Figure 8.135 shows the dynamic magnetic flux and the current behavior observed when a transformer is energized. Energization of a transformer with no residual flux in its cores at peak voltage will not lead to transients. However, the level of saturation of the magnetizing current caused by the change in flux after energization depends on the residual flux and the energization instant. Therefore, the targets should be adjusted taking into account the residual flux. The inrush current can be only minimized by energization when the prospective normal core flux is identical to the residual flux.

An innovative and field-proven approach to residual flux measurement has been developed. It can evaluate the residual flux by integrating transformer deenergization and also compensating the flux value caused by a

small voltage change induced by a remote fault clearing. In 2001, Canada installed two prototype systems which ensure that high-voltage step-up transformers are energized at the ideal instant. Each system consists of a CSS with a new residual magnetic flux measurement system [8.69] that uses the following relation between the magnetic flux  $\Phi$  of a coil with  $N$  turns and the applied voltage  $E$ :  $\Phi = \int E/N + \Phi_r$ , where  $\Phi_r$  is the residual magnetic flux.

The algorithm for evaluating the residual flux generally consists of the following four steps (see also Fig. 8.136):

- (1) The zero level (or offset level) of the dynamic flux must be calibrated precisely. The zero level for the integration of the voltage signal is determined by monitoring several cycles of voltage waves before current interruption.
- (2) The time duration for voltage integration is defined as the time before the voltage amplitude becomes smaller than a specified value where the flux draws a microhysteresis loop.
- (3) Voltage integration is performed over the time determined in the second step.
- (4) The difference between the value obtained in the third step and the zero level evaluated in the first step gives the residual flux.

A novel built-in transformer voltage sensor was developed to measure each phase voltage of the transformer shown in Fig. 8.137 [8.69].

Figure 8.138 shows a typical record of the residual fluxes for three phases measured at transformer deenergization. This was used to determine the optimal energization instant for each phase.

Figure 8.139 shows an example of the dependence of the residual flux patterns on the opening phase angle at random (de)energization in the field. Three patterns were observed in the field measurements (note that the residual fluxes of the three phases sum to zero):

- In pattern I ( $X, -X, 0$ ), two phases have large fluxes with the same amplitude but different polarities. The remaining phase has minimum flux.
- In pattern II ( $X + Y, -X, -Y$ ), all three phases have significantly different fluxes, and one of the phase fluxes has a different polarity from the other two phase fluxes.
- In pattern III ( $2X, -X, -X$ ), one phase has a large flux with a different polarity to the other two phase fluxes, both of which are roughly half the value of the phase with a large flux.

Pattern III is clearly advantageous for the control strategy because the residual fluxes in the second and the third phases are similar to the flux obtained after ener-

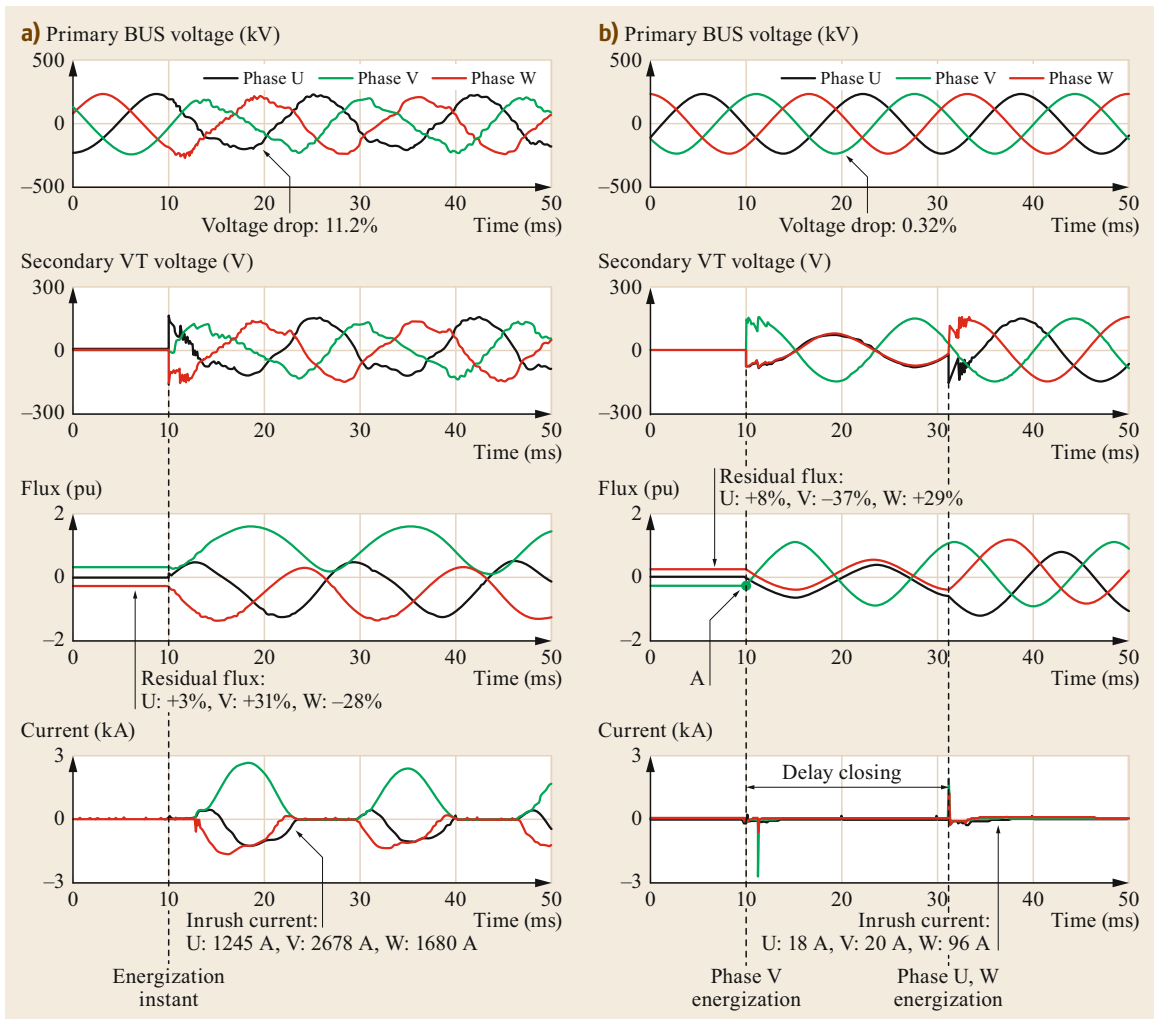

**Fig. 8.136** Residual flux evaluation based on the integration of voltage measurements

**Fig. 8.139** Example of the dependence of the residual flux patterns on the deenergization phase angle

**Fig. 8.140** (a) Simultaneous three-phase energization, (b) controlled energization that takes the individual residual phase fluxes into account

gization of the first phase. This pattern will give flux conditions in the second-phase and third-phase cores that are close to ideal, with a limited closing delay.

This suggests that controlled transformer switching can be further improved through the application of controlled deenergization. In other words, the circuit breaker can deenergize the current at a specific phase angle corresponding to the phase with the largest residual flux at one phase or two phases.

Figure 8.140a shows typical core voltages, currents, and fluxes calculated for simultaneous three-phase energization. High inrush currents ranging from 1245 to 2678 A are obtained due to magnetic saturation in the cores, which causes the voltage to drop by up to 11.2% at the primary bus terminal. On the other hand, Fig. 8.140b shows a typical example of controlled trans-

former energization. The controller chooses to close the phase with the largest residual flux (phase V) first. The first phase is closed at the instant when the prospective normal core flux is identical to the residual flux. The second and third (U and W) phases are closed 1.5 cycles later, at a voltage peak for the first phase. The inrush currents are therefore reduced to below 100 A and the voltage disturbance is effectively suppressed by choosing to deenergize the phase with the largest residual flux first, greatly reducing mechanical and electrical stresses on the transformer [8.70].

### 8.4.5 Line Switching Applications

Energization and autoreclosing of long transmission lines can cause undesirable overvoltages in the trans-

**Fig. 8.141** Optimum target for an uncompensated line equipped with an inductive potential transformer. Making should be performed at a zero crossing of the source-side voltage for lines that are rapidly discharged, such as those equipped with an inductive potential transformer (RC is typically  $< 100$  ms)

**Fig. 8.142** Optimum target for an uncompensated line equipped with a capacitive potential transformer. Making should be performed at a source voltage peak of the same polarity as the trapped charge for lines with no leakage path for the trapped charge, such as those equipped with a capacitive potential transformer. The controller should detect the line voltage polarity at the instant of line charging current interruption

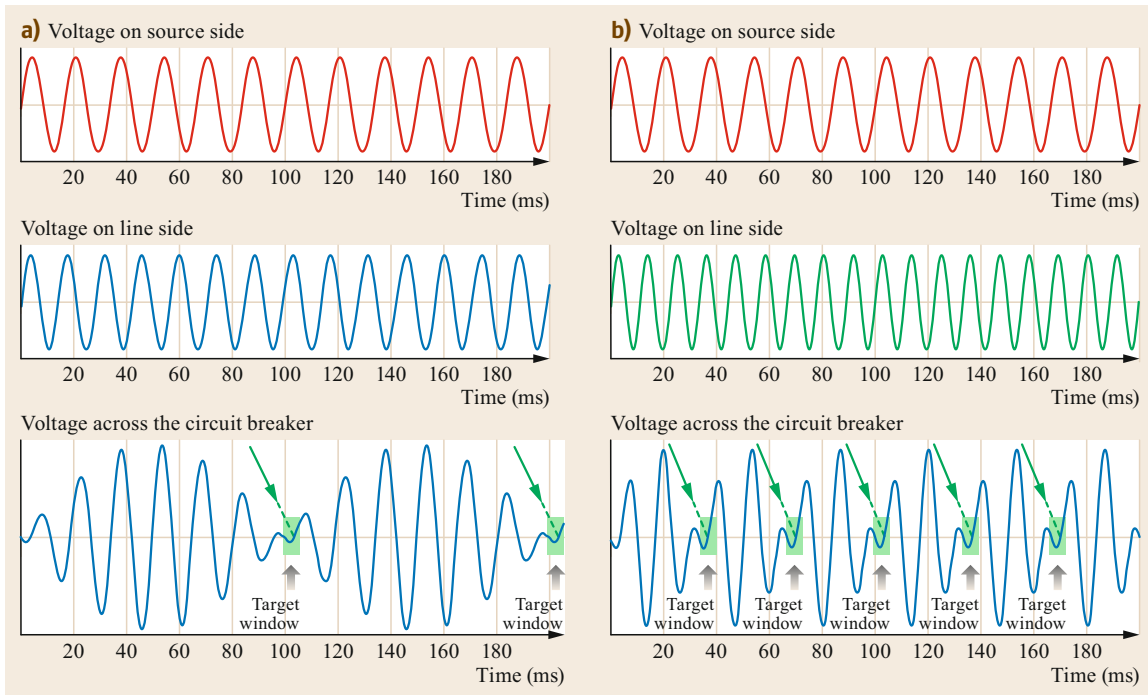

mission network, so special measures for mitigating these overvoltages are employed to meet the insulation coordination. Most commonly, these measures correspond to the application of a MOSA, often in combination with a closing resistor to improve reliability, but this approach is relatively expensive. There is also a growing need to use shunt reactors to mitigate the phase-to-ground transient overvoltages caused by line switching, especially high-speed autoreclosing. The highest phase-to-ground transient overvoltages tend to appear in the middle of the line because they are limited at the ends of the line by the presence of shunt reactors, MOSAs, and CSSs. These overvoltages can be reduced by positioning a MOSA in the middle of the line.

A CSS can potentially reduce reclosing transients and suppress restrikes. It can also provide economic benefits such as eliminating the need for closing resistors and reducing the insulation levels needed for surge arresters and transmission towers. For line applications, a circuit breaker with a high RDDS is generally preferable, although the operating scenario and targeting strategies should be studied thoroughly. Idle-time

compensation is essential for drives with operating times that depend on the idle time [8.63, 71].

The physical phenomenon that governs line-switching overvoltages is the propagation of electromagnetic waves along the line; these are generally called traveling waves. The wave propagation is initiated by the making operation of the circuit breaker, and the initial voltage amplitude is the circuit breaker pre-arc voltage, i.e., the instantaneous value of the voltage across the circuit breaker pole at the instant of line charging current making. One consequence of the propagation of traveling waves is that the optimum making instant for the controlled switching of unload transmission lines is a voltage minimum across the circuit breaker pole. The strategies for different line configurations are as follows:

- (a) For an uncompensated line with an inductive potential transformer, the controller can effectively suppress the surge (to less than 1 pu) by performing controlled closing at voltage zero on the source side. This is because the trapped DC charge is discharged rapidly, typically within 100 ms (Fig. 8.141).

**Fig. 8.143a,b** Optimum making targets for compensated line switching. (a) The voltage across the circuit breaker has a pronounced beat for high degrees of compensation. (b) For lower degrees of compensation, the voltage across the circuit breaker exhibits a complex voltage waveshape with a less pronounced beat pattern

**Fig. 8.144** Arrangement for a series capacitor compensated 550 kV transmission line

- (b) For an uncompensated line with a capacitive potential transformer, there is no leakage path for the trapped charge. The optimum target is a source-side voltage peak of the same polarity as the trapped charge (Fig. 8.142).
- (c) For a compensated line, the degree of compensation significantly influences the line-side voltage. The voltage across the breaker presents a prominent beat (especially for a high degree of com-

pensation) because the line oscillation frequency is typically within the range 30–50 Hz. The optimal instant is a voltage minimum across the CB; preferably during the minimum of the voltage beat [8.72], as shown in Fig. 8.143.

Figure 8.144 presents an example (from Canada) of a series capacitor compensated 550 kV transmission line with a length of 300 km. This system is equipped

**Fig. 8.145** Voltage profiles obtained with a closing resistor or with two or three MOSAs [8.72]

with mid-line series capacitors that provide 50% compensation. Economics resulted in the decision to assign the bypass protection of this bank to a MOSA rated at 2.2 pu, 89 MJ with no self-triggered or triggered gap. The line is equipped with 135 MVA/525 kV three-phase shunt reactors at each end of the line; the reactor at the receiving end is switchable.

The line will be operated with single pole reclosing, so the shunt reactor at the southern end is equipped with a neutral reactor rated at 1600  $\Omega$  for secondary arc damping. The reactor at the northern end is grounded through a surge arrester to achieve a high grounding impedance and therefore optimize the secondary arc control [8.72].

Figure 8.145 compares the voltage profile along a line with a conventional closing resistor to the use of two and three MOSAs with staggered closing. The effectiveness of overvoltage control using a closing resistor decreases when the line length becomes longer than 150 km. It is evident that with three MOSAs, only a small portion of the line experiences voltages over the design target, even with the nonoptimal times inherent to staggered closing.

Figure 8.146 indicates the improvement that can be obtained using a line-connected MOSA. Two alternatives are considered: a MOSA at each terminal of the line or three MOSAs with the third connected mid-line. Note that the objective, to reduce the overvoltage to less than 1.7 pu, can only be achieved using three MOSAs plus controlled closing.

According to the results, the general performance of the CSS is similar to that of the closing resistor in terms of controlling phase-to-ground and phase-to-phase switching transient overvoltages at both receiving ends and mid-line. It is clear that the CSS can substantially mitigate switching overvoltages in the middle of the line. Of course, it should be noted that there is the potential for phase-to-phase TOV mitigation.

**Fig. 8.146** Comparison of various methods of mitigating three-phase reclosing overvoltages

The use of a more compact UHV OH line design significantly lowers the capital costs of the line itself due to the resulting reductions in the dimensions and weights of mechanical structures. Employing both MOSAs and CSSs can potentially allow transmitting large amounts of powers considering the increased economic and environmental constraints of recent years.

#### 8.4.6 Summary

The rapid increase in the use of CSSs can be ascribed to several factors, such as the successful deployment of systems with an effective compensation algorithm in the field, the CIGRE proposal for type-testing recommendations, and versatile operations and controls of transmission systems due to changes in the electrical industry globally. Since CSSs provide significant technical and economic benefits, including enhanced power quality and operational flexibility, they may be incorporated into circuit breaker control systems as standard in the near future [8.73].

CSSs provide many economic benefits when they are applied to shunt reactor banks and transformer energization in power systems. When making at the voltage minimum, a RDDS of at least 186 kV/ms at 60 Hz (155 kV/ms at 50 Hz) is required for 550 kV single-break and 1100 kV two-break GCBs, which corresponds to RDDS = 1.

Step-up power transformers in hydroelectric power plants are frequently switched to cope with daily load variations. Controlled transformer switching that takes into account the residual flux is one scheme that can be employed to effectively reduce the overvoltage caused by transformer energization. Since the effectiveness of a closing resistor at reducing the overvoltage decreases for very long lines (typically longer than 200 km), combined CSS and MOSA use could be one of the solutions used for long UHV and EHV transmission lines.

In the case of transformer energization, inrush currents can be reduced to satisfactory levels through the simultaneous application of a CSS with a gang-operated circuit breaker.

The potential to achieve more compact transmission towers and lines through the associated shunt reactors in addition to MOSAs for TOV mitigation, requires thorough investigation during the planning or engineering design phases of power systems.

## 8.5 DC Circuit Breakers

HVDC transmission has increased in popularity in recent years due to rapid progress in power electronics technology driven by the need to connect increasing numbers of offshore or remote wind farms and/or large hydropower generators. HVDC brings several technical benefits in this context, such as fewer system stability problems compared with AC transmission and lower energy losses during long-distance transmission. In the near future, multiterminal HVDC transmission networks connected to offshore wind farms will be constructed [8.74].

### 8.5.1 HVDC Networks

Two different converter technologies are available for HVDC transmission: line commutated converter (LCC) and voltage source converter (VSC) technology. For LCC HVDC,  $\pm 800$  kV HVDC transmission systems for up to 8 GW have been implemented in China and in India using converters based on thyristors, and  $\pm 1100$  kV UHV DC transmission is under investigation in China. For VSC HVDC, a  $\pm 320$  kV HVDC transmission system for up to 1000 MW using converters based on insulated-gate bipolar transistor (IGBT) devices was brought on-line in 2015.

Multiterminal HVDC networks must continuously operate healthy transmission lines even when a fault occurs at the remote end of the HVDC network. Rapid fault clearing is a prerequisite for a DC circuit breaker because a voltage collapse will spread across the network due to the lower impedance in a HVDC system than in an AC system. The fault clearing time varies depending on the system conditions, including:

1. The DC transmission system configuration
2. The VSC design
3. The transmission capacity
4. Whether a DCL reactor is connected in series with the line/cable
5. The impedance of the line/cable.

As information technology develops, it may become possible to use CSS for fault current interruption, the uprating of modern and aged circuit breakers, and compensated line autoreclosure with a reduced number of surge arresters in the future. Furthermore, data from the monitoring of circuit breakers by the controller could be used for remote diagnostics and condition-based maintenance to further improve equipment reliability and optimize maintenance practice.

Applications of DC circuit breakers in multiterminal HVDC networks are still limited, but available information on DC circuit breakers intended for future HVDC applications is described below [8.75].

### 8.5.2 Current Zero Creation Schemes for DC Circuit Breakers

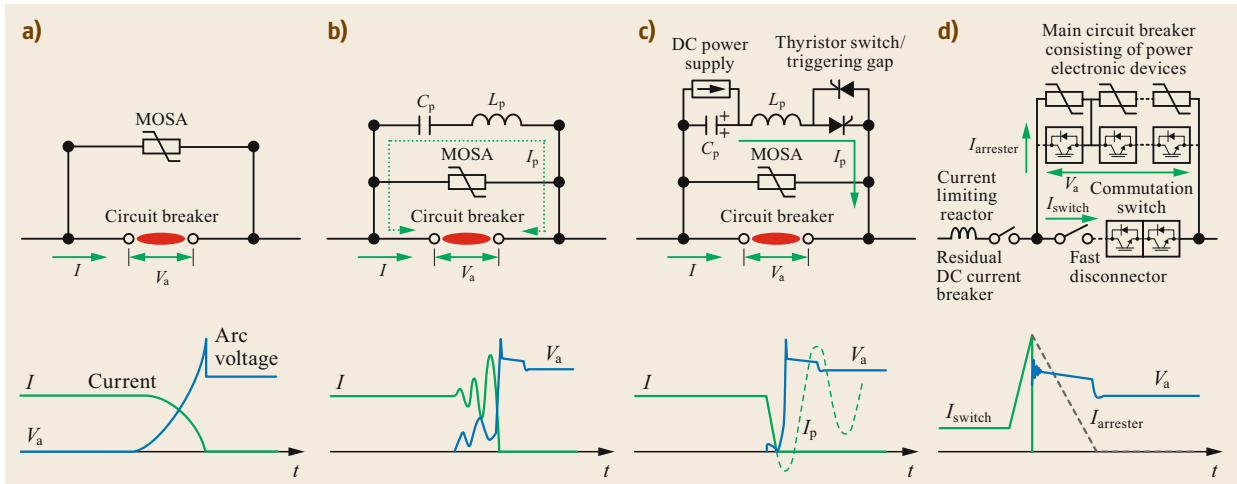

Any DC circuit breaker requires a current zero creation scheme to interrupt the DC fault current because DC current does not have periodic current zeros, in contrast to AC current. Figure 8.147 shows typical current zero creation schemes that can force the creation of a zero current crossing.

#### (a) Arc Voltage Current Limiting Scheme

Here, the DC current is limited to current zero by increasing the arc voltage induced between the contacts of a circuit breaker. The circuit breaker is required to induce an arc voltage that is higher than the system voltage in order to create the current zero. This scheme is often applied to a low-voltage-class DC no-fuse breaker (NFB). For example, a 2 kV air-blast type high-speed switch is used for industrial and railway power systems. Even though a DC circuit breaker that uses this scheme can interrupt a large current of up to 100 kA, it can be difficult to design HV DC circuit breakers that use this scheme because the arc voltage induced by air or SF<sub>6</sub> across the contacts of the circuit breaker is limited to several kV at maximum. This scheme is also applied to most DC disconnecting switches and DC earthing switches used in HVDC LCC and VSC networks.

#### (b) Passive Resonant Current Zero Creation Scheme

In this scheme, a small oscillatory perturbation in the DC current caused by contact separation continues to grow in amplitude until it eventually produces a current zero. The interaction between the arc and the parallel

**Fig. 8.147a–d** DC circuit breakers with different current zero creation schemes. (a) Arc voltage current limiting scheme, (b) passive resonant current zero creation scheme, (c) active resonant current zero creation scheme with current injection, (d) hybrid mechanical and power electronic switch

capacitor and reactor connected across the DC circuit breaker generates an expanding current oscillation with a frequency range of 1–3 kHz. A circuit breaker that can generate a high arc voltage across the contacts (e.g., air) is advantageous when attempting to create a rapidly growing oscillation. A larger capacitance can also facilitate a rapidly expanding oscillation, and there is an optimal reactance to achieve this too. This scheme is often applied to metallic return transfer breakers (MRTBs), which clear faults generated on the neutral return line due to a lightning stroke and commute currents of up to a few thousand amperes to the neutral line in the HVDC transmission line after fault clearing. This scheme generally requires 20–40 ms to create a current zero for a fault interruption of a few thousand amperes.

#### (c) Active Resonant Current Zero Creation Scheme (Active Current Injection Scheme)

This scheme utilizes an external voltage source that can inject a high-frequency reverse current with respect to the DC current, immediately creating a current zero. The external voltage source consists of a precharged capacitor with a reactor and a high-speed switch (e.g., a thyristor switch, a triggering gap, or a mechanical switch) imposes a high-frequency (several kHz) inverse current on the interrupting fault and nominal DC current. This scheme is potentially applicable to the interruption of HV DC fault currents in multiterminal HVDC networks, even though a large capacitor is required in accordance with the DC system voltage. A prototype HV DC circuit breaker that uses this scheme with a HV AC vacuum interrupter has been shown to interrupt faults in up to 16 kA DC within 8–10 ms.

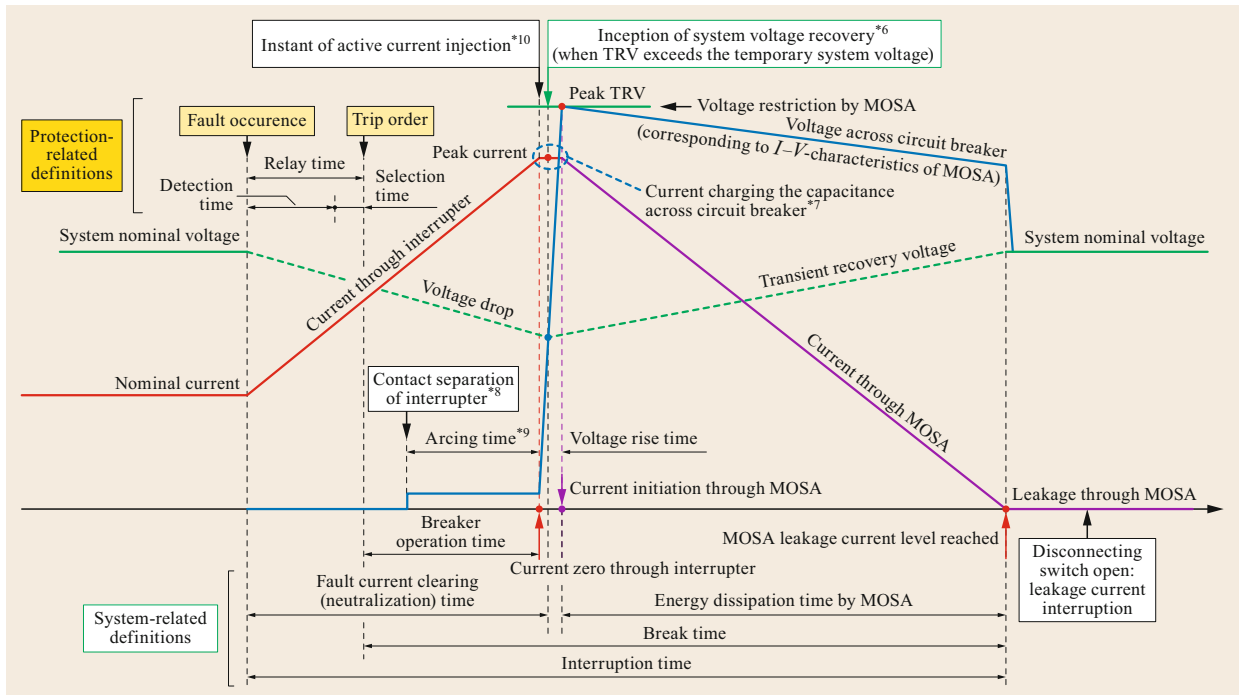

#### (d) Hybrid Mechanical and Power Electronic Switch

This breaker is composed of both mechanical switches and power electronic (semiconductor) devices. The DC circuit breaker commutates the DC fault current from the main circuit, consisting of a high-speed mechanical switch and a commutating power electronic device, to series- and parallel-connected power electronic (IGBT) devices that can block the current within a few ms. A prototype 230 kV DC circuit breaker that was placed in service in multiterminal HVDC networks in China and a 500 kV DC circuit breaker were shown to interrupt 25 kA DC in less than 3 ms. Due to the rapid progress in high-voltage, large-capacity, and low-loss power electronic device technology, this scheme may be applied to AC circuit breakers in the future.

### 8.5.3 DC Current Interruption

Figure 8.148 shows the typical voltage and current behavior during a DC fault current interruption using a mechanical DC circuit breaker with active current injection.

When a fault occurs in a DC system, the fault current through the interrupter unit increases and the system voltage starts to drop. After fault detection, a trip command is issued to the DC circuit breaker and an interrupting unit (typically a vacuum interrupter) starts to open the electrodes. As soon as the vacuum interrupter has secured a sufficient contact gap, the active resonant current injection circuit imposes a high-frequency current with a reversed polarity on the DC current and immediately creates a current zero. When

**Fig. 8.148** Voltage and current behavior during DC current interruption using a mechanical DC circuit breaker with an active current injection scheme. Notes: \*<sup>6</sup> The voltage recovery is initiated when the voltage across the breaker (TRV) exceeds the temporary system voltage. The current through the MOSA is initiated when the TRV is clipped at the restriction voltage by the MOSA. \*<sup>7</sup> The time taken to charge the capacitance across the DC circuit breaker. The capacitance required for active current injection by a mechanical DC circuit breaker is on the order of microfarads. \*<sup>8</sup> The specially designed mechanical DC breaker requires a few milliseconds to open the electrodes (or separate the contacts) after receiving a trip order. \*<sup>9</sup> The arc voltage across the vacuum interrupter is almost constant after contact separation regardless of the contact gap. \*<sup>10</sup> The fault current through the vacuum interrupter is forced to make a current zero at the instant of active current injection, and the vacuum interrupter can immediately interrupt this high-frequency current

the vacuum interrupter can interrupt the high-frequency current, the voltage across the DC circuit breaker suddenly increases and exceeds the system voltage. It is then clipped (limited) by the MOSA restriction voltage (which is typically 1.5 times higher than the system voltage). The transient system voltage begins to recover to the nominal voltage and the MOSA dissipates the energy stored by the inductance in the DC system.

In contrast, Fig. 8.149 shows the typical voltage and current behavior during a DC fault current interruption using a hybrid mechanical and power electronic DC circuit breaker with IGBT devices.

In this case, when a fault occurs in a DC system, the fault current through the interrupter unit increases and the system voltage starts to drop as described before. After fault detection, an intermediate order is issued to turn off the load-commutating IGBT devices in order to commutate the current to the power electronic branch (power electronic interrupter unit, which consists of many IGBT devices connected in series and parallel), and an ultra-

fast disconnecting switch connected to the main circuit opens the commutation branch. When the current starts to commutate to the power electronic branch, the voltage across the hybrid DC circuit breaker increases with the current due to the resistance of the power electronic devices. When a trip command is issued after the current has been fully commutated, the power electronic branch turns off all of the IGBT devices and blocks the current. After the current has been blocked, the voltage across the DC circuit breaker suddenly increases and exceeds the system voltage. Then the voltage across the DC circuit breaker is clipped at the restriction voltage by the MOSA. The transient system voltage begins to recover to the nominal voltage and the MOSA dissipates the energy stored by the inductance in the system.

Figure 8.150 shows a magnified plot of the voltage and current behavior from the instant that there is a current zero through the interrupter branch until the instant that the voltage across the DC circuit breaker is clipped by the MOSA. The capacitance (stray capacitance when

**Fig. 8.149** Voltage and current behavior during DC current interruption using a hybrid mechanical and power electronic DC circuit breaker. Notes: <sup>\*1</sup> Any order before the order to start the interruption process (such as operations referred to in notes <sup>\*2</sup> and <sup>\*3</sup>). <sup>\*2</sup> The instant at which the load-commutating IGBT devices are turned off immediately after fault detection. The voltage across the hybrid DC breaker increases with the current. <sup>\*3</sup> The instant at which the ultrafast disconnecter in the commutation branch (main circuit) is opened. <sup>\*4</sup> The time required to commutate the fault current from the commutation branch using the load-commutating IGBT devices to the power electronic branch of the main breaker. <sup>\*5</sup> The instant at which the power electronic branch in the main breakers is turned off, which immediately blocks and interrupts the current after a time delay to secure the voltage withstand of the ultrafast disconnecter. <sup>\*6</sup> The voltage recovery is initiated when the voltage across the breaker (TRV) exceeds the temporary system voltage. Current flow through the MOSA is initiated when the TRV is clipped at the restriction voltage by the MOSA. <sup>\*7</sup> The stray capacitance across the DC circuit breaker is charged during the period of rising voltage. <sup>\*8</sup> The specially designed mechanical DC breaker requires a few milliseconds to open the electrodes (or separate the contacts) after receiving a trip order

using the hybrid DC circuit breaker) across the DC circuit breaker begins charging when the current is forced to the current zero by either current injection or current blocking.

During the charging of the capacitor, the current that charges the capacitance is almost constant and the voltage starts to recover. When the recovery voltage attains the restriction voltage imposed by the MOSA, the charging current to the capacitance stops, and the current through the MOSA is initiated and then gradually decreases in accordance with the  $I-V$  characteristic of the MOSA unit.

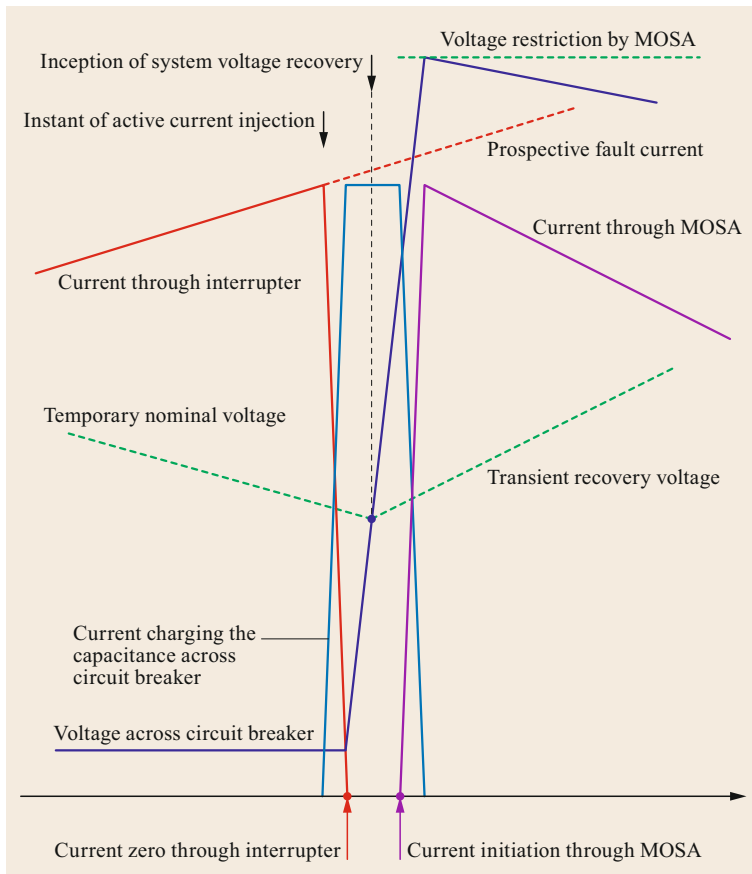

#### 8.5.4 MV and LVDC Circuit Breakers

Figure 8.151 shows a 480 V, 10 kA DC circuit breaker (a molded case circuit breaker, MCCB) that employs

the arc voltage current limiting scheme and is used in industrial applications. When the arc voltage between the electrodes of the MCCB is higher than the system voltage, it limits the current and rapidly creates a current zero for about 5 ms. Figure 8.152 shows an example of the current behavior during DC current interruption (where  $t_1$  is the time to the MCCB trip current level,  $t_2$  is the contact separating time,  $t_3$  is the time from contact parting to peak current,  $t_4$  is the arcing time,  $t_T$  is the total interruption time, and  $q$  is the rate of rise of the current).

Figure 8.153 shows a 1500 V DC circuit breaker used in track power systems that employs the active resonant current zero creation scheme and has an interrupting capability of up to 100 kA. It is equipped with a thyristor switch to impose a reverse current from an external DC power source onto the DC fault cur-

**Fig. 8.150** Voltage and current behavior from the instant at which there is a current zero through the interrupter until MOSA activation

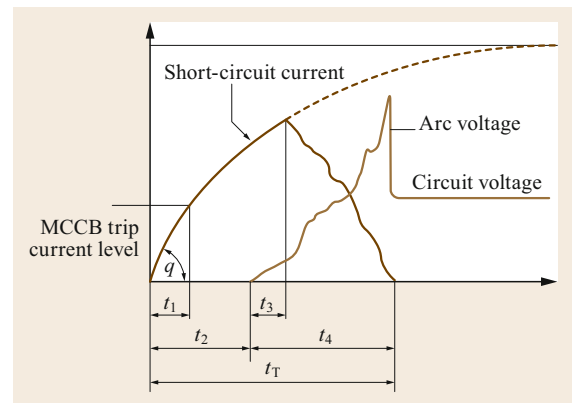

rent and immediately create a current zero. Figure 8.154 shows typical oscillograms obtained when the DC circuit breaker interrupts the fault current within a few milliseconds. After the vacuum interrupter has interrupted a high-frequency current at the current zero, the

voltage recovers to the system voltage and the MO surge arrester dissipates the energy in the circuit.

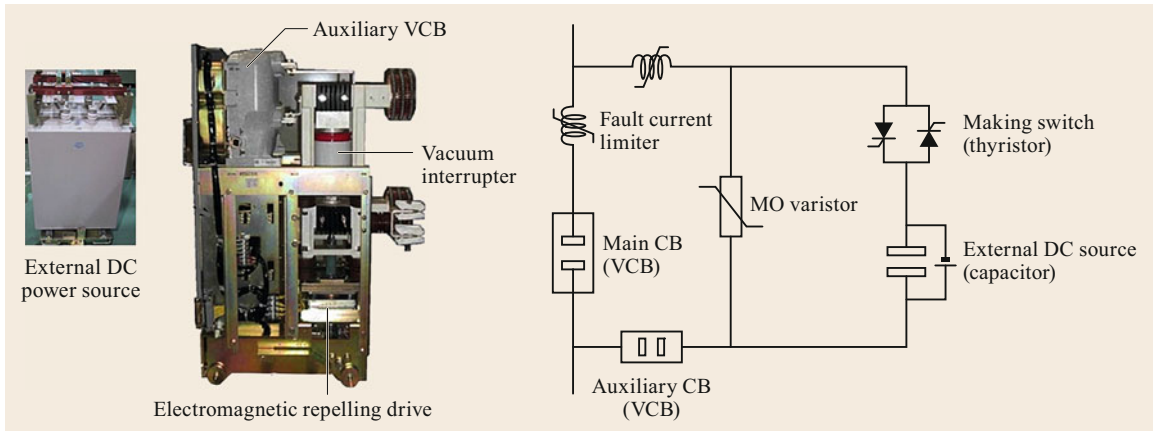

Figure 8.155 shows a 550 kV, 2200 A DC circuit breaker that uses the passive resonant current scheme (often termed MRTB; this breaker is used in the Pacific

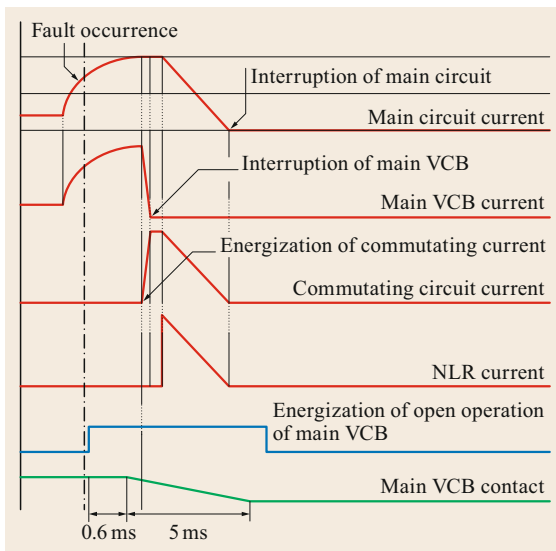

**Fig. 8.151** LV DC circuit breakers that use the arc voltage current limiting scheme. (Courtesy of Mitsubishi Electric)

**Fig. 8.152** Oscillograms showing the behavior of the current during an interruption performed by a LV DC circuit breaker using the arc voltage current limiting scheme

**Fig. 8.153** MV DC circuit breakers that use the active resonant current zero creation scheme, along with the relevant circuit diagram

**Fig. 8.154** Oscillograms showing the behavior of the current during an interruption performed by a MV DC circuit breaker using the active resonant current zero creation scheme

DC Intertie in the United States) [8.76]. This breaker can clear a DC fault generated in a neutral line by performing a closing operation and commutating the current back to the neutral line after fault clearing. Figure 8.156 presents oscillograms showing typical current and voltage behavior during the expansion of the current oscillation that is used to create the current zero.

### 8.5.5 Behavior When Using the Passive Current Creation Scheme

When using the passive resonant current zero scheme, a DC current interruption is initiated by separating the

arcing contacts. A change in the state of the arc during interruption (e.g., a local extension or short circuit of the arc caused by the gas flow) manifests as small perturbations of the arc voltage and arc current, which continue to grow when the circuit conditions are unstable and eventually lead to a current zero.

The influence of small perturbations of the arc voltage and arc current on current oscillation can be evaluated through a combined analysis of the interruption circuit and a mathematical model of the arc. An example of an investigation of the expanding current oscillation phenomenon in case of the passive resonant current zero creation scheme, and the optimization of the inductance and capacitance connected in parallel with the circuit breaker can be evaluated by the simulation with a mathematical arc model.

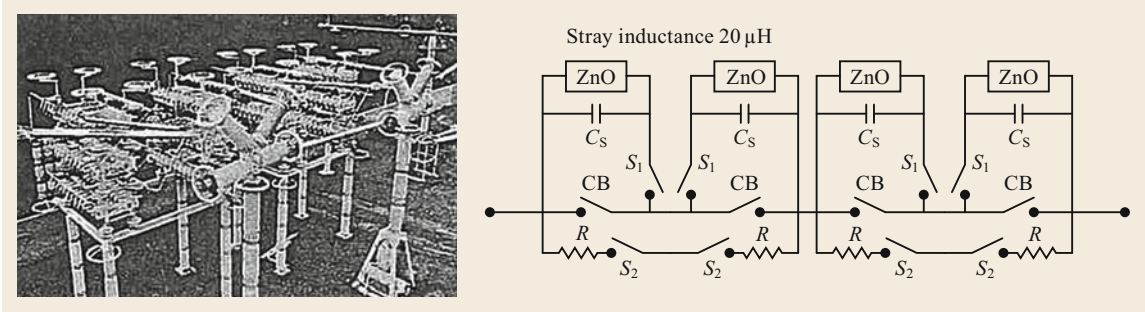

The Mayr arc model has two parameters (the time constant of the arc  $\theta$  and the arc power loss  $n$ ) that express the exchanging sensitivity (energy balance of the arc) of thermal energy between the arc and the gas around it (see Eq. (8.7) below). In addition, using the circuit shown in Fig. 8.157 for a DC circuit breaker that utilizes the passive resonant current zero scheme, the behavior of the arc voltage ( $v_a$ ) and the arc current ( $i_a$ ) in the DC circuit breaker can be expressed as in (8.7–8.10), and their behavior in the circuit can be expressed via (8.8–8.10)

$$\frac{dr_a}{dt} = \frac{r_a}{\theta} \left( 1 - \frac{v_a i_a}{n} \right), \quad (8.7)$$

$$\frac{dv_e}{dt} = \frac{i_0 - i_a}{C_e}, \quad (8.8)$$

$$L_e \frac{d(i_0 - i_a)}{dt} = v_a - v_e - r_e (i_0 - i_a), \quad (8.9)$$

$$v_a = r_a i_a. \quad (8.10)$$

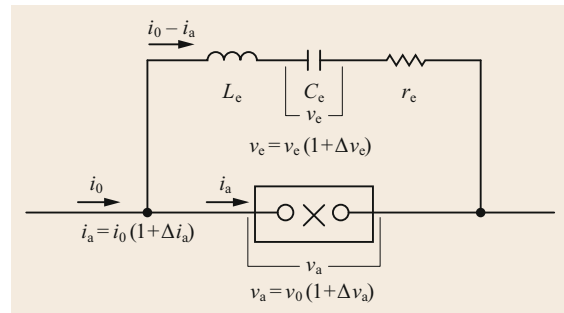

**Fig. 8.155** Photograph of HV DC circuit breakers that use the passive resonant current zero creation scheme, and the relevant circuit diagram [8.76]

**Fig. 8.156** Oscillograms showing the behavior of the current during an interruption performed by a HV DC circuit breaker using the passive resonant current zero creation scheme [8.76]

In these equations,  $i_a$ ,  $r_a$ ,  $L_c$ ,  $C_c$ , and  $r_c$  represent the interruption current, arc resistance, parallel reactance, parallel capacitance, and stray resistance, respectively.  $v_c$  is the voltage across the capacitor. When the arc current  $i_a = i_0$  and the arc voltage  $v_a = n/i_0$ , (8.7) is balanced and the arc current and arc voltage remain constant.

The response to a small perturbation of the arc current  $\Delta i_a$  can be obtained via (8.7) to (8.10) using the

**Fig. 8.157** Circuit configuration for a DC circuit breaker that uses the passive resonant current zero scheme [8.77]

perturbation method, which yields

$$L_c \frac{d^3 \Delta i_a}{dt^3} + \left( \frac{L_c}{\theta} + r_c + \frac{n}{i_a^2} \right) \frac{d^2 \Delta i_a}{dt^2} + \left( \frac{r_c}{\theta} + \frac{1}{C_c} - \frac{n}{\theta i_a^2} \right) \frac{d \Delta i_a}{dt} + \frac{1}{\theta C_c} \Delta i_a = 0. \quad (8.11)$$

This differential equation has either three real solutions or one real and two complex solutions. When the differential equation has two complex solutions,  $\Delta i_a$  is an oscillatory mode. When the real part of the complex solution is positive, the solution  $\Delta i_a$  is unstable and the perturbation grows with continuing oscillation. When the differential equation has only real solutions,  $\Delta i_a$  is a nonoscillatory mode (it increases monotonically when at least one real solution is positive, and it decreases monotonically when all real solutions are negative).

An oscillatory mode is required for a DCCB that uses the passive resonant scheme. Assuming that differential (8.11) can be factorized as in (8.12) below, the general solution of (8.12) for an oscillatory mode is (8.13)

$$(p - \alpha_0)(p - \alpha_1 - j\omega)(p - \alpha_1 + j\omega) = 0, \quad (8.12)$$

$$\Delta i_a = \Delta_0 e^{\alpha_0 t} + \Delta_1 e^{\alpha_1 t} (\sin \omega t + \varphi). \quad (8.13)$$

**Fig. 8.158a,b** Calculated effects of the parallel inductor (reactor) and parallel capacitor on the amplification coefficient (a) and the angular frequency (b) of current oscillation

It can be shown that the amplification coefficient  $\alpha_1$  and the angular frequency  $\omega$  can be expressed as the function with six parameters ( $C_c$ ,  $L_c$ ,  $r_c$ ,  $n$ ,  $\theta$ , and  $i_0$ ). When the arc parameters  $n$  and  $\theta$ , the interruption current  $i_0$ , and the stray resistance  $r_c$  are constant, the relationships of the amplification coefficient  $\alpha_1$  and the angular frequency  $\omega$  to the passive resonant circuit parameters  $C_c$  and  $L_c$  can be obtained.

Figure 8.158 shows the calculated effects of varying the parallel reactance and parallel capacitor on the amplification coefficient and the angular frequency of the current oscillation under specified circuit conditions (interruption current  $i_0 = 3500$  A, stray resistance  $r_c = 0.2 \Omega$ , arc time constant  $\theta = 40 \mu\text{s}$ , and arc power loss  $n = 10$  MW). This figure indicates that, for a given capacitance, there is an optimum reactance at which the amplification coefficient is maximized. Also, the angular frequency  $\omega$  decreases as the circuit parameters  $C_c$  and  $L_c$  increase.

To ensure that the current oscillation grows and eventually produces a current zero,  $C_c$  and  $L_c$  must be selected such that the amplification coefficient becomes positive. For example, when the capacitance is  $30 \mu\text{F}$ , more than  $50 \mu\text{H}$  of parallel reactance is required, although increasing the parallel reactance also increases the time until current zero.

A circuit breaker has a limited arc time (less than about 30 ms) to enable interruption, which does not depend on the interruption scheme used (double-pressure type or single-pressure type). Therefore, it necessary to find a combination of parallel reactance and capacitance that causes the oscillation to produce a current zero within the limited arc time to facilitate interruption.

Figure 8.159a shows the arc voltage and arc current waveforms obtained during an interruption test of

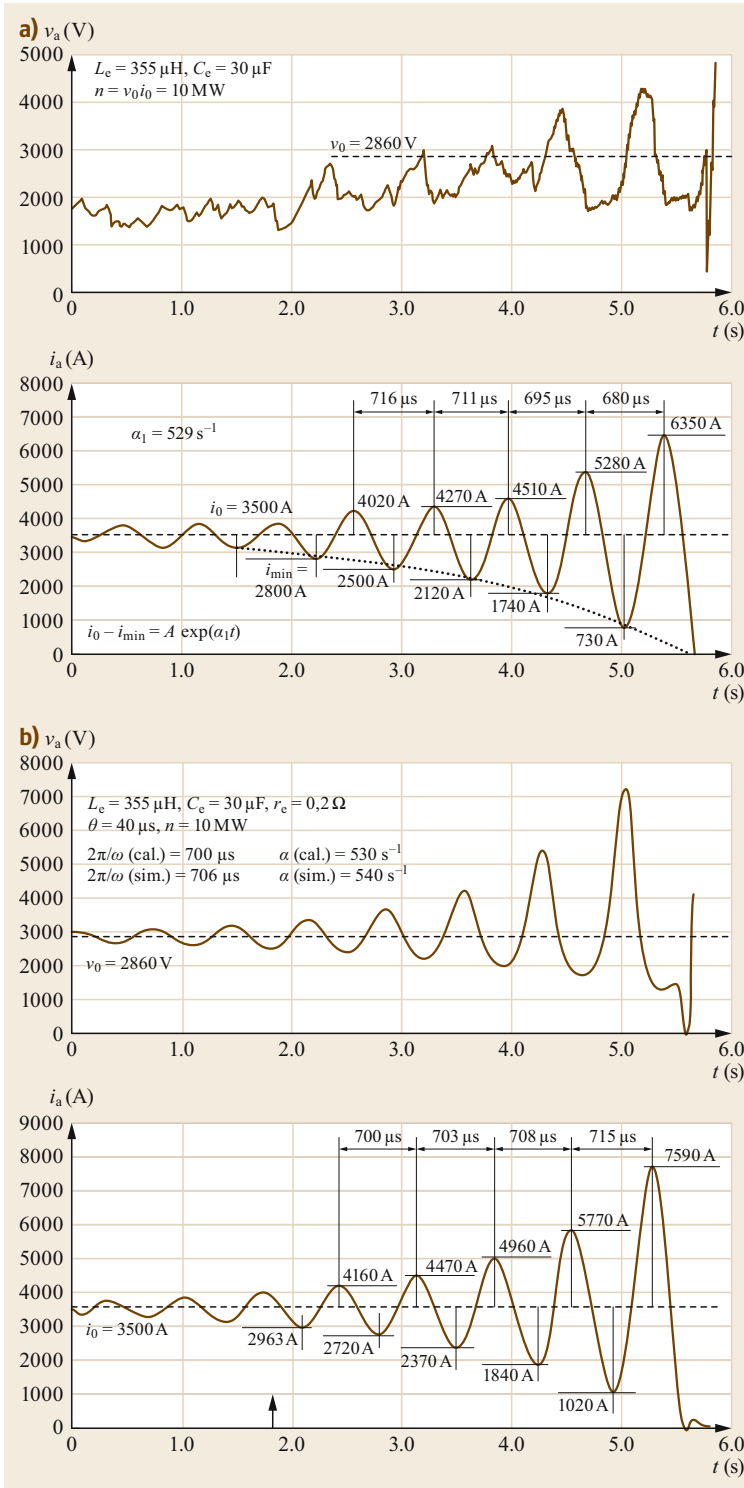

a DC current generation circuit consisting of a three-phase rectifier circuit and a smooth reactor. In this case, the interruption current was 3500 A, and the parallel reactance  $L_c$  and capacitance  $C_c$  were  $350 \mu\text{H}$  and  $30 \mu\text{F}$ , respectively. The stray resistance was  $0.2 \Omega$ . The model breaker was a puffer-type  $\text{SF}_6$  gas circuit breaker. The arc power loss from the arc voltage and interruption current was 10 MW, and the arc constant  $\theta$  estimated from the amplification coefficient and angular frequency was  $40 \mu\text{s}$ . Figure 8.159b shows the calculated waveform, which accurately reproduces the observed waveform shown in Fig. 8.159a. It can be seen that the calculated result reproduces both the amplification coefficient and the angular frequency of the test waveform well.

### 8.5.6 Field Experience of MRTB

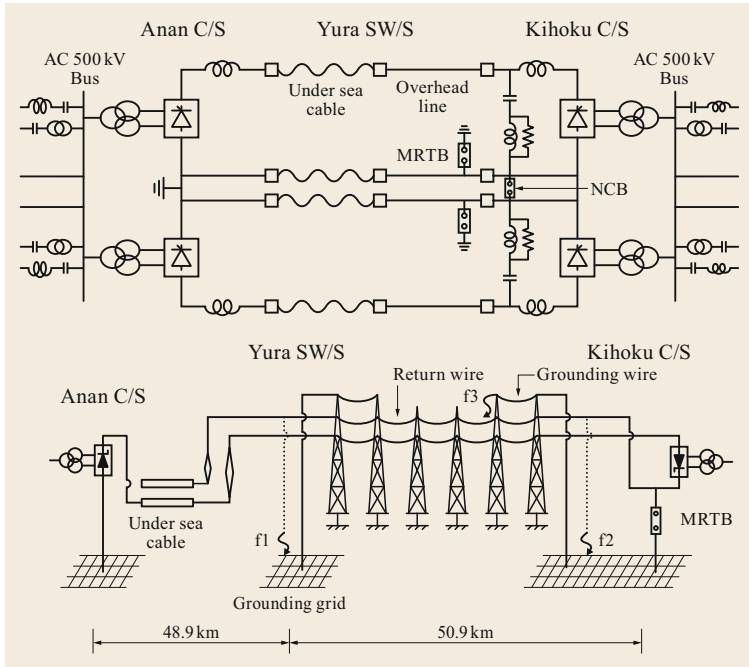

When a DC fault occurs at one pole of a bipolar HVDC system, the operational mode should be shifted from bipolar operation to monopolar operation. In some applications, monopolar operation also requires a switch from ground return to metallic return using the faulted transmission line.

The MRTB connected to the neutral metallic return line is used to clear a DC grounding fault by performing a closing operation. The return current is split into two paths: the ground return and the ground wire. Since the MRTB is directly earthed to the grounding mesh, connection to the MRTB reduces the voltage between the fault point on the neutral line to the ground. Accordingly, an arc generated due to a lightning strike cannot maintain its voltage and the current is rapidly reduced to current zero.

After clearing the DC fault, the MRTB is opened to commutate the current to the neutral metallic re-

**Fig. 8.159a,b** Comparison of the experimental (a) and simulated (b) current and voltage behavior of a MRTB

**Fig. 8.160** Bipolar HVDC system with neutral metallic return lines [8.78]

turn line and thus return to healthy bipolar operation. Figure 8.160 illustrates the system configuration of a real-world bipolar HVDC system with two neutral metallic return lines. Each pole can be operated independently to ensure continued power transmission during maintenance work on one pole or a fault occurrence in one of the metallic transmission lines.

Since the MRTB was first installed in 2000, it has been operated more than 300 times, successfully clearing faults in the neutral line. Figure 8.161 shows an oscillogram obtained when a lightning fault occurred at a transmission tower about 18 km from C/S (converter station). It can be seen that the return line current drops and is commuted to the MRTB. Furthermore, the MRTB interrupts the commuted current 300 ms after closing, and then the return line voltage recovers and the system returns to a healthy condition.

### 8.5.7 Application of the Active Resonant Current Injection Scheme in HVDC Circuit Breakers

A mechanical DC circuit breaker consisting of a HV vacuum interrupter with a rapidly operating mechanism was tested with currents of up to 16 kA [8.80]. In this circuit breaker, the active resonant current zero creation scheme superimposes the high-frequency current with the reverse polarity (as compared with the polarity of DC current) on the DC current to create a zero current on the DC fault current, which was achieved by dis-

charging a precharged capacitor connected in parallel with the interrupter. The MOSA unit of the DC circuit breaker was designed to dissipate up to 4 MJ of energy after current interruption.

Figure 8.162 shows the HVDC circuit breaker test conducted at the KEMA laboratory as a part of the research and innovation program known as the Horizon 2020 project, funded by the European Union under

**Fig. 8.161** MRTB operation during a lightning fault at a transmission tower

**Fig. 8.162** Photograph of the setup for a HVDC circuit breaker test conducted at the DNV GL/KEMA laboratories [8.79]

grant agreement no. 691714 [8.79]. Figure 8.163 shows a schematic of the test circuit of the DC circuit breaker.

The active resonant circuit consisted of a capacitor ( $C_p$ ) as well as a reactor ( $L_p$ ), a spark gap, and a MOSA that were connected in parallel to  $C_p$ . For the DC circuit breaker interruption tests, the discharge time of the precharged  $C_p$  (kept at a constant applied voltage) had a delay of only a few ms following con-

tact separation of the vacuum interrupter. The active resonant discharge created a current zero by superimposing a high-frequency inverse current injected by the series-connected capacitance  $C_p$  and reactance  $L_p$ . The interrupting current was supplied by an AC current source that provided an equivalent DC current when the DC circuit breaker interrupted a peak current from a power-frequency short circuit.

Test conditions were determined in accordance with the dielectric requirements for a high-voltage AC circuit breaker, and the DC interrupting currents ranged from 0.5 kA (corresponding to the nominal current) up to 16 kA.

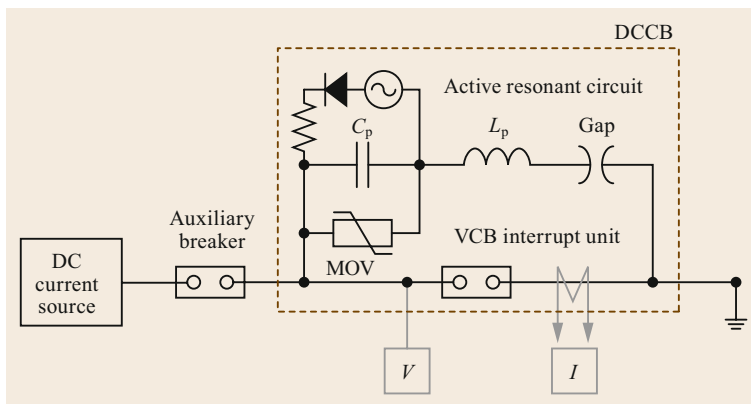

Figure 8.164 shows the full test-sequence waveforms and magnifications of those waveforms recorded during interruption tests on the DC circuit breaker using interrupting currents of 16 and 5 kA. Tests showed that the DCCB successfully interrupted the first current zero created by an injected current when it was used to interrupt currents of 16 and 5 kA.

The rate of rise of the recovery voltage (given by  $L_p di/dt$ ) becomes steeper as the interrupting current decreases. The overvoltage generated after interruption is determined as

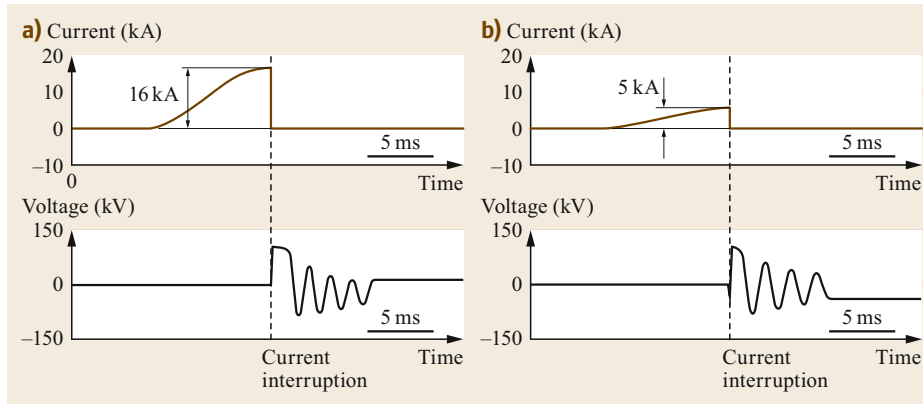

$$V_p = k \sqrt{\frac{L_s}{C_p}} I, \quad (8.14)$$

where  $L_s$  is the inductance of the source circuit,  $C_p$  is the capacitor connected in parallel with the interrupter unit,  $I$  is the breaking current, and  $k$  ( $< 1$ ) is a damping factor caused by stray resistance of each component of the circuit. Therefore, the overvoltage ( $V_p$ ) increases with increasing breaking current  $I$ , but it is limited by the restriction voltage of the MOSA connected in parallel to  $C_p$ .

During a CIGRE session in 2018, China reported the application of a 160 kV, 9 kA mechanical DC circuit breaker with active resonant current injection to

**Fig. 8.163** Test circuit for a DC circuit breaker utilizing the active resonant current zero creation scheme

**Fig. 8.164a,b** Voltage and current behavior of DC CB with current injection scheme tested at interrupting currents of DC 16 and 5 kA

**Fig. 8.165** Photograph of a 160 kV, 9 kA mechanical DC circuit breaker with current injection [8.81]

three terminal HVDC grids (Fig. 8.165). They also conducted an artificial grounding test and confirmed that the DC circuit breaker was able to clear a 1.4 kA DC fault within 3.5 ms.

### 8.5.8 Hybrid Mechanical and Power Electronic Switch

The configuration of a hybrid mechanical and power electronic switch is shown in Fig. 8.166 [8.82]. This type of DC circuit breaker consists of a load com-

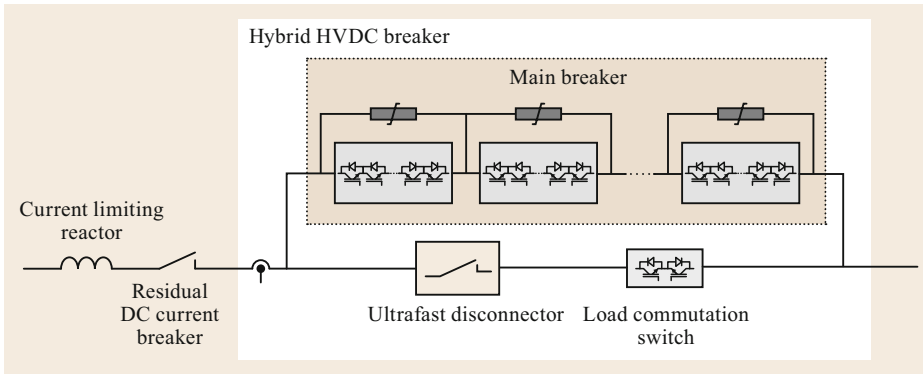

mutation switch, an ultrafast disconnecter, and a main breaker branch. The load commutation switch has a few power electronic devices. This switch can rapidly commute the DC current to the main breaker branch after receiving a trip command. The ultrafast disconnecter is a fast-opening mechanical switch that isolates the load commutation switch from the main breaker during interruption. The main breaker consists of a large number of power electronic devices (IGBTs) connected in series and in parallel. MOSAs are connected in parallel across the main breaker branch to limit the overvoltage after the main breaker interruption.

Figure 8.167 shows the sequence of operations for this type of DC circuit breaker. During normal operation, the load current flows through the load commutation switch and ultrafast disconnecter (Fig. 8.167a). Since the few power electronic devices in the load commutation switch are small and the ultrafast disconnecter is a mechanical switch, the on-state loss from this current path is relatively low.

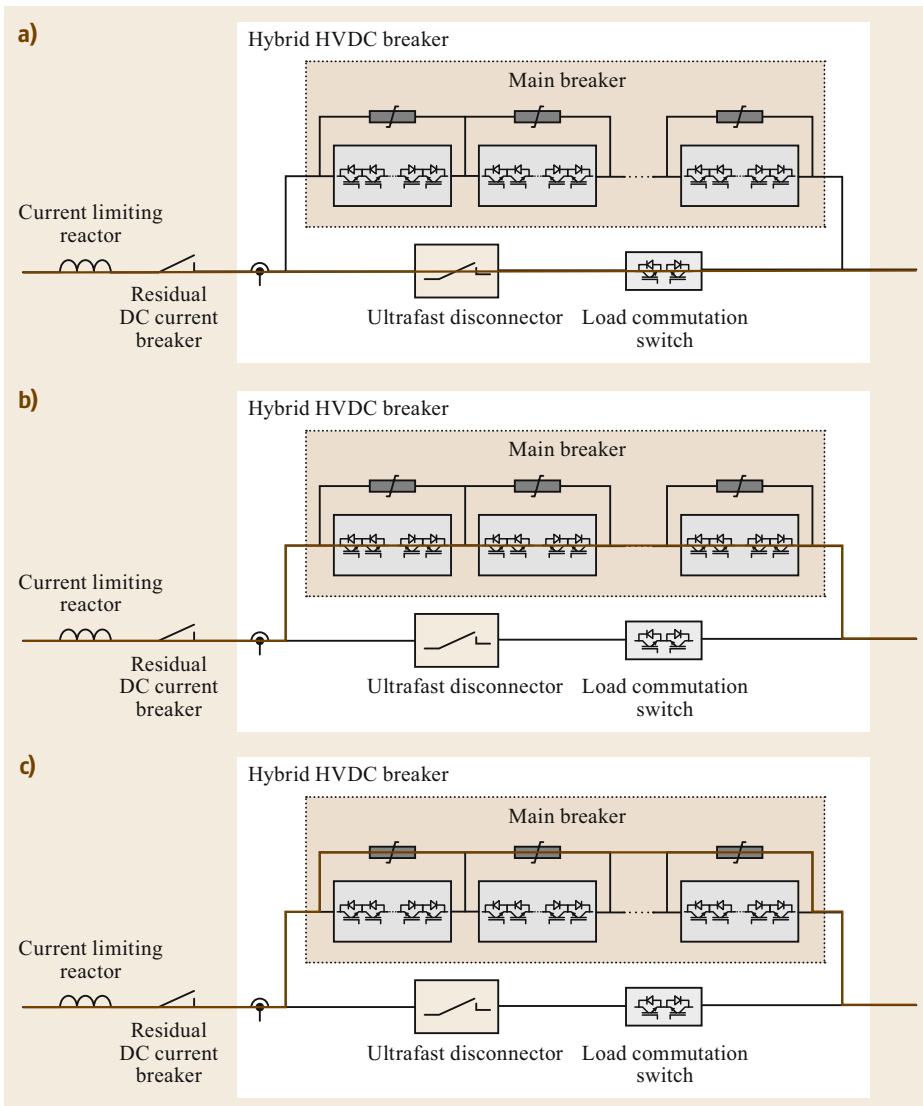

When the DC circuit breaker receives a trip command, the load commutation switch turns off, which commutates current into the main breaker branch (Fig. 8.167b). After current commutation, the ultrafast disconnecter opens. The power electronic devices in the main breaker branch are turned off after a time delay determined by the time needed for the ultrafast disconnecter to achieve the required voltage withstand. Upon turning the main breaker off, the current commutates to the MOSA and the MOSA dissipates energy (Fig. 8.167c). When the current reaches zero, the residual DC current breaker outside the DC breaker opens and interruption is completed.

Figure 8.168 shows test results for an 80 kV hybrid mechanical and power electronic switch. In this test, the DC circuit breaker interrupted a fault current of about 9 kA.

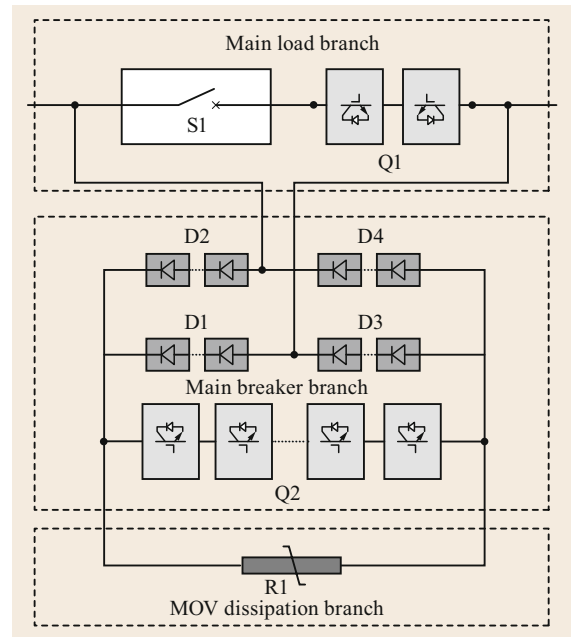

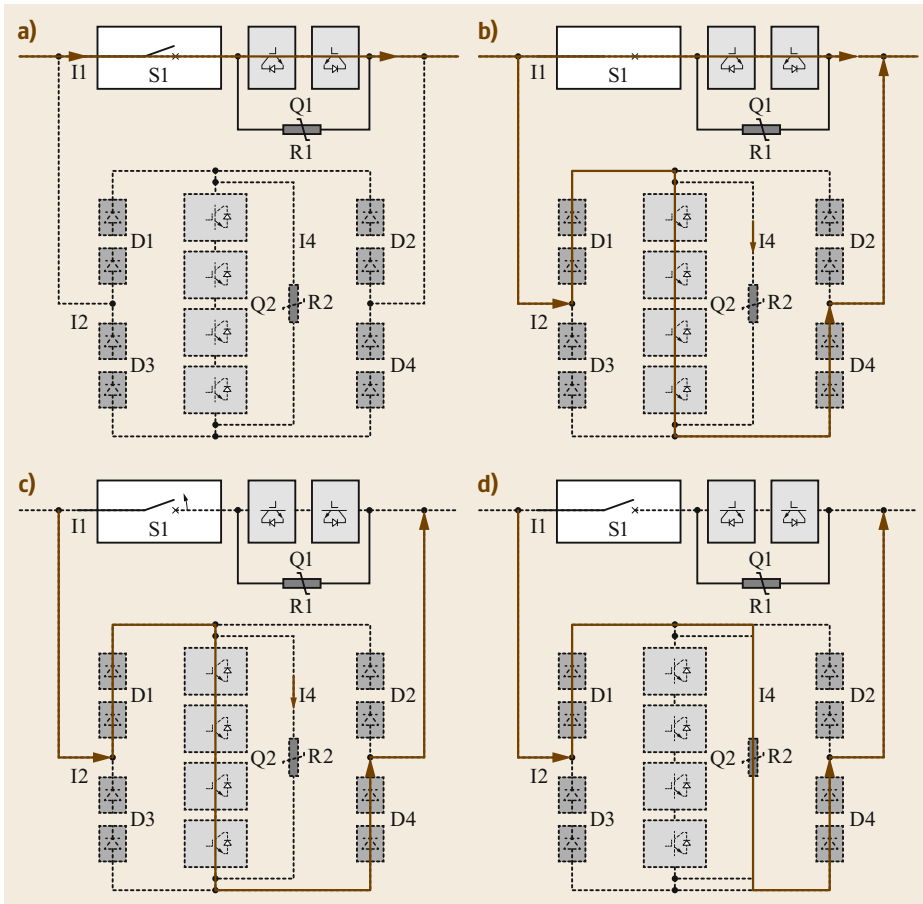

Fig. 8.170 Configuration of the hybrid 500 kV DC circuit breaker

Figure 8.169 shows a photograph of a prototype 535 kV, 26 kA hybrid mechanical and power electronic DC circuit breaker [8.83], and Fig. 8.170 shows its configuration. The hybrid HVDC circuit breaker consists of a main load branch and a main breaker branch. The main load branch includes a fast mechanical switch and an IGBT commutation module. The main breaker

branch consists of series-connected IGBT modules with several diodes and an energy-dissipating MOSA connected in parallel. Figure 8.171 shows the DC current interruption process for the 535 kV DC circuit breaker. A prototype 220 kV hybrid mechanical and power electronic DC circuit breaker of this design has already been installed in a multiterminal HVDC grid in China [8.84].

**Table 8.18** Main switching duties of disconnecting switches (DSs) used in bipolar HVDC systems

Switching duty	DS group in Fig. 8.172	Switching duty	Specification
Line discharging current switching	A1, A2, A3	Interrupt the line discharging current that flows through a snubber circuit in the converter resulting from charge remaining in the lines after the converter has been stopped.	HVDC 0.1 A
No-load line transfer current switching	B	Switch a circuit connected between a no-load positive line and a negative line when a phase-to-ground fault has occurred along the lines. The system is stopped prior to DS operation.	HVDC 0.1 A
Loop current switching	C1, C2	Transfer the loop current through a disconnecting switch (DS) to a bypass switch (BPS) connected in parallel with a converter unit by opening the DS when the converter stops operating. Closing duty is also required when a converter unit starts operating.	LVDC 2800 A
Converter charging current switching	D1, D2	Interrupt the charging current through a converter unit when the converter stops operating. The current present during converter operation includes a ripple current. When the converter unit starts operating, a closing surge is generated by DS operation.	HV DC 1 A

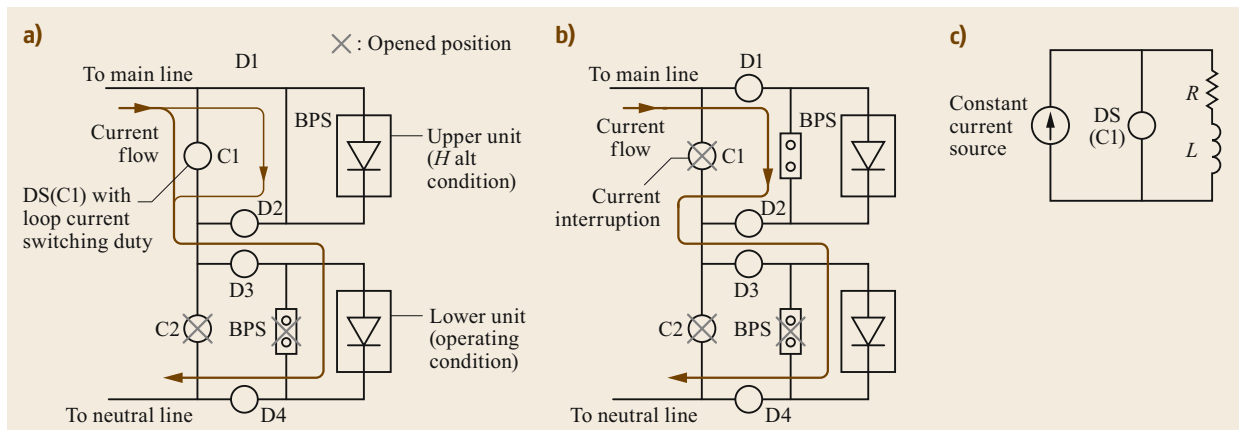

### 8.5.9 HVDC Disconnecting Switches

HVDC disconnecting switches (DSs) are used to disconnect various circuits in HVDC transmission networks. For example, HVDC DSs are used for switching duties such as line or cable charging current switching and no-load line or cable transfer switching, and for disconnecting equipment such as a converter bank (thyristor valve), filter bank, and grounding line. HVDC DSs are also used in DC switchgear to terminate the residual or leakage current through an interrupter after a fault current has been cleared.

Figure 8.172 shows an example of a single-pole diagram of the relevant switching equipment (except for MRTBs) in a bipolar HVDC transmission system in Japan. In general, the requirements for HVDC DSs and earthing switches (ESs) in the HVDC system are similar to those for HVAC DSs and ESs used in the AC system,

but there are additional requirements for some equipment, depending on their applications. Table 8.18 lists the major switching duties imposed on these HVDC DSs [8.66].

- Group A:** Here, the DS is required to interrupt the line discharging current resulting from residual charge in a submarine cable with a relatively large capacitance (approximately  $20 \mu\text{F}$ ). The residual voltage induced in the line after a converter halt is discharged through a snubber circuit in a converter bank at both C/Ss (Anan C/S and Kihoku C/S) to ground. The discharge time constant is about 40 s, which corresponds to a discharging time of 3 min. The discharge current was set to 0.1 A based on the value calculated from the residual voltage of 125 kV and the resistance of the snubber circuit in the thyristor valve.

**Fig. 8.173a–c** Current transfer process for a group C DS. (a) DS closed, (b) DS open, (c) equivalent circuit of the DS ( $R$ ,  $L$ : resistance and induction of loop circuit)

Fig. 8.174 Voltage difference between the DS contacts

- **Group B:** In this case, the DS is normally used to switch a faulted transmission line to a healthy neutral line that is temporarily or permanently used for transmission after the system has been completely stopped. This requires the same specifications as those for group A DSs.
- **Group C:** These DSs are required to transfer the nominal load current from the DS to a bypass switch (BPS) connected in parallel with a converter bank in order to restart the bank unit. The specification of the transfer current is 2800 A in this project.

Figure 8.173 illustrates the nominal current transfer process from the DS to the BPS. First, the upper converter bank unit is stopped and the lower converter bank unit is operated. In order to operate the upper bank unit from a halted condition, DS C1 is then opened to commutate the nominal current into the BPS. The requirements

for group C DSs are based on an analysis of the equivalent circuit for the current transfer process (shown in Fig. 8.173c) and a voltage of 1 V DC at a nominal current of 2800 A. The voltage was calculated for a resistance and inductance per unit length corresponding to the current transfer length including the DC-GIS.

- **Group D:** In this case, the DS is required to interrupt a converter bank charging current when the converter bank unit is stopped. Even if the thyristor valve is halted, a ripple current flows due to the stray capacitance of the converter bank. Analytical results show that the ripple current is very likely to be chopped to less than 1 A, and that the recovery voltage due to the difference between the residual DC voltage on the converter side and the DC voltage on the line side (which includes ripple components) is less than 70 kV, as shown in Fig. 8.174.

Furthermore, the DS is equipped with a closing resistor of 1 k $\Omega$  to suppress switching surges caused by the operation of the DS. Figure 8.175 shows a schematic of the DS with the closing resistor, as well as the closing sequence. Although this resistor is used to suppress the closing surge, the resistor is also included during the opening sequence due to the design of the DS.

The switching performance of HVDC DSs (all groups) is based on that of AC DSs, and HVDC DS performance is established in factory tests performed

Fig. 8.175 DC 500 kV DS with a closing resistor and the closing sequence used

**Fig. 8.176** DC DSs, ESs, CTs, VT, and a MOSA (labeled LA in the photograph) used in the 500 kV DC GIS

under the conditions shown in Table 8.18. There are no significant design differences between HVAC DSs and HVDC DSs except for the creepage distance, which is about 20% longer for HVDC applications.

DC gas-insulated switchgear (DC-GIS) consisting of several HVDC DSs and ESs are also applied in HVDC networks close to a coastline. Figure 8.176 shows an example of DC-GIS (including DC DSs and ESs) that was installed at a converter station in a bipolar HVDC system commissioned in 2000.

### 8.5.10 Summary

DC circuit breakers with different current zero creation schemes have been applied in many industrial applications. MRTBs are commonly applied in bipolar HVDC systems. However, field demonstrations of HVDC circuit breakers in multiterminal HVDC networks are still awaited. CIGRE provides continuous updates on the development of and progress in HV circuit breaker technologies that are applicable to future multiterminal HVDC networks.

DC circuit breakers with active current injection and hybrid DC circuit breakers with IGBT devices have been developed for use up to the 80 kV, 16 kA and 500 kV, 25 kA levels, respectively.

Air- and gas-insulated HVDC disconnecting switches (DSs) have been applied in many bipolar HVDC systems. There are no significant design differences between HVAC DSs and HVDC DSs except for the creeping distance, which is about 120% longer for HVDC applications.

**Acknowledgments.** This chapter focuses on the basics of power-system switching equipment for the benefit of students as well as young engineers who are starting out in their careers and are involved in research into and/or the development, design, production, deployment, and operation of switching equipment used in HVAC and HVDC power systems. The information provided here is based on long-term investigations that were mainly conducted by CIGRE Study Committees 13 and A3. This chapter explains the basics of switching equipment used in power systems, including the interrupting principles of circuit breakers with different technologies, switching phenomena observed in power systems, and the history of circuit breakers, including oil circuit breakers, air-blast circuit breakers, vacuum interrupters, and gas circuit breakers. It also describes some important substation equipment such as surge arresters, instrument transformers, and substation post insulators. This book represents a useful aid to understanding CIGRE publications such as technical brochures, which include state-of-the-art information on emerging subjects but are often targeted at experts.

The author wishes to express his appreciation to all of the switching experts involved in CIGRE activities past and present. In particular, the author is grateful for the kind advice and encouragement given by the main editor of the book, Dr. Konstantin Papailiou. The author is also very grateful for the devoted efforts of many SC A3 experts, and to Dr. Harley Wilson for supporting a review of the technical documents during the publication process.

Hiroki Ito is involved in high-voltage DC and AC circuit breaker research and development. He received his PhD from Tokyo Institute of Technology. He was the technical director of Mitsubishi Electric High Voltage and High Power Testing Laboratories from 2005 to 2012. He was chairman of CIGRE Study Committee A3: *High Voltage Equipment* (now *Transmission and Distribution Equipment*) from 2012 to 2018.

# Overhead Lin

## 9. Overhead Lines

Konstantin O. Papailiou

Overhead transmission lines have formed the backbone of electric power systems over their history of more than 125 years, being at the same time the largest man-made artifacts on Earth. Another peculiarity of overhead lines is that their study encompasses quite a few engineering disciplines, such as electrical, mechanical, civil, and environmental. As system operation issues of lines are covered in Chap. 5, this chapter concentrates on line components. It starts by explaining the design philosophy of lines, with an emphasis on the calculation of typical line loads, mainly coming from wind and ice, and includes the latest findings on electromagnetic fields (EMF) and health. It continues by treating the individual line components, from material selection, manufacturing processes, stress calculations, to special applications. For instance, for conductors, the most costly and important component of a line, emphasis is placed on different types of conductor, their material properties, and what is called their internal mechanics, including sag-tension calculations. However, sufficient space is also dedicated to the ever-important issue of conductor vibrations, thermal rating and monitoring, bundle conductors, as well as new types of conductor. Similarly for insulators, after an in-depth presentation of pollution issues, the focus is on three different types of insulator, i.e., porcelain, glass, and composite. Conductor fittings are addressed next, covering, beside the different types of clamps and joints, also conductor hardware for vibration control, such as Stockbridge and spacer dampers. Line supports, being the most visible component of a line, have seen a significant shift in recent years towards esthetic structures and compactness, while their foundations have benefited from improved designs and new site investigation techniques. The final sections cover construction and maintenance, including new technologies such as robotics, and line uprating and upgrading, the latter reflecting the increasing trend towards augmenting the power transfer capacity of existing lines, as it is not always easy to build new lines. The goal of this chapter is

thus to provide the reader with all the basic information required to understand how an overhead line is designed, constructed, and maintained and help in taking the right decisions regarding material selection, the calculation of external loads and internal stresses, and the choice of appropriate standards and testing procedures. Some 300 references facilitate these tasks.

Additional information and supplementary exercises for this chapter are available online.

## 9.1 History and Present Challenges

Since their first installation in 1891, overhead transmission lines have formed the backbone of electric power systems, with more than a million kilometers now in service worldwide. In Europe alone, more than 200 000 km (system length) at 380 kV and more than 100 000 km at 220 kV are in operation. Lines at lower voltages, often called subtransmission or distribution lines, reach millions of kilometers.

Despite some acceptance problems faced mainly by high-voltage lines in recent years, their future seems bright, as they are considered indispensable for the transmission of bulk electric power over long distances.

This trend is enhanced by the following facts:

- Approximately 20% of the world's population has no access to electrical power.
- Demand for electrical power will more than double by 2035.

Because of this, worldwide investment in electrical networks of approximately USD 20 billion will be required up to this date, 40% of which will go on transmission and distribution networks.

In addition, because of the megatrend in recent years in many countries towards renewables and in particular wind farms, which are often located in remote areas, there is an increasing demand for new overhead lines. As an example, in Germany, a pioneer in the use

of renewable generation, the demand for new 380-kV lines has been estimated to be about 4000 km.

### 9.1.1 First Steps

The first *high-voltage* alternating-current (AC) overhead line was built in Germany in 1891, from Lauffen am Neckar (a small city in Southern Germany) to Frankfurt am Main (Fig. 9.1). The italics indicate that

**Fig. 9.1** First HV AC overhead line

**Fig. 9.2** Development of overhead line (OHL) voltages

high voltage in those days was only 15 kV (although the line was later operated at 25 kV). It is interesting to note that, although industrial-scale transmission of electrical power was developed in direct current (DC) for long-distance transmission for railways between Vizille and Grenoble in France as early as 1883 by Marcel Deprez,

preference was given to AC over DC because the use of the transformer gave AC an essential advantage.

The line had a length of 175 km and was used to provide electrical power to 1000 lamps and an AC motor for an artificial waterfall installed at the premises of the Frankfurt Fair. Based on the technology of telegraph lines at that time, 3200 wooden poles were used to carry the 12.6-mm<sup>2</sup> copper conductors, supported by oil-filled porcelain insulators. No wonder the losses were about 25%.

The father of the transmission project for the Frankfurt Fair was Oskar von Miller from Munich, who later established the Deutsches Museum there. The designers of the electrical equipment were Charles Brown and Walter Boveri from Switzerland, who established the Brown-Boveri Company (BBC) soon thereafter. The designer of the overhead line as well as the electrical pump was Michail Ossipowitsch Doliwo-Dobrowolski from Allgemeine Electricitäts-Gesellschaft (AEG).

What started as a single, point-to-point connection for a rather fancy application became in subsequent

**Fig. 9.3a-d** Milestones of OHL insulators (source Pfisterer Lapp): (a) cap-and-pin porcelain insulators, (b) motor insulator, (c) porcelain longrods, (d) silicone rubber composite insulators

**Fig. 9.4** 1200 kV AC line at a test station in Bina, India (photo: A. Pigini)

years probably the most complex *machine* mankind has ever conceived, the power grid.

### 9.1.2 Important Milestones

It was soon recognized by early overhead line engineers that, to transmit large amounts of electrical power, the current and voltage had to be increased. This spurred intense development of conductors for higher currents and insulators for higher voltages.

As the copper wires originally used were heavy and expensive, aluminum wires were soon introduced, and a seven-strand aluminum conductor was put in service in 1897 in Connecticut. An important milestone was the introduction of bimetallic conductors, namely aluminum conductor steel-reinforced (ACSR) conductors, in 1907. Today's conductors with diameters of 50 mm or more can carry up to 1500 A, and modern high-temperature low-sag (HTLS) conductors (Sect. 9.4.9) even more.

**Fig. 9.5** Study *Walking giants* (photo: Landsnet, Iceland)

The necessity for higher voltages (Fig. 9.2 [9.1]) could only be addressed by the parallel development of suitable insulators (Fig. 9.3). From the invention of cap-and-pin porcelain (or glass) insulators (Fig. 9.3a), which enabled, by simply adding more units, long insulator strings and thus higher voltages, to the so-called motor insulator (Fig. 9.3b) to porcelain long-rods (Fig. 9.3c) to today's silicone rubber composite insulators (Fig. 9.3d), insulators have proven to be an extremely innovative—and reliable—component of overhead lines.

With the introduction of higher voltages and larger conductors, the appropriate support technology had to keep pace. This is visually evident in the development of the towers, the most visible elements of an overhead line: from the wooden poles of the early days (Fig. 9.1), to the impressive structures of 1200-kV AC lines of the present (Fig. 9.4).

In recent years, the esthetics of overhead lines have attracted considerable attention from the public, fostering the development of compact lines and so-called esthetic or design towers [9.2] (Fig. 9.5).

### 9.1.3 Present Challenges

Overhead lines are and will be for a long time the prime medium for transmitting bulk electrical power, despite serious objections from the public in many countries and recent advances in HV underground cable technology. While always an interesting subject, OHL have over the years tended to become *business as usual*, also suffering from the liberalization of electricity markets and the partly negative effects on utility investments. This situation has changed dramatically—and positively for OHL—in recent years with the worldwide megatrend—led by Germany—toward renewables. The result of this development is the requirement for a considerable number of new power transmission corridors. Overhead

lines are thus becoming, not only in Europe, *big business*.

Technically, there is broad agreement that these lines are badly needed to maintain system stability and reliability, with even traditionally critical organizations such as Greenpeace seeming to agree and project financing not representing a barrier. The big issue with system expansion is the strong opposition from the public to new lines, faithful to the well-known not in my backyard (NIMBY) principle. This has resulted in approval processes that last—if they are ever successful—between 10 and 20 years, with endless discussions and mainly emotional arguments from opponents, with the media doing their best to keep the fire burning.

In this context, the Conseil International des Grands Réseaux Électriques (CIGRE; International Council on Large Electric Systems, <http://www.cigre.org>), the largest and most important nongovernmental, nonprofit organization in the field of electrical power networks, and in particular its Study Committee on Overhead Lines (SC B2), which covers all aspects of the design, construction, and maintenance of overhead power lines, play a key role and help all involved stakeholders by providing unbiased information through international

conferences and broadly accepted publications such as technical brochures, major reference works (Green Books), etc.

Related to this, it is interesting to consider which issues are of particular importance to the OHL community worldwide, as determined in a quite recent survey by the Customer Advisory Group (CAG) of SC B2. They are:

- Increase capacity of existing lines
- New materials for use with OHL
- Public acceptance of OHL.

Other issues of interest identified by this survey are:

- Condition assessment and estimated remaining asset life
- Methods to optimize design
- Best construction and maintenance techniques and procedures
- Foundations for difficult soil conditions.

All these are covered extensively in the following sections of this chapter.

## 9.2 Planning

An overhead line is, in a sense, a unique device. Electrically, they are wave guides carrying electromagnetic waves at high power, in most cases over long distances. Mechanically, and because of the long distance issue, they sustain a spectrum of external, mainly climatic loads (e.g., wind and ice) but also temperature variations. The foundations for their supporting structures face a wide variety of soil conditions, from normal soil to hard rock, which call for different foundation techniques. All this, in combination with the potential hazards of high voltages and high currents, requires meticulous planning, design, construction, and maintenance of a transmission line project, while bearing in mind that the most important physical parameter is cost.

### 9.2.1 Planning Process

As in many human activities, the focus of power grids has changed over the years. While at the beginning of electrification capital was not a major issue, investors in grids soon became more price conscious, until current times, where environmental issues have become predominant.

In this sense, and in line with the rapid increase in the awareness and participation of the public, the

initiation and most importantly completion of a transmission line project has become a difficult puzzle, as an appropriate balance must be found between security of supply, safety, sustainability, and as far as possible cost-efficiency, in order to be acceptable to the public and thus politically viable.

New transmission line projects are always initiated by system planners, who have the best overview of present and future system requirements regarding load growth. The system planner should cooperate closely with line designers at an early stage of the project, as their input can significantly influence the design of the line and provide the following information to the line designers [9.3]:

- The profile of the proposed line load on a yearly and daily basis, which is essential for the designer to determine the templating temperature of the line
- The load growth, which is necessary to determine the optimum aluminum area of conductors
- The characteristic impedance (Chap. 5), which is necessary to determine the optimum bundle and phase configuration (for AC lines)
- The voltage of the line, which is often fixed based on the well-accepted rule of thumb for

**Fig. 9.6** Optimum transmission voltage (adapted from [9.4])

the optimum transmission voltage of 1 kV/km (Fig. 9.6).

Because of the latter, the design *window* in the planning stage of new lines is often limited mainly to the choice of the conductor and insulator, and for voltages above 220 kV to the decision on the bundle configuration. Important parameters for this selection process are:

- Line losses
- Corona
- Thermal rating
- Mechanical loads
- EMF limits.

The choice of the insulators depends mainly on the past experience of the utility, the pollution level, and the insulation coordination of the network.

Overhead line supports are often standardized for a utility, so the freedom of choice may be rather limited. On the other hand, because of increased public awareness—and often objections—to new lines, so-called esthetic supports (Sect. 9.7.6) are considered as alternatives.

The next and very important step in the planning process is line route selection and related property acquisitions to establish the necessary right of way (ROW). As this requires negotiations with land owners, which by nature can become emotional, this takes quite a long time to accomplish. CIGRE TB 147 [9.5]

covers the requirements for route selection, consultation models, and property acquisition. After completion, the detailed design stage can begin.

The detailed design phase precedes the execution phase. The output of this phase is a detailed design and costing, which is then presented to management for execution approval, as shown exemplarily here [9.6]:

- Planning information:
  - Reason for the line, including extract from the planning proposal documentation
  - Information from network planners on line requirements, including time and cost constraints
- Survey and environmental:
  - Possible routes with cost options
  - Environmental impact assessment (EIA)
  - Route and profile
- Initial tower, conductor, and foundation combinations:
  - Options selected for analysis
  - Appropriate technology index (ATI) analysis and results
  - Design options for further analysis
- Towers:
  - Tower design chosen
  - Tower schedule summary
- Conductor and earth wire:
  - Final conductor or conductor bundle chosen
  - Final earth wire chosen
- Foundations:
  - Geotechnical survey results
  - Foundation designs for each soil category and tower type
  - Schedule summary of foundation types
- Hardware:
  - Outline of suspension and strain assemblies
  - Damping system used
  - Clamps and fittings
- Insulators:
  - Analysis of pollution and other requirements
  - Insulator options that could be used
  - Final insulator selection
- Performance assessment:
  - Performance analysis of other lines in the vicinity
  - Lightning performance studies
  - Environmental impact studies such as bird pollution/interaction with the line, forest, grass, or cane fires.

The importance of the planning stage and the great attention it deserves are well documented in Fig. 9.7, showing a quite optimistic time schedule for a transmission line project, as nowadays line route acquisition

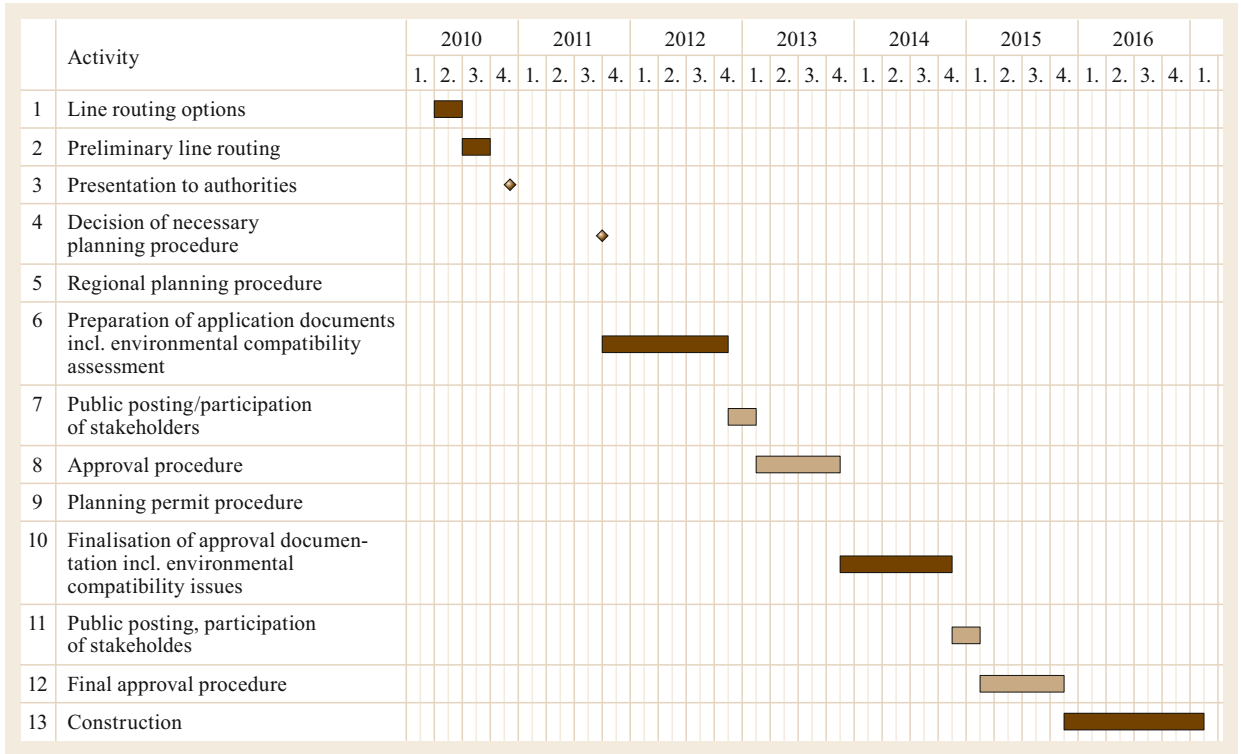

Fig. 9.7 Time schedule of a transmission line project in Germany

alone may sometimes take up to 20 years. Thus, the planning process consumes more than 80% of the project execution time.

