevated proportions of amylopectin to amylase. The *rr* seeds possess greater concentration of free sucrose than round seeded, which leads to the higher osmotic pressure and water content and bigger cell size of wrinkled seeds (Wang et al. 1987). The *rr* seeds lose a greater part of their volume in the course of seed development, and because the testa does not contract along with the cotyledons, it shrinks to produce the wrinkled appearance (Casey and Davies 1993). Later on the wrinkled phenotypes were also reported to occur due to mutation at other loci counting *rb* and *rug* 1, 2, 3 (Wang and Hedley 1991). Notably, all the mutant, viz., *r*, *rb,* and *rug* have analogous exterior appearance, however, *r* mutants can be discriminate based on the starch granule morphology (Bhattacharyya et al. 1990). Starch granules are build up of two types of starch polymers, i.e., amylase and amylopectin. The proportion of amylose in the wrinkled seeds is around twofold of round seeds (Bhattacharyya et al. 1990). Indeed, the wrinkled seeds developed due to mutation in the gene that governs starch-branching enzyme isoform I (*SBE1*) by inclusion of a transposon-like component into the coding arrangement. Two isoforms of starch-branching enzyme, viz., *SBE1* and *SBEII* are expressed in the initial and later phase, respectively, of embryo development. *SBEI* accounted about 1/3 of the amylopectin in matured pea embryos and create a less soluble polymer in comparison to the polymer generated by *SBEII* which may be more effective in catalysis of short chain production (Burton et al. 1995). The mutations of *SBEI* significantly reduce the scale of starch and fraction of amylopectin in the wrinkled genotypes than round (Bhattacharyya et al. 1993). The reduction in starch synthesis and failure of amylase to amylopectin conversion mainly happened due to the loss of SBEI enzyme activities. The metabolic proof and decreased SBE activity clearly designated this enzyme as an imperative determinant in starch content of *rr* embryos (Bhattacharyya et al. 1993). The SBEI play essential role in the construction of usual starch granules that cannot be replaced by other isoforms. In addition, *r* mutant seeds also demonstrated pleiotropic effects and intricate metabolic instabilities, for example, elevated scale of free sucrose, extra lipid, less legumin, and subsidize seed longevity (Bhattacharyya et al. 1990). In *SBEII,* gene mutation has not been recognized by the examination of wrinkled seeds which advocated that the mutation of SBEII does not have any role in wrinkled phenotype, and this could be due to minor involvement of SBEII in amylopectin synthesis and subsequent activity in the course of embryo development (Bhattacharyya et al. 1993). Starch debranching enzymes (DBEs) hydrolyze the α-1,6-glucan branches of amylopectin, this step is essential for the regular synthesis of amylopectin by pruning extra branches (Wang et al. 2014). In fact, two categories of debranching enzyme are there, viz., isoamylase (ISA) and pullulanase (PUL) with different amino acid sequences. Both DBEs are present in peas and have important role in starch metastasis during the development of embryo and in starch breakdown in the course of germination (Zhu et al. 1998). During last decade, three genes coding the diverse isoforms of ISA (*Psisa1*, *Psisa2,* and *Psisa3*) have been identified in peas and these are capable to bind to glucan substrate, although *Psisa2* deprived of catalytic skill (Hussain and Martin 2009).

At the end of the twentieth century, four other loci were recognized which influences starch metastasis: *lam, rug3*, *rug4*, and *rug5*. Mutant of *rug4* locus causes loss of sucrose synthase (*Susy*) activity during the development of pea embryo. The *rug4* mutant develops wrinkled seed and reduced the starch level in the embryo by affecting the supply for starch biosynthesis (Craig et al. 1998). Another locus *rug5* control starch synthase II, and mutation results into modification of starch granule morphological appearance and the configuration of amylopectin (Craig et al. 1998). The *lam* mutation also influences starch synthase enzyme (starch synthase I) and develop starch with low amylose and high amylopectin (Tahir et al. 2011).

Genes governing three isoforms of Susy (*SuSy1*, *SuSy2*, and *SuSy3*) were identified in peas. The starch scale of the *SuSy1* embryo is reduced by 30%, whereas the cellulose level remains constant. The *SuSy1* isoforms in embryos is essential for starch biosynthesis but not required for synthesis of cellulose (Weber et al. 1998). In pea, *rug3* locus is responsible for a plastidial phosphoglucomutase (PGM) enzyme that catalyzes the interconversion of glucose-6-poshpate (Glc-1-P) and Glc-6-P in the cytosol and plastids. Further, five pea mutants at the *rug3* locus developed wrinkled seeds with low amylose and starch content. In pea embryos, Glc-6-P is ingress from the cytosol into the amyloplast where it is reconverted to Glc-1-P by the plastidial isoform of PGM by supplying the substrate for starch synthesis (Harrison et al. 1998). The damage of plastidial phosphorylase (Pho1) enzyme causes substantial decline in the starch magnitude and its configuration (Satoh et al. 2008). Other two *Pho* isoforms, i.e., *Pho1* and *Pho2* were identified in pea cotyledon, of which Pho2 plays a vital role in starch granule development (Van Berkel et al. 1991). Recent literature reported auxin to play an imperative role in regulating starch accrual in pea seeds (McAdam et al. 2017). The auxin deprived mutant *tar2* (tryptophan aminotransferase related 2) develop small and wrinkled seeds with low starch level. The activity of different starch synthesis enzymes and expression of the corresponding genes are condensed in mutants indicative of vital role of auxin in starch accumulation in peas (Meitzel et al. 2021).

The above given facts witnesses the magnitude and composition of starch as polygenic traits, and their overall expressions are environment sensitive. Genetic mechanisms of starch metastasis are well explained in cereal crops, while there is little information in case of legumes. Recently, 132 SNPs were detected within the genes involved in carbohydrate metabolism, of which, 4 SNPs were associated with genes *AGPase_L1*,*GBSSI*, and *SBEII* operating amylose concentration, and 10 SNPs were associated with genes *SBEII, SuSy2,* and *Sps* (Jha et al. 2015b). Partial sequences of 25 candidate genes which represent 16 enzymes concerned to starch metastasis were characterized using a group of 92 pea accessions, which revealed 3 candidate genes (*r*, *UGPase*, *AGPS2*) to be associated with amylopectin chain length distribution (CLD), while amylose level has association with the *r* locus (Carpenter et al. 2017). Most recently, a linkage map has been developed for starch scale using two RIL populations and detected QTL for starch magnitude on LG2b and LG4a in one population, while QTL for starch content on different linkage groups, viz., LG1a, LG3b, LG3c, and LG7a in other population (Gali et al. 2018). The GWAS has been performed for seed starch content in a panel of 135 pea

accessions and subsequently identified 9 SNP markers positioned on LG2, LG3, LG5, and LG7, and one scaffold was associated with starch level (Gali et al. 2019). Genes encrypting raffinose (*rfs*) and stachyose synthases (*sts*) were aligned to LG III and V, respectively (Ellis et al. 2018). Gali et al. (2018) explored three RILs and identified two QTLs for acid detergent fibre (ADF) positioned on LG 4 and two QTLs on LGVII. In another population, QTLs for ADF have been detected on LG IV and LG VIIa. For neutral detergent fibre (NDF), QTLs on LG Va, Ia, IV, and VIIa have been detected. Similarly, in another study five SNPs associated with level of ADF have been identified on chromosomes 5, 6, and 7, and eight on chromosomes 2, 3, 5, 6, and 7, of which, two markers linked with both type of fibre were positioned on chromosomes 6 and 7 (Gali et al. 2019). Further analysis of identified QTLs and discovery of new QTL could pave the way towards improved discerning of the genetic machinery operating the starch metabolism in pea seeds. Genes associated with starch synthesis are thoroughly examined in pea, consequently offers worthy opportunities for the manipulation and modification of pea starch magnitude and configuration considering further scope. In addition, it has been noticed that the total starch level reduces in peas having high protein, and high amylose level increases resistance to ingestion of the starch (Shen et al. 2016).