### 9.2.2 Line Optimization

As mentioned above, the design options for a new line are in most cases de facto limited. In particular in industrialized countries, where the power grid is already well developed, many line components are standardized by the utilities due to logistics, storekeeping, and maintenance issues. Also, alternative line routes are difficult to find in densely populated areas. There are exceptions though: Presently in Germany new cross-country transmission corridors are planned for the better diffusion of renewable power to the grid; these new lines, which will have to be partially undergrounded, will be executed in DC with all design options open.

This is also the case in developing countries, where often long distances in lightly populated areas have to be covered and where financial constraints demand the most cost-efficient solution. Good examples in recent years for such projects are the 1000-kV AC and 800-kV DC lines in China, the 1200-kV AC lines in India, and the very long 600-kV DC and 765-kV AC lines in Brazil and South Africa, respectively.

In such cases, it is important to apply an objective optimization procedure, such as the one described in [9.6].

For AC lines, the line parameters that affect the ability of the line to transmit power over long distances are primarily the resistance, inductance, and capacitance values. The thermal rating can be affected by the height above ground as well as the conductor choice, which affects the sag–temperature relationship of the conductor. An optimal line should have low inductance, high capacitance, and low resistance. To achieve this, it is also important to observe constraints regarding corona and mechanical loading.

Table 9.1 presents the relationship between the surge impedance loading (SIL), corona, mechanical loading, and thermal rating.

For DC transmission lines, the corona limitation related to losses, the corona inception voltage for the conductor  $E_c$ , and  $E_{max}$  are the important parameters. The bundle design and the positive and negative pole separation as well as the voltage chosen for the optimal power flow are critical for the optimization of high-voltage direct-current (HVDC) lines.

Table 9.2 [9.6] summarizes the options relating to conductor and bundle selection for HVDC lines. Note that the SIL mentioned in the AC section is not valid for

**Table 9.1** Relationship between actions taken in AC line design and effect on SIL, corona, mechanical loading, and thermal rating

	SIL	Corona	Mechanical loading	Thermal rating
Phase spacing decrease	Good	Bad	Good (minor effect)	Neutral
Large Al area/cond. (less conductors)	Bad	Bad	Good	Bad
Diameter bundle increase	Good	Bad	Bad (minor effect)	Neutral
High steel content	Neutral	Neutral	Bad	Good

HVDC. Hence, this column is replaced with the voltage drop. In Tables 9.1 and 9.2:

- *Bad* implies that the option chosen will require in-depth study of this parameter and mitigating actions to be taken.
- *Good* indicates that the parameter will be favorably influenced by the action (e.g., the voltage drop will be lower along conductors with large Al area).
- *Neutral* means that the parameter chosen will not be affected by the choice of action.
- *Minor effect* means that the effect is secondary but must be taken into account in the design.

To determine the best set of design options among a number of alternatives, an indicator called the appropriate technology indicator (ATI) has been proposed, utilizing [9.6] the *bang for your buck* concept, the *bang* being in this case the surge impedance loading and the thermal rating of the line and the *buck* being the initial cost, with the life cycle cost also being included to avoid focus on the initial cost only; thus, the higher the ATI, the better the design option.

The following indicators have been proposed:  
For AC lines,

$$ATI_{AC} = w_1 LCC + w_2 \frac{IC}{MVA_{sil}} + w_3 \frac{IC}{MVA_{th}}, \quad (9.1)$$

where the life cycle cost (LCC) includes system losses, maintenance, and the initial cost (IC) of the line,  $MVA_{sil}$  is the surge impedance loading,  $MVA_{th}$  is the thermal limit under contingency conditions, and  $w_i$  are the weights for each term.

For DC lines,

$$ATI_{DC} = w_1 LCC + w_2 P_{cor loss} + w_3 \frac{IC}{MVA_{th}}, \quad (9.2)$$

where LCC is the life cycle cost including system losses, maintenance, and the initial cost,  $P_{cor loss}$  is the power loss due to corona, IC is the initial cost, and  $MVA_{th}$  is the thermal rating of the line.

The terms in (9.1) and (9.2) are normalized to a score out of 10 to enable their addition.

The weights  $w_i$  are determined by the network planners, who determine the importance of each component in relation to the needs of the line in the network; for example, the LCC would be given a high rating if the cost of capital is relatively low but the marginal cost of generation is high. It is recommended that the weights be varied and the option with the highest ranking, representing the most robust design, be adopted.

It is worth noting that, for DC lines, pioneering work was reported in [9.7], where a detailed analysis of a range of line configurations, voltages, and terminal station options was evaluated. Based on this report and in particular on Fig. 9.8 therefrom, the voltage level of a new DC line can be determined for a given power transfer and line length requirement. In this case, the optimization process will be as follows [9.8]:

- Determine the voltage level using the method proposed in [9.7].
- Determine the conductor/bundle configurations that meet the corona level limits for the selected voltage level.
- Determine the range of tower, conductor, and foundation combinations using an objective indicator.
- Once the group of line design options has been finalized, revisit the voltage, converter, and line design options to confirm that the options chosen are indeed valid. If not, the process needs to be restarted.
- Finalize the system design.

**Table 9.2** Relationship between actions taken in DC line design and effect on voltage drop, corona, mechanical loading, and thermal rating

Action	Voltage drop	Corona	Mechanical loading	Thermal rating
+ and – pole spacing decrease	Neutral	Bad	Good	Neutral
Large Al area/cond. (less conductors)	Good	Bad	Good (minor effect)	Bad
Diameter bundle increase	Neutral	Bad	Bad (minor effect)	Neutral
High steel content	Neutral	Neutral	Bad	Good

**Fig. 9.8** Optimal DC voltage as a function of converter station power and line length. Yearly cost: line investment and losses as well as station cost (station losses not included, equal for same station power and different voltage). (Adapted from [9.7])

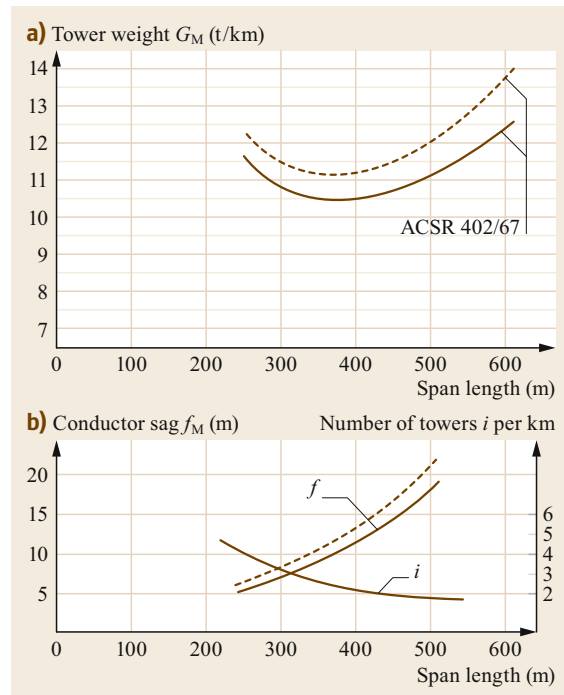

### 9.2.3 Costs

Reliable cost estimation at an early stage of the planning process is advantageous for the utility, in order to forecast and set aside necessary investments. This is not always easy, as the cost interactions of the various line components are rather complex. This situation was well explained in an early, remarkable paper [9.9].

Figure 9.9 presents in a nutshell quite valuable information for the optimum span length of a 220-kV double circuit line using ACSR 402/67 conductors (402-mm<sup>2</sup> aluminum, 67-mm<sup>2</sup> steel), i.e., the often used aluminum-to-steel ratio of 6 : 1, for two different conductor everyday stresses (EDS) at 10 °C. The higher this stress, the heavier the towers and the larger the foundations of the line. On the other hand, in this case, the conductor sag  $f$  and thus the number of towers  $i$  per km will decrease, leading to an optimum span length between 360 and 375 m. The span length with minimum investment costs is normally 10% higher, i.e., around 400 m, because other costs such as insulators, fittings, and earthing are directly proportional to the number of towers.

Interestingly enough, in recent years, there has been a trend in areas with low ice loads towards conductors with higher aluminum content, i.e., aluminum-to-steel ratios of up to 11 : 1 or even all aluminum conductors (AAC). These cost less than ACSR cables with the same aluminum cross-section, and although their lower tension increases the sag, at the same time, because of their smaller weight and diameter, they impose lower mechanical loads, leading to less expensive towers and foundations.

In 2013, CIGRE WG B2.51 carried out a worldwide survey on overhead line costs and published them in [9.6], from which Fig. 9.10 is reproduced, showing the total line cost per route kilometer for a number of

**Fig. 9.9** (a) Tower weight per km  $G_M$  and (b) sag  $f$  (at 40 °C) over the span length for a 380-kV line to determine the optimal span length. *Dashed lines:*  $G_{EDS} = 55 \text{ N/mm}^2 = 17\%$  of  $G_{RTS}$ ; *solid lines:*  $G_{EDS} = 65 \text{ N/mm}^2 = 20\%$  of  $G_{RTS}$  [9.9]

lines in various parts of the world, which partly explains the wide spread of costs.

Table 9.3 from the same source presents a comparison of line component costs between 1991 [9.10, 11] and 2013 [9.6].

Because the sample of answers to the survey in 2013 was considerably smaller than the more than 200 par-

Fig. 9.10 Line costs in US dollars (USD) per route kilometer (adapted from [9.6])

Table 9.3 Comparison of line component costs between 1991 and 2013 (adapted from [9.6])

	Year	Material costs	Construction costs	Cond.	Shield wire	Insul.	Towers	FNDN
For all lines and voltages	1991	63.7	36.3	32.7	3.8	8.1	36.2	19.2
	2013	42.4	57.6	31.8	2.7	7.6	46.3	11.6
For all lines up to 150 kV	1991	64.3	35.7	31.6	4.1	8.8	36.0	19.5
	2013	46.4	53.6	28.6	2.0	7.9	49.6	11.9
For all lines over 300 kV	1991	62.6	37.4	34.1	3.9	6.9	36.4	18.7
	2013	46.8	53.2	35.7	3.0	7.2	42.7	11.4
All single-circuit lines	1991	63.6	36.4	33.1	4.2	8.2	35.6	18.8
	2013	42.8	57.2	33.4	2.8	6.9	43.7	13.3
All double-circuit lines	1991	63.8	36.2	32.0	3.3	7.9	37.1	19.7
	2013	31.0	69.0	24.7	2.3	10.6	58.1	4.3
Guyed-structure lines	1991	59.6	40.4	32.8	3.2	8.3	36.0	19.8
	2013	55.0	45.0	36.5	3.2	6.3	41.3	12.7
Lines with one conductor/phases	1991	64.4	35.6	32.2	4.2	8.5	36.3	18.8
	2013	38.7	61.3	28.3	2.0	7.8	45.1	16.9
Lines with two conductors/phases	1991	64.6	35.4	32.3	4.0	8.1	36.2	19.4
	2013	38.0	62.0	32.3	2.3	10.6	48.4	6.3
Lines with three conductors/phases	1991	60.8	39.2	35.1	3.7	7.0	40.3	13.8
	2013	41.5	58.5	36.6	4.6	6.6	42.6	9.6
Lines with four conductors/phases	1991	61.4	38.6	33.4	2.7	7.6	33.5	22.9
	2013	56.5	43.5	34.2	3.4	7.9	37.9	16.7

Participants in 1991, care should be taken when drawing conclusions. Nevertheless, analysis of the figures reveals certain trends:

- The cost per kilometer of lines increased from 1991 to 2013 in real terms mainly due to cost of labor and environmental issues.
- Design costs average around 20% of the line cost, which includes landowner and environmental considerations.
- Material costs have significantly reduced compared with construction costs.
- There were small changes in the relative shares of conductors, insulators, and fittings in the total line

**Table 9.4** Design parameters and cost breakdown for HV AC OHL

Design parameters	Nominal voltage (kV)				
	110	220	380	500	750
Thermal rating (MVA)	10–350	300–1000	1400–2700	1800–3000	3000–5000
Optimal rating (MVA)	20–100	120–350	500–1200	700–1500	2000–3000
Right of way (ROW) (m)	40–50	55–60	60–70	60–70	80–120
Tower weight (t/km)	15–25	25–35	45–65	20–40	28–50
Concrete for foundations (m <sup>3</sup> /km)	100–200	120–250	150–300	120–250	150–300
Total line costs (k€/km)	125–200	150–400	650–1200	300–600	400–750
Cost breakdown (%)					
Conductors, insulators, and fittings	35–45	40–50	45–55	45–60	45–60
Towers	35–45	35–45	35–45	30–45	30–45
Foundations	15–25	10–20	7–15	7–15	7–15
Planning	5	4	3	3	3

costs, with conductors accounting for about 20% of the total line cost.

- The percentage of costs spent on towers seems to be higher than in 1991. This increase in tower costs as a percentage may be a result of an increased number of angle and strain structures due to environmental pressures resulting in certain line routes which are not conducive to low-cost tower designs.
- Foundations costs have increased at a lower rate than other components.

In addition, Table 9.4 contains valuable information on overhead line parameters and costs, mainly from Europe. The partly lower costs at 500 and 750 kV can be explained by the fact that these are single-circuit lines compared with double-circuit 380-kV lines.

### 9.2.4 Asset Management

Asset management applies to the full life cycle, including planning, design, construction, commissioning, operation, maintenance, and decommissioning. In this sense, asset management is described in [9.12] as “coordinated activity of an organization to realize value from assets.” In addition, as many line faults remain *unknown*—which leads to incomplete analysis and action—another important task of the asset owner should be to reduce the number of unknown faults to a minimum.

The electric utility industry is in a transient condition brought on by privatization, deregulation, and competition. It is becoming increasingly difficult to obtain the required permits and/or funding to acquire new rights of way and build new lines, thus utilities are seeking ways to get the most from their existing OHL assets. In this context, owners and asset managers of overhead lines increasingly have to ask themselves the following questions [9.13]:

- Can investments in the overhead transmission system be justified?
- Can the probability of the next overhead line failure event be reasonably predicted?
- Are the right data in case of a failure event being collected and managed effectively?
- Is the present capability of the overhead line components adequately known?

In the past, such questions were answered using qualitative data and mostly based on personal experience. However, in the future, related decisions will need to be supported by quantitative information and databases which were not previously available. Using these data, risk management techniques can be applied to support management decisions. In the following, some guidelines which should be helpful to answer the questions posed above and take the right decisions are presented [9.14].

#### Investments

The goal of a management decision regarding an investment is to minimize the net present value (NPV) of the annual expenditures over a predetermined investment period. To obtain comparable results, future costs must be discounted to the present [9.14, 15], which can be calculated as follows

$$\text{NPV} = \sum_{i=0}^{i=n} \frac{C_i}{(1+r)^i}, \quad (9.3)$$

where NPV is the net present value of the annual expenditures,  $n$  is the period taken into consideration,  $r$  is the discount rate, and  $C_i$  is the annual expenditures in year  $i$ , with

$$C_i = E_i + R_i, \quad (9.4)$$

**Table 9.5** Annual expenditures related to different levels (adapted for [9.14])

Expenditures connected mainly to	Annual expenditures Planned expenditures	Risk of failure
Company level	Investments	Injury or death Serious damage to the built environment Bad publicity, loss of customers, even more difficulties finding new ROW Cascade <i>failures</i> with electrical system breakdown
System operation level	Energy and <i>capacity</i> losses	Additional energy and <i>capacity</i> losses More expensive power generation Loss of profit due to nondelivered energy Penalties by the regulator
OHL operation level	Operation and maintenance (including landowner compensation for damage to vegetation) Overhead costs for information collection and maintenance of a database	Regular inspections and patrols for checking the condition of OHL Painting, tree trimming, and smaller interventions that are performed regularly Repairs as necessary

where  $E_i$  is the deterministic costs, or planned expenditures, in year  $i$ , and,  $R_i$  is the probabilistic costs associated with a risk of failure in year  $i$ .

These components are discussed below.

### Expenditures

Planned expenditures include the cost of investments and of normal operations. These costs are related to different levels within the company, i.e., the company as a whole, the system operation division—also called electricity commerce—and the overhead lines division. Typical values for such costs are presented in Table 9.5 [9.14].

### Failures

Defects and failures in OHL occur in practice due to:

- Unforeseen external causes such as faults in an adjoining grid, extreme weather conditions, sabotage
- Internal causes such as wear, aging, deformation, poor construction, or material failure
- Operational aspects such as electrical overload, switching faults, and improper functioning of protection and control.

Failures often involve the subsequent effects:

- Fluctuations in the voltage level, leading to disturbances of operational processes of the customer
- Reconfiguration of the system, resulting in increased losses and/or higher generation costs
- Disruption to planned maintenance programs
- Restoration costs
- Financial claims arising from unavailability of the transmission line.

The risk of failure of an OHL is defined based on the probability of failure times the sum of the resulting consequences and whether the event causing failure can be predicted or not.

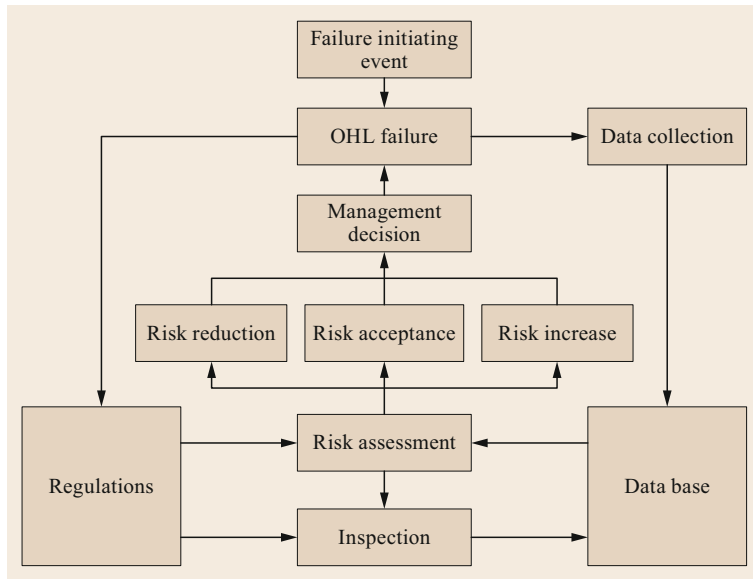

**Predictable Events.** The components of a line are subjected to many types of deterioration, such as wear, fatigue, corrosion, deformation, and elongation. Since they are made from different materials with different properties in different environments, it is likely that some of these components will deteriorate faster than others. The current capabilities including residual electrical and mechanical strength of all OHL components can be determined using appropriate inspection/assessment technology (Sect. 9.9). In addition, if a database of past component capabilities exists, then their future capabilities can be extrapolated. The weakest link, i.e., the OHL component with the highest probability to fail first, can then be determined. This is accomplished by sequentially applying to the line the relevant loading conditions and increasing the related actions stepwise, such as the magnitude of the wind velocity at different angular directions, weight of accreted ice, or combined wind and ice, until the loading on a component reaches its present capability. That represents the critical loading condition for that component, and the probability of occurrence of that loading condition (Sect. 9.3) indicates the reliability level of that component.

Failures due to predictable events can thus be managed using proactive measures, due to their predictability.

**Unpredictable Events.** Unpredictable events can only be managed by reactive measures, since their probabil-

**Table 9.6** Properties of predictable and unpredictable events (adapted from [9.14])

Properties	Failure due to Predictable events	Unpredictable events
The probability of failure is	Relatively high	Relatively low
An economic way to avoid failure	Does exist	Does not exist
<i>Proactive</i> action	Can be taken economically	Cannot be taken economically
In case of proper action, the OHTL	Will survive the <i>event</i>	Will not survive the <i>event</i>
<i>Reactive</i> actions are	Possible depending on economic evaluation	The only opportunities to reduce the <i>risk</i> economically

**Fig. 9.11** Flowchart for OHL asset management (adapted from [9.14])

ity of occurrence cannot be economically reduced using proactive measures. These include, in particular, natural disasters such as hurricanes, cyclones or typhoons, tornadoes, massive ice storms, floods, earthquakes, and earthslides, which fortunately occur infrequently. When they do, these disasters can cause total failure. Intuition, judgment, experience, and information available from a database must be used to assign the probability of failure due to unpredictable events, thus the assignment of such probabilities in situations of uncertainty proceeds on a subjective rather than objective basis (Table 9.6 [9.14]).

**Asset Management Process**

To determine appropriate options that minimize the net present value of annual expenditures over an investment period, an information system and process must be in place. Figure 9.11 [9.14] shows an idealized process in the form of a flowchart of the activities leading to management decisions for an OHL asset. A key role is played by the collection of data, which will be presented here.

**Data Collection**

To be able to carry out a proper failure or defect analysis, a database should be available, being unambiguous and containing, but not limited to, asset data as built, historical data, and in case of a failure, pre-event, event, post-event, and cost data. The following data are important for any transmission line database and can be tagged with an accuracy level index. Finally, a database should include the costs and duration of actions, as well as the costs of replacement of line segments, components, and elements.

*Asset Data as Built.* The asset data as built should be collected on three successive levels:

- Lines and circuits
- Line components
- Elements of components.

The data stored on the three levels allow one to analyze and compare successively the:

- Performance of lines
- Condition of components
- Condition of elements.

*Historical Data.* Three different kinds of historical data on overhead transmission lines can be distinguished:

- Historical actions such as:
  - Replacement or heightening of a support or a part of a line (for instance due to the construction of a railway), stringing of a second circuit, etc.
  - Maintenance or painting, life extension, refurbishment, uprating, upgrading, etc.
- Historical events such as failures, forced outages, etc.
- Historical observations and measurements on defects of assets registered in periodic inspection reports.

*Pre-event Data.*

- Design criteria and applicable manufacturing and construction standards
- As-built/constructed data including all components, elements, their manufacturer, date of commissioning, and location
- All inspection and maintenance records, including location, date, observation, deterioration, and changes or modification to any component or element
- Any refurbishment, uprating, or upgrading
- Climatic and pollution conditions along the line
- Data from any previous event
- Strategic emergency material and equipment inventory.

*Event Data.*

- Agency recording the event
- Exact time of the beginning of the event
- Distinction between incidents involving manual tripping of the line, automatic tripping, automatic tripping with successful auto-reclose, or automatic tripping with unsuccessful reclose (lockout)
- Description of climatic conditions such as wind, precipitation, and ice accretion as well as pollution influencing the line
- Nominal voltage
- Load current immediately prior to the event and an estimate of the fault current

- Name and code of the circuit involved: arm, suspension, insulator, conductor, earth wire, damper, spacer etc.
- Failure during operation, switching in, switching off, or during works
- Switching off by hand or by protection equipment
- Switching off due to electrical phenomenon, secondary installation, inadequate functioning of protection, error in operating or switching, or cause outside control area
- Cause of electrical phenomenon or defect:
  - Unforeseen external causes such as a fault in an adjoining grid, fault at a user, extreme weather conditions, fire, sabotage, birds, cranes, etc. (if weather related, estimated or measured values of wind and/or ice at the failure site and recorded values from nearby weather stations)
  - Internal causes as wear, aging, deformation, poor construction, material, assembly, manufacturing, and adjustment
  - Operational aspects such as overload, switching or testing errors, poor or insufficient maintenance, and improper operation of protection and control
  - Works in or under the line by or on behalf of the owner
- Any required continued investigation activities involving the failed component or element, or of additional similar components or elements, measurements, outside expert opinions, accident reports, formulation of a repair or replacement plan, and cost analysis
- Exact time to start the repair work
- Exact time to complete the repair work
- Exact time of recommissioning the line.

*Post-event Data.* Obviously, every failure or defect causing the line to be switched off should be properly analyzed. This analysis is meant to identify the cause and detect possible deficiencies, wear, etc. of the type of component or element involved in order to take action at other points of installation. The results of such an investigation and the measures taken should be recorded unambiguously in a database. At least, the following aspects should be mentioned:

- Reporting agency
- Time of failure
- Name and code of circuit involved
- Failed component
- Failed element

- Manufacturer and type; number of years in operation
- Voltage level
- Comparison of the condition at the time of failure with the original design criteria (i.e., pollution, mechanical loading or electrical loading)
- Material
- Description of the extent of the damage, including photographs
- Description of the manifestation of the damage, including photographs
- Identification of the cause of the damage
- Measures to be taken and action plan.

In addition, the costs incurred because of a specific failure must be recorded, in particular:

- Loss of income due to undelivered energy
- Cost of increased network losses
- Cost of switching operations
- Customer claims or penalties
- Cost of investigation
- Cost of called-in experts
- Total cost of restoration, including manpower, equipment, materials, and outside contracts

**Data Storage.** Today, an electronic database system is the most convenient tool to store, consult, revise, and extract data. Such a database enables statistics on line performance and component and element condition to

be established. To simplify the data collection and storage process, it is recommended to provide checklists so that inspection results can be stored in the database immediately after an inspection. The date of each data record is important for management decisions and thus should be included.

Evidently, the quality of the data cannot be improved by just recording it in a database. Rather, the quality depends mainly on the crew collecting the inspection information and the inspection technique applied. Both must be recorded with the corresponding date to estimate the quality and reliability. It is also important to specify who is responsible for inputting the data and who is in charge of updating them. Another important factor determining the data quality is the inspection technique. The longer the distance between the inspected item and the sensor, the less reliable the data may be.

Experience has shown that, in the past, many databases on overhead transmission lines have failed. The following reasons have been identified: the lack of reliable data for an extensive database, the lack of motivated manpower to collect, store, and maintain the data, non-user-friendly input and output, and especially the lack of a clearly accepted scope or the lack of integration with other databases.

In general, it is relatively easy to store data for a new line, but updating the database is a challenge and can involve a considerable cost. If it is updated, the database must be easy to use for the design of new lines as well as modifications of old ones.

## 9.3 Line Design

Line design is a rather complex process as it encompasses a variety of distinctly differing disciplines, such as electrical, mechanical, chemical, civil, environmental, and meteorological science. In the following, due to unavoidable space limitations, the focus is placed not so much on design details as physically intuitive and understandable explanations—and partly derivations—of the basic concepts.

### 9.3.1 Design Methods

As stipulated in [9.16], an overhead line (OHL) should be designed, erected, and operated in such a way that, during its life expectancy:

- It shall perform its purpose under a defined set of conditions, with acceptable levels of reliability and

in an economic manner. This refers to aspects of reliability requirements.

- It shall be designed to avoid a progressive collapse (cascading) if a failure is triggered in a defined component. This refers to aspects of security requirements.
- It shall be designed to avoid human injuries or loss of life during construction and maintenance. This refers to aspects of safety requirements.

In this sense, all the components of a line should be designed, manufactured, and installed in such a way that, under the prevailing regular climatic conditions, the rated voltage and current, and the expected short-circuit loads, the line will operate without failure. In addition, the impact of atmospheric and switching over-voltages should be adequately considered.

**Fig. 9.12a,b** Principles of deterministic (a) and probabilistic (b) design methods (adapted from [9.1])

These conditions are best met when a line is conceived following a widely accepted national or international standard. In this section, publication [9.16] is exemplarily used, as it is applied extensively throughout Europe.

Natural phenomena, which cause loads to overhead lines, are stochastic; that is, their occurrence and implications cannot be predetermined but must rather be addressed using adequate statistical methods. This is also the case, albeit to a much lesser extent, for the material properties of the line components and in particular their structural response to external loads. Until recently in line design, a conservative approach, the so-called deterministic approach, was almost exclusively applied. In recent years, the more *realistic* but more complex probabilistic method has been standardized and in some cases applied. The concepts of and differences between these two methods are shown schematically in Fig. 9.12 [9.1].

In the deterministic approach (Fig. 9.12a), the maximum load  $E_{\max}$  is determined or estimated, often based on long-time measurements, comparisons, and approximations. For climatic loads, a return period of occurrence of 50 years is usually considered. The maximum load must be lower by a safety margin compared with the minimum strength  $R_{\min}$  of the examined component. This may be a withstand voltage for an insulator or a tensile strength for a tower member.

On the other hand, in the probabilistic method, the load  $Q$  and strength  $R$  are obtained from a statistical evaluation of a multitude of measurements under the assumption of a probability law. For overhead lines, the Gaussian or Gumbel distribution is used. As there will always be an overlap between the load and strength probability density (Fig. 9.12b), a very small probability of failure  $P_f$  remains, expressed as

$$P_f = \int_0^{E=\infty} f(E)F(R)dE. \quad (9.5)$$

This probability of failure  $P_f$  is related to the reliability of the component in question  $P_r$  by

$$P_r = 1 - P_f. \quad (9.6)$$

The required reliability level—related to a certain return period—thus determines the acceptable level of the probability of failure, which can be adjusted via (9.5), for instance by modifying the parameters of the strength function  $F(R)$ .

The focus below is on the deterministic or empirical approach, as it is still widely used and lines designed in this way have proved over the years to be extremely reliable. The deterministic approach is applied here for the mechanical design of the line and its components, while its electrical design, where the probabilistic approach is more often used, such as for insulation coordination issues, is covered in Chap. 3.

External loads or actions on a line  $E_{\max}$ , for example, due to wind or ice, are contested by the structural response, basically the geometry and material properties of the loaded component. In the case of a conductor under a tensile load, e.g., this would be the conductor cross-section and the modulus of elasticity of the conductor material. This leads to mechanical stresses in the component, which should not exceed a related strength  $R_{\min}$ , above which the component will deform permanently or even fail. Both  $E_{\max}$  and  $R_{\min}$  have to be converted considering appropriate safety margins to specified design values  $E_d$  and  $R_d$ , using (9.26) and (9.8). Thus, the basic design formula in the deterministic approach is

$$E_d \leq R_d. \quad (9.7)$$

We have to consider two limits for the external load sustainability of a component, viz. the damage limit and the failure limit, also called the mechanical strength in this context. On one hand, the damage limit

**Table 9.7** Damage and failure limits of components

Component	Loading	Damage limit	Failure limit
Members of lattice steel towers	Tension, compression	Yield strength	Breaking strength buckling
Poles made of			
– Steel	Bending moments	1% nonelastic deformation at the tower top	Collapse by local buckling or bending
– Concrete	Bending moments	Crack opening or 0.5% nonelastic deformation at the tower top	Collapse of the pole
Separate foundations	Uplift	1° rotation of the support	Excessive uplift of 50–100 mm
	Compression	Reduction of 5% in support strength	Excessive settlement of 50–100 mm
Compact foundations	Overtipping moments	1° rotation of the support	Excessive rotation of 5° or more
Conductors	Tension	Approximately 75% of characteristic strength or rated tensile strength (RTS)	Ultimate tensile strength
Insulators	Tension	Approximately 70% of rated strength	Rupture
Interface fittings	Tension	Permanent deformation	Rupture

**Table 9.8** Partial factors for materials  $\gamma_M$ 

Component	Type of stress	Type of loading	$\gamma_M$
Conductors	Tension	Limit load	1.25
Insulators	Tension, bending	Limit load	2.00
Fittings	All types of loading	Minimum failing load	1.90
Lattice towers			
– Members	Tension, compression, buckling, bearing	Limit load	1.10
– Bolted connections	Shearing, bearing	Limit load	1.25
– Welded connections	Shearing	Limit load	1.25
Poles			
– Made of steel	Tension, compression, bending, buckling	Limit load	1.10
– Concrete	Compression	Limit load	1.50
– Reinforcement	Tension	Limit load	1.15
Guyed towers, anchors	Tension	Limit load	1.60
Foundations	Uplift loading	Limit load	National requirements

is the value of the external load or related internal stress that, if exceeded, will cause damage to the component that will impair its functionality. For example, when its damage limit is exceeded, a post composite insulator will exhibit permanent deflection but will not drop the conductor (Sect. 9.5.5). The failure limit, on the other hand, is the load which will cause permanent failure of the component, due to high deformation, loss of stability (buckling), or loss of mechanical integrity (breakage), which will endanger the safety of the related structure.

Table 9.7 presents the damage and failure limits of various line components according to [9.17]. By their nature, these material properties exhibit a certain degree of scatter. Also, the dimensions of the components in question vary slightly due to production processes. This can be taken into account by reducing a material

property  $R_K$  by a suitable safety factor, in [9.16] called the partial factor for materials  $\gamma_M$  (Table 9.8). Thus, the related design value  $R_d$  becomes

$$R_d = \frac{R_K}{\gamma_M} . \quad (9.8)$$

### 9.3.2 Line Loads

A transmission line is subject to a number of different loads, caused by:

- Conductor weight
- Ice weight
- Wind pressure
- Conductor tension
- Conductor vibrations

**Fig. 9.13** Extreme ice accretion on line conductors leading to line outage (photo: Landsnet, Iceland)

- Temperature variations
- Exceptional loads.

These are, with the exception of conductor vibrations, static or quasistatic loads. In addition there are exceptional loads, which occur accidentally, such as during construction and maintenance, short circuits, differential settlement of foundations, or—very seldom—loads from conductor failures (which can cause a tower cascade), avalanches, and earthquakes. The most important loads for line design, besides the weight of the conductors, are the so-called climatic loads, i.e., wind and ice loads, which are examined below.

### Conductor Weight

The conductor weight and ice on conductors cause the main vertical loads on the components of a line. These loads are transferred via the fittings and the insulators to the supports and ultimately to the foundations.

The conductor weight per unit length can be found in manufacturers' tables. Typical values for high-voltage lines are between 10 and 20 N/m. To calculate the related conductor load, one must know the so-called weight span, which is defined as the distance between the low-point sags of one span to the low-point sag of the next. When there is no height difference between the conductor attachment points at the adjacent spans, the weight span is the arithmetic mean of the length of these spans; otherwise, the weight span has to be calculated using the so-called complementary span method [9.4, pp. 541].

### Ice on Conductors

Ice on the conductor increases the conductor weight; ice loads thus act in the vertical direction. In extreme climatic conditions, they can overload the line, causing catastrophic failure and line outage (Fig. 9.13).

Ice accretion on line conductors is a complex physical process, well described in [9.19]. Table 9.9 lists the main characteristics of the different ice types [9.18], and Fig. 9.14 shows common types of ice on conductors.

Ice loads on conductors with a value  $q_i$  per unit length cause vertical loads as well as increased tension in the conductors. The related loads on suspension insulators and supporting structures can be calculated similarly as for the conductor unit weight, i.e., by using the relevant weight span.

Due to the lack of sufficient statistical data on ice, design values for ice loads are mostly based on experience or long-term applications with positive results. Often, these values are related to the conductor diameter  $d$  and vary according to the topography, i.e., height above sea level and differing climatic and atmospheric conditions. A typical value for  $q_i$  for average ice conditions is 20 N/m.

**Table 9.9** Classification of ice types with typical density ranges (adapted from [9.18])

Ice and snow type	Density (kg/m <sup>3</sup> )	Description
Glaze ice	700–900	Pure solid ice, sometimes icicles underneath the wires. The density may vary with the content of air bubbles. Very strong adhesion and difficult to knock off
Hard rime	300–700	Homogeneous structure with inclusion of air bubbles. Pennant shaped against the wind on stiff objects; more or less circular on flexible cables. Strong adhesion and more or less difficult to knock off, even with a hammer
Soft rime	150–300	Granular structure, <i>feather like</i> or <i>cauliflower like</i> . Pennant shaped also on flexible wires. Can be removed by hand
Wet snow	100–850	Various shapes and structures are possible, mainly dependent on the wind speed and torsional stiffness of the conductor. When the temperature is close to zero, it may have a high content of liquid water, slide to the bottom side of the object and slip off easily. If the temperature drops after accretion, the adhesion strength may be very strong
Dry snow	50–100	Very light pack of regular snow. Various shapes and structures are possible; very easy to remove by shaking of wires
Hoar frost	< 100	Crystal structure (needle like). Low adhesion, can be blown off

**Fig. 9.14a–c** Different types of ice on conductors. (a) Glaze ice (photo: F. Jackl), (b) soft rime, (c) wet snow (photo: Landsnet, Iceland)

**Fig. 9.15** Bora wind causes severe conductor blow-out (photo: F. Jackl)

As an example, the values specified for Germany with respect to altitude are

$$\begin{aligned} q_i &= 5 + 0.1d \text{ N/m} && \text{(below 400 m)} \\ q_i &= 10 + 0.2d \text{ N/m} && \text{(between 400 and 600 m)} \\ q_i &= 15 + 0.3d \text{ N/m} && \text{(between 600 and 750 m)} \\ q_i &= 20 + 0.4d \text{ N/m} && \text{(above 750 m).} \end{aligned}$$

### Wind Loads

Wind can cause severe loads on transmission lines (Fig. 9.15). In particular, wind loads on conductors will cause increased conductor tension, which will not only be transferred via the insulators to the line supports and their foundations, but will also considerably influence the tower top geometry via conductor displacement.

**Wind Action on Line Components.** The value of the force  $Q_{wx}$  caused by a wind blowing horizontally and perpendicular to any element of a line is given by

$$Q_{wx} = q_z G_q G_x C_x A, \quad (9.9)$$

where  $q_z$  is the dynamic wind pressure at height  $z$ ,  $G_q$  is the gust response factor,  $G_x$  is the structural resonance factor for the element considered,  $C_x$  is the drag factor depending on the shape of the element considered, and  $A$  is the area of the element projected onto a plane perpendicular to the wind direction. However, the parameters in (9.9) are defined differently in relevant standards.

The wind pressure  $q_z$  on a surface  $A$  can be calculated from Bernoulli's equation, under the assumption that the kinetic energy at the reference wind velocity  $v_z$  is fully transformed to pressure when the wind is stopped by this surface, i.e.,

$$q_z = \frac{1}{2} \rho v_z^2. \quad (9.10)$$

Use of an air density of  $\rho = 1225 \text{ kg/m}^3$  (15 °C, a.s.l.) yields

$$q_z \approx 0.6 v_z^2 \quad (q_z \text{ in N/m}^2, v_z \text{ in m/s}). \quad (9.11)$$

The reference wind velocity  $v_z$  is obtained from

$$v_z = k v_{\text{mean}}. \quad (9.12)$$

Here,  $v_{\text{mean}}$  is the annual mean of the maximum wind velocity measured in open terrain at a reference height of 10 m above ground and  $k$  is a factor considering the envisaged return period, the number of observation years, and the yearly standard deviation; For example, for a return period of 50 years, a measurement period of 30 years, and a standard deviation of 0.14, one gets  $k = 1.42$ .

The reference wind velocity  $v_z$  increases with height  $h$  above ground due to the boundary effect, since frictional forces reduce  $\rho$  near the ground. It can be calculated from

$$v_z(h) = k_r v_z \ln \left( \frac{h}{z_0} \right), \quad (9.13)$$

**Table 9.10** Terrain categories, roughness length  $z_0$ , and terrain factor  $k_r$ 

Terrain category		$z_0$ (m)	$k_r$
0	Sea or coastal area exposed to open sea	0.003	0.155
I	Lakes of flat and horizontal area with negligible vegetation and without obstacles	0.01	0.169
II	Area with low vegetation such as grass and isolated obstacles (trees, buildings) with separations of at least 20 times obstacle heights	0.05	0.189
III	Area with regular cover of vegetation or buildings or with isolated obstacles with maximum separation of 20 times obstacle heights (such as villages, suburban terrain, permanent forest)	0.3	0.214
IV	Area in which at least 15% of the surface is covered with buildings with average height exceeding 15 m	1	0.233

Note: The terrain categories are illustrated in [9.20].

where  $k_r$  is the terrain factor and  $z_0$  is the roughness length (Table 9.10 [9.16]). The latter can also be used to calculate the turbulence intensity

$$I_v(h) = \frac{1}{c_0 + \ln(h/z_0)}. \quad (9.14)$$

Therein,  $c_0$  is the orography factor, which considers the effects of topography and can be set to  $c_0 = 1$  when the average slope of the upwind terrain is small. Together with  $v_z(h)$  and using

$$q_z = \frac{1}{2} \rho v_z^2, \quad (9.15)$$

one gets the peak wind pressure at a reference height  $h$  above the ground to be used in the calculation of the horizontal wind force on any line component as

$$q_p(h) = [1 + 7I_v(h)]q_z(h). \quad (9.16)$$

The two remaining factors in (9.9), viz. the structural resonance factor  $G_x$  and the drag factor  $C_x$ , differ for different components of the line and are considered in the respective sections.

**Wind Action on Conductors.** For typical conductor sizes, the recommended drag factor is  $C_C = 1.0$ . Also, the structural resonance factor  $G_C$  is called the span factor and considers the spatial effects of the wind on a span, as it is recognized that the wind will not act simultaneously on the whole length of the span. In some standards, this factor drops linearly from 1.0 to 0.7 for spans of 350 to 500 m, respectively. Thus, the wind pressure on the conductors of two adjacent spans will cause the following load on the associated support

$$Q_{WC}(\theta) = q_p(h)G_C C_C d a_W \cos^2(\theta), \quad (9.17)$$

where  $d$  is the conductor diameter,  $a_W$  is the wind span—defined as the arithmetic mean of the spans adjacent to the tower—and  $\theta$  is the angle between the wind direction and the conductor. In the case where the wind

acts perpendicular to the normal conductor,  $\theta = 0^\circ$  and (9.17) becomes

$$Q_{WC}(0^\circ) = q_p(h)G_C C_C d a_W. \quad (9.18)$$

In the case of a conductor bundle, the total wind load is defined as the sum of the wind loads on the individual subconductors, without taking into account any sheltering effects on leeward conductors.

The wind load will cause the conductor to swing; this will affect the distance of the conductor from the other conductors and earthed objects in its neighborhood and has to be adequately considered by respecting the statutory clearances (Sect. 9.3.3). The swing angle  $\varphi_C$  of the conductor follows from

$$\varphi_C = \arctan\left(\frac{q_p(z)G_C C_C d a_W}{m_C g a}\right), \quad (9.19)$$

where  $a_W$  is the wind span and  $m_C$  is the conductor mass per unit length.

**Combination of Wind and Ice Loads.** The wind action on ice-covered conductors must also be considered in the design of line supports, such as an extreme ice load combined with a high-probability wind velocity; in this case, the wind pressure may be reduced by 50%.

The equivalent diameter in m of an ice-covered conductor may be calculated [9.4, p. 185] as

$$D_i = \sqrt{d^2 + \frac{4g_i}{\pi\rho_i}} = \sqrt{d^2 + 0.000170g_i}, \quad (9.20)$$

where  $d$  is the diameter of the conductor [m],  $g_i$  is the characteristic ice load on the conductor [N/m], and  $\rho_i$  is the ice load density [N/m<sup>3</sup>].

The density of the ice  $\rho_i$  may be assumed to be 7500 N/m<sup>3</sup>, and the drag factor to be 1.0.

**Wind Action on Insulators.** Wind forces on insulators result from wind forces on the conductors as well

as from wind pressure on the insulators themselves. The latter is given by the expression

$$Q_{W_{ins}}(h) = q_p(h)G_{ins}C_{ins}A_{ins}, \quad (9.21)$$

where  $q_p(h)$  is the peak wind pressure,  $h$  is the reference height above ground to be used for the insulator set (which is the height of the attachment point on the support),  $G_{ins}$  is the structural factor for the insulator (with a recommended value of 1.0),  $C_{ins}$  is the drag factor for the insulator set (with a recommended value of 1.2), and  $A_{ins}$  is the area of the insulator.

For the design of the insulator itself, the resultant force  $Q_{ins}$  from the weight and the wind load of the suspended conductor has to be considered. This load is important as its direction determines the swing angle  $\varphi_{ins}$  of the insulator and thus the clearance to the line support (Sect. 9.3.3)

$$\varphi_{ins} = \arctan\left(\frac{q_p(z)C_cG_Ld a_W + Q_{W_{ins}}/2}{w_C + w_{ins}/2}\right), \quad (9.22)$$

where  $C_c$  is the drag factor (equal to 1.0 for typical conductors),  $q_p(z)$  is the peak wind pressure,  $G_L$  is the span factor taking into account the effect of the span length,  $d$  is the conductor diameter,  $Q_W$  is the wind span,  $Q_{W_{ins}}$  is the wind load on the insulator set,  $W_C$  is the effective conductor weight taking into account the differences in the level of the conductor attachment points, and  $W_{ins}$  is the dead weight of the insulator set.

**Wind Action on Line Supports.** There are two basic types of line support: The *classical* steel lattice towers and the increasingly used, in particular for compact lines, polygonal or circular poles (steel, concrete, wood, etc.) (Sect. 9.7). For the latter, the calculation of the wind forces is relatively simple, as they have basically a cylindrical shape.

The wind forces on poles can thus be determined by

$$Q_{WP}(h) = q_p(h)G_P C_P A_P, \quad (9.23)$$

where  $q_p(h)$  is the peak wind pressure,  $h$  is the reference height above the ground of the pole,  $G_P$  is the structural factor for the pole (with a recommended value of 1.0),  $C_P$  is the drag factor for the pole (with values between 0.7 for circular and 1.4 for hexagonal cross-section, for wooden poles  $C_P = 0.9$ ), and  $A_P$  is the area (or section) of the pole projected onto a vertical plane perpendicular to the wind direction.

On the other hand, the calculation of the wind forces on steel lattice towers follows basically the same procedure as for other line components as per (9.9), whereby the lattice tower is divided into sections. The related drag factor  $C_T$  depends on the so-called solidity ratio  $\chi$ , defined as the ratio of the effective area  $A_T$  of the tower profile to the circumscribed area of the respective tower section  $h(b_1 + b_2)$  [9.21]

$$\chi = A_T \frac{2}{h(b_1 + b_2)} \quad (9.24)$$

and can be calculated as [9.22]

$$C_T = 3.96(1 - 1.5\chi + \chi^2). \quad (9.25)$$

In case of the usual design with angle sections,  $C_T$  may be assumed to be approximately and uniformly 2.8 [9.22].

**Security Loads.** Security loads as per [9.16] cover one-sided release of static tension in a conductor and conventional unbalanced overloads such as unequal ice loads on adjacent spans, respectively. They cause longitudinal and torsional loads on the line supports and have to be considered accordingly.

**Safety Loads.** Line supports should be able to withstand all construction and maintenance loads that are likely to be imposed on them with an adequate margin of safety, taking into account working procedures, temporary guying, lifting arrangement, etc., as well as loads related to the weight of linesmen, which is assumed not be less than 1.0 kN acting together with the permanent loads.

**Short-Circuit Loads.** Consideration should be given to the effects of the forces imposed on the overhead lines forming part of a transmission system with very high short-circuit characteristics. The main concern during a short circuit is whether uncontrolled swinging of conductors could lead to conductor clashes, resulting in permanent circuit isolation following circuit-breaker operation at that time. The basics of the mechanical effects of short circuits are well explained in [9.23]. Short-circuit conditions may also cause mechanical problems on supports and conductor hardware, such as spacers and spacer dampers. The latter is examined in Sect. 9.6.3.

**Avalanches and Earthquakes.** When routed through mountainous regions, overhead lines may be exposed to avalanches or creeping snow. As such, consideration should be given to the possible additional loads

on the supports, foundations, and possibly conductors. The same applies for lines in seismically active regions, where forces due to earthquakes have to be taken into account, which will depend on the eigenfrequency of the support, the site structure resonance factor—varying with the soil conditions—and the height, weight, and mass distribution of the support. Since the frequency of the support is higher than that of the conductors, the dynamic load from the conductors will not be significant. Conversely, no important effects from the support relative to conductors should be expected.

### Partial Factors for Actions

It is evident from the discussion above that the determination of the different loads is coupled with uncertainties, as most of them are stochastic in nature. Similar to the partial factors for material properties presented in Sect. 9.3.1, partial factors  $\gamma_F$  must also be introduced for actions, which have to be multiplicatively applied to the characteristic value  $E_K$  of a certain action in order to obtain the respective design value  $E_d$ ,

$$E_d = \gamma_F E_K . \quad (9.26)$$

Table 9.11 [9.16] presents recommended values for the partial factor  $\gamma$  and combination factor  $\Psi$  for the actions presented in this section for various reliability levels as per Table 9.12, whereby the reference is level 1.

### 9.3.3 Electrical Clearances

Besides the mechanical issues, line design also has to consider the electrical requirements of a transmission

**Table 9.11** Partial and combination factors for actions (adapted from [9.16])

Action	Sym- bol	Reliability level		
		1	2	3
Variable actions (climate loads):				
Extreme wind load	$\gamma_w$	1.0	1.2	1.4
Nominal wind load	$\Psi_w$	0.4	0.4	0.4
Extreme ice load	$\gamma_i$	1.0	1.25	1.5
Nominal ice load	$\Psi_i$	0.35	0.35	0.35
Permanent actions:				
Self-weight	$\gamma_G$	1.0		
Security loads (accidental actions):				
Torsional loads due to conductor tension	$\gamma_{A1}$	1.0		
Longitudinal loads due to conductor tension	$\gamma_{A2}$	1.0		
Safety loads:				
Construction and maintenance loads	$\gamma_P$	1.5		

**Table 9.12** Reliability levels

Reliability level	Theoretical return period $T$ of climatic actions (years)
1 (reference)	50
2	150
3	500

line, not only from the system perspective (Chap. 5) but also from the reliability and safety point of view. This is basically an issue of insulation coordination (Chap. 3), which leads to certain minimum clearances, which again will influence the support geometry and the necessary right of way (ROW), specifically the distance to objects near the line, such as roads, buildings, crossings with other lines, etc. Nowadays though, in most if not all cases, the ROW will be determined by the imposed electromagnetic field (EMF) limits presented in Sect. 9.3.4.

### Internal Clearances

The geometry of the top of the line supports must be designed so as to ensure that the so-called internal clearances between live parts and supporting earthed structures as well as between conductors within the span, especially in mid-span, are respected. Thereby and because of economic considerations, a very small number of interphase flashovers is considered acceptable, as these will not affect the safety of the public.

In a first step, the conductor and insulator positions due to the action of wind have to be determined. Methods to calculate the conductor and insulator displacement are detailed in [9.24] (Fig. 9.16) for the clearances between live conductors and earthed structures, such as the supports, while [9.25] (Fig. 9.17) gives guidance on the calculation of these displacements for the clearances between conductors within the span. In the case of long spans, differential swing angles may occur between horizontal phase conductors, thus one phase conductor may swing more than an adjacent one, causing reduced clearances. This situation has been designated more recently as *asynchronous swing*, resulting in a tower top geometry design based upon statistical considerations.

In [9.25], valuable information was gathered from quite a large number of countries and completed with information from standards. The related review resulted in a proposal to consider two situations when designing the tower top geometry and mid-span clearances in view of conductor and insulator swing under the action of wind load:

- In *still air* or under moderate winds, there should be adequate clearance to withstand lightning or switch-

**Fig. 9.16** Clearance between insulator set and earthed structure (400 kV, twin-bundle ACSR Finch (ACSR 564/72), 5 min wind velocity, 400 m wind span) (adapted from [9.24])

**Fig. 9.17** Clearances between adjacent conductors in mid-span (400 kV, twin-bundle ACSR Finch (ACSR 564/72), 5 min wind velocity, 400 m wind span) (adapted from [9.25])

ing surge impulse voltages with a probability of more than 90%. Still-air conditions apply to conductor positions occurring during at least 99% of the operation period.

- Under *high wind*, the clearances should be adequate to withstand the power frequency voltage only. The probability of flashovers depends on the probability

**Table 9.13** Type of internal clearance per load case

Type	Electrical stress of the air gap	Load case
1	Lightning/switching impulse voltage	Still-air conditions with maximum conductor temperature or ice load
2	Reduced impulse voltage	Reduced wind load ( $T = 3$ years)
3	Power frequency voltage	Extreme wind load ( $T = 50$ years)

of occurrence of the corresponding wind velocity. For a wind velocity having a return period of 50 years, the probability of flashover will be 1% per year at maximum.

In [9.16], three load cases for the internal clearances are considered. They are summarized in Table 9.13, where  $T$  is the return period of the wind load.

Certain countries consider additional load cases such as galloping (Sect. 9.4.11) and different wind or ice loads on adjacent conductors.

In a second step, the clearances necessary to withstand given electrical stresses have to be determined. These are derived from the electrical characteristics of the transmission system, in particular from its insulation level as per [9.26]. This standard prescribes that, for lines up to 245 kV, lightning (fast front) impulses determine the insulation level, while for lines above 245 kV, switching (slow front) impulses do.

Finally, coordination between the conductor positions and electrical stresses has to be established. For this purpose, [9.25] proposes to consider at least two cases when designing the tower top geometry and mid-span clearance (Table 9.14).

Case 1 is described by the conductor and insulator positions which would occur under the action of the design wind velocities having a return period  $T$  of 50 years. These positions are combined with the clearances required to withstand power frequency voltages. The probability of flashovers depends on the probability of occurrence of the corresponding design wind velocity. For a wind velocity having a return period of 50 years, the probability of flashover will be 1% per year at maximum.

Case 2 is described by the conductor and insulator positions which are assumed not to be exceeded during 99% of the time. These positions are combined with the clearances required to withstand the lightning or switching overvoltages with a probability of more than 90%. The flashover probability is that at which the design overvoltage conditions will be exceeded.

**Table 9.14** Coordination of conductor positions and electrical stresses (adapted from [9.25])

Electrical stress of the air gap	Probability	Conductor and still air or moderate wind during 99% of time	Insulator positions High wind velocity with $T = 50$ years
		High	Low
Power frequency voltage	High	Covered by cases 1 and 2	Case 1
Lightning/switching impulse voltage	Low	Case 2	Not considered

**Table 9.15** Required clearances for power frequency voltages

Voltage level		[9.27]		[9.16]	
$U_R$ (kV)	$U_S$ (kV)	$D_{pe\_pf}$ (m)	$D_{pp\_pf}$ (m)	$D_{pe\_pf}$ (m)	$D_{pp\_pf}$ (m)
110	123	0.32	0.42	0.23	0.37
230	245	0.64	0.85	0.43	0.69
400	420	1.16	1.85	0.70	1.17
500	525	1.68	2.20	0.86	1.47

These clearances apply to the following reference conditions for altitudes not exceeding 1000 m:

- Temperature 20 °C
- Air pressure 101.3 hPa (1013 mbar)
- Humidity 11 g/m<sup>3</sup>.

Between live parts of insulator sets or conductors and earthed components, and between conductors and earth wires, minimum phase-to-earth clearances are required, while between live conductors having differing phases, minimum phase-to-phase clearances must be complied with. Tables 9.15 and 9.16 present the clearances under power frequency and impulse voltages, respectively, for the two system voltage categories mentioned above.

### External Clearances

External clearances have to be respected between the live parts of the line and their neighborhood, so that danger from an electrical discharge to the general public and persons working and/or maintaining the power lines can be avoided. The following situations have to be considered:

- Clearances to ground in remote areas
- Clearances to residential and other buildings
- Clearances when crossing lines or adjacent to roads, railways, and navigable waterways
- Clearances when crossing or running parallel to other power lines or overhead telecommunication lines
- Clearances to recreational and sports areas
- Clearances in other specific situations.

These are often vertical clearances, where the maximum conductor temperature is of paramount impor-

**Fig. 9.18** Definition of external clearances (adapted from [9.4])

tance, as this will result in the maximum conductor sag. Sag calculations (Sect. 9.4.4) should be based on the maximum continuous service temperature of the conductor.

External clearances consist of the necessary electrical distance  $D_{el}$  and an additional safety distance  $D_{add}$  so that neither persons nor objects come dangerously close to the live line (Fig. 9.18 [9.4, p. 59] and Table 9.17 [9.16]).

### 9.3.4 Environmental Issues

The first 380-kV—in practice 400-kV—overhead line worldwide was constructed and put into operation in 1952 in Sweden. Many other similar lines followed in order to keep pace with the enormous demand for electricity necessary to resurrection the economy after World War II. In those days, overhead lines were neither ugly nor beautiful and were not considered harmful to health. On the contrary, it was a privilege to be connected to the electrical grid, which by the way is still the case in many developing countries.

However, things have changed. Since then, the ecological conscience of the public in industrialized countries—and elsewhere—has been awakened, and transmission lines are often criticized and their construction strongly objected to, on one hand due to their visual impact and on the other due to the purported harmful impact of their electromagnetic fields (EMF) on health. This attitude of the public—and some journalists and politicians—has caused in many cases serious delays to the approval and construction of new

**Table 9.16** Required clearances for impulse voltages

Voltage level		Impulse voltages			[9.28]	[9.27]	[9.16]		
$U_R$ (kV)	$U_S$ (kV)	$U_{90\%_{ff}}$ (kV)	$U_{50\%_{ff}}$ (kV)	$U_{max_{sf}}$ (kV)	$D_{pe}$ (m)	$D_{pe}$ (m)	$D_{pp}$ (m)	$D_{pe}$ (m)	$D_{pp}$ (m)
110	123	450	490	–	0.9	0.94	0.96	0.89	1.00
		550	590	–	1.1	1.13	1.17	1.07	1.20
230	245	850	920	–	1.7	1.76	1.83	1.67	1.86
		950	1030	–	1.9	1.97	2.05	1.87	2.07
		1050	1140	–	2.4	2.18	2.26	2.05	2.29
400	420	1175	1270	850	2.4	2.40	2.70	2.25	2.67
		1300	1410	950	2.9	2.80	3.20	2.64	3.15
		1425	1540	1050	3.4	3.25	3.73	3.02	3.68
500	525	1300	1410	950	2.9	2.80	3.20	2.64	3.15
		1425	1540	1050	3.4	3.25	3.73	3.02	3.68
		1550	1680	1175	4.1	3.90	4.48	3.60	4.40

$U_R$  nominal voltage;  $U_S$  highest system voltage for equipment;  $U_{ff}$  fast front (lightning impulse) withstand voltage;  $U_{max_{sf}}$  maximum slow front (switching impulse) withstand voltage;  $D_{pe}$  minimum phase-to-earth clearance;  $D_{pp}$  minimum phase-to-phase clearance

**Table 9.17** Distances  $D_{add}$  (m) to obstacles in addition to  $D_{el}$  (adapted from [9.16])

Crossed obstacle	Maximum conductor temperature; ice load; average wind load	Local ice load
Ground in open countryside		
– Normal ground profile, used by agriculture	5.0	a
– Steep slopes	2.0	a

lines, many of which are badly needed for the integration of the increasing number of renewable energy sources (RES). The industry has reacted and introduced a plethora of measures not only to inform the public but also to comply with the related laws and regulations; the latter will evidently influence line design. In addition, line components have to be selected and de-

signed with consideration of the life cycle assessment (so-called LCA) of the line. In this sense, this section covers:

- Calculation of EMFs
- Impact of EMFs on health
- Other environmental issues

- Consultation models
- LCA.

### Calculation of EMFs

Overhead lines create both electric and magnetic fields with a low frequency of 50 or 60 Hz. Electric fields in general influence electric charges, also on the surface of the human body, affecting the current flow within the body, while magnetic fields induce currents in it, which depend on the dimensions as well as the conductivity of the different parts of the human body. A first necessary step is thus to calculate the electric and magnetic fields in the vicinity of a line.

Nowadays, such calculations are done using computer simulations based on approaches such as the finite element method (FEM) or boundary element method (BEM). The problem can be simplified to a good approximation to be only two dimensional, whereby the conductors are considered to be of infinite length.

**Electric Field.** The electric field resulting from a high-voltage line depends on the voltage, the form of the tower, and the configuration of the conductors. It is easily calculated from Maxwell's equations if the charges on the conductors and the ground are known. In the two-dimensional approximation, a charge  $q$  gives rise to a field strength  $E(R)$

$$E(R) = \frac{q}{2\pi\epsilon_0 R}, \quad (9.27)$$

where  $R$  is the distance to the charge and  $\epsilon_0$  is the dielectric constant of vacuum.

For this calculation, the charges on the conductors and ground first have to be calculated by solving Poisson's equation. This can be done, for example, by means of the capacity matrix. A typical plot is shown in Fig. 9.20 for the conductor arrangement in Fig. 9.19 [9.29]. The maximum root-mean-square (rms) values of the electric field shown there are obtained at the time instants when the voltage of the middle conductor is at its maximal value or passes through zero, i.e., when the voltage values of the left and right conductors are equal.

**Magnetic Field.** The value of the magnetic field  $B(R)$  due to a current  $I$  at a radial distance  $R$  from the conductor is given in the two-dimensional (2-D) approximation considered here by the simple expression

$$B(R) = \frac{I}{2\pi\mu_0 R}, \quad (9.28)$$

where  $\mu_0$  is the permeability of vacuum.

**Fig. 9.19** Schematic of a high-voltage line for EMF calculations (earth wires neglected) (adapted from [9.29])

**Fig. 9.20** Lateral distribution of maximum (rms) electric field  $E$  of the line in Fig. 9.19 at 2 m above the ground with a conductor 20 m above the ground (adapted from [9.29])

The direction of the magnetic field vector is always tangential to concentric circles around the conductor, following the so-called right-hand rule. As in the case of the electric field above,  $B(R)$  is the value of the total magnetic field strength, i.e., the value of the vector sum of the magnetic field strengths of the three phases. Figure 9.21 [9.29] shows the related rms value for the line configuration in Fig. 9.19, and Fig. 9.22 shows a schematic of the three-dimensional (3-D) magnetic field distribution for a line with so-called Danube-type towers. Evidently, the highest field values occur in the center of the span (greatest sag) and fall off rapidly.

**Fig. 9.21** Lateral distribution of maximum magnetic field (rms) of the line in Fig. 9.19 at 2 m above the ground with a conductor at 20 m above the ground

The electric and magnetic field values depend strongly on the line design and in particular on the support geometry and conductor arrangement (Table 9.18 [9.30]). Therein, the influence of these parameters on the radio interference (RI) and acoustic noise (AN), both arising from the so-called corona effect (Sect. 9.4.7), is also shown.

Specifically:

- Compaction is the best way to reduce the EF at ground level.
- Compaction is the best way and increasing the height of the conductor the easiest way to reduce the MF at ground level [9.31].
- Compaction increases the AN and RI levels, as the related EF increases on the conductor surface of the phase conductors.
- The best way to reduce the RI and AN levels is to increase the number of subconductors.

In addition, transposition of the conductors can reduce the EMF considerably [9.32].

**Table 9.18** Influence of line parameters on electrical line design

Parameter	EF	MF	RI	AN
Phase-to-phase distance ↑	↑	↑	↘	↓
Conductor height above the ground ↑	↓	↓	↘	↘
Number of subconductors (for given total cross-section) ↑	↓	=	↓	↓
Subconductor spacing ↑	↗	=	↗	↗
Total conductor cross-section ↑	↗	=	↘	↘

↑ Strong increase, ↓ Strong decrease, ↗ Slight increase, ↘ Slight decrease, = no significant effect, EF: electric field, MF: magnetic field, RI: radio interference, AN: acoustic noise

**Fig. 9.22** 3-D distribution of the magnetic field of a double-circuit line

### Impact of EMFs on Health

In the 1970s, a new issue emerged, namely the purported negative effects that lines might have on public health. In line with the megatrend of the growing environmental awareness of the public, this has become a major concern for the industry, beside line esthetics (Sect. 9.7.6). For many years, this health issue has been closely monitored by a special-purpose, permanent CIGRE working group, WG C3.01, which recently published two state-of-the-art reports, from which the following information is extracted [9.33, 34].

It all started with a study carried out in Denver, Colorado in 1979 [9.35]. The authors were looking for possible environmental factors around the homes of children who had leukemia. The magnetic field produced in houses by the current flowing in the wires was estimated to be about  $0.2 \mu\text{T}$ , and the authors suggested that it might be the reason for this association. The design of the original Denver study was exploratory in nature and subject to many possi-

ble sources of error. Despite the skepticism, the study was given very serious consideration by the authorities, academia, and the industry and led to a vast international research effort. Practically all studies showed that an association between the presence of power lines and childhood leukemia almost certainly could not be attributed to magnetic fields generated by power lines. One of the largest studies carried out among a collection of over than 225 000 electrical utility workers looked at past exposure to magnetic and electric fields in 4154 cases of cancer [9.36]. The cancer risk for all types of cancer among the highest exposed group was not different from the lowest exposed group.

Many of these studies were carried out among exposed workers, where average fields are up to 20 times, with short periods of exposure at up to 1000 times the residential exposure level. Those studies also failed to show an increased risk of cancer. Results consistently showed cancer mortality rates 20–30% lower among workers, compared with the general public, an observation known as the *healthy worker effect*.

Another portion of such studies has examined carcinogenicity in animals: human beings are mammals, and their respective physiology is very similar. Thus, it is no surprise that, among the hundred or so human carcinogens confirmed so far, all of them, with no exception, have been shown to be carcinogenic to animals. For this reason, magnetic field carcinogenicity has been extensively tested on animals. Results are highly consistent: overall, no evidence of an increase in the incidence of benign or malignant tumors including leukemia was reported.

A few experimental studies have been carried out on human volunteers at high field levels up to 3000  $\mu\text{T}$ . The subjects were not able to perceive the presence of the fields, nor were adverse effects or signs of toxicity reported. Thus, the absence of any toxicity at levels up to 30 000 times the average field in homes (0.1  $\mu\text{T}$ ) makes a carcinogenic effect extremely unlikely.

In conclusion, it can today safely be assumed that the hypothesis raised by the Denver study in 1979 is very likely to be a false alarm. The exceptional amount of data accumulated over the last 35 years confirms that fields below the above-mentioned recommended power-frequency magnetic field levels are much too weak to influence human biology.

Despite the fact that no consistent adverse findings have been identified and no particular health effect reported, the International Commission on Non-Ionizing Radiation Protection (ICNIRP) as a precautionary measure has recommended exposure limits of 200  $\mu\text{T}$  for the public and 1000  $\mu\text{T}$  for workers; quite a few countries have implemented even lower values. These values

**Table 9.19** Typical electric and magnetic field value of lines

Line voltage (kV)	Electric field at ground level (1 m height) (kV/m)	Magnetic field at ground level (1 m height) ( $\mu\text{T}$ )
765	8–13	28–32
525	5–9	25–30
420	4–8	22–28
245	2–3.5	20–25
123	1–2	12–15
70	1–1.5	2–2.5

are much lower than typical field values from lines (Table 9.19) but often also from magnetic fields from household appliances.

Electric fields are in general not considered carcinogenic, but they induce electric charges on the body surface that affect the current flow within the body. These currents, depending on their magnitude, may cause eye flickering, stimulation of muscles and nerves, and in extrema the often lethal heat fibrillation. A widely accepted limit is 5 kV/m.

### 9.3.5 Approval Procedure

The approval process for building a new, but also for modifying a line is an important part of the design process, as it takes quite a long time, much more than the time needed to technically plan and build the line (Fig. 9.7). In addition, and as the line has to fulfill increasing and not always easily understandable environmental constraints, the line design often has to be modified during the approval procedure; For example, suspension insulators may have to be replaced with insulated cross-arms (Fig. 9.66) to avoid conductor swing, the height of the tower may have to be increased to reduce the EMFs at ground level, or even parts of the line have to be partially undergrounded, which will require special terminal structures.

A CIGRE inquiry in 1999 [9.5] revealed the top five problems that utilities face when planning an OHL project. These are valid, even more, nowadays:

- EMF health concerns
- Visual impact
- Landowner negotiations and access
- Community opposition
- Property values.

In drawing up proposals for new overhead transmission lines, undertaking environmental impact assessments (EIAs), and seeking rights, permits, and consents to construct, transmission companies are increasingly,

whether legally required or voluntarily, undertaking more stakeholder consultation. Community involvement can be key to the success of often-controversial new transmission infrastructure proposals, requiring the use of innovative and *best-practice* approaches. Public hearings are a key feature of most processes [9.37].

Best practices for consultation models and stakeholder engagement strategies in sustainable development for OHL projects have been summarized in [9.38, 39].

### Consultation Models

Most companies undertake much more consultation than legislation requires. Mandatory consultation requirements often only exist in environmental assessment legislation. Whilst consultation takes time, it also helps identify likely concerns and possible points of objection and helps refine proposals, address concerns, and smooth the eventual permitting process. Companies should establish a consistent approach to mapping stakeholders and understanding their viewpoints, needs, and expectations. Use of independent specialists when considering options, preparing consultation information, and assisting at advisory meetings increases the credibility of the information presented and helps secure understanding and cooperation from stakeholders.

Presenting as much information as possible, trying to get the balance right, and tailoring information to suit the audience, as well as communicating via the best methods available (e.g., company website, detailed publications or brochures, periodic newsletters, advertorials in local newspapers, etc.) and conducting open and engaging consultation with a broad range of representative and interested groups are often used as methods to accelerate the approval procedure.

### Stakeholder Engagement Strategies

Stakeholder engagement should be appropriate for the purpose and the target audience and should be proactive and meaningful. Stakeholders should generally be involved at project stages where they are able to influence an outcome or decision.

The following checklist may prove useful for successful stakeholder engagement:

- Consistent approach
- Project scoping
- Stakeholder identification
- Early engagement
- Targeted mix of consultation/engagement methods
- Open and transparent process
- Feedback to stakeholders.

### Life Cycle Assessment

Life cycle assessment (LCA) is a very valuable tool for overhead lines engineers, planners, and utilities to assist in the evaluation of the impact or interaction of overhead lines and the environment. It can be used and developed across a range of applications from environmental reporting to product improvement and comparison. However, it should be noted that its use has some restrictions.

CIGRE WG B2.15 was set up in 2000 to examine LCA issues as applied to overhead lines and to study aspects of overhead lines relating to environmental concerns. Based on the work across the range of LCA issues investigated and informed by the studies undertaken within the working group and elsewhere, conclusions are presented in [9.40].

The results of actual LCA studies carried out on some of the principal overhead line components lead to the following recommendations:

To reduce the environmental impact, especially in terms of resource exhaustion, it is strongly recommended that lattice steel towers be recycled. This could reduce the amount of iron as well as zinc reserve consumption.

In addition, related to gas emissions as well as resource exhaustion, it is strongly recommended that conductors be recycled. It is commonly known that the energy required to recycle aluminum is about 3% of that needed for original aluminum production. The electrolysis process applied to extract alumina from bauxite for original aluminum production requires a large amount of electricity, while the aluminum recycling process basically consists of melting and molding processes, which need less energy than the electrolysis process.

Another way to reduce the environmental impact is to reduce transmission losses. In this respect, the development of low-resistance conductors seems to represent an effective approach that could be recommended. Upgrading to a higher-voltage may also seem to be effective; however, a more comprehensive analysis of the whole power system would be needed to draw this conclusion.

With regard to insulators, only a small percentage of removed insulators are experimentally recycled as construction materials, and a porcelain insulator recycling system is not fully established. Given that more energy is consumed in the manufacturing processes of insulators than in the raw material manufacturing processes, the establishment of the reuse of removed insulators as value-added materials is desirable.

Another approach to reduce environmental impacts might be to extend the function of insulators as long as possible. In this respect, the development of efficient

and reliable diagnostic methods as well as life span extension technologies is recommended.

Last but not least, efforts should be made to keep the duration of overhead line construction to a minimum, as significant environmental impacts can arise at this stage. It is recommended that environmental manage-

ment plans should be developed and used. If required by the authority or landowner, access roads should be removed and the related material recycled. Maintenance activities should be organized and scheduled to eliminate or minimize the environmental impact, particularly painting of towers.

## 9.4 Conductors

The phase conductors of an overhead power line are considered to be the most important component of the line, since they are required to transmit electric power, and their cost contribution toward the total cost of the line is significant. Conductor costs (material and installation) associated with the capital investment of a new overhead power line can contribute up to 40% of the total capital costs of the line. In addition, the longitudinal (tension), transverse (wind), and vertical loads produced by the conductor system, and the maximum sag at high current levels, largely determine the cost of the towers and their foundations. Consequently, much attention has always been given to proper selection of the conductor to meet present and predicted future load requirements [9.41].

With regard to environmental effects, the conductor system largely determines the corona noise and audible noise levels produced by the line and the electrical resistance, as well as the energy losses over the life of the line.

A relatively recent focus on line uprating (Sect. 9.10) has led to the development of new conductor options and applications and in particular of so-called high-temperature low-sag (HTLS) conductors. This section covers, besides the basic mechanical and electrical properties of conductors, their behavior under wind-induced oscillations, conductor hardware, conductor monitoring, and HTLS conductors.

### 9.4.1 Types and Basic Properties of Conductors

The most widely used form of bare overhead conductors are concentrically stranded, with the outer, current-carrying layers consisting of aluminum wires, helically wrapped around a core consisting of steel wires, whose purpose is to provide mechanical strength. Such conductors are called aluminum conductor steel-reinforced (ACSR). The number of aluminum layers varies from one to four or more in very large-diameter conductors, while the steel core normally consists of 7–37 wires depending on the strength required. In areas with mild

ice and wind loads, the steel core may be replaced with aluminum or aluminum alloy. In lines designed or uprated to maximum design temperatures over 100°C, the steel core may be replaced with special core materials consisting for example of embedded carbon or ceramic fibers. Stranding improves conductor flexibility compared with a solid rod, and thereby its ease of handling and reeling. Stranding also enables the manufacture of considerable lengths of conductors without the need for joining.

All standard overhead conductors are reverse lay; i.e., the direction of rotation of each layer is opposite to that of the layer below (Fig. 9.23). Use of reverse lay reduces the torque that is created in conductors when they are tensioned and which can cause problems during stringing. Reverse lay in addition improves the electrical characteristics, in particular the self-inductance and AC resistance. For phase conductors, the usual convention is to wrap the outer layer with a right-hand lay, as opposed to the shield, also called earth or ground wires, which have a left-hand lay in their outer layer. For conductor layers with equal-diameter wires, each layer has six wires more than the layer beneath it, which provides a good fit between the conductor wires. This and other important information on conductor design and fabrication are covered extensively in [9.42].

An important property of the conductor geometry is the lay length  $\ell_L$  or *pitch*. This is defined as the

**Fig. 9.23a,b** Conductor characteristics. (a) Conductor geometry, (b) direction of lay (adapted from [9.42])

Fig. 9.24 Conductor geometry

axial length of a complete turn of the helix formed by an individual wire in a stranded conductor. The respective lay angle  $\beta_L$  is the angle of the wire axis to the conductor axis.

These properties are best illustrated in terms of a wire that has been *unrolled* from its helix onto a plane (Fig. 9.24). If the diameter of the cylinder defined by the helical axis of the wires in a layer is  $d_L$ , then its circumference is  $\pi d_L$ , and the lay angle  $\beta_L$  is obtained as

$$\beta_L = \arctan\left(\frac{\pi d_L}{\ell_L}\right). \quad (9.29)$$

Lay angles are usually in the region of  $10\text{--}15^\circ$  if the so-called lay ratio, defined as the ratio of the lay length  $\ell_L$  to the mean diameter  $d_L$  of the helix of a wire layer, lies within the values permitted in the respective standards, i.e., between 10 and 17—preferably around 13—for aluminum layers and between 12 and 30—preferably 20–25—for steel layers. These values result in satisfactory layer fill and good handling characteristics of the finished conductor. It should be noted that, the smaller the lay ratio, the more turns the wire makes in a given length and the more flexible the stranded conductor becomes [9.43].

Very early on, i.e., at the end of the 19th century, aluminum-based conductors began to replace the copper conductors that had originally been used. Modern aluminum wires are produced in a rolling/casting process and are called Properzi blanks [9.43]. Some overhead conductors are constructed only from pure aluminum and are referred to as all aluminum conductors (AAC). Because of their relatively low strength-to-weight ratio, these types of conductor are suitable for short spans in distribution networks and for areas where ice and wind loads are limited, as well as for flexible busbars in substations. For added strength, various aluminum alloys with inclusion of magnesium and silicon have been developed, referred to as all aluminum alloy conductors (AAAC), also called Almelec or Al-

Fig. 9.25 ACSR conductor (steel wires are dark shaded)

drey conductors. Their excellent corrosion resistance has made AAACs the conductors of choice for use in coastal areas.

When a higher strength-to-weight ratio is desired, a strength member has to be added to the conductor. This is usually done by including a core of steel wires, leading to the aluminum conductor steel-reinforced (ACSR) configuration (Fig. 9.25) that has been the most commonly used type of conductor worldwide since the beginning of the 20th century, estimated to account for about 80% of the total. ACSR cables are available with a wide range of steel content—from 7% by weight for 36/1 stranding to 40% for 30/7 stranding (Table 9.20) [9.44, Table F.19]. Early designs of ACSR such as 6/1, 30/7, 30/19, 54/19, and 54/7 strandings featured high steel content of 26–40%, with an emphasis on strength perhaps due to fears of vibration fatigue problems (Sect. 9.4.11). Today, the most widely used strandings are 18/1, 45/7, 72/7, and 84/19, with a range of steel content of 11–18%. The high-strength ACSR 8/1, 12/7, and 16/19 strandings are used mostly for overhead ground wires, extralong spans, river crossings, etc.

The steel core wires used in most ACSR overhead conductors are made of medium-strength zinc-coated (galvanized) steel containing 0.50–0.85 wt% carbon with a nominal tensile strength of 1400 MPa, or more seldom aluminum-coated (aluminized) or aluminum-clad steel, in which the aluminum cladding accounts for 25% of the area of the wire, with a minimum coating thickness of 10% of the overall radius.

The multiple-layer aluminum envelope of composite conductors permanently protects the zinc-coated steel wires against corrosion, when the steel cores are greased. However, especially in regions with a hot climate, grease of an inappropriate type could melt and drop from the conductor, thus producing corona discharges. Therefore, attention should be paid to a sufficiently high drop point of the grease (above  $80^\circ\text{C}$ ) and a high viscosity. Standard [9.45] applies to greases.

In homogeneous conductors, i.e., conductors employing only a single material (AAC and AAAC), all the wires have the same diameter; this is also the case

**Table 9.20** Characteristic data of ACSR conductors

Designation	Former code	Cross section total (mm <sup>2</sup> )	Number of strands		Conductor diam. (mm)	Mass per unit length (kg/km)	Rated strength (kN)	DC resistance (Ω/km)	Current-carrying capacity (A)

in some ACSR conductors. However, in the majority of the latter, all the aluminum wires have the same diameter while all the steel wires have another, different diameter. Wire diameters in overhead line conductors range between 2 and 5 mm.

Apart from the *standard* conductor designs, there are also a number of special designs, such as conductors with high steel content for very long spans such as river crossings, smooth-body conductors, and expanded conductors. One way to improve and tailor conductors for special situations is to form the

aluminum wires in a trapezoidal or z-shape. These conductors make better use of their space compared with round-wire conductors and are, therefore, called *compact* (Fig. 9.26).

The proper designation of conductors is an interesting issue. In Central Europe, the conductor name contains the abbreviation of the conductor material(s) and the respective cross-section(s) in mm<sup>2</sup>. For example, a commonly used ACSR conductor with an aluminum cross section of 243 mm<sup>2</sup> and a steel cross-section of 39 mm<sup>2</sup>, in the old days simply called Al/St

**Fig. 9.26** Compact ACSR conductor

240/40 [9.46], is nowadays denoted as 243-AL1/39-ST1A. In other parts of the world, the North American practice is often followed, whereby conductors carry names of flowers, cities, and birds, e.g., Tulip, Rose, and Magnolia for AAC, Akron, Montreal, and Halifax for AAAC, and Pelican, Hawk, and Drake for ACSR.

### 9.4.2 Conductor Manufacture

Conductor manufacture is a complex process and a crucial one as the manufacturing method employed determines the stress regime in the conductor strands, which, in turn, significantly influences the behavior of the conductor under mechanical loads in service.

This is best explained by describing the operation of a so-called orbital strander (Fig. 9.27 [9.47]), which is mainly used for manufacturing smaller conductors with up to 19 strands as well as steel cores of up to 19 strands for ACSR.

In this type of strander, spools of wire are mounted in *heads* which rotate about the conductor axis, with each head supplying the strands for one layer. A *closing die*, usually made of fiber material or wood, forces the strands snugly into their final position. Just before reaching the closing die, the wires pass through so-called *preformers* (Fig. 9.28 [9.47]), which have the task of forming the strands to approximately the shape that they will adopt in the finished conductor. In this way, the built-in stresses and moments in the strands are reduced, as well as their tendency to spring back after cutting. The handling characteristics of these con-

ductors are greatly enhanced by this process. Finally, the capstan supplies the pulling force to draw the layer wires from their spools and also the core wire from its reel. The capstan speed is synchronized to the rotational speeds of the strander heads by gearing, to achieve the desired pitch of the strand helices.

The influence of the manufacturing process has been thoroughly investigated and presented in [9.48] using a 3-D FEM model and verified by extensive full-size tests. In particular it has been shown that the path of the individual wires from their round shape on the bobbin to their helical shape when embedded in the conductor is of paramount importance for the residual stresses in the conductor wires. In Fig. 9.29, the two extreme conditions are shown schematically, together with the FEM simulation results for the axial stresses in the conductor. As can be seen, due to room-temperature viscoplastic effects, stress relaxation occurs during storage, reducing the magnitude of the residual stresses.

### 9.4.3 Tests

#### Wire Tests

Tests of the individual conductor wires are prescribed in a number of national and international standards. Usually, sample tests are carried out on every 10% of the wire length ready for stranding:

- *Wire diameter*: Accuracy two decimal places; max. deviation from value in the standard:  $\pm 0.003$  mm for diameters up to 3 mm,  $\pm 1\%$  above.
- *Wire surface*: Smooth, free from cracks, fissures, and other damage, no inclusion of copper particles in the aluminum wires.
- *Tensile strength*: Tested on a wire sample of 250 mm length; should meet the prescribed value.
- *Wrapping test*: An aluminum sample wire is coiled eight times around a mandrel of the same diameter, then six turns are uncoiled and coiled again; the test is passed if the wire does not break.
- *Galvanizing*: The zinc mass of galvanized steel wire is determined by removing the zinc coat-

**Fig. 9.27** Schematic of orbital strander (adapted from [9.26])

Fig. 9.28 Preforming head (adapted from [9.47])

ing using hydrochloric acid, while the uniformity of the coating is tested by applying the zinc dip test.

- **Resistivity:** In this test, the wire resistance is first measured at a temperature of 10–30°C and then adjusted to the reference temperature of 20°C using

the well-known formula

$$R_{20} = \frac{R_T}{1 + \alpha(T - 20)}, \tag{9.30}$$

where  $T$  is the measurement temperature,  $R_T$  and  $R_{20}$  are the resistance at temperature  $T$  and 20°C, respectively, and  $\alpha$  is the temperature coefficient of resistance.

In this regard,  $\alpha = 23 \times 10^{-6}$  for aluminum and  $\alpha = 11.5 \times 10^{-6}$  for steel; i.e., the ratio is 2 : 1, a value to be remembered for later.

- **Welding:** When aluminum wires are broken during stranding, they can be joined again by welding under the following prerequisites:
  - The number of joints is limited.
  - The minimum distance between two joints in the same wire or any other wire is 15 m.
  - The joints should be rendered smoothly.
  - The joints should withstand a minimum tensile stress of 75 N/mm<sup>2</sup>.

### Conductor Tests

For the finished conductors, the tests listed in Table 9.21 [9.44] are required.

These tests are of particular importance as they provide the necessary input for the mechanical behavior of a conductor in service.

**Stress–Strain Test.** This test describes the behavior of the conductor under mechanical load and is carried out on a conductor sample of at least 400 times the conductor diameter but not less than 10 m. The *test loads* should be applied on the conductor using the follow-

ing steps, where the load should be completely released after each step:

- Initial load of 5% of the *rated tensile strength* (RTS) to straighten the conductor
- Load with 30% RTS and holding the load for 0.5 h
- Reload to 50% RTS and holding for 1 h
- Reload to 70% RTS and holding for 1 h
- Reload to 85% RTS and holding for 1 h
- After the fourth application of load, the conductor is loaded again by increasing the tensile force steadily until the actual breaking strength is reached.

The initial stress–strain diagram is obtained by drawing a smoothed line through the strain point after 0.5 h at 30% RTS and the strain points after 1 h at 50%, 70%, and 85% RTS. The curve should be adjusted to pass through the zero point. The initial stress–strain diagram is represented by the blue line marked *initial modulus* in Fig. 9.30. The characteristic final stress–strain diagram may be determined from the unloading part (from 50%, 70%, or 85% RTS) of the graph, as agreed upon between the manufacturer and client. Figure 9.30 shows an example stress–strain diagram [9.50].

The rated tensile strength (RTS) of bimetallic conductors is determined in accordance with [9.44, Sect. 5.9]. For  $AL_x/ST_{yz}$  and  $AL_z/y_zSA$  conductors, it is equal to the minimum tensile strength  $\sigma_{BAl}$  of the aluminum wires before the stranding process, multiplied by their nominal cross section  $A_{Al}$  plus the tensile stress  $\sigma_{1\%Fe}$  of the steel or aluminum-clad steel wires at 1% elongation on a 250-mm gauge length before stranding, multiplied by their nominal cross section  $A_{Fe}$ .

$$RTS = \sigma_{BAl}A_{Al} + \sigma_{1\%Fe}A_{Fe} \quad (9.31)$$

**Fig. 9.30** Typical stress–strain curve of a conductor (adapted from [9.50])

**Fig. 9.31** Creep curves for ACSR Cardinal (483-AL1/63-ST1A) (adapted from [9.4])

The requirements on the RTS of a conductor are considered to be met by a test when failing of individual wires occurs only after 95% of its rated strength has been reached.

**Creep Test.** Creep is another expression for plastic elongation and is explained in [9.51]. Aluminum strands, and, to a much lesser extent, steel strands used in bare overhead conductors, undergo plastic (i.e., permanent) elongation as the result of tension applied over time. Initial plastic conductor elongation includes the *strand settlement and deformation* which occurs during stringing and sagging (initial *plastic elongation*), plastic elongation which occurs during relatively brief, high-tensile-load events, and long-time *metallurgical creep elongation*, which occurs at everyday tension levels over the life of the line. Metallurgical creep of aluminum is accelerated at sustained high temperatures (above 20 °C). This effect has been extensively studied recently and presented in [9.47].

The creep strain  $e$  of the conductor is described according to [9.52] by

$$e = e_{1h} t^n, \quad (9.32)$$

where  $t$  is the time in hours and  $e_{1h}$  and  $n$  are parameters which depend on the conductor type and load condition.

These values are measured by means of the tests described in [9.53], which are performed on a sample which is at least as long as 100 times the conductor diameter, clamped in a test bench, which keeps the load constant during the test, with an accuracy of  $\pm 1\%$  or  $\pm 120$  N. The measuring intervals are selected on a logarithmic scale, and the results of the tests are then presented on a double logarithmic scale corresponding to the equation

$$\log e = \log e_{1h} + n \log t. \quad (9.33)$$

**Fig. 9.32** Tensile stress decrease  $\Delta\sigma_{Al}$  due to creep in the aluminum wires of different ACSR with a load of 25% RTS at 20 °C (adapted from [9.54])

In this way, the creep strain  $e$  in the ideal case forms a straight line where  $e_{1h}$  is the intersection with the ordinate for  $t = 1$  h and  $n$  is the slope of the straight line. Figure 9.31 [9.4] shows such a creep diagram, presenting a mean straight line through the measuring points on a double logarithmic scale. The creep strain can then be extrapolated out to 100 000 h (approximately 10 years). Indicative data for  $e_{1h}$  and  $n$  can be found in [9.53].

The creep of steel wires is much less significant and is normally neglected. Due to this fact, the creep in the aluminum wires of a bimetallic conductor reduces their tensile load by  $\Delta\sigma_{Al}$  but increases the load in the steel core wires. This load shift also depends on the ratio of aluminum to steel (Fig. 9.32 [9.54]).

#### 9.4.4 Mechanical Properties

Conductors have to sustain a plethora of electrical, mechanical, and environmental loads. Moreover, it is expected that, during the projected lifetime of a line, i.e., 40 years or more, and under all foreseeable conditions, they must not break under high tension, nor fail under fatigue caused by wind-induced oscillations, nor sag such that minimum electrical clearances are compromised. This can be ensured by understanding the behavior of the conductor under such loads and applying appropriate calculation methods [9.51].

##### Tensile Behavior

In a straight piece of conductor loaded in tension, the load  $H$  is distributed in the individual conductor wires following the basic rules of engineering mechanics. In the determination of the tensile forces in the individual wires, it is assumed that the conductor cross-section remains plane and all wires are in the linear elastic region, i.e., that Hooke's law is applicable. The changes in the lay angle and the transverse contraction (Poisson effect) of the wire cross-sections amount to around 2% of the

total tensile stress in the wire and are usually neglected. In a homogeneous conductor such as AAC and AAAC with  $n$  wires of the same diameter  $d$  and with modulus of elasticity  $E$ , the stress  $\sigma$  in a single wire is given by

$$\sigma = \frac{H}{n\pi d^2/4}. \quad (9.34)$$

This is related to the corresponding wire strain  $\varepsilon$  by

$$\sigma = E\varepsilon. \quad (9.35)$$

The situation becomes more complex for a bimetallic conductor, notably ACSR. In this case, the wires of the conductor *stick* to each other, because the tensile load creates radial compression (Fig. 9.51); they are also held firmly together by the conductor hardware, mainly the dead-end clamps (Fig. 9.108). Consequently, the wire strains  $\varepsilon_{Al}$  and  $\varepsilon_{St}$  for the aluminum and steel wires are equal

$$\varepsilon_{Al} = \varepsilon_{St}. \quad (9.36)$$

And since

$$\sigma_{Al} = E_{Al}\varepsilon_{Al} \quad \text{resp.} \quad \sigma_{St} = E_{St}\varepsilon_{St}, \quad (9.37)$$

it follows that

$$\sigma_{St} = \frac{E_{St}}{E_{Al}}\sigma_{Al}. \quad (9.38)$$

From (9.38) and considering typical values of  $E_{St} = 190$  GPa and  $E_{Al} = 55$  GPa as indicated in [9.55] for stranded steel and aluminum wires, respectively, it can be concluded that the tensile stresses in the steel wires of an ACSR are more than three times higher than the corresponding stresses in its aluminum wires.

The value of the stresses themselves can then be calculated as

$$\sigma_{Al} = H \frac{E_{Al}}{AE_C} \quad (9.39)$$

and

$$\sigma_{St} = H \frac{E_{St}}{AE_C}, \quad (9.40)$$

where  $E_C$  is the so-called composite modulus of elasticity of the conductor, given by

$$E_C = E_{Al} \frac{A_{Al}}{A} + E_{St} \frac{A_{St}}{A}, \quad (9.41)$$

and  $A$  is the total conductor area. Calculations using (9.39)–(9.41) show that even modest steel areas (e.g., 11% of the total area) greatly *stiffen* ACSR conductors, increasing the composite modulus from 55 to 70 GPa, i.e., by approximately 25%.

### Thermal Behavior

Conductors do not only elongate when under tension, but also change their length by a fraction  $\Delta L$  under the influence of temperature. For individual conductor wires with original length  $L$ , the following well-known relationship applies

$$\frac{\Delta L}{L} = \alpha \Delta T, \quad (9.42)$$

where  $\alpha$  is the coefficient of linear expansion and  $\Delta T$  is the temperature difference. For the two most common conductor materials, i.e., aluminum and its alloys and steel, the coefficients of linear expansion exhibit a ratio of 2. Specifically, the coefficient of linear expansion of aluminum ( $\alpha_{Al} = 23 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$ ) is twice that of steel ( $\alpha_{St} = 11.5 \times 10^{-6} \text{ }^\circ\text{C}^{-1}$ ). This fact has important consequences in the calculation of conductor sag in a span.

Based on a reasoning similar to that applied for the tensile behavior of a bimetallic conductor above, the composite coefficient of linear expansion can be calculated as

$$\alpha_C = \alpha_{Al} \frac{E_{Al}}{E} \frac{A_{Al}}{A} + \alpha_{St} \frac{E_{St}}{E} \frac{A_{St}}{A}. \quad (9.43)$$

Since the thermal expansion coefficients of steel and aluminum are different, a load shift takes place between aluminum and steel depending on the change of temperature. For a temperature increase, the load shifts from aluminum to steel, whereas the opposite is true for a temperature decrease. In this case, the aluminum strands of the conductor have to carry a greater mechanical load [9.56], which can be critical in the winter period, when this unfavorable characteristic coincides with the highest tension in the conductor. This issue is also important for vibration assessment (Sect. 9.4.11).

### The Catenary

The shape of a conductor suspended from two points at equal height above the ground having between them a distance  $S$  (the span) and loaded by a weight  $w$  (which can be its own weight plus an additional weight, e.g., from ice) and a tensile load  $H$  is a curve called a *catenary* (Fig. 9.33), because it is the curve that an idealized chain assumes (from the Latin *catena* for chain). Its mathematical function can be derived by applying the three conditions of static equilibrium in a plane on the differential elements of the curve as shown schematically on the right-hand side of Fig. 9.33 [9.4]; this leads to the differential equation

$$\frac{d^2 y}{dx^2} = \frac{w}{H} \sqrt{1 + \left(\frac{dy}{dx}\right)^2}. \quad (9.44)$$

Fig. 9.33 The catenary (adapted from [9.4])

Its solution delivers the mathematical expression for the catenary

$$y(x) = \frac{H}{w} \left[ \cosh \left( \frac{wx}{H} \right) - 1 \right], \quad (9.45)$$

which can be simplified to the equation of a parabola

$$y(x) = \frac{wx^2}{2H}. \quad (9.46)$$

The maximum deflection, which occurs at the center of the span  $S$  and is called the sag  $D$ , can be obtained by inserting  $x = S/2$  into (9.45), thus

$$D = \frac{H}{w} \left[ \cosh \left( \frac{wS}{2H} \right) - 1 \right], \quad (9.47)$$

which can be simplified to

$$D = \frac{wS^2}{8H}. \quad (9.48)$$

Equation (9.48) for the sag follows intuition, as evidently the sag will increase with the conductor weight and span length but decrease with the conductor tension. The sag is further proportional to the square of the span length; i.e., when the span length is doubled, the sag will increase four times, which is an important issue for long spans.

These approximations for the catenary curve and the sag are valid when

$$\frac{w^2 S^2}{48H^2} \ll 1, \quad (9.49)$$

which applies for the majority of overhead lines, with the exception of long, steep, or deep spans such as may be found in river, lake, or fjord crossings.

For a typical 380-kV line with a horizontal span length  $S$  of 300 m, equipped with a Drake conductor (ACSR 403-A1/S1A, 26/7) with a weight per unit length  $w$  of 16 N/m and a tension  $H$  of 28 kN, corresponding to 20% of its RTS of 140 kN, the sag  $D$  becomes 6420 mm with the exact solution (9.47) and 6417 mm with the approximation (9.48), i.e., a difference of only 3 mm, evidently well below the practical accuracy of sag measurements in the field. In this context, it is instructive to verify that the condition (9.49) is met

$$\frac{16^2 \times 300^2}{48 \times 28000^2} = 0.0006 \ll 1.$$

The length of the catenary  $L$  between the supports A and B (Fig. 9.33) can be calculated from the line integral of the catenary curve differential  $ds$

$$\begin{aligned} L &= \int_A^B ds = \int_A^B \sqrt{dx^2 + dy^2} \\ &= \int_A^B 1 + \sqrt{1 + \left( \frac{dy}{dx} \right)^2} dx. \end{aligned} \quad (9.50)$$

Inserting (9.45) and under the assumption of (9.49), we obtain a very good approximation for the length of the catenary of

$$L \cong S + \frac{8D^2}{3S}, \quad (9.51)$$

and for the so-called *slack*, i.e., the difference between the catenary length  $L$  and the span length  $S$ , we obtain

$$L - S \cong \frac{8D^2}{3S}. \quad (9.52)$$

For the example, we get  $L = 300.366$  m and  $L - S = 0.366$  m, which is only about 0.1% of the span length  $S$ .