Number of attempt has been made to decipher the genetic foundation of seed iron level and consequently detected various molecular marker and QTLs to facilitate breeding programme. Most recently, five QTLs have been detected which are linked with seed iron content in pea localized on LG VII and II (Ma et al. 2017). Of them, three QTLs appeared in close vicinity to markers earlier associated to iron concentration in a study wherein a set of 94 accessions was used (Diapari et al. 2015). QTLs for seed iron content were also reported in three RILs which were derived by hybridization among European and Canadian cultivars (Gali et al. 2018). QTLs for iron concentration in seed were identified on LG IIIb, however, on linkage group VII none of the QTLs for iron content were noticed (Diapari et al. 2015; Ma et al. 2017). This might be owing to the diverse parents used in mapping population or the derived material was evaluated under multilocation testing (Gali et al. 2018). For rest of the essential micronutrients like zinc and selenium very limited efforts were dedicated to understand genetic foundation of their concentrations in pea seeds. However, two SNPs were identified to be linked with high zinc concentration on LGIII (Diapari et al. 2015). Similarly, one more study also reported a QTL on LG III which elucidating maximum magnitude of phenotypic variance for zinc content in seeds (Ma et al. 2017); nevertheless, the SNPs identified by Diapari et al. (2015) were not in adjacent to the QTL located on LG III. A recently conducted study identified four QTLs concerning to zinc level in seeds along with a noteworthy locus on LG III (Gali et al. 2018). Overall, the above narrated finding suggested that the pea genomic region on LG III have huge potential towards the escalation of zinc content in seeds and identification of the core genes/genomic regions that would be helpful for accelerating biofortification programmes in pea. On a similar note, selenium content in seeds was examined in three RILs and of which, in two populations several QTLs located on LG VII, IV, and Vb were detected and strong environmental effect was also observed (Gali et al. 2018). The chemical

resemblances between selenium and sulphur demonstrated that the QTLs recognized in this report may be loci that encrypt sulphate transporters (White 2016).

6 Molecular Mapping of Health-Related (HR) Genes and QTLs

Understanding the genes and genomic location governing valuable trait requires the comprehensive study of whole-genome sequence data. Pea genome consists of seven pairs of chromosomes with a huge genome size of 4.45 Gb (Gali et al. 2018), mostly comprised of transposons and other mobile elements of Ty3/gypsy family (Macas et al. 2007). The generation and accessibility of genomic tools have been slowed down in pea owing to the late availability of reference genome in public database. With the advancement of cutting-edge tools and cost effectiveness of Next Generation Sequencing Techniques (NGS), momentum jump has been achieved towards marker development and subsequent molecular breeding efforts for enriching pea genomic resources. Pea researchers walked a long way with the partnership of International-National consortium for making available the complete pea genome sequencing platform and paved the way from conventional to molecular breeding era (Madoui et al. 2015).

A molecular marker is a segment of DNA linked to a particular locus in the genome. Molecular markers facilitate to perform MAS for the trait of interest at early growth stage and accelerate genetic progress, thus expedite genetic mapping and QTL analysis. Development of first and second-generation markers like RFLP, RAPD, AFLP, SSR, and CAPS aided for diversity studies and pea genetic improvement towards gene tagging and introgression (Aubert et al. 2006; Burstin et al. 2007; Bourgeois et al. 2011; Ma et al. 2017). With the availability of high throughput SNPs, genotyping has become more efficient, thanks to technological improvements in sequencing and generating genotyping platforms over the past 10 years in pea. Presently SSRs and SNPs markers are the prime choice of the plant breeders owing to their reliability, robustness, and wide distribution throughout the genome. Several SNP arrays have been generated by deploying genotyping-by sequencing (GBS) approach and transcriptome data of diverse pea germplasm set (Kaur et al. 2012; Tayeh et al. 2015a; Alves-Carvalho et al. 2015). Genetic map construction in pea dated back early in 1925 through development of six linkage group, however markers development in relation to HR genes were scarce (Table 3). Mapping efforts concerning seed protein quality was initiated to detect the QTL (Tar'an et al. 2004; Bourgeois et al. 2011; Tayeh et al. 2015b). Three QTLs were detected that was associated with seed nitrogen/protein content (Tar'an et al. 2004). Among these, two QTLs were mapped on LG-III and VI and can explain 45% of the total variation in seed protein and likely to be associated with seed storage protein albumin. Another study detected a total of 14 QTLs explaining 9–46% variation, positioned at 160 cM and 170 cM on LG V, thus highlighted the presence of two QTLs with opposite effects (Burstin et al. 2007). Except for the fabatin-like genes on linkage group VII, none of the QTLs were directly linked to seed protein gene loci. Irzykowska and