Another interesting observation is that the difference between the total tension  $T$  and the horizontal tension  $H$  in the conductor is normally very small, in this case amounting to just over 100 N.

The ratio  $H/w$  (with dimension m), which appears in the preceding equations, is commonly referred to as the catenary constant. An increase in the catenary constant causes the catenary curve to become shallower and the sag to decrease. The catenary constant typically has a value in the range of 500–2000 m for most transmission line catenaries under most conditions, and it also plays an important role in the assessment of conductor vibration severity (Sect. 9.4.11).

**Sag–Tension Calculations.** As explained above, the shape of the catenary changes with the conductor temperature, ice and wind loading, and time (creep). To ensure adequate vertical and horizontal clearance under all weather and electrical loadings, and to ensure that the breaking strength of the conductor is not exceeded, the shape of the conductor catenary under all conditions must be determined. This is done through calculations commonly referred to as sag–tension calculations; these are extensively described in [9.51].

The basic idea behind sag–tension calculations is to relate mathematically two physically distinct conductor states. The first state—designated in the following by a subscript “1”—is defined by the conductor temperature  $T$ , tension  $H$ , and load  $w$  and related to a second conductor state (indicated by a subscript “2”) through a change of the conductor length  $L$ , as the latter depends on the mentioned parameters. The basic conductor state corresponds to the time of installation, when the conductor sag and the related tension with the conductor unloaded and at a known temperature are measured and fixed in such a way that the limiting conductor parameters (Fig. 9.36) are not exceeded. Specifically

$$L_2 = L_1 [1 + \alpha (T_2 - T_1)] \left( 1 + \frac{H_2 - H_1}{EA} \right), \quad (9.53)$$

where  $\alpha$  is the coefficient of linear expansion,  $E$  is the modulus of elasticity, and  $A$  is the area of the cross-section of the conductor in question. Inserting for  $L$  (9.51) into (9.53) with  $D$  from (9.48), we arrive at what is often called in literature the conductor state-change equation

$$\begin{aligned} H_2^2 (H_2 - H_1) + \frac{EA (w_1 S)^2}{24H_1^2} + EA\alpha (T_2 - T_1) \\ = \frac{EA (w_2 S)^2}{24H_2^2}, \end{aligned} \quad (9.54)$$

or in the more convenient stress form

$$\begin{aligned} \sigma_2^2 (\sigma_2 - \sigma_1) + \frac{E (w_1 S)^2}{24A^2 \sigma_1^2} + E\alpha (T_2 - T_1) \\ = \frac{E (w_2 S)^2}{24A^2}. \end{aligned} \quad (9.55)$$

In (9.55) it has been assumed that the conductor behaves linear elastically, with a single elastic modulus and a single coefficient of thermal elongation, which is a reasonably good approximation for many overhead lines, in particular for conductors with a maximum operating temperature up to 60°C. Consequently, it is

called the linear elastic (LE) model. The above cubic equation (9.55) can be solved easily, even analytically.

However, overhead conductors are not purely elastic. They elongate with tension, but when the tension is reduced to zero, they do not return to their initial length; that is, conductors are plastic, and their stress–strain curves are nonlinear (Fig. 9.30). Such curves can be obtained in laboratory tests and then introduced into dedicated software, which can carry out all the necessary calculations using more sophisticated conductor models such as the simplified plastic elongation (SPE) and experimental plastic elongation (EPE) models described in [9.51]. Specifically:

- The LE model ignores the settlement and strand elongation as well as the long-time or high-tension plastic elongation, although these may be allowed for by the use of adequate clearance buffers.
- The SPE model ignores the settlement and strand elongation that occur during initial tensioning of the conductor but accounts for long-time or high-tension creep plastic elongation by considering an equivalent increase in temperature

$$\Delta T_{\text{creep}} = \frac{\epsilon_{\text{creep}}}{\alpha}. \quad (9.56)$$

- The EPE elongation model enables the calculation of both settlement and strand elongation as well as long-time or high-tension plastic elongation based on laboratory conductor test results and an assumed line design and load sequence.

Conductor test data for use in the SPE and EPE models can be found in [9.55].

The various contributions to the conductor elongation are shown schematically in Fig. 9.34 [9.51].

However, the situation becomes more complicated when ACSR are operated at elevated temperatures [9.57]. Such conductors, being composed of two metal components with different thermal expansion rates, show a more complex sag–tension characteristic at elevated temperature. As the temperature increases, the tension carried by the aluminum shell shifts to the steel core as its expansion rate is twice the rate of the steel core. Hence, in steel-reinforced conductors, the percentage of the load supported by the steel core increases as the conductor temperature increases. Above a particular conductor temperature, called the *knee-point temperature* (KPT), the mechanical load carried by the aluminum wires is completely off-loaded to the steel core and hence add to the core’s tensile loading, although there is an understanding that the inner, constricted aluminum wires can sustain a small amount of compression [9.58]. There are

**Fig. 9.34** Contributions to conductor elongation (adapted from [9.51])

**Fig. 9.35** Sag versus temperature of a 300-m span for ACSR Cardinal (54/7) using the LE/SPE and EPE conductor models (adapted from [9.60])

also indications that the KPT is influenced by the manufacturing process [9.59]. High-temperature sags of multiple-layer ACSR conductors may thus be smaller than those predicted by simpler sag–tension models (Fig. 9.35 [9.60]).

Another important issue to be considered in sag–tension calculations is the fact that, in a typical overhead line and depending on the utility design philosophy and the terrain, the suspension spans between dead-end strain structures can vary in length, although normally not over a wide range. If all of the suspension spans were of the same length and reasonably level, and all were subject to the same ice and wind loads, then the sag and tension change with ice and wind and conductor temperature would be the same for all the spans. This is evidently not the case, as changes in conductor temperature or load will yield different tensions in each span. Small movements of the suspension points, however, will equalize the tension between spans.

Although exact sag–tension calculations for multiple, mechanically coupled suspension spans are now carried out using customized software, it is instructive, in order to better understand the physical background of the situation, to carry out the sag–tension calculation for a single *ruling*, also called *equivalent*, span [9.61, 62]. The ruling span is defined by

$$S_R = \sqrt{\frac{S_1^3 + S_2^3 + \dots + S_n^3}{S_1 + S_2 + \dots + S_n}}, \quad (9.57)$$

where  $S_R$  is the ruling span for a line section containing  $n$  suspension spans,  $S_1$  is the span length of the first suspension span,  $S_2$  is the span length of the second suspension span, and  $S_n$  is the span length of the  $n$ -th suspension span.

Since the numerator in (9.57) depends on the cube of the span length, the value of the ruling span is greatly influenced by the longest spans. And, since the tension in all the suspension spans in the line section is assumed to be reasonably equal, once the sag  $D_R$  for the ruling span has been calculated, the sag  $D_i$  in any of the related suspension spans can be calculated as

$$D_i = D_R \left( \frac{S_i}{S_R} \right)^2. \quad (9.58)$$

Using sag–tension calculations, the sagging condition, i.e., the tension in the conductor during installation, can be determined. For this purpose, firstly the limit stresses at the critical conductor conditions (Fig. 9.36 [9.51]) are calculated and the prevailing condition is selected.

These conditions vary depending on the environment, the utility practice, and the standards to be followed; For example, in Germany [9.63], the maximum conductor stresses are calculated for:

**Fig. 9.36** Sag variation with conductor temperature, ice and wind loads, and time after installation calculated from the initial sag during stringing (adapted from [9.51])

- $-20^{\circ}\text{C}$  without ice loads or
- $-5^{\circ}\text{C}$  and ice load according to 4.5.2/DE.1 or
- $-5^{\circ}\text{C}$  and ice load combined with wind load according to 4.6.6.1/DE.1 or
- $+5^{\circ}\text{C}$  with wind load according to 4.4.1/DE.1.

Thereby, the tensile stress at the fixing point of the conductor multiplied by the partial factor  $\gamma_C = 1.35$  should not exceed the value obtained as 95% of the rated tensile strength of the conductor divided by the material partial factor  $\gamma_M = 1.25$ . RTS values of ACSR are listed in Table 9.20.

In addition and at the annual mean temperature, which can be assumed to be  $+10^{\circ}\text{C}$ , the horizontal component of the conductor tensile stress without wind load should not exceed the everyday stress (EDS). Depending on the design of the suspension assemblies and the efficiency of the vibration protection, the horizontal component of the conductor tensile stress may exceed the specified values by up to 25%. Table 9.22 [9.64] lists these values for typical ACSR.

The maximum conductor and structure tensile loads increase with increasing initial installed tension, while the sag decreases. To avoid conductor tensile failure, but also, unless constrained by design, failure of supporting structures plus splices and dead-end fittings under high ice and wind loads, the conductor tension under maximum ice and wind is usually limited to 50–60% of the RTS [9.66]. For this purpose, the conductor’s initial unloaded tension at the time of construction or reconductoring is limited to a rather modest

**Table 9.22** Mechanical characteristics and permissible everyday stress for standard conductors (adapted from [9.64])

value, i.e., 15–25% of the RTS. In addition, limiting the initial and final unloaded tensions to certain percentage ranges of the RTS is common as a means of vibration control, while recent work by CIGRE [9.67] suggests that limiting the so-called catenary constant  $H/w$  for the coldest month is better. This is discussed in Sect. 9.4.11.

### 9.4.5 Thermal Rating

The *purpose* of an overhead line conductor is to carry electrical current safely and efficiently under normal and emergency operating conditions, under all weather conditions, through the whole life expectancy of the line. To avoid overheating and damage to the phase conductors, the line's *thermal rating* is calculated as described extensively in [9.65]. This important document covers static and dynamic thermal rating calculations for both AC and DC operation, particularly at high temperatures and current densities, which are common nowadays because of the increased power flows in the grid.

Figure 9.37 [9.65] shows schematically the various contributions to the thermal state of the conductor and indicates that the resulting temperature distribution in the conductor is not necessarily constant, varying along the line with weather conditions (particularly wind) and at current densities above  $2 \text{ A/mm}^2$  often increasing towards the core by more than  $5^\circ\text{C}$  [9.68].

We concentrate here on the static steady-state condition of the conductor under the reasonable assumption that the conductor will have reached thermal equilibrium, i.e., that its temperature will not change significantly over time. Thereby, conservation of energy must

be observed

$$P_J + P_S = P_C + P_R . \quad (9.59)$$

The different contributing factors are addressed briefly below.

#### Joule Losses

The Joule losses per unit length  $P_J$  in a conductor are mainly caused by the resistance that the conductor material poses to electrons moving within it. This resistance increases with the average temperature of the conductor  $T_{av}$ , which can be explained intuitively by the fact that, as the temperature increases, the amplitude of the vibration of atoms in the metal lattice of the conductor also increases, thus impeding the passage of electrons. The increase in the DC resistance with temperature amounts to approximately 4% for every  $10^\circ\text{C}$  change in the conductor temperature.

$$\begin{aligned} P_J &= R_{DC} I^2 = \frac{\rho_{DC}}{A} I^2 \\ &= \rho_{DC} [1 + \alpha_{20} (T_{av} - 20)] \frac{I^2}{A} , \end{aligned} \quad (9.60)$$

where  $A$  is the cross-sectional area of the conductor.

Additional effects which increase the conductor resistance in the case of AC are the skin effect and magnetic losses [9.69]. Their combined contribution is accounted for in (9.61) by the factor  $k_J$ , which has, with very few exceptions, a value of less than 1.1; i.e., it causes an increase of  $R_{AC}$  with respect to  $R_{DC}$  by a maximum of 10%

$$R_{AC} = k_J R_{DC} . \quad (9.61)$$

Evidently, the main contributor to the Joule, also often called ohmic, losses is the square of the current magnitude  $I$ . For ACSR Drake with a diameter of 28 mm and a resistivity of  $0.073 \Omega/\text{km}$ , they amount to  $6.8 \text{ W/m}$  at 300 A and  $75 \text{ W/m}$  at 1000 A.

### Solar Heating

The solar heat gain per unit length by a conductor  $P_S$  is directly proportional to the conductor diameter  $D$ , the absorptivity  $\alpha_S$  of the conductor surface, and the global radiation intensity  $I_R$  [9.70]

$$P_S = \alpha_S I_R D. \quad (9.62)$$

The value of  $\alpha_S$  varies from around 0.2 for a bright new conductor to near 1.0 for a weathered conductor in an industrial environment after one or more years. As it is not easy to measure the absorptivity accurately, a default minimum value of 0.8 is often used.

The global radiation intensity  $I_R$  is a combination of the direct solar radiation on a surface normal to the sun's beam, the diffuse sky radiation onto a horizontal surface, and the incident radiation reflected from the ground, the so-called albedo. Transmission lines are often rated with a value of  $I_R = 900 \text{ W/m}^2$ .

### Convective Cooling

Convection is the transfer of heat in the direction of a temperature gradient due to bulk movement of molecules within fluids such as gases. The heat transfer from an overhead conductor to the surrounding atmosphere is quantified by the convective cooling  $P_C$ , which depends on the thermal conductivity of the air  $\lambda_f$ , the dimensionless Nusselt number  $\text{Nu}$ , and the difference between the temperatures of the conductor surface  $T_s$  and surrounding air  $T_a$

$$P_C = \pi \lambda_f (T_s - T_a) \text{Nu}. \quad (9.63)$$

There are two types of convection. Natural convection occurs when motion of air molecules is caused by buoyancy forces that result from density variations in the air. Forced convection occurs when a stream of air molecules flows over the conductor surface and transfers heat away from the *hot* conductor to the *cold* surrounding air. Already at quite low perpendicular wind speeds, even less than 0.5 m/s, forced convection dominates and natural convection can be ignored. At very low wind speeds though, natural convection may have a significant effect, becoming the dominant convection mechanism at 0.3 m/s and below; For example, for a Drake conductor at  $100^\circ\text{C}$  in air at ambient temperature of  $40^\circ\text{C}$ , natural convection contributes  $42 \text{ W/m}$  to its cooling while forced convection contributes 82

and  $115 \text{ W/m}$  at a wind velocity perpendicular to the conductor of 0.6 and 1.2 m/s, respectively. The total convection at low wind speeds can be found by adding the natural and forced convection vectorially.

### Radiative Cooling

Radiation is the result of the random movements of atoms and molecules in matter, which takes place at any temperature above absolute zero. Since these atoms and molecules are composed of charged particles (protons and electrons), their movement results in the emission of electromagnetic radiation in the form of photons, which carry energy away from the surface of the object in question, here the conductor. The radiative heat transfer, specifically the radiative cooling  $P_R$  of a conductor, is given by the Stefan–Boltzmann law

$$P_R = \pi D \sigma_B \varepsilon_S \left[ (T_s + 273)^4 - (T_a + 273)^4 \right], \quad (9.64)$$

where  $D$  is the conductor diameter,  $\sigma_B$  is the Stefan–Boltzmann constant,  $\varepsilon_S$  is the emissivity of the conductor surface, and  $T_s$  and  $T_a$  are the temperature of the conductor surface and the ambient, respectively. For bare overhead conductors, radiative cooling is generally much weaker than convective cooling. For a Drake conductor at  $75^\circ\text{C}$  with a suitably conservative wind speed of 0.6 m/s, the convective cooling is approximately three times the radiative cooling per unit length. Inserting (9.60)–(9.64) into (9.59), we get the relationship between the thermal rating, i.e., the maximum current  $I_{AC}$  that the conductor can carry at thermal equilibrium for an ambient conductor temperature  $T_a$

$$I_{AC} = \sqrt{\frac{P_C + P_R - P_S}{k_J \rho_{DC} [1 + \alpha_{20} (T_{av} - 20)] / A}}. \quad (9.65)$$

Table 9.23 presents an example calculation, and Fig. 9.38 [9.71] the strong dependence of the thermal rating on the wind velocity and ambient temperature. The maximum permissible conductor temperature is usually set at  $80^\circ\text{C}$  (Sect. 9.4.9).

### 9.4.6 Corona

Corona is an ionization process caused by the acceleration of electrons in an inhomogeneous electric field. If the field strength is high enough, electrons will acquire enough energy to ionize neutral molecules in the ambient air [9.72]. Thus, new free electrons are created, which, subjected to the same field, likewise ionize

**Table 9.23** Thermal rating of ACSR 265/35 for solar radiation of 900 W/m<sup>2</sup> with wind perpendicular to the line (adapted from [9.71])

Conductor	ACSR 265/35	ACSR 265/35
Wind velocity (m/s)	0.6	2
Ambient temperature (°C)	35	20
Max. conductor temperature (°C)	80	80
Thermal rating (A)	688	1055

**Fig. 9.38** Thermal rating of ACSR 265/35 over ambient temperature with wind velocity as parameter (adapted from [9.71])

molecules, leading through progressive multiplication to partial discharges in the air.

Depending on the voltage polarity, there are two types of such discharge:

- Negative corona or glow, which is characterized by blue light with lower intensity and low audible noise.
- Positive corona or streamers, which is characterized by sparkles with white light and high audible noise, thus being an important design issue for AC and DC lines; for the latter, corona effects get more complicated because of accumulation and wind dispersion of space charges.

The onset field intensity  $E_c$  for corona discharge of conductors can be reasonably well predicted using Peek's formula [9.73], which has been defined based on corona cage experiments

$$E_c = mE_0\delta \left( 1 + \frac{K}{\sqrt{\delta r}} \right). \tag{9.66}$$

For AC voltages,  $E_c$  is the peak value of the field intensity in kV/cm,  $r$  is the radius of the conductor in cm, and  $\delta$  is the relative air density.

**Table 9.24** Typical three-phase corona losses in W/m

Line voltage (kV)	Fair weather	Fog	Rain	Rime
110	0.001	–	–	1.0
220	0.3	2.9	8.0	30.0
380	0.6	4.3	12.0	50.0

Furthermore,  $E_0 = 31$  kV/cm is the breakdown voltage of air in a quasihomogeneous field and  $K = 0.308$  is an empirical factor. These values are also valid for DC voltages with a negative polarity, while for DC voltages with positive polarity  $E_0 = 32.7$  kV/cm and  $K = 0.241$  [9.74]. Peek's formula was developed for smooth cylindrical bodies and not for stranded conductors, whose circumference is by definition not round. In addition, local surface irregularities are produced during conductor manufacture and stringing, which cause local concentrations of the electric field and consequently decrease the corona onset voltage. This is taken into account in (9.66) by including a surface state coefficient  $m$ .

A typical value of  $m$  caused by stranding alone is 0.9; rain may reduce it to 0.6 or even lower.

In practice, it is recommended that the conductor surface gradient of overhead conductors should be limited to about 17 kV<sub>rms</sub>/cm [9.4].

Corona can cause:

- Ozone (O<sub>3</sub>)
- UV radiation
- Corona loss (CL)
- Audible noise (AN)
- Electromagnetic interference (EMI)
- Radio interference (RI)
- Television interference (TVI).

In particular, as shown in Table 9.24, under adverse weather conditions, corona losses can reach values close to those of the Joule losses of the line.

For AC lines, design levels of 70 dB for radio interference and 60 dBA for AN at the edge of the right of way are often used. With the increased sensitivity of the public in respect to OHLs, audible noise caused by corona, in particular in poor weather, has motivated considerable research on understanding the physics of the problem as well as suitable mitigation methods in recent years [9.75].

Another important investigation [9.76] revealed the dependence of the electric field gradient (EF), AN, and RI on various key design parameters of the line, as presented in Table 9.18, and provided recommendations on how to reduce unacceptably high levels of RI and AN, both related to corona discharges.

**Fig. 9.39a–c** Typical conductor bundles and dimensions (adapted from [9.81]). (a) Twin bundles, (b) triple and quad bundles, (c) six and eight conductor bundles

### 9.4.7 Bundle Conductors

For voltages above 220 kV, the conductor diameter required to ensure that the limit of the field intensity at the conductor surface is not exceeded becomes prohibitive, leading to conductor sizes which are difficult to manufacture and to handle in the field; For example, if single conductors were to be used, they would have a diameter of 4.7, 8.5, and 13.8 cm for 400, 735, and 1100 kV AC, respectively [9.77]. This, together with the necessity to maximize the surge impedance load (SIL) of the line, has led to the development of so-called bundle conductors [9.78–80]. Typical bundle configurations are twin bundles for 220 kV, triple and quad bundles for 380 kV, six bundles for 765 kV, and eight bundles for 1000 kV (Fig. 9.39 [9.81]). Incidentally, the first field installation of bundle conductors took place in 1952 for a 380-kV line in Sweden equipped with quad bundles.

As per [9.82] for a balanced three-phase system voltage  $V_{\text{smax}}$ , the average electric field gradient on the surface of the conductor bundle  $E_{\text{avg}}$  (kV<sub>rms</sub>/cm), can be estimated using

$$E_{\text{avg}} = \frac{0.354\sqrt{3}V_{\text{smax}}}{nr_c \ln(D_{\text{eq}}/R_b)}, \quad (9.67)$$

where  $V_{\text{smax}}$  is the maximum system voltage, usually with a 5–10% margin above the nominal system (phase to phase) rms voltage,  $n$  is the number of conductors in the bundle,  $r_c$  (cm) is the outside radius of the subconductors,  $D_{\text{eq}}$  is the equivalent phase conductor spacing with  $D_{ij}$  (cm) being the center-to-center distances among phases, and  $R_b$  (cm) is the geometric mean radius of the bundle (9.68). It is normal to use a 5% margin above the nominal system voltage in corona calculations

$$D_{\text{eq}} = \sqrt[3]{D_{ab}D_{ac}D_{bc}}. \quad (9.68)$$

**Fig. 9.40** Geometry of an  $n$ -conductor bundle (adapted from [9.83])

The maximum field intensity  $E_{\text{max}}$  (kV<sub>rms</sub>/cm) is related to the average field  $E_{\text{avg}}$  by

$$\frac{E_{\text{max}}}{E_{\text{avg}}} = 1 + \frac{2r_c}{D_{\text{min}}}(n-1) \sin\left(\frac{\pi}{n}\right), \quad (9.69)$$

where  $D_{\text{min}}$  is the minimum distance among the  $n$  conductors in the bundle with typical values for a quad bundle of 400 mm in Europe and 457 mm in North America and elsewhere. Thereby the *geometric mean radius*  $R_b$  of a bundle of  $n$  conductors, each with outside radius  $r_c$  (cm), is given by

$$R_b = R \sqrt[n]{n \frac{R}{r_c}}, \quad (9.70)$$

where  $R$  is the radius of the cycle of the locus of the subconductors (Fig. 9.40). Physically, a single conductor of radius  $R_b$  has the same capacitance as the bundle with  $n$  subconductors. Figure 9.41 finally shows the field plots and the reduction factors of the maximum field intensity for different bundle arrangements [9.83].

The second big advantage of bundle conductors is that, while they reduce the series inductance, at the same time they increase the shunt capacitance, and consequently reduce the characteristic impedance of the line. At the same time, the surge impedance load (SIL), which is the limiting factor for the maximum power transfer along long lines, will increase [9.84]. Increasing the number and reducing the spacing of the subconductors as well as decreasing the distance between the phases of the line are favorable for a higher SIL (Table 9.1); For example, in a recent project in Brazil for a more than 600-km-long 500-kV AC line, by introducing expanded six-conductor bundles with 2580-mm spacing in lieu of the usual quad bundles of 457 mm, the SIL of the line was increased considerably from the standard 1000 to 1640 MW [9.6], i.e., by more than 60%, although this is partly counterbalanced by higher costs due to the use of more subconductors, difficulties encountered during the stringing of the bundle, and also problems during maintenance because of the large size and reduced rigidity of the related fittings.

Fig. 9.41 Field plots and reduction factors of different bundle arrangements (adapted from [9.83])

### 9.4.8 Earth Wires

Most overhead transmission lines operating at voltages of 110 kV or above are provided with earth wires, which are also called shield or ground wires. In this context, the term *earth wire* is used for all types of conductors at earth potential. The main purpose of earth wires is to protect the conductors against the direct incidence of lightning strokes, which can cause line outages. Because of this, earth wires are earthed at each tower and have to carry, during the normal operation of the line, only small currents due to electromagnetic induction or electrostatic effects, resulting in negligible losses.

However, when a phase-to-earth short circuit occurs, a short-circuit current, often with significant magnitude, will flow through the earth wire and heat it up adiabatically, meaning that, because of its short duration, there will be no heat transfer to the environment. Earth wires thus have to be selected so that they should not exceed the maximum permissible temperature as per their material properties. This temperature is often indicated in the range of 160–220 °C. The design of earth wires under short-circuit conditions can be carried out according to [9.85]. Table 9.25 [9.4] lists technical data and maximum short-circuit currents of some typical steel earth wires.

In addition, the tensile stresses and sags of earth wires and the relevant stringing conditions need to be established so that the separation between earth wires and conductors at mid-span is wider than their separation at the towers. It should also be demonstrated that long-term vibrations with large amplitudes that could cause unacceptable damage do not occur. Thus, attention should be given to their proper vibration protection. It is usual to set the earth wire sag as 90–95% of the conductor sag at the average yearly temperature (everyday condition), for instance 10 °C in Europe, then to

ensure that the earth wire sag never exceeds the conductor sag.

In the past, earth wires having low conductivity, such as steel strands or AL1/STyz (ACSR) conductors with low aluminum content, were mostly employed, and they are still used in several countries. However today, most utilities, especially in Europe, have changed to the use of larger AL1/STyz (ACSR) conductors.

In some developing countries, the use of earth wires has been extended to the transmission of small amounts of energy at lower voltages, thus enabling rural electrification schemes [9.86]. Also the utilization of earth wires to carry telecommunication signals on integrated glass fibers has become very popular. Such earth wires are called optical ground wires (OPGW), and they are available in various designs:

- Self-supporting optical ground wires (OPGW)
- All dielectric self-supporting cables (ADSS)
- Optical fiber cables attached to earth or messenger wires.

Optical fiber cables and their design, installation, and maintenance are aptly described in [9.87]. Because the inclusion of optical fibers results in sensitivity to mechanical damage, particular attention must be given to the proper selection of their fittings. This issue is covered in detail in [9.88–90].

### 9.4.9 High-Temperature Conductors

One of the most successful methods to increase the power transfer capacity of an existing line without extensive reconstruction is to increase the current it can safely carry by reconductoring it with so-called high-temperature low-sag (HTLS) conductors. The term *safely* has two aspects here: Firstly, as an increase in current will also increase the temperature of the con-

**Table 9.25** Technical data of steel earth wires

Shield wire type	Cross-sectional area $A$ (mm <sup>2</sup> )	Specific heat $c$ (W s/(kg K))	Resistivity $\rho$ ( $\Omega$ mm <sup>2</sup> /m)	Specific mass $\gamma$ (kg/(m mm <sup>2</sup> ))	Short-circuit duration		
					0.2 s (kA)	0.5 s (kA)	1.0 s (kA)
49-ST1A	49.5	481	0.192	0.00778	4.9	3.3	2.4
66-ST1A	65.8	481	0.192	0.00778	6.6	4.4	3.2
93-ST1A	93.3	481	0.192	0.00778	9.2	6.2	4.5
117-ST1A	117.0	481	0.192	0.00778	11.6	7.8	5.6

**Fig. 9.42** Loss of strength (annealing) of hard-drawn aluminum wire (adapted from [9.92])

ductor, it has to be considered that conventional hard-drawn aluminum [9.91] recrystallizes at temperatures above 100 °C and loses its mechanical strength over time (Fig. 9.42 [9.92]). This applies to aluminum-magnesium-silicon alloys [9.93] as well and is called *annealing*. Annealing occurs via the diffusion of atoms within a solid material, here aluminum, so that the material progresses towards its equilibrium state. Heat increases the rate of diffusion by providing the energy needed to break bonds. The movement of atoms has the effect of redistributing and eradicating dislocations and allows the metal to deform more easily, increasing its ductility. Temperatures below 300 °C do not affect the tensile strength of steel strands, but extended operation above 200 °C can damage the galvanization on steel wires. Aluminum conductors having a steel core (ACSR) also experience a loss of their total strength if operated above 100 °C, but since the strength of the steel core is unaffected, the reduction in the tensile strength of the aluminum strands is of less concern than for conductors made entirely of aluminum or aluminum alloy.

Secondly, the elevated temperature will cause greater conductor sag, which may violate the required clearances along the line. In this regard, it is worth mentioning that the conductor sag at elevated temperatures is influenced by some additional factors, which will increase it unfavorably. This is evident from Ta-

ble 9.26 [9.92], where the influence of these factors is quantified.

To address these issues, in the last years, HTLS conductors have been developed [9.92, 94]. They are capable of operating continuously at temperatures of at least 150 °C and as high as 250 °C during emergencies. For HTLS conductors with zirconium-aluminum wires [9.95], it is generally agreed that the emergency temperature should not apply for more than 10 hours per year. The main types of HTLS conductors are described below.

An ACSS (aluminium conductor steel-supported) consists of a steel core with one or more layers of aluminum, showing no difference in appearance or geometry from ACSR, including the possibility of being compacted. They can operate continuously up to 250 °C, because, since the aluminum wires have been annealed in the factory before stranding, there is no concern that the conductor will lose strength at high temperatures. When an ACSS is heated up in service, the aluminum wires elongate and quickly shift their load onto the steel core. From this point onwards, the conductor essentially behaves as a steel conductor, that is, its thermal elongation and modulus of elasticity are those of the steel core. In addition, and since the elongation at failure of annealed aluminum wires is approximately 20%, compared with that of the steel core, which is limited at 1%, the conductor can utilize the steel core at its full strength. Moreover, the high elongation of the aluminum means that the creep properties of the conductor are ruled by the steel core, which usually exhibits very low creep. For further increase of the conductor ampacity, trapezoidal wires (TW), as shown in Fig. 9.43a, are used.

(Z)TACSR (Fig. 9.43b) has the same construction as conventional ACSR, with galvanized steel wires for the core and (Z)TAL, i.e., thermally resistant zirconium-aluminum alloy wires, which do not anneal at temperatures up to 210 °C. On the other hand, it has the same thermal elongation behavior as ACSR, which will affect clearances. Thus, such conductors are mainly installed in new lines expecting high power transfer and for which high sags can be considered in the design stage.

**Table 9.26** Typical error magnitudes in high-temperature sag calculations (adapted from [9.92])

	ACSR Drake	ACSR Condor	ACSR Tem
Aluminum area (strands) (mm <sup>2</sup> )	403 (26)	403 (54)	403 (45)
Steel area (strands) (mm <sup>2</sup> )	66 (7)	53 (7)	28 (7)
Final tension at 20 °C (N)	25 800	23 150	19 100
Equivalent span length (m)	250	250	250
Sag at 20 °C (m)	4.84	5.06	5.36
<b>Effects of calculation methods on final 120 °C sag (m)</b>			
Calculation assuming constant modulus	7.76	7.78	8.53
Graphical method with no AI compression	7.00	7.53	8.53
Graphical method with typical 20 MPa maximum compression	7.32	7.73	8.53
<b>Additional sag errors at 120 °C (m)</b>			
Temperature difference core/surface	+0.03	+0.05	+0.06
Change of elastic modulus versus temperature	+0.15	+0.11	+0.06
High-temperature creep	0	0	+0.50
Multiple span effects	+0.6 to -1.0	+0.5 to -0.9	+0.5 to -0.8
Effect of core magnetization losses	0	+0.07	+0.05
Effect of manufacturing temperature	±0.14	±0.12	0

**Fig. 9.43a–f** HTLS conductors: (a) ACSS/TW, (b) (Z)TACSR, (c) (Z)TACIR, (d) ACCR, (e) ACCC, (f) G(Z)TACSR (adapted from [9.94])

The increased sag issue can be addressed by using (Z)TACIR (Fig. 9.43c), which has galvanized or aluminum-clad Invar alloy steel wires in lieu of the steel strands of (Z)TACSR. Invar is an iron-nickel alloy with a coefficient of thermal expansion of around one-third that of galvanized or aluminum-clad steel wire. These conductors can operate continuously up to 210 °C with relatively low sag.

G(Z)TACSR or gap-type conductors have a small gap between the steel core and innermost shaped aluminum layer, to allow the conductor to be tensioned on the steel core only, thereby allowing the low-sag properties of the steel core to be exploited over a greater temperature range. The gap is filled with heat-resistant grease, to reduce friction between the steel core and aluminum layer and prevent water penetration.

Aluminum conductor composite reinforced (ACCR) (Fig. 9.43d) is an HTLS conductor consisting of zirco-

nium-aluminum alloy strands over a reinforcing core of ceramic fibers in an aluminum matrix. The high elastic modulus of the aluminum composite core and its low thermal elongation rate (half that of steel) makes this conductor particularly useful for existing lines with heavy ice loads and minimum high-temperature sag clearances.

Finally, aluminum conductor composite core (ACCC) is a HTLS conductor with a single-strand carbon-reinforced high-temperature thermoset resin core and trapezoidal annealed aluminum wires. The core has a very low thermal elongation rate, making this conductor very effective for limiting sag at high temperatures, while because of the thermoset resin, the manufacturer recommends a maximum continuous operating temperature of 180 °C.

Figure 9.43 [9.94] portrays all these conductors, while Fig. 9.44 [9.92] compares their sag variation with

**Fig. 9.44** Sag versus temperature for different HTLS conductors; *dashed horizontal line* depicts maximum sag of an equivalent ACSR Drake for 420-m span (adapted from [9.92])

conductor temperature for ACSR Drake in a 420-m-long span.

However, it should be remembered that, for high currents  $I$  such as those in HTLS conductors, the ohmic losses, which vary with  $I^2$ , become prohibitive for line lengths above approximately 80–100 km, thus the benefits of installing such conductors may be limited. Further, the application of some types of HTLS conductors is still a developing technology, requiring better calculation tools and additional laboratory and field test data.

### 9.4.10 Real-Time Monitoring

As an alternative or sometimes in addition to HTLS conductors, real-time monitoring (RTM) systems can be employed to determine the rating of the line in real time. They consist of devices that measure directly or indirectly the temperature and sag of the conductor. From these measurements, the actual thermal rating or ampacity of the conductor can be calculated. The main objectives of an RTM system are therefore to:

- Determine the actual sag in critical spans and corresponding mean conductor temperature
- Compare the actual sag with the maximum allowable sag or maximum permissible temperature in each of these spans.

Using this information, *safe buffers* for the critical spans based on the known actual load can be determined

and converted into electrical loads for each critical span.

Such thermal rating methods can be direct or indirect. Direct methods involve measuring at least one physical parameter of the line, such as tension, temperature, vibration frequency, or ground clearance, which is then used to derive parameters such as sag, temperature, and tension where not directly measured. With indirect methods, weather parameters are first measured and then used in conjunction with conductor electrical load data to calculate the temperature and subsequently the sag and/or tension of the conductor. These are described in [9.96], from which the following information is extracted.

#### Donut Devices

So-called donut devices were probably the earliest RTM systems to be conceived and used. They employ temperature sensors and are clamped directly onto the conductor (Fig. 9.45). They can measure simultaneously, besides the conductor surface temperature, the line-to-ground voltage and the actual current, and transmit these data to a base station or the next control room for evaluation. They are cheap and easy to apply, but their relatively high mass acts as a heat sink and can negatively influence the vibration behavior of the conductor.

#### Tension Monitoring

Tension monitoring systems are probably the most often used. They measure the conductor tension using

**Fig. 9.45** Power donut (adapted from [9.96])

**Fig. 9.47** Monitoring through vibration analysis (adapted from [9.96])

**Fig. 9.46** Load cells (red) for tension monitoring (adapted from [9.96])

a load cell installed on the earth side of a dead-end insulator string (Fig. 9.46) and transmit this information wirelessly to the line operator. There, the tension can be expertly converted to a conductor temperature and sag, thereby enabling calculation of the actual conductor current and possible reserves in the thermal rating of the line. Tension monitoring systems are well developed, robust, and proved in numerous installations worldwide, but their installation is rather complicated.

#### Monitoring Through Vibration Analysis

In a relatively recent development, the conductor tension and sag—and *backwards* therefrom the conductor temperature—can be derived by detecting the fundamental frequency of the span due to aeolian vibrations (Sect. 9.4.11) using a so-called smart monitor (Fig. 9.47), which can be applied anywhere along the span. Such monitors are light, easy to install, self-sustaining (by harvesting energy from the conductor), and capable of data transmission, although operating experience remains limited.

### 9.4.11 Conductor Vibrations

Conductor vibrations are quite a common phenomenon and, if not properly damped, can cause serious damage not only to the conductors themselves but also to other line components. Such vibrations are part of a broad class of external line loads, the so-called dynamic or cyclic loads, such as loads caused by conductor rupture, short circuits, ice shedding, and rarely seismic loads. We will concentrate here on so-called wind-induced vibrations, as they are by far the most common.

Wind-induced vibrations started to plague overhead lines with the wide introduction of aluminum-based conductors early in the 20th century, due to their greater susceptibility, mainly due to their low weight compared with the copper conductors previously used. In addition, because of its metallographic structure, aluminum is quite sensitive to fatigue. To understand this better, consider the various mechanisms of vibration excitation by wind as well as their consequences for the fatigue strength of the conductor involved.

Three main types of wind-induced vibrations are recognized: aeolian vibrations, wake-induced or sub-span oscillations, and galloping. Their main properties are summarized in Table 9.27 [9.97]. Anecdotally, for 1 case of galloping, there are 10 cases of subspan oscillations and 1000 cases of aeolian vibration.

#### Aeolian Vibrations

**Wind Excitation and Strouhal Frequency.** The most common type of wind-induced conductor motions are the so-called *aeolian vibrations*, named after Aeolus, the keeper of the winds in Greek mythology. They are excited by moderate, laminar winds, and their peak-to-peak amplitude seldom exceeds one conductor diameter. Physically, the flow of a fluid, here air, interacting with a cylindrical shape, here the conductor, has been observed to generate so-called von Kármán vortices, which are shed in a downstream wake (Fig. 9.48). The pressure fluctuation due to such vortex shedding is responsible for up- and downlift forces on the conductor with a prevailing frequency equal to the Strouhal fre-

**Table 9.27** Comparison of types of cyclic conductor motion (adapted from [9.97])

	<b>Aeolian vibration</b>	<b>Conductor galloping</b>	<b>Wake-induced oscillation</b>
Types of overhead lines affected	All	All	Lines with bundled conductors
Approximate frequency range (Hz)	3–150	0.08–3	0.15–10
Approximate range of vibration amplitudes (peak-to-peak) (expressed in conductor diameters)	0.01–1	5–300	Rigid-body mode: 0.5–80 Subspan mode: 0.5–20
Weather conditions favoring conductor motion – Wind character – Wind velocity (m/s)	Steady 1–7 (3.5–25 km/h)	Steady 7–18 (25–65 km/h)	Steady 4–18 (15–65 km/h)
Conductor surface	Bare or uniformly iced (i.e., hoarfrost)	Asymmetrical ice deposit on conductor	Bare, dry
Design conditions affecting conductor motion	Line tension, conductor self-damping, use of dampers, armor rods	Ration of vertical natural frequency to torsional natural frequency: sag ratio and support conditions	Subconductor separation, tilt of bundle, subconductor arrangement, subspan staggering
<b>Damage</b>			
Approximate time required for severe damage to develop	3 months to 20+ years	1–48 h	1 month to 8+ years
Direct causes of damage	Metal fatigue due to cyclic bending	High dynamic loads	Conductor clashing, accelerate wear in hardware
Line components most affected by damage	Conductor and shield wire strands	Conductor, all hardware, insulators, structures	Suspension hardware, spacers, dampers, conductor strands

**Fig. 9.48** Aeolian vibration initiated by vortex shedding (gray arrow: wind velocity, brown arrows: up- and downlift forces)

quency  $f_s$  (in Hz)

$$f_s \approx 0.2 \frac{v_w}{d_c} \quad (9.71)$$

In this expression,  $v_w$  is the wind velocity perpendicular to the conductor in m/s,  $d_c$  is the conductor diameter in m, and  $S$  is the so-called Strouhal number, which for aeolian vibrations has a (dimensionless) value in the range of 0.2. Consequently and as explained later, when the velocity of the wind is such that the Strouhal frequency of the vortices approaches a modal frequency of the conductor, the latter will start moving transverse

to the wind direction. In reality, aeolian vibrations occur over a range of wind velocities, and once the conductor starts to vibrate, a lock-in effect takes place and the vortex-shedding frequency is controlled by the vibration, even if the wind velocity varies in the range of 90–130% of the initial wind velocity.

**Wave Equation and Natural Frequencies.** The conductor movements propagate as traveling waves to the span extremities, where they are fully or partly reflected and superpose to form standing waves along the span. In this case, the conductor can be modeled as a taut

string with negligible flexural rigidity, obeying the well-known wave equation [9.98–101]

$$T \frac{\partial y^2}{\partial x^2} = m \frac{\partial y^2}{\partial t^2}, \quad (9.72)$$

from which the shape of the conductor can be obtained as a harmonic oscillation in space and time

$$y(x, t) = y_{\max} \sin\left(n\pi \frac{x}{L}\right) \sin(\omega t), \quad (9.73)$$

with a propagation velocity of

$$v = \sqrt{\frac{T}{m}} \quad (9.74)$$

and a wave impedance of

$$Z_c = \sqrt{mT}, \quad (9.75)$$

where  $T$  is the conductor tension,  $m$  is its mass per unit length,  $y_{\max}$  is the maximum vibration amplitude,  $L$  is the span length, and  $n$  is the order of the vibration mode. Considering that

$$n \frac{\lambda}{2} = L \quad (9.76)$$

and the definition

$$v = f\lambda, \quad (9.77)$$

combination of (9.74) and (9.76) with (9.77) yields the spatial frequency of the  $n$ -th vibration mode as

$$f_n = \frac{n}{2L} \sqrt{\frac{T}{m}}. \quad (9.78)$$

This mode can only be excited if its characteristic frequency  $f_n$  coincides with the Strouhal frequency  $f_s$ , i.e., by equating (9.78) with (9.71) and solving for  $n$

$$n = 2Lf_s \sqrt{\frac{m}{T}} = 0.4 \frac{v_w L}{d_c} \sqrt{\frac{m}{T}}. \quad (9.79)$$

For example, for a Drake conductor (ACSR 400/70 mm<sup>2</sup>, (26×4.44 Al + 7×3.47 St) with 28 mm diameter and a mass of 1.63 kg/m), tensioned at 28 000 N in a 400 m span, the 43rd mode is excited at a wind velocity of 1 m/s and the 215th mode at a wind velocity of 5 m/s, the corresponding wavelengths  $\lambda = 2L/n$  being 18.6 and 3.7 m, respectively.

The situation is different in the vicinity of the suspension clamp, where the conductor is considered to be fixed, i.e., the tangent to its deflection is horizontal. At this location, the bending stiffness of the conductor cannot be neglected and plays an important role in determining the stress regime within the conductor [9.102, 103].

**Table 9.28** Terrain categories and characteristics for aeolian vibration assessment (adapted from [9.67])

Terrain category	Terrain characteristics
1	Open, flat, no trees, no obstruction, with snow cover, or near/across large bodies of water; flat desert
2	Open, flat, no obstruction, no snow; e.g., farmland without any obstruction, summer time
3	Open, flat or undulating with very few obstacle; e.g., open grass or farmland with few trees, hedgerows and other barriers; prairie, tundra
4	Built-up with some trees and buildings, e.g., residential suburbs; small towns; woodlands and shrubs. Small fields with bushes, trees, and hedges

**Energy Balance Principle.** When a conductor starts to vibrate, the energy imparted to it by the wind  $P_w$  will feed the vibration and continuously increase its amplitude. The relative wind power input  $P_w/S$  (where  $S$  is the span length) depends on the maximum vibration amplitude  $y_{\max}$ , also called the antinode or the free loop amplitude, the excitation Strouhal frequency  $f_s$ , and the conductor diameter  $d_c$  and can be approximated as

$$\frac{P_w}{S} = f_s^3 d_c^4 \text{fnc} \left( \frac{y_{\max}}{d_c} \right), \quad (9.80)$$

where the function is usually determined by measurements in wind tunnels and given by [9.104]

$$\begin{aligned} \text{fnc} \left( \frac{y_{\max}}{d_c} \right) &= 0.2256 + 0.1677 \left( \frac{y_{\max}}{d_c} \right) \\ &+ 101.62 \left( \frac{y_{\max}}{d_c} \right)^2 \\ &- 99.73 \left( \frac{y_{\max}}{d_c} \right)^3. \end{aligned} \quad (9.81)$$

Typical curves for this function are shown in Fig. 9.49 [9.105].

It has been recognized and is easily understood that terrain is the single most important factor for the excitation of aeolian vibrations. This has to do with the amount of turbulence created by the terrain and particularly by the ground cover; For example, wind blowing over a desert area (Fig. 9.50a) or a water body, such as a lake, will be more laminar in nature and thus more favorable for conductor vibrations than the same wind blowing over a built-up area with trees and buildings (Fig. 9.50b). To facilitate vibration assessment, four terrain categories with growing turbulence intensity have been introduced [9.67] (Table 9.28).

**Fig. 9.49** Maximum wind power input coefficient  $fnc(y_{\max}/d_c)$  per unit length for a single conductor as obtained by different researchers (adapted from [9.105])

**Fig. 9.50** (a) Terrain category 1 per Table 9.28, (b) Terrain category 4 per Table 9.28

Fortunately, in addition to the resistance that the surrounding air poses to the conductor movement (aerodynamic damping) and the intrinsic damping of the conductor material (Coulomb damping), the conductor itself contributes the greatest amount to its so-called self-damping. To understand this issue, consider that, when the conductor is tensioned, the radii of the helices of the conductor wires are reduced, imposing a lateral pressure on the crossing points with the underlying wires (Fig. 9.51 [9.106]). In reality, these point-to-point contacts have an elliptical shape (Fig. 9.52) with a size that depends on the material properties of the wires and the tension level; i.e., the *softer* the material and the higher the tension, the larger the contact area. When the conductor starts to vibrate, it actually bends and, at low amplitudes, the friction between the wires is high enough to prevent sliding; i.e., the wires *stick* together. However, above a certain vibration amplitude,

this interwire friction is overcome and the wires start to slip over one another [9.102, 103], firstly only at the edges of the contact ellipses, which is called *microslip*, and then via rigid-body motion, i.e., *full slip*. Evidently, during this process, energy is dissipated at each wire contact, and the sum of the energy dissipated over all contacts within the conductor results in the *self-damping* of the conductor. Intuitively, self-damping decreases with increasing conductor tension, as the onset of the wire slip is then retarded, and increases with the vibration frequency and amplitude, as these will increase the bending of the vibration loops and thus facilitate wire slip. Figure 9.53 [9.1] confirms these observations.

Conductor self-damping is usually measured in the laboratory using dedicated test spans [9.107], forming the basis for [9.108], which describes the current methodologies, including apparatus, procedures,

**Fig. 9.51** Tension-induced compression in a conductor (adapted from [9.106])

**Fig. 9.52** Elliptical contacts at the surface of conductor aluminum wires (photo: U. Cosmai)

and accuracies for such measurements and data handling. Publication [9.109] provides details of various self-damping measurements of several conductors and OPGWs originating from five different laboratories. Data measured on laboratory spans are generally expressed empirically using a power law [9.110]

$$P_{\text{diss}} = \frac{P}{L} = \frac{kA^l f^m}{T^n}, \tag{9.82}$$

where  $P/L$  is the power per unit length dissipated by the conductor,  $A$  is the antinode displacement of the vibration, and  $f$  is the frequency of the vibration, while  $l$ ,  $m$ , and  $n$  are the amplitude, frequency, and tension exponents, respectively. The so-called conductor factor  $k$  combines the conductor diameter  $D$  (mm), its rated strength  $RS$  (kN), and its mass per unit length  $m$  (kg/m) [9.97]

$$k = \frac{D}{\sqrt{RSm}}. \tag{9.83}$$

Using the empirical rule (9.83), the self-damping determined using short laboratory spans can be extrapolated to actual, much longer spans.

Self-damping data have always been difficult to measure and obtain. In case no experimental data are available, an alternative is to use the so-called similarity laws [9.111]. These laws are derived from the assumption that self-damping should be the same for all

**Fig. 9.53** Self-damping of ACSR 560/60 ( $d_c = 32$  mm) over vibration frequency  $f$  at a free-field bending angle of  $20^\circ$  with EDS as parameter (adapted from [9.1])

conductors of the same construction. Noiseux’s findings can be expressed in the form

$$\frac{P}{L} = D^4 \sigma_{\text{Al}}^{-2.76} A^{2.44} f^{5.63}, \tag{9.84}$$

where  $D$  is the overall conductor diameter (mm) and  $\sigma_{\text{Al}}$  is the stress in the aluminum wires in  $\text{N/m}^2$ .

If the wind power input and the power dissipated through self-damping are now plotted on the same diagram versus the dimensionless amplitude  $y_{\text{max}}/D$  (Fig. 9.54), the prevailing amplitude of vibration can be determined from the point of intersection of these two curves; at this point, energy equilibrium occurs. This is the idea of the energy balance principle (EBP) [9.110]

$$E_W = E_C, \tag{9.85}$$

where  $E_W$  is the energy imparted to the conductor by the wind and  $E_C$  is the energy dissipated by the vibrating conductor.

In most cases, the conductor self-damping mechanism is insufficient to control the levels of vibration within limits which do not produce high accumulation of damaging fatigue cycles. Therefore, often additional, external damping has to be considered, and the EBP equation becomes

$$E_W = E_C + E_D, \tag{9.86}$$

where  $E_D$  is the minimum energy dissipated by the dampers (Sect. 9.6.3), indicated by the dashed area in Fig. 9.54.

**Fig. 9.54** EBP explained schematically (source U. Cosmai)

The EBP acts in the frequency domain; i.e., one mode of vibration at a time is considered, and the steady-state solutions corresponding to the maximum vibration amplitude which could be excited on that conductor at that frequency are computed; this is considered to be acceptable for most engineering applications, as it is on the safe side.

On the other hand, Fig. 9.55 shows the calculation results for a real case, where the arrow marks the *balanced* amplitude for a wind input with 5% turbulence and the self-damping curve of the conductor for a given frequency.

**Fatigue.** The wire movement in the conductor is, on one hand, beneficial towards vibration control, as it is by far the major contributor to the conductor self-damping. However, on the other hand, it is also the main factor causing internal conductor damage, via a phenomenon called *fretting fatigue* [9.112]. This occurs at locations where the conductor is fixed by hardware and mainly at suspension clamps (Fig. 9.105).

There, conductor bending but also lateral contact forces which influence the wire slip are the highest within the span. When the wires start moving, surface material is abraded, i.e., for aluminum wires, aluminum oxide, a hard, powder-like substance with black color, which acts as an abrasive. In combination with the high local stresses in the contact areas, but also the high bending stresses in the bulk of the wire, cracks can be initiated at local surface imperfections (Fig. 9.56) due to irregularities in the wire material properties or caused during manufacturing. These cracks start propagating across the wire until it fails (Fig. 9.57a). As the remaining sound wires will then have to carry a higher mechanical load, if the vibration continues, further wire failures will take place until the full conductor fails (Fig. 9.57b), with detrimental consequences. It is worth noting that wire failures will often occur in the inner layers of the conductor and be concentrated in the lower part of the conductor close to the clamp mouth, making it difficult to detect them during visual inspections.

**Laboratory Fatigue Tests.** In these tests, the conductor is forced to vibrate at various amplitudes until a predetermined number of wires fail. In this way, the so-called *S/N* or Wöhler curve of the conductor is determined [9.113]. It was recognized early on that the conductor endurance capability depends largely on the associated hardware, namely the suspension clamp [9.114], and it is thus recommended to carry out such tests using the same conductor clamp combination as used in the field [9.115]. As these tests are time consuming and rather expensive, a generic *S/N* curve has been proposed [9.54], viz. the so-called safe-border line, which can be used to determine the conductor endurance limit. This can be either a dynamic bending stress/strain or the so-called bending amplitude. The

**Fig. 9.55** EBP in a real case (source J.L. Lilien)

**Fig. 9.56** Crack initiation in a wire (picture L. Cloutier)

**Fig. 9.57a,b** Wire failure (a) leading to conductor rupture (b) (photos U. Cosmai)

latter is the dynamic peak-to-peak bending amplitude measured at a distance of 89 mm (equal to 3.5 in) from the last point of contact (LPC) of the conductor with the clamp (Fig. 9.58 [9.81]).

**Field Measurements.** Vibrating conductors are complex mechanical systems for which field measurements are indispensable in order to determine their vibration activity and also to check related theoretical predictions. For quite a few years now, the state of the art has been to monitor conductor vibrations in the field under real-life conditions using modern vibration recorders [9.116]. The majority of these recorders measure the bending amplitude  $Y_b$  versus the vibration frequency and the corresponding number of cycles. Modern recorders (Fig. 9.59) work autonomously for many months and store and transmit the measured data to a base station; such mea-

**Fig. 9.58** Definition of bending amplitude (adapted from [9.81])

**Fig. 9.59** Modern vibration recorder in the field (photo: Pfisterer Sefag)

surements and the associated data evaluation procedures are described in [9.117, 118].

**Vibration Safe Design.** To control aeolian vibrations to acceptable levels, a methodology had to be developed to establish limits beyond which vibration will not harm the conductor.

One way to do this, predominantly in the design stage, i.e., before the line has been built, is to limit the conductor tension or a parameter related to it. For many years and still nowadays, the recommendations of the so-called CIGRE EDS panel were followed [9.119]. These prescribed the so-called everyday stress (EDS), i.e., the stress in the conductor at the average yearly ambient temperature, and the related tensile load, as a percentage of the RTS of the conductor, with a value of 20% often being used (Table 9.29 [9.67]).

However, this has proved to cause problems in certain cases of ACSR and also to be rather on the high side for monometallic conductors such as AAAC. For this purpose, the subject has been reassessed and new recommendations have been issued [9.67]. They are based on  $H/w$ , the ratio between the tensile load  $H$  (N) of the conductor and its weight per unit length  $w$  (N/m).

**Table 9.29** EDS panel recommendations for safe design tensions as a percentage of RTS (adapted from [9.67])

	Unprotected lines	Line equipped with		
		A armor rods	Dampers	Both
Copper	26			
ACSR	18	22	24	24
Aluminum conductors	17			
Aldrey conductors	18		26	
Steel conductors				
– Rigid clamps	11			
– Oscillating clamps	13			

**Table 9.30** Recommended admissible conductor safe design tension at the average temperature of the coldest month as a function of terrain category, valid for homogeneous aluminum and aluminum alloy conductors Ax (AAC and AAAC), bimetallic aluminum conductors Ax/Ay (ACAR, aluminum conductor alloy reinforced), and steel-reinforced aluminum conductors A1/Syz (ACSR) (adapted from [9.67])

Terrain category	Terrain characteristics	(H/w) <sub>adm</sub> (m)
1	Open, flat, no trees, no obstruction, with snow cover, or near/ across large bodies of water; flat desert	1000
2	Open, flat, no obstruction, no snow; e.g., farmland without any obstruction, summer time	1125
3	Open, flat or undulating with very few obstacle; e.g., open grass or farmland with few trees, hedgerows and other barriers; prairie, tundra	1225
4	Built-up with some trees and buildings, e.g., residential suburbs; small towns; woodlands and shrubs. Small fields with bushes, trees, and hedges	1425

Here,  $H$  is the initial horizontal tension before any significant wind and ice loading and before creep at the average temperature of the coldest month at the site of the line. For single conductors, this parameter depends mainly on the terrain (Table 9.30).

On the other hand, adding dampers in a span is expensive and may allow higher conductor tensions resulting in significant cost savings during line construction. For this reason, based upon extensive theoretical studies and in-depth evaluation of field experience, additional recommendations for single conductors which consider the effect of Stockbridge dampers (Sect. 9.6.3)

**Fig. 9.60** Recommended safe design tension for single conductor lines ( $H$ : initial horizontal tension;  $w$ : conductor weight per unit length;  $L$ : actual span length;  $D$ : conductor diameter and  $m$ : conductor mass per unit length). Terrain categories: green line: open, flat, no trees, no obstruction, with snow cover, or near/across large bodies of water or flat desert; blue line: open, flat no obstruction, no snow, e.g., farmland without any obstruction, summer time; black line: open, flat, or undulating with very few obstacles, e.g., open grass of farmland with few trees, hedgerows and other barriers, prairie, tundra; red line: built-up with some trees and buildings, e.g., residential suburbs, small towns, woodlands and shrubs, small fields with bushes, trees, and hedges (adapted from [9.67])

when added at both ends of a span have been prepared [9.67]. This practice is summarized in Fig. 9.60, where the *safe design zone – no damping* applies to undamped and unarmored single conductors, the *safe design zone – span end damping* constitutes a zone where full protection of single conductors against aeolian vibrations is assuredly feasible by means of one or more Stockbridge-type dampers set at the span extremities, and finally in the *special application zone*, aeolian vibrations, it is recommended that line designers determine the availability of adequate protection before finalizing the design.

For bundle conductors, which are not so sensitive to aeolian vibrations due to the interaction of the sub-conductors, the safe  $H/w$  value is recommended as a matter of prudence to be limited to 2500 m in any terrain category and irrespective of whether they are equipped with spacer dampers (Sect. 9.6.3), although there is evidence that quite a few bundle lines have operated for many years safely at higher  $H/w$  values [9.67].

A second approach to vibration safe design is to limit the conductor stresses/strains that occur during vi-

**Fig. 9.61a,b** Schematic of a subspan oscillation of a twin (a) and quad (b) bundle (adapted from [9.81])

bration. This happens in the design stage of the line through the application of dedicated simulation software [9.104]. Most such programs first calculate the displacements at the antinode as well as in the vicinity of critical locations, mainly at the suspension clamps; these are then converted to stresses or equivalent strains in the conductor, which can be compared with their corresponding limit values obtained from tests in the laboratory or the field.

**Internal Conductor Mechanics.** An important issue that has kept researchers busy for decades is how to properly estimate conductor stresses. The simplest way to do this is to assume that the vibrating conductor bends as a rigid cylindrical body under tension, whereby all its individual wires act independently. This approach provided the basis for the famous Poffenberger–Swart formula (9.87) [9.120], which is widely used in the industry for converting the bending amplitude  $Y_b$  at a distance  $x_b$  from the last point of contact of the conductor with the suspension clamp (Fig. 9.58) to the wire stress  $\sigma_a$  at the top of the conductor at the suspension clamp

$$\sigma_a = \frac{d_a E_a p^2 / 4}{e^{-px_b} - 1 + px_b}, \quad (9.87)$$

where  $E_a$  is the modulus of elasticity of the wire material, normally aluminum,  $d_a$  is the wire diameter,  $EI$  is the minimum bending stiffness of the conductor

$$EI = n_{Al} E_{Al} \frac{\pi d_{Al}^4}{64} + n_S E_S \frac{\pi d_S^4}{64}, \quad (9.88)$$

and

$$p = \sqrt{\frac{H}{EI}}. \quad (9.89)$$

This formula assumes that, during vibration bending, the wires act individually; i.e., they bend around their own axis. However, for low amplitudes, the conductor acts more like a solid body with all its wires sticking together; this will considerably increase the bending stiffness of the vibrating conductor, which will vary

during a vibration cycle, as the curvature of the conductor then changes continuously. This concept was presented for the first time in [9.102, 103, 121] and has formed the basis for further developments of this issue since then [9.122]. In recent years, powerful simulation software has also been extensively used for such calculations [9.106].

For vibration safe design, the following *limit values* are widely used:

**IEEE Maximum Allowable Bending Strain.** In 1966, the Institute of Electrical and Electronics Engineers (IEEE) provided an evaluation criterion for aluminum-based conductors based on a maximum allowable bending strain [9.123]. A value of 150  $\mu\text{inch}/\text{inch}$  (microstrain  $\mu\epsilon$ ) peak to peak was given as a conservative value, and it was suggested that maximum strains on the order of 200  $\mu\epsilon$  peak to peak may well prove to be safe. With accumulating experience, these limits were found to be rather conservative, and values up to 300  $\mu\epsilon$  peak to peak have been adopted by many utility specifications. Subsequently and in order to reduce the severity of the method, some concessions have been granted [9.118]:

- The bending amplitude may exceed the endurance limit for no more than 5% of total cycles.
- No more than 1% of the cycles may exceed 1.5 times the endurance limit.
- No cycles may exceed 2 times the endurance limit.

**EPRI Endurance Limits.** In 2009, the Electric Power Research Institute (EPRI) suggested a bending stress endurance limit of 8.5 MPa for multilayer ACSR conductors, which corresponds to a bending strain of 247  $\mu\epsilon$  peak to peak. For multilayer AAAC conductors, a more conservative limit of 5.7 MPa, which corresponds to a bending strain of 165  $\mu\epsilon$  peak to peak, was introduced [9.97]. It is worth noting that, comparable values for ACSR, i.e., 9.09 MPa and 264  $\mu\epsilon$  peak to peak, can be deducted from the CIGRE Safe Border Line [9.54], which is considered asymptotic at  $5 \times 10^8$  cycles, the upper limit for laboratory tests.

**Fig. 9.62** Typical ice shape as observed on a line conductor, which may cause galloping (adapted from [9.81])

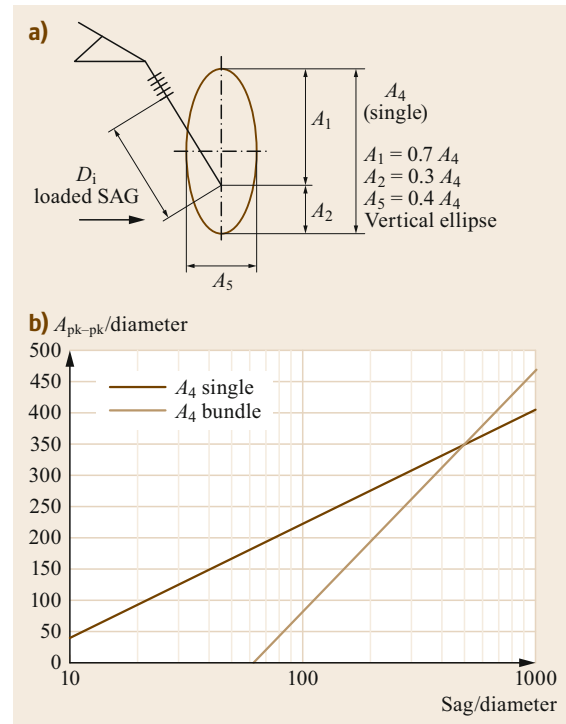

**CIGRE Life Expectancy Estimation.** As early as 1979, the CIGRE developed a method to estimate the life expectancy of a vibrating conductor [9.54]. This method is quite common in the automotive and aircraft industries for structures undergoing fatigue and is based on the assumption that fatigue damage is accumulated linearly in the structure material, independently of the sequence of loads causing it; this is expressed by the so-called Miner rule [9.124]. The method is useful mainly for quantitative comparison of similar setups, i.e., the same conductors in the same vibration environment, but with different clamps or different dampers. Details of related measurements and their evaluation are described in [9.117].

### Subspan Oscillations

Subspan oscillations are wake-induced oscillations. They occur only on conductor bundles and are caused by the wake produced by the windward conductors of the bundle on the leeward ones. The mechanism of subspan oscillation takes the form of one or two loops between adjacent spacers in a span, with nodes at or near the spacers. The trajectories of individual subconductors are elliptical, and windward–leeward pairs of subconductors often move approximately in phase opposition (Fig. 9.61 [9.81, 97]).

The frequencies of subspan oscillations lie in the range of a few hertz. They occur at wind speeds in the range of 8–20 m/s, and their amplitudes may be high enough to cause subconductors to clash, produce damaging strains on the wires at spacer clamp locations, and lead to excessive forces on the spacer arms that may lead to subconductor wire damage and spacer clamp loosening.

Typical values for the ratio  $a/d$ , i.e., the ratio of the bundle separation  $a$  to the conductor diameter  $d$ , usually lie in the range of 10–17, with ratios of 12 or below being considered critical. Analytical simulations and measurements lead to a limit on the maximum subspan length depending on the wind [9.125]; For in-

**Fig. 9.63a,b** Ellipse for clearance design against galloping (a) and curves for galloping maximum peak-to-peak amplitude  $A_{pk-pk}$  over sag (b), both related to conductor diameter (adapted from [9.81])

stance, for a site characterized by high wind speeds ( $>20$ – $25$  m/s), this value should be around 65 m. In nonsevere conditions, maximum subspan lengths of around 80 m have been used without problems. Short end subspans (25–45 m) prevent subspan oscillations at span extremities, which can damage insulators and hardware. Also the use of unequal (staggered) subspan lengths in conjunction with spacers or spacer dampers has proved to be effective against subspan oscillations, with a subspan ratio, i.e., ratio of the lengths of two adjacent subspans, of around 0.85–0.9 being the optimum solution [9.126].

### Gallopings

Of all the wind-induced motions of overhead transmission line conductors, galloping is the most noticeable and spectacular. The resulting damage can be equally dramatic and very costly, with broken conductors and fittings, damaged tower components, and even whole towers collapsing. Galloping is the oscillation of single or bundle conductors due to wind action caused by, in most cases asymmetrical, accretion of ice or wet snow on the conductors (Fig. 9.62 [9.81]), although instances of non-ice-related galloping have also been recorded.

**Table 9.31** Overview of antigalloping devices (adapted from [9.81])

No.	Device name	Applic.	Weather condition		Line construction			Comments
			Glaze	Wet snow	Distribution	Single transmission	Bundle	
1	Rigid interphase spacer	Widely used	Yes	Yes	Yes	Yes	Yes	Prevents flashovers, reduced galloping motions
2	Flexible interphase spacer	Widely used	Yes	Yes	Yes	Yes	Yes	Prevents flashovers, reduced galloping motions
3	Air flow spoiler	Widely used	Yes		Yes	Yes	Yes	Covers 25% of span limited by voltage extensive field evaluation
4	Eccentric weights and rotating clamp spacers	Used in Japan	No	Yes	No	Yes	Yes	Three per single span, one per spacer per subconductor
5	AR twister	Used in USA	Yes		Yes	Yes	Yes	Two per span
6	AR winddamper	Used in USA	Yes		Yes	Yes	Yes	Two per span
7	Aerodynamic galloping controller (AGC)				Yes	Yes	Yes	Number based on analysis
8	Torsional control device (TCD)	Used in Japan		Yes	No	No	Yes	Two per span
9	Galloping control device (GCD)	Used in Japan		Yes	No	No	Yes	Two to four per span Uses armor rods if tension is high. Most extensive field evaluations
10	Detuning pendulum	Widely used	Yes		Yes	Yes	Yes	Few cases have been reported where detuning pendulums increased galloping amplitude
11	Torsional damper and detuner (TDD)	Experimental	Yes	Yes	No	No	Yes	Two or three per span

Galloping can be characterized by:

- Frequencies from 0.08 to 3 Hz
- Maximum galloping amplitude of ten, exceeding the conductor sag
- Minimum wind velocity of approximately 25 km/h.

Galloping is a complex aerodynamic/aeroelastic instability, which on the one hand has caused serious operational problems on transmission lines since their inception and on the other hand attracted quite early interest from many scientists, who have tried to describe it [9.127, 128]. Galloping theory is beyond the scope of this book; we will concentrate here on some practical recommendations.

A detailed analysis of a great number of observed and recorded cases of galloping [9.129] has resulted in the suggestion of an elliptical form for the locus of a galloping conductor (Fig. 9.63a) and its magnitude

(Fig. 9.63b). This should be considered in the clearance design of a line known to exhibit or suspected of experiencing galloping.

There are three main classes of countermeasures against galloping:

- Making lines tolerant to galloping by robust design, provision of increased phase clearances, or controlling the mode of galloping with interphase spacers (Sect. 9.5.5)
- Interfering with the galloping mechanisms to prevent galloping from building up or from attaining high amplitudes
- Removal of ice or preventing its formation on conductors [9.130].

A list of antigalloping devices is presented in Table 9.31 [9.81].

## 9.5 Insulators

According to [9.131], an insulator is a “device intended for electrical insulation and mechanical fixing of equipment or conductors which are subject to electric potential differences”. In this sense, insulators in an overhead line have the primary responsibility of separating the system potential present at the conductor from the earth potential present at the support. It is interesting to note that their name comes from the Latin word *insula*, island—which comes from the Greek word *νήσος* (read *níssos*)—i.e., a piece of land separated by water from the mainland. In addition to fulfilling their electrical duty not only under the system voltage but also under over-voltages from lightning and switching operations, they have to transfer safely the mechanical loads acting on the conductor to the support and achieve this under all, partly very adverse, environmental conditions. A power flashover can occur in all three voltage scenarios. To ensure safe behavior in such a situation, insulators are often equipped with so-called insulator protection fittings (Sect. 9.6.2). The atmospheric pollution ultimately determines the shape of the insulator, i.e., its shed profile, which exists mainly to combat the leakage current due to surface contamination of the insulator, which applies to hydrophilic insulators, while hydrophobic insulators have water repellency as their primary leakage current suppression mechanism. Whereas a 3-m-long column of air provides sufficient insulation for a 400-kV AC conductor, a surface liable to outdoor contamination must provide at least three times that path length [9.132] or the required creepage distance in accordance to the in-situ conditions. In addition, the mechanical integrity of the insulator is of paramount importance for the proper functioning of a line, as its loss will most probably lead to loss of power with all its detrimental consequences and may also cause serious damage and injuries.

Insulators have their origin in 1849, with the introduction of the so-called Siemens insulator for the telegraph line from Frankfurt a. M. to Berlin, followed by the insulators designed by Brown for a 8-km-long, 2-kV DC line from Kriegstetten to Solothurn in Switzerland and in 1891 for the 15-kV AC (later 25-kV AC), 175-km-long line from Lauffen on the Neckar to Frankfurt am Main in Germany (Fig. 9.1).

### 9.5.1 Classification

Several criteria exist for the classification of insulators depending on their:

- Material
- Shape
- Function.

#### Material

Nowadays, three materials are used for insulators:

- Ceramic
- Glass
- Polymer.

Ceramic (mainly porcelain) insulators were the first to be used, followed a few decades later by glass, with polymer or composite insulators, also called nonceramic insulators (NCI), coming many years later (in the 1960s) but now dominating the greatest market share worldwide.

#### Shape

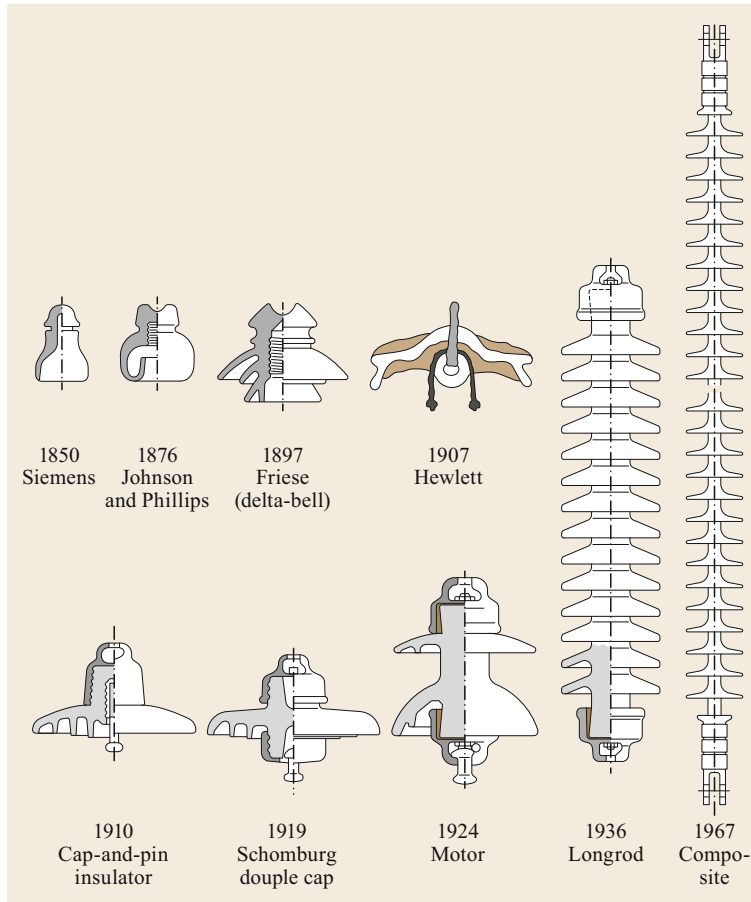

Over the years, three basic insulator shapes have evolved:

- Bell
- Cap and pin
- Longrod.

Although bell-type porcelain insulators were the first to be used, they were mechanically too weak to support the larger conductors over longer spans necessary for increased power transmission and the required higher voltages. For this purpose, cap-and-pin insulators were developed at the beginning of the 20th century in porcelain and from the 1920s in glass. Bell-type insulators, also called pin insulators, are still used as support insulators for low voltage (LV) and medium-voltage (MV) lines.

According to [9.133, 134], overhead line insulators can be classified into two types, type A and type B. Type A insulators are characterized by the fact that the length of the shortest puncture path through the insulating body is at least half of the flashover path on the insulator surface. This applies to longrod insulators. Such insulators are considered to be puncture proof. Insulators in which the length of the shortest puncture path through the body is less than half of the flashover path are classified as type B insulators, for instance cap-and-pin insulators. They are considered to be not puncture proof.

The understandable wish of many users to install puncture-proof (type A) insulators on their HV lines could be fulfilled by advances in the manufacturing technology of porcelain longrod insulators (as puncture-proof solid-core insulators cannot be manufactured from glass) and in particular the possibility of manufacturing large bodies of porcelain without air pockets, leading in around 1936 in

**Fig. 9.64** Historical development of overhead line insulators (source Pfisterer Lapp)

**Fig. 9.65** Double tension string (adapted from [9.112])

Germany to the development of the porcelain longrod, a logical development of the first double-shed solid-core and thus puncture-proof insulator, the so-called motor insulator developed in 1917/19 in Switzerland. Finally, the introduction of polymer materials, mainly silicone rubber for HV insulation, led in the

1960s to the concept of composite longrod insulators.

On rare occasions, hollow-core composite insulators have also been used for transmission lines, e.g., as insulated cross arms in compact lines [9.135], with their main application being as housings of HV equipment in substations [9.136].

Figure 9.64 summarizes the historical development of overhead line insulators.

### Function

The function of an insulator on a line primarily determines the mechanical loads it must sustain. As shown in Figs. 9.65–9.67 [9.112], one can distinguish between:

- Ties, such as suspension or dead-end insulators, which are loaded in tension (Fig. 9.65)
- Struts, such as posts in insulating cross-arms, which are loaded in compression (Fig. 9.66)
- Beams, such as vertical and horizontal posts, which are loaded in bending (Fig. 9.67).

**Fig. 9.66** Horizontal strut in an insulating cross-arm (adapted from [9.112])

**Fig. 9.67** Vertical post insulators in the so-called trident configuration (adapted from [9.112])

### Geometry

Common to all insulator types are the following geometric properties.

**Connection length:** Shortest distance in air between the two end fittings. This dimension is important for the necessary clearances and thus the tower width and height.

**Arcing distance:** Shortest path in air between the two insulator end fittings. This dimension determines the flashover properties of the insulator when not polluted and is thus important for the insulator coordination of the power system.

**Fig. 9.68** Dimensional properties of cap-and-pin insulators (porcelain/glass) (adapted from [9.137])

**Fig. 9.69** Dimensional properties of longrod insulators (porcelain/composite) (adapted from [9.138])

**Creepage or leakage distance:** Path along the insulator surface between the end fittings. This dimension determines the pollution performance of the insulator (Sect. 9.5.2).

Figure 9.68 [9.137] shows schematically these properties for a cap-and-pin and Fig. 9.69 [9.138] for a composite longrod insulator.

The electrical characteristics of a nonpolluted insulator, i.e., the lightning, switching, and power frequency withstand and flashover voltages, whether wet or dry, depend mainly on its arcing distance (Fig. 9.70). However, in polluted conditions, the creepage distance formed by the insulator shed profile is the key, as explained in Sect. 9.5.2.

Fig. 9.70 Withstand voltages versus arcing distance

## 9.5.2 Pollution

The corrugated shape of the insulator surface, independent of the insulating material used, is necessary to ensure its performance under pollution. For the proper selection of insulators and the determination of their relevant dimensions to be used in high-voltage systems with respect to pollution, an IEC standard [9.139–142] forms the basis from which the following information is extracted. CIGRE publications [9.143–145] are a useful complement for those wishing to study the performance of insulators under pollution in greater depth.

### Pollution Flashover

The prerequisite for good insulator design with respect to pollution is a basic understanding of pollution flashover. This is described in [9.139]. For the so-called predeposit pollution (type A), we distinguish the following phases:

- *Phase 1:* The insulator becomes coated with a layer of pollution.
- *Phase 2:* The surface of the polluted insulator becomes wetted. The wetting of an insulator can occur by moisture absorption, condensation, and precipitation. Precipitation by heavy rain may wash away the electrolytic components of part or the entire pollution layer without initiating other phases in the breakdown process, or it may promote flashover by bridging the gaps between sheds. Moisture absorption occurs during periods of high relative humidity (> 75%) when the temperature of the insulator and ambient air are the same. Moisture can also gain access to the pollution layer at lower relative humidity if the pollution is hygroscopic. Condensation usually occurs at sunrise or just before, when moisture in the air condenses on the insulator surface, whose temperature is lower than the dew point.
- *Phase 3:* Once an energized insulator is covered with a conducting pollution layer, surface leakage currents flow and their heating effect starts (within a few power-frequency cycles) to dry out parts of the pollution layer. Under the modeled assumption of a uniform pollution layer, this occurs where the current density is highest, i.e., where the insulator is at its narrowest. These result in the formation of what are known as dry bands.
- *Phase 4:* The pollution layer never dries uniformly, and in places the conducting path becomes broken by dry bands which interrupt the flow of leakage current.
- *Phase 5:* The line-to-earth voltage appearing across multiple dry bands (which may be only a few millimeters wide) causes air breakdown, and the dry bands are bridged by arcs which are electrically in series with the resistance of the still wet and conductive portion of the pollution layer. This causes a surge of the leakage current each time the dry bands on the insulator spark over.
- *Phase 6:* If the resistance of the still wet and conductive part of the pollution layer is low enough, the arcs bridging the dry bands are sustained and may finally continue to extend along the insulator, bridging more and more of its surface. This in turn decreases the resistance in series with the arcs, increasing the current and permitting them to bridge even more of the insulator surface. As a rule of thumb, flashover becomes very likely after bridging 2/3 of the creepage distance. Ultimately, it is completely bridged and a line-to-earth fault (flashover) is established.

**Table 9.32** Typical environments (adapted from [9.139])

Example	Description of typical environments
E1	> 50 km <sup>a</sup> from any sea, desert, or open dry land > 10 km from man-made pollution sources <sup>b</sup> At a shorter distance from pollution sources than mentioned, but <ul style="list-style-type: none"> <li>• prevailing wind not directly from these pollution sources</li> <li>• and/or with regular monthly rain washing</li> </ul>
E2	10–50 km <sup>a</sup> from the sea, a desert, or open dry land 5–10 km from man-made pollution sources <sup>b</sup> Within a shorter distance than E1 from pollution sources, but <ul style="list-style-type: none"> <li>• prevailing wind not directly from these pollution sources</li> <li>• and/or with regular monthly rain washing</li> </ul>
E3	3–10 km <sup>c</sup> from the sea, a desert, or open dry land 1–5 km from man-made pollution sources <sup>b</sup> Within a shorter distance from pollution sources than mentioned above, but <ul style="list-style-type: none"> <li>• prevailing wind not directly from these pollution sources</li> <li>• and/or with regular monthly rain washing</li> </ul>
E4	Further away from pollution sources than mentioned in E3, but <ul style="list-style-type: none"> <li>• dense fog (or drizzle) often occurs after a long (several weeks or months) dry pollution accumulation season</li> <li>• and/or heavy, high-conductivity rain occurs</li> <li>• and/or there is a high nonsoluble deposit density (NSDD) level, between 5 and 10 times the equivalent salt deposit density (ESDD)</li> </ul>
E5	Within 3 km <sup>c</sup> of the sea, a desert, or open dry land Within 1 km of man-made pollution sources <sup>b</sup>
E6	At a greater distance from pollution sources than mentioned in E5, but <ul style="list-style-type: none"> <li>• dense fog (or drizzle) often occurs after a long (several weeks or months) dry pollution accumulation season</li> <li>• and/or there is a high NSDD level, between 5 and 10 times the ESDD</li> </ul>
E7	Within the same distance of pollution sources as specified for <i>heavy</i> areas and <ul style="list-style-type: none"> <li>• directly subjected to sea spray or dense saline fog</li> <li>• or directly subjected to contaminants with high conductivity, or cement-type dust with high density, and with frequent wetting by fog or drizzle</li> <li>• desert areas with fast accumulation of sand and salt, and regular condensation</li> </ul>
<sup>a</sup> During a storm, the ESDD level at such a distance from the sea may reach a much higher level	
<sup>b</sup> The presence of a major city will have an influence over a longer distance, i.e., the distance specified for seas, desert, and dry land	
<sup>c</sup> Depending on the topography of the coastal area and the wind intensity	

For so-called instantaneous pollution (type B), such as salt spray, salt fog, or industrial acid fog, which can occur in areas located close to the coast or near chemical plants, the flashover process starts at phase 3 and can progress rapidly to phase 6. A particular case of type B pollution is a bird streamer. This is a type of bird excrement, which, on release, forms a continuous, highly conductive (20–40 kΩ/m) stream of such length that the air gap is sufficiently reduced to cause flashover. In this case, the insulator geometry and characteristics play little or no role and the best solution may be to fit bird-dissuasive devices appropriate to the local fauna and structure design.

#### Insulator Design for Pollution

Standard [9.139] describes the three basic approaches to insulator selection and dimensioning for pollution, i.e.:

1. Use past experience
2. Measure and test
3. Measure and design.

For the purposes of standardization, five classes of site pollution severity (SPS) are qualitatively defined in [9.139], from very light pollution to very heavy pollution as follows:

- a Very light
- b Light
- c Medium
- d Heavy
- e Very heavy.

Typical pollution environments are indicated in Table 9.32 [9.139], where E2 corresponds to light, E3 to medium, E5 to heavy, and E7 to very heavy pollution.

**Fig. 9.71** RUSCD as a function of SPS class for AC

**Creepage Distance.** The SPS class is used to determine the reference unified specific creepage distance (RUSCD) for AC voltages (Fig. 9.71 [9.139–142]), i.e., the creepage distance of an insulator divided by the rms value of the highest operating voltage  $U_m$  across the insulator. This definition differs from that of the specific creepage distance, where the line-to-earth value of the highest voltage for the equipment is used (for AC systems usually  $U_m/\sqrt{3}$ ). For line-to-line insulation, this will result in a value that is  $\sqrt{3}$  times that given by the definition of the specific creepage distance in [9.146], now replaced by [9.139–142]. In Fig. 9.71, the bars are preferred values representative of a minimum requirement for each class. If exact SPS measurements are available, it is recommended to take a RUSCD which corresponds to the position of the SPS measurements within the class by following the curve shown.

It is worth noting that there is no difference in the RUSCD between insulators made from different materials, specifically the well-documented advantages of polymer insulators under pollution [9.2], which can result in a reduction of RUSCD by up to 30% if their hydrophobicity is not lost.

**DC Applications.** For DC voltages, the design process is complicated by several factors [9.140], as DC insulators exhibit a greatly different pollution behavior compared with those operating at AC. This is mainly due to electrostatic effects because of:

- The influence of wind, particle size, etc. on the accumulation of pollution
- The composition of the pollution (low-solubility or slow-dissolving salts)
- The effect of the amount of nonsoluble deposit
- The contamination uniformity ratio (CUR)
- The effect of diameter on pollution accumulation
- The nonuniformity of the pollution layer along or around the insulator
- The effect of diameter on pollution performance

**Fig. 9.72** RUSCD for DC and type A pollution ( $ESDD_{DC}$  at  $NSDD = 0.1 \text{ mg/cm}^2$ )

**Fig. 9.73** RUSCD for DC and type A pollution (SES: site equivalent salinity)

- The effect of insulator material on pollution performance.

Due to these, some early applications of nonceramic insulators were for HVDC lines, where the superior behavior of polymer material is indisputable [9.147]. This is recognized in [9.140], where polymer materials, which exhibit hydrophobicity but also have the capability to transfer hydrophobicity to the pollution layer, are referred to as hydrophobicity transfer materials (HTM). They require less RUSCD (in mm/kV) as shown in Figs. 9.72 and 9.73 [9.140]. These figures also indicate that, for the proper design of DC insulators under pollution, site severity measurements are necessary as indicated in the parameters on the abscissa ( $ESDD_{DC}$ ,  $NSDD$ ,  $SES_{DC}$ ). Details are given in [9.140].

SPS Class	Deviations for CF	
a	None	3.5 Minor, 4.25 Major
b	None	3.625 Minor, 4.4 Major
c	None	3.75 Minor, 4.55 Major
d	None	3.875 Minor, 4.7 Major
e	None	4.0 Minor, 4.85 Major

CF 2.5 3.0 3.5 4.0 4.5 5.0 5.5

**Table 9.33**  
CF values for ceramic and glass AC insulators

SPS Class	Deviations for CF	
a	None	
b	None	
c	None	Minor, Major
d	None	
e	None	

CF 2.5 3.0 3.5 4.0 4.5 5.0 5.5

**Table 9.34**  
CF values for polymer AC insulators

**Table 9.35** CF values for DC insulators

Glass and porcelain insulators	Composite and hybrid insulators, non-HTM	Composite and hybrid insulators, HTM
Cap and pin typically below 3.4 Rarely greater than 3.75	Line insulators typically below 4.5 Rarely greater than 4.8	Typically below 4.5 Rarely greater than 4.8
Posts, long rods and hollow cores typically below 3.5 Rarely greater than 4.0	Posts and hollow cores typically below 4.4 Rarely greater than 4.6	

The final step is to determine the  $USCD_{req}$  of the insulator in question, i.e.,

$$USCD_{req} = RUSCDC_d C_a, \quad (9.90)$$

where  $C_d$  is the diameter correction factor, which considers the effect of diameter on the pollution withstand performance of the candidate insulator and applies only to insulators with diameters above 250 mm, i.e.,  $C_d = 1$  for line insulators, and  $C_a$  is the altitude correction factor given in [9.148] as

$$C_a = e^{n \frac{H}{8150}}, \quad (9.91)$$

where  $H$  is the height above sea level in meters. The current design practice in industry is to use  $H - 1000$  instead of  $H$  in (9.91) and to only apply the correction above 1000 m. Until further information is available, a value of 0.35 is suggested for  $n$ .

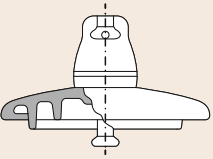

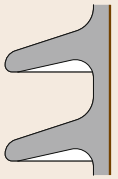

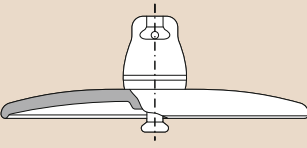

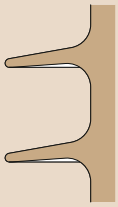

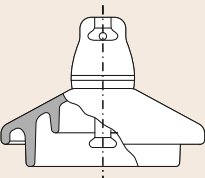

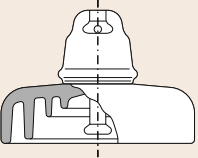

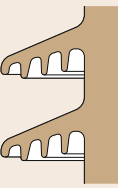

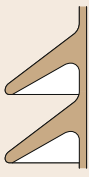

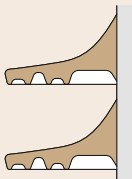

**Creepage Factor.** The creepage factor (CF) is equal to  $l/s$ , where  $l$  is the total creepage distance and  $s$  is the arcing distance of the insulator unit (Figs. 9.68 and 9.69); it is used as a global check of the overall density of the creepage distance. For cap-and-pin insulators, the CF is determined for a string of five insulators or more. CF values encountered in DC applications are often higher than those used for AC because, in general, a higher creepage distance is needed for given insulator length in DC. It is important to bear in mind that greatly increasing the CF can have no or even a negative effect on the performance. Tables 9.33 to 9.35 [9.140–142] contain recommendations for the CF of AC and DC insulators.

**Shed Profiles.** In order to obtain the required creepage distance as explained above, but also in order to keep a certain portion of it dry and more resistant to accumulation of pollutants, various insulator shapes and profiles have been developed over the years. In addition, variations in the nature of the pollutant may make some shapes of insulator more effective than others. It should be borne in mind that the minimum or maximum overall length of the insulation is an important imposed parameter, e.g., for insulation coordination or tower height. Table 9.36 summarizes the main characteristics of each type of profile. More advice on profiles is given in the relevant parts of [9.139–142].

**Corrosion.** Another issue arising from pollution is the corrosion of the insulator fittings and in particular of the connection pins of cap-and-pin insulators.

When the surface of the insulator becomes contaminated and wet, a biased leakage current starts to flow,

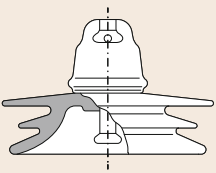

**Table 9.36** Typical profiles and their main characteristics (adapted from [9.139–142])

<p><b>Standard profiles</b> Standard profiles are effective for use in <i>very light</i> to <i>medium</i> polluted areas where a long creepage distance or an aerodynamically effective profile is not required</p>	 <p>Cap and pin standard discs insulators</p>	 <p>Porcelain standard profile, long rod insulators, post insulators, hollow insulators</p>
<p><b>Aerodynamic or open profiles</b> Aerodynamic or open profiles prove to be beneficial in areas where the pollution is deposited onto the insulator by wind, such as deserts, heavily polluted industrial areas or coastal areas which are not directly exposed to salt spray. This type of profile is especially effective in areas that are characterized by extended dry periods. Open profiles have good self-cleaning properties and are also more easily cleaned under maintenance</p>	 <p>Aerodynamic disc insulators</p>  <p>Porcelain long rod insulators, post insulators, hollow insulators</p>	 <p>Polymeric long rod insulators, post insulators, hollow insulators</p>
<p><b>Anti fog profiles</b> The use of anti fog profiles with steep sheds or deep under-ribs is beneficial in areas exposed to a salt water fog or spray, or to other pollutants in the dissolved state. These profiles may also be effective in areas with a particulate pollution precipitation containing slow dissolving salts. They can also be effective in areas with low NSDD and slow dissolving salts</p>	 <p>Steep anti-fog disc insulators</p>  <p>Deep under-ribs disc insulators</p>  <p>Deep under-ribs on porcelain long rod insulators, post insulators, hollow insulators</p>	 <p>Steep porcelain long rod insulators, post insulators, hollow insulators</p>  <p>Steep polymeric long rod insulators, post insulators, hollow insulators</p>  <p>Under-ribs on polymeric long rod insulators, hollow insulators, post insulators</p>

causing electrolytic corrosion of the pins. Even under AC voltages, corrosion takes place, and is enhanced when the leakage current has a DC component. The corrosion is much more harmful for DC voltages be-

cause the current is unidirectional but also because, as explained above, the deposition and formation of pollution are enhanced via electrostatic phenomena related to DC. Corrosion will, on one hand, reduce the diameter

**Table 9.36** (Continued)

<p><b>Alternating shed profiles</b> Alternating shed arrangements are in general feasible for all profiles, although steep sheds are less beneficial. They offer increased creepage distance per unit length without penalizing performance in heavy rain or icing. Similar benefits to open profiles are also provided by simple alternating profiles</p>	 <p>Alternating shed disc insulators</p>	 <p>Porcelain long-rod insulators, post insulators, hollow insulators</p> <p>Polymeric long rod insulators, post insulators, hollow insulators</p>

**Fig. 9.74** Corroded pin of a glass cap-and-pin insulator; note the reduced diameter of the pin and the rust products at the boundary with the dielectric

of the pin and thus the mechanical strength of the insulator, while on the other, the related rust products may cause cracks through expansion and subsequent failure of the dielectric (Fig. 9.74).

The corrosion resistance of insulators can be improved on the one hand by using reinforced galvanized fittings, i.e., by increasing the average coating zinc mass specified in [9.133, 134] of  $600 \text{ g/m}^2$ , corresponding to  $85 \mu\text{m}$ , up to  $140 \mu\text{m}$  for very high-corrosion areas such as coastal areas, and on the other by using a so-called sacrificial zinc sleeve (Fig. 9.75a), a must for HVDC insulators made of glass or porcelain. The cast iron cap itself can also suffer from corrosion. However, the time required for significant corrosion of the cap is longer than for the pins, and the corrosion effects are not so dramatic. As a remedy, a zinc collar is often used (Fig. 9.75b).

The zinc sleeve has a large electrochemical potential difference to iron and thus acts as a sacrificial electrode at the cement boundary where the current flows. Because of this, the boundary remains free from accumulation of corrosive products, which, as men-

tioned above, could become detrimental for the insulating body. The standard [9.150] specifies the minimum requirements for the zinc sleeve.

**Mitigating Measures.** There are various ways to improve the pollution performance of insulators. This can become necessary in case of a poor original design of the insulator or when a new industry, such as a cement plant, is built close to the line and at the same time insulator replacement is prohibitive because of costs or clearance violations. The definitive solution is to install composite (polymer) insulators (Sect. 9.5.5), which exhibit excellent pollution performance. Alternatives include [9.151]:

- Booster shed
- Shed extender
- Shed protector
- Coating
- Semiconducting glaze
- Washing.

Among these techniques, washing is still quite often used in areas of extreme (in particular desert-type) pollution, in the great majority of cases being undertaken with the line energized, which is referred to as *live* or *hot line washing* [9.143]. In addition, coatings have gained a certain popularity, in particular for substation insulators where replacement with composite insulators is not always feasible. The good service record of silicone rubber insulators for outdoor applications has stimulated the development of room-temperature vulcanized (RTV) silicone rubber coatings [9.152], service experience of which has shown that the useful life of

**Fig. 9.75a,b** Zinc sleeve on pin (a) and zinc collar on cap (b) (source [9.149])

a RTV coating can vary from less than a year to many years.

### 9.5.3 Porcelain Insulators

Porcelain insulators have the longest history, well above 100 years, and an excellent service record. Due to historical developments, two types have emerged: the cap-and-pin type and longrod type (Fig. 9.76).

While cap-and-pin insulators are used worldwide, longrod insulators are mainly installed in Central Europe, as well as some Middle East and other countries with serious desert pollution because of the excellent aerodynamic properties of their sheds, which hinder the accumulation of pollutants. For both types, the arcing distance and creepage distance can easily be adjusted to specified flashover values and the pollution regime, respectively, by simply adding more units.

Cap-and-pin insulators retain their integrity when a cap shatters (which is not the case for longrods), and because of their inherent flexibility, they are much less sensitive to bending loads such as those caused by load transposition in double strings, which, if not adequately addressed by special hardware, can cause a problem for longrods [9.153].

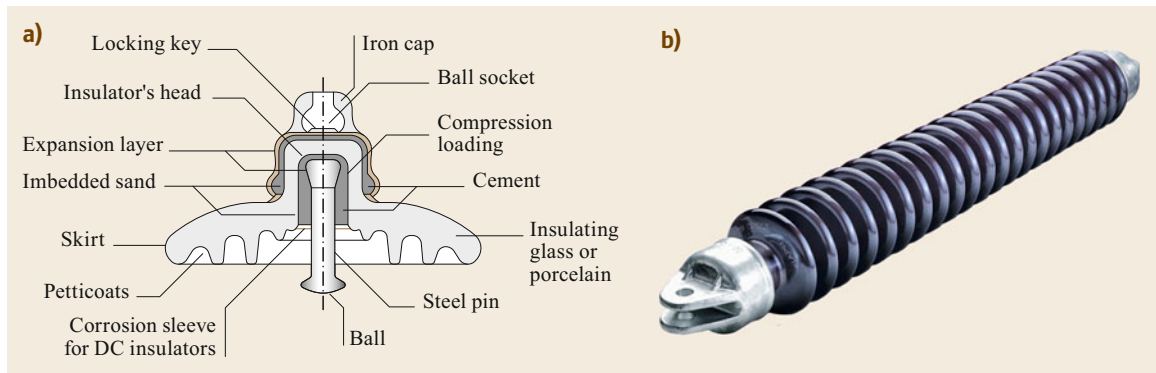

On the other hand, porcelain longrods offer certain advantages over (porcelain or glass) cap-and-pin insulators: They are puncture proof and can be easily

protected against power arcs. They also show excellent performance, in particular when heavily contaminated, and, because of their fewer intermediate fittings compared with cap-and-pin strings, they are not prone to cascade flashovers and have very low radio interference values. They are standardized in [9.154].

Porcelain insulators are made from quartz porcelain C-110 for low-strength insulators or C-120 or C-130 aluminum oxide porcelain for high-strength insulators, all according to [9.155]. Their main material properties are specified in [9.156].

Porcelain insulators are manufactured using a wet process, so called because a considerable amount of water is added to the raw materials, i.e., ca. 50% clay as the base material, ca. 25% quartz or alumina as the filler, and ca. 25% feldspar as the flux, with the aim of wetting the other ingredients and facilitating their dissolution in the melt.

These are quite complex processes that have been continuously developed over long time. They are based on extensive manufacturer-specific knowhow and require stringent quality control at all stages in order to obtain a low-porosity and thus mechanically strong porcelain body. Also, the glazing process is of paramount importance, as the glaze not only forms a smooth and easily washable surface, but also seals it and thus practically eliminates crack initiation from surface imperfections. In addition, as it has a lower ther-

**Fig. 9.76a,b** Porcelain cap-and-pin (a) longrod with clevis caps, overall length 1270 mm (b) (source Pfisterer Lapp)

**Fig. 9.77** Compressive stresses in the porcelain shell caused by tensile load (adapted from [9.137])

mal expansion coefficient compared with the porcelain bulk material, it induces beneficial compressive stresses upon the insulator surface.

Last but not least, the porosity of the porcelain depends strongly on the maximum firing temperature and its duration, the optimum being  $1150 \pm 15^\circ\text{C}$ .

#### End Fittings

End fittings are used to transfer the mechanical loads acting on the conductor, such as wind and/or ice loads, to the porcelain dielectric (Sect. 9.3.2) and from there to the line support. The main materials in use are malleable or ductile iron, forged steel, and rarely, for distribution insulators, aluminum. Ferrous fitting materials are hot-dip galvanized with a minimum of  $600\text{ g/cm}^2$  zinc, resulting in a minimum zinc thickness of  $85\ \mu\text{m}$ , and are attached to the porcelain using Portland cement for cap-and-pin insulators or lead-antimony alloy for longrods. There is also an important difference in the mechanical action of the fittings. Cap-and-pin fittings, on one hand, when loaded in tension, impose compressive stresses upon the porcelain body (Fig. 9.77 [9.137]). Longrod fittings, on the other hand, transfer the external tensile loads via their conical shape and the resulting shear stresses at the metal–porcelain interface, resulting in axial tensile stresses in the porcelain body of the insulator (Fig. 9.78).

End fittings are well standardized [9.157, 158] in order to enable easy replacement and exchange with other insulator types, including those made of glass or composite. For cap-and-pin insulators, ball-and-socket connections prevail. These are secured by W-clips or split pins, the latter providing a more reliable coupling in a string, as the cross-section area of a split-pin is twice that of a W-clip.

**Fig. 9.78** End fitting of a longrod porcelain insulator (source Pfisterer Lapp)

#### 9.5.4 Glass Insulators

Although the first LV overhead lines built in the 1880s used glass insulators, adapted from counterparts used in telegraph lines, the glass quality in those days could not cope with the higher loads which came with increasing voltages and the need for heavier conductors and longer spans. This changed with the introduction of the glass toughening process around 1930, since when glass insulators have been used extensively worldwide in overhead lines up to the highest voltages. They are shaped with few exceptions, e.g., glass pin insulators for distribution, as cap-and-pin insulators (Fig. 9.79). As in the case of porcelain cap-and-pin insulators, their arcing and creepage distances can be adjusted by simply adding more units. Similarly, because of their inherent flexibility, they are not sensitive to bending loads and they also retain their integrity when a cap shatters, this being on the one hand an advantage for easy spotting during inspections, while on the other attracting shooting enthusiasts, who enjoy the explosion-like shattering of the toughened glass shell. While they require fewer production steps and their shell is thinner than porcelain—because glass is a more homogeneous material and thus a better dielectric—their manufacturing process is very energy intensive and there is considerable variation amongst the few available renowned manufacturers in terms of raw material quality, composition, and processing, in particular toughening, which is a knowhow-intensive procedure.

The raw materials for the glass dielectric consist of ca. 57% silica (silicon dioxide found in nature as quartz), ca. 9% limestone, ca. 14% soda ash, ca. 4% feldspar, ca. 11% dolomite, and ca. 6% other mineral salts. About 1/3 of the mass is cullet, i.e., glass

**Fig. 9.79** Glass insulator (source MacLean Power Systems)

which has shattered during the production process or been rejected during inspection, as well as unused gobs of glass from mold changeovers. Cullet contributes to the stability and consistency of the manufacturing process [9.159]. The raw materials are crushed and mixed, then delivered to the furnace for melting, which is a critical step in the production sequence, as on the one hand it has to ensure very high homogeneity of the molten mass and on the other it has to be designed in such a way that it can run for years at temperatures up to 1400 °C without shutdowns, e.g., for maintenance. The glass exits the furnace in the form of a calibrated molten glass gob and is delivered to a preheated cast iron mold for pressing into shape at a temperature just over 1000 °C. Spinning after removal from the mold allows the internal screw shape to form inside the glass shell. This is followed by the decisive and critical toughening process, whereby the surface of the shells is cooled using jets of cold air, while their body remains molten. As the body contracts at a faster rate than the surface, this results in tensile stresses in the body and compressive stresses at the surface, leading to higher tensile strength, improved fatigue characteristics, higher puncture voltage, and higher impact resistance of the glass insulator. Subsequently the shells are immersed in cold water for thermal shock treatment, during which the great majority of defective shells can be recognized and eliminated. Finally, the assembly of the metal fittings, i.e., the cap and pin, takes place; these are fastened to the glass shell normally by using alumina cement. The process ends with testing. It is advisable to store the finished glass insulators before packing, as the considerable stress redistribution that occurs in the glass shell during this period will lead to self-shattering of some insulators, which can then be removed from delivery.

### End Fittings

The end fittings of glass insulators are very similar to those of porcelain cap-and-pin insulators. The pins are normally steel forgings, as they have to exhibit greater uniformity and higher strength than can be achieved by casting. The latter is used to make the caps from malleable iron. Both the caps and pins are hot-dip galvanized for corrosion protection then covered with a bituminous paint wherever they will come into contact with the alumina cement. As mentioned above, when deemed necessary for DC applications or use in highly polluted areas, a zinc sleeve is pressed around the pin to form a sacrificial electrode and protect it from corrosion.

### 9.5.5 Composite Insulators

The development of composite or nonceramic insulators basically started in the 1940s, when organic materials, namely epoxy resins, started being used for indoor high-voltage insulators, being advantageously lightweight and impact resistant, and also enabling large complex parts [9.160]. Unfortunately, field trials outdoors with such structural insulators led to many failures, so cycloaliphatic epoxy resins are now only used on a small scale for some distribution and railway insulators. Progress developed instead towards composite insulators, i.e., insulators where the various duties of the insulator, such as mechanical, electrical, and environmental, are shared between its different components. Composite insulators for overhead lines were developed as early as 1964 in Germany [9.161], where the first units for field testing were provided in 1967. In the late 1960s and early 1970s, manufacturers from Germany, France, the UK, the USA, and Switzerland introduced the first generation of commercial composite transmission line insulators. They came into general use in the 1980s and today account for (together with polymer distribution and hollow core apparatus insulators) approximately 40% of the insulator market worldwide. In fact, the number of units of composite insulators installed has grown exponentially, reaching more than 20 million units for AC lines today (Fig. 9.80 [9.162]). In addition there are more than 100 000 units installed on HVDC lines, confirming the advantages of composite insulators for HVDC applications as recognized early on [9.147], mainly because of their superior performance in comparison with ceramic insulators under the more intense and concentrated pollution in the DC field, which makes them considerably shorter than porcelain or glass strings. This is decisive for the tower silhouette and the ROW width, and thus the costs of DC overhead lines.

**Fig. 9.80** Estimated growth in composite insulator ( $\geq 69$  kV) use in AC transmission lines

This extraordinary and for many unexpected development has been enabled by the following factors:

Advantageous properties:

- The connection length and dry arc distance can be easily and precisely adjusted to grid and site requirements.
- The creepage distance can be similarly adjusted by proper choice of the size, shape, and number of sheds.
- They are not prone to vandalism (gunshots).
- They offer high bending strength and are flexible, thus not being endangered by load transposition.
- They show excellent pollution performance because of their surface hydrophobicity and hydrophobicity transfer to the pollution layer.
- They have low weight (e.g., for 400 kV, 10% of an equivalent ceramic insulator string).

Positive service experience:

- The continuous research by a few dedicated manufacturers has eliminated the flaws in the early generations of composite insulators.
- The creation of numerous international standards has enabled unbiased comparison and selection of insulators.
- More than 40 years of positive field experience worldwide, also and in particular in high pollution environments (marine, desert, and industrial).
- CIGRE and other surveys have consistently shown very low failure rates, comparable to those of porcelain and glass [9.162–165].

New applications:

- With the introduction of high-power transfer over long distances with line voltages up to 1200 kV AC and 1000 kV DC, composite insulators with single lengths of 10 m and above and mechanical ratings

**Fig. 9.81** Structure and elements of a silicone rubber composite insulator

up to 1000 kN offer significant cost savings because they are much lighter and considerably shorter than ceramic insulators.

- Because of the shift towards renewables—*green energy*—in many countries, a voltage upgrade or a voltage conversion from AC to DC of existing transmission lines is often the preferred approach to comply with the related significant variations in power transfer. This is feasible only with the use of composite insulators [9.166].
- Increasing environmental concerns by the public regarding the construction of new lines can often be addressed by proposing compact lines (Fig. 9.151), which are more slender and optically less obtrusive. Such lines have become practically feasible only through the use of composite insulators [9.167].

Competitive prices:

- The dissemination of knowhow by the few suppliers of raw materials, e.g., silicone, and production machinery companies led to a large number of new manufacturers, mainly in developing countries, and thus significantly lower production costs.
- At the same time, due to economies of scale and automated industrial production, the prices of the few experienced, renowned manufacturers have also declined dramatically in the last years, while at the same time the quality of their products has continuously improved.

The structure of composite insulators has basically remained unchanged over the years (Fig. 9.81 [9.2]). They consist of:

- A fiber-reinforced plastic (FRP), also known as glass-reinforced plastic (GRP), rod with high mechanical strength to take up the external loads and provide the internal insulation
- Metal fittings at both ends of the rod for transmission of mechanical loads
- A polymer housing with sheds surrounding the rod, designed to provide the necessary creepage distance and to achieve the best performance under pollution.

**Table 9.37** Elastic properties and mechanical strengths of FRP rods (adapted from [9.168])

Elastic property (GPa)		Mechanical strength (MPa)	
$E_1$	44	$\sigma_{11+}$	1038
$E_2, E_3$	10.3	$\sigma_{11-}$	-794
$G_{23}$	4.3	$\sigma_{22+}, \sigma_{33+}$	32
$G_{31}, G_{12}$	5.1	$\sigma_{22-}, \sigma_{33-}$	-141
$\nu_{23}$	0.5 [-]	$\tau_{12}, \tau_{13}$	54
$\nu_{31}, \nu_{21}$	0.32 [-]	$\tau_{23}$	$\approx 30$

### FRP Rod

The heart of any composite insulator is the FRP rod. It is made of thousands of glass fibers ( $\varnothing 10\text{--}30\ \mu\text{m}$ ) embedded in an epoxy resin matrix (Fig. 9.82 [9.168]). A glass content of 60–70 wt% enables a high axial tensile strength of the rod of around  $1000\ \text{N}/\text{mm}^2$ . On the other hand, the FRP rod, being a so-called orthotropic material, is mechanically weak in the transverse direction, i.e., perpendicular to the fibers. This has to be adequately considered in the design and the method of application of the end fittings—which are isotropic—to the rod. Table 9.37 [9.168] presents the elastic and strength properties of a typical FRP rod. Typical rod sizes range from 12 mm for distribution insulators up to 250 mm for heavy-duty post insulators or insulated cross-arms.

Nowadays, FRP rods are manufactured using the pultrusion process (Fig. 9.83 [9.2]), with diameters of up to 250 mm and lengths up to 15–20 m or even higher if needed. Various methods are used to control the quality of pultruded rods. These include determination of the density and the modulus of elasticity and measurement of the glass-transition temperature  $T_g$ . In addition, a dye penetration test [9.169] is used as a design and, due to its simplicity, also as a routine test, in order to detect fine cracks, seeds, and pores in the rod, which can become detrimental during service.

**Glass Fibers.** The glass fibers are manufactured by pulling from a glass melt and are wound directly in parallel, without twisting, onto bobbins. This is known as *direct roving*. Rovings used in rod manufacture can be differentiated by the fiber diameter, the sizing (coatings

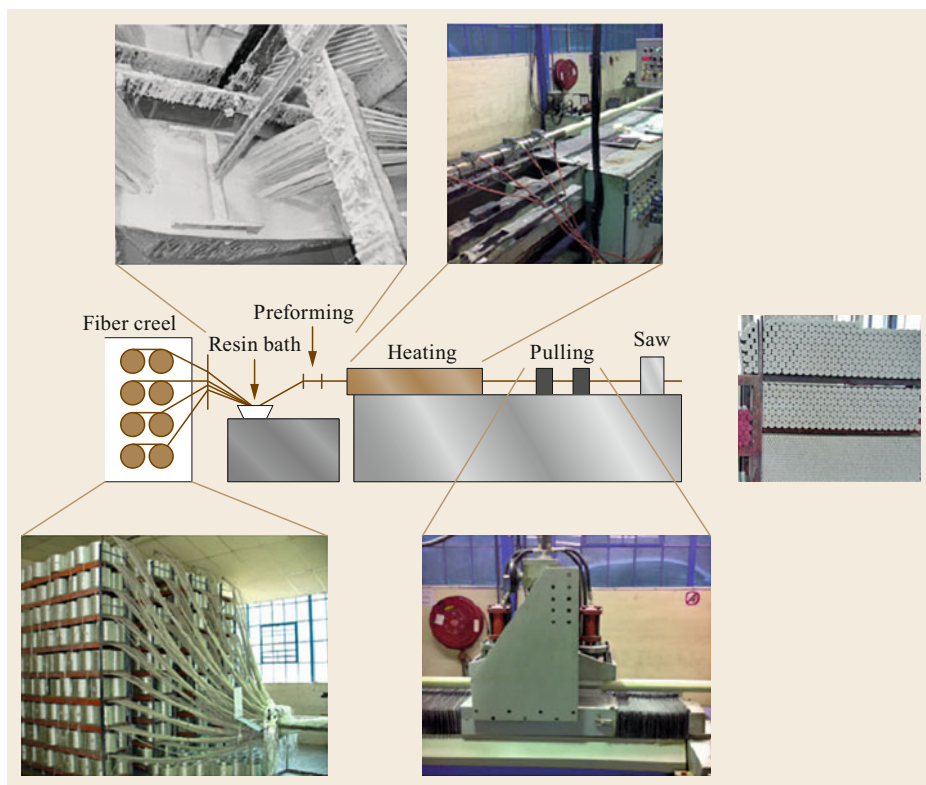

with protective layers, or combined protective layers with adhesive agents), the tex number (tex numbers between 4400 and 9600 are common for rod pultrusion, meaning rovings with a weight of 4.4 and 9.6 g/m, respectively), and the level of corrosion resistance, as explained below.

Glass fibers used in the FRP rods of modern insulators—in particular insulators loaded in tension—are in most cases made from E-CR glass. This is an acid-resistant glass, which does not contain boron and which in recent years has in most cases replaced the E-glass previously in use, in order to avoid so-called brittle fractures [9.170]. These are *clear-cut*, planar fractures of the FRP rod followed by a broomstick-type fracture (Fig. 9.84 [9.171]), which occasionally plagued early composite insulators. They take place under relative low (15–20% of the failing load) tensile loading conditions and are mainly attributed to acidic moisture ingress, whether from external corona or internal partial discharges, at the connection of the rod to the end fitting. Their occurrence in the field and their failure mode chemistry have been extensively investigated and are presented in [9.172, 173]. The influence of the resin as a possible cause of the susceptibility of FRP rods to brittle fracture is also explained therein. An acid withstand test to determine the glass quality of the FRP rod of an insulator is prescribed in [9.174–176].

**Epoxy Resin.** For the impregnation of the glass fibers, various thermosetting plastics, such as epoxy resin, vinyl ester resin, unsaturated polyester resin, or blends thereof, have been used. High-quality insulators primarily use epoxy resins as it safeguards important properties of the FRP rod such as the breaking strain and glass-transition temperature  $T_g$ ; For example, if the failing strain of the epoxy resin is lower than that of the glass fiber, the composite material will behave similarly to the pure resin and fail prematurely, as the tensile strength of the glass fiber is not fully utilized. On the other hand,  $T_g$  specifies the temperature above which the rod softens [9.174–176]. A  $T_g$  range of 110–160 °C is advantageous for composite insulator rods because of the processing of the insulator hous-

**Fig. 9.82** Cross-section of a FRP rod at two different magnifications, showing the glass fibers and epoxy matrix

**Fig. 9.83** FRP rod pultrusion process

**Fig. 9.84** Brittle fracture of the FRP rod of a composite insulator

ing. When high-temperature vulcanized elastomers are used, a high  $T_g$  will prevent rod deformation in the injection mold, which would result in rod eccentricity and an undesirable asymmetric thickness of the polymer housing.

#### End Fittings

Steel fittings are typically used for composite solid-core insulators. Depending on the application and load, these are either steel castings (EN-GJS 400) or steel forgings

(CK 45). Forged steel is the material of choice for insulators which are subjected to tensile loads greater than 70 kN. It is characterized by a modulus of elasticity of  $E = 200\,000\text{ N/mm}^2$ , Poisson's ratio of  $\nu = 0.29$ , tensile strength of  $\sigma^- = 1000\text{ N/mm}^2$ , and compressive strength of  $\sigma^+ = 800\text{ N/mm}^2$ .

**End Fittings for Composite Longrods.** Because of the need for substitution compatibility with porcelain and glass insulators, the connection dimensions for composite longrod insulators are based on the standards for conventional insulators [9.157, 158], being standardized in [9.178] up to 550 kN. Typical end fittings are shown in Fig. 9.85 [9.138]. Their dimensions have been standardized in such a way that composite insulators are fully interchangeable with porcelain or glass insulators. End fittings are hot-dip galvanized with a zinc layer thickness of  $85\ \mu\text{m}$  in accordance with standard industry practices and [9.133, 134]. When greater layer thicknesses of up to  $150\ \mu\text{m}$  are required for highly corrosive operating conditions such as deserts and coastal routes or DC applications, it is important to ensure that delamination resulting from partial splintering of the zinc layer does not occur during the crimping of the end fitting to the rod. DC applications may further require an additional sac-

Fig. 9.85 Types of end fittings for composite longrod insulators

Fig. 9.86 Load-time curve of a composite insulator (adapted from [9.177])

rificial zinc collar on the outer contour of the end fitting, similar to the one used for glass insulators (Sect. 9.5.4).

**Relation of Loads.** The majority of composite insulators for overhead lines, whether used as suspension insulators or as dead ends, are loaded in tension and are sometimes called composite longrods, having typical rod diameters between 16 and 32 mm. Their key mechanical parameter is the *specified mechanical load* (SML), defined as the load that the insulator must withstand in a 1-min tensile test after a 96-h test at 70% of its value; it is determined in a type test. In addition, each composite longrod has to pass a routine test at the so-called *routine mechanical load* (RML), which corresponds to 50% of the SML. A third important mechanical parameter is the *damage limit load* (DLL). This is the threshold tensile load below which hardly any fibers will fail, even if the load is applied to the insulator for an *infinite* period of time. The DLL of high-quality insulators can be assumed to be up to 60% of the *average failing load*  $M_{avg}$ . These loads and the load-time behavior of a composite insulator are shown schematically in Fig. 9.86 [9.177]. The related physical background is well explained in [9.179, 180].

**Crimping.** One of the most critical procedures in the manufacturing process of a composite insulator is the application of the metallic end fitting to the FRP rod. This is understandable, as the two materials have distinctly different elastic and strength properties (Table 9.37). Historically, the first composite insulators used conical or wedge-type fittings to be followed by polygonal compressed, crimped fittings (Fig. 9.87). The latter have been proven to show by far the best long-term performance under static and dynamic loads [9.181, 182] and thus are today the state of the art for most composite insulator manufacturers.

The crimping process is accomplished using hydraulic presses with octagonal tools, depending on the outer diameter of the end fitting (Fig. 9.88). This is mechanically complex, as during the compression stage, the steel of the end fitting will deform plastically while the rod will deform elastically. After the maximum crimping pressure has been reached and released, the metal fitting springs back, i.e., it is partly relieved of its elastic deformation, while its remaining, permanent plastic deformation continues to apply a radial pressure to the circumference of the FRP rod. Consequently, the stresses in the FRP rod are then approximately 30% lower than during crimping. The rod stresses caused by crimping are even higher than the stresses occurring at

**Fig. 9.87a–c** Development of end fittings for composite insulators: (a) conical, (b) wedge, (c) crimped

**Fig. 9.88** Crimping tools

the ultimate tensile load of the insulator, i.e., at failure. For this reason, high-quality manufacturers have introduced the acoustic emission technique, which enables continuous monitoring and safeguarding of the quality of the crimp during manufacturing [9.183].

The mechanical behavior of crimped end fittings has been thoroughly investigated in [9.168]. An important result therefrom is that the fitting–rod interface, and thus the composite insulator, when properly crimped, will fail in traction when the shear strength of the FRP rod, typically  $50 \text{ N/mm}^2$ , has been exceeded. This will become evident by a *clean* pull-out of the rod from the end fitting (Fig. 9.89a). When a *broom-type* failure occurs (Fig. 9.89b), this is a sign of sharp edges within the fitting which have predamaged the FRP rod. In this case, the insulator will most probably not reach its rated tensile strength. More critical is a *lateral* failure of the rod (Fig. 9.89c), as in this case the insulator has been overcompressed and the rod has been partly fractured during the crimping process. Although such an insulator will probably pass the routine RML test (50% of the SML), *hidden* rod fractures may well lead to insulator failure in service.

Based on the discussion above, the following simple formula can be derived for the ultimate tensile load  $F_{\max}$  of a composite longrod insulator

$$F_{\max} = 2\pi r l \tau_{\max} \quad (9.92)$$

where  $r$  is the rod diameter,  $l$  is the crimping length, and  $\tau_{\max}$  is the ultimate shear stress of the rod, generally around  $50 \text{ N/mm}^2$ .

For example, for a typical insulator with  $r = 9.285 \text{ mm}$ ,  $l = 50 \text{ mm}$ , and  $\tau_{\max} = 50 \text{ N/mm}^2$ , this yields a maximum tensile load  $F_{\max}$  of  $155 \text{ kN}$ , which compares well with the measured value of  $148 \text{ kN}$ .

**End Fittings for Composite Post Insulators.** A common application of composite insulators is horizontal posts (Fig. 9.90). In this case, the insulator is predominantly loaded perpendicular to its axis, i.e., in bending.

**Fig. 9.89a–c** Failure modes of crimped composite longrod insulators: (a) correctly compressed, (b) rod predamaged, (c) overcompressed (adapted from [9.168])

**Fig. 9.90** Composite post insulator for 245 kV; red circle: the so-called gain base (source: Insulator News and Market Report, INMR)

The resulting nonuniform stress distribution over the FRP rod cross-section requires higher-diameter rods than for longrods. Typical rod diameters for posts are 44, 51, 63, 76, and 88 mm and nowadays can go up to 250 mm.

Typical end fittings of composite posts are shown in Fig. 9.91. These are mainly steel castings which are fastened by bolts at the base fitting, which in turn attaches to the supporting structure. One can distinguish between a bendable base made from formed steel and a fixed base made from cast iron (Fig. 9.92), which mates with the quite common 5" bolt circle, 4 bolts end fitting of the insulator. Whereas the bendable designs allow for some articulation of the insulator, the fixed base does not. Both bases come in flat and gain designs, i.e., with 0 and 12° upsweep angles, respectively, the latter marked by a red circle in Fig. 9.90, and also with alternative attachment options for a flat or round pole surface. The end fittings are attached to the rod mostly using a similar compression technique, as described above for longrods, but also using epoxy glue or temperature shrinking as alternatives.

**Relation of Loads for Line Posts.** The following loads characterize the bending performance of a composite line post [9.184]:

- The *specified cantilever load* (SCL) is the bending load which an insulator can withstand at the conductor side during testing.
- The *cantilever failing load* (CFL) is the maximum load which is achieved during testing of the insulator; it should be higher than the SCL.
- The *maximum design cantilever load* (MDCL) is the limit for the loads occurring during operation; it should be at least 25% below the DLL.

Another important load is the *damage limit load* (DLL), which is the load above which damage to the core is initiated. A relatively simple test to determine the DLL (and thus the MDCL) is to measure the load–deflection curve of the post in a short-time test. Such a curve is shown in Fig. 9.93 [9.168]. The load at which the slope of the curve starts to change is the DLL of the insulator, above which cracks will start forming in the inside of the rod, being practically invisible from the outside. This fast-track test is very practical compared with the MDCL test prescribed in [9.184], which is a tedious 96-h test and thus often *overlooked* during the inspection and acceptance process.

An important feature of composite post insulators is that, because of the high flexibility of the FRP rod, there is no physical separation of the insulating body in the event of mechanical failure of the insulator, as is the case with brittle porcelain insulators. Thus, there is no risk of a catastrophic dropping of the conductor. The term *safe failure mode* is introduced in [9.185] to describe this. For example, a composite post typically used for voltages from 36 to 52 kV and having an SCL of 10 kN, after sustaining prior damage as a result of the CFL test, was subjected to a 96-h test at 5 kN in accordance with the MDCL test procedure of [9.184] and passed this test successfully without any visible external damage to the FRP rod, let alone physical separation thereof.

The bending behavior of composite posts has been thoroughly studied and is presented in [9.168, 186], where the following simple analytical formula for the cantilever failing load (CFL) is derived

$$\text{CFL} = \frac{\pi r^3 \sigma^-}{4(L-l)}, \quad (9.93)$$

**Fig. 9.91** Typical end fittings for composite posts (source MacLean Power Systems)

**Fig. 9.92** Bendable and fixed bases as gain bases with upsweep angle of  $12^\circ$  (source MacLean Power Systems)

**Fig. 9.94** Chemical structure of polydimethylsiloxane (PDMS), with  $n$  being the number of repeating monomer units (adapted from [9.187])

**Fig. 9.93** Load–deflection curve of a 38-mm composite post insulator (adapted from [9.168])

where  $r$  is the rod diameter,  $\sigma^-$  is the compression strength of the rod,  $L$  is the insulator length, and  $l$  is the attachment length of the end fitting to the rod. If  $L = 760$  or  $1030$  mm,  $l = 70$  or  $90$  mm,  $r = 25.5$  or  $31.7$  mm, and  $\sigma^- = 800$  MPa then  $CFL = 15$  and  $20.7$  kN, respectively, for the two insulators tested in [9.168] with diameter of 51 and 63 mm, respectively. These values are consistent with the values obtained by testing, i.e., 15.6 and 21.7 kN.

### Silicone Rubber (SR) Housing

The polymer housing of a composite insulator has the double duty of protecting the FRP rod, which, if left unprotected in particular against ultraviolet (UV) radiation and pollution, will become brittle and degrade, but also providing the necessary creepage distance in order to avoid pollution flashovers. This is the reason why polymer insulator housings and in particular their sheds mimic the well-known shape of the sheds of ceramic insulators.

Concerning overhead line insulators, for many years, various polymers such as ethylene propylene di-

ene monomer (EPDM), ethylene propylene monomer (EPM), liquid silicone rubber (LSR), room-temperature vulcanized (RTV) and high-temperature vulcanized (HTV) silicone rubber (SR), but also polytetrafluoroethylene (PTFE, often called Teflon), have fought for this application. Nowadays, the material of choice for polymer insulators is doubtless HTV SR, because of its superior properties and performance in the field.

**Properties of Silicone Rubber.** The main components of silicone rubber are:

- Base polymer
- Fillers (pyrogenic or precipitated silica, quartz powder, and others)
- Vulcanizers (peroxides, H-siloxane)
- Catalysts (platinum compounds, tin compounds, and others)
- Additives (adhesive agents, softening agents, pigments, and others)
- Carbon blacks (pigment types, conductivity types, and special types)
- Aluminum trihydrate (ATH), i.e.,  $Al_2O_3$  (aluminum hydroxide).

Normally, the base polymer is a three-dimensionally cross-linked polydimethylsiloxane (PDMS). Silica, having a specific surface area between 100 and  $400\text{ m}^2/\text{g}$ , is incorporated to improve the mechanical properties. The tracking and erosion properties can be usefully improved by adding, e.g.,  $Al_2O_3$ , aluminum trihydrate (ATH). For a rubber to be considered a silicone rubber, it must consist of a polymer having an inorganic main backbone chain of Si–O bonds, where each silicone atom is bonded to two methyl groups (Fig. 9.94 [9.187]).

This structure explains some of the remarkable chemical and physical properties of this elastomer. Its high flexibility even at low temperatures is a result of the low intermolecular bonding forces; i.e., the cause of the flexibility is inherent in the silicone polymer itself and is not achieved by the addition of softeners. Thus, even at high temperatures, no sweating out of

**Fig. 9.95a,b** Hydrophobic surface behavior of a SR insulator when new (a) and polluted (b) (source Pfisterer Lapp)

softeners with the resulting unpleasant effects of contamination of the environment and no embrittlement of the polymer material can occur. Silicone rubber exhibits good thermal stability and excellent resistance to ozone, corona discharge, and moisture. As silicone dioxide also possesses good insulating properties, concentrated electrical discharges (e.g., flashovers, which at their bow can reach temperatures of up to 1300 °C) do not result in the formation of conducting tracks in silicone rubber, unlike the case of other elastomers, and also no corrosive or directly toxic products are formed; silicone rubber is completely free of halogens. Silicone rubber is classified as slow burning and should pass the [9.188] vertical burning test in class FV 0. When exposed to flame, the main combustion products formed are water vapor and carbon dioxide, leaving silicone dioxide as a solid residue. The main Si–O-bonded backbone of silicones has a high dissociation energy (100–120 kcal/mol) compared with the lower dissociation energies of hydrocarbons of 85.5 kcal/mol for C–O and 82.6 kcal/mol for C–C. In turn, this results in silicone rubber having good UV radiation resistance. Additionally, PDMS has a very low surface free energy and a very flexible backbone. This flexibility of the backbone allows PDMS to rearrange itself, resulting in quick regeneration of the surface characteristics of the silicone rubber. In particular, the low surface tension makes the surface very hydrophobic (Fig. 9.95a) and allows the diffusion of low-molecular-weight (LMW) content to pollution layers, encapsulating them and rendering also these hydrophobic via so-called hydrophobicity transfer (Fig. 9.95b). This is not the case for porcelain and glass, which are hydrophilic. A guide for the measurement of the hydrophobicity of insulator surfaces has recently been updated [9.189].

As mentioned above, HTV silicone rubber is the preferred material for OHL insulators. This is mainly because it exhibits superior tracking and erosion performance under the local surface discharges that can occur when pollution is heavy and hydrophobicity is temporarily lost. To achieve this, an amount of > 50% by weight of ATH filler is required. An easy way to determine whether the silicone rubber used for an insulator is indeed of HTV grade is to measure the Shore hardness of the sheds, which should be between 65 and 75 Shore A, but also to determine the specific weight of a piece of rubber cut from the shed, which should be above 1.5 g/mm<sup>3</sup>. LSR, which is sometimes sold as HTV, has a Shore A hardness below 60 and a specific weight of around 1.2 g/mm<sup>3</sup> [9.190]. The reason is that LSR, which is fluid with a viscosity of 10 000–30 000 mPa s, is much easier to process than HTV, which is solid with a viscosity of 5–20 × 10<sup>6</sup> mPa s. However, it is worth noting that solely adding a certain quantity of ATH is not per se sufficient. Rather, the entire system (polymer, fillers, treatment of fillers, etc.) needs to be optimized in a balanced manner [9.191]. In addition, recent research has examined the possibility of improving the electrical and mechanical properties of silicone rubber by the addition of nanoparticles [9.192].

**Manufacturing of SR Housings.** The traditional methods applied to process silicone rubber for insulator housings are compression molding, transfer molding, and injection molding. The latter is the most well-developed method and is used by the majority of established manufacturers of composite insulators. However, this process is demanding and requires, besides considerable investment in production machinery and molding

**Fig. 9.96** Injection molding of a 420-kV SR composite insulator using the stepping technology (source Pfisterer Sefag)

technology, high-level process knowhow. Specifically, with pressure levels of up to 1500 bar and temperatures up to 200 °C, there are a quite a few challenges to obtaining a void-free housing regarding the following process parameters:

- Mold temperature
- Injection unit temperature
- Plasticizing profile and dynamic pressure
- Injection velocity and pressure
- Filling of cavity
- Postfilling pressure
- Preheating in the injection piston
- Vulcanization time
- Process time for injection unit
- Velocity profile at the clamping unit
- Mold clamp force.

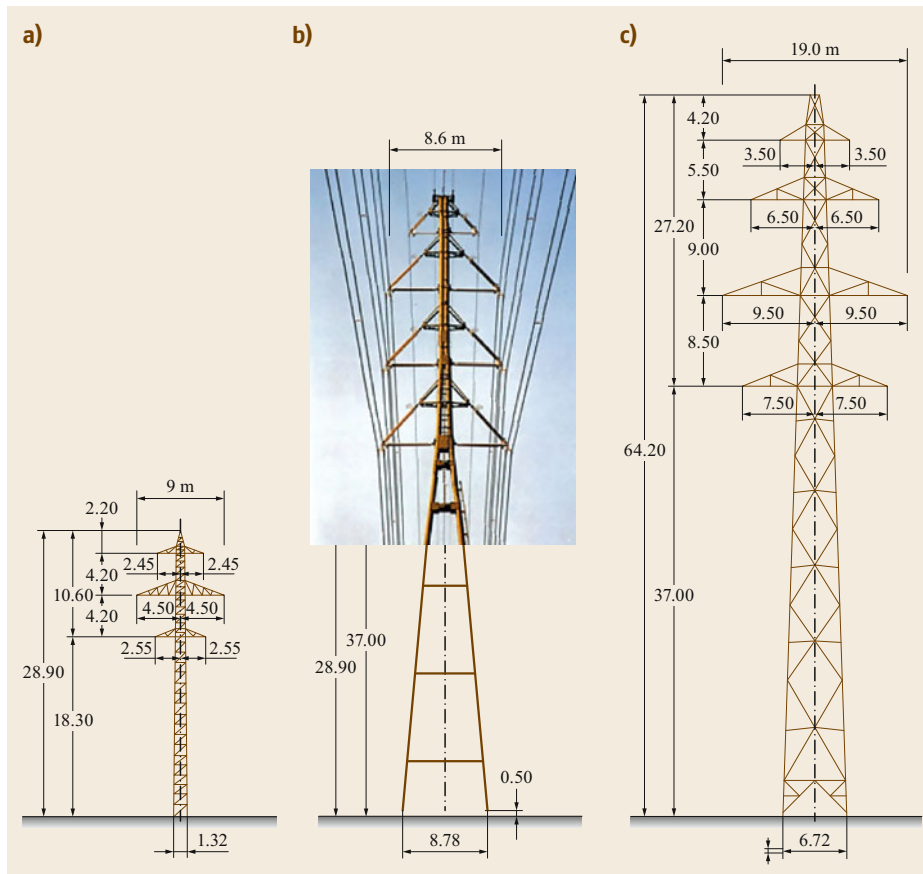

In addition, HTV stepping, viz. the injection of SR on the FRP rod while the preceding section of the insulator housing is being vulcanized in the mold, has been successfully used for longrod insulators since the 1990s and enables the manufacturing of composite insulators with no length restriction (Fig. 9.96). In this regard, due to the high vulcanizing temperature and the process pressure that arises, special attention should be paid to centering the rod.

**Fig. 9.97** Flexibility of modular process (adapted from [9.2])

Indeed, depending on the length of the mold, even rods with a diameter of 88 mm may be deformed when using an asymmetrical injection nozzle system, thus jeopardizing the minimum requirement of a uniform 3 mm thickness for the SR sheath around the rod. HTV stepping is also suitable for a high degree of automation, thus minimizing human error, such as in the ACIM (automated continuous injection molding) method [9.2].

A viable, well-developed alternative is the modular manufacturing process. In this approach, the rod is first covered with a uniform HTV SR sheath with minimum 3 mm thickness, by using an extrusion process, while the individual HTV SR sheds, which are produced separately by compression molding, are subsequently applied to the SR sheath of the rod by radial expansion and vulcanized thereon with the aid of a special RTV-based silicone adhesive. This modular process offers a high degree of flexibility regarding creepage for a given connection length (Fig. 9.97 [9.2]), at the cost of an additional interface between the sheds and the sheath of the rod, which, if not manufactured properly, may create problems during service.

**Fig. 9.98a–c** Steel lattice tower of existing 125-kV line (a) and Swiss compact line (bipod) for 400 kV/132 kV (b) and standard design (lattice) (c) (source INMR)

An important feature common to both of these methods, i.e., HTV injection molding and the modular process, is the interface between the SR and the rod. This must be absolutely tight, as any ingress of moisture via air pockets at the interface will cause partial discharges and ultimately catastrophic failure of the insulator through a so-called *flashunder*. High-quality manufacturers use automated spraying and detection techniques based on a suitable, visually easily detectable primer on the rod, which will ensure seamless and durable application of the SR onto the rod.

#### Unique Applications of Composite Insulators

In recent years, composite insulators have come to play an increasing role in new, innovative solutions for the realization of so-called esthetic line supports and also in the uprating of existing overhead lines, i.e., lines to carry substantially higher electrical power than they were originally designed for. Both issues are related, on one hand, to the increased demand worldwide either for new lines, often because of the massive expansion of renewable energy sources (RES), but also because the first generation of HV OHL is reaching the end of its

expected useful life (the first 400-kV OHL was put in operation in 1952 in Sweden), and on the other hand, the increased public opposition to new lines because of their purported health hazards (Sect. 9.3.4). For both issues, the massive development of composite insulators in recent decades has been decisive, as documented by the following two application examples.

**Compact Lines.** Compact lines were first developed in the 1970s but only started to become more popular with the widespread introduction of composite insulators, because the insulated cross-arms that are indispensable for the design of compact lines are loaded primarily in compression and are subject to relatively large deformations, which can be better sustained by composite than conventional insulating materials (porcelain and glass). More specifically, the following properties of composite insulators are advantageous for use in insulated cross-arms:

- High bending strength
- Elastic limit in the region of ultimate strength
- High ultimate strain
- Nonbrittle.

**Fig. 9.99** The 400-kV tennis racket tower in Western Switzerland (adapted from [9.193])

A good example is the world's first 400-kV compact line using composite insulators, which was installed in Switzerland in 1998 [9.135]. The line became necessary as the existing 125-kV line (Fig. 9.98a) was no longer sufficient to carry the increased power demand in the region of Lake Geneva and had to be replaced by a 400-kV line. The conventional steel lattice towers that are normally used for this type of line (Fig. 9.98c) require a considerable right of way (ROW), which was not available at certain locations where the route had to pass very close to inhabited buildings. The solution was to design very slender two-dimensional (2-D) towers and use insulated cross-arms with composite insulators for the 400-kV circuits and also for the two single-phase 132-kV circuits for the feeder lines of the Swiss Railways, SBB (Schweizerische Bundesbahnen) (Fig. 9.98b). It is worth noting that, because at that time, available FRP rod sizes were restricted to 76 mm, which could not take the compressive loads, hollow-core composite insulators had to be used. Interestingly, at another location along this line, a so-called landscape tower, so called because it lies in a specific landscape (in this case the local tennis club), was installed, becoming well known as a unique, tennis racket tower

**Fig. 9.100** 400-kV interphase spacer in the transmission line at the Vorab Glacier in Switzerland (adapted from [9.194])

(Fig. 9.99 [9.193]). Its delicate, spider-like phase arrangement could only be realized using lightweight and optically nondisturbing composite longrod insulators.

**Interphase Spacers.** Line compaction is primarily based on the principle of minimizing interphase spacing. As a result, there is greater risk of interphase flashovers, i.e., when two phase conductors are moved close to one another as a result of wind, ice shedding, or short circuit. This can be avoided by the use of interphase spacers (IPS). Although some applications of porcelain IPSs are known, the increased use of IPSs in recent years has been enabled only by the introduction of composite insulators, mainly because of their low weight and high flexibility; For example, Fig. 9.100 shows such an IPS in a critical span of a 400-kV line at altitude of 3000 m at the Vorab Glacier in Switzerland. At this location, serious damage often occurred during winter, when sudden ice shedding caused the conductors to jump by up to 20 m and detrimentally clash with each other [9.194]. The individual IPSs between two phases are between 10 and 12 m long and weigh approximately 100 kg, including their special fittings which allow fully articulated coupling to the phase conductors, thus preventing damage in the event of sudden movements. Each IPS consists of four to five silicone composite insulators having a rod diameter of 76 mm. Such IPSs have been used with success since 1995; that is to say, there have been no outages caused by ice shedding since their installation.

Another interesting application, this time for MV lines, is shown in Fig. 9.101. In this case, a second 12-kV circuit could be installed on an existing 50-/12-kV line on concrete poles with the help of silicone compos-

**Fig. 9.101** IPSs enable the addition of a second 12-kV circuit on an existing 50/12-kV line in Switzerland

**Fig. 9.102** IPS under heavy compressive load

ite IPSs, which were installed around every 40 m along the span, helping to maintain the required midspan clearances. In the meantime, thousands of such IPSs have been operating successfully for many years in Switzerland.

**Mechanical Design of IPSs.** Interphase spacers predominantly have to sustain compressive loads and are designed using the well-known Euler formalism. Because of their high flexibility (Fig. 9.102), an exact calculation using third-order bending theory [9.195] reveals an additional compressive load reserve of approximately 30% compared with the critical Euler load

$$P_{\text{Euler}} = \frac{\pi^2 EI}{L^2}. \quad (9.94)$$

This condition is met when the diameter  $d$  of the IPS is related to its length  $L$  by

$$d > \frac{L}{100}. \quad (9.95)$$

## 9.5.6 Insulator Tests and Standards

The paper [9.196] provides a good overview of the development of standards for insulators and their relation to the evolution of insulator technology. Tests for all types of insulators are well established and described in numerous standards. Table 9.38 [9.16] summarizes standard electrical test requirements, while Table 9.39 [9.4] is a good check-list for the required insulator tests.

A comprehensive list of standards for composite insulators can be found in the “Standards” chapter of [9.2]. In addition though, for composite insulators, the following issues are of particular importance:

### Intensified Testing

While there are numerous stringent design tests for composite insulators, bulk volume orders of the same have to pass only relatively *easy* routine tests. It cannot therefore be excluded that some inferior-quality samples will also *pass*, which subsequently may cause problems during service. To avoid this, certain meaningful and at the same time simple tests were proposed in [9.190] under the philosophy of *intensified inspection and acceptance tests*. These comprise:

#### Visual Inspection.

- Overall appearance of the insulators
- Voids in the housing
- Sealing area.

#### Tensile-Loaded Insulators.

- 96-h acid test of rod
- Tensile load up to failure, control of failure mode (Fig. 9.89).

#### Bending-Loaded Insulators.

- Simplified verification of MDCL (Fig. 9.93).

#### Material.

- Adhesion test before and after boiling.
- Verification of physical housing properties, in particular specific weight and Shore hardness.
- Tracking and erosion test as per [9.197] with housing sample from a finished insulator (Fig. 9.103).

As an example from this list, the adhesion test is briefly explained here, as it is not only easy to perform, but is also of extreme importance for the service performance of the insulator, because if there is no proper

adhesion between the housing and the rod, ingress of moisture and subsequent partial discharges (PD) can destroy the insulator.

Firstly, squares are cut on the surface of the housing, penetrating to the rod (Fig. 9.104a). A pair of pliers is then used to grip and pull the squares of sili-

**Fig. 9.103** Modified tracking and erosion test [9.197]; only little erosion of reference material after 6 h at 4.5 kV; poor materials will fail much sooner, i.e., in 40–70 min

cone vertically from the rod surface (Fig. 9.104b). This easy test is performed on the housing preferably twice, firstly without any pretreatment and secondly after boiling. The boiling process as per [9.177] is used, i.e., the specimens are immersed in a vessel of boiling solution consisting of deionized water with 0.1 wt% NaCl for 42 h.

Good adhesion to the rod should result in a cohesive failure of the rubber (Fig. 9.104c), rather than an adhesive failure between the rubber and the rod (Fig. 9.104d). The aim of this test is to ascertain the quality of the bonding between the housing and the core. If insulator designs with overmolded end fittings are used, the bonding between the end fitting and housing can be evaluated in the same way.

#### Tests for Composite Insulators Withdrawn from Service

Composite insulators are still a relatively new technology, and it is thus understandable that their users, mainly electrical utilities, are keen to evaluate an insulator population in order to enable one or more of the following:

- Provide an indication of population health/life expectancy and therefore determine whether to leave

the population or individual units in service or to take any countermeasures such as removal of the units

- Determine the inspection/assessment frequency
- Modify design philosophies, e.g., new pollution maps, *E*-field grading, and need for power arc protection.

This is best done by testing insulators which have been in service as described in [9.198], which is based on similar work presented in [9.199] for conventional insulators. The start of such tests is always a thorough visual inspection. This requires considerable knowhow and experience but is indispensable to determine the status and/or aging mode of the insulator and subsequently define the test philosophy and procedure. Such tests can include:

#### Mechanical Investigation.

- Verification of SML
- 96-h load-time test.

#### Electrical Investigation.

- Dry power frequency withstand voltage test (PF dry)
- Wet power frequency withstand voltage test (PF wet)
- Dry lightning impulse withstand voltage test (BIL)
- Wet switching impulse withstand voltage test (if applicable,  $U_m > 245$  kV) (BSL)
- Quick salt fog
- Rapid clean fog
- Modified clean fog.

#### Material Analysis. Housing materials:

- High-voltage water diffusion test [9.177]
- High-voltage low-current discharge resistance test [9.200]
- Modified tracking and erosion test [9.197]

**Fig. 9.104a–d** Simple adhesion test. (a) Cutting the surface, (b) pulling the housing with pliers, (c) good bonding to the rod, (d) poor bonding to the rod (adapted from [9.177])

- Thermogravimetric analysis (TGA)/differential scanning calorimetry (DSC) for determination of filler content and material fingerprinting
- Fourier-transform infrared (FTIR) analysis for determination of chemical nature and material fingerprinting
- X-ray fluorescence (XRF)/X-ray diffraction (XRD) analyses for material identification
- Gravimetric analysis for determination of filler content
- Flammability test [9.177]
- Hardness test [9.201], preferably carried out before and after prestressing by boiling
- Measurement of surface roughness (ISO 4287)
- Test on interfaces and connection of end fittings [9.177] (*design test*)
- Tightness of the interface between the insulating body and metal end fittings, sealing verification test in accordance with [9.177] (*sample test*)
- Tests of the housing [9.202]: 1000h, wheel test, 5000h test in order to assess the tracking and erosion performance of service-aged housing materials and housing designs.

Core materials:

- High-voltage water diffusion test [9.177]
- TGA/DSC for determination of filler/fiber content and material fingerprinting
- FTIR analysis for determination of chemical nature and material fingerprinting
- XRF/XRD analysis for material identification
- Dye penetration test [9.169].

## 9.6 Fittings

Overhead line fittings, sometimes also called line hardware or line accessories, serve for the mechanical attachment, electric connection, and protection of conductors and insulators. In relevant standards, fittings are frequently designated as accessories which may consist of elements or assemblies.

Fittings for conductors serve to terminate, suspend, or join the conductors and are directly connected to the conductors. Suspension and dead-end clamps, connectors, branch-off clamps, vibration protection fittings, as well as bundle spacers lie within this category. According to their function, they may form an assembly consisting of several elements, e.g., suspension and dead-end clamps including the required connecting links.

Fittings for insulator sets and other attachments serve to connect the tension or suspension insulators with the attachment points at the supports. In case of

End fittings:

- Thickness of galvanizing coating in accordance with [9.133, 134]
- Structural analysis of the metal material by means of raster electron microscopy (REM) analysis (ground and polished material samples).

### Surface Layer Analysis.

- Pollution accumulation (mainly ESDD, NSDD, and surface conductivity)
- Surface changes (e.g., chalking, discoloration, surface cracking, etc.)
- Wettability class [9.189]
- Grade of hydrophobicity transfer mechanism (HTM) [9.203]
- Hydrophobicity transfer (HT) [9.204]
- Chemical analysis of the pollution layer by means of FTIR or atomic absorption spectrometry (AAS)
- XRF and XRD analyses.

The results of these tests can be compared with those carried out on samples in storage, e.g., insulators from warehouse stock, if available. Major deviations may be suggestive of aging. CIGRE publication [9.198] contains a number of very interesting case studies on real applications of the said.

### In-Service Diagnostic Methods

CIGRE has published two documents on this topic [9.171, 205]. A brief summary of the relevant diagnostic methods is given in Sect. 9.9.

insulator strings, components to connect insulators with each other also lie within this category, while the insulators themselves are excluded. These fittings comprise all the components arranged between the assembly of the dead-end or suspension clamps and the first detachable element at the support, e.g., the jointing pin or U-bolt. Yoke plates, corona protection fittings, and grading rings are also included.

Most fittings look like simple pieces of metal. However, they must sustain all kinds of mechanical, electrical, chemical, and environmental loads. Therefore, it is important to understand their function and underlying design principles.

Fittings should be designed so as to:

- Avoid damaging the conductor under service conditions

- Withstand the mechanical loads relevant to installation, maintenance, and service, the designed service current, including short-circuit current, the service temperatures, and environmental circumstances
- Ensure that individual components are secured against becoming loose during service
- Exhibit limited corona effects, better than the performance of the conductor on which they are installed.

Fittings for live-line maintenance should be suitably designed for safe and easy handling with current hot line techniques.

The surfaces of compression fittings in contact with the conductor or earth wire should be protected from becoming contaminated before installation, and brittleness of the finished parts should be avoided by adopting suitable materials and manufacturing processes.

Nonmetallic materials such as elastomers, if employed, should exhibit good resistance to aging and be capable of withstanding service temperatures, without detrimental changes in their properties. These materials should show adequate resistance to the effects of ozone, ultraviolet radiation, and air pollution over the whole range of service temperature. They should not induce corrosion in materials which are in contact with them [9.206].

### 9.6.1 Conductor Fittings

Conductor fittings are those line accessories which are in direct contact with the conductor or earth wire, such as:

- Suspension clamps (top clamps, helical ties, distribution fittings)
- Tension or dead-end clamps
- Connectors or joints
- Branch-off or T-clamps
- Aerial markers
- Vibration dampers
- Spacers and spacer dampers.

#### Suspension Clamps

Suspension clamps are used to suspend the conductor from a suspension or straight-line support (Fig. 9.105) and have to fulfill a number of important duties:

- Withstand the mechanical loads imposed by the conductor
- Avoid damage to the conductor in the clamp area
- Prevent/reduce strand failures because of vibration
- Offer high corrosion resistance

Fig. 9.105 Suspension clamp

- Provide a sufficient corona inception voltage
- Withstand short circuits and have low contact resistance and low electrical losses
- Allow simple and safe installation.

Because practically 99% of conductor vibration failures occur very near to or at the suspension clamp location, its design is of great importance for the mechanical integrity of the conductor and thus the operational safety of a line. The Task Force on Suspension Clamps of CIGRE SC 22, WG 01 prepared, in 1989, a guide for good clamp design, which is summarized below with reference to Fig. 9.106 [9.207].

**Body and Keeper Profile.** The profile of the clamp body should follow the curvature of the conductor and thereby not reduce its failing load, whereby an optimum profile design of the body and keeper must be found for different load assumptions and contact length of the suspension clamp. The profile of the body must be rounded and curved into a bell mouth at the ends to avoid damage to the conductor during the variation of the exit angle due to conductor tension variations. This consideration should also apply to the keeper design when conductor uplift is assumed. To prevent damage to the conductor surface, all parts of the clamp that are in contact with the conductor should be smooth.

**Turning Angle.** The profile of a suspension clamp should accommodate the various required turning angles, for example:

- Low-tensioned conductor with a high turning angle: assumption of high temperature
- High-tensioned conductor with a small turning angle: assumption of low temperature
- High-tensioned conductor with a high turning angle: assumption of ice or wet snow load.

**Fig. 9.106** Technical terms related to suspension clamps ( $\gamma$ : exit angle;  $\gamma_m$ : maximum exit angle,  $\alpha$ : turning angle,  $\alpha_m$ : maximum turning angle) (adapted from [9.207])

As is often the case, the proper selection of the turning angle is ultimately a compromise. With turning angles of the conductor at the clamp end normally lying in the range of  $\alpha = 10\text{--}20^\circ$ , the majority of suspension clamps are designed with a maximum turning angle of  $\alpha_m = 30^\circ$ .

**Mobility.** A suspension clamp should be able to rotate in a longitudinal vertical plane in order to accommodate asymmetrical loads and different spans on each side of the clamp, whereby the axis of rotation should not be placed more than a few conductor diameters from the conductor axis, in order to reduce additional bending stresses upon the conductor. In this context, keeping the clamp mass low and thus reducing its rotational inertia is an advantage. *Metacentric* suspension clamps (Fig. 9.105) present the minimum moment of inertia, i.e., the maximum mobility.

**Sliding.** The suspension clamp should, on one hand, keep the conductor locked in place, but on the other, slip at a known sliding force to avoid tension overloads and consequential damage to the conductor. This is achieved mainly by applying a specified pressure on the conductor via the clamp keeper and related fastening elements, typically U-bolts. With a high torque on the clamp bolts, the yield point of the strands can be

exceeded on a bare conductor. Even under armor rods, strains on the order of 500–1000 microstrain have been measured on aluminum strands.

Some utilities install *controlled sliding clamps* as a mechanical fuse at selected locations, to avoid line cascade. The conductor must slide within such clamps as a result of either conductor rupture or an exceptional, unbalanced ice load. The load that will cause the conductor to slide through the clamp is nowadays based on controlled tightening of the clamp bolts; these clamps are called *controlled tightening clamps*. Details on such clamps and load control devices (LCD) in general can be found in [9.208].

**Common Clamps.** Different types of suspension clamps are used in transmission construction:

- Bolted suspension clamps on bare conductor
- Bolted suspension clamps over armor rods
- Helically attached elastomeric suspension clamps (HAES)
- Elastomeric suspension clamps without helical rods (ES).

*Bolted clamps on bare conductor* (Fig. 9.105) are the most commonly used, on some 50% of all installations.

**Fig. 9.107** Helically attached elastomeric suspension (adapted from [9.209])

They come in various shapes and are simple to install, competitive in price, and when properly designed and manufactured, offer adequate support and protection to the conductor.

*Bolted clamps over armor rods* are used in around 25% of suspension clamp applications. They consist of helically formed wires which are wrapped around the conductor, effectively stiffening it at the suspension location. A larger-size clamp body is then placed over the armor rods.

*Helically attached elastomeric suspension (HAES)*, also known by its commercial name *Armor-Grip Suspension (AGS)* (Fig. 9.107), utilizes elastomeric inserts and helical attachment rods, which have proved to be beneficial in situations with severe conductor motions. This approach is probably used in around 10% of suspension applications, predominantly on OPGW and ADSS. On the other hand, it costs more than metal-to-metal clamps, and its installation is longer and more complicated due to several loose components, especially for hot-line installations. CIGRE recently published recommendations for safe design tensions with such clamps [9.209], establishing an allowable increase of 10–25% in  $H/w$  (Sect. 9.4.11) for the HAES.

*Elastomeric suspension (ES)* clamps, which utilize an elastomeric insert—but no helical rods—in the metallic clamp body, are becoming more popular. These clamps are lighter and cheaper than the HAES, and it takes less time to install them. In addition, fatigue tests have shown that the fatigue performance of conductors is improved with ES compared with standard clamps.

### Tension Clamps

Tension or dead-end clamps hold the conductor at support locations where the full mechanical tension of the conductor has to be sustained, such as at terminal towers, anticascading towers, and heavy angle towers. There are four main types of tension clamps:

**Fig. 9.108** Compression-type tension clamp with sag adjusting plates

- Compression clamps
- Wedge clamps
- Helical terminations
- Bolted clamps.

*Compression clamps* (Fig. 9.108) are the most commonly used clamps worldwide. They are composed of two main parts: an aluminum or aluminum alloy tube, compressed over the conductor, and a steel terminal inserted into the aluminum tube and joined by compression to attach the clamp to the insulator string. In ACSR, the steel core is inserted into this terminal and also compressed. Compression takes place using hydraulic tools, whereby different dies are required for conductors of different sizes. This compression process is of great importance, as it is crucial for the long-term performance of the clamp. Evidently, readjusting the conductor or shifting the clamp after installation is not possible. Using compressed dead-end clamps, conductor sag adjustment can be performed by using turnbuckles or adjustable extension links or plates (Fig. 9.108).

*Wedge-type clamps* (Fig. 9.109) do not require special tools for installation and are relatively simply to fit. Correction of conductor sag can be achieved by shifting the clamp, so that sag adjusting plates or links are not necessary. Wedge-type clamps are in particular suited to monometallic conductors and to bimetallic conductors with more than one aluminum or aluminum alloy layer and low steel content. They consist of a wedge system tailored and fixed to the conductor and of a one- or two-piece clamp body with pins to which the terminal straps of the insulator set are attached. According to the design principle of the wedge-type clamp, the wedge system slides within the wedge body when the conductor tensile force increases. As a consequence, there is a progressive rise of the transverse force on the conductor, which will increase the holding force of the clamp accordingly. In case of bimetallic conductors, the steel core participates adequately and sufficiently at the to-

**Fig. 9.109a,b** Wedge-type clamp (a) and in service (b) at an angle tower with jumper (source Pfisterer Sefag)

tal holding force due to frictional interlocking with the aluminum layers of the conductor. The greasing of the steel core may impair the extent of interlocking [9.210].

**Helical Terminations.** *Preformed dead-end rods* distribute the radial compression forces required for the friction locking over a longer section than dead-end clamps and, therefore, are in particular suitable for terminating metallic ground wires with optical fibers (OPGW), dielectric cables with optical fibers (ADSS), and other aerial cables. They are also often used in distribution lines.

Preformed dead-end rods also meet all the requirements on conductor terminations (Fig. 9.110). They can be simply installed by bare hand without tools and are widely used worldwide. They consist of several helically formed circular metal rods, the inner diameter being somewhat smaller than the outer diameter of the conductor to be terminated. The tensile forces are transferred onto the conductor through the helices by means of friction generated by radial pressure. The length and shape of the preformed dead-end rods keep the radial pressure at a low level and thus avoid any damage to the conductor. This inner surface of the preformed dead-end rods is sand-covered to increase the ultimate terminating forces. To meet the corona and RIV requirements and for safe handling, the rod extremities are

**Fig. 9.110** Helical termination with adjustable extension links at the Suez crossing; *inset*: rod ends with parrot bill shape

**Fig. 9.111** Bolted dead-end clamp (*pistol grip*)

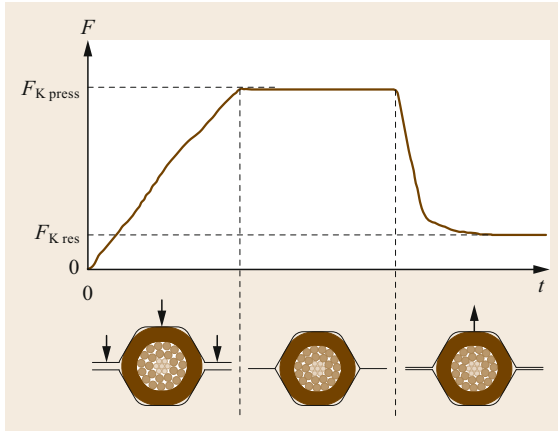

rounded, which is known as *ball-ending*. However, for most HV applications, the rod extremities assume a *parrot bill* shape to enhance the electrical performance of the inlet (Fig. 9.110).

Bolted dead-ends (Fig. 9.111) are occasionally used to terminate conductors for lower-voltage transmission and distribution lines. In such fittings, the conductor passes through this clamp without being cut. The bolt torque and the length of the clamp are calibrated to prevent slipping of the conductor and avoid any damage to its outermost layer. Correction of conductor sag can be achieved by shifting the clamp, so that, as for wedge-type clamps, sag adjusting plates or links are not necessary.

### Connectors

Connectors, also called joints or splices, are fittings that connect two pieces of the same phase conductor or the same earth wire or enable a branch-off or tap. There are two main types of connectors: full-tension and nontension.

Full-tension joints—and dead-end clamps—being tensile loaded, must sustain the conductor with 1.55 times the tensile forces in case of maximum load, or by 0.85 times 95% of its rated tensile force; the lower value

**Fig. 9.112** Compression force variation during the compression process (adapted from [9.211])

is decisive [9.63]. In addition, connectors intended to carry the rated current of the conductor should not, when subjected to the maximum continuous current in the conductor or to short-circuit currents, exhibit corresponding temperature rises greater than those of the associated conductor. Further, the voltage drop across current-carrying conductor fittings should not be greater than the voltage drop across an equivalent length of conductor.

Full-tension joints for high-voltage lines are in their great majority of compression type. These consist of an aluminum or aluminum alloy sleeve for monometallic conductors. Joints for ACSR conductors also have an additional steel sleeve for joining the steel cores. As described for dead-end clamps, the compression is applied using hydraulic tools with generally hexagonal dies.

The compression process in general, i.e., for all types of compression hardware, might look simple, but is in reality a complex problem in elastoplasticity, as during the compression process the joint and conductor experience high plastic deformations. The external compression force  $F_{K,press}$ , generated in most cases by hydraulic tools, is applied to the often hexagonal steel die and transferred via the tubular aluminum joint body to the conductor. In this way, the conductor and joint are plastically deformed and thus form-locked. When the external compressive load is removed, the conductor and joint spring back, whereby the elastic springback of the conductor is limited by the lateral rigidity of the joint. Thus, as the permanent compression force  $F_{K,res}$  between the conductor and joint is about 20% of the original compression force  $F_{K,press}$  (Fig. 9.112 [9.211]), also frictional locking opposes external tensile loads (Fig. 9.113 [9.212]).

However, experience has shown that the failure of a joint is usually the result of an increased electrical

**Fig. 9.113** Joint resistance to traction via form and frictional locking (adapted from [9.212])

resistance due to corrosion, leading to an unacceptable increase in temperature and unstable mechanical conditions. Very few joints have been reported to display failure resulting purely from mechanical loads. The reported events involving mechanical failures have occurred on joints that have been asymmetrically installed, i.e., where the intrusion of the aluminum layers of an ACSR at one end of the joint has been less than 2.5 times the conductor diameter [9.213]. The most important qualification factor for the proper function of a joint is his electrical resistance. This can be calculated based on an empirical model (Fig. 9.114) [9.214]

$$R_s = \frac{1}{\frac{1}{R_c 2(L_1+x)} + \frac{1}{R_{asc} 2L_1}} + \frac{R_{con}}{D} 2L_2 + \frac{1}{\frac{1}{R_c 2L_2} + \frac{1}{1.08 + R_{asc} + 2L_2}} + R_{as} 2L_3, \quad (9.96)$$

where  $R_s$  is the joint resistance ( $\mu\Omega$ ),  $D$  is the conductor diameter (m),  $L_1$  is the length of the entrance (m),  $L_2$  is the length of the contact area (m),  $L_3$  is the length of the uncompressed part (m),  $x$  is the length of conductor outside the joint (m),  $R_c$  is the conductor resistance ( $\mu\Omega/m$ ),  $R_{as}$  is the aluminum sleeve resistance when uncompressed ( $\mu\Omega/m$ ),  $R_{asc}$  is the aluminum sleeve resistance when compressed ( $\mu\Omega/m$ ), and  $R_{con}$  is the contact resistance ( $\mu\Omega$ ).

For example, a new joint with dimensions  $D = 0.0286$  m,  $L_1 = 0.075$  m,  $L_2 = 0.155$  m, and  $x = 0.005$  m and partial resistances  $R_c = 67.4 \mu\Omega/m$ ,  $R_{as} = 19.5 \mu\Omega/m$ ,  $R_{asc} = 21.4 \mu\Omega/m$ , and  $R_{con} = 60$  n $\Omega$  has a resistance  $R_s = 13.76 \mu\Omega$ , which amounts to just 28% of the resistance of the same length of conductor, here an ACSR Zebra, with  $R_c = 49.54 \mu\Omega$ .

Publication [9.213] proposes the following acceptance criteria for joints on old transmission lines, which should trigger replacement of the joints:

**Fig. 9.114** Distribution of electrical resistance in a joint for ACSR (adapted from [9.214])

- For joints where a failure and a drop of the conductor have a high influence and endanger the reliability of the line:  $R_{\text{joint}} < 70\%$  of  $R_{j,T_j=T_c}$ , i.e. the—measured—joint resistance should be less than 70 % of the calculated resistance value at which the joint and the conductor would be at the same temperature
- For joints where a failure and a drop of the conductor have an influence and jeopardize the reliability of the line:  $R_{\text{joint}} < R_{j,T_j=T_c}$
- For joints where a failure and a drop of the conductor have a low influence on the reliability of the line:  $R_{\text{joint}} < R_{j,T_j=T_c+10\text{K}}$ ,

where  $R$  is resistance,  $T$  temperature,  $j$  joint and  $c$  conductor.

Recently, and with the increasing tendency of transmission line owners to operate their lines with conventional conductors at higher temperatures, even above  $100^\circ\text{C}$  [9.57], better understanding of the design and operation of the related joints has become necessary. In this regard, extensive research has revealed, based upon long-term tests with duration of up to 3.5 years [9.211], that properly designed and installed joints show stable long-term performance up to temperatures of about  $150^\circ\text{C}$ .

For nontension connections, such as in the jumpers at heavy angle, anticascading, or strain towers, so-called parallel groove clamps are often applied (Fig. 9.115). For such devices, a good and stable contact

**Fig. 9.115** Parallel groove clamp

**Fig. 9.116** Conductor failure in a parallel groove clamp due to faulty installation (source: Richard Bergner Holding GmbH & Co. KG, RIBE)

between the conductor and the clamp body is essential, and quite a few disastrous outages (Fig. 9.116) have been caused because of poor contact, fading contact force, and/or not properly cleaned conductor and clamp surfaces just before the installation.

**Repair Sleeves.** When only a few elementary wires of the conductor outer layer are broken, repair sleeves can be used to restore 100% of the mechanical strength and the electrical resistance of the damaged conductor. Repair sleeves generally consist of two interlocking semi-circular elements that are installed by compression. Repair sleeves made from short armor rod sets are also used.

#### Fittings for HTLS Conductors

With the increased use of HTLS conductors (Sect. 9.4.9), best practices for their fittings become of importance. For this purpose, a worldwide survey has been launched and its results presented in [9.215]. The main findings therefrom are summarized here, although it must be considered that, since at the time of the survey the majority of HTLS conductors were in operation in Japan (things are different nowadays), the responses may overweight Japanese practices.

**Suspensions.** The most common type of suspension reported was a bolted clamp over armor rods, being used in over 70% of the responses. Bolted clamps were used in 19% of the responses, while elastomer cushioned clamps were used in 11% of the responses. The elastomers must be able to perform satisfactorily and not degrade over time at these high conductor temperatures.

**Dead-Ends.** The most common type of dead-end reported was a compression dead-end, being used in 62% of the responses. The balance of the responses used a wedge-type or bolted dead-end.

**Fig. 9.117** Warning sphere (note the intrusions on the top for easy handling) (source Pfisterer Sefag)

**Spacers.** The most common type of spacer reported was rigid (59%), followed by flexible spacers (30%). Articulated and spacer dampers made up the balance.

The use of rigid spacers on bundled spans is a typical Japanese practice: in other countries this practice is opposed in favor of spacer dampers with flexible and articulated spacers.

**Splices.** The two-piece compression splice was by far the most reported type, being used in 82% of the responses. Single-piece compression splices made up the balance.

**Dampers.** Stockbridge-type dampers were used in 32% of the responses. In some applications, a short set of armor rods was placed on the conductor before installing the clamp of the damper. Double torsional dampers were used in 54% of the cases (all from Japan). No dampers were reported in 7% of the responses. In some cases, helical dampers or festoon dampers were reported.

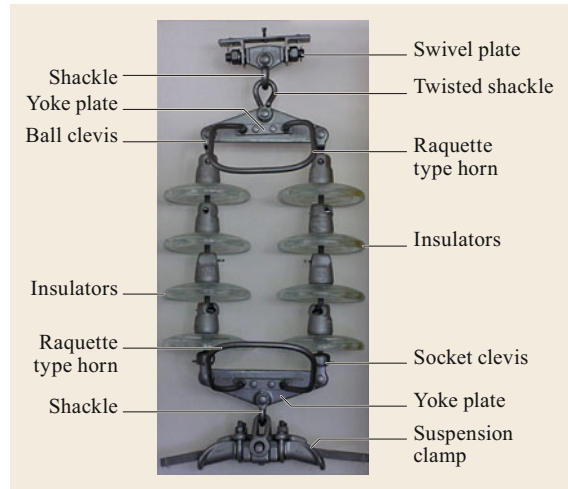

#### Aircraft Warning Markers

Aircraft warning markers (AWM) are highly visible indicators in daylight, used on power lines to warn low-flying airplanes and helicopters of the obstruction. The most common AWM is the warning sphere shown in Fig. 9.117. AWMs are covered in [9.216].

Night warning devices using lamps energized by the line voltage or current are also available and in use in many countries.

#### Fittings for Distribution Lines

Distribution lines [9.217] are in this context LV and MV lines with voltages up to and including 33 kV, where of-

**Fig. 9.118** Suspension string with string fittings (source U. Cosmai)

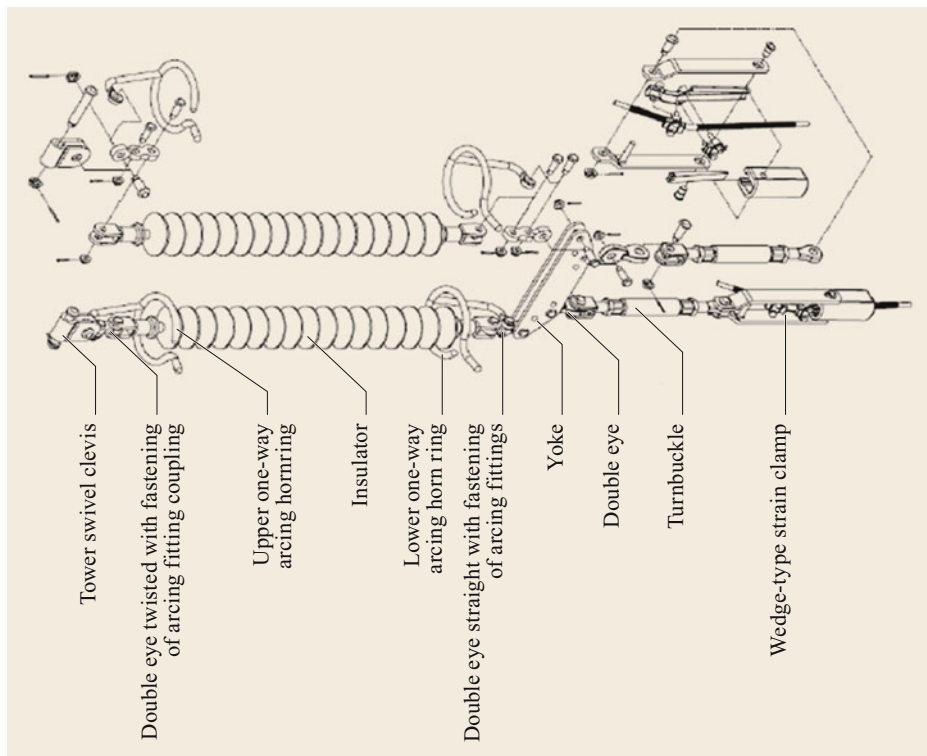

ten shackle (LV) and post (MV) insulators are used. In this case, the conductors are fastened to the insulators by either a soft wire binding or a so-called stirrup-type binding. With ACSR, it is customary to wrap the conductor with soft aluminum tape before fitting the stirrups. At straight line positions, the conductor is bound in the top groove of the insulator; at angle positions, this is done in the side groove so that the insulator and not the binder takes the conductor lateral pull. As an alternative, preform wire wraps are often used for securing the conductor to insulators for MV and LV lines.

#### 9.6.2 Fittings for Insulator Strings

String fittings connect the conductor fittings to the insulators and the insulators to the support. A subcategory are the insulator protection fittings. Figures 9.118 and 9.119 show a suspension and a tension string, respectively, where the different types of fittings are indicated.

String fittings are mainly produced from structural steel (straps, yoke plates), forged steel (ball fittings), and iron castings (sockets, clevises) and are then practically always hot-dip galvanized in accordance, for example, with [9.218] with a recommended minimum zinc thickness of 40–50  $\mu\text{m}$ .

These fittings must be able to withstand the specified mechanical loads as well as the electrical short current loads caused by power arcs and short-circuit conditions. Figure 9.120 shows the different types of couplings in use. The general requirements are specified in [9.206], while the standards for their dimensions are listed in Table 9.40.

**Fig. 9.119** 110-kV double tension string for twin bundle and the related string fittings (source Pfisterer Lapp)

**Fig. 9.120** Couplings for string fittings

**Table 9.40** Standards for dimensions of string fitting couplings

Fitting type	Applicable standard
Eye–clevis	IEC 60471 and DIN 48074: Eyes and clevises; connecting dimensions
Ball–socket	IEC 60120: Dimensions of ball and socket couplings of string insulator units ANSI C 29.2/52-3 for Ball 16, /52-5 for Ball 18, /52-8 for Ball 22 IEC 60372: Locking devices for ball and socket couplings of string insulator units – Dimensions and tests

Last but not least, string fittings must withstand short circuits, and the related temperature increase should not influence their mechanical functionality or

damage their protective zinc coating. For this purpose, their short-circuit current density should be limited to  $70 \text{ A/mm}^2$  (1 s) for fittings loaded in tension, and to  $80 \text{ A/mm}^2$  (1 s) for unloaded fittings, such as, for example, power arc protection fittings.

#### Insulator Protection Fittings

Insulator protection fittings, such as arcing horns and arcing rings, are indispensable components of insulator strings, in particular for high voltages. The voltage limit is almost a *philosophical* matter: The tendency in Europe is to use protection fittings for 50 kV and above, while in the Americas this often happens from 145 kV or even 220 kV upwards.

In any case, such fittings are installed in order to control power arcs due to:

- Overvoltages from lightning strokes and switching maneuvers
- Pollution flashovers
- Bridging of the air gap, i.e., by animals or so-called bird-streamers (feces of birds, released while flying off from the top of an insulator)
- Insulator failure in case of composite insulators because of *flashunder*
- Reduced clearances because of strong winds, ice shedding, or galloping

**Fig. 9.121** Schematic movement of the power arc (current  $I$ ) to the foot point by the fitting and correct shape of its extremity E (sacrificial sphere)

- Reduction of the insulation strength of the air gap, e.g., because of *sugar cane fires* below the line.

Power arcs can reach temperatures above 5000 K, thus the main duty of arc protection fittings is to speedily take over the arc and move it away from the insulator, so that it will not be thermally overstressed, with porcelain and glass being far more sensitive than composite insulators in this regard. This is done by offering the arc a conductive path and a suitable burning point in the form of a sphere, i.e., with enough sacrificial material (Fig. 9.121 [9.219]). The material loss at the end burning point can be calculated for steel with  $0.4 \text{ cm}^3/(\text{kA s})$  and for aluminum with  $1.4 \text{ cm}^3/(\text{kA s})$ ; For example, for 420 kV, a sphere diameter of 80 mm is required for a RIV level of 40 dB. This diameter far exceeds the above-mentioned requirements for the material loss caused by the power arc.

Steel is the preferred material versus aluminum for insulator protection fittings, for the following reasons:

- The speed of arc root movement is higher for steel by—empirically determined—50%. This reduces the thermal effect of the power arc on the protection fitting, while for aluminum, there is an unfavorable combination of lower speed and lower melting point.
- The combustion heat of aluminum is five times higher than that of steel. This correlates with a higher heat radiation intensity of burning aluminum as well. This increases the risk of insulator damage, as evaporated aluminum can precipitate onto the insulator surface and lead to reduced insulation performance.
- The higher thermal conductivity of aluminum would lead to a faster heat transfer into the struc-

**Fig. 9.122** C-ring for combined power arc and corona protection (source Pfisterer)

ture of the bulk material, and due to its low melting point, the aluminum profile can be deformed.

Consequently, an aluminum arc protection device equivalent to a steel design would require more material, which would negate the weight advantage of aluminum.

Power arc protection fittings should preferably have an orientation so that the forces during a power arc event support the movement of the power arc away from the insulator. Also, if possible, the end burning point should not face towards the conductor, which will prevent the power arc from moving onto the conductor or its damage by flying molten steel particles from the fitting.

For higher operating voltages, the field gradient at the insulator extremities, and primarily at the hot end, reaches values above the corona inception voltage. This is more critical for composite insulators, because of the small diameter of their core compared for example with porcelain longrods. Consequently, their grading rings should reduce the field gradient on the polymeric material of the insulator below the recommended maximum of  $4.5 \text{ kV/cm}$  [9.220].

Arc protection fitting designs are also available for addressing both tasks, i.e., power arc and corona field control, such as the so-called C-ring (Fig. 9.122).

The best practice for composite insulators is to not attach the power arc protection fittings directly to the insulator end fitting (Fig. 9.123a), as if this is not the case (Fig. 9.123b), the full short-circuit current will pass through it and possibly overheat and radially expand it to the extent that the core will slip out and the insulator will lose its mechanical integrity. Also, the glass-transition temperature of the rod may be ex-

**Fig. 9.123a,b** Best practice for positioning an arc protection fitting on a composite insulator end fitting. **(a)** Configuration for high-current power arc, **(b)** configuration for low-current power arc

ceeded. The trade-off is a longer insulator string, which can become problematic in some cases, such as when replacing conventional insulators by composites, because of clearance issues. Recommendations on the use of power arc protection fittings for composite insulators have been published in [9.221, 222].

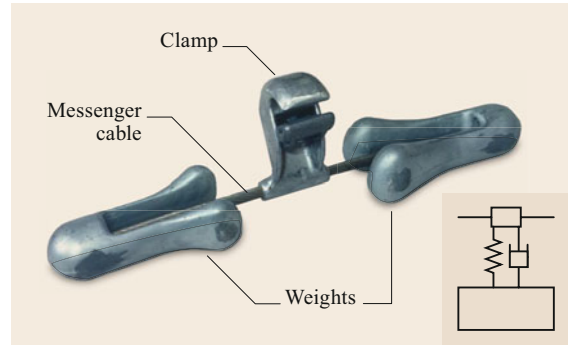

### 9.6.3 Vibration Dampers

Since the early days of high-voltage overhead transmission, wind-induced vibrations (Sect. 9.4.11) have been a major cause of concern to line engineers, as, if not controlled, they can cause wire and in extreme cases conductor failures due to fatigue. An early requirement in the industry was thus to develop suitable vibration dampers.

#### Stockbridge Dampers

The most widely used damper is the Stockbridge damper, so named for its inventor [9.223]. The Stockbridge damper was invented in the 1920s by George H. Stockbridge, who was an engineer for Southern California Edison. Stockbridge obtained US patent 1675391 on 3 July 1928 for a *vibration damper*. His patent described three means of damping vibrations on lines: a sack of metal punchings tied to the line, a short length of cable clamped parallel to the main cable, and a short length of stranded cable called a *messenger* with a concrete mass fixed at each end. It would be this last device that developed into the widely used Stockbridge damper (Fig. 9.124).

**Basic Theory.** The Stockbridge damper is a so-called tuned mass damper (TMD), i.e., a device that suppresses the vibration of a primary structure, here the conductor, by transferring its energy to a secondary mass. In a first approximation, the Stockbridge damper can be modeled as a spring–mass–damper system,

**Fig. 9.124** Stockbridge damper as a mass–spring system

where the counterweight is the mass, and the messenger wire the spring (Fig. 9.124). The energy dissipated by friction at the interlayer contact points of the messenger wires in the form of heat is represented in the schematic inset in Fig. 9.124 with a viscous damping dashpot. The Stockbridge damper strongly influences the vibration at its point of attachment to the conductor through the application of an interface force and an interface bending moment, causing a local distortion of the deflection shape of the conductor.

Neglecting the mass of the messenger cable and of the attachment clamp and assuming the messenger wire to be linear elastic with a constant bending stiffness and no self-damping, the eigenfrequencies of one half of the Stockbridge damper can be calculated as [9.101]

$$\omega_{1,2}^2 = 2k \frac{\frac{1}{3}L^2M + J_a - LGM}{MJ_a - M^2G^2} \mp \frac{\sqrt{(\frac{1}{3}L^2M + J_a - LGM)^2 - \frac{1}{3}L^2(MJ_a - G^2M^2)}}{MJ_a - M^2G^2}, \quad (9.97)$$

and the spring constant  $k$  of the messenger cable as

$$k = \frac{3E_m J_m}{L^3}. \quad (9.98)$$

$O$  is the center of gravity of the counterweight,  $O'$  is the attachment point of the cable to the counterweight,  $G$  is the distance between  $O$  and  $O'$ ,  $M$  is the counterweight mass,  $J_a$  is the moment of inertia of the counterweight about the point  $O'$ ,  $L$  is the length of the messenger cable,  $E_m$  is the Young's modulus of the cable, and  $J_m$  is the moment of inertia of the cross section of the messenger cable (considered as a homogeneous beam).

In reality, the bending behavior of the messenger cable obeys a similar bending process as explained

**Fig. 9.125** Load–deflection curves obtained from bending tests on a Stockbridge damper

in [9.102, 103] for conductors; i.e., the messenger bending stiffness is nonlinear, specifically it decreases, because of the wire slippage, with increasing curvature or deflection [9.224]. In other words, if we consider the messenger wire as a spring, it becomes *softer*, which is evident in Fig. 9.125 [9.98, 99] from the decreased slope of the bisectors of the hysteresis curves. Because of this, the resonance frequencies of the damper will move toward lower values. This will beneficially increase the damper response and reduce the vibration amplitude as, at the same time, the energy dissipated by the damper, equivalent to the area of the hysteresis in Fig. 9.125, will considerably increase. Thus, the effect of nonlinearity is to make the damper self-tuning.

Equation (9.99) defines and Fig. 9.126 presents  $P_d$ , the power dissipated by the damper over a complete cycle, and the resonance frequencies of a Stockbridge damper when new and after a fatigue test as prescribed in [9.225]

$$P_d = \frac{1}{2} F_c v_c \cos \varphi, \quad (9.99)$$

where  $F_c$  is the force at the damper clamp,  $v_c$  is the clamp velocity, and  $\varphi$  is the phase angle between the force and velocity.

Another important characteristic of a Stockbridge damper is its mechanical impedance  $Z_d(\omega)$ , i.e., the relationship between the driving force  $F_c$  at the damper clamp, the clamp velocity  $v_c$ , and the phase angle  $\varphi$  between said force and velocity. The damper impedance is frequency but also clamp velocity dependent

**Fig. 9.126** Power dissipated by a Stockbridge damper before (blue) and after (red) fatigue test (source RIBE)

dent (Fig. 9.127 [9.226])

$$Z_d(\omega) = \frac{F_c}{v_c} e^{j\varphi}. \quad (9.100)$$

The peaks in this figure correspond to the eigenmodes of the damper, also shown schematically on top, which can be reasonably excited in the aeolian vibration regime: At the first and second (lower) eigenfrequencies, the outer ends of the two weights are the points of maximum motion, whereas at the second and fourth (upper) eigenfrequency, the motion of the weights is a rotation about their own center of gravity. For a given vibration amplitude of the damper clamp, e.g., when tested on a shaker, the greatest dissipation occurs at these resonant frequencies. However, they may not be the frequencies providing greatest dissipation when the damper is attached to a span, because if the force resonances have sharp peaks, the damper clamp will be hard to drive since it then presents high mechanical impedance to the vibrating conductor. On the other hand, reduced damper performance also occurs when the damper is too easily driven by the conductor and does not produce sufficient energy dissipation. This may happen at frequencies between and outside the resonances.

**Damper Design.** A good damper design has thus to consider the proper choice of damper weight, shape, and moment of inertia in such a way that it should not resist too *softly* between resonances neither too *stiffly* at resonances, as well as the sharpness and spacing of the resonances. For the latter, two approaches are currently used. One is to employ closely spaced resonances, so that at least one is partly excited. The other is to use a special messenger cable with a high loss factor and

**Fig. 9.127**  
Impedance of  
a four-resonance  
(4-R) Stockbridge  
damper at different  
clamp velocities

thus produce broad, low resonance peaks in the overall damper response.

An interesting approach is to design dampers by taking advantage of the electromechanical analogy, i.e., the fact that the mechanical relationships for a vibrating conductor and the electrical relationships for a long transmission line are equivalent [9.227, 228]. Specifically and in a first approximation, the damper impedance (9.100) should be in the range of the wave impedance of the conductor (9.75) in order to provide optimum damping. However, the former varies with frequency and the second with changes in unit mass and tension (e.g., by ice loads), thus perfect matching is only possible for a specific vibration frequency. Nevertheless, a properly designed vibration damper can provide effective damping when the damper impedance is in the range of 0.5–3 times the characteristic impedance of the conductor [9.229].

**Damper Placement.** Even the best damper will malfunction if not placed properly on the conductor. For this, there are two approaches: In the first, dedicated software is applied to calculate the damper location on the conductor using adequate modeling of the conductor and damper [9.104]. This approach is particularly useful in critical cases, such as long spans with high conductor tension. The second approach, applicable in *standard* situations, is more practical and is

based upon experience and a good understanding of the physics involved. Specifically, regardless of how effective a damper is, it cannot be expected to reduce the amplitude of vibration to zero, as a small amount of vibration will always be necessary to actuate the damper. In addition and as explained above, the damper is not equally effective at all the vibration frequencies that the conductor will encounter. In this sense, it is generally accepted that, if the damper is placed at a distance  $S_d$  from the clamp equal to 80% of the shorter vibration loop, i.e., at the highest vibration frequency occurring at the highest wind velocity  $v_{w_{\max}}$  causing aeolian vibrations, normally 7 m/s (Sect. 9.4.11), it should provide sufficient damping in the relevant wind velocity range of 1–7 m/s (Fig. 9.128). Combining (9.76) and (9.79) yields

$$S_d = \frac{2d_c}{v_{w_{\max}}} \sqrt{\frac{T}{m}}. \quad (9.101)$$

An average value for  $S_d$  is 2 m.

If a second damper is deemed necessary, e.g., for span lengths above 400 m, then it should be placed approximately at the same distance from the first damper towards the span. In spans to be equipped with two dampers, the best solution is to apply one damper per span end, positioned at the same distance from each end. For tension–suspension spans, when using one

**Fig. 9.128a,b** Recommendations for Stockbridge damper placement: vibration profile under low winds (a) and high winds (b)

damper, the damper should be placed near the suspension clamp. Since tension clamps are vibrationwise less critical than suspension clamps, the installation of a vibration damper at a tension clamp as well as near other fittings such as warning spheres can be based on the recommendations above for suspension clamps. Table 9.41 summarizes recommendations for the necessary number of dampers by a well-known utility [9.230].

**Damper Materials and Construction.** For the *messenger cable*, so called because Stockbridge's original model used the type of cable employed, at that time, in overhead telephone lines, galvanized steel is most common, although the 7-strand messenger cables originally employed have now been replaced by 19-strand cables because of their superior damping capacity (more interwire contact points). Messenger cables made of stainless steel are used in polluted areas.

*Damper clamps* must be as light as possible, and care must be exercised in selecting the clamp materials, especially those that are in contact with the conductors, to avoid any corrosion problems. For the clamps, primary aluminum alloys are used for aluminum- and steel-based conductors, with only a few cases of steel clamps for steel shield wire. Clamps are either cast directly onto the messenger cable or cast separately and then assembled onto the messenger cable by compression. They are designed in a cantilever hook shape that

**Fig. 9.129** Cantilever hook clamp of a Stockbridge damper (source Pfisterer Sefag)

allows the damper to be easily attached onto the conductor during installation (Fig. 9.129). Also, in case of clamp loosening, the damper may slip toward the center of the span, but the hook clamp prevents the damper from falling to the ground. Damper clamps contain a single bolt of galvanized steel, with a plain washer and a split washer or a *Belleville washer*, and must be designed to avoid losses of clamp pressure and to prevent loosening.

The first *damper weights* were bell-shaped masses of galvanized cast iron, installed on the messenger cable by means of tapered aluminum sleeves. Later, an assembly technique based on pouring zinc alloy or aluminum between the messenger cable and the hole in the mass was developed. Alternatively, zinc-aluminum alloys with density similar to cast iron have been used for the masses, being cast directly on the messenger cable. Also, forged steel masses, or extruded steel rods or tubes bent upwards, have been used; these masses are compressed onto the messenger cable.

**Other Types of Dampers.** Over the years, other types of dampers have also been developed, such as the Elgra damper, the Haro damper, the festoon damper, the tor-

**Table 9.41** Number of dampers depending on span length and terrain (adapted from [9.230])

Terrain	Vegetation	Span length (m)			
		< 150	150–350	350–550	> 550
Hilly or valleys parallel with the line	Other type of vegetation from dense forest on one side to flat terrain with no obstacles	0	1	2	2
Flat or valleys perpendicular to the line	Other type of vegetation from dense forest on one side to flat terrain with no obstacles	1	1	2	4
Lakes or water courses		1	2	2	4

**Fig. 9.130** Shaker test of a Stockbridge damper (source Pfisterer Sefag)

sional damper, dampers with elastomeric articulations, spiral impact dampers, and Bretelle dampers [9.214]. However, none of these could really compete with or replace the Stockbridge damper, and their use has been restricted to certain countries and/or special applications, like the festoon damper for long fjord crossings in Norway and the Bretelle damper in France.

**Damper Tests.** Dynamic testing of dampers takes place according to [9.225]. Therein the following test methods are described:

- Inverse standing wave ratio (ISWR) test
- Power test
- Decay test
- Forced response (shaker) test (Fig. 9.130).

The latter is quite popular, as it allows the dynamic characteristics of the damper to be established and is at the same time easier to accomplish in comparison with the other tests, which require the damper to be tested when attached to the conductor in a laboratory test span. However, the drawback of the shaker test is that only the vertical motion of the damper can be considered, whereas in reality the damper also rotates slightly, thereby providing an additional contribution to the energy dissipation, especially when the damper is close to a vibration node of the conductor.

The shaker test is also important in order to establish the fatigue performance of the damper. A sign of fatigue in the messenger cable of Stockbridge dampers is the drooping or sagging of the masses. Such damage may be caused by excessive vibration levels, an inadequate damping system, or poor quality of the damper. It may also be caused by gallop-

**Fig. 9.131** Typical spacer damper for quad bundles (source Pfisterer Sefag)

ing or ice-shedding events. In corrosive environments, e.g., near the sea, corrosion of the messenger cable may be a failure mechanism. In these environments, stainless-steel messenger cables can be advantageously used.

From the two alternative methods proposed in [9.225] for the damper fatigue test, the most commonly used is the one which excites vibration with constant amplitude of 0.5 mm (zero peak) at the higher resonant frequency of the damper and accumulates 10 million cycles.

### Spacers and Spacer Dampers

Early in the 20th century, when, in order to transmit more power, line voltages started to increase dramatically, limits because of corona and surge impedance soon became prominent, the solution to both issues being the introduction of bundle conductors [9.78–80] (Sect. 9.4.7), and with them, a new type of fittings, i.e., spacers and spacer dampers. Their main duty is to maintain the design geometry of the bundle and at the same time avoid clashing of the bundle subconductors because of wake-induced oscillations (Sect. 9.4.11), gusts, or short circuits as well as twisting of the bundle because of unequal ice loads. At a later stage and in a clever design move, damping properties were also integrated into the spacers to suppress disturbing aeolian vibrations of the subconductors; they became spacer dampers. A spacer damper is a device which keeps the

**Fig. 9.132** Working principle of spacer dampers, shown for a twin spacer damper. *Inset*: elastomer bushing (source Pfisterer Sefag/U. Cosmai)

subconductors of a bundle apart in a given geometrical configuration and at the same time can reduce aeolian vibrations and subsan oscillations of the subconductors.

Nowadays, the vast majority of bundle fittings are spacer dampers, with the possible exception of twin bundles. For these, flexible, articulated, or semirigid spacers are often combined with Stockbridge dampers placed on each subconductor. An exploded drawing of a typical spacer damper for quad bundles is shown in Fig. 9.131.

In general, spacers and spacer dampers must withstand the mechanical, electrical, and environmental loads imposed during installation, operation, and maintenance, without failures and without damaging the conductors.

A good reference on various designs, materials, and service experience of spacers and spacer dampers can be found in [9.125]. For reasons of brevity, we present therefrom two important features, viz. the properties of the elastomer material used for vibration damping and the proper clamp design, as the latter has been in many cases a cause of concern and serious damage to the related conductors.