Trait	QTL /LGs	Mapping Population	Marker system	Map distance (cM)	References
Protein	03 QTLs (LG-VI))	88 RILs between 'Carneval' × 'MP1401'	193 AFLPs 13 RAPDs 01 STS (sequence tagged site) marker	1274	Taran et al. (2003)
	5 QTLs (LG-II, V, VII)	114 plants of F_2 generation from a cross between Wt10245 × Wt11238	204 markers morphological, isozyme, AFLP, ISSR (Inter Simple Sequence Repeat), STS, CAPS and RAPD markers	2416	Irzykowska and Wolko (2004)
	14 QTLs (LG-I, III, IV, V, VI, VII))	139 RILs between Térèse' and K586	249 SSRs	1113	Burstin et al. (2007)
	77 QTLs (LG-V) and 11 LGs	F_2 generations derived from Wt11238 × Wt3557 Wt10245 × Wt11238	282 morphological, isozyme, AFLP, ISSR, STS, CAPS, and RAPD markers	853	Krajewski et al. (2012)
	7 LGs	RIL population from the following crosses: VavD265 × Ballet (211 individuals) Cameor × Melrose (120 individuals) Kazar × Cameor (84 individuals) Kazar × Melrose (118 individuals)	SNPs, SSRs, RAPDs, RFLPs AFLPs, etc. 6188 8503 7013 3917	794.9	Tayeh et al. (2015a)
Vicilin	7 QTLs (VicB, Vc-2-5 (LG II, III, V)	157 RIL population between 'Cameor', 'VavD265', and 'Ballet'	Seed protein markers	–	Bourgeois et al. (2011)

(continued)

Table 3 (continued)

Trait	QTL /LGs	Mapping Population	Marker system	Map distance (cM)	References
Starch metabolism	7 LGs	Térèse × K586 (Pop1, 139 F7 RILs) Térèse × Champagne (Pop2, 164 F8 RILs)	63 SNPs and 15 Indels markers, CAPs, and RAPDs	1458	Aubert et al. (2006)
Seed mineral content	82 QTLs	RIL population (F6) derived from 'Kiflica' and 'Aragorn'	114 SSRs and 1608 SNPs	1310.1	Ma et al. (2017)
Dietary fibre, seed protein, minerals, and phytate acid	16 QTLs (LG-Ib and LG4a: Seed protein) (LG-IV, VII and VIIa: acid detergent fibre) (LG-Ia, IV, Va, and VIIa: neutral detergent fibre (LG-IIb and LG-IVa, LG-Ia, LG-IIIb, LG-IIIc, and LG-VIIb: seed starch content) (LG-IIIb: seed Fe content) (LG-VII, LG-IV, and LG-Vb: seed Se content 4 QTLs for seed Zn content (two on LG-VI; one each on LG-Ia and LG-IIIb) (LG-IIIa, LG-V, and LG-VIa: seed phytate content)	RIL population developed from PR-02 (Orb × CDC Striker), PR-07 (Carerra x CDC Striker), and PR-15 (1–2347-144 × CDC Meadow)	2066, 3023, and 3444 SNPs for three different population	951.9, 1008.8 and 914.2 cM for three different populations	Gali et al. (2018)
Phytic acid and phosphorus content	7 LGs	RIL population with 94 individuals derived from cross between 1–2347-144 × CDC Meadowe	341 SNPs	771.6	Sindhu et al. (2014)