**Elastomer Bushing and Clamp Lining.** The working principle of spacer dampers, shown exemplarily in Fig. 9.132 for a twin spacer damper, is that, during aeolian vibration of the attached subconductors, the inertial forces of the the spacer damper frame initiate rotation of the spacer damper clamps, which leads to dissipation of energy as the related articulations contain damping elements, generally made of elastomer (Fig. 9.132, inset). The most widely used elastomers are chloroprene (neoprene) rubber, EPDM rubber, NBR (nitrile butadiene rubber), silicone rubber, and special compounds. These elastomers should be semiconductive, because nonconductive elastomers are liable to experience electrical discharges as a result of the pollutants

**Fig. 9.133** Spacer damper clamp bolt with Belleville and plain washer (source U. Cosmai)

coating their surface. Such discharges encourage further growth of carbon deposits, leading to escalation of the tracking situation and generating radio interference and audible noise. Elastomers with too high a carbon content and, therefore, too high a conductivity, are subjected to overtemperatures that can cause accelerated aging and galvanic corrosion between the elastomer and spacer components, as well as the conductor strands in case of elastomer-lined clamps. Elastomers for spacers have to withstand contact with the oils and greases used in conductors and stringing machinery. In addition, the elastomers should not absorb water. Damping elastomers used in spacer damper articulations should exhibit high hysteresis losses, appropriate stiffness, and good fatigue resistance over the entire range of service temperature. Last but not least, they should be suitably protected, as corona activity on conductors and fittings increases the presence of ozone, which rapidly deteriorates organic materials; these materials also need to be protected from ultraviolet radiation.

The dynamic behavior of spacers as related to wind-induced vibrations is a complex matter and lies beyond the scope of this book. Different methodologies are available and are well described in [9.81, 104].

**Clamp Design.** Spacer and spacer damper clamps should be designed in order to:

- Avoid high, localized clamping stresses; this is a function of clamp length, clamping force (bolt torque), and clamp geometry.
- Avoid damage to the conductor due to clamping surface irregularities; the conductor contact surfaces must be smooth.
- Minimize the possibility of incorrect installation.
- Ensure that, if feasible, all components are captive; bolts may be peened or, if in a blind tapped hole, secured by an O-ring to the clamp keeper, which

**Fig. 9.134** Different designs of spacer damper clamps (source U. Cosmai)

itself may be secured to the body of the clamp by a tie or captive hinge.

- Incorporate a stored energy mechanism, like a Belleville washer, to prevent clamp loosening due to temperature cycling and conductor creep. This is a conical spring washer and should be supported by a plain washer (Fig. 9.133).
- Exert an adequate, nondamaging long-term axial and torsional grip on the conductor.

**Fig. 9.135** Subconductor clashing during short-circuit test

- Be manufactured from a material that is compatible with the conductor and generally avoids corrosion.
- Be profiled to minimize the possibility of corona and RI discharge at specified line voltages.
- Be easily installed on the conductor, possibly also using hot line/helicopter techniques.
- Facilitate ground-level inspection to verify correct installation.

These requirements have led to various designs of space damper clamps, as shown in Fig. 9.134.

One important design load on spacers and spacer dampers is caused by electromagnetic forces arising from short-circuit currents in the subconductors of the bundle. Short-circuit currents cause strong attractive forces between the subconductors, which induce large deflections and even clashing of the subconductors (Fig. 9.135 [9.81]), consequently considerably increasing the subconductor tension. The latter results in significant compressive loads on the clamp arms of the spacer, which can reach up to 15 kN and above for short-circuit currents in the region of 50 kA, which are not uncommon nowadays. These forces are usually calculated by the method proposed in [9.231], although this underestimates their magnitude by about 25–30% for short subspans, e.g., in jumper locations, and high short-circuit currents, e.g., at towers close to a substation. In such cases, it is recommended to apply more sophisticated methods [9.232] that consider the subspan length. This is important because, the shorter the subspan, the greater the pinch force  $F_{pi}$  and the greater the compressive load  $F_c$  on the spacer or spacer damper.

#### 9.6.4 Tests

Conductor and insulator fittings should be tested in accordance with the requirements of [9.206] or equivalent standards. Specific tests for vibration dampers and spacers can be found in [9.225] and [9.234], respectively. Tests relevant for new conductor and insulator fittings are listed in Table 9.42 [9.206].

**Table 9.42** Tests on new fittings (adapted from [9.206])

	Spectral analysis to investigate the carbon and nitrogen content			

In addition, and as in many parts of the world lines are about to exceed or have already exceeded their projected design life of say 40–50 years, testing on aged fittings, i.e., fittings which have been in service for more than

30 years, are also of importance, as the failure of a fitting can have catastrophic consequences. Recommendations for such tests, based on international best practices, can be found in [9.233] and are listed in Table 9.43.

## 9.7 Supports and Foundations

Overhead line supports are definitely the most impressive components of an overhead line. They are also, together with the conductors, the most expensive line components. Over the years, their shape and materials have undergone a great development. In recent decades, so-called esthetic supports have come to play an ever-

increasing role in line design, as they are a serious option to address the public sensitivity to environmental issues. Since supports are earthed, they have to safely sustain and conduct lightning strokes to ground, thus their proper earthing is very important. However, above all, line supports carry (in the full sense of the word)

a great responsibility for the reliability and safety of the line, as their failure can have catastrophic consequences. On the other hand, to properly support the line conductors, supports require solid foundations into the ground. The operational safety of the supports is thus irrevocably connected with the stability of their foundations. In addition, foundation movements can cause severe and unexpected loads on the supports and thus have to be understood and controlled.

In this regard, this section covers:

- Support types (poles, steel lattice towers, new materials)
- Design
- Esthetic supports
- Prototype tests
- Foundations
- Grounding
- Earthing.

### 9.7.1 Wood Poles

Wood was the first material to be used in the supports of overhead lines (Fig. 9.1). Today, with few exceptions, wood poles are mainly used for low-voltage (LV) and medium-voltage (MV) lines, say up to 50/69 kV (Fig. 9.136 [9.235]). They are classified as light, medium, and stout. An often used wood for poles comes from the Scots pine (*Pinus silvestris*), generally referred to as redwood [9.236]. An important issue for wood poles is that they have to be adequately protected against decomposition by fungi (rot). To avoid this, impregnation is necessary, but care is required in the selection of proper chemicals, as some of them can cause health hazards and pollute the environment. The characteristics of wood poles for overhead lines are covered in [9.237].

In cases of increased transverse loads at angle or terminal positions, double, guyed, or so-called A-frame poles are used. In some countries, wood poles in the form of H-frames have also been used for higher voltages up to 345 kV.

#### Design

The design of a self-standing wood pole (Fig. 9.137 [9.4]) is straightforward. The pole is basically a cantilever beam loaded in transverse direction. The maximum bending moment at ground level becomes

$$M = Ph + Q_w \frac{L}{2}, \quad (9.102)$$

where  $P$  is the transverse load at the top of the pole due to the wind action on the conductors and  $Q_w$  is the wind

**Fig. 9.136** Wood pole (adapted from [9.235])

load on the pole itself. This bending moment causes tensile and compressive stresses in the pole cross-section, given by

$$\sigma = \frac{N}{A} \pm \frac{M}{W}, \quad (9.103)$$

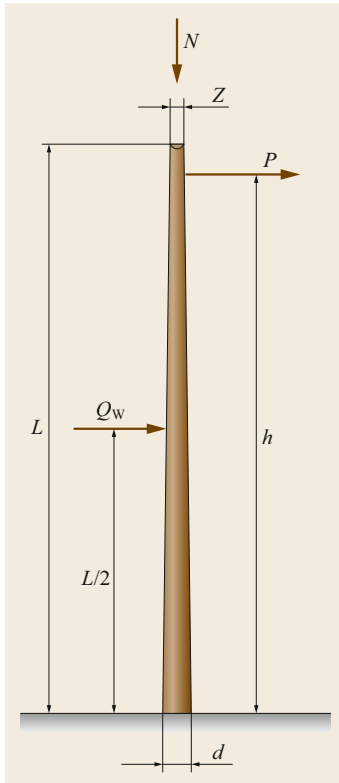

where  $N$  is the force from axial loads such as the weight of the conductors, the dead weight of the pole, and the vertical component of the stay load in case of guyed poles,  $d$  is the diameter,  $A = \pi d^2/4$  is the area, and  $W = \pi d^3/32$  is the section modulus of the pole cross-section at the ground.

As wood is a relatively flexible material, it is important to consider the maximum pole deflection at the top, which can be calculated as [9.4]

$$f_d = \left( \frac{P}{3} + \frac{Q_w}{8} \right) \frac{h^3}{EI}, \quad (9.104)$$

where the modulus of elasticity  $E$  can be assumed to be 10 000 N/mm<sup>2</sup>,  $I$  is the moment of inertia at ground level given by  $I = \pi d^4/64$ , and  $d$  is the pole diameter. Considering the resilience of the upper soil layers, the length  $h$  and diameter  $d$  in (9.104) should be related to a cross section approximately 0.5 m below the ground surface level. According to [9.16], it is recommended that the deformation be limited to a maximum of 10% of the pole length under the relevant external load.

Wood poles are normally inserted directly into the ground. The subsurface length of the pole should be, as

**Fig. 9.137**  
Schematic for  
the calculation of  
a wood pole

**Fig. 9.138** Line with concrete poles (adapted from [9.238])

a good practice, one-sixth of its total length, but a minimum of 1.6 m. In case of soft soils, a crushed stone ring is placed around the base of the pole to provide sufficient grip of the pole in the ground.

### 9.7.2 Concrete Poles

Concrete poles are often used for lines in the voltage range of 60–150 kV (Fig. 9.138 [9.238]) and very rarely up to 400 kV. Their main advantage is that they practically do not require maintenance. Other advantages are their slim shape and narrow base as compared with lattice towers. On the other hand, they are quite bulky and heavy, so their transport over long distances becomes arduous, an issue which has encouraged local production, mainly in developing countries. Often, site accessibility is a critical issue for the use of concrete poles as OHL supports.

According to how they are manufactured, they can be divided into the following two categories.

#### Spun Concrete Poles

These poles are manufactured by spinning of two-piece horizontal molds which are rotated quickly around their longitudinal axis. This leads to centrifugal accelerations of 10–30g and thus to very dense, high-strength con-

crete. The steel reinforcement can be either slack or prestressed and is placed in the mold before the start of the spinning process. An innovative alternative is the use of carbide fibers instead of steel for prestressing, thus reducing the concrete thickness and pole weight as well as avoiding possible steel corrosion by water ingress [9.239].

#### Vibrated Concrete Poles

These mostly have a square but sometimes H cross-section, and they are produced locally. The steel reinforcement is placed in metallic molds with suitable cross-sections, then the concrete is poured in and compacted using vibrators attached to the outer surface of the molds every 1.5–2.0 m along the length of the pole. The vibration frequency lies between 3000 and 15 000 Hz.

#### Design

Concrete poles can be dimensioned using standard design methods for reinforced and prestressed concrete.

#### Foundations

The majority of concrete poles use so-called block concrete foundations (Fig. 9.139 [9.4]). For small-size poles, up to a total length of approximately 15 m and

**Fig. 9.139** Design of monoblock foundations for concrete poles (adapted from [9.4])

for prismatic foundation bodies, with a height  $t$  greater than their width  $b$ , the load is predominantly transferred by lateral embedment. The design will be conservative if the contribution of the foundation base is—as often—neglected. Assuming the pivoting axis of the foundation body at two-thirds of its depth, and further a parabolic distribution of the bearing lateral pressure between the foundation body and the soil, the maximum bearing pressure  $\sigma_e$  occurs at the foundation lower edge

$$\sigma_e = 12M \frac{h + (2/3)t}{bht^2}. \quad (9.105)$$

The significance of  $h$ ,  $b$ , and  $t$  can be seen in Fig. 9.139 [9.4]. The virtual height of the load attack  $h$  results from the ultimate moment  $M$  and the sum of the transverse

loads  $H$  according to

$$h = \frac{M}{H}. \quad (9.106)$$

The permissible or ultimate moment is obtained from

$$M_u = \frac{\sigma_u t^2 b}{\gamma_M 12(h + (2/3)t)}, \quad (9.107)$$

where  $\gamma_M$  is the partial safety factor and amounts to 1.0 for characteristic values with a minimum of 1.2 for ultimate values.

A good review of foundation design methods is given in [9.240].

### 9.7.3 Metallic Poles

Metallic poles are currently made of carbon steel, mainly from high-strength low-alloy material, although aluminum has also been used sometimes.

Solid-wall *steel poles* with various designs are used for low-, medium-, and high-voltage lines. *Polygonal conical poles* usually have 8-, 12-, or 16-sided shapes, whereby the plates are bent and finally welded in longitudinal direction. The steel grades S235 and S355 are mainly used for these poles. The lengths of the poles sections or their parts are limited to approximately 9–15 m by the weights/lengths for transportation and galvanization capabilities. The joints required for taller pole lengths can be designed as *slip joints* (overlapping) or *flange joints* with prestressed high-tensile bolts (Fig. 9.140 [9.4]).

Bolted flange joints are necessary for poles used for higher loads, for which prestressed high-strength bolts, e.g., with strength grade 8.8 or 10.9, are used. The flange joints can be arranged outside or inside the pole shaft. In case of an inside arrangement, the dimensions of the pole must be sufficiently wide to enable arrangements of cut-outs and ladders inside the pole.

Regarding their finishing, steel poles should preferably be hot-dip galvanized. Sometimes, painting sys-

**Fig. 9.140** Typical pole cross-sections and joints of steel poles (adapted from [9.4])

**Fig. 9.141a,b** Steel pole foundations: (a) sand box direct embedment type; (b) flanged base plate type

tems are also required for esthetic purposes, since hot-dip galvanizing surfaces do not have a uniform color appearance.

Steel pole design follows the basic rules of engineering mechanics. Special care should be taken when openings are required in the pole shaft, e.g., for small access doors, as the design must take them into account, as the cross-section will become an open section profile at such locations, where warping torsion has to be considered.

The top deflection of steel poles should be limited, since those poles are quite flexible. The following limits are recommended:

- At EDS condition: maximum top deflection equal to or less than 1.5–2% of the pole height
- At ultimate load: 4–5% of the pole height.

Steel poles often use monoblock concrete foundations, or more seldom piles for soft soil conditions. They are either directly embedded in the concrete or placed in a dense sand concrete box, or even connected on the top surface of the foundation body by means of flange and anchor bolts (Fig. 9.141 [9.4]). The design of these foundations follows the same principles and procedures as for concrete poles (Sect. 9.7.2).

#### 9.7.4 Composite Poles

A rather new development is the use of composite poles made of fiber-reinforced polymer (FRP) (Fig. 9.142). To this end, CIGRE very recently published an extensive document [9.241], from which the following information is extracted.

FRP poles consist of E-glass embedded in a resin matrix. Commonly used resins are epoxy, polyester,

**Fig. 9.142** FRP cross-braced H-frame

vinyl ester, and polyurethane. Additives are used to improve some of the properties of FRP, such as its UV protection, fire resistance, flow improvement, abrasion resistance, etc., while fillers are applied to reduce the weight. Although their material costs are higher than for traditional materials, their low weight enables lower installation costs. Also, due to their long service life and low maintenance requirements, life cycle costs can be lower with FRP components. Their foundations follow the same practices as other pole-type supports (Fig. 9.143).

**Fig. 9.143a,b** Typical foundations for FRP poles: (a) crushed stones around the pole shaft in rock; (b) barrel with backfill in normal soil

**Fig. 9.144** Common tower types

### 9.7.5 Steel Lattice Towers

For higher voltages, e.g., normally above 110 kV, steel lattice towers are still the choice of preference, the main reason being that, when properly designed, they can achieve relatively long spans economically. In addition, when orderly maintained, they have a long service life, and as they are modular, they are easy to transport from the manufacturing plant to the site. Their modular concept is also advantageous when modifications in case of uprating (Sect. 9.10) or repairs of individual tower members become necessary. They also provide easy

adaptation to the terrain by means of an adaptable system of body and leg extensions.

Over the years and depending on system planning, the number of circuits to be supported, experience, topography, etc., a plethora of tower shapes have been installed. They can basically be grouped into self-supported and guyed towers. Figure 9.144 shows various common tower shapes [9.242].

#### Materials and Layout

Publication [9.243] gives a good overview of industry practices for lattice tower design and detailing. The

**Table 9.44** Yield and ultimate tensile strength of tower steel profiles and bolts (adapted from [9.4])

Steel grade	Bolt grade	Yield strength $f_y$ (N/mm <sup>2</sup> )	Ultimate strength $f_u$ (N/mm <sup>2</sup> )
S235		235	360
S355		355	510
	4.6	240	400
	5.6	300	500
	8.8	640	800
	10.9	900	1000

materials used in the fabrication of line supports should comply with the requirements of [9.244, 245] or equivalent standards. In general, high-strength steel of grade S355 and mild steel of grade S235 are used. Members are practically always connected with bolts compliant with [9.246] or equivalent. The relevant properties of tower steel profiles and related bolts are listed in Table 9.44 [9.4]. Low-tensile bolts of grades 4.6 and 5.6 are often preferred, as they exhibit, because of their relative high ductility, benign deformation behavior at failure.

In most cases, lattice towers have a square cross-section, although there are some cases with a rectangular cross-section. Their absolute width on the upper part and their width gain are selected by optimizing the strength and length of the steel profiles; these should be selectable from the available standard sizes. Gain values of 40–50 mm/m for suspension towers and 60 mm/m for angle towers have proven useful. Often the lowest part of the tower is designed with even higher width gains, as this enlarges the cross-section at ground level, reducing the forces on the tower legs and consequently the size of the foundations. An interesting early publication focused on the influence of such tower geometry parameters on the economic design of steel lattice towers [9.247].

Figure 9.145 [9.4] shows typical brace arrangements for leg members with their related *effective buckling length*  $L$ . The distance between the brace connections should be reduced as much as possible in order to avoid secondary bending of the leg sections in between.

**Fig. 9.145a–d** Brace arrangements of steel lattice towers for (a) light, (b) moderate, (c) high, and (d) very high loads (adapted from [9.4])

Single angle sections are the most widely used and economic design profile; they are manufactured from 40×3 mm up to a size of 250×28 mm. For towers supporting multicircuit lines and, particularly, for very tall towers, member designs with higher strength may be necessary. In these cases, cruciform sections made up of two, three, or four angle sections are used for leg members.

While formerly rivets were used for lattice steel towers, bolted connections predominate by far today. This connection element is adequate for the hot-dip galvanization process. The individual members and bolts can be galvanized separately and bolted together afterwards.

For leg members, either butt joints or lap joints are used (Fig. 9.146 [9.4]). Butt joints can be designed with two shear planes and are preferred in case of towers with higher strengths to facilitate the erection. Lap joints save material but are not frequently used anymore because of their inherent eccentricity and relatively higher erection costs.

All nuts should be secured against loosening. Frequently, *spring washers* are used for this purpose, or a strong adhesive. Alternatively, the nuts can be punched on three points spaced at 120° and protected with anticorrosive dyes.

To ensure a long service life, adequate protection against rust is of great importance. Whenever possible, hot-dip galvanizing should be applied, while, already in the tower design stage, the length of the galvanizing facilities (length of the zinc bathtub) has to be taken into consideration. Lengths up to 9 m for member sections are common [9.243]. The best corrosion protection is achieved by the so-called in-factory duplex system, i.e., by coating the steel members after their galvanization.

### Tower Types

Steel lattice towers, as with all other types of line support, can be distinguished based on their function in the transmission line, i.e., suspension, angle, terminal towers, etc. A typical classification is based on the line route deviation angle:

**Fig. 9.146a,b** Leg member joints: (a) butt joint, (b) lap joint (adapted from [9.4])

- *Suspension or tangent towers (S)* support the conductors in a straight line and up to small line angles up to say  $3^\circ$ ; they are equipped with suspension insulators.
- *Light angle towers (LA)* support the conductors up to line angles of  $10^\circ$ , seldom up to  $20^\circ$ ; they are equipped with suspension insulators.
- *Angle towers (A)* must be designed to sustain the resultant component of the conductor tensions when the line changes direction; they are equipped with tension insulators.
- *Tension or strain (T) towers* have to sustain the full conductor—and ground wire—tensions in the line direction but also for relatively large line angles up to  $60^\circ$ . They serve as rigid points of the line and are equipped with tension insulators.
- *Dead-end or terminal towers* are used to terminate the line, e.g., at a substation or an overhead to underground change-over station, and are equipped with tension insulators.
- *Tie-off towers* are used where a branch-off of the line is required; such a design is the so-called *Mercedes tower*.

### Structural Design

As with every lattice structure, tower design proceeds via the following steps:

- Assess external loads
- Group into load cases
- Calculate forces in tower members (legs, braces, cross-arms)
- Calculate stresses in tower members
- Verification of members and connections.

**Loads and Load Cases.** External loads basically arising from conductors and insulators, i.e., self-weight, ice

**Table 9.45** Standard load cases (adapted from [9.16])

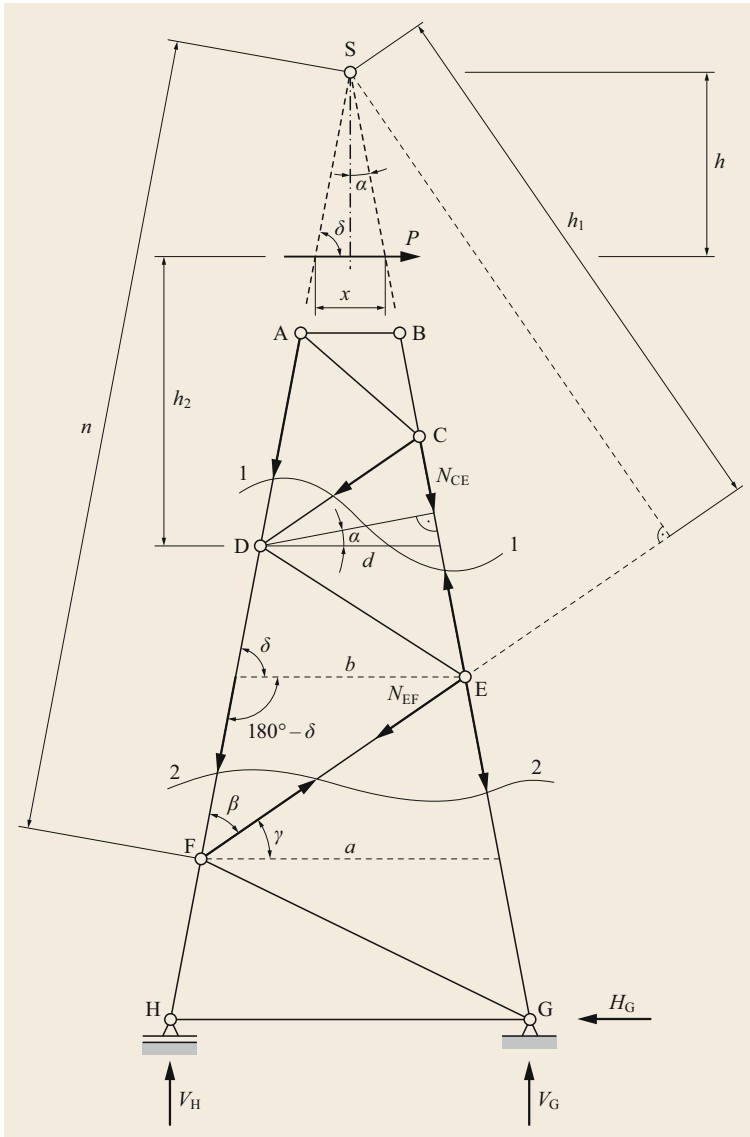

Load case	Conditions
1a	Wind loads (transverse, longitudinal, inclined)
2a	Uniform ice loads on all spans
2b	Uniform ice loads, transversal bending
2c	Unbalanced ice loads, longitudinal bending
2d	Unbalanced ice loads, torsional bending
3	Combined wind and ice loads
4	Minimum temperature with/without wind loads
5a	Security loads, torsional loads
5b	Security loads, longitudinal loads
6a	Safety loads, construction and maintenance loads
6b	Safety loads, loads due to the weight of linesmen

and wind loads, and conductor tensions, have been adequately dealt with in Sects. 9.3 and 9.4. The next step is to group loads together into so-called *load cases*, which take into account probable scenarios of load combinations. From the relevant standards, for example [9.16], the load cases are prescribed in Table 9.45. In all load cases, the vertical component of the so-called permanent actions, i.e., self-weight of supports, insulator sets and other fixed equipment, as well as the weight of conductors from the adjacent spans, should be included. It is common and helpful to display the forces for every load case schematically in the form of so-called load-ing trees.

It is worth mentioning that the so-called security loads (load cases 5a and 5b in Table 9.45), which arise from one-sided release of conductor tension, for instance when a conductor breaks, are intended to prevent cascading or uncontrollable failures and are by nature dynamic. What is normally done, though, is to load the supports with the related residual static load (RSL), applying a dynamic impact factor to compensate the peak dynamic effect [9.248]. An option against the detrimental effects of a broken conductor is to install controlled sliding clamps (Sect. 9.6.1) [9.208].

**Structural Analysis.** The core of any structural design is the calculation of the forces and subsequently of the *stresses* acting in the components of the structure, here in the case of steel lattice towers, the legs, the braces, and the cross-arms. The method of analysis for transmission line towers has advanced quite a lot since the first towers were designed. In the beginning, transmission line engineers often had to use graphical analysis methods such as the so-called *Cremona plan* to determine the member forces. However, with the introduction of computers, simulations using the finite element method (FEM) were developed, mostly based on a linear elastic 3-D truss model. Thereby members are assumed to be axially loaded and having pinned connections. For more deformable structures, such as guyed towers or poles, nonlinear

**Fig. 9.147** Schematic for the calculation of the tower member forces

analysis is required. A good overview of computer programs available for line support calculations is given in [9.238].

Nevertheless, it is quite educative to present here some simplified calculations, which can be performed *by hand* and which give quite satisfactory results. For this purpose, when the tower body has, as is often the case, a square cross-section, the external loads acting on the tower are split and deemed to act equally on the two related parallel tower faces, thus the factor 2 in (9.110) and (9.123). In this case, the tower faces can be treated as plane trusses and simple analytical methods can then be applied to determine the member forces.

**Calculation of Tower Member Forces.** The equivalent static system is shown in Fig. 9.147. The easiest approach is to use the method of sections, viz. the so-called *Ritter method*, i.e., to divide the truss into two sections—which evidently have to be in equilibrium with themselves—in such a way that only three members are cut (slices 1–1 and 2–2). Applying, after cutting along 1–1, the equilibrium of moments at node D and assuming that this node is in static equilibrium, it is possible to calculate the load on main member CE as

$$2N_{CE}d \cos \alpha - Ph_2 = 0 . \tag{9.108}$$

Thus,

$$N_{CE} = + \frac{Ph_2}{2d \cos \alpha} . \quad (9.109)$$

Establishing a generic equation with all external loads for calculation of any main member ( $m$ ) we get

$$N_m = \pm \frac{\sum_i M_i}{2d \cos \alpha} , \quad (9.110)$$

where  $N_m$  is the force for any main member ( $m$ ) in tension or compression,  $\sum_i M_i$  is the sum of the moments due to all external loads  $P_i$  above the panel of the main member ( $m$ ) at the node (O) opposite to the considered main member ( $m$ ),  $d$  is the width of the truss in the main member ( $m$ ) or panel, and  $\alpha$  is the inclination angle of the main member in relation to the vertical direction.

Again, looking at Fig. 9.147 and *cutting* along 2–2, it is possible to calculate the load on the diagonal EF by applying the equilibrium equation of moments at point S as

$$-Ph + N_{EF}xh_1 = 0 . \quad (9.111)$$

Thus,

$$N_{EF} = + \frac{Ph}{h_1} . \quad (9.112)$$

But

$$h = \frac{x}{2} \tan \delta , \quad (9.113)$$

$$h_1 = n \sin \beta , \quad (9.114)$$

and with

$$n = \frac{a/2}{\cos \delta} , \quad (9.115)$$

it follows that

$$h_1 = \frac{a}{2 \cos \delta} \sin \beta . \quad (9.116)$$

Taking

$$\frac{b}{\sin \beta} = \frac{l_{EF}}{\sin \delta} , \quad (9.117)$$

one gets

$$\frac{\sin \delta}{\sin \beta} = \frac{l_{EF}}{b} . \quad (9.118)$$

Therefore,

$$N_{EF} = \frac{Px \sin \delta}{2 \cos \delta} \frac{2 \cos \delta}{a \sin \beta} , \quad (9.119)$$

or

$$N_{EF} = \frac{Px \sin \delta}{a \sin \beta} = \frac{Px l_{EF}}{a b} . \quad (9.120)$$

Rearranging leads to

$$N_{EF} = \frac{Px}{ab/l_{EF}} . \quad (9.121)$$

Or, considering two parallel panels as mentioned above,

$$N_{EF} = \frac{Px}{2ab/l_{EF}} . \quad (9.122)$$

Thus, for a generic external load system, the force  $N_d$  on the generic diagonal ( $d$ ) becomes

$$N_d = \pm \frac{\sum_i P_i x_i}{2ab/l_d} , \quad (9.123)$$

where  $N_d$  is the force for any diagonal ( $d$ ) in tension or compression, depending on the direction of that diagonal,  $P_i$  are the external loads applied on the structure above the panel where the diagonal ( $d$ ) is located,  $x_i$  is the truss width at level  $i$  where the load  $P_i$  is applied (i.e.,  $x_1$  at  $P_1$ ,  $x_2$  at  $P_2$ , etc.),  $a$  is the lower truss width in the panel of the diagonal ( $d$ ),  $b$  is the upper truss width in the panel of the diagonal ( $d$ ), and  $l_d$  is the length of the diagonal ( $d$ ).

However, considering that there are often two crossing diagonals per truss panel (a so-called *tension/compression* structural system or just *composed truss*) (Fig. 9.145 cases (c) and (d)), then the generic equation to calculate the member forces on diagonals becomes

$$N_d = \pm \frac{\sum_i P_i x_i}{2 \times 2ab/l_d} , \quad (9.124)$$

where one diagonal is always in tension (+ sign) and the other in compression (– sign).

The maximum leg forces can be obtained by superposition of the individual leg forces coming from the horizontal loads (transverse or longitudinal) on the tower, in  $x$ - and  $y$ -direction, and—in a minor part—by the vertical loads (conductor, tower, and insulator self-weights and ice loads); these are considered to be equally distributed between the four legs. However, note that, as horizontal loads caused by the wind must also be considered in the opposite direction, the same leg will have to be designed for the maximum tension and compression forces.

**Fig. 9.148** Tower member loaded in tension—*net cross section* (adapted from [9.238])

**Selection of Member Size.** The verification and selection of member size to adequately resist the member forces follows the classical, strength of materials approach; For example, a member loaded in tension will have a cross-section large enough to sustain the related tensile material stresses, whereby the derating effect of boreholes needed for the connection elements (bolts) has to be considered, resulting in a *net cross section resistant area* (Fig. 9.148 [9.238]).

According to [9.243, 249], the tensile stress on a tension member can be calculated as

$$f_t = \frac{P}{A_n} \leq f_y, \tag{9.125}$$

with

$$A_n = A_g - nd_0t + t \sum \left( \frac{s^2}{4g} \right), \tag{9.126}$$

where  $f_t$  is the tensile stress on the net area,  $f_y$  the yield strength of the material,  $P$  the axial force acting on the bolt,  $s$  the distance between holes in the direction parallel to the axial force,  $g$  the distance between holes in the direction perpendicular to the axial force,  $A_n$  the net cross section area,  $A_g$  the gross cross section area,  $n$  the number of holes,  $t$  the plate (angle) thickness, and  $d_0$  the hole diameter.

When the load is eccentric, i.e., when the profile is connected on only one side, the cross-section has to be reduced by 10%, thus the effective cross section  $A_e$  becomes

$$A_e = 0.9A_n. \tag{9.127}$$

In the critical case of compression, members experience and ultimately fail in buckling, an instability issue. Thereby, the limit load depends not only on the material properties but also on the geometry of the loaded element. It can reasonably be assumed here that the slender members of steel lattice towers can be considered to be straight and compressed only axially, i.e., neglecting lateral loads on the member, which would cause bending moments. The resistance of a member to compressive loads is determined from buckling curves. Figure 9.149 [9.4] shows such curves from two of the most widely used standards. Therein,  $\lambda$  is the so-called

**Fig. 9.149** Buckling curves as per [9.16] (1, 2) and [9.249] (3) (adapted from [9.4])

**Table 9.46** Slenderness ratio limits

Leg members and chords	$L/i \leq 150$
Primary bracing members	$L/i \leq 200$
Redundant members	$L/i \leq 250$
Tension-hanger members	$L/i \leq 375$
Tension-only members	$300 \leq L/i \leq 500$
Web member—multiple lattices	Not specified
Horizontal edge members	Not specified

slenderness ratio, defined by

$$\lambda = \frac{L}{i}, \tag{9.128}$$

$$i = \sqrt{I/A},$$

where  $L$  is the unsupported buckling length, which depends on the type of bracing (Fig. 9.145), and  $i$  is the radius of gyration around the profile axis perpendicular to the assumed direction of buckling ( $I$  is the second moment of area and  $A$  is the cross-sectional area of the profile).

As per [9.243, 249], the slenderness ratio  $\lambda$  should be limited to the values in Table 9.46.

All members which can be used as steps to climb the tower during erection and maintenance works should be designed to support the related bending loads (due to personnel, equipment, etc.). These are deemed to act in the center of the steel member in question and amount according to [9.16] to 1.0 kN with a partial factor of  $\gamma_p = 1.5$ . For this load case, calculations are performed for a beam hinged at both ends, delivering the maximum allowable member length  $L_{max}$  for commonly used profiles (Table 9.47 [9.4]).

### Connections

The design of the connections follows standard methods from machine elements. Specifically for bolted connections, which are almost exclusively used in steel lattice

**Table 9.47** Maximum length for tower members loaded with 1.0 kN in bending (adapted from [9.4, Sect. 12.5.12])

Section	$L_{\max}$ (m)	
	S235 steel	S355 steel
35 × 4	0.57	0.85
35 × 5	0.68	1.02
40 × 4	0.75	1.12
40 × 5	0.90	1.35
45 × 4	0.95	1.43
45 × 5	1.16	1.74
50 × 4	1.19	1.78
50 × 5	1.46	2.19
50 × 6	1.69	2.54
55 × 4	1.45	2.17
55 × 5	1.77	2.67
55 × 6	2.10	3.15
60 × 5	2.13	3.19
60 × 6	2.52	3.77

towers, the following two loading situations should be considered:

**Shearing of the Bolt.** The cross-section of the bolt is subjected to shear. The related shear stress should not exceed the limit shear stress of the bolt, as presented in Table 9.44 for *single shear* connections (Fig. 9.150a)

$$f_v = \frac{N}{nA_g} \leq F_u, \quad (9.129)$$

or, for *double shear* (Fig. 9.150b),

$$f_v = \frac{N}{2nA_g} \leq F_u, \quad (9.130)$$

where  $f_v$  is the shear stress acting on the bolt,  $N$  is the force acting on the joint,  $n$  is the number of bolts in the joint,  $A_g = \pi D^2/4$  is the cross section of the bolt with  $D$  being the bolt diameter, and  $F_u$  is the ultimate shear stress of the bolt.

**Bearing Pressure.** The shearing forces are introduced to the bolt shank through the bearing pressure on the

bore face of the profile (Fig. 9.150c). This can be calculated for *single shear* connections as

$$f_p = \frac{N}{nDt} \leq F_p \quad (9.131)$$

and for *double shear* connections as

$$f_p = \frac{N}{2nDt} \leq F_p, \quad (9.132)$$

where  $f_p$  is the bearing stress acting on the bore hole,  $N$  is the force acting on the joint,  $n$  is the number of bolts in the joint,  $D$  is the nominal bolt diameter,  $t$  is the plate thickness, and  $F_p$  is the ultimate bearing stress.

It should not exceed the ultimate tensile strength of the related profile (Table 9.44).

### Prototype Tests

It is current practice for new OHL support designs to be validated by full-scale prototype tests [9.250]. Clients, designers, and tower manufacturers meet in a test facility area at a so-called *test station*, for simulation of all the extreme operational conditions to be supported by the structure during its expected lifetime. IEC standard [9.251] provides the basis for the performance of all such full-scale prototype tests around the world.

Full-scale tests are carried out on tower prototypes to verify the design method and related assumptions, the detailing process, as well as the quality of the materials and fabrication procedures. In this sense, full-scale tests are performed in the following circumstances:

- To verify the compliance of the support design with the specifications, known as *type tests*
- To validate the fabrication process
- As part of the research and development of an innovative support.

The tests to be performed can be of *normal* or *destructive* type. They are considered to be *normal tests* when they are carried only up to 100% of the specified design loadings. As a general rule, all loading cases that are critical for any support member should be simulated during the normal tests. On the other hand, *destructive*

**Fig. 9.150a–c** Schematic of single (a) or double shear (b) and bearing pressure on bolted connections (c)

**Fig. 9.151** Visual side-by-side comparison of conventional and compact 420-kV lines with the same power transfer capacity (adapted from [9.252])

tests are carried out to provide information on the actual versus predicted behavior or, in case of suspension towers, to determine the real failure load and then judge whether the result is acceptable in terms of security and cost.

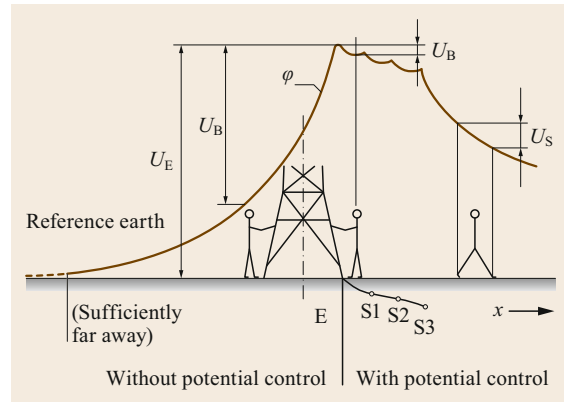

### 9.7.6 Esthetic or Landscape Supports

As mentioned above, in recent decades, there has been considerable resistance from the public against new—and even existing—overhead lines, the suggested alternative being underground cables (Chap. 10). One concern is often the purported health hazards related to EMF (Sect. 9.3.4), the other being the supposedly disturbing visibility of overhead lines in the landscape. Evidently, the visual impact of a line is mainly caused by the shape and appearance of its supports, thus it is no surprise that network owners and line designers started addressing these concerns early on, leading to the development of so-called *esthetic* or *landscape* supports, which are briefly presented below.

For this type of supports, CIGRE prepared a seminal publication [9.235], which includes practically all available information on esthetic supports. Their development has followed basic ideas to:

- Compact the lines and the supports as much as possible
- Reduce the number of structural elements on the towers
- Make them invisible or camouflaged in the landscape.

The next step was to design esthetic solutions for unique places, for a single line, or to develop standard esthetic solutions. A good example of a unique support

**Fig. 9.152** Voltage distribution close to the support in case of a fault ( $U_E$  earthing voltage,  $U_B$  touch potential,  $U_S$  step voltage,  $\phi$  surface potential,  $S_1, S_2, S_3$  ring electrodes connected to the earth electrode E for earth potential control,  $x$  distance to the earth electrode E) (adapted from [9.4])

is the *pylône raquette* (tennis racket tower) in Switzerland (Fig. 9.99), which helped the approval of a badly needed new 400-kV line [9.135].

Recently, and with the general acceptance by utilities of composite insulators, the so-called compact lines with improved esthetics are gaining ground (Sect. 9.5.5 [9.253]). They are becoming the choice of preference in many countries, to facilitate the construction of new lines, also in cases with limited space (Fig. 9.151 [9.252]).

### 9.7.7 Earthing

Earthing or grounding systems are installed in the structures of a transmission line with the following primary objectives [9.254]:

- To provide a preferential path to earth for currents generated by faults in the line
- To provide a grounding system with a resistance low enough to enable the overcurrent protection to detect a ground fault in the line
- To provide a preferential path to earth for lightning discharge currents
- In urban areas, to control the step and touch voltages generated during ground faults on the line
- To reduce the rise in the ground potential of the structure during a lightning discharge and thereby the probability of occurrence of *back-flashover*.

When a phase-to-ground fault occurs on an overhead line, one of the most probable paths of the current flow is to or from earth. This results in a potential rise on the grounded support and voltage gradients

**Fig. 9.153** Schematic of the Wenner four-point method (adapted from [9.255])

on the surface of the ground surrounding the support (Fig. 9.152 [9.4]). Requirements to protect the public in the vicinity of grounded line supports from the hazard of electrical shock caused by power frequency faults were presented in a recent CIGRE publication [9.255], whereby the related methods can also be applied in the case of faults caused by lightning and related overvoltages (Chap. 3). The earthing resistance of the electrode for a given current discharge is the ratio of the potential difference between the electrode and a distant point on the earth, in volts, and the current discharge in amperes. It consists of three parts:

1. Resistance of the electrode itself and its connections
2. Contact resistance between the electrode and the adjacent soil
3. Resistance of the surrounding earth.

A low value of the tower earthing resistance, with  $10\ \Omega$  often being recommended, is a prerequisite to reduce the possibility of back-flashovers: When lightning strikes a tower (or the overhead ground wires), the current on the tower in combination with the earthing resistance causes a rise of the tower voltage, which becomes much larger than the phase conductor voltages. If this voltage difference exceeds a critical value, a flashover occurs, called *back-flashover*. The term *back* refers to the fact that the highest voltage is on a part of the power system normally at ground potential, i.e., the tower or the shielding wires.

To design a grounding system, the soil resistivity must be known. Typical values are indicated in Table 9.48 [9.16]. For more accurate results, the soil resistivity should be measured in situ. This is commonly done by the *Wenner four-point method* (Fig. 9.153 [9.255]). As the probe penetration depth  $b$  is practically always much smaller than the distance  $a$  between the electrodes, the soil resistivity  $\rho_E$  can be determined accurately enough by

$$\rho_E = 2\pi aR, \quad (9.133)$$

where  $R$  is the measured resistance ( $R = V/I$ ).

**Table 9.48** Typical soil resistivities (adapted from [9.16])

Type of soil	Soil resistivity $\rho_E$ ( $\Omega\text{m}$ )
Marshy soil	5–40
Loam, clay, humus	20–200
Sand	200–2500
Gravel	2000–3000
Weathered rock	Mostly below 1000
Sandstone	2000–3000
Granite	Up to 50 000
Moraine	Up to 30 000

Details of earthing calculations can be found in [9.4, 16, 254, 255].

The worldwide practice regarding overhead lines is to solidly earth the earth wires at each tower as well as solidly earth the tower to the ground. For the latter, the following methods are widely used (often in combination):

- Connection of reinforcing of foundation to tower steel
- Counterpoise conductor laid in a horizontal trench
- Earthing rods driven at the base of the tower.

The dimensions of the earth electrodes and earthing conductors should be rated such that the permissible temperature of  $300\ ^\circ\text{C}$  for copper and steel or of  $200\ ^\circ\text{C}$  for aluminum will not be exceeded.

Mechanical strength and *corrosion resistance* determine the minimum dimensions of electrodes and earthing or bonding conductors. In this sense, the minimum cross section for earthing conductors is  $16\ \text{mm}^2$  for copper,  $35\ \text{mm}^2$  for aluminum, and  $50\ \text{mm}^2$  for steel. Electrodes having direct contact to earth should withstand mechanical or biological attack, oxidation, formation of an electrolytic couple, and electrolysis. The dimensions listed in Table 9.49 [9.16] comply with these requirements.

### 9.7.8 Lightning Protection

Lightning discharges (Chap. 3) constitute the main cause of most nonprogrammed outages of electric systems. International statistics show that about 65% of *line outages* originate from lightning strokes that hit the overhead transmission lines [9.256]. However, it is possible to reduce the number of line outages to an acceptable level by using a convenient protection scheme, with adequate installation of earth wires and appropriate earthing of the towers.

While protection issues as a whole are covered in Chap. 13, earthing issues were discussed in the previous section, and lightning protection by earth wires is briefly treated below. An excellent overview of the lightning

**Table 9.49** Minimum dimensions of earth electrode materials ensuring mechanical strength and corrosion resistance (adapted from [9.16])

Material	Steel	Type of earth electrode	Minimum size			Coating/sheath		
			Core Diameter (mm)	Cross section (mm <sup>2</sup> )	Thickness (mm)	Single value (μm)	Average values (μm)	
Steel	Hot-galvanized	Strip <sup>a</sup>	–	90	3	63	70	
		Profile (inc. plates)	–	90	3	63	70	
		Pipe	25	–	2	47	55	
		Round bar for earth rod	16	–	–	63	70	
		Round bar for surface earth electrode	10	–	–	–	50	
		With lead sheath <sup>b</sup>	Round wire for surface earth	8	–	–	1000	–
	With extruded copper sheath	Round bar for earth rod	15	–	–	2000	–	
	With electrolytic copper sheath	Round bar for earth rod	14.2	–	–	90	100	
	Copper	Bare	Strip	–	50	2	–	–
			Round wire for surface earth	–	25 <sup>c</sup>	–	–	–

Pipe			20	–	2	–	–	
Tinned		Stranded cable	1.8 <sup>d</sup>	25 <sup>c</sup>	–	1	5	
Galvanized		Strip <sup>a</sup>	–	50	2	20	40	
With lead sheath <sup>b</sup>		Stranded cable	1.8 <sup>d</sup>	25 <sup>c</sup>	–	1000	–	
		Round wire	–	25 <sup>c</sup>	–	1000	–	

<sup>a</sup> Strip, rolled, or cut with rounded edges, <sup>b</sup> not suitable for direct embedding in concrete, <sup>c</sup> in conditions where experience shows that the risk of corrosion and mechanical damage is extremely low, 16 mm<sup>2</sup> may be used, <sup>d</sup> diameter of single wire

**Fig. 9.154** Shielding angle  $\theta$  and protected area of an earth wire for a Danube-type tower (adapted from [9.258])

performance of overhead transmission and distribution lines is given in [9.257]. In regions with high or even medium *keranic* levels, it is standard practice to equip transmission lines with earth wires to shield them against lightning discharges, as these can cause, if the *lightning stroke* hits the conductors directly, considerable damage and even conductor failures.

Earth wires are installed with shielding angles  $\theta$  that usually vary between  $10^\circ$  and  $35^\circ$ , depending on the importance of the line and the *keranic* level (Fig. 9.154 [9.258]).

## 9.7.9 Foundations

Foundations are the last part in the chain of load transfer from the external loads on an OHL to the ground; their role and consequently their proper design are crucial to the reliability and safety of the line. Foundation design faces considerable challenges, as it is closely related to the properties of the soil, which are not always easy to determine, while the soil conditions may also vary considerably along the route of the line. For this reason, serious consideration should be given to site investigations, and it is good and current practice to adopt an additional safety coefficient for foundation design of 1.10–1.20 (depending on the tower type) in comparison with normal tower design.

### Site Investigations

Evaluation using various in situ tests together with an indication of geotechnical information that may be derived from in situ test results (Table 9.50 [9.259]) and

**Table 9.50** Comparison of ground investigation methods (adapted from [9.259])

Method	Advantages	Disadvantages
Trial pit	Allows detailed examination of ground conditions Easy to obtain discrete and bulk samples Rapid and relatively inexpensive	Limited by machine size Not suitable for sampling below water or excavation in rock Greater potential for disruption/damage to site than boreholes or probe holes Depth restricted to 4.5 m below ground level Width and height restrictions of equipment
Cable percussion	Allows greater sampling depth than with trial pits, window sampler, or probing Can penetrate most soils Allows collection of undisturbed samples Enables installation of permanent sampling/monitoring wells	Not suitable for investigation in rock Smaller sample volumes than for trial pits More costly and time-consuming than trial pits Width and height restrictions of equipment
Rotary boring	Allows greater sampling depth than with trial pits, window sampler, or probing Can penetrate all soils and rocks Allows collection of undisturbed samples Enables installation of permanent sampling/monitoring wells	Smaller sample volumes than for trial pits More costly and time-consuming than trial pits Width and height restrictions of equipment
Window sampler	Allows greater sampling depth than with trial pits Undisturbed samples of the complete soil profile can be recovered A variety of measuring devices can be installed once a hole is formed Substantially faster than cable percussion Portable, so can be used in areas with poor or limited access	Not suitable for investigation in rock and cannot penetrate obstructions Depth restricted to 8 m under favorable circumstances Smaller sample volumes than for trial pits Poor sample recovery in noncohesive granular soils Width and height restrictions of equipment
Cone penetration test (CPT)	Allows greater sampling depth than with trial pits Substantially faster than cable percussion	Not suitable for investigation in rock and cannot penetrate obstructions No sample recovery Ground water level not recorded Width and height restrictions of equipment
Dynamic probing	Essentially a profiling tool Portable, so can be used in areas with poor or limited access Very quick and inexpensive	Not suitable for investigation in rock and cannot penetrate obstructions No sample recovery Ground water level not recorded

laboratory tests for determining specific geotechnical design parameters (Table 9.51 [9.260]) are also often used to complement the field observations.

### Foundation Types

Foundations can be categorized as follows:

- Compact foundations:
  - Monoblocks
  - Direct embedment
- Separate foundations
- Spread footings
- Drilled shaft foundations
- Piles
- Anchors
- Raft foundations
- Grillage foundations.

There are also various subcategories. For example, anchor foundations can be divided into various types as shown schematically in Fig. 9.155 [9.259].

### Foundation Design

Basically, all foundation designs should comply with the following main stability conditions:

- The capacity to support the loads coming from the towers
- The ability to distribute them in a manner compatible with the soil capacity in terms of compression, uplift resistance, and shear stresses.

The design of concrete monoblock foundations for poles was briefly presented in Sect. 9.7.2. Hereunder, the focus is on the basic design of typical foundations

**Table 9.51** Laboratory tests—geotechnical design parameters (adapted from [9.260])

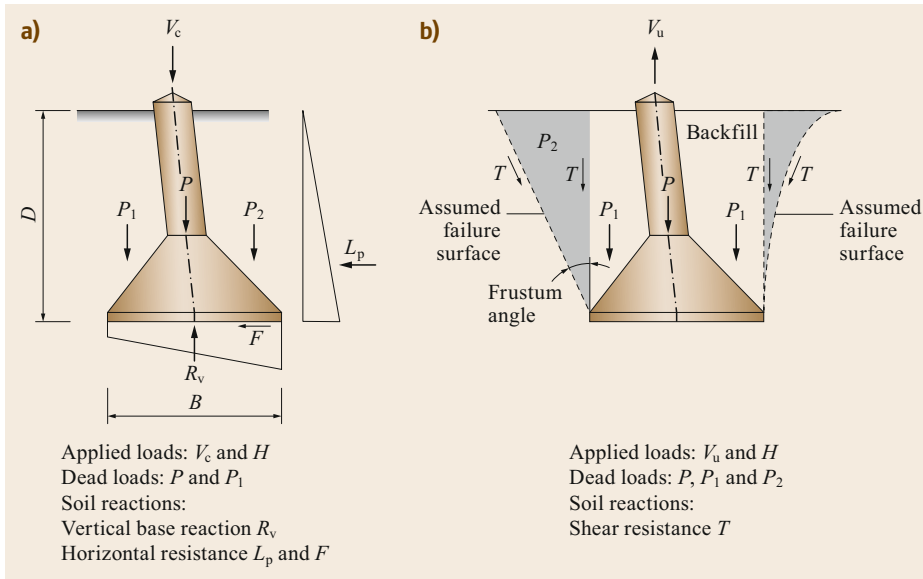

Category of test	Name of test or parameter measured	Remarks
Classification	Moisture content	Used in conjunction with liquid and plastic limits, it gives an indication of undrained strength
	Liquid and plastic limits (Atterberg limits)	To classify fine-grained soil and fine fraction of mixed soil
	Particle size distribution	Identification of soil type
	Mass density	
Soil strength	Triaxial compression	Both undrained and drained tests or undrained tests with measurement of pore pressure and required
	Unconfined compression	Alternative to undrained triaxial test for saturated nonfissured fine-grained soil
	Laboratory vane shear	Alternative to undrained triaxial test or unconfined compression test for soft clays
	Direct shear box	Alternative to the triaxial test for coarse-grained soils
Soil deformation	One-dimensional compression and consolidation tests	Compressibility indices for the in situ soil
Rock strength	Uniaxial compression and point load test	
Chemical	Mass loss in ignition	Measures the organic content in soils, particularly peat

**Fig. 9.155** Different types of anchor foundations (adapted from [9.259])

for steel lattice towers, and in particular of separate foundations for each tower leg, these being the most common type for high-voltage lines.

Each leg of a steel lattice tower and subsequently the related foundation must be able to sustain both

compression and uplift loads, as both wind directions perpendicular to the line axis have to be considered. Table 9.52 [9.261] provides an indication of the magnitude of the loads on the foundation for different voltage levels and tower types.

**Fig. 9.156a,b** Free body diagram of spread foundations: (a) compression, (b) uplift (adapted from [9.259])

**Fig. 9.157a,b** Free body diagram of drilled shaft foundations: (a) compression, (b) uplift (adapted from [9.259])

**Table 9.53** Soil parameters

Parameter	Sand	Clay
Frustum angle ( $^\circ$ )	30–35	10–20
Shear resistance (N/mm $^2$ )	0	20–40

**Table 9.52** Forces on legs of steel lattice towers (adapted from [9.261])

Tower type	Voltage (kV)	Uplift (kN)	Compression (kN)
Suspension	110	10–25	12–30
	220	20–40	25–50
	380	30–150	40–180
Tension	110	30–60	35–80
	220	40–100	80–120
	380	80–200	100–350
Special (e.g., river crossing)		$\leq 400$	$\leq 450$

**Fig. 9.158** Anchoring of steel leg members in the concrete foundation (adapted from [9.4])

**Fig. 9.159** Full-scale test arrangements for a rock anchor foundation (adapted from [9.259])

The compressive loads are mainly resisted by the allowable soil pressure at the bottom of the foundation, and the uplift loads by the weight of the soil contained within an assumed failure surface. In some cases, also the shear forces acting at the surface of the foundation body in contact with the soil are taken into account. This concept is shown schematically in Figs. 9.156 and 9.157 for spread and drilled shaft foundations, respectively [9.259].

According to this design concept, the soil parameters are crucial; they can be determined from soil investigations and laboratory tests as explained above, but also from previous experience. For an initial assessment, the values in Table 9.53 are often used.

## 9.8 Construction

The construction of a high-voltage overhead line is a complex undertaking, being unique due to the fact that very few if any construction sites are so extended as a transmission line site. This requires high logistical skills but also considerable geotechnical expertise, as the soil and thus foundation type can and in most cases will change drastically along the line route. In addition, line construction encompasses the stringing of long lengths of conductors, which is a very special and demanding process not required in other construction works. In this sense, line construction has to

*Anchoring of leg members (stubs) into the concrete can be carried out either using additional cleats or by bonding between the leg member stubs and the concrete alone (Fig. 9.158 [9.4]). Usually, a connection just above ground level, between the lower main member and the stub itself, is provided to enable physical separation between the tower and the respective foundation. This practice is important for tower erection, but also facilitates the installation of a new tower over the existing foundation in case of tower failure.*

For system-critical lines and/or extreme soil conditions, full-scale foundation tests—primarily for uplift—are recommended, being by nature complex and costly, as is evident from Fig. 9.159 [9.259]. Thereby, the load on and displacement of the foundation are recorded.

follow highly demanding quality standards, also because the life expectancy of lines is set quite high by the asset owners, with values of 40–70+ years not uncommon, and some lines over 100 years old still being in service. In this sense, line construction considerably influences line maintenance, as it may initiate the application of suitable maintenance practices, including hot line techniques and robotics, as in most cases lines cannot be easily disconnected from the network for maintenance and/or repair purposes. Other challenges worth mentioning are difficulties with access and the

need to work in parallel on many fronts with many crews.

### 9.8.1 Survey and Tower Spotting

The on-site activities start with the transfer of the selected route to the terrain, in particular by fixing the angle points. The line axis is designed as a straight connection of the line angle points. Along the line axis, center-line beacons are installed to identify and secure the line. This step is called line alignment. A survey of the longitudinal profile follows, whereby the terrain and all objects within the right of way are surveyed, such as roads, stretches of water, buildings, and trees. The pegging of the support sites, characterized by their centers, and the survey of diagonal profiles at tower sites in inclined terrain, complete the survey activities on site.

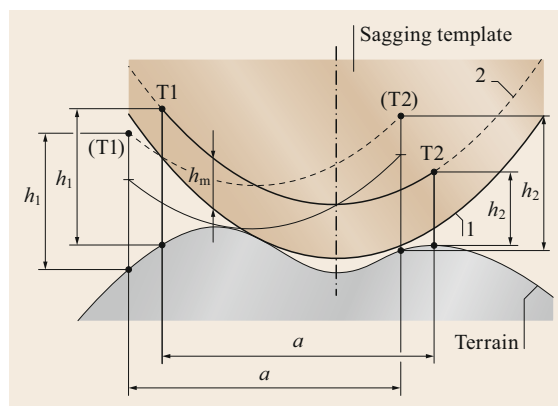

As in other fields, survey procedures have profited greatly from digitalization and automation. While in the past surveys were carried out using classical topography methods, i.e., using tachymeters, nowadays the process is accelerated and simplified and its accuracy improved, either by the use of so-called total stations, i.e., automatically recording theodolites, or with the help of real-time global positioning system (GPS) systems. Both approaches enable the measurement, correction, and immediate evaluation directly on site with a mean precision of profile points below 10 mm over distances up to 3 km [9.4, Sect. 15.3].

So-called indirect survey systems are also often used to record the route corridor, either based on photographs (*aerial photogrammetry*) or using signals obtained by scanning.

The more recently developed light detection and ranging (lidar) method adopts rotating lasers installed on an airplane or helicopter to scan the Earth's surface and existing installations such as overhead lines.

Using GPS, the position of the helicopter can be controlled to provide a continuous three-dimensional determination of the laser positions. The helicopter flies at approximately 100 m above the ground at around 50 km/h. The laser scanning method enables one to survey the position of any objects in three dimensions. It is possible to scan 200 km of lines per day, whereby digital profiles are obtained with the relevant information on the terrain, infrastructure, and existing lines.

As a result of the terrain survey, a longitudinal profile of the line route with all information relevant for the detailed line design such as type of terrain and utilization, crossed traffic roads, waters, and railways is available. In the next step, the support locations have to be defined and the support types and heights determined; this is known as tower spotting, which in the past was done manually by the design engineer. Although nowa-

**Fig. 9.160** Manual tower spotting with the aid of a sagging template (1: ground clearance curve; 2: conductor catenary curve; T1: suspension tower 1; T2: suspension tower 2;  $h_1$ : height of T1;  $h_2$ : height of T2;  $h_m$ : minimum ground clearance;  $a$  span length) (adapted from [9.4])

days this process is carried out by specialized computer programs, it is instructive to understand its basic principles (Fig. 9.160 [9.4]). The route profile drawing and a template showing the catenary to the same scale as the profile drawings were used, and a so-called sagging template was produced based on the sags related to the expected equivalent span (ruling span, Sect. 9.4.4) and maximum conductor temperature. In parallel to the ground curve, which is represented by the edge of the template, the conductor catenary is shown at a distance according to the stipulated ground clearance. If the template touches the terrain, this parallel curve represents the conductor position and enables the conductor attachment points to be determined and the clearances to crossed objects to be checked.

### 9.8.2 Transportation and Site Clearance

Line construction is basically a serious logistics issue, as heavy material has to be transported and correctly deposited at construction sites—the tower locations—which are a few hundred meters apart and often span from the beginning to the end of the line over distances of many—sometimes hundreds—of kilometers. This activity is combined with the construction of access roads required to bring in materials and construction equipment to the individual tower sites and also for the clearing of the ROW of the line from vegetation, as this, if left to grow, can cause—and has caused—serious operational problems, such as persisting earth faults. Clearing techniques range from the use of shear blades to remove most of the vegetation to the use of chain saws to remove individual trees as well as manual methods in sensitive, selective clearing areas.

### 9.8.3 Foundations

Foundations provide stability to the supported structures and protection from extensive deformation or failure; if not constructed properly, the consequences for the overall transmission line system can be catastrophic. Publication [9.262] provides a comprehensive overview of various foundation options and also contains an installation guide, a review of health and safety concerns, as well as an assessment of the environmental impacts and various mitigation measures. On the other hand, [9.263] deals with the installation of the micropiles and ground anchors that are often used for terrain with poor soil conditions or difficult access. An additional source of good information on foundation installation is the standard [9.264].

#### Excavation

The foundation installation process starts with excavation. To start with, a trial pit is excavated at a structure site to identify the soil conditions. Hydraulic excavators are often used for the excavation in normal soils such as clay. Excavations with unshielded walls may only be performed in unsaturated soils and while maintaining safe wall inclination. In rock, hydraulic hammers or explosives may be required. Other construction equipment used in excavations include trucks, energy generators, vibration plates, jumping jacks, vibration hammers, levelers, etc. During excavation, water should be prevented from entering the foundation excavation; when required, an appropriate drainage system is used. During foundation works, increasingly extensive—and costly—measures are required to minimize the negative impact on the environment and surroundings.

#### Concrete and Reinforcement Works

In a first step, the tower stub angles are positioned in the excavation prior to insertion of the steel reinforcement. Proper alignment of the steel stub angles is achieved by the use of rigid steel templates. The reinforcement bars/rods should be joined by means of tie wire or welding. To ensure proper setbacks, plastic distance holders providing a minimum distance between the reinforcement and formwork are used.

The concrete used in foundation works may be mixed directly at or delivered to the site from a concrete mixing plant. While pouring the concrete in the foundation pit, the free drop height of the concrete mix should be made as small as possible, i.e., should not exceed 100 cm. After pouring, the most widespread method of concrete consolidation is vibration. In practice, vibrations are applied to the mix for 10–30 s using internal or external vibrators. Proper concrete curing is essential to achieve the desired mechanical parameters. The concrete, particu-

larly in the summer time, requires proper humidity to be maintained. Unrestricted water evaporation can lead to undesired concrete shrinking. Therefore, the concrete must be protected from water loss due to extensive wind and temperature, using a special curing compound, covering with foil, or pouring with water.

#### Backfilling

Backfilling is crucial to achieve the desired uplift resistance; i.e., the main target of proper backfilling is to achieve soil characteristics close to those of natural soil, the most popular method being the compacting of the backfill. For this purpose, noncohesive backfill should be placed in layers of 20–25 cm and compacted using vibration plates, jumping jacks, or vibration hammers. Compaction can be improved by dampening the filling with water. Another method for increasing the load-bearing capacity is stabilization with cement. Cohesive soils should be condensed in layers every 20–25 cm, using nonhammering methods, e.g., tamping rollers or vibration plates. Dampening the filling soil with water is in this case a gross mistake.

### 9.8.4 Supports

Essential for the efficient erection of steel lattice towers, the most common type of line supports in all parts of the world, is good logistical planning, as multiple resources are active simultaneously on site and also large quantities of steel angles, nuts and bolts, and gusset plates have to be delivered from a marshaling yard called the *cemetery* at the different tower locations bundled by *component*.

#### Tower Erection

This is amongst the activities posing the highest safety risks to the construction crews, and therefore it requires special individual and collective protection and strict compliance with safety rules. As a general safety rule, every piece of equipment, tools, ropes, pulleys, hooks, safety clamps, etc. must be inspected, calibrated, and have their nominal capacity tested and certified, prior to release to sites and being put into service. There are four main methods of erection of steel lattice transmission towers, as described below.

**Manual Method.** This method consists of building the tower, member by member, from the bottom upwards. The tower members are laid down serially on the ground according to their sequence and as close as possible to their erection position, to avoid delays. While this approach is still used extensively in many parts of the world, it is a labor-intensive and low-productivity method and is only suitable if the use of heavy equip-

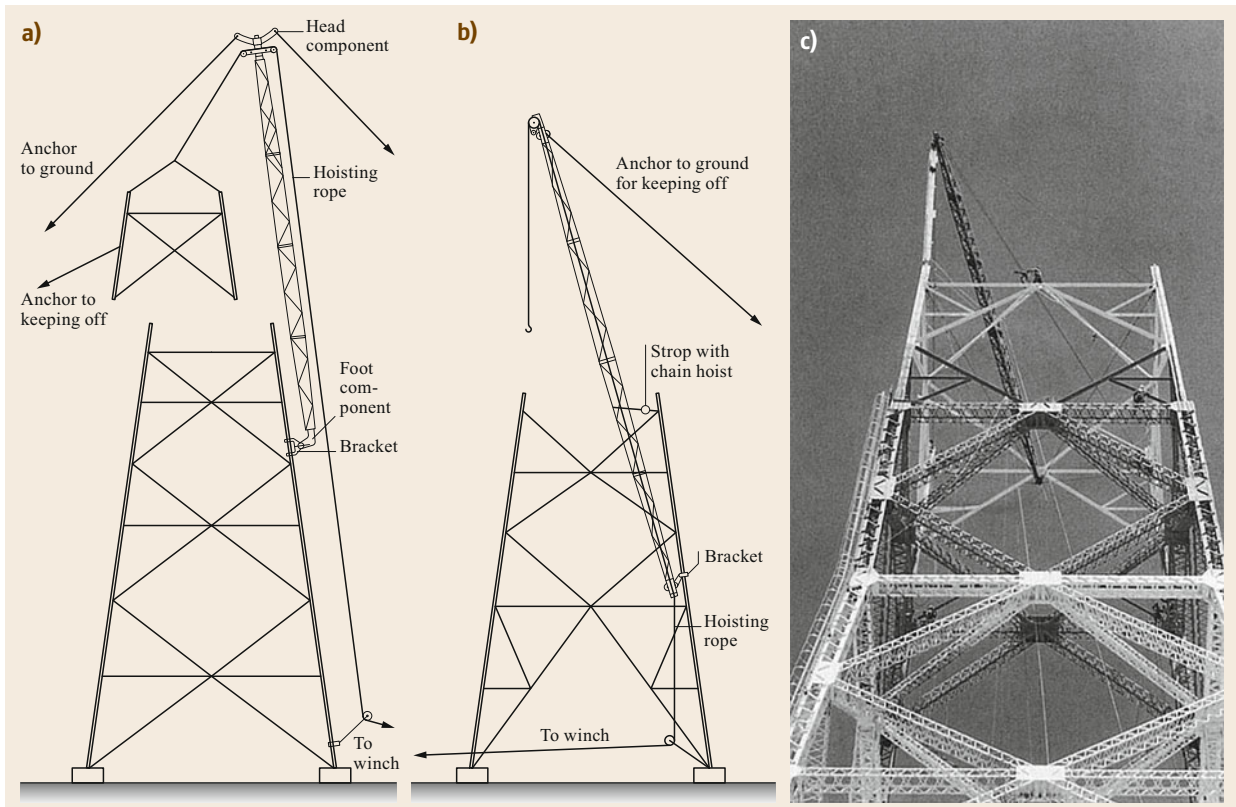

Fig. 9.161a–c Erection with a gin pole outside (a), inside (b), and at the center (c) of the tower body (adapted from [9.4])

ment, such as a crane or helicopter, is not feasible and there is qualified and cheap labor available, and/or access to the tower location is difficult.

**Section Method.** This method consists of preassembling the major sections of the tower on the ground and then rigging and lifting them using a gin pole. The gin pole used consists of a steel or aluminum truss-type beam, approximately 10 m long and held in place by means of guys. We distinguish between an *outside* and an *inside* gin pole (Fig. 9.161a,b), and a gin pole at the center of the tower (Fig. 9.161c); the picture shows the erection of the tower for the Suez Canal crossing, the latter being especially suited for towers with large width and/or at tower locations with limited space, as no anchors to the ground are necessary.

**Tilting Method.** This method consists of assembling the whole tower or part of it on the ground and then lifting it as a complete unit using a mobile crane (Fig. 9.162). This is the most productive method for the erection of self-supporting towers, particularly in flat terrain with good access conditions.

Fig. 9.162 Lifting of the upper part of a 400 kV Danube type tower (photo Eduard Steiner AG/CH)

**Fig. 9.163** Tower erection using a helicopter (photo Edward Steiner AG/CH)

**Helicopter Method.** The use of helicopters may be advantageous when towers have to be erected within very short periods of time, lines are converted, or access is difficult, e.g., in mountainous terrain. The use of helicopters, however, is expensive and connected with stress for the erection staff, and to a great extent weather dependent. To achieve an economic advantage, the components of the tower are preassembled on the ground surface corresponding to the capacity of the helicopter used (Fig. 9.163). It may be worth mentioning that helicopters have weight-lifting limitations of up to 8000 kg.

Wood, concrete, and steel poles are often erected by manual tilting, with the use of cranes, or in difficult terrain by helicopters.

**Installation of Bolts.** After erection, the bolts (and nuts), which have been placed but not fully tightened in order to give the structure some flexibility to sus-

tain erection loads, have to be fixed (a torque wrench is mandatory), observing the prescribed torques as per Table 9.54 [9.4].

### 9.8.5 Conductor Stringing

Installation of overhead conductors is unique, as its theater of activities is a long, narrow corridor of a few kilometers in length, being considered by many to be the most challenging task in transmission line erection. Careful planning and a thorough understanding of pull requirements and stringing procedures are needed to prevent damage to the conductor during stringing operations. The selection of stringing sheaves, tensioning methods, and measurement techniques are critical factors in obtaining the desired sagging results. Conductor stringing, sagging equipment, and techniques are discussed in detail in [9.265]. There are three stringing methods: the tension method, the slack method, and the helicopter method. These are briefly described below.

#### Tension Method

By far the most common method used for conductor stringing is the tension method. In this method, the conductor reel is mounted on a payoff that is capable of applying a braking force to the reel to maintain tension on the conductor. The conductor is then strung (or *reeved*) through a multigroove bull-wheel tensioner so that the conductor is under tension during pulling and is not allowed to contact the ground (Fig. 9.164 [9.4]). At the other end of the line section to be strung, i.e., between two strain towers, sits the nowadays hydraulically driven, *twin bull-wheel puller*, in order to haul the conductor, but also the pilot and/or the pulling rope.

It is important to coordinate the bull-wheel speed with the puller speed to prevent excessive sagging or dynamic loading (*jerking*) of the conductor during the pull. In a typical tension stringing operation, blocks, also known as *travelers* or *sheaves*, are attached to each structure or the end of an insulator string. For new constructions, a pilot line is pulled through the blocks and used to pull in a heavier pulling line, which is then used to pull the conductor through the blocks, while for re-conductoring applications, the existing conductor can be transferred to the blocks at each tower, then connected to the new conductor and used to pull in the new conductor as it is removed.

**Table 9.54** Typical torques for bolt tightening (adapted from [9.4])

Bolt type	M12	M16	M20	M22	M24	M27
Bolt diameter (mm)	12	16	20	22	24	27
Torque (N m)	40–60	80–120	130–180	190–230	300–340	475–610

Fig. 9.164 Stringing of a twin bundle conductor (adapted from [9.4])

#### Slack or Layout Method

Slack stringing of a conductor is limited to lower-voltage distribution lines and smaller conductors, where some surface damage is tolerable. The conductor reel(s) are placed on reel stands (*jack stands*) at the beginning of the stringing location. The conductor is unreeled from the shipping reel and dragged along the ground by means of a vehicle or pulling device. This method requires heavy traffic in the ROW and is not recommended for transmission applications.

#### Helicopter Method

Helicopters are engaged in stringing operations in case of terrain with difficult relief and poor accessibility to the support locations and at the same time reduce construction time considerably. The main tasks are as follows:

- Linemen are transferred via helicopter to each structure, where they climb the towers. They then hang the stringing wheels on each conductor suspension point, i.e., at the line end of the insulator string.
- Synthetic rope is hooked onto the helicopter and pulled through the stringing wheels.
- Wire rope is connected and pulled back the opposite way through the stringing wheels.

Fig. 9.165a,b Basket grip (a) and swivel (b) (adapted from [9.266])

- The conductor is connected and pulled back through the stringing wheels using a puller located on the ground, as in most cases it is too heavy to be pulled by the helicopter.
- The stringing wheels are removed from each suspension point.

#### Ancillary Equipment

During stringing, it is necessary to use the proper tool to grip the conductor strands evenly to avoid damaging the outer layer of wires. The preferred grip type is often referred to as a *basket grip* (Fig. 9.165a). It is often used because its flexibility and small size make it

**Fig. 9.166** Single lined block (adapted from [9.266])

easily pulled through blocks during the stringing operation. A *swivel* should be installed between the pulling grip and pulling line, or between grips when double-socked, to allow free rotation of both the conductor and the pulling line (Fig. 9.165b) [9.266].

Also crucial to the success of stringing is the use of proper stringing blocks (Fig. 9.166 [9.266]). These consist of one or more sheaves or pulley wheels enclosed in a frame to allow their suspension from insulator strings and with a latching mechanism for insertion and removal of the conductor during the stringing operation. Blocks are designed for a maximum safe working load, which must not be exceeded during pulling or sagging.

Sheaves are often lined with neoprene or urethane to prevent scratching of the conductor, while the block diameters (at least 20 times the conductor diameter) and groove design must be properly sized for the conductor being used. Proper maintenance is essential, since high longitudinal tensile loads can develop on transmission structures if a block should *freeze* during tension string-

**Fig. 9.167** Sagging thermometer (adapted from [9.266])

ing, possibly causing conductor and/or structure damage and posing a safety risk to the construction crews.

Since most sagging information is given relative to the conductor temperature, a sagging thermometer (Fig. 9.167 [9.266]) should be used to accurately determine the temperature of the conductor. This handy equipment contains a bimetal thermometer mounted on a short piece of a conductor mock-up, allowing the user to accurately determine the temperature of the conductor being sagged and not just the ambient temperature.

### Sagging

Once the conductor has been pulled in and is lying in the blocks, the conductor can be pulled up to the design or *sagging* tension, as determined in Sect. 9.4.4. For this purpose, a grip is applied to the free end of the conductor and the grip is attached to a ratcheting tensioning device, like a come-along, to pull the conductor up to sag.

There are three different methods available for sagging lines, using a transit, a stopwatch, and a dynamometer. Publication [9.265] lists three methods of sagging conductors with a transit: *calculated angle of sight*, *calculated target method*, and *horizontal line of sight*. In the stopwatch method, by initiating a pulse on a tensioned conductor and measuring the time required for the pulse to move to the nearest termination and back, the tension and sag of the conductor can be determined. Sagging with a *dynamometer* is sometimes used for small conductors over one or two spans.

Last but not least, sagging must consider the unavoidable conductor creep described in Sect. 9.4.3. To provide for creep, the conductor sag should be calculated not for the ambient temperature during sagging but for a lower temperature; the temperature difference  $\Delta T$  can be calculated from

$$\Delta T = \frac{e}{\alpha}, \quad (9.134)$$

where  $e$  is the creep strain (Sect. 9.4.3) and  $\alpha$  is the coefficient of thermal expansion of the conductor (Sect. 9.4.4).

Often, crews wait some days or even weeks before fixing the conductor in the clamps in order for the conductor creep to have settled.

OPGW stringing is similar, but typically involves fiber splicing, a specialized activity.

### 9.8.6 Installation of Conductor Hardware

For installation but also inspection and maintenance, it is common to work in-span on the conductors, shield wires, and perhaps optical ground wires (OPGW). This

**Fig. 9.168** Spacer installation on a horizontal twin bundle with the help of a cart [9.267] ◀

is often done by using carts or man-baskets, although sometimes the work is done without any apparatus at all to support and transport the person(s) on the wires. Working in-span on conductors is common, especially when accessibility using alternative methods such as the use of bucket trucks, cranes, or helicopters is problematic or restricted. Carts are wheeled rigs that ride along single and bundle conductors, ground wires, and OPGW. Typical examples of their use are for installation of spacers, dampers, or aircraft warning markers (Fig. 9.168 [9.267]).

## 9.9 Maintenance

### 9.9.1 Maintenance Activities and Strategies

Due to difficulties encountered in building new and even upgrading existing lines, and since many lines worldwide are approaching their design life or beyond, a good maintenance strategy is important to ensure their integrity and reliable operation. Defects and failures of overhead lines occur in practice due to:

- External causes such as lightning, earth faults in the grid, extreme weather conditions, and very seldom sabotage, as well as mechanical impacts (i.e., vehicular collisions)
- Internal causes such as wear, aging, deformation, corrosion, and poor construction or materials
- Operational aspects such as electrical overload, switching overvoltages, and improper functioning of protection and control
- Approaching the projected end of life of the line.

*Maintenance activities* can be divided into three basic categories:

- Periodic normal maintenance
- Preventive maintenance or component repair
- Emergency restoration or repair.

Periodic normal maintenance consists of activities such as:

- Vegetation management
- Tower painting
- Insulator washing.

The optimum time intervals between these activities can be determined based on risk assessment and cost evaluation [9.268, 269].

Preventive maintenance or component repair consists of activities such as:

- Damaged insulator replacement
- Conductor repair
- Joint replacement
- Spacer and spacer damper replacement
- Repair of structural tower members or foundation repair
- Correcting electrical clearance problems, as these may have been affected by conductor creep, new buildings near the line, etc.

Finally, *emergency restoration* is usually a result of component failure and therefore line failure, or the result of major storm damage, sabotage, or delayed maintenance [9.270]. The key to the development of an adequate emergency response plan is for the asset owner and senior management to commit to a proactive long-term plan for responding to anticipated emergency situations, and the formulation of a corporate policy on how the utility will respond to emergencies.

Formulating a successful transmission line *maintenance strategy* is dependent on the transmission line asset owner's drivers and constraints. The maintenance strategy will depend on the asset owner's particular environment, the existing condition of assets, and perhaps most importantly, how critical a line is to the operation of the network. However, no matter what the maintenance activities are, they all share similar requirements that must be considered when developing a successful maintenance strategy. These include:

- Prioritizing the transmission lines
- Periodic inspection of the lines
- Database management

- Consideration of in-house or outsourcing of maintenance work
- Performing live work or deenergized work
- Planning for people, equipment, and training
- Finding outside resources
- Condition assessment
- Benchmarking and continual improvement.

### 9.9.2 Common Defects and Condition Assessment of Line Components

In the following, common defects found in different line components are presented, together with the techniques currently employed for their detection in situ.

#### Conductors and Associated Hardware

**Corrosion.** Steel corrosion of conductors is principally caused by industrial and salt pollution in the environment in the presence of moisture. The state of conductor corrosion is often checked using a so-called overhead line corrosion detector (OHLCD). It introduces eddy currents into the conductor from a coil that clips around the conductor and measures with a second coil the irregularity in the induced magnetic field in regions where the galvanization of the steel core has been attacked. The OHLCD can also be used on ground wires made of galvanized steel by adding to the sensing head a plastic shell with an adequate number of aluminum wires fit in it to simulate an ACSR conductor.

Aluminum corrosion of conductors by sulfurous pollutants deposited on the outer surface of the conductor causes pitting of the surface. Normally, this type of corrosion is evenly spread on the outside of the conductor and does not reduce its strength to the same extent as internal corrosion; it can be detected by visual inspection of conductor bulging due to the corrosion products from the discoloration of the aluminum strands.

**Damage from Wind-Induced Vibration.** As explained in Sect. 9.4.11, overhead lines are often affected by wind-induced vibrations; these can initiate the following forms of damage:

- Drooping/missing/slipped vibration dampers (Fig. 9.169)
- Missing nuts from suspension clamps or hardware
- Split pins missing or displaced
- Corona rings or insulator strings displaced
- Broken conductor strands (Fig. 9.57)
- Aircraft warning markers moved or missing
- Loose or broken tower members
- Severe wear of suspension hardware (Fig. 9.170) [9.271].

Fig. 9.169 Drooping vibration dampers (20 past 8 o'clock look)

Fig. 9.170 Wear of string hardware

Inspection techniques include visual inspection from the ground or a helicopter, use of a stabilized video camera (helicopter), and corona measurements. The latter help to detect broken strands as their sharp edges lead to high field gradients that cause high-frequency corona discharges (Sect. 9.4.6). Quite recently, an innovative equipment which can detect broken strands, also inside the conductor, using x-ray technology was presented [9.272].

**Conductor Joints.** Most joints used on ACSR are of the compression type, although bolted joints are often used in jumpers. Inadequate compression due to poor joint design or problems during installation, such as use of the wrong dies, can lead to aluminum oxide formation within the joint, a related resistance increase, and excess current flowing in the steel core of the conductor, which can then overheat and ultimately rupture. Consequently, the electrical resistance of a joint is the main factor used to assess its condition (Sect. 9.6.1). Measurement of joint temperature using infrared photography—normally with resolution of

**Fig. 9.171** Thermographic joint inspection performed from the ground (adapted from [9.271])

1 °C—from the ground (Fig. 9.171 [9.271]), and comparison with the detected temperatures at the conductor, can be a time-saving method that enables a utility to get a good indication of the condition of the joints along a line. A recommendation for the evaluation of such measurements is proposed in [9.273].

The absolute temperature difference method can be described as follows:

- a. Detection principle: The highest temperature of conductors or line fittings 1 m from the measured object, operating normally, acts as the reference temperature. The temperature of the measured object is  $t$ , then there is  $\Delta t = t - t_a$ , and  $\Delta t$  is used to judge the thermal defect. It is regarded as a minor fault when  $\Delta t$  is below 10 °C; it is regarded as a general fault when  $\Delta t$  is between 10 and 20 °C; and it is regarded as a serious fault when  $\Delta t$  exceeds 20 °C.
- b. Detection characteristics: The absolute temperature difference method is able to eliminate the effects of an additional temperature rise caused by solar radiation. At the same time, because of the inaccuracies of parameters such as similar orientation, detection distance, environmental temperature, humidity, and wind speed, the errors decrease correspondingly.

Further details are described in [9.213] as well as other measurement methods such as:

- Electric resistance test
- Magnetic resistance test

- Radiography (x-ray) test
- Boroscope test.

**Aged Fittings.** Nowadays, as the erection of new lines faces problems in many countries, it is of paramount importance to develop reliable testing techniques for the evaluation of aged string and conductor fittings and to decide whether it is safe for them to remain in service or if they have to be replaced. This issue is covered extensively in [9.233]. Therein, aged fittings are defined as those installed for over 30 years. It is also recommended to cut out a representative number of fitting samples with a sufficient length of conductor without opening the fittings.

**Carts for In-Span Work.** As line components age, concerns arise regarding the safety of in-span work insofar as it increases the mechanical tension in the conductor, which may be weakened. Publication [9.267] identifies the factors that affect the structural integrity of aged conductors and the risks associated when carts are used, and provides guidelines for inspection and assessment of safe conditions as well as alternative methods for dealing with presumed unsafe conditions. These include lowering the damaged conductor to the ground or to the level of another undamaged conductor, using a bucket truck or a crane, a helicopter, or applying robotics (Sect. 9.9.4).

### Insulators

**Porcelain Insulators.** Broken insulator sheds can result from vandalism and defects induced during the manufacturing process. However, the main cause of failure of porcelain cap-and-pin insulators is corrosion of the steel pin in the cap and of the pin assembly, as the expansive corrosion products create a tensile hoop stress, which leads to radial cracks in the porcelain. On the other hand, porcelain longrods have very seldom failed because of unnoticed inferior quality of the raw material.

**Glass Insulators.** With glass insulators, discharges erode the glass and pin, and after fairly minor surface damage, the imbalance in the internal mechanical stresses in the toughened glass causes the shed to shatter completely.

Publication [9.199] provides guidance on how to check the state of insulators and determine the appropriate time for their replacement.

**Composite Insulators.** For composite insulators, which in the meantime have developed as a viable alternative to porcelain and glass, degradation can occur through premature aging or internal manufacturing de-

fects. The latter are the subject of discussion when live line working (Sect. 9.9.3) is an issue, as they cannot be easily detected visually.

**Inspection Techniques.** The inspection techniques listed below can be used for porcelain and glass insulators:

- Visual inspection
- Insulator voltage drop
- Electric field
- Infrared (IR) thermography
- Ultraviolet (UV) detection
- Radiofrequency/microwave emission detector.

In addition, for composite insulators, directional wireless acoustic emission, combined IR–UV measurements (Multicam), and a recently developed high-frequency high-voltage measurement tool, which is directly applied to the insulator using a hot-stick, can be used as fault-detection techniques.

The assessment of aged, old, or failed composite insulators, in order to evaluate their technical condition and reach a conclusion regarding their residual life expectancy with the help of specific laboratory testing, is covered extensively in [9.198].

### Supports

**Steel Towers.** Most supports are constructed using galvanized steel members. Normal maintenance practice is to paint them with protective coatings at regular intervals, typically 10–25 years, depending on the pollution level of the environment. In addition, the support members can be subjected to buckling due to soil movement, loose bolts, or broken members. Excessive wind movements can also cause loose bolts and member failure.

The following inspection techniques may be used to assess the steel structure condition:

- Visual climbing inspection
- Binoculars
- Telescope
- Camera
- Electronic paint and galvanizing thickness measurement
- Cross-hatch cut test.

The latter is the method by which the adhesion values for the paint on the support members as specified in [9.274, 275] can be ascertained.

**Wood Poles.** The main damage to which wood poles are subjected is the degradation of their mechanical

strength due to wear and decay of the wood or the action of insects and woodpeckers. Decay takes place mainly in the ground line zone, where humidity, fungi, bacteria, and pollutants may penetrate inside the pole through natural cracks in the wood or passages created by insects. To protect the pole from these agents, the wood is treated prior to installation. Supplemental in situ treatments may be applied to prolong the life expectancy.

### Concrete Poles

Concrete poles may suffer from cracks in the concrete caused by inappropriate manufacturing (poor mixture or short curing). Water ingress can then corrode the steel bars and even cause catastrophic damage. Remedial approaches include sealing of the cracks by special design and bandaging of the pole by fiber-reinforced tapes at the crack location.

### Foundations

Although for the majority of foundations, when properly constructed, there are no significant modes of degradation, many utilities have to deal with subsurface corrosion. Also, cracks on the upper part of the foundation are relative frequent. Uplift failures can occur if the stub is insufficiently encased in the block or the cleating is inadequate, as well as corrosion of the tower steel when moisture and oxygen are present. These can be detected by using appropriate inspection techniques ranging from the simple (visual) to sophisticated, such as *surface-penetrating radar* and *acoustic pulse echo*. It is also prudent to check the earthing conditions, as this may have deteriorated, e.g., through corrosion of the earthing rods or poor contact of the earthing leads.

## 9.9.3 Live Line Work

Live line work (LLW), i.e., work on energized circuits, has been carried out in different parts of the world for many decades. Live work is the preferred method of maintenance when system integrity, system reliability, and operating revenue are at a premium and removal of the circuit from service is not acceptable. Live work may also be beneficial—and has been used—in construction, upgrading, and uprating.

Most maintenance operations that are performed deenergized can also be performed using live work techniques. To do so requires proper operating procedures that take into account the complexity of the task and technical standards with regards to equipment, procedures, safety, and quality assurance as described in [9.276].

The feedback from utilities performing live work on overhead lines is that the cost is comparable to that in

**Fig. 9.172** Replacement of twin spacers on a live 500-kV line with a helicopter

deenergized conditions. However, there is a minimum additional cost of 1 or 2 more days for preparation of live work plans. The following case study from [9.276] is instructive in order to understand the importance of LLW:

In this case study, a number of spacers which had damaged the conductor had to be replaced live on a 500-kV line with twin ACAR conductors in the USA. Consideration was given to completing the work either deenergized or live. With circuit outage constraint charges of USD 75 000 per hour, the decision was made to complete the work as live work over a 22-day period using a helicopter (Fig. 9.172), which involved changing 6208 spacers with a total cost of under USD 800 000, corresponding to approximately 10 h of outage cost.

#### 9.9.4 Transmission Line Robotics

The expected increase in live line work approaches has stimulated the development and use of robotic devices to minimize the risk to field personnel safety and maintain power system reliability. In the following, an overview and assessment of the future possibilities for transmission line robotics is presented, extracted

**Fig. 9.173** UAV with propeller side protection and camera for visual inspections (adapted from [9.277])

from [9.277]. The following classes of robots are identified:

*Ground-based robots* are designed to remotely capture and control energized conductors and execute tasks that are far beyond human capability from a mechanical and electrical stress perspective and cannot be easily performed with traditional live line tools such as hot-sticks.

*Line-suspended robots* are designed to perform visual inspection of transmission lines in difficult areas, such as large rivers or mountainous terrain. For this purpose, they are equipped with different types of cameras as well as special sensors, e.g., in order to measure the electrical resistance of splices, to record corona-induced audible noise, and to detect corrosion and/or broken conductor strands. One of the first applications of such robots has been conductor deicing [9.278].

*Aerial-based robots* are also designed to perform visual inspections, but in this case unmanned aerial vehicles (UAV) are used. These are normally equipped with GPS, camera, and image transmission equipment and are able to fly on predetermined routes along the power transmission line and wirelessly transmit the images taken to the base station (Fig. 9.173 [9.277]). The inspection costs of this UAV are about half when compared with the costs of a conventional manned helicopter.

Other types of robots have been developed for live line dry cleaning with brushes and live line inspection of insulators by measuring the resistance and the voltage distribution along the insulator, as well as for performing simple repair work such as installation of repair rods.

## 9.10 Uprating and Upgrading

Many countries with major electrical infrastructure are frequently confronted with four coinciding critical issues:

- Much of this infrastructure was constructed in the 1950s and 1960s, which result in the age of the assets being over 50 years.
- The design life of much of the infrastructure is in many cases about 50 years and has matured beyond the engineering serviceability and/or economic life and requires some form of life extension.
- The need to increase the capacity of the existing infrastructure places extraordinary demands on utilities to establish strategies to uprate the existing infrastructure.
- Approvals for the construction of new overhead lines are often difficult to obtain and in many cases result in critical delays to meet network capacity needs.

These issues and how they can be addressed are discussed in detail in [9.279], wherefrom the information presented here is extracted.

Therein, *upgrading* is defined as increasing the original structural strength of an item due to, for example, a requirement for higher meteorological actions or increasing the original electrical performance of an overhead line. Upgrading results in a decrease in the probability of failure but does not change the consequences of failure.

*Uprating* is defined as increasing the electrical characteristics of a line due to, for example, a requirement for higher electrical capacity or larger electrical clearances. Since uprating will mainly increase the electrical capacity of the line, consequently it will potentially increase the consequences of a line failure.

A few years ago, the CIGRE launched a questionnaire to determine international practice on this subject, the response being excellent. The answers and their evaluation are included in [9.279] and can be summarized as follows:

- 43 utilities from 20 countries representing all continents responded.
- 183 lines with voltages ranging from 33 to 765 kV were described.

- In many cases, high-temperature low-sag (HTLS) conductors (Sect. 9.4.9) were used to increase the current plus composite insulators (Sect. 9.5.5) to modify the tower-top geometry in order to increase the voltage.

Table 9.55 presents the share between uprating and uprating applications.

The factors affecting the decision for uprating/upgrading works mentioned in the answers to the questionnaire are ranked below according to preference (total votes 40):

- 68% (27 votes): lower investment of the works
- 58% (23 votes): lower life cycle assessment costs (investments, losses, O&M)
- 35% (14 votes): unacceptable mechanical or electrical reliability
- 18% (7 votes): real return periods lower than design
- 13% (5 votes): political costs of unavailability.

Last but not least, the uprating/upgrading costs were compared with the construction of a new equivalent line, yielding quite a wide range from zero to 100% with a mean of 33% and a median of 20%.

### 9.10.1 Uprating

In recent years, technologies for line uprating have been developed. The basic idea is to use existing line corridors to transfer more power, which can be done by increasing the line current, the line voltage, or both (Table 9.56).

For uprating actions, increasing the current rate is significantly more popular than increasing the voltage level, with 71% or 30 cases for increasing the current rate and 24% or 10 cases for increasing the voltage level. Table 9.57 provides a list of the most common voltage and current uprating mechanisms and the associated techniques, methods, and processes. More details can be found in [9.279].

The following factors should be taken into account before increasing line ampacity:

- Cost of losses: Uprating a line without increasing the aluminum area of the conductors or decreasing

**Table 9.55** Share of uprating and upgrading applications (adapted from [9.279])

Main action	Uprating	Upgrading	Total
No combination	Uprating only 57% (24 cases)	Upgrading only 12% (5 cases)	69% (29 cases)
Combination	Uprating with upgrading 21% (9 cases)	Upgrading with uprating 10% (4 cases)	31% (13 cases)
Total	78% (33 cases)	22% (9 cases)	100% (42 cases)

**Table 9.56** Options for uprating

Increasing	Method	Tool
Current rating	Increasing temperature	Increasing height attachment point Retensioning
	Reconductoring	Compact/smooth conductor High-temperature conductor
	Special engineering methods	Statistical approach Real-time approach
Voltage level	Reinsulation	Adding/substituting insulators, adjusting gaps Cross-arm modification
	Ground clearance	Increasing height attachment point Retensioning
	Phase-phase distance	Conversion of 2 to 1 circuit New tower top

the resistance will result in increased losses. The increased cost of losses, preferably from a system rather than a single line viewpoint, needs to be determined to decide on the best action to take.

- Condition of current-carrying clamps: The clamps need to be in a position to carry an increased current load. This implies that clamps that appear sound at

present loads may fail at the increased load. These connectors therefore need to be checked, preferably by resistance checks to ensure that the resistance of the clamp is lower than that of an equivalent piece of conductor.

- Actual templating or design temperature: The actual as-built templating or design temperature is normally found to be different from that assumed in the determination of the ampacity. This is due to sagging or surveying or location of towers not being as planned. It is therefore critical to determine the present templating or design temperature of the line. This can only be achieved by surveying the line with the temperature of the conductor known.
- Condition of conductor: The conductor could have been damaged by gunshots, lightning strokes, vibration, poor securing of clamps, or other such incidents. The entire conductor therefore has to be checked in detail. Any nicks or damaged strands need to be repaired using repair sleeves or equivalent.

#### Uprating Case Studies

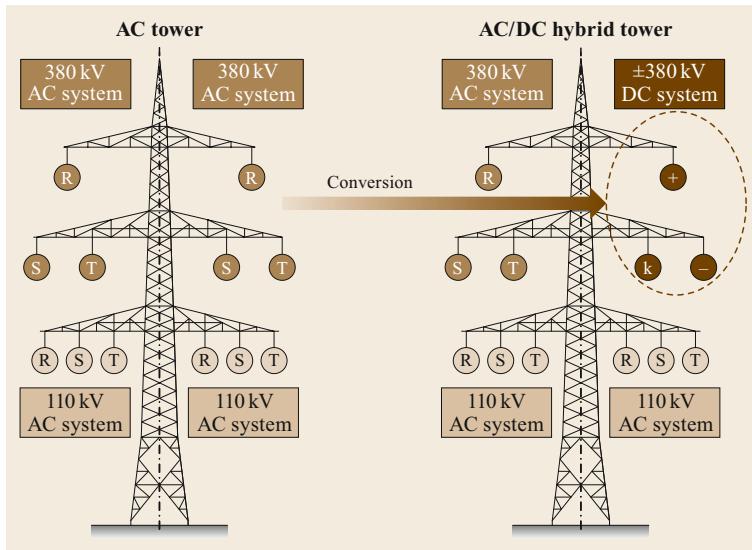

The following case studies are presented exemplarily, being at the time of writing more or less at an experimental stage. More case studies as well as updated information on uprating and upgrading can be found in [9.280].

*400-kV AC/DC Hybrid Line.* Conversion from AC to DC offers certain advantages for long-distance power

**Table 9.57** Mechanisms for uprating (adapted from [9.279])

Method	Technique and solution	
<b>Increased thermal rating</b>		
Increase conductor rating	Conductor replacement	Increased conductivity area High-temperature conductors Composite conductor systems
	Modify rating criteria	Meteorological study
Increase conductor temperature and maintain ground clearance	Conductor tension	Increase tension Negative sag devices
	Increased conductor attachment height	Structure body extension Insulator cross-arms Interspaced structures
Increased thermal rating by active line rating systems	Line thermal, sag, tension, and/or climatic conditions measurement	Line sag or tension monitors Conductor distributed temperature sensing Weather stations
Probabilistic rating	Actual load profile Modify rating criteria	Temporary increase in rating Probability-based meteorological study
High surge impedance	Conductor bundling and geometry	Physical reconfiguration
<b>Increased voltage rating</b>		
Increased electrical clearances	Insulators Increased conductor attachment height	Insulator body extension Structure body extension Insulator cross-arms Interspaced structures

**Fig. 9.174** Hybrid 380-kV line with conversion from AC to DC (source Amprion)

**Fig. 9.175** Cross-section of the new LWC 604 mm<sup>2</sup>: Aluminum alloy wires in dark brown, hollow elements in light brown (source APG, Austrian Power Grid)

transmission. In particular, in DC, the conductors can be utilized up to their thermal limit, while in AC the surge impedance loading (SIL) often becomes the limiting factor. This interesting subject was covered in an early paper [9.281]. Presently, in a pioneering project in Germany, one of the two circuits of a 380-kV AC line was converted to a  $\pm 380$ -kV DC bi-pole, with the third conductor being used for the metallic earth return (Fig. 9.174). One major prerequisite was to use the same conductors and towers. This was only possible by replacing the existing porcelain strings by composite insulators, as these have proven, significantly better pollution performance in particular under DC, thus their length can be accommodated within the existing tower top geometry. More details about hybrid lines in general can be found in [9.282] and about this project in [9.283].

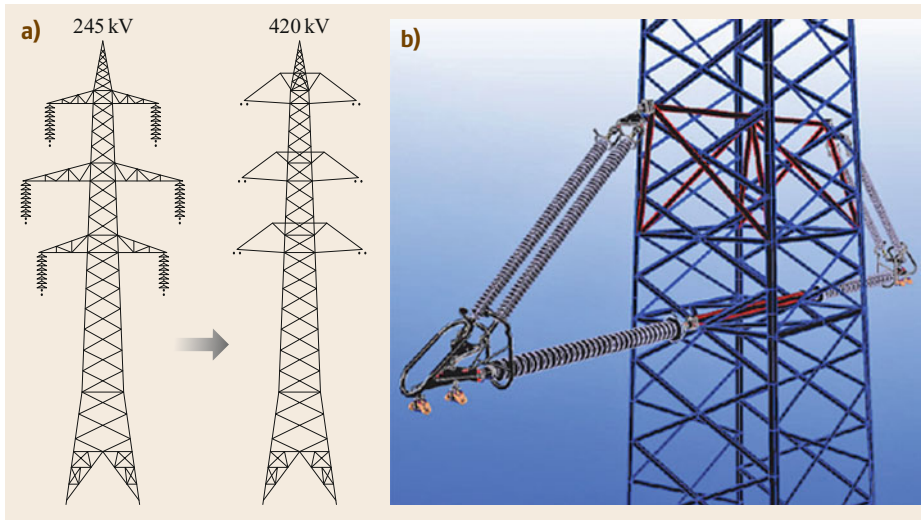

**Conversion of a 245-kV AC Line to a 420-kV AC Line.** A study from Austria was presented in [9.284], where the line uprating was twofold. On one hand, the original

ACSR conductors were replaced by newly designed so-called low-weight conductors (LWC), i.e., conductors with the same amount of aluminum but a higher diameter of 39 mm (Fig. 9.175), which is advantageous to increase their current-carrying capacity and reduce the corona noise. On the other hand, the metallic cross-arms of the steel lattice towers were replaced by insulating cross-arms with composite insulators (Fig. 9.176), enabling the increase of the line voltage from 245 to 420 kV using the same tower body.

**CompactLine.** This is quite a new concept developed in Germany [9.285]. The idea is to utilize existing 220-kV corridors with a new design of 380-kV low-visibility pylons. In order to do this, the conductor sag has to be limited, which is made possible by suspending the quad bundle conductors from a tightly strung high-strength steel rope (Fig. 9.177) similar to those used in funiculars. In order to keep the support top geometry and the ROW narrow, V-strings with high-strength composite insulators were installed (Fig. 9.178).

## 9.10.2 Upgrading

The main reason for upgrading is to increase the availability of the line. Often, meteorological data collected over many years reveal that there could be higher ice and wind loads on the transmission lines compared with the loads that the lines were originally designed to withstand. Due to this fact, lines need to be upgraded to maintain reliability. New transmission line modeling techniques allow more detailed analyses to assess the adequacy of various transmission line components and thus help to quantify the need for upgrading.

**Fig. 9.176a,b**  
Upgrading of 245 kV AC to 420 kV AC (a) using composite insulating cross-arms (b) (source APG)

**Fig. 9.177** Low-profile pylon of the CompactLine with composite V-strings—last works before commissioning in summer 2018 (source 50hertz)

**Fig. 9.178** Low-profile pylon of the CompactLine with composite V-strings—last works before commissioning in summer 2018 (source 50hertz)

Successful upgrading of transmission lines depends on a number of factors that must be considered. These factors can be classified as:

- Environmental factors
- Operational factors
- Mechanical and electrical degradation factors.

Some examples of various factors are given in Table 9.58 [9.269].

The basic criterion for upgrading a line uses the return period of the limit wind load (or of the limit ice load when applicable), by designing the line for a higher return period (say increasing it from 50 to 80 years). The reliability is a result of the combination of the load

**Table 9.58** Factors affecting life and performance of a transmission line element (adapted from [9.269])

Environmental factors	Operational factors	Mechanical and electrical degradation
<b>Climate:</b> i. Overloading due to ice and/or wind ii. Extreme temperatures iii. Ultraviolet exposure iv. Fungi <b>Pollution:</b> i. Acid rain ii. Salt spay iii. Fertilizer use iv. Industrial gases v. Lightning strikes vi. Fires <b>Other external factors:</b> i. Vandalism (gunshots, theft, abuse) ii. Wildlife (i.e., woodpeckers, rodents, insects) iii. Mechanical impacts (cars, farm equipment, planes)	i. High-temperature operation ii. Increased continuous current iii. Increased fault current iv. Lack of maintenance v. No outage time available for maintenance vi. Installation of telecommunication structures vii. Higher ground clearance viii. Higher voltage level <b>External factors:</b> i. New obstacles in the vicinity of the line (i.e., roads, buildings)	i. Loosening or breakage of connections ii. Fatigue of materials caused by vibrations iii. Corrosion iv. Material wear v. Degradation of insulation

**Table 9.59** Methods and tools for upgrading (adapted from [9.269])

Method	Tool
Reducing impact of climatic loads	Compact/smooth conductor Decreasing ice accretion Decreasing number of sub-conductors Decreasing number of circuits
Increasing characteristic strength	Support: leg members Support: bracings Foundation: uplift Foundation: compression

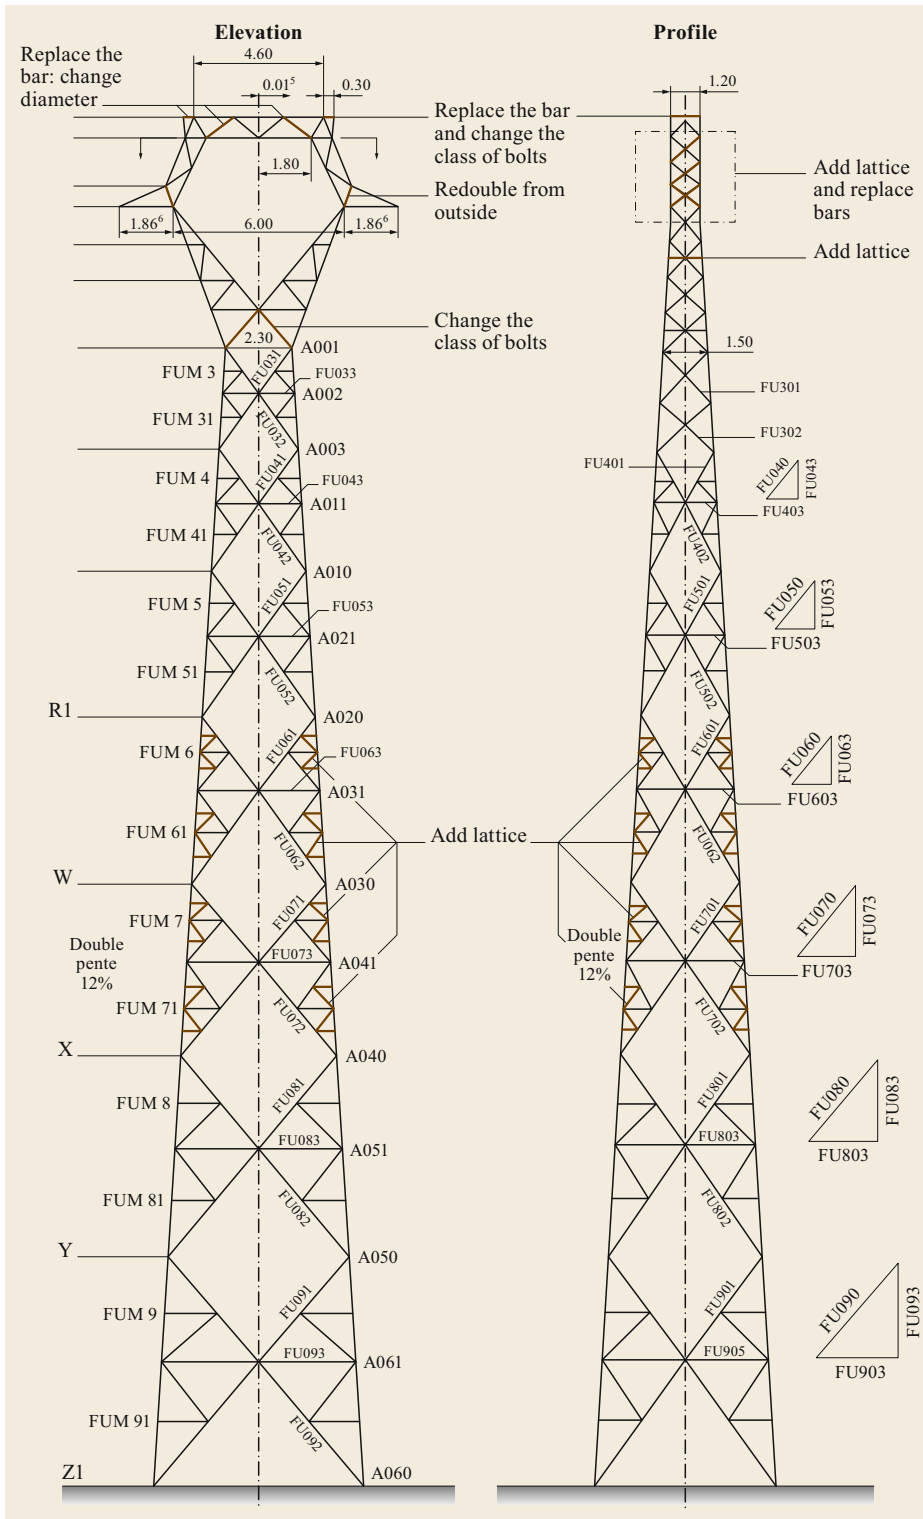

and strength of the overhead line. It is obvious that reliability can be increased by either decreasing the impact of climatic loads or increasing the characteristic strengths (Sect. 9.3). The main methods and tools to upgrade overhead lines summarized in Table 9.59 are from [9.269], where further details can be found.

#### Upgrading Case Studies

**Electrical Upgrading: Replacement of Glass or Ceramic Insulators with Composite Insulators.** In the USA, one utility has replaced both 138-kV, 230-kV, and  $\pm 500$ -kV DC and 500-kV AC ceramic insulators with silicone rubber composite insulators in high-contamination urban areas, with the result of eliminating washing on these lines. Since their installation in 1985 (Fig. 9.179 [9.269]), there have been no reports of insulator flashovers due to contamination (Sect. 9.5.2) on the towers with composite insulators.

**Fig. 9.179** Replacement of ceramic insulators with composite insulators (adapted from [9.269])

**Mechanical Upgrading: Strengthening of Steel Lattice Towers.** In December 1999, storms with wind speeds up to 180–200 km/h caused unprecedented damage to the French electrical network. Implementation of 18 000 (!) *anticascade* towers (Fig. 9.180 [9.269]) was decided to limit the spatial extent of damage to the network in case of exceptional climatic events in the future. One of the goals of this program was to reinforce the mechanical strength of existing towers as well as their foundations and to avoid replacing them, with the objective of controlling costs and limiting the environmental impact of the measure.

**Fig. 9.180** 225-kV anticascade tower showing reinforcement actions

## 9.11 Conclusions and Further Reading

This chapter presents an overview of the history, design, materials, and applications of overhead transmission lines, the backbone of electric power systems from their very early days. Despite the fact that this is a very conservative industry—and rightly so—overhead lines and their components have seen remarkable innovations over recent decades, such as composite insulators, high-temperature conductors, and composite poles, but also new erection and maintenance techniques, notably supported by robotics. Also the ever-present digitalization has reached this industry with GPS-based geoinformation systems plus applications for asset management and such, this being only the beginning. Doubtlessly, overhead lines face acceptance problems in many countries, mainly because of their appearance and the purported health hazards of their electromagnetic fields. Although the industry has reacted with esthetic supports as well as extensive research into said health issues, there is a tendency to partially or even fully place lines underground. As often, there are pros and cons for both technologies, i.e., overhead lines and underground cables. A well-balanced, authoritative but also objective opinion, as provided by CIGRE, on this issue is presented in [9.286, 287]. Nevertheless, because of the huge demand for new transmission corridors, in particular in developing coun-

tries, but also thousands of kilometers of aged lines in Europe and North America, which have to be replaced in the foreseeable future, the great majority of electric power transmission will still be overhead, with a shift to extra high voltage (EHV) and ultra high voltage (UHV) and HVDC. Evidently, this chapter, being part of a handbook which covers the whole power system, cannot go into all the details, but is restricted to basic theory and applications. For further reading, the following *classic* books can be recommended: The books (in German and English) by Kiessling et al. [9.1, 4], which cover the subject extensively and also include quite a few numerical examples, and the more recent CIGRE Green Book on *Overhead Lines* [9.288], which in its more than 1000 pages, not only presents the experience of a plethora of well-known international experts, but also cleverly compiles hundreds of CIGRE publications, which contain the consensual opinion of the worldwide community in this field.

### 9.11.1 Additional Information and Exercises

Additional information and supplementary exercises relating to this chapter can be found at [https://go.sn.pub/SHb\\_PowerSystems\\_Papailiou\\_OverheadLines](https://go.sn.pub/SHb_PowerSystems_Papailiou_OverheadLines).

### Konstantin O. Papailiou

Malters, Switzerland  
konstantin@papailiou.ch

Konstantin O. Papailiou has spent his entire career of more than 40 years in Power Systems and in particular Overhead Lines. Until his retirement, he was the CEO of the Pfisterer Group, a company he served for over 25 years. He has held leading positions in various international technical societies and standardization bodies and is also involved in power engineering education. Since 1976 he is strongly involved with CIGRE, and has served as Chairman of its Study Committee “Overhead Lines”. In 2020, he received the CIGRE Medal, the organization’s highest distinction.

# Underground

## 10. Underground Cables

Pierre Argaut

This chapter on insulated cables comprises 13 sections. Section 10.1 is an introduction to this topic that highlights the role of CIGRE in the development of insulated cables, while Sect. 10.2 gives the current state of cable development, describes modern high-voltage (HV) alternating current (AC) systems and the various types of cables used in them, and explores emerging trends in cable design.

Some basics of the theory of insulated conductors are given in Sect. 10.3 to prepare the reader for subsequent sections, including discussions of electrical fields, electrical characteristics of cable systems. In Sect. 10.4, the basic design aspects of insulated cable systems are introduced, such as insulation coordination, ageing mechanisms, special bonding issues, calculation of cable characteristics and rating.

In Sect. 10.5, various applications of insulated cables are described. The main configurations of cable systems in networks are described and the technical issues associated with each configuration are discussed: matching Cable and OHL ratings, Harmonic resonance, Ferranti effect, magnetic field. Offshore generation cables are explored in depth.

Section 10.6 covers cable design and manufacturing. Major steps in the manufacturing processes of lapped and extruded cables are described. Various options for extrusion lines are compared. Submarine cable armoring is discussed. The manufacture of accessory components is also described, including the various molding and casting processes, which depend on the materials used.

Section 10.7 deals with the construction, laying, and installation of cable systems. Traditional techniques are reviewed and innovative techniques are introduced, such as trenchless technologies: mechanical laying, pipe jacking, microtunneling and horizontal drilling. Installation in tunnels or shared structures is detailed. The main installation configurations are illustrated using examples.

In Sect. 10.8, issues relating to testing are addressed. As indicated in the introduction to the

chapter, testing has been a major issue since insulated cables were first invented and used. The introduction of extruded HV and EHV (extra-high voltage) cables would have been impossible without stringent testing procedures.

Various aspects of the operation of insulated cable systems are covered in Sects. 10.4–10.8. Fluid-filled and extruded cable systems operation have been presented. Also briefly described are monitoring techniques that can optimize equipment usage: management of the overload capacity of underground systems, partial discharge (PD) monitoring, and sheath condition monitoring. Strategies for protecting against short circuits are also addressed. To complete this information, Sect. 10.9 is covering the maintenance of land and submarine cable systems and the various diagnostic techniques that are available. Repair and methodologies that are used to limit repair times, such as fault location, are also included in this section. Main failure causes of cable systems are inventoried. Appropriate maintenance strategies are proposed, and tools for asset management are overviewed. Examples of maintenance guidelines, fault-location techniques, and rapid-response repair are also briefly presented.

Appropriate maintenance strategies are proposed, and tools for asset management are overviewed. Examples of maintenance guidelines, fault-location techniques, and rapid-response repair options are given for land and submarine cables.

Section 10.10 introduces the various options for upgrading and uprating existing cable systems. The life expectancy of an underground cable system is usually more than thirty years, which makes it difficult to predict the changes that will occur in the cable environment or how the operating conditions will evolve during the expected lifetime of a cable system. Addressing the need for a cable system to meet a higher demand can be highly problematic. Replacing a power link or installing an additional circuit requires significant financial investment. It may even be impossible for the op-

erator to extend the system in some congested areas. The difficulties involved in obtaining planning permission for new sites also favor extending the lifespans of existing facilities, often with the goal of transmitting higher power with higher reliability in order to minimize the duration of asset unavailability.

Life Cycle Assessment is discussed in Sect. 10.11. A new technology—superconducting cables—offers interesting options for both AC and DC cable systems, as described in Sect. 10.12. Finally, other undergrounding options (gas insulated lines, GILs) are briefly described in Sect. 10.13.

## 10.1 From the First Electric Telegraph to the Foundation of the CIGRE Study Committee on Insulated Cables

As explained in Sect. 9.1 of this book, the first industrial-scale transmission of electrical power was developed on a long distance DC transmission between Vizille and Grenoble in 1883 by Marcel Deprez (1843–1918) for railways, followed by the first installation of AC overhead transmission lines in 1891, in Germany at the voltage of 15 kV and a frequency of 40 Hz. Very soon, the need to increase voltages and currents for higher amounts of electric power transmission was recognized and huge progress was made in the development of overhead line (OHL) voltages as shown in Fig. 9.2.

Parallel to this, the early days of cable industry started by underground distribution of electricity for telegraphy purposes. Buried insulated wires or wires drawn into conduits were tried but very little was done until the advent of the Edison lamp in 1879 and the need to transmit higher power in lighting networks.

As for overhead transmission, the possibility to increase voltage and current for higher power was depending on the development of suitable insulation material.

In underground transmission, cable conductors must be covered by an insulating material along their entire length, and insulated conductors must withstand the full operating voltage of the circuit at any point.

The history of insulated cable is therefore highly linked to the progress of the insulation materials from Gutta-percha (used in telegraphy for the first transatlantic cable in 1868 until about 1930) to paper insulation and later to modern polymeric extruded insulation [10.1].

Gutta-percha was a gum extracted from certain tropical trees, an isomer of rubber becoming supple and malleable at 100 °C and recovering consistency of leather when cold. It could not be used for land cables, owing to the instability of its properties in the air and to its inadequate mechanical characteristics. For the insulation of power cables an evolution of insulation was therefore needed. Two tendencies forced their way in the 1880's:

- The use of vulcanized material: vulcanized natural rubber was known since 1839 but was expensive.
- The use of impregnated material: in 1890, single-core cables at 3000 V, insulated by paraffin and colophony-impregnated jute, were laid in Paris, while similar cables at 2000 V had been already laid in Rome and Milano in 1886.

Later, cable for lighting and power progressively reached the voltages of 5 kV, and 25 kV in 1900 in the US (rubber insulated). At the end of the 19th century, the voltage of 10–11 kV was reached in several countries. In 1911, the first links of high-voltage cables with impregnated paper insulation were commissioned at 60 kV in Germany and 50 kV in Spain. The different steps of this evolutions are well described in several publications listed in Sect. 10.B. It should be noted that one of the earliest technologies called *mass-impregnated cables* developed more than 120 years ago, is still in use, especially for HVDC transmission up to 500 kV and more.

HVAC transmission required some technological advances to increase electrical field and consequently attain higher service voltages and higher transmitted power. One big step forward was achieved when came the idea of the well-known metallic screen placed over each insulated conductor, making possible to realize screened multi-core cables.

Insulated cables were addressed by CIGRE (Conseil Internationale des Grands Réseaux Électriques) from the very beginning, starting with a discussion in the 1921 session under the heading *Construction of Lines* and the sub-heading *Underground and Submarine Lines*. The main subjects considered for discussion (preferential subjects) were:

- Utilization limits of single and multicore cables for AC and DC
- Determination of electric constants
- After laying tests.

A *panoramic* paper on very-high-voltage underground and submarine lines by Couffon, Geoffroy, and Gosselin from France, the first CIGRE paper on insulated cables, was initially presented, and a lively and interesting discussion followed, during which the situations in different countries were compared. At that time, paper-insulated mass impregnated cables for voltages up to about 60 kV were already available. However, design stresses and operating temperatures were limited to avoid early failures caused by ionization and, although there was already a need for higher-voltage cables with the ability to carry more power, it was unclear at that time how this need would be met.

In the 1923 Session, there were seven papers on insulated cables (three from France, two from the Netherlands, one from Italy, and one from the UK), and similar

numbers were put forward in the 1925 Session (five papers) and 1927 Session (seven papers).

It is interesting to note that during the 1923 Session, the Italian delegate Angelo Barbagelata presented a sample of a radically new cable, the basic characteristics of which had been patented by Luigi Emanuelli in 1917. This cable, he argued, was entirely suitable for utilization at 130 kV and completely eliminated the problem of ionization, which had been a subject of intensive discussion at both the 1921 Session and the 1923 Session. He was, of course, referring to the cable which would become known as the self-contained oil-filled (OF) cable. By 1924, a pilot 130 kV installation utilizing this type of cable had been successfully tested in a substation near Milan, as reported in a 1925 Session paper by Luigi Emanuelli himself. This installation, in the words of the official 1925 Session report, “proved the possibility of undergrounding very high voltage overhead lines”.

During the 1927 Session, the General Assembly of CIGRE, having noted the large and growing interest in insulated cables, decided to create a specific Study Committee to deal with this subject. This committee celebrated its 90th anniversary in 2017.

It is particularly interesting to note that 1927, the year in which the Insulated Cables Study Committee was created, also marked the start of the era of modern high-voltage cables, the evolution of which has been and still is one of the main concerns of the Committee. It was during that year, in fact, that the first two long underground OF cable lines operating at 132 kV were put into service in Chicago (29 km of cable) and New York (58 km of cable). The cable voltage barrier, which had up to that point made it practically impossible to reliably deploy cables for voltages higher than 60 kV, had been broken once and for all. Since then, insulated cables have always been able to reliably carry the highest voltages required by electric power systems. So 1927 was a very good year to start a CIGRE Study Committee on high-voltage cables! From the very beginning, this Study Committee has been at the forefront of cable technology, paying close attention to the technical developments arising from the evolution of this technology and, through its work, facilitating the adoption of innovative solutions. Test methods have been agreed and recommended, new solutions have been examined and described, fertile exchanges of views have taken place between users and manufacturers and, par for the course, heated technical discussions have occurred between the manufacturers themselves. The introduction of higher-voltage laminar cable systems (220 kV in the mid-1930s and 400 kV in the 1950s and 1960s),

the evolution towards higher power-carrying capacities, comparisons of different high-voltage cable solutions, the deployment (starting in the 1960s) of extruded cable systems for increasingly high voltages (currently used commercially for up to 550 kV), progress in high-voltage submarine cables (for which the CIGRE test recommendations are still the only internationally recognized de facto standards), the introduction of HVDC cables, and the development of new techniques, systems, and installation methods have all been topics addressed by the Study Committee on Insulated Cables.

A historical perspective on the technical evolution of power cables is presented in a paper prepared for the conference Jicable 1984: *From impregnated paper to polymeric insulating materials in power cables* [10.1].

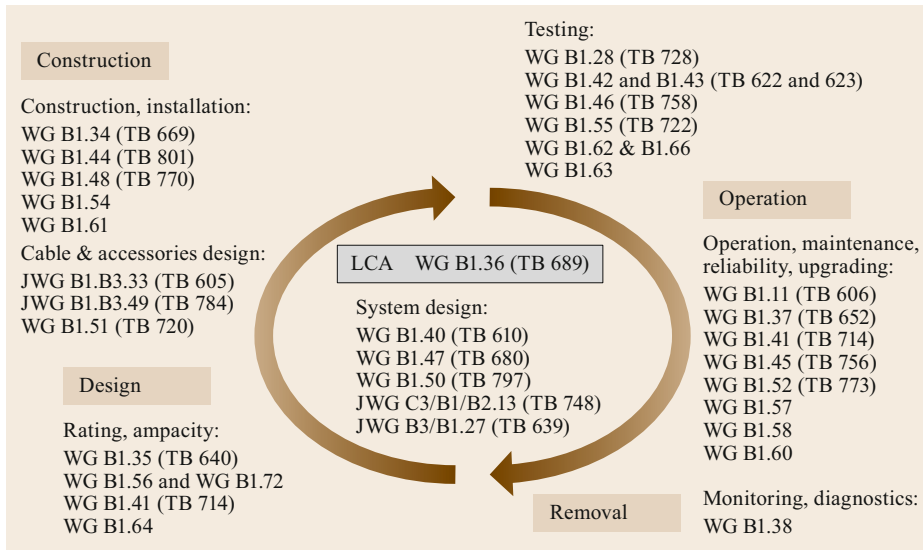

As recalled in the contribution of Study Committee B1 published in *Electra* magazine [10.2] and in the recent Annual Report of SC B1 [10.3], the first Study Committee (SC) on power cables, designated SC 2, was founded in 1927, just a few years after CIGRE itself was founded in 1921. It became SC 21 in 1967 and SC B1 in 2002, and is one of five Study Committees that deal with subsystems (SC B).

During most of its history, SC B1 (formerly SC 21) has focused its activities on technical work and has issued a large number of technical documents, including recommendations used to prepare IEC standardization (e.g., IEC 62067, which was urgently needed by utilities to specify qualification tests for 400 kV cable systems). Since the reorientation of CIGRE to better satisfy the needs of its target groups, SC B1 has extended its work to include economic, environmental, and social aspects of the evolution of the electric power industry.

The field of activity of SC B1 is the development and operation of all types of AC and DC insulated cable systems for land and submarine power transmission. Historically, it has focused mainly on HV, EHV, and (more recently) UHV (ultra-high voltage) [10.4], but MV (medium-voltage) cable applications are receiving increasing attention from SC B1, and Working Groups (WGs) that address specific issues in this area have been launched in recent years.

The scope of the work of SC B1 covers the whole life cycle of insulated cables: the theory, design, applications, manufacture, installation, testing, operation, and maintenance of these cables, as well as diagnostic techniques for them. This scope is illustrated by Fig. 10.1, where most recent and current working bodies are positioned along the life cycle. Information regarding recent working bodies of CIGRE is given in the most recent annual report of SC B1 published in

**Fig. 10.1** Scope of the work of SC B1 (updated in June 2020; courtesy of CIGRE)

April 2020 [10.3]. Future annual reports from SC B1 will update this information.

Subsequent sections of this chapter will cover most of these aspects of the life cycle of insulated cables in power systems.

All the information given in the following sections derives from the most recent technical brochures (TBs) and reports published by SC 21/B1 and by other Study Committees such as SC D1 (on materials and emerging technologies) and SC B4 (on HVDC transmission) in which HVDC cables play an important role.

Reference is made to these documents, allowing the reader to find more detailed, unbiased information on the topic at hand. The reader can also consult many other relevant publications in the bibliography and other documents cited in this chapter. The standards published by the International Electrotechnical Commission (IEC) that are mentioned in this chapter can be found on the official website of the IEC [10.5].

A tutorial presented by SC B1 at the Lund Symposium in 2015 [10.6] is a good example of the exchange of information regarding HVDC cables.

## 10.2 Current State of Cable Development

A considerable amount of highly technical information, including specifications and guides, is currently available on the transmission of bulk electrical power from one area to another. This information can be obtained from bodies such as CIGRE, IEC, national standards, and the Institute of Electrical Technology (IET). There are, however, very few publications that explain the fundamentals of these technologies such that it can be understood by a nontechnical person or a person not involved in this industry on a day-to-day basis.

### 10.2.1 Basics of Power Transmission

Two of the fundamentals of power transmission are the voltage and current levels used to transmit the power from one area to another. Current is the flow of electricity through the conductor. If one thinks of electricity in

terms of water flow, then voltage is equivalent to pressure, i.e., it drives the current through the conductor in the same way that pressure drives water through a pipe. Roughly speaking, the power is the voltage multiplied by the current.

In alternating current (AC), the standard practice internationally is to transmit the power using a three-phase system with three metallic conductors in what is called a circuit to carry the electric current. The size of the conductor governs its ability to carry current: the larger the conductor, the more current it can carry.

Conductors must be insulated from the ground in order to be able to withstand the voltage applied; again, the more insulation they have, the higher the voltage that can be applied.

Three conductors may be combined in an OHL circuit (Chap. 9), an underground cable (UGC) circuit, or a gas-insulated line (GIL) circuit [10.7].

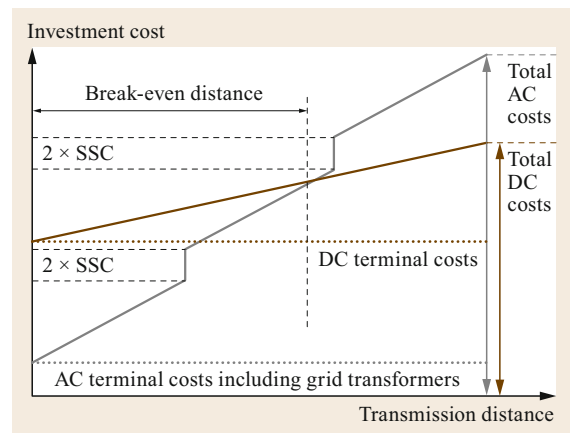

The integration of a HV cable system into a network is covered by TB 250, published by CIGRE WG B1.19 [10.8]. Statistics and service records of UG extruded cables can be found in CIGRE TB 338, published by CIGRE WG B1.07 [10.9], and TB 379, published by CIGRE WG B1.10 [10.10]. WG B1.57 is currently at work updating TB 379 and providing new statistics and recent service records.

Direct current (DC) is the other way to transmit power. As noted in TB 536, published by JWG C4/B4/C1.604 in April 2013 [10.11], HVDC installations date back to the 1950s. This technology exhibits characteristics that have already made it much more attractive than HVAC transmission for specific applications, such as very long distance power transmission, long submarine cable links, and the interconnection of asynchronous systems, as well as bulk energy transport. These characteristics are listed here:

- *Almost no limitation on transmission line length.* In contrast to AC cables, the absence of charging current in DC cables leads to virtually unlimited transmission distances via DC. The environmental advantages of this are mostly related to the transmission medium: since there is no need for reactive compensation, the use of HVDC makes it easier to place cables underground. In the case of overhead lines, the required right-of-way for HVDC transmission is much smaller than that for AC for the same transmitted power. Also, the electromagnetic field emission does not pulsate and can be reduced to a minimum. Ability to offer some advanced control functions within the AC network: optimal power flow control, voltage control, system transient stability improvement, low-frequency damping, the prevention of system cascading failure ... The availability and performance of these features are dependent on the HVDC converter technology, as discussed in TB 536 [10.11].
- *Increased transmission capacity.* For a given conductor cross-section, HVDC transmission can transfer more current than conventional HVAC transmission can. Accordingly, the conversion of a HVAC line into a HVDC line increases its transmission capacity.

For current link lengths of tens of kilometers to a few hundred kilometers, the decision to use AC or DC depends on the costs of both options, including the cost of converter stations.

Converters are designed to transfer large amounts of power over long distances, for instance in sea crossings, where AC cables cannot be used because of their large capacitive currents. The thyristor-based HVDC

**Fig. 10.2** Cost comparison of AC transmission and DC transmission for a given power capability (adapted from [10.11])

system is economical for cables longer than the *break-even distance* (a few hundreds of kilometers), as shown in Fig. 10.2 (in the figure, SSC is short for series and shunt reactive power compensation of AC lines, which is required due to the length of the lines).

In the following paragraphs, we focus mainly on AC transmission and extruded cables, for which there are a great number of recent relevant CIGRE documents, rather than DC transmission. However, when applicable, differences from DC transmission are pointed out, while related work in progress within CIGRE is mentioned, and reports that are expected to be published in the near future are included in Sect. 10.B.

### 10.2.2 AC Underground Cables

As mentioned above, an AC underground (UG) cable circuit usually consists of three power cables and one communication cable installed in the ground. Increasingly, following the recommendations of CIGRE WG B1.02 in TB 247, a thermal monitoring system is also laid in parallel [10.12]. A typical design of a XLPE (crosslinked polyethylene) power cable is shown in Fig. 10.3, while Fig. 10.4 shows a 400 kV LDPE (low-density polyethylene) cable. Other examples are given in subsequent sections.

Before we proceed any further, it is important to convey a rough idea of the size of a typical modern underground project.

The larger the conductor, the more current it can carry, and the thicker the insulation, the more voltage it can withstand. The cables are manufactured in highly specialized factories, and they are currently delivered in drum lengths of 600–1000 m, as shown in Fig. 10.5 (taken from TB 250 published by

**Fig. 10.3** Typical design of a modern XLPE cable (adapted from [10.7])

WG B1.19 [10.8]). For some applications where transportation limitations are favorable, drum lengths can be 2000 m or more, as explained in TB 680 published by WG B1.47 [10.14].

As an example, for drums containing 1000 m of cable, a circuit 10 km long would require  $10 \times 3$ , i.e., 30 drums in total. Twenty-seven joints would be needed to join the cables together (implying  $27/3 = 9$  joint bays or manholes and associated civil works),

as well as three terminations or sealing ends at each end.

Terminations can be installed in substations or transition compounds (Fig. 10.6), or directly on towers/poles (Fig. 10.7).

The cables are typically installed in one of the following arrangements:

**Fig. 10.4** Typical very-high-voltage LDPE cable used underground for voltages of 170–500 kV (adapted from [10.13])

**Fig. 10.5** Typical cable drums for 400 kV cables (adapted from [10.8])

**Fig. 10.6** EHV transition compound (adapted from [10.8])

**Fig. 10.7** HV terminations installed on a pole (adapted from [10.8])

**Fig. 10.8** Cables installed directly into the ground with native soil backfill (adapted from [10.15])

**Fig. 10.9** Construction swathe for installing cables cross-country; a width of 8 m is typically required for a single trench (adapted from [10.13])

- Directly in the ground (Figs. 10.8 and 10.9)
- In ducts installed in the ground (Fig. 10.10)
- In concrete troughs (Fig. 10.11)

**Fig. 10.10** Cables installed in ducts (adapted from [10.13])

- In a tunnel (Fig. 10.12)
- In a pipe or pipes that are drilled into the ground using drilling equipment and pass under an obstacle or encumbrance (horizontal directional drilling, HDD; see Fig. 10.13)
- On a cable tray attached to a bridge (Fig. 10.14).

Installation in a tunnel or shared structure (such as a bridge) is covered by TB 403 [10.18].

For buried installations, the backfill used to reinstate the trench around a buried cable is a critical engineering component of the cable system, as it (along with the surrounding material) is the means of conducting the heat produced during the operation of the cable to the ground surface, where it is dissipated to the atmosphere. Therefore, the thermal properties of these materials, which are assumed in the design of the cable system, are crucial to the correct operation of the system. As mentioned before, a thermal monitoring system is increasingly installed with such systems [10.12] to optimize the operation of the system. CIGRE WG B1.45 has very recently published TB 756 on this topic [10.19].

Figure 10.11 shows concrete troughs with a lid at ground level. Note that troughs are normally filled with

**Fig. 10.11** Cables installed in troughs (adapted from [10.13])

cement-bound sand to ensure that they are capable of taking traffic or similar loads. In other configurations, troughs are buried at greater depths.

The photograph presented in Fig. 10.12 shows two cable circuits with room for two more circuits in the future. Forced air ventilation may be needed to achieve the required rating for the cables and to ensure the

**Fig. 10.12** Cables installed in a tunnel (adapted from [10.16])

safety of personnel who are carrying out inspections or working in the tunnel. Tunnel design and safety systems is a complex area of design and needs to be considered very carefully to ensure the right balance is achieved.

The photographs in Fig. 10.13 show equipment used for HDD and pipes installed by HDD. More photographs on HDD can be found in later sections of the chapter.

The length that can be drilled depends on the hole size required and the composition of the ground. Drilling lengths exceeding 2000 m are possible.

Depending on the soil and cable rating conditions and the length/profile, it may be possible to put all three cables inside one pipe, or three separate pipes inside a casing pipe may be required.

The design of an underground cable circuit depends on many factors, including:

- *Route availability.* It must be possible to route the underground circuit. The impact of other services that may conflict with the cable route either now or in the future must be considered.
- *Route topography.* If the terrain is very uneven or has lots of hills, it may be difficult to route the circuit.
- *Urbanization.* If the line is to be routed through an urban area, future building or road developments may impact on the circuit.
- *Flooding.* This may undermine the installed cable circuit.
- *Conductor size.* The size of the conductor is dependent on the current to be carried and on the increase in the temperature of the surroundings permitted by regulations. Of course, the size of the conductor also has an impact on the weight and size of the cable drum being delivered; the maximum conductor size currently used is 2500 mm<sup>2</sup>, and drum lengths are typically 600–1000 m long. Jointing of cable

**Fig. 10.13a,b** Drilling machine (a) and pipes (b) for HDD (adapted from [10.17])

**Fig. 10.14** Cables on a cable tray attached to a bridge (adapted from [10.18])

lengths is then required every 600–1000m. The need for jointing bays must be accounted for (e.g., civil works). This explains why there is a strong drive to use longer cable lengths, as it reduces the cost of civil works and jointing. The sizing of the conductor and the overall design of the cable are therefore very important.

- *Soil thermal conductivity.* Heat is created as current flows through the cable when it is delivering power. The conductor size has an impact on the heat losses from the cable. For a cable installed in the ground, this heat must travel through the ground before it is released into the air. The thermal conductivity and temperature of the ground therefore also have an impact on the cable sizing.
- *Cable pulling.* The route and drum lengths and route topography must be such that the cables can be pulled into the selected installation arrangement (trench, duct, tunnel, etc.).

- *Electrostatic effects.* Underground cables have no electrostatic effects initiated by the cable, as the electric field is contained inside the cable.
- *Electromagnetic field.* In this case, the current sets up a magnetic field that must be considered when designing the underground circuit. In some countries there are specific limits—for example, those set by the International Committee on Non-Ionizing Radiation Protection (ICNIRP). It should be noted that underground cables have higher electromagnetic fields than overhead lines close to the cable, but the fields fall off more rapidly with distance from the cable. This topic is addressed in [10.8, 20, 21].

As discussed in TB 250 [10.8], the *Study Area* is the area where the impacts are assessed. It includes the locations of the two ends of the projected underground cable system, and the likely extent of the physical and visual influence of the potential underground cable route corridors between these two points. Since all of the factors listed above can vary along the route of a projected cable link, the Study Area is divided into several sections.

### 10.2.3 Integration of a New Cable System into a Network

Prior to the public unveiling of any new transmission line project (OH or UG), it is important to conduct detailed preparatory studies of the political and social situation in the region affected by the project. It is advantageous to collect information regarding previous large construction projects in the region (especially projects concerning roads, railways, or pipelines). The reactions before, during, and after the completion of these projects may be indicative of the community's involvement in cases affecting the area. Groups of cit-

izens who previously actively protested against other technical construction projects may quickly reemerge to oppose a transmission line project.

Political power relationships should also be studied, such as important politicians or other influential figures who are connected to, are domiciled in, or are elected for the area. Such figures often exert a strong influence on the final design of a transmission line project. It is also important to consider any alliances between local politicians and protest movements.

The results of these preparatory studies may give an idea of the political difficulties that will be encountered during the regulatory process of the project, and how to introduce the project to the public.

The decision to use underground cables in a network or in a section of a transmission line often results from a failure to gain permission to build an overhead line in the area. Therefore, the local community will often consider the decision to use underground cables a success in their fight against new overhead lines and the transmission company in question. The public will then often build up strong political pressure to increase the length of the underground section and thus reduce the lengths of new overhead lines. Consequently, increasingly long underground cable connections are being implemented, as recently reported in [10.14] and discussed in later sections of this chapter.

In many respects, underground cabling is considered to be an environmentally friendly but expensive solution compared to overhead lines. However, when discussing the location of the transition compound (Fig. 10.6) and the length of the underground cable section, the public will probably not display any moderation. This is because increased construction costs for a transmission line project normally do not affect the local community's budget. Many decision-makers have little or no knowledge of underground cable technology, and it is commonly believed that cable projects can be implemented without encountering any problems. There is a great need to supply information to both decision-makers and the public about the sizes of HV underground cable projects. Once the decision has been made to take the underground option, a course of action can be determined.

CIGRE JWG B1/B2/C3.13 has published TB 748 addressing environmental issues associated with high-voltage transmission lines in urban and rural areas [10.22].

The flow chart in Fig. 10.15 (proposed in [10.8]) gives a typical example of a *step-by-step* approach to the planning and design process. However, in practice, iterative actions are often involved. It must be emphasized that the decision on whether or not to build a line

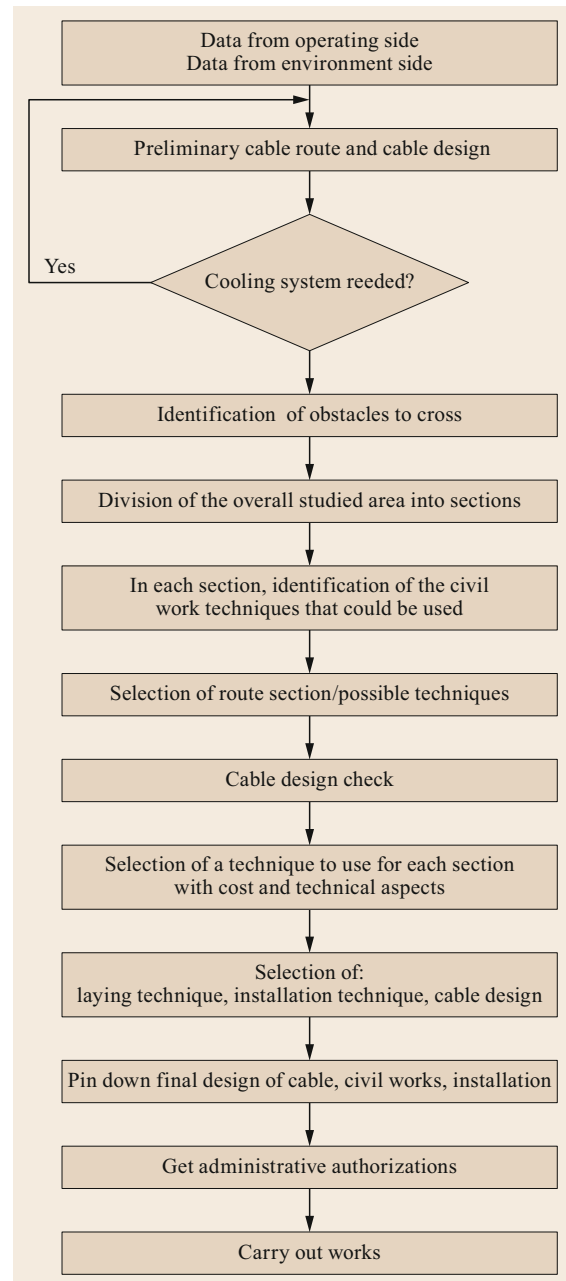

Fig. 10.15 Flow chart for a new cable system (adapted from [10.8])

can depend on different conditions in different countries.

As shown in this diagram, the Study Area is divided into sections depending on the factors listed above. For each of those factors, the UG line is designed taking into account all of the input data for the given section.

Of course, for the overall design of the project, the most important parameters will be those associated with the network, such as system voltage, frequency, basic insulation level (BIL), and some other parameters that are listed in subsequent paragraphs. In addition, each Study Area section is designed through the application of methodologies proposed and detailed later in this chapter.

#### Parameters Dictated by the Network

System planners seek to optimize the parameters that apply to the overall transmission system. They perform network studies that focus mainly on insulation coordination, transient stability, short-circuit levels, and load flow.

#### Main Equipment Parameters

When a utility determines a standardization policy and develops technical requirements, the main characteristics of the primary equipment must be specified by asset managers in close consultation with designers.

The following parameters may be defined:

- The short-circuit current ratings of the equipment, including the supporting structures
- The maximum load currents permissible through the components (which are related to the maximum current-carrying capacities of the lines and underground cables) in normal operation and in overload conditions.

#### Fault Clearance Times

In order to comply with the requirements of the network (system stability) or the specifications of particular utilities, specified fault clearance times must not be exceeded.

Fault clearance times and the reclosing policy may influence the selection of components, the size of the metallic cable screen, and the installation design (depth of burial), as well as the dimensioning of the earthing grid and the mechanical strength of the equipment.

### 10.2.4 Reasons for the Growth in the Number of Long Cable Systems

Typical examples of elements of current UG cable projects were touched upon in previous sections. Insulated cables are now used at the 550 kV level, and tests have indicated that UHVAC extruded cables will soon be available for use at the 800 kV level. In the meantime, self-contained fluid-filled (SCFF) cable systems are already available for higher voltage levels [10.4].

As explained in [10.14, 23], there are several reasons for the strong growth in the use of long HV

and EHV insulated cables operated with AC. Whilst HVAC and EHVAC cables have been available for many years, their use for long-length applications has often been limited by the cable capacitance, dielectric losses, current-carrying capacity, and high installation costs. However, cable performance has greatly improved due to the introduction of cable designs that use new materials, modern processing techniques, and the development of accessories, associated equipment, and installation techniques. At the same time, the cost of supplying and installing underground cables has been significantly lowered.

Until recently, power transmission network designs were principally based on OHLs, mainly because of costs but also for technical reasons: there is no need to compensate for the cable capacitance in OHLs, and there are higher installation costs for undergrounding due to environmental conditions and requirements.

Today, there are often demands to transfer power from renewable energy sources to the grid or to provide electric power to remotely located plants as quickly as possible. In many countries, the process of getting the environmental approvals needed to build an overhead line may take many years, whereas the process of obtaining approval to install underground cables in public areas such as roads and road reserves may be much quicker. The net result is that an AC cable link is often built in a shorter time, leading to a quicker return on the investment, which often justifies the decision to use an AC cable link.

For connections to offshore wind farms, the use of AC cable often provides a lower-cost solution than DC cable when factors such as converter costs, space requirements, and overall system losses are accounted for (Fig. 10.2). At the same time, there is also an interest in reducing transmission losses and gaining community support for improved public safety by providing a supply that is not affected by extreme weather conditions (which appear to be more common these days).

When all of these factors are considered, there can sometimes be a real advantage to adopting an insulated cable transmission solution.

### 10.2.5 Overall Description of Modern HVAC Systems

High-voltage cables form an integral part of any electricity transmission and distribution network. Such a system may consist of different types of cables and a wide range of necessary accessories. For long cable links, it is also necessary to compensate for reactive power generation by installing large reactors at appropriate locations. The design of a high-voltage system is therefore extremely important and requires components

of the highest quality. A high-voltage cable system for a long-distance link must be custom designed to account for power demand and installation conditions. As such, the highest competence is required from system planning through to final testing. As an example, some cables may have an increased insulation thickness to reduce the cable capacitance and therefore the effect of reactive power on the cable system.

A HVAC cable system consists of cables, terminations, joints, link boxes, an earthing system, remote monitoring systems, and compensation reactors. Cables are available in both three- and single-core designs for land and submarine applications, but single-core cables are typically used for long cable lengths on land and three core cables are typically used for long submarine cable lengths. In both cases, optical fiber elements are included in the cable to measure the operating temperature, as conditions may vary along the cable route. Because of transportation restrictions, a land cable is composed of several lengths (each up to 2000 m long), which are installed and jointed together using pre-molded joints. For a submarine system, jointing small lengths together at sea is often not a feasible solution, so the cables are manufactured by jointing together cables up to 10–20 km long in the factory using flexible factory joints *with the same dimensions and properties as the cable*, resulting in cables with very long lengths (over 100 km). The transport capacities of cable installation vessels are in the thousands of tons.

Submarine cables are used for three main reasons:

- To connect two power grids
- To transport power that is generated offshore
- To connect an offshore platform.

Compensation systems take up valuable space on offshore platforms, so compensation is usually carried out at the onshore end of the cable (where practical) when transporting power generated offshore and connecting to offshore platforms.

A submarine cable system is often designed to allow for redundancy because the economic consequences can be very serious if a cable is damaged and out of service. For example, if a cable connecting an offshore wind farm is out of service, the power generated by the wind farm cannot be transferred to land, so the loss of income for the owner is substantial. In addition, the time needed to carry out a repair operation offshore can be quite long. Hence, the solution is often to have two cables installed in parallel. If one cable fails, the other can still be operational for half of the power transfer capacity.

For submarine cables, both ends of the cable are earthed, in strict contrast to land cables, where single-

core cables tend to be more common for long-length and high power transfer requirements. In these land cable systems, special sheath bonding arrangements are required. These so-called cross-bonded systems provide the advantage of an increased rating, but (more expensive) sectionalized joints are required, together with special link boxes that must be installed adjacent to the joint pits/manholes.

The joints used for submarine cables are similar to vulcanized factory joints, and vulcanized or prefabricated joints are used to repair these cables. Typical maximum lengths for HVAC submarine links may be up to 100 km for 400 kV or 200 km for 132 kV. For land cables, longer lengths are made possible through the addition of reactive compensation along the route (Fig. 10.49).

### 10.2.6 Cable Design Trends

As noted in the introduction to this chapter, HV and EHV cables have traditionally been insulated with paper impregnated with oil under pressure. Various designs have been used and significant improvements have been made to increase the operating temperatures and ultimate ratings of such cables, which have an excellent service record. However, as explained later, there are various technical, installation, and service limitations of these designs, such that there are presently very few plants worldwide that produce AC cables based on this technology.

In the last few decades we have seen very rapid development in HV and EHV cable technology that uses crosslinked polyethylene (XLPE) as an insulating medium. As an example, modern XLPE cables have lower dielectric constants and higher operating temperatures than very early paper-insulated, oil-impregnated cables, so they are many times more efficient. Whilst modern pressurized oil-filled cables have higher operating temperatures, XLPE cables are easier to manufacture, which has led to a dramatic increase in the supply and use of these HVAC cables.

There are currently at least ten fully qualified manufacturers of XLPE-insulated AC cable rated at 500 kV worldwide, and the demand for such cables is growing significantly due to the growth of major cities.

Most HVAC submarine cables are three-core cables. Each core contains a conductor: copper or aluminum. Submarine cables often use copper because, although it is more expensive, its electrical resistance is lower, so the cross-section required is smaller than when aluminum is used, meaning that less material is required for the outer layers. Furthermore, it has often been argued that the corrosion resistance of copper is better than that of aluminum, especially in a marine envi-

ronment, but this is actually of little relevance, as a well-designed cable will never allow the conductor to come into contact with seawater.

Hence, aluminum is now becoming more widely accepted because of its lower cost and weight and its better mechanical properties (strength to weight). This is particularly the case for deep installations and dynamic situations.

*For submarine cables*, the insulation system used can be XLPE or SCFF, although—except for very high voltages—most HVAC submarine cables are currently made with XLPE insulation.

The insulation system is protected from the water by a metallic layer, such as lead alloy or a welded metallic sheath, which is also used as electrical screen. A PE layer is extruded to protect this metal sheath. The three phases are laid together and optical fiber elements are often laid in the interstices between the cores, along with some other materials (e.g., PP ropes or PE profiles). The bundle is then protected from mechanical damage by metallic armor made of steel wires. An outer protective covering often made of PP yarns is applied outside the armor.

*For land situations*, different types of cables are available, including LPOF (low-pressure oil-filled), HPGF (high-pressure gas-filled), HPFF (high-pressure fluid-filled), EPR (ethylene propylene rubber), PE (polyethylene), XLPE, GIL-SF<sub>6</sub> (SF<sub>6</sub> gas-insulated lines), and superconducting cables. However, as mentioned above, except in some countries that have considerable experience with fluid-filled cable systems, most new long-length AC cable links are supplied with single-core XLPE cables. Copper conductors are still specified when there are very high current-carrying

capacity requirements, but, due to their lighter weight and the increasing need for longer lengths, aluminum conductor cables are becoming far more common. The trend for long lengths of cable with large conductors means that the mechanical forces exerted due to thermal expansion under load require very careful consideration during system design. This issue is addressed in [10.24].

The insulation thickness of XLPE cables is mainly determined by the withstand voltage. In the case of long-length EHV cables, the insulation thickness will also influence the reactive power produced by the cable.

Reactive compensation is usually achieved by installing shunt reactors (Fig. 10.49). These make the system more complex due to electrical and spatial issues, additional losses, and the need for redundancy. Therefore, it may be desirable to reduce the reactive power produced. This can be done by increasing the insulation thickness or by decreasing the conductor size, although the latter is often impractical.

Thicker insulation results in lower capacitance, which will translate into less reactive power compensation and reduced dielectric loss and charging current. However, increasing the insulation thickness of a XLPE cable has some negative consequences, the most important of which is the maintenance of the quality of the extrusion process when processing very long runs of HV cable. Whilst the insulation thickness may be increased by only a few millimeters, this could lower investment and operational costs for long lengths of EHV cables. Also, some of the additional costs of a cable system with more insulation can be recouped, as less investment in reactive compensation is required and system losses will be lower.

## 10.3 Basics of Cable System Design

As mentioned above, the sections of this chapter largely focus on AC (rather than DC) transmission and extruded cables, as a large number of relevant CIGRE SC B1 documents on these topics have become available in recent years. For specific issues regarding HVDC cables, the reader is advised to read publications from SC D1 [10.11, 25] and the tutorial prepared by SC B1 for the Lund International Symposium [10.6].

### 10.3.1 Introduction to AC Link Modeling

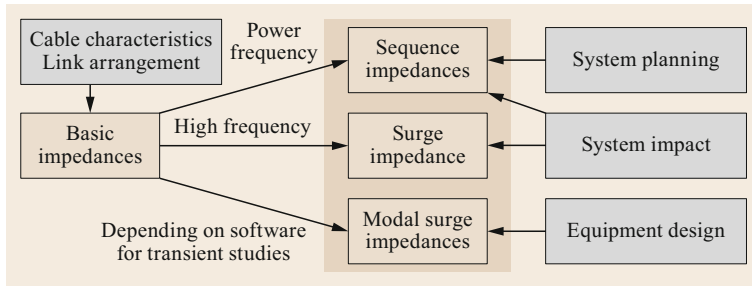

The electrical characteristics of underground transmission cables are significantly different from those of

overhead lines. These differences must be taken into account during system planning, design, implementation, and operation. Modeling is one of the tools used by engineers when designing AC lines and integrating them into HV networks.

Since the very beginning (1927!), one of the most important issues to address during the various stages in the design of UG lines has always been the electrical characteristics of the cables.

In fact, following many years of investigation in this area, it is now clear that successive design phases require different electrical characteristics of the cables.

In this section, various electrical characteristics of cables are defined and introduced, including:

**Fig. 10.16** Electrical characteristics considered in system studies (adapted from [10.26])

- Basic impedances
- Sequence impedances
- Surge impedances.

Relevant formulae are available in the literature. For instance, the formulae used to derive these impedances from common cable and link designs (as identified by the WG; see Appendix A of [10.26]), are given in [10.26]. Critical analysis has been carried out to define the applicability of these formulae; some new formulae are proposed in the technical brochure, which also highlights the need for further studies.

The electrical characteristics considered depend on the study to be carried out. According to [10.27], the models required during system design may be classified into three main categories (Fig. 10.16):

- A *system planning* study determines where new lines are needed as well as the voltage and current ratings, and considers major auxiliary equipment such as shunt compensation.  $N-1$  contingencies are considered at this stage, and overhead versus underground options may be explored. The basic study tool used during system planning is a power flow program, and positive-sequence power frequency models are adequate at this stage.
- A system design or *system impact* study determines the impacts of choosing cable rather than OHLs (and vice versa) on the rest of the power system. The basic project parameters have been determined by this stage. Concerns include harmonic resonance, short-circuit currents, transient stability, voltage stability, and system relaying. The models used vary from positive-sequence to three-phase models, and from power frequency up to a few kHz.
- An *equipment design* study establishes detailed protection and operating procedures for the cable, sheaths, switchgear, shunt compensation, and related equipment. The basic study tool used at this stage is an electromagnetic transients program, which can also handle grounding and bonding connections. Accurate high-frequency models are necessary for many of these studies.

Application to transient studies is not addressed in detail in [10.26], this issue being less a question of cable modeling than the way models are used. More details about transient modeling and transient studies can be found in [10.27].

As a complementary way to get pertinent characteristics, measurement techniques should be considered.

### 10.3.2 Cable System Types

A cable system is as a combination of many different parameters that can influence the electrical characteristics of the cable system. These parameters can be classified into three main categories:

- *Cable design*: all the components of the cable itself
- *Configuration of installation*: all the parameters and dimensions relating to the position of the cables in the surrounding medium
- *Screen bonding*: parameters relating to the electrical connection between the metallic cable screen and the ground, including the possible use of an earth continuity conductor.

Some data on typical cable system design are given in the literature.

#### Land and Sea Cable Types

The evolution of insulated cable development has resulted in three main types of land and sea AC cables: fluid-filled cables (FF), gas-filled cables (GF), and extruded cables.

Figure 10.17 subcategorizes these cable types based on the type of insulation used.

It should be noted that HVAC underground cables with SCFF, XLPE, or EPR insulation usually have a single core, while those that utilize HPFF or HPGF insulation generally comprise three insulated conductors inside a steel pipe.

A typical power cable can consist of four or six main layers: conductor/insulation/metal screen/outer sheath, or conductor/insulation/metal screen/insulation/armor/outer sheath (Fig. 10.18).

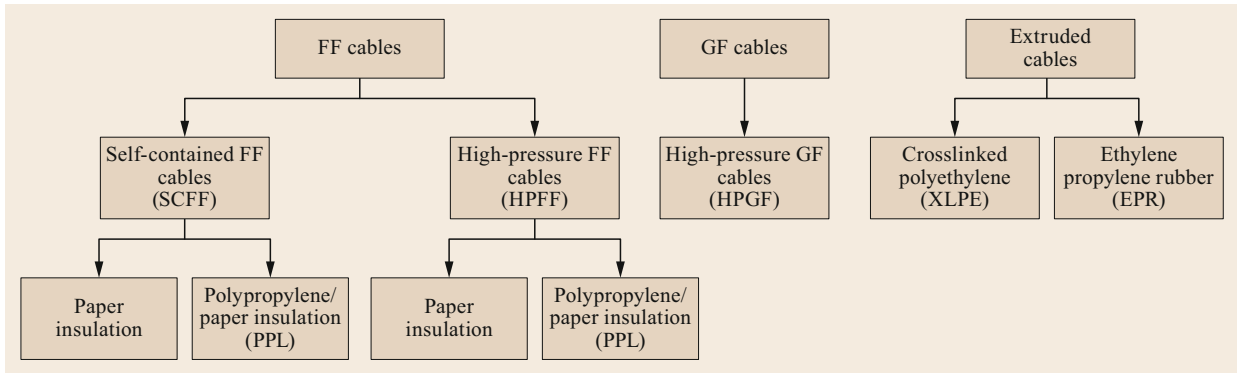

Fig. 10.17 Important types of land and sea cables (adapted from [10.26])

Fig. 10.18 Main components of a single-core cable (adapted from [10.26])

While most HV underground cables have a single core without armor, HV submarine cables have either a single core with armour or—more often—three *four-layer* single-core cables inside a common layer of armor. These cables are referred to as three-core cables.

### Single-Core Cables.

**Conductor.** The purpose of the conductor is to transmit the required current with low losses. Different conductor designs are shown in Fig. 10.19. Hollow conductors usually use oil or water to cool the conductor. Stranded and segmental conductors provide more flexibility and exhibit a reduced skin effect.

The conductor used in HV and EHV cables is either copper (Cu) or aluminum (Al). Compared to Al, Cu has a lower specific resistance, which means that, for the same current capacity, a smaller cross-sectional area of Cu is needed. Ignoring economic considerations, the main advantage of Al over Cu is that it is less dense, so

an Al cable will be much lighter than a Cu cable with the same current rating.

Most conductor materials and designs are referenced in IEC 60287-1-1 (except for oval and aluminum segmental designs). The material and design used affect the DC and AC resistance of the conductor. The methods used to calculate the resistance of the conductor are found in IEC 60287-1-1; the DC and AC resistances at the maximum operating temperature are assigned the symbols  $R'$  and  $R$ , respectively.

The current-carrying capacities of thick stranded conductors can be substantially reduced by skin and proximity effects, which are electromagnetic effects that produce an uneven distribution of current over the cross-section of the conductor and hence effectively increase its resistance.

The *skin effect* is the tendency for current to flow predominantly at the periphery of a conductor due to the internal magnetic field in the conductor. The skin effect in a single-core cable is similar to the skin effect in a solid cylindrical conductor with the same DC resistance per unit length.

The *proximity effect* is the tendency for current to flow along one side of a conductor due to the interaction of the magnetic field of the current in the conductor with the currents in adjacent conductors. The proximity effect can be calculated using formulae developed for solid cylindrical conductors provided that the resistance of the conductor is divided by a factor  $k_p$ , which is the ratio of the resistance of the path along the strands to the resistance of the path across the strands. This factor depends on many parameters, such as the surface condition of the strands, the lay of the strands, the impregnation of the core, and the tightness of the insulation on the core.

As noted in [10.28], the AC resistance of a conductor will be greater than the DC resistance of the conductor due to the skin and proximity effects. Solid conductors will be worst affected by these effects.

**Fig. 10.19**  
Conductor designs for HV cables (adapted from [10.26])

**Fig. 10.20** HV cable with an enameled conductor (adapted from [10.7])

The presence of strands in the conductor will disrupt the proximity effect. The skin effect is only reduced in Milliken conductors (Fig. 10.19). Both effects decrease the difference between the AC resistance and the DC resistance. Some manufacturing processes such as extrusion may impact on the stranding (e.g., by compressing the strands together). Milliken conductors are specifically designed to maximize the disruptive effect of strands and optimize the AC resistance of the cable. This disruptive effect of strands can be further enhanced by increasing the electrical resistance between the individual strands using some form of surface treatment (oxidation or enameling, as shown in Fig. 10.20).

The AC resistance can be derived from the DC resistance via two coefficients representing the skin and proximity effects. The methods used to calculate skin and proximity effects for Milliken conductors in extruded cables are given by the IEC.

**Table 10.1** Proposed values for  $k_s$  and  $k_p$  (adapted from [10.29])

Type of conductor	$k_s$ value	$k_p$ value
For enameled copper wires and aluminium wires	0.25	0.15
For oxidized copper wires (value based on a unidirectional study)	0.35	0.20
For interlayer insulated copper	0.50	0.37
For unidirectional stranding of bare copper wires	0.62	0.37
For bidirectional stranding of bare copper wires	0.80	0.37

Reference [10.29] provides extensive guidance on calculating AC resistances for these conductor designs and for conductors with large ( $> 1600 \text{ mm}^2$ ) cross-sections. Given the complexity of these calculations, the publication recommends that the AC resistance should be measured during type tests. When measured values are not available, the publication recommends that the classical IEC 60287 formula should be used, but with the coefficients revised to the values given in Table 10.1.

WG D1.54 is currently establishing guidelines for the basic principles and practical methods to measure the AC and DC resistance of conductors of power cables and overhead lines.

**Insulation.** There are three practical dielectrics for HV and EHV cables: impregnated multilayered paper, oil-filled paper, and an extruded polymer such as XLPE. The purpose of this insulation is to protect the conductor and ensure that there is no connection between the two current-carrying components of the cable: the conductor and the metal screen.

**Fig. 10.21**  
Some screen  
designs (adapted  
from [10.26])

Due to the insulation between the two current-carrying components, HV cables closely resemble very long cylindrical capacitors. AC loads will therefore draw a capacitive charging current per phase (denoted  $I_C$ ) that is proportional to the permittivity  $\epsilon_r$  and the link length.

This charging current is superimposed on the current that is designed to be carried by the conductor. Therefore the length of the cable is limited because of the capacitive load of the cable. The critical length, which is discussed in more depth in other CIGRE documents [10.8, 14, 28], is the length of cable required for the current rating to be completely consumed by the capacitive current, meaning that no active power can flow through the cable. The critical length of the cable decreases as the voltage and the permittivity of the insulation increase.

**Semiconductive Screens.** A field-smoothing or semiconductive layer is placed between the insulation and the conductor and also between the insulation and the sheath.

Semiconductive layers are included in order to:

- Equalize and reduce the electrical stress in the cable dielectric by preventing local field enhancement in nonhomogeneous areas such as the individual wires of the conductor or screen. The semiconductive layers eliminate the effects of the individual wires on the field distribution.
- Prevent the formation of gaps or voids between the voltage-carrying components of the cable (conductor, screen, and metal sheath) and the insulation layer due to mechanical stress, e.g., cable bending or the differential expansions of the various materials under varying thermal stress. A solid and

permanent bond between the semiconductive layers and the insulation prevents the occurrence of partial discharges (this design aspect is very important in polymer-insulated cables, as they have no impregnating medium).

Models do not normally include semiconductive layers. That is, the models include several conductive layers, such as the conductor and metal screen, and insulation materials in between, but no semiconductive layers. Instead, the semiconductive layers are considered part of the insulation, with the thickness and permittivity of the insulation modified accordingly.

**Metal Screen.** The metal screen is a metallic covering of the cable that is used for electrostatic screening and provides a return path for the capacitive charging current. It is also used to conduct the earth fault current when there is a fault in the cable. When a composite metallic screen is used, a sheath is often included to ensure water tightness. Watertight material can be placed on either side of the metal screen. Some examples of screen designs are given in Fig. 10.21.

To minimize sheath overvoltages at the ends of the cable and the current flowing in the metal screen, special screen connection techniques are used. Screen bonding techniques are discussed in more detail in other sections (see also Figs. 10.24–10.26).

**Bedding.** Bedding is used to reduce thermomechanical stresses on the metal screen caused by thermal expansion of the insulation or to fill voids in or around cable, between the metal screen and the armor. Armored cables use a single layer of an insulating bedding compound. Bedding compounds are elastomer based and

consist of a variety of polymer blends or polymers. The exact formulation depends on the cable construction and application.

Bedding compounds make cables round for easier pulling. In addition, by protecting the metal screen from mechanical and/or water damage, bedding compounds can also increase field lifetimes. The bedding layer may act as both an insulating layer between the metal screen and the armor and a water barrier.

**Armor.** Land cables are generally not armored cables, whereas submarine cables are armored to support the cable weight during laying and to provide mechanical protection to the cable during operation.

Depending on the installation depth and the risk of third-party damage, a double layer of armor may be used.

A nonmagnetic material is used for single-conductor cables, whereas galvanized steel wires or strips are preferred for three-core cables.

The armor increases losses and strengthens the electromagnetic screening of the cable, which in turn minimizes the proximity effect from adjacent cables and lowers the stress on the sheath caused by high currents during conditions such as earth faults.

**Outer Covering.** The primary function of the outer covering of the cable is to provide mechanical protection against the surroundings. For land cables, the outer covering is normally a sheath made of high-density polyethylene with a relative permittivity of 2.3. This outer sheath is the final layer of an underground cable and is often covered with a semiconductive compound.

In submarine cables, extruded polymeric sheaths or servings made from wound polyethylene yarn layers may be used.

**Three-Core Cables.** There are many different kinds of three-core cables. In the HV range, they normally consist of three cores inside a common armor or pipe (Fig. 10.22); in this case, each core is similar to a single-core cable without armor (as described above).

Two main types of three-core HV cables can be distinguished. The first are known as *separate-screen cables* (e.g., SL or SA cables, which have separate lead or aluminum sheaths, respectively). In this case, the three cores are assembled together, using fillers to keep the cable round.

The other main type are termed *pipe-type cables*, in which the three cores are pulled simultaneously inside a steel pipe. The pipe is then filled with an insulating medium, either oil or gas (nitrogen) pressurized to about 15 bar.

Skid wires are used to reduce the coefficient of friction between the cores and pipe during installation.

### Configuration of Installation

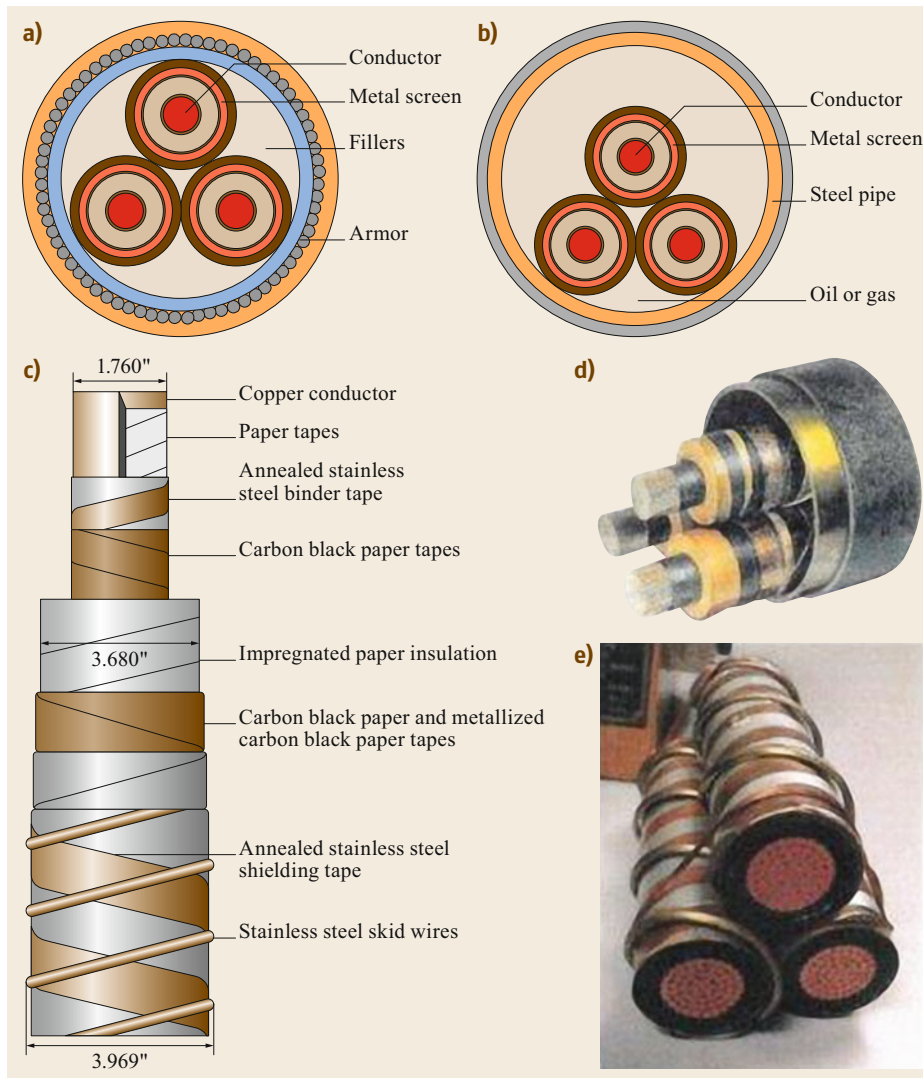

Configurations of installation vary widely according to, for example, the country in which the cable is installed, the construction method used, and the applicable regulations. Some of these configurations have already been briefly described above. More information can be found in subsequent sections of this chapter and in [10.13] (WG B1.60 is currently working to update this document).

In this section, the configuration of the installation is considered to be the set of parameters that can influence the electrical characteristics of the cable system. Very similarly, they can also influence the cable rating (as described in more detail later), since the cable losses can depend on the electrical configuration. The main parameters considered are the relative positions of cables (Fig. 10.23) and the presence of cable transposition.

**Land Cables.** Generally speaking, the construction method used for cable installation will determine most of the parameters of the configuration:

- **Directly buried cables.** Directly buried cables are usually laid in a flat or touching trefoil formation. Some cases also use an open trefoil formation. The spacing between the cables will largely depend on the space available and ampacity considerations. Typical spacings used range between no spacing at all (touching cables) to 4–5 cable diameters. In a double circuit configuration, the spacing between the two circuits can be much larger, up to a few meters.
- **Cables in a trough, filled or unfilled.** This type of installation can use cables in a flat or touching trefoil formation. Due to limited space in the cable trough, the spacing between cables is usually minimal.
- **Cables in a duct.** Cables in a duct tend to be in positioned in a triangular or open trefoil formation. In some cases, flat and/or vertical formations may be used (Fig. 10.8). For this kind of installation, the cable spacing is usually 2–5 cable diameters.
- **Cables in a tunnel.** A wide variety of formations are used for cables in a tunnel as each installation is unique. The spacing between cables is usually large, as these important installations can carry very large loads at very high voltage (Fig. 10.12).

The use of directional drilling may lead to large cable spacing (e.g., 1 m).

**Fig. 10.22a–e**  
Three-core cables:  
(a) separate screens,  
(b) pipe-type cable,  
(c) 345 kV HPFF  
cable, (d) 225 kV  
HPFF cable,  
(e) 69 kV HPFF  
cable (adapted  
from [10.26])

**Cable Transposition.** Cable transposition is used in some countries to reestablish symmetry in a nonsymmetric system. In a three-phase system, each cable (phase) is positioned in each of the three available positions for a third of the length of the system, resulting in a more balanced system. Some countries use cable transposition in a systematic way, transposing cables at each joint location along the links, while other countries do not use cable transposition at all.

**Submarine Cables.** Submarine cables often use a three-core system in which all three cable cores are wound together, resulting in a symmetric system.

For very large cross-sections and higher voltages, single-core cables are generally used. In that case, the spacing between phases is typically very large with re-

spect to the cable diameter (from a few meters up to hundreds of meters or more), much larger than in any land cable installation.

The interactions between the cables—and thus the cable impedances—depend on the arrangement of and the spacing between cables.

The sequence impedances are only rigidly determined for a trefoil arrangement or a flat formation with transposed cables, as explained in [10.26].

The impact of any magnetic shielding installed at the links is not considered here (for an in-depth discussion of this topic, see [10.21]).

#### Screen Bonding Methods

As mentioned above, special techniques are used to connect the metal screen in order to minimize sheath

**Fig. 10.23a–d**  
Various cable layouts for single-core cable systems: (a) touching cables, (b) nontouching cables, (c) triangle configurations, (d) links involving 2 circuits (adapted from [10.26])

overvoltages at the ends of the cable and the current flowing in the metal screen.

The technique used should comply with the design of the cable and accessories during normal operation and even during a failure.

The underground line and the method available for the screen connections is subdued to:

- Electric induction on the sheath during normal operation as well as in the case of a fault.
- Specific rules relating to the maximum voltage that can be induced in the sheath near to any point that someone can touch (wiping bells at the terminations, for example). The voltage allowed varies between 35 and 400 V depending on the country and the regulations applied.
- The resistivity of the ground, which influences the voltage in the sheath.
- The value of the asymmetric factor, which is taken into account during a fault at the power frequency.
- Surge arrester specifications.

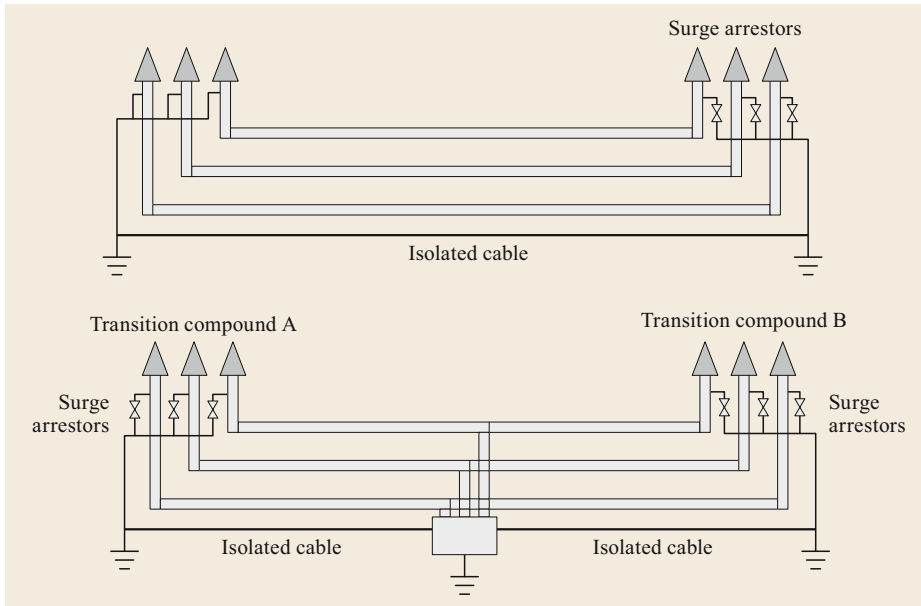

Reference [10.30] includes detailed discussions and calculations relating to modern methods of bonding to a metal screen. Only the most basic design considerations are presented below. Three main types of earthing connections can be distinguished (Figs. 10.24–10.26). In this context, [10.31] is a complementary text that explores *Earth potential rises in specially bonded systems*.

**Solid Bonding Method.** The simplest method of connecting a metal screen is solid bonding (Fig. 10.24), where the metal screen is connected to earth at both ends. This connection method results in large steady-state losses, as induced current is permitted to flow in the metal screen. The voltage level in the sheath is close to zero along the line because it is due only to capacitive currents.

**Single-Point Bonding Method.** This method, illustrated in Fig. 10.25, stops current from flowing in the screen but does not eliminate the potential for problems with sheath overvoltages at the ungrounded end.

**Fig. 10.24** Solid bonding arrangement (adapted from [10.26])

**Fig. 10.25** Single-point bonding arrangements (adapted from [10.26])

Some countries do not use an earth continuity conductor (ecc) along the line; the earth is used to return the fault current during a failure. In other countries, surge arresters are not used.

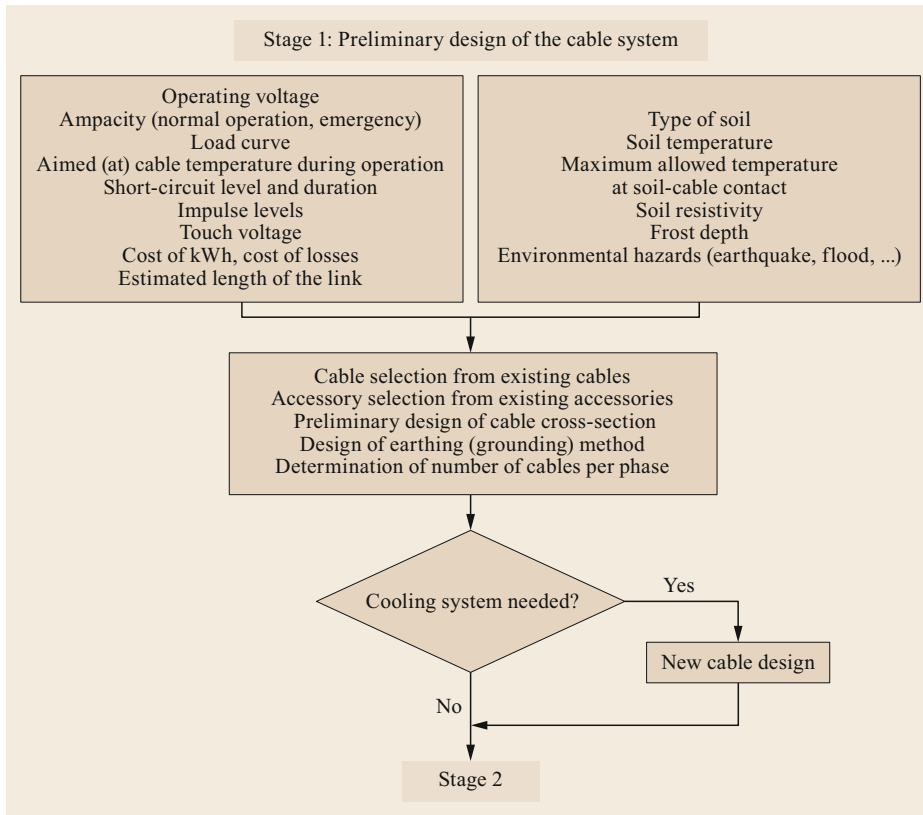

**Cross-Bonding Method.** Long cables usually have cross-bonded sheaths. This grounding method, shown in Fig. 10.26, consists of essentially sectionalizing the sheaths into elementary (minor) sections and cross-connecting in after three consecutive sections (known as major sections). To control possible overvoltages, surge arresters are usually connected to the cross-

bonded points and the sheaths are generally solidly grounded at major section ends.

Induced sheath currents can be canceled out using this method, which results in an improved transmission capacity for an underground cable or a much cheaper cable design for a given transmission capacity; however, permanent and transient voltages can still appear in the sheath and in the metallic parts at the ends of the cable sections. An earth continuity conductor connected to grounding points may be installed to reduce overvoltages that stress the sheath surge arresters during phase-to-earth short circuits.

**Fig. 10.26** Cross-bonding arrangement (adapted from [10.26])

**Fig. 10.27** Stage 1 of the step-by-step approach (adapted from [10.13])

### 10.3.3 Step-by-Step Approach to Cable System Design

Taking into account both operational and environmental data, a preliminary route and a preliminary cable design are selected. After that, as the study progresses, various technical issues will be encountered before the design of the cable and accessories and the laying technique(s) to be used are chosen. The main technical aspects considered during this process are:

- Electrical characteristics
- Thermal dimensioning and rating calculations
- Economic optimization of the conductor area (i.e., *cable sizing*)
- Short-circuit characteristics
- Main insulation coordination
- Grounding technique
- Protection and reclosure issues
- Magnetic fields.

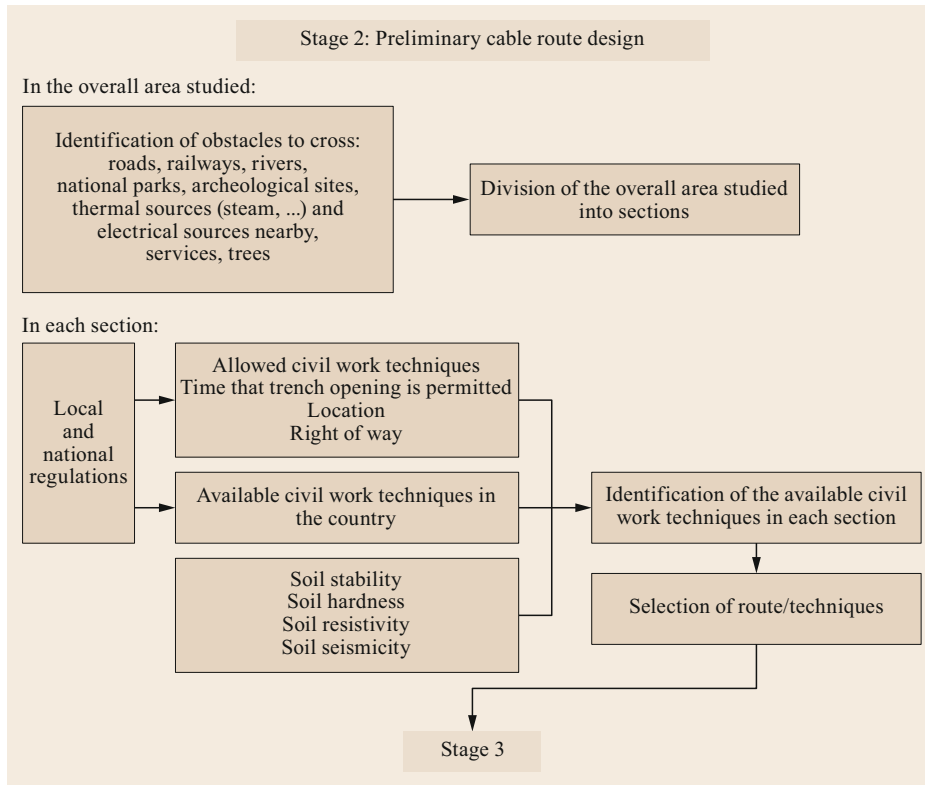

Some elements of the toolbox used to design the cable system are provided in Sect. 10.4.

#### Methodology

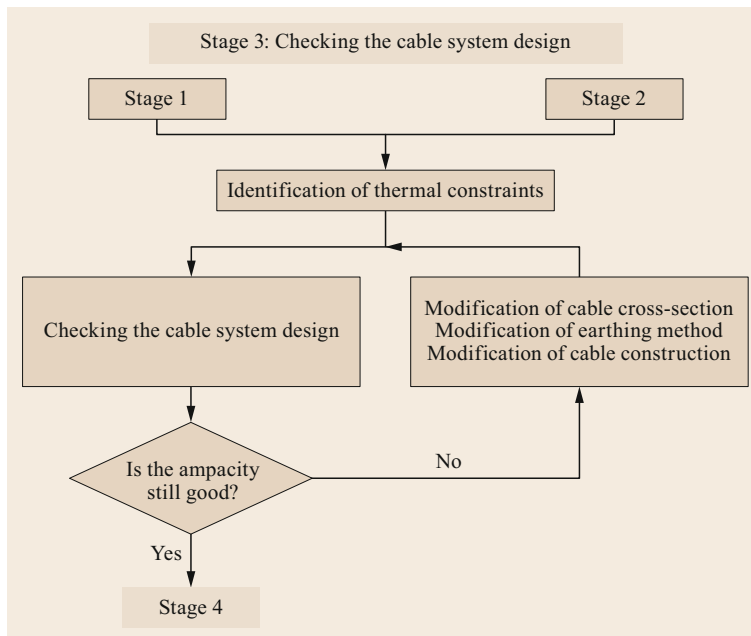

When an engineer is starting a new project, their main consideration is always how the project can be managed to ensure that it is as effective as possible from technical and economic perspectives.

A methodology for a step-by-step approach to cable system project management is proposed by WG B1.17 in [10.13]. The purpose of the chart shown in Figs. 10.27–10.31 (created by WG 21-17 [10.13]) is to help inexperienced engineers to manage their projects. Experts with considerable underground cable system project management experience will bypass some of the proposed steps.

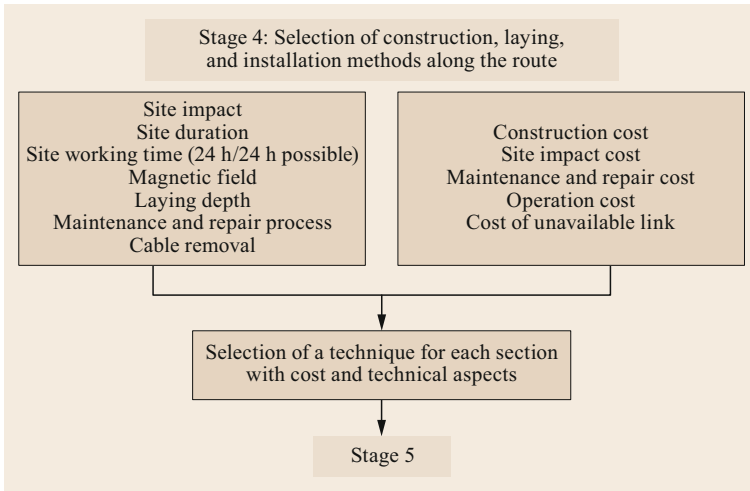

It is clear that this is very much an integrated process: the impacts of the various stages are considered during the process, and steps are taken to modify previous and subsequent stages of the process in order to achieve the optimal end result.

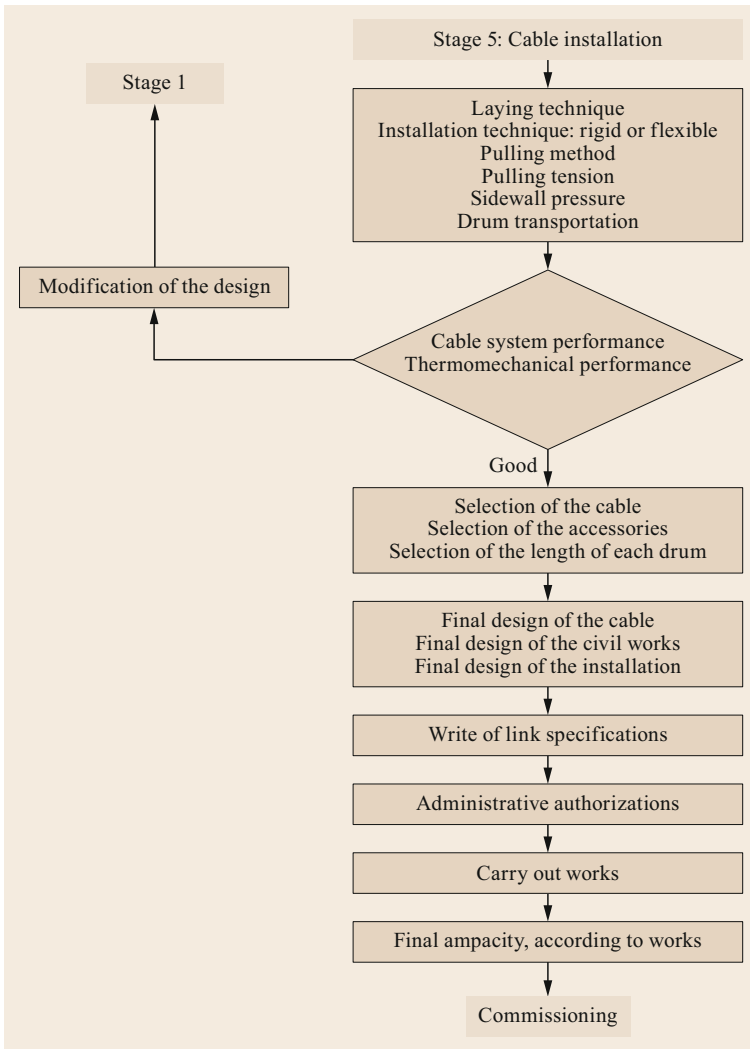

**Fig. 10.28** Stage 2 of the step-by-step approach (adapted from [10.13])

**Fig. 10.29** Stage 3 of the step-by-step approach (adapted from [10.13])

**Fig. 10.30** Stage 4 of the step-by-step approach (adapted from [10.13])

**Fig. 10.31** Stage 5 of the step-by-step approach (adapted from [10.13])

## 10.4 AC Cable Theory in Underground Cable System Design

Two of the fundamentals of power transmission are the voltage and current that are used to transmit the power from one area to another. The current is the flow of electricity through the conductor. As noted above, using the water flow analogy, voltage is equivalent to pressure, i.e., it drives the current through the conductor in the same way that pressure drives water through a pipe. The voltage multiplied by the current is, roughly speaking, equal to the power.

In AC transmission, the standard practice internationally is to transmit the power using a three-phase system with three metallic conductors in a circuit to carry the current. The size of each conductor governs its ability to carry current, i.e., the larger the conductor, the more current it can carry. The conductors must be insulated from the ground in order to be able to withstand the voltage applied; again, the more insulation there is, the higher the voltage that can be applied.

The three conductors may be assembled in an overhead line (OHL) circuit, an underground cable (UGC) circuit, or a gas-insulated line (GIL) circuit.

The basic theory associated with the design of UGCs is described in this section (more detailed information on the topics covered here is available in various publications from CIGRE SC 21/B1 and CIGRE session proceedings). Some of the basics of DC transmission are also described below.

### 10.4.1 Electric Fields in AC Cables

Before we dive more deeply into the theory behind UGC design, it is important to understand what is meant by the electrical stress within the cable insulation and

at the interface between the cable and the accessories (joints and terminations).

For a radial field around a conductor, the equipotential lines are cylindrical and concentric to the conductor, and the electrical stress in kV/mm at a distance  $r$  in mm from the axis is given by

$$E(r) = \frac{U_0}{r \ln \left( \frac{R_e}{R_i} \right)},$$

where  $U_0$  is the phase to ground service voltage in kV,  $R_i$  and  $R_e$  are the internal and external radii of the insulation,  $D = 2R_e$  is the diameter over the insulation, and  $d = 2R_i$  is the diameter over the conductor or the semiconductive layer.

The greatest stress  $E_{\max}$  occurs at  $r = R_i$  on the conductor (or the inner semiconductive layer), and the lowest stress  $E_{\min}$  occurs at  $r = R_e$  on the surface of the insulation layer (Fig. 10.32)

$$E_{\max} = \frac{2U_0}{d \ln \left( \frac{D}{d} \right)}$$

and

$$E_{\min} = \frac{2U_0}{D \ln \left( \frac{D}{d} \right)}.$$

$E_{\max}$  is a crucial influence on the aging of the insulation and the performance of the cable under impulse.  $E_{\min}$  is an important factor in the compatibility of the cable with the associated accessories (joints and terminations), especially for extruded cables.

**Fig. 10.32** Electrical field in an AC cable (adapted from [10.4])

**Cable Insulation Aging: State of the Art**

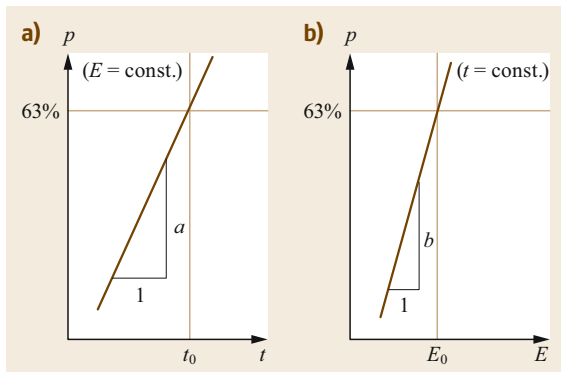

The electrical performance of cable insulation generally decreases over time due to the degradation of the insulating materials. The mechanism of the aging process varies with the physical properties of the materials used for the insulation. These mechanisms are briefly explained in [10.32].