Wolko (2004) deployed a RIL population between large- and small-seeded parents (Wt10245 × Wt11238) and reported five substantial QTLs for total protein content accounting for 18.3–25.5% of variation. Among these, three (prot-2, prot-3, and prot-4) were located in LG-V with high LOD values (4.4–5.3), whereas the two other QTLs, viz., prot-1 in LG-II and prot-5 in LG-VII revealed lower LOD (2.2 and 2.4). Afterwards, mapping populations were developed by crossing three pea cultivars with differential protein content, viz., Cameor, VavD265, and Ballet. In Cameor × VavD265, 7 LGs were detected with 6952 markers with a map length of 752.6 cM, whereas, in cross between VavD265 × Ballet, 850.1 cM map distance was covered with 6188 markers (Bourgeois et al. 2011; Tayeh et al. 2015b).

Globulins are the main kind of seed storage protein in peas which is further classified in to 11 S legumins and 7 S vicilins/convicilins. The distribution of these two classes of protein is influenced by genotype and the growing environments (Casey et al. 2001). Genetic analysis and DNA hybridization as well as sequence characterization of DNA and protein in pea detected four classes of legumin and five classes of 7 S protein genes and their respective QTLs (Newbigin et al. 1990). For fine characterization of globulin protein genes in pea, integrating two-dimensional electrophoresis (2D)-based proteomic and QTL mapping strategy was deployed involving 157 RIL population developed from three contrasting parents (Cameor, VavD265, and Ballet) with differential protein level by the Composite Interval Mapping (CIM) procedure. It was detected that 40 multigene families were involved in regulation of pea storage proteins where four gene classes were uncovered which are responsible for legumin biosynthesis in pea (Casey et al. 2001). The framework of three sets of legumin genes were well characterized by utilizing F_2 and F_6 individuals from selected crosses exploring RFLPs. They were mapped on chromosome 7 close to *r*, while the other maps to a locus near *a* on chromosome 1. The third class of legumin gene was likewise connected to *a*, according to the findings of one of the tested crosses (Domoney et al. 1986). The mRNA from developing pea seeds was used for construction of cDNA plasmid bank for characterization of vicilin coding genes, which further unveiled two different classes of vicilin genes that were initially synthesized as provicilin with subsequent processing at C-terminal peptide as well as post translational endo-proteolytic cleavage. The accumulation of convicilin was chiefly regulated by cis-regulatory regions whereas; both cis- and trans-regulatory regions were governing vicilins and legumins accumulation in pea. In vitro protein digestibility and protein composition appear to be significantly regulated by LG-IIa (Bourgeois et al. 2011). Recently, genome sequence information of the reference genome of cv. Cameor annotated 12 genes for legumin; 9 genes for vicilin and 2 genes for convicilin along with RY motifs (CATGCATG) associated with seed specific transcriptional regulation in pea (Kreplak et al., 2019). *LecA* gene was discovered which is the key gene governing lectin content in pea as well as associated with symbiotic N_2 fixation with *Rhizobium* in pea nodules (Domoney et al. 2013). Lectin is considered as an antinutritional factor due to poor digestibility. A knockout mutant was detected in pea with loss of function of *LecA* gene without any compensation regarding symbiotic N_2 fixation (Rayner et al. 2018). Similarly, *PA2* gene is governing another undesirable protein fraction albumin in pea seed.

Reference genome of cv. Cameor detected all together nine genes governing *PA2* and eight genes coding for another major albumin, *PA1* (Kreplak et al. 2019). However, in recent investigation it was detected that pea albumin having adequate sulphur containing amino acids which are essential for human being. Lipoxygenases (LOX), a subclass of seed storage proteins that controls the production of hydroperoxides from fatty acids, were found in pea. In pea seeds, there are two major LOX polypeptides (LOX-2 and LOX-3), and two or three genes at the *lox* locus positioned on LG IV encode these polypeptides (North et al. 1989). In recent years, attempt has been made to tag the genomic regions related with carbohydrate metabolism and seed storage protein accumulation in pea and to detect the SNP variation related with various HR genes (amylose, total starch, and crude protein concentration) for future marker assisted breeding programme (Jha et al. 2015b).

High density linkage map with less confidence interval is useful for QTL detection of major agronomic and economic traits in many crops including pea. GBS approach with simultaneous SNP detection has been extended for construction of high-resolution maps in pea to unveil the QTLs for seed mineral content (Ma et al. 2017). The study detected 6, 37, and 46 QTLs for seed weight, seed mineral content, and seed mineral concentration respectively, which explained phenotypic variation (PV) ranging from 2.4% to 43.3%. Another study by Gali et al. (2018) also deployed GBS approach for simultaneous detection of genome wide SNPs and QTLs associated with dietary fibre, seed protein, and mineral concentration using three RILs namely, PR-02, PR-07, PR-15 derived by cross of Orb × CDC Striker, Carrera × CDC Striker, and 1–2347-144 × CDC Meadow, respectively, at Crop Development Centre (CDC), University of Saskatchewan, Canada, employing single seed descent method. QTL mapping was executed employing CIM through QTL cartographer. Seed protein concentration QTLs have been detected on LG-Ib and LG-IVa of PR-02 with maximum LOD values of 5.0 and 3.4, respectively, and accounted up to 15.9 and 10.3% of the PV. Notably, QTLs were also detected for different fractions of dietary fibers. Four linkage groups were found for acid detergent fibre (ADF), including two QTLs on LG VII that individually accounted for 28.0% and 26.2% of the PV in the PR-02 population. Significant QTLs for ADF were discovered on LG IV and VIIa for the PR-07 population. With regard to neutral detergent fibre (NDF), in the PR-02 population, identified QTLs on LG-Va, and in the PR-07 RIL population, identified QTLs on LG Ia, IV, and VIIa, accounting for up to 44% of phenotypic variance. On LG-IIb and LG-IVa of PR-02, LG-Ia, LG-IIIb, LG-IIIc, and LG-VIIb of PR-07, numerous QTLs for seed starch content were found. The largest LOD value represented by LG-VIIa was 8.4, and 20.1% of the phenotypic variance was elucidated by this QTL. QTLs for seed iron (Fe) concentration were found over four LGs of PR-02, and the QTL on LG-IIIb was highly significant with LOD values of 7.6 and 6.3. Based on two phenotypic experiments, three linkage groups of the PR-02 population were shown to have QTLs for seed selenium (Se) content. Of these, LG-VII embodied QTLs within the same linkage group region in both trials and demonstrated a phenotypic variance up to 15.0%. In two of the six trials for seed Se content in the PR-7 population, QTLs on LG-IV and LG-Vb were found. For seed zinc (Zn) concentration, four QTLs were found: two on LG-VI of PR-02 and one

each on LG-Ia and LG-IIIb. With a LOD value of 13.7 and a PV of 25.8%, the QTL on LG-IIIb was highly significant. QTLs for seed phytate content were mapped in PR-15 population. Three linkage groups, viz., LG-IIIa, LG-V, and LG-Via were shown to include QTLs for this characteristic, with the LG-V QTL being found in all four trials evaluated in two sites (Gali et al. 2018). The recognized QTLs linked with HR genes in pea are valuable treasure for marker assisted breeding programme for improving seed quality traits in pea.

7 Map-Based Cloning of HR Genes/QTLs

An innovative method that pinpoints the underlying origin of a genetic variation is map-based cloning (MBC). Without prior knowledge of specific genes, MBC can access a practically infinite resource of induced and natural genetic variation. Therefore, scientists are attempting to use this method in model plants to clone the orthologues genes in related plant species. *Medicago truncatula* and *Lotus japonicus* are considered as model legumes as these are diploid with eight and six chromosomes, respectively, and having relatively small genome size of around 500 Mb (Cannon et al. 2009). These model legume species facilitate to transfer the genomic resources into target legume crops for better understanding of development as well as evolutionary biology. High degree of synteny between model species and pea facilitate to deploy cross species gene-based markers for unveiling the homologous genome segments. A comparison of the genomes of pea (*P. sativum*) and alfalfa (*M. truncatula*) has been done through comparing linkage maps of both the species to understand the co-linearity between the linkage groups and the presence of conserved and orthologues genes using gene-based RFLP and PCR markers (Kalo et al. 2004). Considering the model legume *M. truncatula,* it was discovered that the *ABI5* transcription factor is a key factor in determining the accumulation of seed globulins. This study also characterized loss-of-function *abi5* mutants in pea, showing that the mutants had higher levels of other important seed proteins and lower vicilin concentrations (Le Signor et al. 2017). Further, SNP variation was detected in *O2like* gene in pea that is similar to *opaque2* in maize, a bZIP transcription regulating factor with having significant role in management of protein content (Jha et al. 2015b).