The aging of cables with lapped impregnated insulation is mainly influenced by the operating temperature. Gas production in the insulation due to thermal degradation is the main aging process for this cable type. As long as the gas can be dissolved in the impregnating liquid, the electric withstand stress will remain nearly constant. The applied AC stress does not have a significant influence on the aging provided that it is held below the partial discharge inception stress. *Therefore, the effect of electric aging is negligible in such cables.*

The aging of cables with extruded insulation is significantly influenced by the electrical stress applied. Assuming that the physical process responsible for the aging does not change, the time to breakdown for a given stress as well as the breakdown stress at a particular time are stochastic values that are represented by homogeneous distribution functions. The results of many tests have shown that both values may be approximated by Weibull distributions [10.33] with two parameters (a scale parameter at 63% probability  $t_0$  or  $E_0$  and a Weibull slope  $a$  or  $b$ ; see Fig. 10.33).

According to this mathematical model, the breakdown probability as a function of time for a given cable at constant electrical stress is

$$p(t) = 1 - \exp \left[ - \left( \frac{t}{t_0} \right)^a \right].$$

**Fig. 10.33a,b** Weibull distributions of the breakdown time at constant stress (a) and the stress at a particular time (b) for extruded cable insulation. Both  $x$ -axes use a log scale, while the  $y$ -axes use a double log scale (adapted from [10.32])

For the same cable, the breakdown probability as a function of the electrical stress applied for a given duration can be written as

$$p(E) = 1 - \exp \left[ - \left( \frac{E}{E_0} \right)^b \right].$$

These two distribution functions can be combined such that the complete equation for the breakdown probability of a given cable sample is

$$p(t, E) = 1 - \exp \left[ - \left( \frac{t}{t_0} \right)^a \left( \frac{E}{E_0} \right)^b \right].$$

For a constant breakdown probability, the following relation may be derived from the above

$$\left( \frac{t}{t_0} \right)^a \left( \frac{E}{E_0} \right)^b = \text{const.}$$

We now introduce the lifetime exponent  $n$  as the quotient of the Weibull slopes  $b$  and  $a$

$$n = \frac{b}{a}.$$

The lifetime law for extruded cable insulation then becomes

$$E^n t = \text{const.}$$

Published values of the lifetime exponent  $n$  for XLPE range from 12 to 20.

According to the lifetime law for extruded cable insulation, applying high electrical stress for a short time causes the same aging as applying low electrical stress for a longer duration, assuming that all other operating conditions remain unchanged. The design philosophy for extruded cables must consider this effect. Basic values of the design stresses are usually derived from short-term tests. Considering the aging effect, it is important to ensure that there is a sufficient safety margin to cover accelerated aging effects due to (for example) temporary overvoltages and surges during the required lifetime.

The different aging behaviors of cables with lapped impregnated insulation and cables with extruded insulation is another reason for the different design and testing philosophies specified in the relevant standards and recommendations for these two types of cables. Typical differences between the lifetime curves for lapped and extruded cable insulation are shown qualitatively in Figs. 10.34 and 10.35.

**Fig. 10.34** Lifetime curve for extruded cable insulation (adapted from [10.32])

**Fig. 10.35** Qualitative lifetime curves for lapped and extruded cables (adapted from [10.32])

#### Design Practices for Insulated AC Cables

The insulation of AC cables consists of a number of thin paper tapes wound around the conductor. The conductor is circular, except in external gas pressure cables, which use oval-shaped conductors. Depending on the type of cable used, the insulation is impregnated with low-viscosity oil or with a nondraining high-viscosity insulating mass.

The surface of the conductor is irregular to some degree due to the interstices between the individual wires. To suppress the creation of pockets of concentrated electrical stress at these irregularities, several layers of semiconductive carbon-black paper tape are applied onto the conductor surface. For high-voltage cables, it is essential to generate an undistorted radial electric field inside the insulation. Therefore, semiconductive carbon-black paper tape is applied over the insulation too, normally in combination with metal-coated paper tape.

**Basic Insulation Designs of High-Voltage AC Cables with Lapped Insulation.** In order to achieve an AC withstand characteristic with a sufficiently long duration, it is necessary to avoid ionization inside the insulation. Ionization can occur in gas-filled voids, which can form in the insulation due to the expansion

and contraction of the cable components at different rates during load cycles. Several cable types that use different mechanisms to overcome the ionization problem have been developed in order to create so-called thermally stable cables.

**Low-Pressure Oil-Filled Cables with Paper Insulation.** The paper insulation of low-pressure oil-filled cables is impregnated with low-viscosity insulating oil. During the heating phase of a load cycle, the expanding oil can flow through longitudinal channels inside the conductor (or in the interstices of three-core cables) to oil expansion vessels, in which the oil is stored under pressure. When the load is reduced and the cable cools down, the vessel forces the oil back into the cable. This mechanism stops voids from occurring in oil-impregnated cables.

The impregnated core is covered by a metallic sheath, which can be an extruded lead sheath with reinforcement or a corrugated aluminum sheath. An anticorrosion layer (compound) is applied over the metallic sheath, and this anticorrosion layer is covered with an extruded oversheath (PE or PVC).

Low-pressure oil-filled cables are used up to a rated voltage of 500 kV. Cables for higher rated voltages have already been developed and successfully tested. The power-frequency withstand stress of this type of cable is about 40 kV/mm, and the maximum stress under operating conditions varies between 10 and 15 kV/mm. The insulation thickness is normally designed on the basis of a maximum permissible lightning impulse stress of 90–95 kV/mm, depending on the conductor design.

**Low-Pressure Oil-Filled Cables with Polypropylene Paper Laminate Insulation.** Low-pressure oil-filled cables with conventional paper insulation are of limited use at extra-high voltages (> 500 kV) due to the resulting dielectric losses, which are proportional to the square of  $U_0$ . Therefore, an alternative tape material called polypropylene paper laminate (PPL) has been developed. The dielectric loss factor of low-pressure oil-filled cables with PPL insulation is about 2.5–3 times lower than that of conventional paper insulation.

The overall cable design in this case is similar to that of conventional low-pressure oil-filled cables. The insulation thickness is again determined by the maximum permissible lightning impulse stress, which is in the range of 100–110 kV/mm due to the enhanced material properties of PPL. The maximum power frequency withstand stress is about 45 kV/mm, and the maximum stress under operating conditions is 17–20 kV/mm.

Cables with paper or PPL insulation were known as low-pressure oil-filled (LPOF) cables until the 1970s,

**Table 10.2** Typical stresses in service for AC lapped cables

Voltage class (kV)	Low-pressure oil-filled (LPOF) or SCFF cables		High-pressure oil-filled (HPOF cables)		High-pressure gas-filled (HPGF) cables	
	$U_m \leq 170$	$U_m > 170$	$U_m \leq 170$	$U_m > 170$	$U_m \leq 170$	$U_m > 170$
AC voltage (kV/mm)	10	15	10	14	8	10
Lightning impulse (design criterion) (kV/mm)	85	95	80	90	60	80
Switching impulse (kV/mm)	75	85	70	80	50	70

when synthetic dielectric liquids began to replace the mineral oils that had previously been used. They are now generally known as self-contained liquid-filled (SCLF) or self-contained fluid-filled (SCFF) cables.

**High-Pressure Oil-Filled Cables.** This type of cable consists of three impregnated-paper-insulated conductors that are drawn into a steel pipe. The steel pipe is subsequently filled with oil maintained at a pressure of approximately 15 bar. Due to this high operating pressure, the insulation remains free of voids during any operational conditions. Regulating equipment consisting of pressure monitors, pumps, and valves control the operating pressure. When the load increases and the cable heats up, the expanding oil flows into a storage container. During a cooling period, the oil is pumped back into the cable. High-pressure oil-filled cables have been constructed for rated voltages of up to 500 kV. This type of cable has only rarely been used in recent installations. Its AC withstand stress is approximately 50 kV/mm and its lightning impulse withstand stress is 100 kV/mm.

**External Gas Pressure Cables.** The paper-insulated cores of external gas pressure cables are impregnated with high-viscosity synthetic oil. Directly over the core, a gastight lead diaphragm sheath is applied, which is exposed to an external gas pressure of about 15 bar. During heating periods, the lead sheath expands due to the internal pressure of the expanding impregnating oil. When the cable cools down, the external gas pressure forces the lead sheath back to its original position. In this way, the insulation remains free of voids. The conductors are oval-shaped to enable this action of the lead diaphragm sheath. External gas pressure cables can be designed as either self-contained cables (earlier installations) or pipe-type cables (more recent installations). Pipe-type cables consist of three cores pulled into a common steel pipe. The steel pipe is filled with compressed nitrogen. External gas pressure cables are used up to rated voltages of 275 kV. Typical lightning impulse design stresses for these cables are in the range

of 85–95 kV/mm; typical operating stresses vary from 8 to 13 kV/mm.

**Internal Gas Pressure Cables.** The insulation of internal gas pressure cables is impregnated with a high-viscosity nondraining insulating compound. Such cables, in contrast to external gas pressure cables, do not have a sheath. Either individual non-laid-up cores, each protected by a gliding wire, or laid-up multicore cables with flat steel wire armor are fed into a steel pipe. The pipe is filled with nitrogen at a pressure of about 15 bar. The gas can penetrate into the insulation and fill any voids that are formed in the insulation due to expansion and contraction during thermal cycles. Due to the high pressure of the gas inside the voids, ionization is suppressed.

The maximum rated voltage for internal gas pressure cables is 110 kV, and typical lightning impulse design stresses vary from 80 to 90 kV/mm. Under operating conditions, the maximum AC stress is usually 8–10 kV/mm (Table 10.2).

**Insulation Design.** The electrical stress that occurs within the extruded insulation of HV and EHV cables was investigated in detail in the 1990s. Important CIGRE publications deal with this topic [10.33–35]. Such insulation consists of an extruded layer of polyethylene (PE), crosslinked polyethylene (XLPE), or ethylene propylene rubber (EPR) around the conductor. The conductor is circular for HV cables.

As mentioned above, the surface of the conductor is irregular to some extent due to the interstices between the individual wires. To stop electrical stress from building up at such irregularities, an extruded layer of semiconductive material is applied onto the conductor surface. For HV cables, it is essential to achieve an undistorted radial electric field inside the insulation, so an extruded semiconductive material is also applied onto the insulation.

In order to achieve an AC withstand characteristic with a sufficiently long duration, it is necessary to stop

**Table 10.3** Typical stresses in service for AC extruded cables

Voltage class (kV)	Polyethylene (PE)			Crosslinked polyethylene (XLPE)		
	$U_m \leq 170$	$170 < U_m \leq 300$	$U_m > 300$	$U_m \leq 170$	$170 < U_m \leq 300$	$U_m > 300$
AC voltage design stress (kV/mm)	7	11–12	16	7	11–12	16
Lightning impulse (kV/mm)	70	80	80	70	80	80
Switching impulse (kV/mm)	60	70	70	60	70	70

ionization (partial discharges, PDs) from occurring in gas-filled voids inside the insulation and at the interfaces between the insulation and the semiconductive layers. This is realized by using appropriately defined process parameters and by bonding the three extruded layers.

An extruded lead sheath, an aluminum sheath, or a wire screen encloses the insulated core. The cable is provided with reinforcement for some applications. There is an extruded oversheath (PE or PVC) over the sheath or screen.

Cables with extruded insulation are now used up to a rated voltage of 500 kV. The power-frequency withstand stress of this type of cable is about 40 kV/mm, and its maximum stress under operating conditions is usually around 16 kV/mm. The thickness of the insulation is normally designed based on the maximum permissible AC voltage stress (Table 10.3).

#### 10.4.2 Basics of Electric Fields in DC Cables

Whilst cables with extruded insulation are generally used for electricity distribution, medium-voltage (MV) cables, and for the transmission of low voltages, extruded materials have recently become the insulation of choice in AC and DC transmission circuits for underground cables used in many utility EHV applications.

Recommended insulation thicknesses for AC cables are tabulated in standards (IEC or national standards and utility specifications). For MV cables, the standards and specifications impose a nominal thickness. For HV cables, however, insulation thicknesses are chosen by the cable manufacturer based on experience and validation via type tests and (where applicable) prequalification tests.

The insulation thickness of a DC cable is chosen by the cable manufacturer taking into account both the capacitive electrical stress (caused by possible transient voltages, e.g., switching and lightning impulses) and the resistive electrical stress (caused by the DC voltage in normal operation). The latter strongly depends on the temperature difference across the insulation, the material used, and the manufacturing process applied.

When applicable, the degassing time and the temperature after extrusion are important parameters for the manufacturer to consider since the level of by-products resulting from the curing process in the insulation can strongly influence its electrical performance.

Specific materials have been developed for DC applications, and new materials are currently being developed. Once the most suitable insulation material has been defined, particular attention must be paid to the cleanliness of both the incoming material and the material handling performed in the plant. The required level of cleanliness strongly depends on the rated voltage of the cable.

Extruded submarine HVDC cables are used commercially up to  $\pm 320$  kV. Extruded  $\pm 525$  kV HVDC cables for underground applications are available, and it is expected that they will be made available for submarine use soon. Mass-impregnated (MI) submarine HVDC cables can be used for all voltages, even those over  $\pm 500$  kV. However, mass-impregnated cables cannot be used for HVAC voltages because of ionization in cavities.

The insulation system must be tested in accordance with the relevant standard/recommendation.

In a first approach to analyzing the insulation behavior in DC cables, Fig. 10.36 shows the distribution of the electrical stress inside the insulation of a cold isothermal HVDC cable and the corresponding distribution in the insulation of a loaded HVDC cable. The stress distribution in the insulation is controlled by the ohmic resistance of the insulation layers. In the cold isothermal cable, the specific resistivity of all the insulation layers is almost uniform, and the resulting stress distribution is shown by the gray curve. After running the cable with a load, a thermal gradient will appear in the insulation, causing the specific resistivity of the insulation close to the conductor to be lower than that of the insulation furthest from the conductor. The resulting electrical stress distribution is indicated by the brown curve in Fig. 10.36.

A more detailed analysis of the insulation behavior in DC cables is given in [10.25]. As stated in [10.25], there are a number of formidable challenges associated

**Fig. 10.36** Electric fields in DC cables (adapted from [10.36])

with the process of designing the solid insulation for HVDC equipment that are not (or are less frequently) encountered when designing HVAC equipment.

One fundamental issue is the considerably higher electrical stresses involved, which derive from the compact nature of DC devices/systems. For AC insulation, the electrical design is generally separated from the mechanical and thermal design. In a DC device, however, the electrical design cannot be separated from the mechanical and (in particular) the thermal designs.

A clear example is the strong effect of temperature on insulation conductivity and charging dynamics. TB 520 presents an overview of the key material properties that determine the behavior of solid DC insulation constructions. These properties are important not only for the design process but also for testing. To stress the differences between AC and DC design, properties are identified that play a minor role in AC insulation but a major role in DC insulation. Also, a number of purely AC properties are included, when they are important in connection with DC voltage application and when changing an applied DC field in particular.

Knowledge of the temperature and electric field distributions is of prime importance in the design and testing of an insulation system, as the temperature and electric field are the major sources of stress in the insulation. In an AC design, the electric field distribution is mainly determined by the geometry and permittivity, but it is not as straightforward to determine the field distribution in a DC design. Under steady-state conditions, the DC field distribution is determined mainly by the specific conductivity of the insulation and to a lesser extent by the space charge in the insulation. The specific conductivity is strongly affected by temperature and more weakly by the local electric field. Thus, both the temperature distribution in the insulation and the temperature dependence of the specific conductiv-

ity need to be determined before the electric field can be studied. This is complicated by the fact that the conductivity is also affected by the electric field and that conductive losses from the dielectric affect the temperature distribution. A good example of the major effect of a temperature gradient in an insulation construction is the concept of field inversion in a HVDC cable. Space charge can be generated when charge traps are filled or when there are variations in the conductivity of the insulation, and the effect of this space charge on the electric field distribution must be quantified. To date, this can only be achieved by directly measuring the space charge distribution. It is hoped that in the future it will become possible to adjust the space charge behavior by directly controlling the trap distribution in the dielectric, for instance.

### 10.4.3 Detailed Calculation of the Electrical Characteristics of Cable Systems

As was mentioned earlier, the characteristics of electrical cable systems have been among the main topics addressed by the study committee since it was created; these issues are addressed in [10.26].

All of the formulae reported in the literature were derived based on some assumptions. These assumptions are fulfilled by most of the older cable designs, as those were the main designs used at the time that the formulae were derived. However, the assumptions may or may not be applicable to more modern cable designs. Therefore, studies have been carried out to extend the applicability of the basic formulae.

Simple formulae that may be derived for power frequency considerations are given in [10.26]. They are used to get expressions for the sequence impedance and for the surge impedance, as detailed in Chap. 4 of [10.26].

Further improvements are needed to the formulae. The required improvements are listed in [10.25] for further consideration.

### 10.4.4 Rating Calculations

The cable rating refers to the amount of current a cable system can carry without exceeding the design limitations—particularly the insulation temperature limitations—of the cable system at any position along the circuit. The current rating is highly dependent on the physical construction of the cable, the installation conditions, and expected loading patterns.

It should be noted that system failures due to power cable overloading are rather rare, which is probably explained by the fact that most of the cable systems in use today carry relatively moderate loads. This also means

that if there are significant load (profile) changes in the future, we may approach the limitations of the current ratings of power cable systems much more closely than we are presently. Given the ongoing developments in renewable energy and energy usage, it appears that this topic (the current ratings of power cables) will only increase in importance.

TB 640 [10.28] provides guidance for cable engineers who are attempting to calculate current ratings for new and existing power cables. However, establishing an accurate cable rating for each power cable system regardless of its situation or age is rather difficult, as only a selection of the wide range of existing cable designs and installation and operating situations are covered by the calculations presented in existing standards. For this reason, CIGRE addressed the ratings of insulated AC and DC power cables, including buried, submarine, and in-air installations, as well as the problems associated with establishing the ampacity of the cable circuit for unusual configurations and installation conditions.

TB 640 includes the following:

- A consideration of the starting points—the thermal properties of the cable environment—for cable rating calculations
- A guide to methods of calculating current ratings in situations that are not (fully) covered by existing IEC standards
- A discussion of the tools and techniques available for calculating cable ratings.

#### Calculating the Current Rating of a Power Cable

The first part of [10.28] considers the most important aspects of current rating calculations. Overall issues with rating calculations that must be addressed at a more strategic level before performing the calculations are discussed, such as the grid situation, load factors, time-dependent load flows, and emergency operation. Important considerations include the factors that limit the current ratings of power cables and margin sizes in rating calculations. The following should be noted:

- The accuracies of the starting points, calculation methods, and calculation tools should be relatively evenly balanced. Although a calculation method with an accuracy of a few percent is available for some situations, it is not realistic to expect the same accuracy for the starting points.
- The margins in any rating calculations should be considered during the bidding and design phases of a new cable project, as well as during the operation phase when existing cables are considered.

#### Starting Points for Rating Calculations

TB 640 provides information on the starting points (input information) for rating calculations [10.28]. The results of a worldwide survey elucidate the starting points that are actually used in practice, as well as the starting points that are actually needed to perform rating calculations correctly. Recommendations for improving the setting of starting points are made.

The origin and quality of the data that should be used are defined, and the evaluation of a cable routing in terms of current rating is discussed. Installation conditions and soil parameters are described in detail.

The results of the survey indicate that, in practice, most starting points are assumed or are estimated as conservative values, although there is a growing tendency to perform improved evaluations of such parameters for new installations. This means that there is great potential to better utilize cables by improving the starting points.

#### Calculation Methods and Procedures

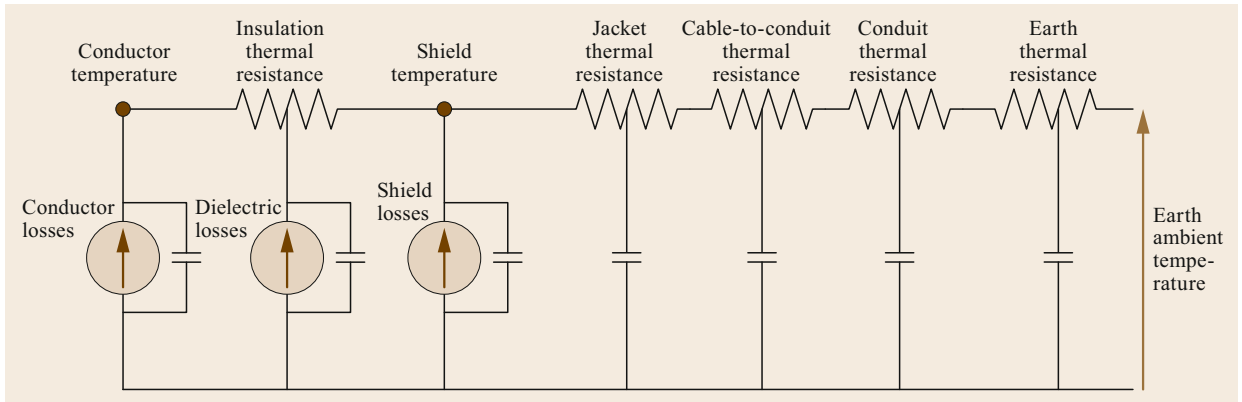

In TB 640, additional guidance for calculating current ratings is given over what is described in the IEC standards for some situations. The specific situation of interest can be found in [10.28] by checking lookup tables, mind maps (e.g., Fig. 10.26), and its chapters and sections.

Guidance on the calculations is given in several ways. The reader is often referred to existing standards, although hints, tips, and descriptions are also given. The WG found that it is very important to give guidance to engineers who need to perform difficult rating calculations.

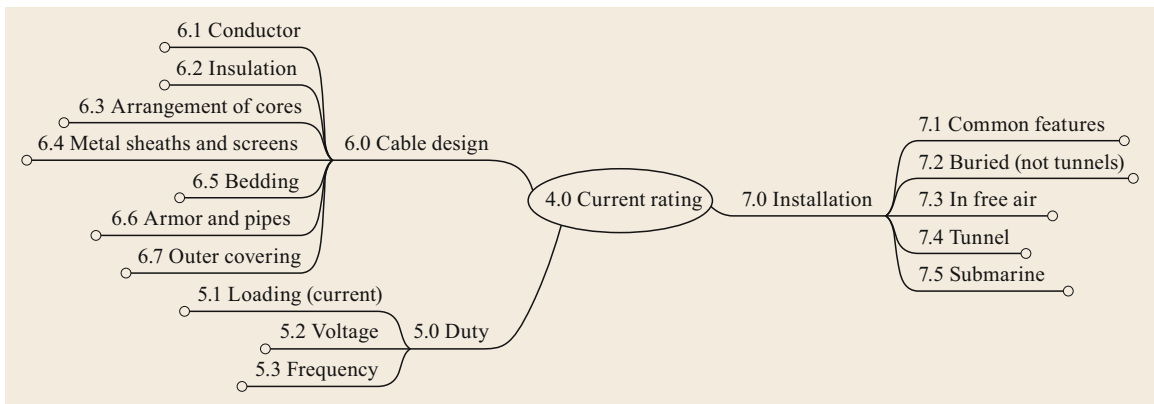

The situations that are discussed comprise:

- *Duty aspects*: cable loading variations (continuous, daily cyclic, emergency, arbitrary, and short-term loading patterns) and the effects of DC and AC at different frequencies
- *Cable aspects*: cable design issues that lead to losses (e.g., skin and proximity effects, dielectric losses, sheath/screen and armor losses) as well as the thermal resistances of cable materials
- *Installation aspects*: installation issues that lead to variations in the heat dissipated from power cables (the TB contains about 50 pages of information on this alone, with discussions of buried cables, in-air cables, cables in different kinds of tunnels, and cables for submarine applications).

Most calculations of underground cable ratings performed using analytical methods make use of the fundamental concept of heat transfer through a solid medium by thermal conduction. The basis for this evaluation

**Fig. 10.37** Equivalent thermal circuit for an extruded or SCFF cable installed in a conduit (adapted from [10.28])

**Fig. 10.38** Overview of the aspects that can affect current ratings (adapted from [10.28])

is an equivalent thermal circuit that is developed to model a specific cable construction. The thermal equivalent is based on the temperature rise resulting from heat flowing through a thermal resistance and capacitance. The thermal capacitance of the various cable layers and surrounding earth introduces a delay in the response of the temperature to changing load conditions that depends on the specific heat characteristics of the cable components and the environment in which the cable system is installed. An example of an equivalent thermal circuit for an extruded or self-contained fluid-filled cable installed in a conduit is shown in Fig. 10.37.

The cable system design parameters that affect current ratings can be divided into three broad categories: duty, cable design, and installation. This is summarized in Fig. 10.38.

In TB 640, each aspect is evaluated in detail, and calculation methods that can accommodate the described situation are recommended. Appendix D of [10.28] gives detailed mind maps for the relevant sections (5/6/7) of the brochure to aid the reader.

As an example, Sect. 7.1 of [10.28] discusses common aspects that can affect many cable installation types (such as the impact of parallel metal conductors), rather than providing the same discussion for each installation. In parts of Sects. 6 and 7, some aspects (e.g., sheath losses) are covered in one section (the metal sheath section) and that discussion is then referenced in other sections (such as in the description of the impact of AC voltages on sheath losses). This avoids any duplication of discussions of calculation methods.

*The most widely used documents for current ratings are the IEC series of standards.* Cable engineers who are experienced in performing current rating calculations will be familiar with the aspects of a cable system described in IEC 60287 (in terms of losses, thermal resistances, and base assumptions). For those experienced cable engineers, Appendix C of [10.28] includes a table that contains a list of calculation methods that are missing from the IEC standards (Table 10.4). The methods in the table are indexed in a similar fashion to IEC 60287 and contain cross-references to the appropriate sections of [10.28].

### Using Calculation Tools and Techniques

TB 640 [10.28] also provides information on available calculation techniques and tools (both static and dynamic, as used for instance in dynamic rating systems, DRSs) as well as the application of distributed fiber optic temperature sensing (DTS) systems. The use of dynamic calculation tools in dynamic rating systems is discussed in detail. The described calculation tools are categorized into analytical (ladder network), empirical, and numerical models, the latter based on finite differences, finite elements, boundary elements, or fluid dynamics.

The results of a global survey of real-world experiences with the various calculation tools and techniques and with DRS and DTS systems is reported in TB 640. For example, experiences of the limitations and problems with DRS and DTS systems are described.

### Recommendations for Future IEC Standardization

TB 640 [10.28] was created to provide clarity on how to perform current rating studies for a wide range of cable

installations. By providing these guidelines, it is hoped that companies worldwide will use similar approaches to deal with similar problems, such that solutions to even the most difficult problems will also become available over time.

It provides results, techniques, and discussions that aid the selection of starting points, as well as calculation methods and tools that can be used to obtain accurate results. Furthermore, it defines areas that require future work by experts and provides recommendations for new work to be performed by CIGRE that are currently being acted upon.

Table 10.4 lists calculation methods that, when [10.28] was published (in December 2015), were missing from IEC Standards or were included in IEC Standards but generated incorrect results. An entry in this table does not necessarily imply that the IEC Standard should be changed, as the omission or error may be negligible, the situation alluded to may be rare in the real world, or the solution may be too complex for inclusion in an IEC Standard.

**Table 10.4** A list of potential improvements to IEC standards (adapted from [10.28])

Section	Description
<b>Losses (conductor)</b>	
6.1	IEC 60287-1-1 Table 2: Skin and proximity effects missing for oval conductors and aluminum sector-shaped
6.3.4	Skin and proximity effects for concentric cables
7.1.3.1	Proximity effects for multiple circuits or multiple cables per phase
<b>Losses (dielectric)</b>	
6.2.2	IEC 60287-1-1 clause 2.2: Calculation of capacitance for sector-shaped or belted cables is not included
<b>Losses (sheath and armour)</b>	
6.4.2	IEC 60287-1-1 clause 2.3 does not cope with copper wire screen and metal sheaths in the same cable
7.1.1	IEC 60287-1-1 clause 2.3.1 to 2.3.6.2: No method for calculation of sheath losses for unequal cable spacings (but method for AC conductor resistance is included) for single core cables. Sheath losses can only be calculated for flat spaced and trefoil formation
6.6.1	IEC 60287-1-1 clause 2.4.2: Armour losses for multi core cables within a common armour are too large when calculated using IEC 60287
7.1.3	IEC 60287-1-1 clause 2.3: The sheath losses of several circuits. The IEC standard considers losses in the three phases of the same circuit without consideration of the effect of neighbouring circuits
7.1.3.4	IEC 60287-1-1 clause 2.4: The electromagnetic effect of several circuits on losses in armours. The IEC standard considers magnetic losses in the three phases of the same circuit without consideration of the effect of neighbouring circuits
5.3.1	IEC 60287-1-1 clauses 2.3 and 2.4: For single phase cables with a separate neutral cable with different construction to the phase cable, the electromagnetic effects of losses in sheaths/armours needs calculation
6.3.4	IEC 60287-1-1 clause 2.3: Sheath loss on concentric cable
5.3.1	IEC 60287-1-1 clause 2.3: Specially bonded two phase single core cables
7.1.11	IEC 60287-1-1 clause 2.3: The effect of an earth continuity conductor on cable rating in a single point bonded system. Additionally other parallel metallic paths may be installed
7.1.6	IEC 60287-1-1, general: The effect of charging current on cable current rating for very long cable routes
7.1.9	IEC 60287-1-1, general: Losses in metalwork near to cable systems, including potentially magnetic materials
6.6	IEC 60287-1-1, general: Cables in magnetic pipes. At the moment, only the pipe type cables in trefoil or cradled configurations are considered in the IEC 60287. This includes the installations in large casings crossing roads, tracks, rivers, etc. This would appear to be an issue for pipe jacking

## 10.5 Challenges in Cable System Implementation

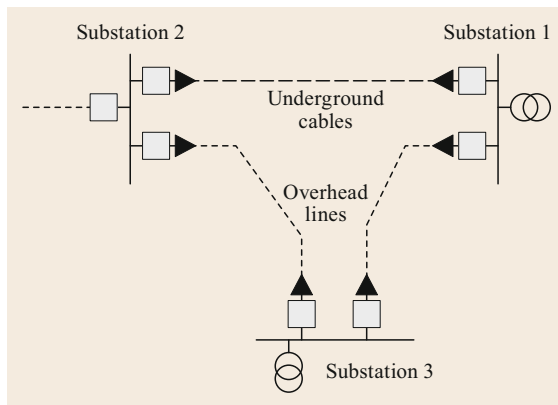

In most countries, transmission grids generally consist of overhead lines for technical and economic reasons. In situations where the use of HV underground cables could not be avoided, the shortest length of cable possible has traditionally been used, except in very densely populated countries such as Singapore and Hong Kong, where underground cable links are an essential part of the grid. However, long HV cables are becoming increasingly common in many countries due to environmental issues and time constraints (it can often take a long time to obtain the permission to construct new overhead lines, and new overhead lines are not permitted at all in some areas).

The incorporation of long HV cables into a grid introduces new technical and environmental challenges. Reasons for this include the different electrical properties of HV cables compared to overhead lines and the different civil construction works (e.g., water crossings, railways, and highways) involved. The effects of electrical capacitance, thermal inertia, impedance, magnetic and electric fields must also be considered, as well as testing methods.

### 10.5.1 Main Cable Configurations

Various configurations are in use, such as single-circuit, double-circuit, and triple-circuit lines with different arrangements of transformer and generator connections.

Many types of connections—including overhead lines, underground cables, or both—are employed. The lengths of transmission lines and cables can vary significantly. In order to provide for high transmission loads, some circuits can consist of more than one cable per phase.

**Fig. 10.39** Underground cable system in a meshed network (adapted from [10.32])

A number of commonly used cable configurations have been identified. The main cable circuit configurations have been identified by JWG 21/11 and are described in TB 189 [10.32] and TB 250 [10.8]. They are given in Figs. 10.39–10.43 and are representative of the most common situations in practice. In any of these figures, each cable could potentially consist of several cable systems.

#### Meshed Underground Network

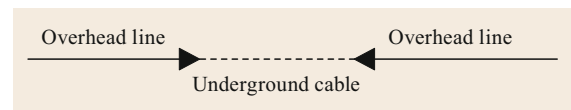

Some parts of a HV network may be entirely underground. This is often the case in large towns, where urbanization limits the construction of overhead lines. Cables connect the busbars in the system, as indicated in Fig. 10.39.

#### Siphon

A siphon (Fig. 10.40) is an underground cable that connects two overhead lines. No switching device is located between the lines and the cable. This configuration allows a HV link to pass through areas that are too wide for an overhead line span, such as rivers or small lakes. This configuration also allows a transmission line to pass through or near a protected site or an urbanized area. Transitions between overhead and underground sections are achieved using either simple terminations installed on poles or towers or in a special fenced-off area called a *transition compound*.

#### Substation Entrance

An underground cable is often used as the interface between an overhead line and a substation (Fig. 10.41), especially when it is a gas-insulated substation. This configuration allows more compact stations to be de-

**Fig. 10.40** A siphon—an underground cable connecting two overhead lines (adapted from [10.32])

**Fig. 10.41** Underground entry to a substation (adapted from [10.32])

**Fig. 10.42** Power generator output (adapted from [10.32])

**Fig. 10.43** Power or auxiliary transformer supply (adapted from [10.32])

signed, and is particularly useful when there are a large number of incoming overhead lines.

#### Power Generator Output

An underground cable may be used to carry power from an inaccessible generator to a busbar, as shown in Fig. 10.42. In many hydropower stations, the generator is located inside a mountain. In order to save space, the generator is connected directly to the step-up transformer, with no circuit breaker. The secondary side of the transformer is connected to an outdoor substation by a cable that may be several kilometers long. The (air-insulated or gas-insulated) substation is connected to one or more overhead lines.

#### Power or Auxiliary Transformer Supply

In this configuration, a cable is connected between a high-power busbar and the power transformer or the auxiliary transformer of a power unit (Fig. 10.43). The cable is usually short.

### 10.5.2 Connecting to Offshore Generators

The issue of connecting offshore generators to a network has been addressed by WG B1.40 in TB 610 [10.36].

This section discusses the various aspects of system design that should be considered when designing an offshore infrastructure that will be used to collect and transport generated power to an onshore electrical infrastructure.

A detailed examination of the various components of an offshore network is provided in [10.36], as well as examples of existing offshore networks.

The various network topologies given in [10.36] allow the reader to compare the initial capital expenditure (CAPEX) with the long-term operational expenditure (OPEX) for a number of different solutions. The development of an offshore network often impacts the onshore grid as the transmission system must be expanded to accommodate the additional power generated offshore.

In this section, we consider the typical requirements (as specified by the transmission system operator, TSO) when applying for a connection to a transmission system, as well as the key parameters that form part of the grid code. Critical issues that arise when designing a system—such as the impact of reactive compensation, reducing system losses, and determining load profiles—are discussed.

Although the solutions given below are mainly based on offshore wind power generation, the philosophy used is also applicable to all other types of offshore generation. Furthermore, the issues discussed for export cables may also be relevant to the submarine cables generally used in the infrastructure for offshore energy generation. It should also be noted that relevant system aspects (e.g., voltages, frequencies, and protection) are discussed by WG B4.55 in TB 619 [10.37].

#### Connections to Shore: Types and Topologies

Different solutions for connecting to the shore can be distinguished according to the locations and the number of offshore generation plants considered.

To identify the optimal solution, the following aspects must be taken into account:

- The rated power of the offshore generation plant (or the power supply to the offshore structure)
- The distance to shore, including the onshore connection length
- The CAPEX and OPEX for the each type of connection
- Redundancy, which will have a financial impact
- The losses for the different solutions
- The voltage drop over the AC cables
- Cable derating due to the thermal influence of multiple cables laid in parallel
- The possibility of landing of several cables
- Environmental impacts
- Permits.

The following solutions are mainly used for offshore generation (or power supplies):

- *Medium voltage (MV) solution*: MV cable connecting offshore generators (array cables) and MV

**Fig. 10.44** Example of the connection of a small offshore wind farm to an onshore grid using MV cables (adapted from [10.36])

export cables without an offshore high voltage substation (OHVS).

- **HVAC solution:** MV cable connecting offshore generators (array cables), offshore high voltage substation with transformer and HVAC export cable.
- **HVDC solution:** MV cable connections offshore (array cables), offshore high voltage substation with transformer, HVAC export cable to offshore AC/DC converter station and HVDC export cable to shore.
- **Combined HVAC and HVDC solution:** HVAC connections between more offshore high voltage substations. HVAC connections from each offshore substation to AC/DC offshore converter station. From converter station a HVDC connection to shore.
- **Offshore grid solutions:** Connections to more offshore high voltage substations and/or more onshore grids (interconnectors).

#### MV Solution

Probably the simplest solution is to connect the wind farm to shore via one or more export cables loaded at the  $U_m = 36$  kV level (Fig. 10.44). This solution is useful for smaller wind farms that are relatively close (typically less than 20 km) to shore. The offshore MV cable will be connected to a substation on land. The voltage is usually raised to the required grid voltage by a step-up transformer on land.

#### HVAC Solution

For offshore generators that are further from shore or have a higher power output, the preferred solution is to use an offshore high-voltage substation (OHVS) to collect all of the power generated at the MV level and then use a HVAC export cable to transport this power to shore.

Figure 10.45 shows an example of the connection of an offshore substation to shore via one export cable circuit. The generated power is transmitted via this ca-

**Fig. 10.45** Using array cables and an export cable to transmit power generated offshore to shore (adapted from [10.36])

**Fig. 10.46** Using array cables and two HV export cables to transmit power generated offshore to shore (adapted from [10.36])

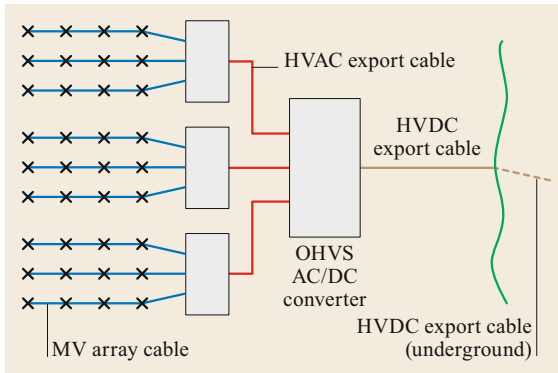

ble to an onshore substation, where it is passed on to the onshore grid. This solution is particularly useful for larger wind farms that are further from shore, typically 20–70 km. In this case, it is recommended that the voltage level of the export cable should be adjusted to the voltage level of the onshore substation; otherwise an extra transformer will be needed on land.

A second export cable circuit can also be installed to increase the availability and reliability of the overall system (Fig. 10.46). In this case, it is also recommended that two or more (depending on the total power generated) transformers should be used at the OHVS.

Instead of using two HV export cable circuits, it may also be possible to use one EHV (e.g., 245 kV) export cable circuit. In this case, there is a choice to be made between using two export cable circuits of lower voltage, which offers redundancy if one of the export cables fails, or using one export cable circuit at a higher voltage with no built-in redundancy if there is a cable failure. Aside from the issue of redundancy, these two solutions have different CAPEXs and OPEXs.

#### HVDC Solution

The HVDC solution is mainly used for offshore generation sites that are far from shore (> 70 km). Several

**Fig. 10.47** Scheme for HVDC connection to three offshore wind farms (adapted from [10.36])

offshore generation plants, each with their own OHVS, will usually be connected to one AC/DC offshore converter station. The generated power is passed from this offshore converter station to shore by means of a HVDC connection. This is because the transmission capacity of a HVDC cable link is higher than that of a HVAC cable link for the same conductor size. This cluster or hub solution has the advantage that the length of cable needed is less than that required in the situation where each offshore wind farm is connected to shore separately. Other advantages are reduced installation costs and fewer landfalls. One of the main disadvantages of this solution is that failure of the main export cable can result in a significant drop in electricity production, which may disturb the balance of the system. Figure 10.47 shows an example in which several offshore generators are connected to an offshore substation, which is in turn connected to shore via one export cable.

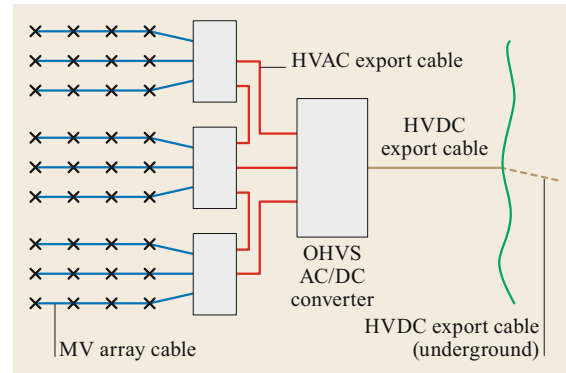

#### Combined HVAC/HVDC Solution

Another solution used to increase the redundancy in the offshore collector grid is to interconnect the different platforms at the HV level (Fig. 10.48).

#### Offshore Grid Solutions

Multiple offshore generation sites are often situated close together. In this case, it can be more prudent to look for a combined solution that can bring the power generated by all of the offshore generators to shore or to different shores.

There are some challenges involved with implementing such a solution. First of all, it is very costly to build and maintain offshore constructions and installations. Secondly, if a HVDC grid is built with multiple terminal converters, it may be necessary to ensure, for example, that a commutation failure will not switch off more than one line, so a HVDC circuit breaker

**Fig. 10.48** Scheme of a combined HVAC AND HVDC solution for collecting the power generated by multiple offshore power generation plants (adapted from [10.36])

must be introduced. The various options for offshore generation connection including offshore grid were the topic of a recent CIGRE Symposium in Aalborg (Denmark) [10.38].

#### 10.5.3 Effect on the Grid

The implementation of AC cables in HV and EHV grids significantly influences the electrical parameters of the grid. For instance, it influences the steady-state voltage due to the production of reactive power. This will be especially noticeable to grid operators when there are low-load conditions in the grid. Generators or dedicated shunt reactors positioned in the grid must absorb this surplus reactive power.

The impedance of a cable connection is far lower than that of an overhead line at the same voltage level. This influences the current distribution between the cable and overhead line when they are operated in parallel, which can cause unbalanced and inefficient use of the overall transmission capacity of the system. This is normally restored by installing series reactors (Fig. 10.49) in the cable circuit. Other alternatives are to insert series capacitors into the overhead line section or to adjust the transmission capacity at the design stage. In the latter case, the transmission capacity of the cable would need to be related to the ratio of impedances. This may require an exceptional cable rating, which is rarely practical.

The application of long HV and EHV cables will significantly change the harmonic impedance of the grid. If a large amount of cable is added, peaks in the impedance curve can strengthen, and the lowest resonance point will slide downwards to the power frequency.

There are two main concerns here: the risk of resonance due to switching actions and the amplification of higher harmonic distortion in the grid. This distortion

**Fig. 10.49** Series reactor in a 380 kV hybrid line (adapted from [10.14])

would already be present or would have been introduced by a customer (for example by a wind farm, or by motors with power electronics).

Switching actions can lead to resonances with substantial voltage rises or overvoltages. Such problems can be particularly severe when switching large transformers and long cable connections. The amplification of higher harmonic voltages causes additional currents that can cause equipment (e.g., transformers, generators, motors, current transformers, and cables) in the transmission grid to overheat. It can also cause issues with grid protection and motor controllers.

Therefore, the reliable application of long AC cable connections necessitates detailed system modeling studies. If the study results show that resonance or unacceptable amplification of higher harmonics can occur, suitable measures must be taken. Naturally, the countermeasures applied depend on the nature of the identified problem and its severity.

Due to different electrical and physical properties of cables and overhead lines, it may be necessary to change existing protection policies and schemes. Most important in this respect are the influence of cables on line-distance relays (impedance relays) and autoreclosure policies for hybrid lines.

The extent to which an AC grid is influenced by the inclusion of an underground cable and the measures that must be taken because of it vary significantly depending on the voltage level, the grid configuration, the short-circuit level, and the reason for using the cable in the power system.

A long AC cable connection feeding a small load (e.g., an oil platform) yields significantly different challenges from those associated with a connection to an offshore wind farm. Partial undergrounding of EHV

overhead line circuits also provides additional challenges. This means that the technical and economic optimization of a long AC cable connection can vary significantly depending on the situation.

### Matching Cable and OHL Ratings

It is much cheaper to achieve a high transmission capacity with an OHL than with an underground cable. The OHL current rating is based on the properties of the conductor and static environmental conditions (temperature, wind speed, and solar radiation). If the same conductor is used for an underground cable, it will have a lower current rating. This is due to the thermal insulation afforded by cable materials and the surrounding ground. The current rating can be increased by making the conductor thicker and more conductive (i.e., using copper instead of aluminum), but this approach is less effective for large conductor sizes due to the skin effect. It can be economically unattractive to match OHL and underground cables based on continuous ratings due to the larger cross-sections or number of cables per phase needed for underground cables.

In many circumstances, the thermal inertia of the underground cable (see the section on rating) needs to be considered when matching a cable to an OHL. This can result in the use of smaller conductor sizes, cheaper conductor materials, and fewer cables per phase, as this will reduce the required installation trench width. The implementation of a smaller installation swath not only reduces civil costs but may also ease right-of-way requirements and allow the cable system to be installed in narrow corridors. Reducing the number of cables per phase also results in less maintenance and, especially for high-voltage cables, less reactive power.

When matching the current rating of a cable system to an overhead line and examining the possibility of using thermal inertia, there are several factors that can be considered. These factors include expected circuit loads and preloads, the dynamics of the load, the cable environment, the laying configuration, and the application in the grid. In particular, the system or circuit operator's requirements for the overall circuit will be a significant driver.

The current rating of an overhead line is determined by either the electrical clearance (allowable sag) or by a thermal limit linked to the preservation of mechanical properties. This continuous or static rating of the overhead line is determined based on the supposed worst-case environmental conditions.

If the grid has an  $n - 1$  safe operation, the current rating during this condition can be set to a lower level in order to reduce cable costs in a hybrid connection.

In the first case, called a pre-fault, the cable in the hybrid connection can be temporarily loaded up to the continuous rating of the overhead line.

In the second case, called a post-fault, if the system operator can guarantee to limit the post-fault rating to a set period of time (for example 24 h) and to not repeat this emergency rating for some agreed time (e.g., until the cable has cooled to its pre-fault rating temperature), then it may be possible to match the post-fault overhead line rating to an emergency cable rating.

In these cases, the continuous current rating of the cable is less than that of the overhead line, allowing the use of a smaller cable. It should, however, be noted that the current-carrying capacity of the overhead line has been compromised. This method is described as emergency ratings in IEC 60853.

If the system operator can guarantee to limit the post-fault rating to a set period (for example 24 h) but may have to repeat the post-fault operation, then it may be possible to match the overhead line rating to a cyclic cable rating. It should be noted that this guarantee to limit the post-fault rating must be given when the transmission network is being planned, and it may be difficult to give such a guarantee because fault durations can be difficult to predict. For example, fixing a cable fault can be a lengthy process (several weeks is not uncommon), causing a considerable delay before the circuit returns to full service. Practical examples are given in [10.14].

### Dynamic Cable Rating

The previous section described how the cable and overhead line ratings can be matched using the thermal inertia of the cable, an assumed preload, and a possible load cycle. This enables the cable system design to be optimized and reduces costs.

Dynamic rating is also economically attractive for wind farm connection, where cables are rated to 70–80% of the full wind-farm rating for example. If periods of high wind strength can be predicted (from observational statistics), then dynamic cable ratings can be applied in a reliable way. Dynamic cable rating is a cost-saving solution and is even more effective when used in combination with distributed temperature sensing (DTS) [10.12]. If this solution is chosen, the operator should monitor the cable connection and may need to constrain the output of the wind farm. This topic was very recently covered by CIGRE WG B1.45 in TB 756 [10.19].

Preload and load-cycle information can also be used for existing cable connections for which only continuous ratings have been calculated (according to IEC 60287) previously. Applying dynamic ratings to existing cable connections allows a potential increase

**Fig. 10.50** 150 kV cables with PT 100 elements at a hot-spot (adapted from [10.14])

in transmission capacity of up to about 30%, depending on the cable type and cable laying configuration as well as the preload and load cycle. It should be noted that higher dynamic ratings can be reached if the actual cable temperature or other system data (such as historic loading levels) can be accessed, or if real-time measurements are available. Dynamic ratings can be higher due to a lower preload rating, as there are often more dynamics in the load cycle and lower environmental temperatures than assumed during the design calculations. The temperature of a cable can be measured with PT elements at the locations with the worst thermal conditions (*hotspots*) (Fig. 10.50). This can be a particularly effective approach for optimizing grid operations by allowing more power to be transmitted than the grid was designed for, or allowing outages that would not normally be considered.

### 10.5.4 Protection Systems

Protection systems used for HV and EHV grids often assume that overhead lines are used. The introduction of cable connections or hybrid connections can therefore lead to a modified protection philosophy. Most issues caused by cables can be mitigated using modern protection devices, which can be digital or numeric and can deal with different types of connections. Additional high-voltage equipment associated with cables such as series and shunt reactors must also be protected. This can be done within the protection zone of the connection or by a separate differential protection system.

Autoreclosure is typically designed for overhead lines, where many faults only occur temporarily. This is not the case with underground cables, where a fault in the insulation cannot heal itself. Autoreclosure is not applicable to full cable connections but should be con-

sidered for hybrid connections. There are a range of policies that can be applied, each of which has its own advantages and disadvantages.

From an insulation coordination perspective, surge arresters are not always needed to protect the cable insulation, although they can still be useful in hybrid lines, where reflections and earth potential rises can occur at transition points [10.30, 31].

#### Power Cable and Hybrid Link Protection

Line distance protection is widely used in HV transmission grids because it does not require telecommunication channels between both ends of the line. Distance protection relays are based on a linear increase in the impedance over the length of the line. If the impedance drops below an adjusted minimum, the fault is within the protection zone, and the line will be switched off.

Distance protection can be used for cables too, but underground cables have different electrical properties. Cable return paths can vary depending on the fault type (core–sheath or core–sheath–earth), the location of the fault (distance to the cross-bonding or grounding point), and the way that the metal sheath is earthed (single point, solid-bonded, cross-bonded, or other). This can lead to a deviation of the linear impedance curve, causing the limits of the protected zone to be determined inaccurately. This is especially true if there is insufficient distinction in the last 20% of the impedance curve, as it is important to determine the setpoint for the first protection zone in this range.

Systems with long cross-bonded cables show smaller deviations of the linear impedance curve due to the decreased relative impedance of each section. Detailed studies are necessary to identify the right setting for the distance relays. Capacitive currents are sometimes neglected for overhead lines but they must be considered for long cable systems.

Differential protection is normally the preferred reliability protection system for cable connections, with line distance protection used as a backup system.

If hybrid links (partial undergrounding, for example a siphon) are present, different impedances are connected in series. On the one hand, this makes it harder to determine the minimum impedance setting for the distance protection, but on the other hand the influence of the cable section on the total impedance decreases as the overall connection increases in length. Modern digital distance relays are a big step forward: they can also deal with multiple cable sections in a hybrid line. If the level of protection provided by line distance relays is unclear, differential protection can always be applied. This is the normal choice for full cable connections, but telecommunication channels are not always available for existing partial undergrounding.

To summarize, cable systems can be protected by distance protection. It is easier to reach an acceptable level of accuracy for longer cable lengths than for (very) short lengths. Differential protection of a full cable connection is preferable, but its dependence on telecommunications must be managed.

#### Autoreclosure and Lockout Systems

Autoreclosure is widely used after faults in overhead lines. The aim of autoreclosure is to optimize the availability of circuits and thus improve the security of supply. For hybrid connections, a range of autoreclosure strategies are available:

- A lockout system for faults in the cable section
- An unchanged autoreclosure system
- No autoreclosure.

Each of these strategies has its own advantages and disadvantages, and all of them are applied worldwide.

Lockout systems give the best performance, as autoreclosure is still available with these systems but it will not operate when there is a cable failure. There is no additional damage and no further voltage dips with a fault in the cable. However, to detect this fault, measurement and telecommunication channels to the substations are required. A lockout system applies differential protection over the cable section, so current transformers are needed. Such a system is more difficult to implement if there are numerous cable sections in an overhead line.

However, there are considerable financial and space-related disadvantages of using a lockout system. If slip-on current transformers are used at the ends of the cable system, failure of the cable sealing ends will still activate the autoreclosure.

In some circumstances, the use of autoreclosure with hybrid connections is acceptable. The choice of whether to use autoreclosure involves a risk evaluation. A benefit of using autoreclosure is that it keeps the system simple. Issues that need to be considered in this case are the expected number of faults in the cable section (far fewer than in the overhead line section), the additional cable damage, the risk of fire or other injuries, and additional voltage dips.

For hybrid lines with relatively short overhead line sections, the removal of autoreclosure may also be considered. Many factors play a role when deciding whether to remove autoreclosure, such as the failure rate (the protection level against lightning strikes), the amount of redundancy in the meshed grid, and safety aspects (especially in highly urbanized areas). Although removing autoreclosure is not advisable, this approach is used to some extent in the Netherlands for 150 kV

**Fig. 10.51** Relative voltage increases due to the Ferranti effect at different voltage levels and for various conductor cross-sections (adapted from [10.14])

hybrid lines in a highly meshed grid, and has not led to any significant deterioration in the security of supply over a period of more than 15 years.

New technical developments in protection equipment have led to an improved ability to distinguish between an overhead line section and a cable section. This ability means that it is possible to apply autoreclosure only when the fault is in the overhead line section. Autoreclosure can cause overvoltages, especially at transition points where overhead lines are connected to underground cables. Careful examination of this phenomenon is necessary to determine the appropriate cable design, including whether to install any surge arresters in the transition compounds.

### 10.5.5 Voltage Effect (Ferranti Effect)

When the power cable line is operating with an open circuit and the voltage is applied at one side, the voltage increases at the opposite side of the line. This effect is caused by the charging current of the cable capacitance.

This may present an issue after the circuit has been installed and the cables must withstand the HVAC voltage used in a soak test or resonance test. The test voltage  $U_{test}$  is specified by the standards IEC 60840 and IEC 62067. Due to the Ferranti effect, when  $U_{test}$  is applied to one side of the circuit, the test voltage at the remote end will be  $U_{test} + \Delta U$ .

The voltage increases shown in Fig. 10.51 are based on the characteristics given in Table 10.5. The cables are laid in a flat formation 300 mm apart, losses from the metallic screen are 1%, the dielectric loss factor  $-\tan \delta = 0.0005$ , and the the working frequency is 50 Hz.

**Table 10.5** Characteristics of extruded cables (adapted from [10.14])

Phase-to-phase voltage (kV)	66	132	230	400	500
Copper conductor size (mm <sup>2</sup> )	2000	2000	2500	2500	2500
Diameter over conductor (mm)	55	55	64	64	64
AC resistance of conductor ( $\mu\Omega/m$ )	16.13	16.13	14.16	14.16	14.16
Insulation capacitance (nF/km)	375	269	249	219	192

The hyperbolic increase in voltage along the power line must be estimated prior to the HVAC commissioning test of the cable because the test voltage and the no/low-load operation voltage are higher than the nominal voltage  $U_0$ .

### Testing After Installation

The power line owner and the cable contractor must agree on the voltage to be applied on one side of the circuit, given that the voltage will be higher at the remote end. Also, one or multiple shunt reactors located somewhere along the power line are sometimes included in the HVAC test, in which case the voltage rise(s) at the location(s) of the shunt reactor(s) must be calculated beforehand and will influence the selection of the test voltage, which must be agreed upon by the line owner, the cable supplier, and the shunt reactor provider. Additionally, the inclusion of a voltage divider on both sides of the power line is recommended as a means to measure the voltage during the HVAC test.

### Under No or Low Load

The voltage must be no higher than the maximum cable voltage  $U_m$ , which is the reference for cable design and qualification (i.e., 245 and 420 kV, respectively, for 230 and 400 kV cables). Alternatively, a higher  $U_m$  value than that specified by the IEC standards can be defined, especially for cable lengths that will be installed on the side of the circuit where the voltage is higher than  $U_m$ .

### 10.5.6 Zero-Miss Phenomenon

Reactive power compensation by shunt reactors connected directly to the cable will help to reduce the

voltage drop in the grid caused when a long length of cable is energized. If the amount of reactive compensation is more than 50%, the zero-miss effect can occur. This effect can happen in the first few seconds after switching on a cable and connected reactors. Due to the temporary aperiodic current component of the shunt reactors, it takes a few hundreds of milliseconds before the current has its first zero crossing, necessary for opening the circuit breaker without reignition.

There are several ways to solve this problem: the amount of compensation directly connected to the cable can be decreased, point on wave switches can be applied, a preinsertion resistor (closing resistor) can be fitted, or single-phase tripping can be used. As only the healthy phases experience this zero-miss effect, it is possible to postpone the opening time of this phase by a few milliseconds until the effect has passed, which is referred to as automatic sequential switching (first the faulty phase is switched off, then the reactor, and after a few hundred milliseconds the healthy phases are switched off).

For weak grids, one utility in Europe has chosen a solution in which the cable and reactor each have their own circuit breaker. The reactor is connected to the busbar and not to the cable. The breakers work simultaneously to keep the voltage drop within the defined limits and to stop the zero-miss effect from occurring.

### 10.5.7 Switching Off Capacitive Currents

High-voltage cables are highly capacitive by nature. The longer the cable, the higher the capacitive current that must be switched off. Switching capacitive currents can be difficult for a circuit breaker because the voltage is near to maximum when the current becomes zero and restrike can occur. A small capacitive current can be even harder to disconnect than a large one.

Table 10.6 shows that for a long length of high-voltage cable, the no-load capacitive current can exceed the guaranteed capacitive interruption current of the circuit breaker. IEC 62271-100 specifies that a circuit breaker must be able to disconnect a no-load capacitive current of 250 A. Additional testing may be necessary to ensure that the requirements are fulfilled (e.g., 220 kV, 50 km, 1200 mm<sup>2</sup> gives  $50 \times 7.6 = 380$  A of charging current).

**Table 10.6** Indicative values of the charging current for different conductor cross-sections and voltages

Voltage (kV)	220	220	400	400
Cross-section (mm <sup>2</sup> )	1200	2500	1200	2500
Charging current (A/km)	7.6	10.8	13	17.4

### 10.5.8 Harmonic Resonance

The phenomenon of resonance in long AC cables in a grid dominated by overhead lines is a concern, as it can cause unacceptable voltage rises or equipment to overheat due to additional currents. This resonance can occur at the power frequency (50 or 60 Hz) as well as at higher order harmonics of the ground frequency and at interharmonics.

Resonance due to the application of a cable (high capacitance) occurs due to the resulting change in the harmonic impedance of the grid whereby the frequency of a harmonic current or voltage matches that of a peak in the impedance curve. There are two types of resonance in the grid: switching actions or short circuits (damped oscillation) and amplified background higher harmonic voltages (driven oscillation). The latter are fed into the grid by a source. Well-known sources of higher harmonic currents include frequency controllers of motors, HVDC connections, and converters in wind turbines.

Both series and parallel resonances can occur. Series resonance can be generated when energizing a cable. The resonance occurs between the inductance of the grid (the source) and the energized cable when there is a frequency component in the energizing current that corresponds to the resonance frequency of the induction–capacitance (LC) combination.

Parallel resonance can occur during the energization of a transformer. The resonance arises between the inductance and the capacitance of the grid (to which a long cable is connected). The inrush current of a transformer is dominated by a second harmonic component that can be responsible for resonance in the grid at the point of switching.

As more cables are added the resonance frequency of the grid declines.

Switching actions can cause resonance frequency excitation and must be further investigated. Research in the time domain can be performed to detect unacceptable voltage rises (in terms of amplitude and duration). In addition to the short circuit power also the damping by resistance ( $R$ ) of the grid and the load play a role in the degree of over voltages caused by resonance. The extent is often known only approximately and in case of doubt it may be necessary to perform additional measurements.

If a system study indicates an unacceptable transient overvoltage (TOV) due to switching actions, measures must be taken.

### 10.5.9 Magnetic Field

Various requirements must be met when implementing new high-voltage connections. For instance, it is

necessary to fulfill the requirements for electric and magnetic exposure. In this respect, underground cables have some benefits. Due to the presence of the insulation screen and the metallic sheath there is no exposure to electric fields, and there are numerous options to reduce the exposure to magnetic fields.

The main reason for the increased magnetic exposure with high-voltage cables is the suppression of the sheath current by the cross-bonding system and the spacing between the single-phase cables. Both of these steps are taken to optimize the current rating and to lower the costs.

To lower the magnetic exposure levels, the circuit impedance may be changed. For power system planners, it is important to know how the cable system will actually perform in practice. If measures to decrease the magnetic field change the connection impedance, the current distribution in the interconnected power system and short-circuit current levels may also be affected.

Magnetic fields from underground cables can induce voltages in nearby insulated metallic structures such as pipelines if the cables and pipelines are laid in parallel over very long lengths. Safety and corrosion issues can occur in such cases. There are various methods to reduce magnetic field exposure in order to meet requirements at specific locations. The impact of magnetic fields on current ratings is covered by TB 559 [10.21].

### 10.5.10 Life Expectancy

HV and EHV cables are designed to have a typical economic lifetime of 40 years (according to tests and international standards, e.g., those of the IEC). In reality, the technical lifetime of these cables is much longer. Many oil-filled cables that are in use today are over 40 years old, and the operational costs of those cables have not increased significantly over the years.

External damage or incidental internal faults in the cable system are relatively easy to repair, and the repair costs are only a small fraction of the initial investment cost. Thus, repair allows the lifetime of a cable to be extended.

The main reasons for removing a cable from service are a lack of transmission capacity (sometimes combined with the scenario where there is a lack of space to install a new cable with a higher transmission capacity without removing an old cable) and unacceptable oil leakages. In a few cases, end of cable life is caused by degradation of the insulation. Many HV oil-filled cables have been in service for over 60 years, but in many of those cases it has been necessary to replace or recondition the oil-pumping or monitoring systems.

Modern HV XLPE cables have been in operation since the mid-1970s and are continuing to provide excellent performance. They have the same repair options as oil-filled cables, but unlike those cables, XLPE cables cannot leak.

A range of issues must be considered when attempting to maximize cable lifetimes. These issues can be categorized as follows:

- Cable design and manufacturing
- Cable route planning and installation
- In-service maintenance.

#### Cable Design and Manufacturing

There are various cable design considerations. First, the quality of the XLPE insulation must be of the highest possible standard and the most advanced method of applying the insulation should be employed. Second, the selection of an appropriate metal sheath and outer sheath in accordance with the installation method and the environment is crucial. The intended installation technique and the environment of the laid cables will influence the choices that can be made in this regard. When the outer sheath is damaged, an induced voltage causes a current that will flow through this damaged point, degrading the metal sheath and potentially overheating the cable. If the outer sheath is damaged, corrosion can then occur, further damaging the metal sheath (especially if it is aluminum).

A third important aspect is the radial water barrier. When the metal shielding is broken, moisture (water) can penetrate towards the cable insulation and spread itself over a very long length due to capillary action. If this is not addressed in the cable design, it may mean that a substantial length of cable will need to be replaced when failure occurs.

#### Cable Route Planning and Installation

When planning the cable route, and subsequently during operation, the presence of heat sources (other cables, steam pipes, tubes for heating) near to the cable must be avoided or, at the very least, taken into account during engineering. Pulling forces must not be exceeded and damage to the outer sheath must be avoided during cable installation or the service life of the cable will be reduced.

#### In-Service Maintenance

To maximize the service life of the cable, it is important that the outer sheath remains in place over the metallic sheath to avoid water entry. It is also important that link boxes are kept in good condition and that the bonding leads are fully water blocked to stop water from migrat-

ing into the box. Finally, it must be ensured that the cable design temperatures during operation and short circuits are not exceeded. As discussed later, online monitoring of cable temperatures and route conditions is a useful tool for routine maintenance. Well-known threats to the cable that can occur in its environment include depressions in the ground, changes in the groundwater level, trees with deep roots, and any heat sources close to the cable, such as highly loaded cables and heating pipes.

### 10.5.11 On-Site Testing

Testing long AC cables, especially HV and EHV cables, is a challenge due to the amount and size of the test equipment required.

The most important test—the voltage withstand test of XLPE cables—can only be done with an AC voltage. The much easier DC voltage test is not suitable for testing XLPE cables because a DC voltage can leave space charge within the insulation or at interfaces between the cable insulation and the components used in the termination and jointing accessories. These space charges can remain after the DC voltage has been switched off, causing localized high electrical stress in the insulation system when the cable is energized with AC, which would in turn initiate partial discharges and subsequent cable system failure.

In the cable factory, XLPE cables and individual accessories are tested using AC with a typical frequency of 50 or 60 Hz and test equipment with parallel (primary) or series (secondary) reactive compensation.

HV and EHV XLPE cable systems are typically tested on-site using AC with a frequency in the range 10–300 Hz. A mobile resonance test is performed with series reactance (an example of this is given in Fig. 10.102 in Sect. 10.7.1).

To test long AC cables, we need to compensate for the charging current, which is directly related to the frequency and the test voltage as follows

$$I_c = 2f\pi CV,$$

where  $I_c$  is the charging current in A,  $f$  is the test frequency in Hz,  $C$  is the cable capacitance in F, and  $V$  is the test voltage in V.

To compensate for this very high charging current, we need to use high reactive HV compensation (*exciter*) coils, which are very heavy because they contain large amounts of copper and steel. This makes on-site testing very difficult and expensive. One solution is to lower the AC frequency. The standard IEC 62067 prescribes a lowest frequency of 20 Hz, and this has been used for many years to test HV and EHV circuits. A more recent document, CIGRE TB 490 (published by WG B1.27), recommends a minimum of 10 Hz [10.39].

Over the past five years, there has been a dramatic increase in partial discharge testing of new installations around the world, although many utilities still do not perform PD tests. CIGRE TB 728, recently published by WG B1.28 [10.40], provides useful guidance for non-experts in on-site PD measurement. This document collates information on PD testing and presents guidelines and recommendations.

However, testing at this lower frequency is costly due to the equipment required, the space needed for that equipment, and the transport costs involved. Hence, there is currently a global debate on whether to lower the frequency even further, to 0.1 Hz, or whether to adopt the oscillating wave system (OWS) or the damped AC (DAC) system, both of which are currently used to test MV cables. These systems are much smaller, less expensive, and easier to transport. However, there are some important issues that need to be considered for HV and EHV AC systems.

First, research clearly shows that during withstand testing, breakdown is directly related to the energization time at a given frequency, so much longer testing times or higher test voltages will be needed if the 0.1 Hz test is adopted.

This is not a problem for MV cable systems, as they can accept higher test voltage levels, but it could present an issue for HV and EHV systems that are specifically designed for operational and system voltages.

Second, there is concern that space charge could remain in the system if the voltage is not reversed within a very short time interval, meaning that the results of withstand testing with a DAC system could be questionable.

Since this important subject is quite complex, CIGRE WG B1.38 is currently preparing a technical brochure to provide guidance on tests of AC and DC cable systems using new technologies after laying. This document is expected to be completed in early 2021.

### 10.5.12 Practical Implementation of System Design

#### Choosing Between AC and DC Voltage

Given the trend for longer AC and DC cables, it is important to fully understand the benefits and limitations of both systems. The choice of AC or DC is very much dependent on the load transfer requirements and the grid, whether a land or submarine link is needed, and other requirements. Each project needs to be considered on a case-by-case basis, and it should be noted that a DC link is always possible if it is not practical for economic or technical reasons to provide an AC link.

In many situations, an AC solution should be less expensive and lead to lower losses for a radial connection. It is important to carry out an analysis of the power

system losses, total installed capital costs (Fig. 10.2), and operating costs.

Although only two cables are required for DC compared with three for AC, the construction costs, which are often the major factor in the urban environment, may be almost the same for both. The costs for DC conversion are still relatively high, and the losses—albeit substantially lower than they used to be, due to the introduction of modern VSC systems—are still significant. However, if power flows are required in both directions and the route length may need to be increased at a later stage, the selection of modern DC technologies may be justified [10.6, 14].

Having decided that an AC link is the optimum solution, the next step is to consider the transmission voltage, cable design, and general installation method.

### Reactive Compensation

This section provides only a brief overview of system design issues relating to the implementation of reactive compensation on long AC links. For a more complete understanding of the technical issues associated with reactive compensation, the reader is referred to CIGRE TB 556 from WG C4.502 [10.27].

Underground cables produce reactive power according to

$$Q_{\text{cable}} = 2\pi fCV^2,$$

where  $Q_{\text{cable}}$  is the reactive power in var,  $f$  is the power frequency in Hz,  $C$  is the cable capacitance in F, and  $V$  is the line voltage in V.

The reactive power is proportional to the square of the voltage and the cable capacitance. Since the cable capacitance is proportional to the cable length, the reactive power increases linearly with the cable length. Reactive power has two side effects. The first is that it causes the steady-state voltage to rise in the grid and the cable itself. While the grid load and ordinary transformers in the network consume some reactive power, they do not consume enough to compensate for long cable links. The second effect is that it introduces a current into the cable, limiting the transfer of active power. As said above, at a critical cable length, the cable current rating is completely consumed by the capacitive current, meaning that no active power flows through the cable.

To operate the grid and the cable itself within the required limits while also preserving the effectiveness of the cable connection (or to optimize the current rating), it may be necessary to apply reactive power compensation (Figs. 10.49 and 10.52).

Reactive compensation is an optimization process involving many factors such as the voltage level, conductor cross-section, losses, amount of compensation

**Fig. 10.52** Reactive compensator for a 30 km 345 kV PPLP pipe-type cable in the USA (adapted from [10.14])

(partial or full), type of load on the cable (inductive load, generator/wind farm), compensation method (generators, reactors, power electronics), compensation location (effectiveness and available space), level of built-in redundancy, and costs. More detailed information can be found in [10.14].

### Cable Sheath Bonding

Induced sheath voltages must also be considered when designing underground cable links. The induced sheath voltage depends on the cable length, phase current, mean diameter of the metallic sheath, phase spacing, power frequency, and the arrangement of the phases (e.g., trefoil or flat). The aim of sheath bonding is to protect the cable sheath/joint shield break against transient overvoltages. During the transient/subtransient, the surge wave energy resonates along the line at high frequency. These high-frequency overvoltages can cause joint failure and sheath damage.

CIGRE TB 283 [10.30] (published in 2005 and edited by WG B1.18) provides details of current practices around the world concerning the bonding of high-voltage cables and how to calculate the induced voltage/current according to the grounding system used.

Most countries have a national standard that governs the maximum standing voltages allowed at the power frequency, as this is an important safety issue, particularly for maintenance crews. They are typically in the range 50–400 V. If the upper limit of this range (400 V) is acceptable, the number of cable junctions can be reduced, lowering the cost of the project.

Calculations of induced cable sheath voltages (working frequencies and transients) must be performed at the design stage to guide the selection of the appropriate protection/grounding system for the power circuit. Methods of calculating induced voltages are given in [10.30]. A power line model of the electrical circuit can also be

utilized to estimate continuous/transient induced voltages, or special software can be employed.

The standard surge voltage level of the protective jacket/sheath is given by IEC 60229. The cable junction and the concentric bonding lead cable that connect the cable metallic screen to the sheath voltage limiter (SVL) cabinet must also be designed to withstand surge overvoltages.

SVLs are used to protect sheath sectionalizing insulation (a discontinuity electrical node in surge wave propagation) during transient phenomena. SVLs are installed in sealed boxes either underground, in tunnels, or in the air, depending on the locations of the cable joints as well as the terminations. A physical barrier is usually installed in transition compounds linking overhead lines to underground cables to avoid any contact with the SVL. Without the protection provided by the SVL, the occurrence of transient phenomena could lead to failure and damage to the junction/protection sheath. The job of the SVL is to chop peak overvoltages and reduce the number of transient overvoltage signals that occur during transient phenomena. WG B1.50 has recently published a Technical Brochure providing guidance on the design, testing, operation, and monitoring of SVLs [10.41].

As noted in a previous section (see Figs. 10.24–10.26), the following bonding arrangements are generally used in high-voltage cable systems:

- Cross-bonding
- Single-point bonding
- Solid bonding.

## 10.6 Cable Designs

The insulation of lapped cables consists of a number of thin paper tapes wound around the conductor. The conductor is generally circular. Depending on the type of cable, the insulation is impregnated with a nondraining, high-viscosity insulating mass (i.e., mass-impregnated cables) or with low-viscosity oil.

As previously noted, the surface of the conductor is somewhat irregular due to the interstices between the single wires. To stop electrical stress concentrations from forming at such irregularities, several layers of semiconductive carbon black paper tape are applied onto the conductor surface. For high-voltage cables, it is essential to generate an undistorted radial electric field inside the insulation. Therefore, semiconductive carbon black paper tapes are also applied over the insulation, normally in combination with metal-coated paper tapes.

In order to achieve an AC withstand characteristic with a sufficiently long duration, it is necessary to stop

The *cross-bonding system* is the method most commonly used for long onshore/land links. Cross-bonding the metallic cable sheaths causes the induced sheath voltages to cancel out. This reduces circulating currents, resulting in reduced sheath losses and higher cable circuit ratings.

The *single-point bonding system* is generally used in substations when the cable route is relatively short and it is uneconomical to use the cross-bonding method.

*Solid bonding* is the simplest bonding method. It requires the metallic cable sheath/screen to be connected to earth at both ends of the circuit. The solid-bonding method results in higher sheath losses than obtained with other bonding methods due to higher circulating currents in the metallic sheath/screen, resulting in reduced cable circuit ratings. Solid bonding is used in situations where a reduced power-transfer capability is not a major concern. When this arrangement is used, the cable circuit design is simpler, allowing the utility to divert the cable circuit when required without impacting on cable circuit ratings. Solid bonding is generally used for three-core MV cable circuits and for single-core cable circuits where sectionalized joints are not readily available.

For submarine power cable links, the only feasible grounding system is a two-point solid-bonding scheme, which ensures watertight protection of the cables.

The grounding system of a long HVAC power link may consist of a cascading combination of several types of grounding schemes, for instance two-point bonding + cross-bonding + single-point bonding.

ionization from occurring inside the insulation. Ionization can take place in gas-filled voids; such voids can form in the insulation due to the different expansion and contraction rates of the cable components during load cycles.

A solution to this problem was discovered in 1917 by Emanuelli, who proposed a cable containing a hollow conductor that kept the paper insulation under positive pressure regardless of the temperature of the cable by connecting the cable to tanks filled with very fluid mineral oil, which were placed all along the cable route. Although such a *fluid oil cable* had never been installed or tested before, Emanuelli became convinced that it could be used at higher voltages, so he tested it by connecting the fluid oil cable to a 132 kV line. In 1926, he accepted an order for an oil fluid cable that could accommodate this voltage from New York, then another order from Chicago. A year later,

he constructed a 70 kV three-phase cable of this type in Milan.

In 1932, he connected a test cable to the 220 kV network at Cislago in Italy. The results of these tests were highly satisfactory and prompted four French cable manufacturing units to construct the first 220 kV link in Paris 220 kV. This link, commissioned in March 1936, was 18.5 km long.

The maximum voltage gradient in the insulation was 9.5 kV/mm, whereas the field in a mass-impregnated paper cable was about 5 kV/mm. The work of Emanuelli provided the basis for achieving the highest voltage levels used in underground power transmission. Several types of cables that use different mechanisms to overcome the ionization problem and to achieve so-called thermally stable cables have been developed.

### 10.6.1 Mass-Impregnated Cables

The historical perspective given in [10.1] details the evolution of power cables from the birth of the industry to the mid-1980s and the arrival of UHV extruded cables. From the earliest history of power cables, two main types of materials have been used to insulate cables:

- Vulcanized material
- Impregnated material.

Mass-impregnated (MI) paper insulation for 10 kV cables appeared in 1890 and was continuously improved. Over the years, mineral compounds have replaced vegetable-derived substances as the impregnating ma-

**Fig. 10.53** Cross-section of a mass-impregnated cable (adapted from [10.6])

terial, carbon-black paper screens have been adopted for conductors and insulation, and new grades of paper have been introduced, as have thin papers, to increase the impulse strength of the insulation. By 1960, wax-filled compounds were being used in insulation, as they are less fluid and more electrically stable than oil resin compounds.

The fundamentals of the mass-impregnation technique have remained the same, and variants of it have been used in the vast majority of the cables employed by public and private power networks across a wide range of voltages, from low to 60–70 kV and exceptionally 90 kV.

Indeed, mass-impregnated cables were used in HVDC applications as far back as 1906, after which HV and EHV levels were gradually attained for these cables, mostly in submarine links, e.g., to the isle of Gotland in 1954 ( $\pm 100$  kV), from France to England in 1961 ( $\pm 100$  kV), to Vancouver Island in 1969 ( $\pm 300$  kV), and the Skagerrak Strait link in 1976/1977 ( $\pm 250$  kV).

Figure 10.53 shows an example of a mass-impregnated cable used for submarine applications. This type of cable can be used at EHVDC levels.

### 10.6.2 Self-Contained Fluid-Filled Cables

In 2016, CIGRE WG B1.37 published TB 652, which is a guide to operating self-contained fluid-filled (SCFF) cable systems [10.42]. The information given in [10.42] (which is summarized below) can guide the reader towards a better understanding of the differences between SCFF and extruded cable systems.

#### Examples of SCFF Cables

Figures 10.54–10.59 show several examples of SCFF cables with various conductors and shields.

**Fig. 10.54** 500 kV SCFF cable with a compacted circular conductor and a corrugated aluminum sheath (CAS) (adapted from [10.42])

**Fig. 10.55** 400 kV SCFF cable with a Milliken copper conductor and a corrugated aluminum sheath (note the helical duct support) (adapted from [10.42])

**Fig. 10.57** Example of a 500 kV single-core SCFF submarine cable (adapted from [10.42])

**Fig. 10.56** 500 kV SCFF cable with a 1600 mm<sup>2</sup> copper keystone conductor and a lead sheath (adapted from [10.42])

**Fig. 10.58** Example of a 90 kV three-core SCFF cable; note the heavily coated armor wires that are typical of submarine cables (adapted from [10.42])

**Fig. 10.59** A typical cross-section of a single-core SCFF cable, showing its component parts (adapted from [10.42])

### SCFF Cable Fundamentals

Self-contained fluid-filled cables (SCFF) are cables in which the conductor insulation is composed of multiple layers of paper impregnated with a low-viscosity dielectric fluid encased in a metallic sheath (usually a lead alloy or aluminum). For single-core cables, there is generally a central hollow core that allows the dielectric fluid to move freely along the cable. A three-core SCFF cable usually has a separate helical duct (or ducts) that is bound up in the fillers, with the cores inside its metal sheath. However, some three-core cables are constructed without fillers and the space between the insulated cores allows the fluid to flow freely within the metal sheath.

Heat and vacuum treatment during the manufacturing process removes air and moisture from the papers. The papers are then impregnated with a low-viscosity fluid to prevent the formation of voids and the associated ionization when energized. The fluid is contained at low pressure within a metal sheath in the form of corrugated aluminum or lead alloy (suitably reinforced). An extruded plastic oversheath provides corrosion protection for the sheath. The fluid must be maintained at positive pressure at all times. During operation, the cable fluid expands into sealed storage tanks as the conductor temperature increases and flows back into the cable as the conductor cools.

Three-core SCFF cables are typically limited to voltages of 150 kV or less and conductor cross-sections of 630 mm<sup>2</sup> or less due to manufacturing, cable size, drum handling, and installation limitations.

Submarine cables normally require the application of further mechanical protection in the form of round or flat wire armor that is completely surrounded by synthetic bedding and serving.

Polypropylene paper laminate (PPL), sometimes also referred to as PPP or PPLP, depending on the country of origin, was developed to reduce dielectric losses and increase the impulse strength of the cable insulation. PPL consists of a film of polypropylene coated on both sides with a layer of paper. It is lapped onto the conductor in the same way as for paper-insulated cable. It is similarly hermetically sealed and impregnated with cable fluid maintained at a positive pressure. However, its technical advantages are offset by higher costs, and it is generally only used as an alternative to paper-insulated SCFF cables at extra-high voltages.

Low-pressure cable sheaths are normally made to sustain internal pressures of 5.25 bar with transients of 8 bar. However, pressures of up to 15 bar can also be sustained by some sheaths. For these designs, the accessories must be chosen appropriately, and the cable reinforcement design must be verified. Such high-pressure systems may be used for submarine systems or for high-pressure fluid-filled (HPFF) pipe-type cables.

### Hydraulic Aspects

The appropriate hydraulic design of a SCFF cable system is critical to its reliable operation, and the design used depends largely upon the vertical profile of the cable installation. This is conveniently described graphically by expressing pressure in terms of meters of fluid (Figs. 10.61–10.63). The vertical profile of the cable and the fluid pressure (static or transient) can be depicted on the same diagram, with the pressure at any point in the system given by the difference between the pressure line of interest and the cable profile.

This hydraulic system design takes into account the cable route and elevation (or vertical profile) as well as the thermal expansion and contraction of the cable fluid caused by temperature variations in the cable system. It ensures that any overpressures caused by temperature transients do not cause mechanical damage to any part of the system, including the cable, accessories, and the feeding system. It is normal for longer routes or routes through undulating terrain to be divided into a number of hydraulically separate sections using stop joints that maintain electrical continuity but isolate adjacent hydraulic sections. The design must also ensure that pressures do not fall below well-defined values so that positive pressures are maintained at all times.

**Fluid Volume Variations.** Temperature variations cause changes in the cable fluid volume. Minimum volume occurs at the minimum temperature (i.e., during winter) with the cable unenergized. Maximum volume occurs at the maximum temperature (usually in summer) under maximum load or during emergency (overload) conditions. Cable fluid reservoirs (usually pressure tanks) positioned at the cable end(s) and possibly at intermediate positions along the cable must accommodate the *static* fluid volume variations. These reservoirs (also known as feeding pressure systems) can be divided into constant-pressure and variable-pressure systems.

**Gravity Fluid Tanks.** Constant-pressure systems are characterized by a feeding system consisting of *gravity tanks*: tanks that do not have internal gas cells and are designed to absorb pressure variations. Since this type of feeding system was the first to come into service, very old SCFF cable systems (in which the original fluid was mineral oil and short cable routes with flat profiles are used) generally belong in this category. Since the tank pressure cannot vary, the tank must be installed such that the tank is at a higher position than the highest system point. The tank must be able to contain all fluid expansion from the cable and the accessories under the hottest conditions and return the fluid to the system by gravity under the coolest conditions whilst

maintaining a positive pressure. Small changes in pressure due to changes in fluid levels in the tank are usually ignored.

**Prepressurized Fluid Tanks.** The SCFF cables in service today are most likely to use prepressurized tanks as their fluid reservoirs. These tanks contain a number of sealed, flexible, expanding cells that contain pressurized gas, usually carbon dioxide or nitrogen. The expansion of the cable fluid is compensated by the compression of these cells. The tank capacity and the pressure setting must be such that the minimum static pressure is higher than the highest system point and the maximum static pressure does not cause unacceptable pressure values for the cable and accessories at the lowest system point. The relationship between the fluid volume and the corresponding pressure of a cable fluid reservoir of a specified type is obtained from either a suitable experimental curve or by performing calculations based on the perfect gas law.

Figure 10.60 shows predicted and experimentally determined pressure–volume curves for a typical 120 L variable-pressure fluid tank. The middle curve is the experimentally determined one, obtained at ambient temperature; the other two curves were derived from the middle curve, via the perfect gas law, for the extreme (seasonal) ambient temperatures expected at the location of the system studied. Positions 1 and 2 in Fig. 10.60 show that a 50 L expansion due to a change in temperature from  $-20$  to  $+50$  °C will result in a static pressure change from  $0.5$  kg/cm<sup>2</sup> (5.8 m of fluid) to  $2.2$  kg/cm<sup>2</sup> (25.3 m of fluid).

**Fig. 10.60** Pressure–volume curves obtained at different ambient temperatures for a typical 120 L variable-pressure tank; the *middle curve* was determined experimentally, whereas the *outer curves* were predicted using the *middle curve* and the perfect gas law (adapted from [10.42])

The variation in cable fluid volume can also be calculated using the perfect gas law according to

$$\Delta V = \left( \frac{T_1}{P_1} - \frac{T_2}{P_2} \right) \frac{P_0 V_0}{T_0},$$

where  $\Delta V$  is the change in fluid volume in L,  $P_1$  and  $P_2$  are the absolute values of the maximum and minimum pressure in kg/cm<sup>2</sup>,  $T_1$  and  $T_2$  are the absolute values of the maximum and minimum ambient temperature in K, and  $P_0$ ,  $V_0$ , and  $T_0$  are the initial pressure, volume, and temperature of the gas inside the cells of the oil tank in kg/cm<sup>2</sup>, L, and K, respectively.

Provided the value of  $P_0 V_0 / T_0$  is known for the type of oil reservoir under consideration, this formula provides a relatively easy way to evaluate the relation between fluid volume, pressure, and temperature.

**Static Pressure Considerations.** Gradual variations in temperature result in pressure changes that equalize throughout the cable system. In this case, gravity tanks experience only very small changes in pressure due the volume variations caused by changes in temperature. However, the pressure in prepressurized feed tanks changes significantly with the volume variations caused by temperature changes. The minimum static pressure in such a tank usually occurs in winter with the cable deenergized (no dielectric losses), whereas the maximum static pressure of such a tank tends to occur in summer with the cable under maximum load conditions.

These two extreme static pressure conditions must be considered in conjunction with the route profile to ensure that there is no risk of excessive static pressures or underpressures in the cable, forcing that part of the cable to negative pressure.

Figure 10.61 shows route and pressure profiles for a SCFF cable under static pressure conditions. In this example, the minimum cable pressure occurs at the feeding end termination, while the maximum static pressure occurs 650 m along the cable, where the route profile is at its lowest elevation.

**Transient Pressure Considerations.** Sudden load (and sometimes voltage) variations cause pressure transients in the system. Under extreme operating conditions, the maximum transient pressure must not cause excessive pressures in the cable system whilst the minimum transient pressure must remain positive and above the cable's elevation profile at all points along the circuit route. Longer-length cable routes and those laid in terrain with severe variations in elevation tend to experience higher transient pressures. It should also be noted that lower-viscosity fluids experience lower transient pressures.

**Fig. 10.61** Route and pressure profiles for a SCFF cable under static pressure conditions (adapted from [10.42])

**Heating Transients.** The maximum positive transient pressure occurs in winter, during energization (dielectric losses are added), or when the maximum load is applied suddenly (or in a sufficiently short period of time). Under these conditions, the temperatures of the conductor and other cable layers increase but not as quickly as the temperature of the cable fluid does. The initial temperature rise is the steepest and causes a large transient increase in the volume of the liquid, which then flows through the cable towards the pressure tanks at static pressure. The fluid encounters hydraulic resistance, which is also highest initially, due to the increased viscosity of the fluid at the lower temperature. The cable experiences a pressure transient during this phase.

The general expression for the pressure variation with respect to the static pressure at the feeding end is

$$\Delta p = \left( ABLu - \frac{ABu^2}{2} \right) \times 10^{-4},$$

where  $\Delta p$  is the pressure difference in  $\text{kg}/\text{cm}^2$ ,  $A$  is the volume expansion per unit time and unit length in  $(\text{m}^3/\text{s})/\text{m}$ ,  $\text{m}^3/(\text{s m})$ , or  $\text{m}^2/\text{s}$ ,  $B$  is the friction coefficient of the oil duct per unit length of cable in  $\text{kg s}/\text{m}^6$ ,  $L$  is the length of the hydraulic cable section in m, and  $u$  is the distance along the cable from the feeding end in m.

In particular, the maximum pressure difference between the extremities of a cable fed from only one end is

$$P = \frac{ABL^2}{2} \times 10^{-4}.$$

In other words, halving the feed length by feeding fluid from both ends causes the pressure to drop by three-fourths.

Since the pressure at the tank is set to the static pressure, the pressure at the other end of the line (or at the center of it if the cable is fed from both ends) must inevitably be higher, and is taken into account in the system design.

Figure 10.62 shows an example of the maximum positive pressure transient for a hydraulic section fed from one end only. In this example, the maximum pressure (calculated and observed experimentally) occurs at 1900 m.

**Cooling Transients.** Large negative pressure transients can cause some sections of the system to drop below the minimum design pressure or even to enter the negative pressure regime (partial vacuum).

Cooling transients are more complex to evaluate. The most negative cooling transient occurs when the system is energized with maximum load and suddenly deenergized after a particular *critical time* on the order of a few hours.

Figure 10.63 shows pressure profiles for a SCFF cable under various cooling transient conditions. The cooling transient from a hot condition is unlikely to cause an underpressure due to the high initial static pressure in the tank. There is no cooling transient at the minimum static pressure as the cable is already at its coolest. As the cable system starts to transition from cold to hot (when energized with maximum load), the potential cooling transient increases. There comes a critical time when the combination of the increasing potential cooling transient and only a moderate increase in static pressure results in the largest possible negative pressure transient. In this example, minimum pressure occurs 1350 m along the cable.

**Multiple Hydraulic Sections.** When a circuit is long or its elevation varies significantly along the route, stop

**Fig. 10.62** Route and pressure profiles for a SCFF cable under maximum heating transient conditions (adapted from [10.42])

**Fig. 10.63** Route and pressure profiles for a SCFF cable under cooling transient conditions (adapted from [10.42])

joints are installed that separate the cable route into hydraulic sections while maintaining electrical continuity. This allows the cable system to operate within its design limitations. The stop joints may be connected to tanks that provide feed points to each hydraulic section, or separate feed points can be installed at joints along the hydraulic sections to suit the route profile. This mitigates the risk of excessive static and transient pressures.

Figure 10.64 shows route and pressure profiles of a SCFF cable system with stop and feed joints (the route profile is identical to those in previous figures). The transient pressures are depicted using dashed lines. Detailed annotation has been omitted from the diagram to reduce clutter.

A stop joint has been added (arbitrarily) at 500 m. The feed tank at 0 m caters for fluid volume variations in the section from 0 to 500 m. Since this tank feeds a shorter section, the maximum static pressure of the tank is lower than before. Reducing the section length

also reduces the maximum transient pressure. This pressure difference is 1/16 of the original example. The maximum cable pressure at 500 m is 35.5 m of fluid under maximum static pressure conditions. The transient pressure is less (32.3 m of fluid).

A feed tank has been added at the end of the circuit (at 2000 m), and a feed joint has been added (arbitrarily) at 1350 m. The tanks at these two feed points cater for fluid volume variations in the section from 500 to 2000 m. This also results in a lower maximum tank static pressure than before. The maximum cable pressure at 650 m is 32.5 m of fluid under maximum static pressure conditions. The maximum transient pressure occurs at 550 m (30 m of fluid), but is less than the maximum cable pressure. The minimum cable pressure occurs at 1350 m and equals the minimum tank static pressure. The very low transient pressures in the section from 1350 to 2000 m are due to an effective fluid section length of only 325 m (two end tanks feeding a 650 m section).

**Fig. 10.64** Route and pressure profiles of a SCFF cable system with stop and feed joints installed (adapted from [10.42])

**Submarine Cables.** Submarine cables have a similar design to underground cables from an electrical perspective, but they are specially designed from a mechanical perspective to handle the large axial stresses that occur during installation and the hydraulic challenges encountered by submarine cables.

Both aluminum and copper conductors have been used. Various lead alloys have been used for submarine cable sheaths. Submarine cables have strong longitudinal armor, and different armor designs are applied. The simplest consists of one layer of round steel wires that introduces a torque in the cable when axial tension is applied.

The hydraulic aspects must be considered in a slightly different way to those for land-based cables. Submarine cables often have much longer circuits than those considered for land installations, as the hydraulic circuit cannot be interrupted along the route. This has resulted in single-core cables with large oil ducts, up to 40 mm in diameter, and the use of extra-low-viscosity fluid (3–5 cSt at 20 °C.)

Submarine fluid-filled cables have been in service for more than 60 years. Cables from the 1950s are still in use. Submarine cables were originally used to cross water courses that were too wide to cross with overhead lines.

Cable lengths were originally limited by manufacturing equipment. However, this limitation was overcome with the introduction of factory joints. The need for longer and larger cables also resulted in the construction of submarine cable factories that are close to the sea and have their own loading facilities to minimize problems with transporting very long lengths from the factory to the laying vessel.

Traditionally, cables were laid directly on the sea bottom without additional protection. At shore landings (the splash zone; typically down to water depths

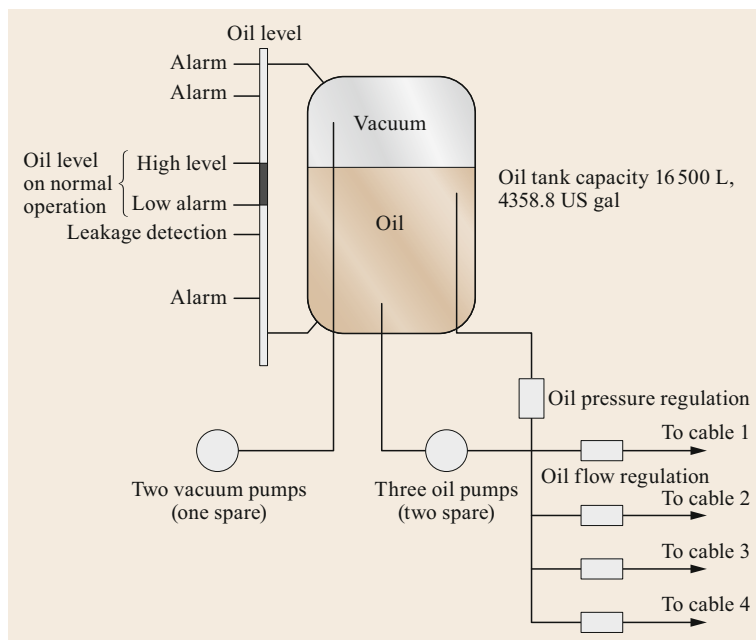

of 10 m), the cables were protected in different ways to minimize or eliminate wear and tear and to suppress corrosion issues, especially with the armor. Types of protection used included trenching where there were trenchable conditions, or the addition of mechanical structures when trenching was not possible. However, since the 1990s it has become increasingly common to protect the entire cable length, preferably by trenching. If trenching is not possible, other protection methods are used, such as rock dumping or mattress coverings of various kinds. More detailed information on this topic and relevant references are given in a later section.

The fluid feeding system for a submarine cable can consist of pressure tanks for short and shallow crossings, similar to land-based cables. Longer and deeper crossings use pumping plants installed at one or both ends of the crossing. Submarine cables carrying voltages up to and including 170 kV are often manufactured as three-core cables, while SCFF cables used for higher voltages always are single-core cables. With the development of conductors with large oil ducts and the use of extra-low-viscosity fluid, cable lengths of up to 60 km between pumping plants have been installed.

Some cable installations have additional corrosion protection systems. This can be a passive system, such as adding anodes to selected parts of the cable. Active systems, such as suppressed current systems, are also added to some cables.

#### Feeding Pressure Systems for Submarine Cables.

Submarine cables normally have circuit lengths that are much longer than those considered for land installations as it is not possible to interrupt the hydraulic circuit along the route. This may require the hydraulic section to be long and deep, necessitating special feeding systems such as pumping plants. Pumping plants for submarine SCFF cables were introduced around 1980,

**Fig. 10.65** Schematic of a typical pumping plant (adapted from [10.42])

when the technology used for HPPF pipe-type cables was adapted to the low-viscosity cable fluids used in SCFF cables. Depending on the feeding pressure required, designs may use a pumping plant installed in one pumping station with a crossover device at the opposite end or pumping stations at both ends.

In terms of transient pressure variations, in addition to the checks performed for land applications, the *apparent profile* of the route must be taken into account due to the difference in the densities of oil and water and applied to the water depth at any point. This generates a further pressure profile, which should not present negative pressures at any point along the route.

The mechanical considerations already discussed for land cable applications are even more important for submarine applications due to the higher system working pressures involved.