Starch or amylum is the most abundant form of storage carbohydrate in pea seeds composed of amylose and highly branched amylopectin. Attempt has been made to characterize the key genes for getting better insight about the starch biosynthetic pathways through generating array of mutants with differential starch concentration. Various mutant forms (*Iam*, *r*, *rb*, *rug3*, *rug4,* and *rug5*) have been generated targeting the key enzymes like granule bound starch synthase Ia (GBSSIa) (Dry et al. 1992), starch branching enzyme I (SBEI) (Burton et al. 1995;), ADP-glucose pyrophosphorylase (AGPase) (Burgess et al. 1997), phosphoglucomutase [Plastidial] (PGM) (Harrison et al. 1998), sucrose synthase (SuSy1) (Barratt et al. 2001), and starch synthase II (SSII) (Craig et al. 1998). The generated mutant in pea with altered or absence of the targeted genes also exhibited pleotropic effects on the seed shape

changed from round to wrinkled with a 50% reduction of starch content and an increase in lipid and sucrose content.

Large and stable genomic clones for crops with complex genome are frequently created and stored using bacterial artificial chromosomes (BACs), which are employed as a genomic library. The first BAC library in pea consisting of partially HindIII-digested DNA fragments with a mean size of 105 kb was developed considering pea cv. PI269818 for isolation of disease resistance genes and genes governing economic traits (Coyne et al. 2007). A sequence-based physical mapping technique called whole genome profiling (WGP) makes use of sequence tags produced by NGS. A recent study by Gali et al. (2019) utilized pea cv. 'Cameor' for construction of BAC library for localization of the gene through physical mapping for further structural and functional annotation followed by genome sequencing as well as positional cloning of the mined genes having economic importance.

8 Omics Approaches in Relation to HR Genes

In recent decades, the newly emerging omics-based approaches facilitate towards locating genes/QTLs governing the traits of interest and further make available the robust markers platform for marker assisted breeding programme. Microarray or RNA sequencing technology as well as the recent cutting edge NGS based transcriptome assembly can generate valuable genomic resources and markers that can be assembled for construction of highly saturated genome maps, improve genotyping technologies (sequencing and resequencing), and identification of additional markers like SNPs and EST-SSRs (Kaur et al. 2012). Pea had relatively meagre genomic resources compared to the model legume until the first pea reference genome assembly (Kreplak et al. 2019) became available. This offered pea genomics-assisted breeding a new momentum. The estimated pea genome is 3.92 Gb in size, spanning 88% of the reported genome assembly. This reference genome assembly has offered several contigs, transcripts, markers, and GBS platforms for their further annotation. The creation of integrated linkage maps and the comparison of markers across various studies have been made easier by the alignment of sequence reads to a common reference genome sequence. In pea, the transcriptome analysis has been mostly carried out to unveil the host pathogen interaction and pathogenesis related proteins (Winter et al. 2016), genes, and transcripts related with the mechanism underlying abiotic stress resistance (Chen et al. 2013; Bahrman et al. 2019), and there is scantiness regarding transcriptome analysis in relation to HR genes. However, the gene expression atlas developed in pea using the variety "Little Marvel" (Franssen et al. 2011) or by using another two cultivars (Kaspa and Parafeld) by Sudheesh et al. (2015) and Alves-Carvalho et al. (2015) generated valuable transcripts atlas that will further boost up reverse genetic studies, fine mapping, allele mining, and identification of candidate genes. In another study, eight diverse accessions of pea and five RIL populations were deployed to generate genome wide transcriptome-based SNP arrays using Illumina