A further design requirement for a submarine SCFF cable is to maintain a positive fluid flow out of the cable in order to prevent water ingress until the damage can be sealed and cable repair can be implemented.

Submarine SCFF cables differ from land SCFF systems in which each phase of the circuit is hydraulically separated from the others to avoid fluid loss from the two undamaged phases. In submarine systems, the normal practice is to interconnect the hydraulic circuit of the entire system, which allows to compensate the flow of a leak by pumping fluid through the remaining healthy cables. For a cable system with one pumping station and one crossover device/manifold, when a fault occurs at the cable end close to the crossover device location, the pumping plant feeds the leak from one

end, through the two undamaged cables and through the crossover device at the opposite end.

For three-phase cables, it is advisable to have feeds at both ends.

**Submarine Cable Pumping Plants.** A submarine pumping plant consists of a large vacuum-sealed fluid storage tank, vacuum pumps, fluid pumps, valves, and measuring devices. A representative schematic of such a plant (showing project-specific capacities) is depicted in Fig. 10.65. The plant also incorporates a regulation system that maintains the fluid pressure in each cable between preset values based on fluid flow calculations. The system includes alarms that are activated by abnormal conditions; they can be set for values of high or low pressure or a particular fluid level in the tank that indicates the presence of a fluid leak.

A series of flow-limiting valves are installed at the pumping plants and at the crossover devices to limit fluid loss resulting from a cable fault. This system is designed to ensure enough fluid flows out of the cable duct to prevent water ingress at the point farthest from the feed point.

A typical fluid-feeding system design for a submarine cable takes into account the worst feeding conditions, which normally corresponds to a cable cut at the end furthest from a feeding point, considering the oil viscosity and the cable load.

At the maximum operating temperature, a large volume of cable fluid moves from the cable into the pumping plant tanks. When a cable failure occurs, the heating transient ceases and the cooling transient starts.

**Fig. 10.66** Schematic of a typical very long submarine connection (adapted from [10.42])

The cable cools rapidly at low ambient temperatures, causing a large volume of fluid to move from the storage tanks into the cable to compensate for the contraction of the fluid within the cable as well as potential fluid loss from the point of failure. At low ambient temperatures, the tank fluid viscosity is relatively high, so the hydraulic resistance is also high for the cable fluid, which is now forced towards the fault location.

The design of the cable fluid feeding system for a submarine SCFF cable with pumping plants must take the worst-case feeding condition into account. This occurs when the circuit is energized to full load and a failure causing a severe leak occurs at the point on the line furthest from the pumping plant during the heating transient. In this scenario, the fluid initially expands from the cables into the tank(s) during the heating phase (the conductor and fluid are still to reach their maximum operating temperatures) and the fluid exits the cable at the leak location during the cooling phase. Since this fault time is similar to the energization time, the fluid is still cold and consequently its viscosity is high, requiring a sufficiently high pressure to feed the fault location. This condition determines the value of the pressure necessary to feed the cable with a positive pressure with respect to the water pressure at the most remote fault point.

For a cable system with a pumping plant at each end, the worst-case feeding condition will correspond to a severed cable close to one pumping plant. For a cable system with one pumping plant and a crossover device, it will be a severed cable close to the pumping plant

with a fluid feed through one or two healthy cables to the crossover device and returning through the section of cable connected to the crossover.

Figure 10.66 shows a schematic for a typical very long submarine connection with pumping plants at each end of the submarine crossing.

### 10.6.3 Extruded Cables

As mentioned above, increasing operating and maintenance costs for fluid-filled cables prompted the search for other insulating materials. Polyethylene (PE) was tested, but its maximum operating temperature was found to be too low. A much more suitable material was eventually identified: crosslinked polyethylene (XLPE), which is now one of the most common and well-established insulating materials in modern extruded high-voltage cable design. Since the 1970s, fluid-filled cables have gradually been replaced with extruded dielectric cables (Fig. 10.67).

Even today, the popularity of XLPE cables for both land and submarine applications continues to grow rapidly. A major reason for the success of XLPE as an insulating material is its excellent electrical, mechanical, and thermal properties. Its most advantageous features are its low dielectric loss and dissipation factor and its high electrical breakdown strength, modulus of elasticity, and tensile strength. Low operating and maintenance costs combined with good system availability lead to low lifetime costs for XLPE cable systems.

**Fig. 10.67** HV XLPE cable with a corrugated aluminum sheath (adapted from [10.14])

It should be noted that significant technological improvements have been made to the XLPE itself, as well as the methods used to manufacture it, since its introduction in the mid-1960s. The influence of manufacturing quality and raw material purity on the properties of the resulting XLPE was soon discovered, so triple extrusion and dry curing techniques were introduced into XLPE manufacturing. These processes are performed in a sealed environment, ensuring a very high level of cleanliness and therefore quality of the XLPE insulation.

In the triple extrusion process, the inner semiconductive screen, the XLPE insulation, and the insulation screen are all extruded simultaneously. The insulating material is then vulcanized under pure nitrogen. XLPE is a polymeric insulation material based on pure polyethylene (PE). In the vulcanization process, the peroxides in the XLPE form free radicals at elevated temperature and pressure, and these free radicals react with hydrogen in the polyethylene chains. This triggers the chains to react with each other, forming an intricate and complex crosslinked (i.e., crossbonded) network of polyethylene chains.

Although XLPE is derived from PE, PE and XLPE are very different both mechanically and chemically, and the characteristics of XLPE make it far better suited for electrical applications than PE. Indeed, XLPE was developed because of its very useful electrical properties, especially its low loss levels, which are due to its low dielectric constant and negligible dissipation factor.

XLPE is a suitable insulating material for conductor temperatures up to 90 °C, which is the normal maximum operating temperature for XLPE cables. XLPE cables can, however, withstand up to 250 °C under short-circuit conditions. Consequently, these cables have both a high overload potential and a high safety margin.

### New Trends in the Design of Extruded Cables

In the 1980s, power cables generally had a lead sheath or a corrugated aluminum sheath, as described above. However, laminated coverings were beginning to attract interest as a means to obtain lighter and cheaper cables. The first studies of aluminum laminated screens were carried out in the late 1980s. Such screens are now also considered to be advantageous for environmental reasons. TB 446, published by WG B1.25, provides guidelines for the use and testing of advanced laminate designs [10.43].

**New Trends in Laminated Coverings.** A metal laminated covering consists of several layers of plain (not corrugated) metal and plastic materials bonded together to achieve a special set of properties: bending ability, radial water tightness, electrical functions.

It can be used to carry the capacitive current, and the circulating and short-circuit currents. Three main cable designs have been identified:

- Combined design
- Separate design
- Separate semi-conductive design.

**Combined Design.** Laminates combining plastic with copper or another metal are also used. Such a combined design (CD) utilizes the combined properties of these two components. CDs comprise:

- XLPE insulation
- Semiconductive bedding (water swellable if required)
- Thick metal foil, either welded or glued, that is coated and bonded to the outer sheath (usually HDPE) and carries the full short-circuit current.

Additional wires can also be added to match the short-circuit requirement. The metal foil is mainly aluminum; copper can be used as well. However, when copper wires are used in combination with a welded aluminum foil, it is recommended that a nonmetal tape should be placed between them to avoid possible corrosion. A photograph of a CD cable is shown in Fig. 10.68.

**Separate Design.** This design concept was introduced in the 1980s, when the need for a radial moisture barrier in cables with only a wire screen and a PE and PVC jacket became apparent—water trees could form in the insulation of those cables, causing cable faults. The idea of using a laminated moisture barrier was not, however, a new one; this approach was already being used in telecommunication cables.

This separate design (SD) concept utilizes separated mechanical and electrical properties. Bending ability

**Fig. 10.68** 500 kV cable with a combined design (adapted from [10.43])

and water-tightness are mechanical properties ensured by the thin metal foil bonded to the outer sheath. While the wires within ensure the electrical functionality. Such a design includes:

- XLPE insulation
- Copper or aluminum wires
- Water swelling tapes to block the screen area
- Coated laminated metal foil, e.g., 0.2 mm Al with a 0.05 mm coating on one side
- An oversheath (usually MDPE or HDPE).

The metal used is generally aluminum, although copper or other metal laminated foils can also be used. A photograph of a SD cable is shown in Fig. 10.69.

**Separate Semiconductive Design.** The separate semiconductive design (SscD) was introduced in Japan in the 1980s for the same reason as SD was introduced.

In the SscD, electrical and water tightness properties are separated using semiconductive plastic-coated foil. Such a design comprises:

**Fig. 10.69** 400 kV cable with a separate design (adapted from [10.43])

**Fig. 10.70** 275 kV cable using a separate semiconductive design (adapted from [10.43])

- XLPE insulation
- Round copper wire screen with nonswelling semiconductive tape below
- Thin Pb or Al foil (typically 0.05 mm thick) that has glue on one side and is coated with (typically) 0.05 mm thick semiconductive plastic on the other side (the screen side)
- An oversheath (usually PVC).

The first SscD cables used lead laminated foil. Nowadays aluminum laminate is used too. A photograph of a SscD cable is shown in Fig. 10.70.

**Concluding Remarks on Laminated Covering Designs.** Compared to extruded sheaths, the use of laminated coverings (especially aluminum laminated coverings) decreases the weight and diameter of the cable, allows for improved pulling techniques, and permits longer delivery lengths on a drum, which, in turn, decreases the number of joints required in a circuit link. Thus, the use of laminated coverings can significantly reduce the cost of the cable system.

Since the late 1990s, cables with an aluminum laminate screen bonded to a PE oversheath have progressively superseded those with a lead sheath or a PVC oversheath in many countries.

#### 10.6.4 Accessories for Extruded Cables

A CIGRE Green Book dedicated to accessories for HV extruded cables will be published very soon (see Sect. 10.B). The reader is kindly invited to use that book or the following Technical Brochures to obtain more information in this regard:

- CIGRE WG 21.06: TB 89 *Accessories for HV Extruded Cables* [10.44].
- CIGRE WG 21.06: TB 177 *Accessories for HV Cables with Extruded Insulation* [10.45].
- CIGRE WG B1.06: TB 303 *Revision of Qualification Procedures for HV and EHV AC Extruded Underground Cable Systems* [10.46].
- CIGRE WG B1.24: TB 415 *Test Procedures for HV Transition Joints for Rated Voltages 30 kV to 500 kV* [10.47].
- CIGRE WG B1.22: TB 476 *Cable Accessory Workmanship on Extruded High Voltage Cables* [10.48].
- CIGRE WG B1.29: TB 560 *Guidelines for Maintaining the Integrity of XLPE Cable Accessories* [10.49].
- CIGRE JWG B1/B3.33: TB 605 *Feasibility of a Common Dry Type Plug-in Interface for GIS and Power Cables Above 52 kV* [10.50].
- CIGRE WG B1.42: TB 622 *Recommendations for Testing DC Transition Joints for Power Transmission at Rated Voltages Up to 500 kV* [10.51].

Work is also in progress within SC B1 to address issues relating to working under induced voltages or currents. WG B1.44 has very recently published TB 801 to address this issue [10.52].

In TB 758 [10.53], published by WG B1.46, one chapter describes the main cable conductor designs and explains that not all connectors are suitable for all conductor designs. Another chapter provides a short introduction to connection theory. It explains that connectors in accessories may be exposed to significant thermal and mechanical stresses and presents in-depth information on the installation of various connector types as well as proposals for development tests.

All of these topics will be included in the forthcoming CIGRE Green Book on accessories, together with the contents of TB 622 [10.51].

Below, we provide some examples of the items included in TB 89 [10.44] and TB 177 [10.45], published by CIGRE WG 21.06.

### Joints

As noted in TB 89, a joint is the insulated and fully protected connection between two or more cables. It is also termed a *splice*. The following types exist:

- Straight joints
- Transition joints
- Screen interruption joints
- Y branch joints.

In [10.44], and in the CIGRE book [10.54], each of the joint designs is illustrated with a diagram to show the

type of insulation. To aid clarity, other important design details are omitted. The design requirements common to each type of joint are:

- (a) A high-current connection between conductors
- (b) Joint insulation that meets the same performance standard as the cable
- (c) A high-current connection to permit the flow of short-circuit current between the two cable sheaths or screen wires
- (d) A metallic joint shell or screen wire connection that is electrically insulated from the earth potential to match the insulating integrity of the cable oversheath
- (e) Protection of the joint and cable insulation against water ingress
- (f) Protection against corrosion of the joint metal work.

The majority of the HV extruded cables intended for voltages of greater than 60 kV have a single core, so straight joints of the single-core type are illustrated. Three-core joints employ the same types of insulation and are grouped together in one housing.

A straight joint, also termed a *straight splice*, connects two cables of the same type. Such joints include:

- Taped joints
- Prefabricated joints
- Field-molded joints
- Heat-shrink sleeve joints
- Back-to-back joints.

Prefabricated joints are now the most popular type of joint by far. Hundreds of these joints are in service at the highest voltage levels (500 kV AC) worldwide.

Prefabricated straight joints employ insulation that has been preformed and tested in the factory. The molding of elastomeric insulation (e.g., silicone rubber, EPR, EPDM) and the casting of thermoset resin insulation are usually used to manufacture these joints.

**Composite Type.** In this case, two factory-premolded elastomeric stress cones are inserted into a central insulator of cast thermoset resin, as shown in Fig. 10.71. Pressure is maintained at the stress cone to central insulator interface and at the cable core interface using a compression device that usually consists of metal springs.

**Premolded One-Piece Type.** Here, a single premolded elastomeric sleeve forms the insulation, as shown in Fig. 10.72. This sleeve includes insulation, a connector screen, stress control profile screens, insulation screens, and, where applicable, screen interruption.

**Fig. 10.71** Prefabricated composite joint (adapted from [10.44])

**Fig. 10.72** Premolded one-piece joint (adapted from [10.44])

**Fig. 10.73** Premolded two-piece joint (adapted from [10.44])

Interfacial pressure at the sleeve to cable core interface is maintained by the elastic memory of the sleeve.

**Premolded Two-Piece Type.** This is a two-piece joint (Fig. 10.73) that is similar to the one-piece type but with elastomeric insulation comprising a large-diameter premolded sleeve that is stretched to fit on top of a smaller-diameter elastomeric adaptor molding.

**Premolded Three-Piece Type.** The three-piece joint has insulation comprising a large-diameter, cylindrical, elastomeric molding that is stretched to fit onto two elastomeric adaptor moldings.

### Terminations

A termination, also termed a *pothead*, is a connection between a cable and other electrical equipment, as described in [10.44]. Types of termination include:

- Indoor terminations
  - Temporary terminations.
- (a) A high-current connection from the cable conductor to an external busbar
  - (b) Insulation to the same performance standard as the cable
  - (c) Provision of support to the cable
  - (d) Ability to withstand cable thermomechanical loads and external forces such as wind, ice, and busbar loading
  - (e) A high-current connection to permit the flow of short-circuit current from the cable metallic sheath or shield wires via a bonding lead to the system earth
  - (f) A connection to the cable metallic sheath or earth wires that is electrically insulated from the earth

potential to match the insulating integrity of the cable oversheath

- (g) Protection for the cable insulation and sheath against the ingress of atmospheric water and the ingress of pressurized dielectric liquid or gas from adjacent metal-clad busbar trunking.

Some termination designs are filled with either a dielectric liquid or pressurized SF<sub>6</sub> gas to provide insulation. Such designs must be able to withstand the effects of the thermal expansion of the insulant. The incompressible nature of a dielectric liquid requires that an expansion volume be provided. The expansion volume can be an air- or gas-filled space that is usually at the high-voltage end of the insulator, or it can be (i) an external header tank, (ii) an external pressurized feed tank, or (iii) a gas-containing internal flexible accumulator that is usually at the low-voltage end of the termination.

When an internal air volume is used, the terminations can only be installed vertically. If they need to

be installed inclined, horizontal, or inverted, it is usual to fill the termination completely with insulating liquid and to provide either external compensation or an internal flexible accumulator containing gas. An expansion volume is not necessary for gaseous insulation because of its compressible nature, but either the termination must be designed to withstand the increased pressure or an external gas cylinder must be connected to limit the pressure to an acceptable level.

As an example, one of the most popular termination types is the dry-type GIS termination.

**Prefabricated Composite Dry Metal-Enclosed GIS Terminations.** For this termination, a premolded elastomeric stress cone is inserted into a cast thermoset insulator (Fig. 10.74). Pressure is maintained at the stress cone to insulator interface and at the stress cone to cable core interface via metal springs. It is not necessary to fill the insulator with either gas or insulating liquid, thereby dispensing with the need to provide pressure monitoring and compensation equipment and/or a thermal expansion reservoir.

JWG B1/B3.33 has published TB 605 regarding the feasibility of a common dry-type plug-in interface for GIS and power cables above 52 kV [10.50]. Following the recommendations of TB 605, JWG B1/B3.49 has published TB 784, which gives a description of a standard termination for a voltage of 145 kV [10.55].

### Transition Joints

A transition joint connects two cables of different types; for example, a polymeric extruded cable to a self-contained fluid-filled cable. Transition joints are sometimes employed to connect cables of the same type if they have different conductor sizes, in which case they are designed to withstand imbalanced conductor thermomechanical forces. Types of transition joint include:

- Polymeric extruded cable to mass-impregnated cable transition joints
- Polymeric extruded cable to oil-filled paper cable transition joints
- Polymeric extruded cable to gas-pressurized paper cable transition joints.

As an example (which can also be found in [10.44]), Fig. 10.75 shows a type of transition joint that can be used at HV/EHV levels.

Recommendations for testing transition joints have been published by:

- CIGRE WG B1.24 in TB 415 for AC cables up to 500 kV [10.47]
- CIGRE WG B1.42 in TB 622 for DC cables up to 500 kV [10.51].

**Fig. 10.74** Prefabricated composite dry metal-enclosed GIS termination (adapted from [10.44])

**Fig. 10.75** A polymeric extruded cable to oil- or gas-filled paper cable transition joint (single-core, fed type) (adapted from [10.44])

### 10.6.5 Accessory Workmanship

CIGRE TB 476 on cable accessory workmanship for extruded high-voltage cables was published in October 2011 [10.48].

TB 476 covers workmanship associated with the jointing and terminating of AC land cables, incorporating extruded dielectrics for the voltage range from 30 kV ( $U_m = 36$  kV) to 500 kV ( $U_m = 550$  kV). This brochure complements TB 177 [10.45]. Although a short chapter in TB 476 covers general risks and skills, the bulk of the document focuses on the specific technical risks and the skills needed to mitigate those risks during each phase of the installation. This TB is not an instruction manual; it provides guidance on the aspects that must be carefully considered when evaluating the execution of the work to be performed. High-voltage cable accessories are manufactured using high-quality materials and very sophisticated production equipment. Recent technical and technological developments in the design, manufacturing, and testing of this equipment have made it possible to obtain premolded joints and stress cones for terminations up to 500 kV and cold shrink joints up to 400 kV. One of the conclusions of TB 476 is that internal failure rates of accessories—particularly for XLPE cables—are higher than those of other components, and are thus of great concern due to the major impact of such a failure. Therefore, the focus on quality control during jointing operations must be maintained.

Many utilities have adopted the *system approach*, in which the cables as well as the major accessories are purchased from the same supplier. Some utilities request that the link should also be installed by the supplier or by a contractor under the supplier's supervision in a *turnkey* fashion. The main advantage of this approach is that the full responsibility for the materials and workmanship is clearly the supplier's. On the other hand, some customers have adopted the *component approach*, in which cables and accessories are purchased from different suppliers and installation is entrusted to a third party. In all cases, the installation must be car-

ried out by qualified jointers who follow the jointing instructions provided by the accessory supplier.

International standards such as those from the IEC and IEEE provide guidelines on the interface between the cables and accessories. However, it is strongly recommended that the compatibility of the different components of the link should be verified by the relevant engineer. It is vitally important for the interface between the cables and the accessories to be managed such that the potential technical risk (e.g., from cables and premolded accessories that have incompatible diameters or other incompatible dimensions or characteristics) is minimized.

One of the international trends in cable technology has been to reduce the cable insulation thickness, which increases the electrical stress. This trend has been driven by greater knowledge and better quality of the insulating material as well as improvements to the extrusion process. Cables and accessory components are made under well-defined factory conditions, and their quality and reliability are assured by adhering to well-defined specifications. However, because the accessories are assembled on-site, even though this job is carried out by skilled and well-trained jointers, it is often performed under more delicate and less strictly controlled conditions than in the factory. This means that correct assembly is even more important, as—given the increased electrical stress caused by the reduced insulation thickness—bad workmanship will sooner or later lead to accessory breakdown.

It should be noted that most of the new HV cable links currently being considered will use XLPE-insulated cables.

TB 476 captures the state of the art in jointing and is considered to define best practices internationally. However, it should be acknowledged that other practices that are not explicitly covered in this brochure are not necessarily bad practices. Great care should be exercised and the approach should be agreed upon in advance when departing from practices recommended in TB 476 [10.48].

**Fig. 10.76** Example of a single-core cable design (adapted from [10.39])

While TB 476 does not directly refer to failures or the consequences of failures, it is a comprehensive document on the assembly of cable accessories. If used properly, it can provide vital advice on how to avoid failures due to bad workmanship.

### 10.6.6 Submarine Extruded Cables

#### Current Technologies for Extruded Submarine Cables

An increasing number of submarine cables are being installed due to the development of offshore wind farms and offshore oil platforms as well as the need to interconnect islands and to bridge power systems across harbors, rivers, lakes, gulfs, seas, and inlets. The CIGRE recommendations for testing HV and EHV submarine cables are published in TB 490 prepared by WG B1.27 [10.39] and completed for mechanical aspects in TB 623 prepared by WG B1.43 [10.56].

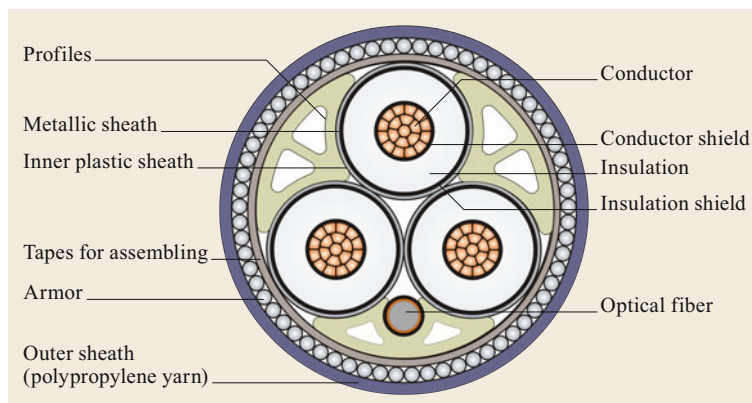

Submarine cables can have either a single core (Fig. 10.76) or three cores (Fig. 10.77). The advantages and disadvantages of each design are listed in Table 10.7.

**Water Tightness.** Submarine cables can have either a wet or a dry design. A wet design allows water to migrate into the cable insulation and the conductor. Dry designs are normally used for the HV and EHV submarine cables considered in this section (as described in TB 490 [10.39]) to achieve the requested service life. Water blocking or water tightness in both the radial and longitudinal directions is crucial. WG B1.55 has recently published TB 722 [10.57], which provides recommendations for additional testing of submarine cables rated from 6 kV ( $U_m = 7.2$  kV) to 60 kV ( $U_m = 72.5$  kV), to address extruded MV and HV AC cables with reduced expected service lives.

Water tightness is the ability of a dry cable design to resist water penetration at the maximum submersion depth of the submarine cable. Water tightness is important for both normal operation and during cable failures, when the physical integrity of the cable is compromised. A weakness in either the conductor or the metallic sheath will reduce the water tightness of the cable.

If a cable fails during its in-service life, water penetration along the cable—either within the conductor or under the metal sheath—must be limited. This will minimize the length of cable that needs to be replaced during repair. Water tightness is improved by selecting the appropriate conductor design, water blocking method used for the conductor, and type of water blocking utilized under the metal sheath.

Water typically penetrates less than 30 m along the cable, although this can vary considerably depending on the design of the cable.

**Fig. 10.77** Example of a three-core cable design (adapted from [10.39])

**Table 10.7** Advantages and disadvantages of single-core and three-core cables

Single-core design	Three-core design
<p><i>Pros</i></p> <ul style="list-style-type: none"> <li>– Lighter weight</li> <li>– Smaller diameter</li> <li>– Longer lengths</li> <li>– Possibly requires fewer joints to be fitted at factory or on-site</li> <li>– Higher current rating</li> <li>– Improved security, can add a fourth cable</li> <li>– Voltage rating can be 500 kV or higher</li> <li>– Reduced repair costs and spares</li> </ul>	<p><i>Pros</i></p> <ul style="list-style-type: none"> <li>– Balanced magnetic field</li> <li>– Minimum sheath circulating currents and voltages</li> <li>– Lower installation costs</li> <li>– One trench on seabed</li> <li>– Lower protection costs</li> <li>– Includes optional FOC (fiber optic cable)</li> </ul>
<p><i>Cons</i></p> <ul style="list-style-type: none"> <li>– Higher magnetic field</li> <li>– Greater installation costs</li> <li>– Individual seabed trenching increases costs</li> <li>– Higher protection costs</li> <li>– Sheath current must be considered</li> </ul>	<p><i>Cons</i></p> <ul style="list-style-type: none"> <li>– Lower current rating</li> <li>– Heavier</li> <li>– Large diameter</li> <li>– Decreased security of cable system</li> <li>– All three phases must be repaired after a fault</li> </ul>

**Conductors.** The design of the conductor influences the water penetration rate or the degree of water blocking of the conductor. Conductor designs can be regular, compressed, compact, solid, or Milliken (also known as type *M*) stranded conductors, or they can be key-stone shaped. A regular stranded conductor consists of circular strands with interstices or spaces between the strands. Compressed conductors have reduced or flattened strands in the outer layer, but the interstices or spaces between the remaining strands remain the same as those for a regular conductor. A compact conductor with reduced spacing between strands is formed by squeezing each conductor layer in a die. A solid conductor will not allow any water penetration, but using such a conductor will lead to a very stiff cable with higher AC losses. For HV and EHV cables, type *M* conductors (Fig. 10.19) are widely used for conductors larger than 800–1200 mm<sup>2</sup> to limit AC losses and achieve more cable flexibility. Semiconducting tapes are normally used between the segments, but there are still interstices unless layer compaction is included in the design. Strand blocking and water-swallowable powders, swellable yarns, or tapes are added to guarantee that the conductor is water blocked. Strand blocking utilizes either a compound that is installed during the stranding or laying-up of the conductor or a pumped compound that is forced into the conductor interstices after the cable has been manufactured. Water-swallowable powders and tapes (with different efficiencies in pure water and salty water) are installed in the conductor during manufacture by adding a powder or applying a fabric tape within the conductor.

**Insulation System.** Most submarine HVAC cables with extruded insulation systems utilize crosslinked polyethylene (XLPE) as insulation. The insulation system consists of an inner conducting screen, an insu-

lation layer, and an outer semiconducting screen. The semiconducting inner and outer screens contain carbon black as an active conducting filler. The properties of the semiconducting screen compounds and the quality of the associated extrusion process are important influences on HV and EHV cable performance. For example, the properties of these compounds are affected by the percentage of carbon added, the carbon particulate size with respect to the base polymer, the dispersion of the carbon through the base polymer, and the extrusion properties of the compounds. In some cases, a volume resistivity stability test may be performed if these properties are a critical influence on cable performance.

The crosslinking of polyethylene (in particular low-density polyethylene, LDPE) is an irreversible process (i.e., the XLPE cannot be remelted) that results in the formation of a three-dimensional network that makes the insulation more thermally stable. This process is implemented after extrusion.

Whilst cables with extruded insulation have found widespread use in electricity distribution systems and for the transmission of lower voltages, extruded materials have only recently become the insulation of choice for underground cables used in EHV transmission circuits. The first submarine cable to use extruded XLPE as an insulation system was introduced in 1973 and used for 84 kV, while the first submarine XLPE cable for 420 kV was installed in 2006.

Another extruded insulation system that may be used is EPR (ethylene propylene rubber), but the applicability of this insulation is mainly limited to systems with  $U_m \leq 150$  kV. EPR differs from XLPE in that it includes fillers to increase mechanical strength and chemical stability. Although EPR is often considered to have better electrical characteristics in the presence of water, its disadvantages are lower electrical design

stress and higher dielectric loss, implying that is mainly useful at lower voltages.

**Metal Screen/Sheath.** The most commonly used metal screen/sheath consists of an extruded lead alloy sheath covered by an extruded anticorrosion polymeric sheath or a semiconducting tape. However, other metal sheath materials are under consideration or being implemented as alternatives to lead alloy sheaths.

The thickness of the metal sheath is dictated by mechanical and electrical criteria.

The metal sheath needs to exhibit a high level of mechanical performance: consistency, bendability during manufacture and installation, and resistance to fatigue during operational thermal cycling.

The suitability of lead alloys sheaths from the perspective of fatigue resistance has been demonstrated by decades of experience with HV and EHV submarine cables containing laminated insulation and, more recently, extruded insulation land cables and HV extruded insulation submarine cables. The CENELEC standard EN 50307-2002 on lead and lead alloy sheaths and sleeves of electric cables highlights the depth of knowledge of and experience gained in the metallurgical control of lead alloy morphology.

Setting practical criteria for calculating the maximum permissible strain on the lead sheath is very difficult because it is complicated to model the behavior of the cable during load cycling. This complexity is due to differences in the fatigue resistance coefficients.

The metal sheath must also have a minimum cross-sectional area to allow for the passage of short-circuit currents without exceeding the maximum permissible temperature at the end of the short circuit (IEC 61443). Additional wires could be used in single-core cables to increase their short-circuit current capabilities. When semiconductive layers are used on each core of a three-core cable, the distribution of the short-circuit current among the three parallel paths must be taken into account.

Continuity of the lead sheath over factory joints is achieved by applying a lead sleeve with a larger diameter over the joint, drawing the sleeve to the underlayer diameter, and then wiping it onto the lead sheath of the cable.

The polymeric anticorrosion oversheath is either insulating or semiconducting in nature and is usually polyolefin based. When an insulating oversheath is used, an overvoltage will occur between the metal sheath and the surrounding metal armor during cable system transients. To avoid dielectric breakdown of the insulating oversheath, a semiconductive oversheath is often used. Alternatively, earthing connections have to be inserted between the metal sheath and the armor at regular distances

along the cable. Particular attention must be paid to the water tightness between the metal sheath and the armor at the earthing connections. Possible corrosion should be taken into account. The cross-sectional area, together with the contact resistances, will direct the flow of capacitive current towards the armor and the sea. Possible overheating by short-circuit currents through these connections is also a sizing parameter.

Radial water tightness is currently provided only by the metal sheath. Longitudinal water tightness is therefore only provided under the metal sheath. This is achieved using semiconductive water-swellaable tapes that are either helically lapped or longitudinally wrapped around the core.

To ensure circularity when laying-up the cores of a three-core cable (onto which the armor will be applied), its outer spaces are filled with non-water-swellaable PP yarns or plastic fillers. A copper tape may be applied as an equalizing counter-helix.

**Armor.** For submarine cable, metal wire armor is normally applied to provide enough tensile strength during the installation. When a cable is installed in the sea, it must withstand the pulling tension  $T = W \cdot d + H$ , where  $W$  is the weight of the cable weight in the water,  $d$  is the depth of the water, and  $H$  is the bottom tension. The tensile strength of a cable is generally verified by mechanical tests performed in accordance with CIGRE recommendations for the mechanical testing of submarine cables [10.56, 58]. For example, the recommendations require the cable to withstand the test condition of  $T = 1.3W \cdot d + H$  for a water depth of < 500 m. Therefore, the armor must be designed to meet this condition.

Copper, steel, or stainless steel wires are normally used as armor. The material chosen depends on various conditions such as the installation method used, operation and cost.

In single-phase submarine cables, the steel armor causes high iron loss, so nonferrous materials such as copper or stainless steel are used, or a return copper conductor is added in conjunction with steel wires to reduce the magnetic flux in the steel wire armor. The reason for this approach is that the magnetic field from the current in the conductor creates eddy currents, leading to heat losses in the armor and other metal parts of the cable under the screen. If the armor was made of a magnetic material such as steel, additional losses due to magnetization would be significant.

For three-core cables, the magnetic field from a symmetrically loaded cable will be significantly lower. The armor, however, is positioned close to the cable cores, where the magnetic field cannot be ignored. Three-core submarine cables typically utilize steel wire

**Table 10.8** Typical values of the permissible tensile stress for various materials used in armor wires

Material	Copper	Steel	Stainless steel
Max. stress (MPa)	60–90	90–600	250–450

armor for cost savings. If the transfer capacity of the cable system must be maximized at a certain voltage level, it is possible to replace the steel armor wires with stainless steel wires. Recent measurements of the steel losses for three-core armored cables have shown that the relevant formulae in IEC 60287 yield higher values than those actually measured. Therefore, the methods used to calculate magnetic losses in the steel armor of three-core cables may need to be reassessed. The magnetic properties of the materials are important when considering losses. From a mechanical perspective, due to its relatively low permissible tensile stress, copper cannot be applied in case the pulling tension due to the very heavy weight of the cable and/or installation in very deep waters is too high. In this case, steel or stainless steel is applied. In more severe cases, a double layer of armor is applied to increase the pulling strength and antitorsion properties of the cable. Typical values of the permissible tensile stress for copper, steel, and stainless steel are shown in Table 10.8.

Figure 10.78 shows schematics of typical cables with a single or double layer of armor wires.

**Outer Protection.** Regardless of whether it has a single-core or three-core design, a submarine cable must have outer protection. Apart from its mechanical function, the outer protection for land-based cables may also have an electrical function. For submarine cables, the outer protection normally has a mechanical function

but it is also there to keep the anticorrosion material (e.g., bitumen) in place. The outer protection may consist of either a plastic sheath or, more commonly, one or more layers of yarn over the underlying armor layer(s). One or more threads of yarn may be applied, each with a different color, to make it easier to locate the cable visually after installation. The yarn also stabilizes the armor mechanically so that the risk of birdcaging during cable handling is reduced.

#### Current Technologies.

**General Considerations for Factory Joints.** The factory joint is manufactured prior to the armoring operation so that the section of cable containing the joint can be continuously armored without any discontinuity or appreciable distortion of the armor wires in the vicinity of the joint. The main aims of a factory joint are that it should not impose any restrictions on further cable handling or installation operations, and that it should not cause variations in the mechanical and electrical performance of the cable (Fig. 10.79). This generally implies that factory joints need to be fully flexible and to have the same bending radius, pulling force limit, and coiling performance (if applicable) as the original cable.

If the joint imposes some limitations on handling, these limitations must be declared, so that special precautions can be taken during the handling and installation of the joint.

The defined length of a factory joint is the removed length of the metal sheath/outer semiconductive screen ( $X_1$  in Fig. 10.80) plus 1 m at each side of that length (i.e., the defined length of the joint is  $X_1 + 2$  m). For three-core cables, the length of the factory joint is the distance from the beginning of the first core joint to the end of the last core joint plus 1 m at each end of the core joint.

**Fig. 10.78a,b** Schematics of the cross-sections of cables with single (a) and double (b) layers of armor wires (adapted from [10.39])

**Fig. 10.79** Diagram of a factory joint with the same dimensions as the cable (not to scale; adapted from [10.39])

**Fig. 10.80** Defining the length of a factory joint (adapted from [10.39])

Factory joints are required for the following reasons:

- The maximum continuous extrusion length is limited (due to, e.g., filter cleaning and scorch formation).
- There is a limitation on the cable length that can be stored (e.g., on process platforms).
- Limitation of degassing equipment and process incl. size of degassing chamber and the power required to heat the cable.
- Limitation in the laying-up baskets content for three-core cables.
- There is a limitation on the power of the AC testing equipment.
- The cable core could be damaged during handling if factory joints are not used.

In general, the higher the voltage and the larger the cable size, the shorter the individual cable lengths and (therefore) the greater the number of joints that need to be included for a given delivery length.

However, the number of factory joints included in a cable should be limited. Together with improved process compatibility and an advanced testing protocol, this will ensure that the best cable quality is available for the intended application.

In any case, a factory joint should have a robust structure and a highly reliable design and assembly procedure, which should lead to the same design life for the factor joint as for the remaining cable system.

**Typical Procedure for Factory Jointing.** The same procedure applies for single-core or multicore cables, although the joints for the latter are created before laying up the cores.

The two cable ends are suitably prepared.

The conductor is jointed by means of a compression ferrule or by welding. It is better if the conductor joint has the same diameter as the original cable.

The cable core (inner semiconductive layer, insulation, and outer semiconductive layer) is reconstructed using tapes before a curing step is performed. This process can be carried out in separate phases.

Water-swallowable tapes, metal tapes, and/or protective layers are restored.

Lead sheath reconstruction is performed with an extruded lead sleeve that is inserted at one end before the conductors are jointed.

The plastic sheath is reconstructed via taping, heat-shrinkable tubing, or by local extrusion or molding.

Alternative techniques for factory jointing may be developed in the future.

**General Considerations for Repair Joints.** A repair joint is applied to the complete cable, usually onboard a repair vessel or barge. Therefore, the repair vessel or barge should be suitably equipped and have sufficient space to perform the required operation onboard. Repair joints can be divided into three main categories depending on their handling characteristics:

Type A1: Fully flexible joint

Type A2: Flexible joint with some mechanical restrictions

Type B: Rigid joint.

Like a factory joint, a repair joint should have a robust structure and a highly reliable design and assembly procedure that give it the same design life as the rest of the cable system.

It may not be necessary to install the repair joint at the maximum water depth. If the maximum allowable water depth for the repair joint is less than the maximum allowable water depth of the cable, a suitable repair procedure should be performed, including an appropriate length of spare cable to span the deepest point of the route.

Similarly, when the maximum tensile force of the repair joint is lower than the allowable tensile force for the cable, any limitation/restriction that this may represent in terms of repair procedures or environmental conditions (e.g., maximum sea wave height, currents, or wind speed during the repair operation) should be specified.

It should also be noted that it is necessary to have repair joints on hand for most long submarine cable systems. Appropriate storage conditions for these joints should be provided. Requirements for other spare parts such as cable and the shelf lives of joint components should also be taken into account.

**Typical Procedure for Repair Jointing.** There are a variety of repair jointing procedures for different cable constructions that are based on the manufacturer's or installer's know-how and experience.

Fully flexible repair joints commonly have a similar design to factory joints, especially those used for medium-depth/deep-water applications, while rigid joints often use premolded or preassembled bodies.

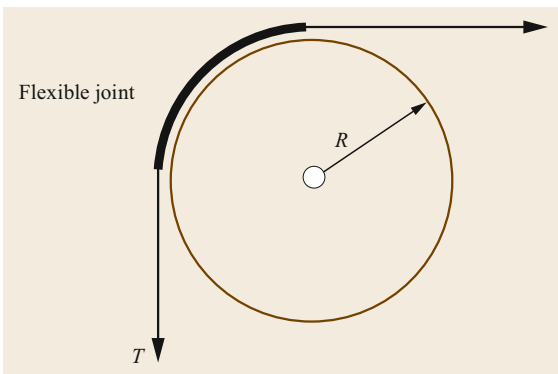

Flexible joints with some mechanical restriction apply to both designs (A1 and A2), though they commonly use premolded or preassembled bodies.

Particular attention should be given to the jointing of the armor to ensure that there is no slack in the armor wires, as this overstresses the inner cores during handling.

The defined length of a repair joint is the length of armor removed ( $X_2$  in Fig. 10.81) plus 1 m at each end of that length (i.e., the defined length of a repair joint is  $X_2 + 2$  m in total).

**Fig. 10.81** Defining the length of a repair joint (adapted from [10.39])

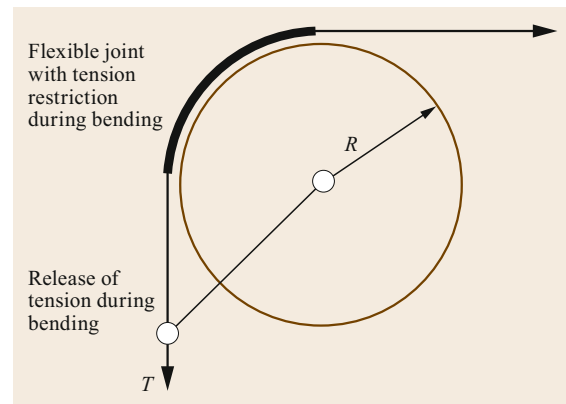

**Fig. 10.82** Fully flexible joint bent over a sheave ( $T$  is the tensile force in N/m and  $R$  is the bending radius in m; figure adapted from [10.39])

*Type A1: Fully flexible joint.* This joint can be bent to a minimum bending radius  $R$  (m) under a tensile force  $T$  (N/m) of the same magnitude as the tensile force that can be applied to the cable itself (Fig. 10.82).

*Type A2: Flexible joint with some mechanical restrictions.* This type of joint can be bent (to the same or a larger bending radius than the minimum bending radius of the cable) over the sheave with low or no tension (minimal tension could mean tens of meters of cable weight); see Fig. 10.83.

After bending, the joint can be pulled with a tensile force  $T$  that is the same as the maximum tensile force that can be applied to the cable itself (Fig. 10.84).

*Type B: Rigid joint.* This cannot be bent or passed through the laying equipment. It must be handled and deployed in a special way, using a crane or similar equipment. In this case, the mechanical stress on the joint/cable depends on the joint design/handling. In any case, the bending radius of the cable should be

**Fig. 10.83** Flexible joint with some mechanical restrictions that is pulled over the sheave by a lower tension than that in the cable (adapted from [10.39])

**Fig. 10.84** Flexible joint after it has been pulled over the sheave (adapted from [10.39])

**Fig. 10.85** Rigid joint lowered by a crane and joint-laying equipment (adapted from [10.39])

**Fig. 10.86**  
Example of a rigid repair joint with bending stiffeners (adapted from [10.39])

above the specified minimum value during joint handling/deployment (Figs. 10.85 and 10.86).

The cable and joint assembly may also be subjected to partial torsion during laying.

**Sea/Land Transition Joints.** A transition joint between a submarine cable and a land cable in a specific project is normally a rigid joint consisting of prefabricated joint bodies, similar to a rigid repair joint for a submarine cable. The testing of a sea/land transition joint should follow the appropriate standard and recommendations for land cables.

The mechanical demands on a sea/land transition joint can differ from case to case. If the submarine cable is jetted into a level seabed and the sea/land joint is placed on the shore, the armor may only need to be terminated, while the situation is different for steep slopes and there may be a need to fix the submarine cable by the armor. This issue needs to be addressed on a project-by-project basis.

If the armor needs to be fixed to hold the weight of the cable, various designs can be considered. One possibility is to terminate the armor in a steel fixture that is rigidly connected to an anchoring block made of concrete. This block or plate may be used as the floor of the joint system.

In any case, the conductor joint needs to have the same mechanical properties as the connecting land cables.

### 10.6.7 New Installation Trends

In the past, when it came to crossing difficult terrain, rivers, roads, and train tracks, overhead lines were the only solution. Today, however, we have directional drilling techniques with the ability to drill for up to 2.5 km. Whilst there has always been the option to use multipurpose tunnels, newer construction techniques that utilize drilling machines or precast assemblies have made such structures more cost-effective. Similarly, where there are open areas, the use of mechanized cable-laying systems (similar to those used to install pipelines) is becoming increasingly practical. Also, the

ability to install submarine cables has advanced considerably during the last 20 years. The net result of all these factors is that the overall cost of long-length AC cable links has dropped, as noted in TB 680 published by WG B1.47 [10.14].

### Associated Equipment

Electric fields in high-voltage terminations and joints must be controlled so that the electrical strength of the insulation of the surrounding material is not put at risk. There are different methods for achieving this (e.g., geometric, refractive, or resistive field control), depending on the voltage level. Geometric field control is generally achieved with premolded stress cones and splicing blocks.

The outer part of a cable termination may consist of a porcelain or composite insulator with sheds, depending on the environment. The internal field control component is normally a premolded stress cone, and the internal space may be dry or filled with insulating oil. There are different types of terminations, such as those for outdoor installations or indoor GIS installations.

There are several different types of joint for land and submarine applications. Many joints have a premolded one-piece body (Fig. 10.72), and joints are available with or without screen interruption depending on the sheath bonding methods used for the system. These prefabricated parts and materials for accessories comprise stress cones for field control, insulators, and housings. The materials used are EPR or EPDM, silicone, epoxy, porcelain, paper and special insulating fluids. These terminations and joints must be installed by very skilled and well-trained personnel.

### Joints and Terminations

Prefabrication lowers the risk of installation-induced failure by making the process of installation easier, leading to better system reliability. The reliability and performance of a HV/EHV cable circuit depends on the quality of the cable and the accessories as well as the quality of the installation of the system components on-site.

The cables are produced in the factory in a controlled process that uses selected clean material of the

highest quality, and are submitted to rigorous routine tests before delivery.

It is important that the same quality standards are applied to all components of the accessories when they are manufactured and (in particular) when they are assembled on-site [10.45, 48].

Modern HV/EHV cable accessories are manufactured using high-quality materials and sophisticated production equipment. Recent technical and technological developments in design, manufacturing, and testing have made it possible to obtain premolded joints and stress cones for terminations rated up to 550 kV, as well as cold shrink joints for voltages up to 420 kV. To ensure that the internal failure rate of accessories for XLPE cables is no higher than that for other system equipment, it is vital to impose strict quality control when manufacturing and assembling HV accessories. It is also very important to manage the interface between the cables and the accessories in order to reduce the technical risk. The HV/EHV cables and accessories used for important HV cable circuits have usually passed a system type test. This is the topic of CIGRE TB 476 [10.48].

**System Approach Versus Component Approach.** As said before, in each of these options, it is strongly recommended that the compatibility of the different components of the link should be verified by appropriate testing and/or calculations.

TB 303 [10.46] proposes some practical tools such as functional analysis to deal with possible changes in components of an approved HV or EHV cable system.

**Main Accessories Needed for a HV/EHV Cable Circuit. Air-Insulated Terminations (Outdoor Terminations).** Air-insulated terminations are generally used outdoors to terminate the HV/EHV cables in air-insulated substations or on poles. They can have porcelain or composite insulators (Fig. 10.87) and can be fluid-filled or unfilled (dry). The design adopted may depend on the local environment with respect to the required BIL, maintenance requirements, pollution, reliability, and altitude. Composite insulators are increasingly used for extra-high voltages. The technical and economic advantages of these insulators are significant and originate from their low weight, ease of handling, safety during explosions, intrinsic hydrophobic characteristics, and reliability during exceptional events such as earthquakes, system faults, and vandalism. WG B1.54 is currently at work studying the behavior of cable systems under large disturbances (earthquakes, storms, floods, fires, landslides, and climate change). WG B1.51 has published TB 720 on fire-related issues for cables installed in air to address this important issue [10.16].

**Fig. 10.87** Typical HV termination with a composite-type insulator (adapted from [10.49])

**GIS and Oil-Immersed Terminations (Transformer Terminations).** EHV and HV cables can also be terminated directly on SF<sub>6</sub>-insulated switchgear (GIS) (Fig. 10.88) and transformers to eliminate air-insulated interfaces.

GIS and oil-immersed terminations (transformer terminations) are constructed very similarly. The electrical stress control for GIS and oil-immersed terminations follows the same approach usually employed for outdoor sealing ends, i.e., it uses a premolded elastomeric stress relief cone.

Proven dry versions of HV/EHV GIS and transformer terminations are available (Fig. 10.74). They have definite advantages compared to fluid-filled types such as no risk of a leak, no need for maintenance, simplified installation (plug-in types), and safety in the case of failure. IEC 62271-209 defines the interface between the HV/EHV cable and the switchgear. As mentioned earlier, CIGRE JWG B1/B3.49 has published TB 784 [10.55], to propose a standard 145 kV GIS Termination as proposed in TB 605 [10.50].

**Fig. 10.88** Typical EHV GIS termination installed in a horizontal position (adapted from [10.49])

**Fig. 10.89** Typical unburied joint installed in a cable chamber/manhole (adapted from [10.49])

**Joints.** Modern HV/EHV voltage joints usually have a premolded elastomeric joint body with an additional covering to protect against moisture and mechanical damage. The additional covering could be a heat shrink tube or metal housing with additional insulation housings/coffins. The joint protection should be chosen according to the type of cable sheath used and, in particular, the location of the joint. Unburied joints may be used in tunnels, on bridges, or in underground chambers or similar enclosures (Fig. 10.89).

The design of the cable joint needs to take the sheath bonding method into account and must be able to withstand sheath voltages under fault conditions. Accessory suppliers offer various types of joints and their associated hardware for various sheath bonding systems, including:

- Shield break or cross-bonding joints
- Earthing joints
- Straight joints.

Accessory suppliers recommend various methods for achieving proper positioning of the premolded or cold shrink joint body and offer special joint installation tools.

## 10.7 Installation Techniques

As noted before, this topic is covered by TB 194, as published by WG 21.17 [10.13]. Methods that can be used to more accurately account for the thermomechanical forces associated with large conductor cross-sections are proposed in TB 669 from WG B1.34 [10.24]. Consequently, it was decided that TB 194 should be updated (by WG B1.61). This update will also consider work published in TB 714 [10.15]

The magnitudes of the forces and motions generated by the cable in the joints (and terminations) must be taken into consideration by the system designer. This includes the civil work aspects of the HV/EHV circuit. The accessories must be positioned and supported. Similarly, the cable must be laid and fixed such that the cable accessories are not exposed to inappropriate mechanical stress [10.13, 24].

**Equipment for Earthing, Bonding, and Screen Disconnection.** Most HV cable accessory suppliers as well as various specialized companies offer equipment that facilitate efficient and reliable earthing, bonding, and disconnection of cable screens, depending on the design of the circuit.

**Surge Arrestors to Protect Cable and Accessories.** Whilst it is important to install surge arrestors at locations where an overhead line enters a substation in order to protect the substation equipment from the effects of lightning, there are differing opinions regarding the need to use surge arrestors to protect cables connected to overhead lines.

When a long cable circuit is directly connected to the substation in an outdoor switchyard, surge arrestors are typically used to protect the substation equipment from a phase-to-earth overvoltage, just as for an overhead line. A similar arrangement is also provided when there is a short section of cable inserted into an overhead line circuit (siphon). It is, however, questionable how effective this will be on a long cable link given that the high impedance of the cable may reduce this transient effect.

**Sheath Voltage Limiters.** Surge protection devices known as sheath voltage limiters (SVLs) are used in link boxes and at termination structures to protect cable sheaths from phase-to-earth faults. When EHV cables are connected to GIS terminations within a substation, special surge protection is provided directly at the GIS.

by WG B1.41 and in TB 770 (on trenchless technologies) [10.59] by WG B1.48.

As explained in TB 714, the backfill used to reinstate the trench around a buried cable is a critical engineering component of the cable system because it (in conjunction with the surrounding material) allows the heat produced during the operation of the cable to be conducted to the ground surface, where it is dissipated

into the atmosphere. Therefore, the thermal properties of these materials, which are assumed during the design of the cable system, are just as important to the correct operation of the system as the selection of the appropriate thermal design. This design is generally derived using detailed calculations that often involve using a computer to perform finite element analysis, as explained in the section of this chapter on rating calculations (Fig. 10.38), whereas the backfill may be installed by manual laborers with no knowledge of the performance requirements of a backfill, other than perhaps the fairly obvious need to support whatever is above (such as a road surface).

Similarly, TB 770 on trenchless technologies [10.59] addresses the factors to be considered when deciding which trenchless technology—HDD, pipe jacking/microtunneling, pipe ramming, or plowing—is best suited to the installation of the circuit of interest. A general summary of the advantages and disadvantages of these four trenchless techniques is provided below. Together with TB 714, TB 770 is an important complement to TB 640 [10.28].

### 10.7.1 Selection of the Best Cable Design According to the Installation Method

It is important to select the cable design and accessories that will provide the best possible service life. For land installations, the use of long lengths of cable is recommended to reduce jointing costs and improve reliability of supply. This will require a robust cable design in order to avoid any damage during installation. It should be noted that while civil costs have been reduced by the introduction of new construction methods, *traffic management costs* can be significant, implying that the use of ducted sections and tunneling in city areas may be the optimal approach.

### 10.7.2 Routes and Rights of Way

When it comes to the installation of OHLs, circuit transmission line designers prefer open fields, whereas those in charge of cable installation prefer roads and railway easements in order to reduce transportation costs and avoid issues with gaining easements on public and private land. Today, even the refurbishment of an OHL with old easements is very expensive and restrictive, as most rural land is subject to environmental protection issues of some kind.

Trenches can be excavated by conventional means with excavators, but trenching machines with rock saws and directional boring techniques are becoming increasingly popular. In some countries, the direct plowing of cables in road reserves and public land is performed.

### 10.7.3 Route Planning: Traffic Management and Security

Traffic management and security requirements should be fully understood and managed during cable installation works. Where there is the potential for cable installation work to disrupt access to private driveways, such disruptions should only be permitted after notifying the occupants of the affected properties. All disruptions should be planned with a clear understanding of, and due regard for, specific requirements of the occupant, and should be kept to an absolute minimum.

There should be minimal impact on pedestrian access. Areas of conflict such as pram crossings at road intersections should be managed with steel plates to cover the trench, and suitable barriers, temporary fencing, and para webbing should be installed to protect and delineate the public and traffic. The security arrangements should remain in place on-site until all cables between joint bays are fully secured or covered by specialized backfill.

### 10.7.4 Installation Methods and Definitions

There are three basic methods of installing cables:

- Rigid constrained
- Semiflexible constrained
- Flexible constrained.

#### Direct Burial and Plowing: Rigid Constrained Installation

For directly buried sections, the cable trench should remain open for the complete section between joint bays until the cable is installed (Fig. 10.90). On completion

**Fig. 10.90** Cables installed in an open cut trench and directly buried (adapted from [10.14])

of the excavation works, the trench should be appropriately shored, dewatered, and cleaned prior to the start of the cable installation works. The base of the trench needs to be inspected to ensure it is firm, relatively smooth, and free of rocks, rubble, or sharp objects. The trench bottom then needs to be filled with approved bedding of suitable thermal resistivity as per the design requirements (see CIGRE TB 714 [10.15] for further information). After the cable has been installed, the trench should be backfilled and then the cables should be tested to ensure that they were not damaged during installation and backfilling before final reinstatement is carried out.

#### Ducts (Conduits and HDD): Semiflexible Constrained Installation

The use of conduits and directional drilling is becoming commonplace in underground cable installations. However, drainage can be an important issue both during and after construction. When an unsealed duct is created (Fig. 10.91), water tends to use the duct for drainage. This is not an issue on flat land, but when the duct is very long, e.g., > 5 km, there is generally a change in elevation or the water table level along the route. Ultimately, the outcome is that the land is flooded, leading to loss of property, property damage, and/or loss of crops. So, when using ducting, special care needs to be taken to ensure that the joints are watertight (fusion

Fig. 10.91 Duct installation (adapted from [10.14])

welds) and that the duct is adequately sealed at both ends.

#### Performing Civil Works.

- First, the trench is dug. Then the bottom and side faces must be trimmed so that the trench presents uniform dimensions. Depending on the soil quality, the side faces of the trench may need to be timbered with wooden props.
- Cable spacers are placed at regular intervals (usually every meter) along with the ducts for the power cables and two smaller ducts at both sides of the trefoil. These smaller ducts are for the earth continuity wire, but they are often placed in cross-bonding connections too.
- A first layer of concrete (Fig. 10.92) is poured on the trench; this must cover the two bottom ducts of each circuit but not the top one.
- This concrete layer must be thoroughly compacted to remove air bubbles, as the presence of air bubbles would lead to higher thermal resistivity of the concrete. This operation can be carried out with a cement vibrating machine.
- The upper duct and the ground continuity wire ducts of each circuit are then installed, as are smaller ducts for communication cables if they are required by the design.
- A second layer of concrete is poured to cover the upper ducts. If ducts for communication cables are required on top of the circuit, a third layer of concrete will be needed after installing them. As with the previous layers, the concrete must be vibrated to eliminate voids and entrapped air (Figs. 10.93 and 10.94).

Fig. 10.92 Double-circuit trench after the first layer of concrete has been poured in (adapted from [10.14])

**Fig. 10.93** Photograph showing the uppermost ducts (red) of two circuits (the other four ducts are under the first layer of concrete) (adapted from [10.14])

**Fig. 10.94** Photograph showing communication cable ducts on top of HV circuits as well as the third (final) layer of concrete (adapted from [10.14])

The last layer of concrete is screened to obtain a flat surface. The joint bays are sometimes made of precast concrete sections, but they are often manufactured on-site. They can be unfilled or filled with sand, but in either case the earthing or cross-bonding box is installed in an unfilled separate chamber for maintenance purposes.

When calculations of the pulling force suggest that it could be difficult to lay the cables at certain points along the line, small sections of the trench are not filled with concrete so that supplementary pulling machines can be used.

Once the concrete is fully hardened, the remaining space in the trench is covered with soil.

Before the cables are pulled into the conduits, a proving mandrel must be pulled through each duct to check its integrity and circularity.

Advantages of this type of installation compared with directly buried cables:

- The civil works do not need to be executed in synchronization with the cable-laying works; they can be done well in advance, at the most convenient time, at each point along the cable route. This is highly convenient for residential and industrial areas, where the digging and trench preparation can be rather disruptive.
- Given the potential for damage due to erroneous digging, the concrete volume around the cables provides strong mechanical protection for the HV line.
- The cables are surrounded by a volume of material with a low thermal resistivity, the value of which is known precisely. Also, concrete is not subject to moisture migration (drying-out effect), which guarantees a higher transmission rating for the line.

Disadvantages of this type of installation compared with directly buried cables:

- The cost of the civil works is higher.
- Fault repairs to the line are more expensive and take longer because it is more difficult to access the damaged part of the cable.
- The minimum bending radius in the cable route is significantly higher, which can be a problem in urban projects. A different type of installation can be used at specific points where the cable route cannot be adapted to the minimum bending radius of the ducts.
- Even with HDPE ducts, pulling forces during cable laying are notably higher than those needed to install directly buried cables with the help of rollers. This adds another layer of difficulty for complex cable routes.

When open cut excavation is not possible for practical reasons (e.g., for deep crossings, river crossings, and busy highways), two types of underbores are widely used for cable installation.

**Horizontal Directional Drilling.** Horizontal directional drilling (HDD) is a steerable trenchless method of installing underground conduits and cables in a shallow arc along a prescribed bore path using a surface-launched drilling rig. This method has minimal impact on the surrounding area and is used when trench-

**Fig. 10.95** Directional bore across an intersection (adapted from [10.14])

**Fig. 10.96** HDD machine (adapted from [10.14])

ing or excavating is not practical. It is suitable for a variety of soil conditions and jobs including road, landscape, and river crossings, depending on whether the required equipment and experienced contractors are available locally. Different types of heads are used during the pilot-hole process to suit different soil conditions.

The elevations of the bore vary from the shallow open-pit level to the required depth of the crossing and back to ground level at the other end. A directional drilling machine drills the bore, and the cable conduit is drawn back through the bore. The depth of the bore can be monitored and adjusted to the specifications of the bore profile drawing during the drilling process (Figs. 10.95 and 10.96).

**Sleeve Bore/Microtunneling.** Sleeve bore or microtunneling is a technique used to construct small tunnels. In most cases, a remotely operated microtunnel boring machine (MTBM) is used. MTBMs are very similar to tunnel boring machines (TBMs) but smaller (Fig. 10.97).

In most microtunneling operations, the machine is launched through an entry eye and cable conduits are pushed behind the machine—a process that is often called pipe jacking. As the machine advances, more tunnel liner or conduit is pushed from the starting shaft

**Fig. 10.97** Microtunneling (adapted from [10.14])

through the entry eye (Fig. 10.98). Voids between the sleeve and conduits are filled with grout.

The photograph presented in Fig. 10.99 depicts regular HDD with four tubes in one hole. The fourth tube is a spare tube for HV cable.

The photograph in Fig. 10.100 shows HDD for a 380 kV cable circuit with six individual drillings (two cables per phase to reach maximum capacity) that are filled with water and provide water circulation as an option.

**Fig. 10.98** Sleeve bore (adapted from [10.14])

**Fig. 10.100** HDD for a 380 kV cable circuit with six individual drillings (adapted from [10.14])

**Fig. 10.99** Regular HDD with four tubes in one hole (adapted from [10.14])

**Fig. 10.101** Spacer used when installing cables in ducts (adapted from [10.14])

TB 680 [10.14] provides several examples of HV line installation around the world.

An example (from Spain) of underground high-voltage cable lines installed in ducts embedded in a concrete volume is given in TB 680. These ducts are usually made of high-density polyethylene (HDPE). They have two layers—a corrugated outer layer and a smooth inner layer. HDPE presents good resistance to the chemical agents present in soil and has a lower friction coefficient than polyvinyl chloride (PVC), which facilitates cable laying. Duct spacers are used along the line (Fig. 10.101). These devices have several functions:

- During laying works, they guarantee a safe thickness of concrete between the ducts, thus preventing the steel wire rope used for cable pulling from breaking the duct and entering the adjacent duct in the curved sections of the line.

- They separate the cables, which reduces the proximity effect in the conductors and facilitates heat dissipation, thus increasing the capacity of the line.
- They have gauge pins, which are used to ensure that the nominal width and height of the concrete volume are respected.

Figure 10.101 shows that the spacers are usually shaped to accommodate not only the HV cable ducts but also the earth continuity conductor (ECC) ducts and communication cable ducts [10.14]. Figure 10.102 shows a schematic of a typical single-circuit HV cable trench [10.14].

When this type of installation is employed, it is not possible to perform an outer sheath test to check the resistance between the ground and the cable screen. The best solution to this problem is to include a coextruded semiconductive layer over the outer sheath of the ca-

**Fig. 10.102** Schematic of a typical HV cable trench (adapted from [10.14])

**Fig. 10.103** Infrastructural facilities that utility companies are permitted by law to construct under roads in Japan (adapted from [10.14])

ble. A graphite coating can also be used but is very likely to be wiped away during cable laying (though it can help to reduce the friction quotient during this process).

In another example (from Japan) provided in TB 680, the following practices are reported:

- Utility companies prefer to use the duct method because it is easier to replace the cable if cable breakdown occurs.
- Utility companies have the right to construct infrastructural facilities such as power cables, water and sewage pipes, gas pipes, telecommunication

**Fig. 10.104** Microtunneling in Japan (adapted from [10.14])

**Fig. 10.105** Reinforced concrete sleeve (adapted from [10.14])

lines, and subway lines under roads by law in Japan (Fig. 10.103). Therefore, permission to install underground transmission lines is almost always granted from the road administrator.

- The microtunneling technique is used to cross rivers, railways, and roads with heavy traffic when excavation is difficult or impractical. Microtunneling using a reinforced concrete sleeve is employed to construct small tunnels (Fig. 10.104). After the tunnel has been constructed, pipes are installed in the sleeve (Fig. 10.105).

#### In Air: Flexible Constrained Installation

Underground cables are designed to be *flexible*, as this makes it easier to find an appropriate route via a tunnel or bridge to cross waterways, highways, railways, and other infrastructure (Figs. 10.106, 10.107).

There are two different situations for flexible constrained installation:

**Fig. 10.106**  
Example of flexible constrained, snaked, and cleated cable installation arrangements (adapted from [10.14])

- Dedicated infrastructure is used (this situation is restricted to specific cables)
- Multipurpose infrastructure is used.

In both scenarios the cables are *snaked* (i.e., they meander sinusoidally) and are cleated to the support structures. TB 194 [10.13], the reference document of CIGRE SC B1 on installation techniques, reviews the theory behind the use of two different approaches to the installation of flexible systems in air: the Western approach and the Japanese approach. Both techniques are detailed in TB 194 [10.13] and TB 669 [10.24].

**The Western Approach.** Flexible cable supports are systems that allow the cable to expand in length and to deflect laterally to accommodate this expansion when the cable is heated, as well as to return to the original formation on cooling. In order to control the movement of the cable within predetermined limits, the cable is usually initially installed in an approximately sinusoidal formation with cleats at appropriate intervals such that expansion will lead to an increase in the amplitude of the sine wave.

Because the flexible system accommodates cable expansion, it does not present the high values of thrust that occur in a rigidly restrained system.

There are two possibilities for flexible systems that use the Western approach. The first is a *cleated cable that moves in the vertical plane*. Here, the cable is held in *widely spaced* cleats (Fig. 10.12), and the cable sags between the cleats. This sag increases as the temperature rises.

The other possibility is a *cleated cable that moves in the horizontal plane*. In this type of installation, the cable is arranged in a sinusoidal formation in the horizontal plane, with cleats fixed at the points of flexure along the sinusoidal wave. One option is swivelling cleats that are capable of rotating about a vertical axis

**Fig. 10.107** Example of flexible installation with snaked cables (adapted from [10.14])

as the cable moves, but the use of fixed cleats that are approximately as long as the cable diameter and have a rubber lining 3–5 mm thick is favored. These cleats must be installed at an appropriate angle.

The movement of the cable due to thermal cycling will be strongly influenced by the friction between the outside surface of the cable and the support between the cleats. It is essential to support the cable such that it only moves across a low-friction support in the horizontal plane and to allow adequate air movement around the cable to avoid derating.

**The Japanese Approach.** In the Japanese approach, the design of the snaking applied to the cable is specified. Details are given in TB 194 [10.13] and TB 669 [10.24], and some relevant photographs are provided in TB 403 [10.18].

As explained in TB 403 [10.18], tunnels are very expensive to build and are therefore only used in congested city centers. In this respect, it can be economically attractive to combine an underground cable with other preexisting structures. Such multipurpose tunnels can be attractive, but additional aspects must be considered, such as ventilation, fire protection, division of liability between owners, and security (tunnel access privileges). Laying HV cables in the close proximity of other cables or pipelines can only be done after an intensive survey. Thermal and electrical effects of the cables on each other and safety aspects during normal operation and maintenance must be investigated.

Very few long-length AC cable circuits are installed completely in tunnels due to the high cost of doing so, but this approach is becoming more common in big cities. Many of them are installed in Japan.

In Japan, power cables for underground transmission lines are generally installed in ducts or tunnels.

**Fig. 10.108** Cable installation by motor-driven rollers in a tunnel (adapted from [10.14])

It is therefore necessary to reduce the number of accessories to limit construction costs and construction periods when tunnels are used. This implies that the length of cable between two accessories needs to be as long as possible. As a result, the cable is sometimes transported by sea or river rather than on land. For example, the maximum cable span length was recently increased to approximately 1800 m for 500 kV cables and approximately 2500 m for 275 kV cables.

New methods have been developed to conduct cable installation works efficiently in a tunnel. Synchronized motor-driven rollers that are set up on the floor of the tunnel are used to install the cable (Fig. 10.108). Sensors positioned along the cable installation route can

**Fig. 10.109** Cable installation by a hauling machine (adapted from [10.14])

be used to ensure that the rotating motor-driven rollers are stopped if there is any abnormal behavior during installation. The velocity difference between each roller is controlled to avoid cable buckling and cable sheath damage. Motor-driven rollers are light and easy to install, but many rollers are needed to move the cable because of the small driving force per roller. On the other hand, it is difficult to use motorized rollers when the tunnel is steep, as significant driving force is needed to move the cable.

In this case, hauling machines (Fig. 10.109) are required. The rotation of a caterpillar belt moves the cable. Due to the large gripping force of the caterpillar, the hauling machines must be synchronized.

## 10.8 Testing

### 10.8.1 Fluid-Filled and Mass-Impregnated Cables

The international standards for testing FF and MI cables are well established. Recommended test voltage levels are currently limited to 600 kV for DC applications, although higher voltages are under consideration. WG B1.66, recently launched by SC B1, is currently looking into the possibility of producing recommendations for testing at the 800 kV DC level.

### 10.8.2 Extruded Cables

#### Role of Testing and Condition Monitoring in Extruded Cable Systems

The role of testing and condition monitoring in HV extruded cable systems is outlined by WG B1.29 in TB 569 [10.49].

*Testing.* The role of testing during all stages of system design, set up, and in-service is clearly important to both the supplier and end user, as it can be used to prove that a cable system meets the expectations of the customer. In addition, once a cable system is in service, it may be beneficial to carry out in-service testing to assess the condition of the system and its components. This section examines the types of testing and condition monitoring that may be carried out when assessing a cable system. It is not intended to be an exhaustive account of cable testing but to provide guidance on the areas that should be considered. The level of testing required for a cable system should be decided upon by the customer, based on risk and performance requirements.

International standards for underground cable systems generally define design rules and testing procedures to assess a cable system and ensure it meets the requirements for reliable operation during its de-

sign life. These generally focus on preventing failure rather than actions that can be taken to mitigate the consequences of a fault. Some national standards or individual utility specifications have introduced fault simulation testing and specify requirements for the performance of the system under these conditions (e.g., an internal arc test is carried out by some utilities to evaluate the consequence of an internal fault; this is among the requirements of IEC 62271 for switchgear testing).

It should be noted that a cable system includes the cable, terminations, joints, internal terminations, joint components, filling media, connectors, screen connections, bonding, and so on, so great care must be exercised during testing to ensure that all of the components are properly represented and identified in testing regimes.

**Development Testing.** Development testing is carried out by the cable accessory supplier during the design of a new accessory. The results of these tests may indicate (to the manufacturer, and, where required, the customer) any changes and improvements that can be made to a cable accessory. Examples of development tests include environmental tests such as the salt/fog, rain, and pollution tests carried out on composite insulators, which are not covered by international cable standards. These tests are performed by manufacturers to evaluate the long-term performance of their products and are carried out to test specifications defined in-house. IEC 61462 edition 1.0 covers the test procedures used for composite insulators in AC overhead lines with nominal voltages exceeding 1000 V.

The results of development testing are generally not specified by customers, but they may inform a decision on the suitability of a cable termination or joint for use in a particular application or location; for example, the suitability of terminations for use in areas with high levels of pollution.

Development tests are performed by the manufacturer during the development of a new accessory to check its long-term performance and to assess safety margins. These tests include:

- Analyses of electrical, mechanical, and material compatibility
- Electrical tests to breakdown and mechanical and thermal tests of prototypes
- Wet and pollution tests of outdoor terminations
- Electrical and thermal tests of connectors
- Mechanical tests of premolded components (on the insulators and connectors)
- Fire and disruptive failure performance, including internal power arc testing of terminations.

**Insulators.** IEC 61462 on composite hollow pressurized and unpressurized insulators for use in electrical equipment with rated voltages of greater than 1000 V specifies both design and type test requirements for self-supporting composite insulators. The tests in this IEC standard are designed to provide information on material selection, manufacturing processes, material thickness and adhesion, and end-fitting material selection and attachment.

To complete the development of a new accessory, construction drawings should be prepared for all components, and a full-size prototype will need to be manufactured and subjected to tests. If the prototype includes specific components such as premolded parts and composite and epoxy resin insulators, it is necessary to develop the technology to produce these components.

The tests should show the limits on the performance of the accessory and guarantee an appropriate safety margin with respect to the test values stated in the relevant IEC standard.

The tests carried out must ensure that the entire family of accessories are able to withstand the stresses that they may be subjected to during their operational lifetimes.

The termination may be exposed to a saline solution with a concentration that depends on the level of pollution it will experience. It is then subjected to an AC voltage test under these conditions. For composite insulators with a polymeric coating that tends to suffer from surface aging, the pollution test is performed after aging the coating for 1000 h in saline fog (Fig. 10.110) or a multi-stress ageing test of 5000 h (see IEC 62217).

**Connectors.** Development testing of connectors (Fig. 10.111) may also be performed. Thermal cycling of the connectors and contacts used in the accessories is

**Fig. 10.110** Salt-fog test of an insulator (adapted from [10.49])

**Fig. 10.111** Tests of connectors (adapted from [10.49])

carried out at medium voltage according to IEC 61238-1. During the test, the changes in the temperature and electric resistance over time are recorded. Short-circuit current tests are also performed on the connectors. Very recently, WG B1.46 published TB 758 on test regimes for HV and EHV cable connectors [10.53] to address this issue.

**Filling Fluids.** Equipment manufacturers must verify the compatibility of an oil or fluid with a housing material and associated assembly processes and should perform health and safety assessments before the oil or fluid is used within that housing material. This is especially true when new types of fluids or other fillers are considered. Some manufacturers have developed their own qualification procedures, with test conditions specified in terms of temperature, duration, safety, and final acceptance criteria. These are added to the other tests that must be carried out in the development phase.

**Prequalification Tests.** Prequalification tests are long-term tests that are carried out to assess the performance of a cable system and to replicate in-service duty. The test arrangement should be representative of the conditions where the cables are installed (e.g., fixed and flexible sections with both joints and terminations should be tested in order to closely replicate the cable system). These tests are intended to verify the thermomechanical and electrical behavior of the cable and accessories. In some local standards, it is also a requirement to monitor and record the pressure of any insulating media used in order to assess the robustness of any sealing arrangements. After testing, all

accessories are examined to check for any changes or deterioration that might affect their performance.

Prequalification testing is only specified in IEC 62067 and 60840 for cable systems above 150 kV, for systems where the conductor screen stress is designed to be greater than 8 kV/mm, or for systems where the insulation screen stress is designed to be greater than 4 kV/mm.

**Type Tests.** Type tests are carried out on the complete cable system (Fig. 10.112) and are required for all voltages and design stresses. These tests are a minimum requirement to show that specific cables and

**Fig. 10.112** Type-test loop for a 400 kV system (adapted from [10.49])

accessories are fit for a specific purpose. The type tests specified in IEC 60840 and IEC 62067 focus mainly on the short-term voltage withstand performance of the cable system. They consider AC, overvoltage, and lightning transients along with material aging effects. Following the completion of these tests, the cable system must be shown to be free of partial discharges or to only experience discharges that are below a certain specified level. If partial discharges are present (even if they are below the level specified), it may be prudent to identify the cause of this discharge. Once the tests are completed, it is important to disassemble all accessories and closely inspect them for any signs of electrical activity or physical changes that may not have caused an electrical discharge but may still cause mechanical or operational problems. Interpretation of the test results will be based on previous experience with development, prequalification, and other type tests.

**Short-Circuit Tests.** WG B1.29 identified that short-circuit behavior was not addressed by any of the IEC standards relating to HV cable systems. Several utilities have independently taken the step of specifying an additional type test to check the behavior of terminations (especially those containing insulating fluid) when they are subjected to short circuits. Two short-circuit scenarios need to be considered in this context:

- A low-energy external fault. In this case the fault current passes through the conductor. The fault is external to the accessory.
- A high-energy internal fault. In this case the fault is the result of component failure or arcing inside the accessory.

Depending on the design and installation, consideration should be given to whether it is necessary to perform one or both of the above tests to cover the worst-case condition.

**Sample Tests.** Sample test requirements are outlined in IEC 60840 and 62067. These tests are to be carried out on a specified number of components and complete accessories during a production run. When the main insulation of the accessory cannot be routinely tested, IEC 60840 states that a partial discharge test and an AC voltage test should be carried out on the fully assembled accessory. The characteristics of individual components should be verified in accordance with the specifications of the accessory manufacturer through either test reports from the supplier of the component or internal tests. Components should also be inspected against their

drawings, and there should be no deviation outside of the declared tolerances.

**Routine Tests.** Routine tests are carried out on some supplied accessory components. These tests should form part of a robust quality control regime and provide confidence in the quality of the accessory. Among these tests, the main insulation of prefabricated accessory designs is required to undergo AC voltage and partial discharge tests. Finally, each component should be visually inspected for defects.

Insulators filled with oil, gas, or any other material should also undergo a pressure test before delivery.

**Tests of Filling Materials.** Filling materials such as polybutene or synthetic oil are selected based on their material parameters and characteristics and are approved during the development, prequalification, and type tests. Specification IEC 60836 covers silicon oil.

It is recommended that a *fingerprint* of the filling material should be determined after delivery, as this fingerprint might be useful during condition assessment programs or failure analysis.

Well-established material fingerprint techniques include:

- AC electric strength
- Dielectric dissipation factor
- Fourier-transform infrared spectroscopy (FTIR)
- Thermogravimetric analysis (TGA).

**Commissioning Tests.** Commissioning tests are carried out on the assembled cables, joints, terminations, bonding, and earthing once the installation is completed. These final tests performed on the cable system prior to energization provide a final check that the system has been correctly designed and installed. The requirements for commissioning tests vary depending on the type of circuit installed and the consequences of failure.

Very few tests can prove the longevity of cables, joints, and terminations. However, it is recommended that an AC insulation test should be carried out with partial discharge monitoring (if possible) of all joints and terminations. Ideally, this should be implemented using a resonant test voltage generator (Fig. 10.113), as the cable system can then be energized off-line and at low energy, minimizing the risk of a disruptive accessory failure during the test. The tests may provide an early warning of potential failure points before a subsequent breakdown of the complete cable system in service leads to bigger problems. Commissioning tests should be performed according to the relevant IEC standard.

**Fig. 10.113** On-site commissioning test performed with three mobile test sets simultaneously due to the cable length (adapted from [10.49])

**Fig. 10.114** Discharge tracks on the PE outer serving of the cable due to a defect (adapted from [10.49])

It is possible to carry out an AC test by energizing the termination with the system voltage (a soak test) and to use on-line partial discharge monitoring. This is not ideal, as noise from the system can mask discharge activity within the accessory. In addition, if a breakdown does occur it will lead to a disruptive failure of the joint or termination (as the full system short-circuit current is available to flow through the failed accessory), which may lead to an outage and power disruption. Such a failure presents a safety risk on-site and introduces a significant delay into the commissioning of the circuit while the affected components are replaced.

A DC oversheath test should also be carried out to ensure that the cable system and its accessories are insulated from earth. In Fig. 10.114, the discharge tracks are a consequence of fault location pulses.

**Condition Monitoring.** In TB 420, which provides generic guidelines for lifetime condition assessments of HV assets and related knowledge rules, it is recommended that a database of information on each piece of equipment should be established as the equipment ages [10.60]. Useful information on the aging process during the full service life includes loading, maintenance test results, fault history, general ambient and

environmental conditions, and details of any site incidents.

A structured methodology to analyze and prevent in-service failures is recommended in order to effectively manage the aging of HV cable accessories. One suggestion for such a methodology is given in [10.60, clause 4.2]. The final step in this methodology is to gather the outputs from this process into a management strategy that can be used for:

- Preventative maintenance
- Decisions regarding equipment change-out
- Improving the specification, design, or manufacture of new equipment.

Regarding preventative maintenance, there are many possible approaches to monitoring the condition of terminations and unburred joints. These vary from visual inspection to on-line monitoring and regular testing while out of service.

Figure 10.115 gives an example of a condition monitoring technique (X-ray imaging).

The monitoring to be carried out depends on:

- The importance of the circuit
- The history of the circuit and its accessories
- The potential repair time
- The potential cost of the outage
- The potential cost of the damage
- The effect on reputation
- The potential damage from the failure
- The effectiveness of the monitoring system adopted
- The availability of monitoring tools and trained personnel
- The cost of monitoring.

**Fig. 10.115** Example of a condition monitoring technique (X-ray imaging) (adapted from [10.49])

Figure 10.115 shows an X-ray image of a outdoor cable termination used to check any internal displacement of the top connector.

A list of condition monitoring tools is detailed in TB 559 [10.21]. To assist in the selection of a monitoring tool, each tool is described under a number of headings, including:

- *Experience*: each condition monitoring tool is categorized as either a well-established (W) tool or one that is under development (D).
- *Effectiveness*: some diagnostic monitoring tools are considered (based on cost, time required, and results) to be more effective (i.e., useful: U) than others (less useful: L) at finding damage or degradation that will eventually lead to system failure.
- *Level of expertise required*: low or high, depending on whether the tool can be used by a general

operator or only by a trained technician/engineer, respectively.

- *Cost*.

### Testing Extruded Cables for DC Application

The basic principles of DC extruded cable system testing are similar to those discussed above.

In April 2012, CIGRE WG B1.32 published TB 496, which provides recommendations for testing DC extruded cable systems for power transmission at rated voltages up to 500 kV [10.61].

This very important document is the basis for testing of extruded cable systems that have been recently installed or are in the process of installation.

With the huge increase in projects with high system voltages, SC B1 has decided to launch a new Working Group, B1.62, to prepare recommendations for rated voltages up to 800 kV.

## 10.9 Maintenance

This section gives some general guidelines.

Detailed guidelines can be found in TB 279 published by WG B1.04 (all types of cables) [10.62], in TB 358 published by WG B1.09 [10.63], and in TB 652 (fluid-filled cables) published by WG B1.37 [10.42]. SC B1 has directed WG B1.60 to update TB 279, and an update to TB 358 [10.63] is also being considered.

### 10.9.1 Land Cables

#### Maintenance Guidelines

Most HVAC lines should have a specifically designed maintenance program, including periodic tests of the outer sheaths and inspections of the link boxes and SVLs (sheath voltage limiters). These tests and inspections should be scheduled in advance to ensure that all of the necessary permissions and authorizations can be obtained on time and that all of the points in the system that must be visited are accessible.

**Terminations.** The terminations and their structural supports should be examined visually, along with the condition of the clamps that support the cable ends, and appropriate maintenance work should be implemented.

The quality of the *connection contacts* can be checked using an infrared camera that can detect hotspots.

If the arrester has a surge counter, the data from it should be checked regularly as part of the condition reliability maintenance (CRM) program.

**Outer Sheath Test.** An outer sheath test should be performed two years after the system was commissioned and then at least once every five years. However, more frequent testing of systems located where the ground has high levels of humidity or systems in which the outer sheath is made up of PVC may be considered. In this case, the voltage test level needs to be carefully selected to avoid damaging the outer sheath, especially when the system has been in operation for many years. This test should also be performed after any major repair of the cable system.

Access to the link boxes is required to test the outer sheath. It is possible to test one of several major sections of the line in a single operation, depending on the type of equipment and the section length.

To save time, the SVLs can be kept in place during the outer sheath test if desired. In this case, the voltage of the test must be adjusted to a level that the SVLs can withstand. This should be considered during the line design stage when the SVLs are selected. If the link boxes have been filled with epoxy resin (to prevent water ingress and electric arcs), the test will need to be performed with the SVLs fully assembled.

**Link Boxes and Sheath Voltage Limiters.** If the link boxes are not filled with any substance, visual inspection is the simplest way to check their watertightness. Checking the SVLs visually will also help to detect major failures in these components. Inspections of link boxes and their SVLs should be performed on a regu-

lar basis, after any short circuit in the cable system, and after a major system failure.

Additionally, each SVL should either be substituted or tested every ten years to check their condition by analyzing their  $I$ - $V$  characteristic curve. This test can be performed on-site with portable equipment or in a laboratory.

Outdoor link boxes should also be inspected on a regular basis (e.g., every 2–5 years) as they may be exposed to wide temperature fluctuations and sometimes to direct sunlight, leading to significant variations in the internal pressure of the box, which may affect their watertightness. In this case, frequent inspections are advisable.

The use of specific sensors to protect the circuit from vandalism and detect the penetration of water into link boxes should also be considered.

### *Monitoring the Cable Route.*

**Flexible Constrained Systems.** In tunnels or other locations in which cables are installed in the open air, the mechanical fixations of the system should be examined every five years as well as after short circuits or severe climate conditions.

**Underground Systems.** To achieve good reliability, fast repair times, and long service lives, it is necessary to implement monitoring procedures for all of the factors that may harm the cable system. The main issue to check for is any change to the local environmental conditions since the system was commissioned. To minimize risk, routine checks of the state of the system must be performed and complete documentation of these checks must be maintained and available; for example:

- Check if there are changes in the surrounding properties that may have an influence on the cable system.
- Note any change of drainage as this will impact on the current carrying capacity of the cable system
- Nearby building activities may jeopardize the security of the cable.
- Change of ground vegetation, newly build roads or the like may have a long-term impact on the soil parameters resulting in a change of current carrying capacity.
- Check all the signs along the cable route.
- Check if the cable route documentation has been updated by activities that are subject to approval.
- Check spare parts, if any, and in particular those components with limited shelf life.
- Check and update the list of land owners alongside the cable route who must be asked for permission to enter their land in case of a cable failure.
- Communicate to local authorities the persons to be contacted if activities are being undertaken near the cable route.

The cable route cannot be checked from the desktop only. A visual inspection is necessary, supported by clear and coherent documentation. In rural areas, it may be possible to inspect the route with the aid of drones.

If the line incorporates a distributed temperature sensing (DTS) system, any localized temperature rise or hotspot it detects should be investigated. If the installation is not equipped with such a system, routine supervision of the line must be implemented.

The use of internet-based geographic information systems to monitor conditions along the cable route should be approached with caution unless there is clear information about the frequency with which the aerial photographs are updated and the dates that the maps were created.

Close attention must be paid to any alterations along the cable route, such as changes in the ground level due to civil works and significant growth of vegetation (as the roots can dry out the soil).

**Fault Location.** Fault location in AC and DC land and submarine links is addressed in detail by CIGRE WG B1.52 in TB 773 [10.64]. It is important to obtain the necessary permits to get access to the cable system.

**Cable Fault Location Procedure.** The cable fault location should be considered as a procedure covering the following steps:

- Notification of the fault by utility
- Disconnecting and earthing of the cable circuit by utility
- Preliminary discussions to identify the fault by all concerned parties
- Carry out fault location by utility/special contractors
- Identify fault location
- Excavate fault location area to access the cable fault
- Physically locate the fault
- Civil construction works & preparation of the joint bay
- Carry out repair works
- Cable testing and energise.

**Cable Fault Location Methods.** Cable faults are generally located through fault resistance measurements. If there is a low fault resistance or it can be reduced using a high-voltage DC source, the Murray loop bridge method is often adopted. In other circumstances, time-domain reflectometry (TDR) is often used; in this case,

**Table 10.9** Cable fault location methods

Method	Fault characteristics
Impulse reflection method (TDR)	Low-resistance faults, determination of cable end, cable cut, joint location with impedance change
Secondary/multiple impulse method (SIM/MIM, $\approx 80\text{--}90\%$ of all faults)	High-resistance faults, low-resistance faults
Impulse current method (ICM, for long cables)	High-resistance faults, low-resistance faults
Decay method (breakdown voltage higher than 32 kV)	Low-resistance faults
Burn-down techniques, modification of fault characteristics (e.g., influence of water in joints)	High-resistance faults, low-resistance faults
Bridge measurement	Low-resistance faults, cable sheath fault

it is highly desirable to compare the new trace with the latest TDR trace of the healthy system. To precisely locate the cable fault, it is necessary to confirm its position along the cable using further (TDR) measurements, a surge generator and acoustic location (search coils), or any other HV fault location method.

Table 10.9 gives an overview of conventional cable fault location methods.

If there is an integrated optical fiber in the cable damaged by the fault, OTDR can potentially provide an accurate fault location. If the fiber is not damaged, an acoustic method may be feasible.

Surge generator cable fault locators (*thumpers*) provide prelocation and pinpoint cable fault location. The ICM (impulse current method) is preferred for extensive underground cable fault location and for pinpointing cable faults in water-damaged cable joints. A surge generator fault locator (cable thumping) permits very rapid and precise location of cable faults and thus reduces the amount of excavation required. Surge generators have a time-controlled surge output: they periodically produce a discharge in the cable in order to acoustically locate the flashover at the fault using a ground microphone and receiver.

When a high current is used to detect an outer sheath fault, the cable sheath can get damaged in another location. Consequently, after finding and repairing a fault, the outer sheath must be tested again to check its integrity. When a cable is installed in a duct (dry), it may be difficult to pinpoint the fault location due to the insulating properties of the duct.

Currently available technology allows any system fault to be detected with high accuracy. Very often, faults happen in fixed positions (joints, terminations), so if a fault is detected in the vicinity of these accessories, they should be inspected visually first of all.

When an apparently spontaneous fault in the insulation happens, it is often due to the actions of an external or third party, which may be apparent upon arrival at the location of the fault. If the fault is found to be due to external damage, it may be necessary to check the records of the local authorities for previously issued permits.

**Accessory Failures.** Most reported accessory failures are caused by aging or improper installation. Accessory failures are expected to increase with increasing demand for heavier loading operations and high load fault currents, which contribute to aging by imposing thermal stresses.

Accessories undergo either mechanical or thermal failure. Sometimes the accessories have not been installed properly, resulting in mechanical failure. Thermal failure is the result of high resistance heating or individual strands failing, with the same consequences.

These situations can either melt components or cause the joint to lose its connection. Failures generally show evidence of both mechanical and thermal failure. Guidelines in this regard are given in TB 560 from WG B1.29 [10.49].

#### Access to Route Information

It is essential to document the cable route and right of way (ROW) to facilitate monitoring and fault location. The following aspects of the cable route must be documented in detail during cable installation:

- Joints and joint pits
- Terminations
- Cable loops
- Grounding systems, link boxes, and earth cables
- Fiber optic cables
- Laying details such as direct burial, cable ducts, duct laying, and backfill
- Crossings of, e.g., cables, pipes, and roads.

*As-built* cable route drawings are vitally important for long-length HV underground cable systems. These drawings show the finished condition of the work following construction and acceptance, and are a crucial requirement for any HV underground cable project.

#### Typical Durations of Repair Works

When planning the circuit, the utility should consider the total time required for the outages needed to carry out repair works.

The duration of repair works should be specifically defined for each project. The time needed to obtain the necessary authorizations and permits must be considered, which will depend on both the installation type and the local regulations.

The time needed to install high-voltage joints and terminations will depend on the voltage level and the type of insulation used in the cables. Estimates provided by manufacturers are generally based on one jointing team consisting of two jointers and one assistant working 8 h per day. It should be noted that repairs are seldom performed on a 24-h basis, and several teams are often employed to reduce the time taken to get the circuit back in service.

### 10.9.2 Submarine Cables

#### Maintenance Guidelines

Submarine HVAC lines can be surveyed using a remotely operated vehicle (ROV). Equipment for monitoring the laying depth of the cable is available. It is strongly recommended that this operation should be done once a year in areas with high morphological dynamics to prevent the cable from being uncovered. This operation can be performed less frequently in areas with more a stable seabed.

As in any other offshore operation, a ship with appropriate equipment is required, and the operation can only be performed under suitable weather conditions.

Complete geographic information system documentation of the cable route must be provided for every HV submarine line. This is used as a reference to detect any changes to the cable using the data collected by the ROV.

An anchoring map must be provided to any ship operating in the vicinity of a HV submarine cable. This must be a requirement before any vessel (even a recreational boat) is allowed to approach the cable.

#### Origin and Nature of Cable Failures

Repairing submarine cables is an expensive and time-consuming operation as they are very long, remotely located, and difficult to access. Depending on the time taken to locate the fault, the extent of the damage, the time needed to mobilize a suitably equipped ship and crew, and legal discussions about liability, a repair can take weeks, months, or even years. Because of the extensive test program performed on submarine cables when they are manufactured and before they are delivered, internal failures due to issues with the cable itself are rare. Most failures of submarine cables have natural causes; they are often due to human activities. TB 398 published by WG B1.21 deals with third-party damage to underground and submarine cables [10.17]. Furthermore, damage to submarine cables can occur at various times during the lifetime of the cable, i.e., before or after commissioning.

Examples of damage that can occur before commissioning are:

- Overpulling or overbending of the cable due to a loss of the digital position (DP) of the boat installing the cable
- Anchoring damage due to the mooring of the laying barge
- Damage during burial caused by the trenching/burying equipment
- Damage caused when the cable is passed from the transportation vessel to the installation vessel
- Emergency cable cutting due to extreme sea conditions.

After commissioning the cable, natural events that may lead to cable damage include:

- Fatigue at free-hanging sections due to tidal and wave motions
- Abrasion caused by moving material on the seabed
- Underwater landslides or sea-bottom movement induced by seismic events.

However, most of the events that damage cables are due to human maritime activities, including:

- Fishing activities (e.g., trawling and the use of explosives in shallow waters)
- Anchoring
- Dumping of material
- Shipwrecking
- Dredging
- Other submarine installations.

The failure of a submarine cable can have severe consequences both economically and operationally. Thus, a reliable repair should be performed in the shortest possible time. There are no standard cable repair procedures for a submarine cable, although guidelines are available. The owner of the cable system must compile a comprehensive fault location and repair procedure for each cable section according to those guidelines.

Parameters such as the laying depth, cable length, and cable size vary with the cable considered, making each repair operation different from any other. However, a general strategy can be defined. When a cable fault occurs, the following steps should be performed:

- Fault detection and location
- Repair operation planning
- Securing a suitable vessel for the repair, as well as suitable equipment and a qualified crew
- Mobilization of the vessel, equipment, and crew
- Loading the repair joints and spare cable
- Cable recovery or removal of the damaged section of the cable

- Cable repair onboard the vessel
- Relowering the cable/protecting the cable.

### Fault Detection and Location

As already stated above, the issue of fault location in AC and DC land and submarine links is addressed in detail by CIGRE WG B1.52 in TB 773 [10.64].

The fault detection and location steps are important ones in the repair process. The position of the fault along the cable will strongly influence the extent of the repairs required and the means to implement them. It also influences the type of vessel and equipment required. The long length of the line makes it more difficult to pinpoint the exact location of the fault, but it is nonetheless crucial to precisely locate the fault, as cutting the cable at the wrong point can increase both the costs and the duration of the fault repair.

Several methods can be employed to locate the fault, some being more accurate than others. Combining different tests often gives the most accurate results.

For three-core cables, the problem is generally a failure of the insulation on one core, so the first step is to identify the faulty core. Insulation resistance measurements will allow the faulty core to be identified.

Almost all of the submarine three-core cables installed today include at least one fiber-optic element between the power cores. This fiber-optic element is a good indicator of a fault. Indeed, if the armor and possibly the metallic screen of the power cable are damaged, the optical fiber element will probably also be destroyed. Thus, when possible, performing optical time-domain reflectometry (OTDR) from both ends will highlight a discontinuity or a stressed optical fiber and yield the approximate location of the fault.

A failure can also be located by performing time-domain reflectometry (TDR) in the faulty core. This can be done from only one end, but it should be performed from both ends if possible as this will give significantly more accurate measurements. The best results from TDR are obtained for breaks or low-resistance faults. It is very important to get a TDR trace performed upon commissioning and during the regular routine maintenance program.

Another method of locating a fault is to use Murray loop bridge measurements. This can be done if one of the other cores in the cable is not faulty. This method is simple and often allows the fault to be pinpointed to within 1% of the cable length provided that the temperature variation along the route is accounted for.

Even though all of the methods described above give good results, the application of a more accurate method is then recommended in order to identify the

precise location of the fault and thus avoid unnecessary cable wastage. One such location method is to inject a tone current into the faulty core and pass a vessel or ROV equipped with search coils over/along the cable. The search coils will detect the change in magnetic field across the fault. Methods that use emerging technologies such as frequency-domain reflectometry (FDR) are also options.

### Planning the Repair Operation

Once the fault has been located, other information such as the depth or the sea current at the fault location must be obtained before the repair operations can be planned. It is also necessary to assess the condition of the sea bottom at the fault location and perform a survey of that area.

The repair method that should be employed depends on several parameters, such as the water depth, the weather, current, and soil conditions, the type of joint involved, and the results of an unexploded ordnance (UXO) survey. Analysis of this information will lead to the selection of the most suitable vessel, equipment, and crew for the operation. Furthermore, uncertainty over the weather conditions should be considered. It can be challenging to find a suitable window to perform an offshore repair in winter or the storm season.

All aspects and parameters of the operation should be carefully planned to achieve the most efficient operation and avoid expensive mistakes offshore.

The choice of vessel will depend on the location of the fault and the type of repair to be done, but some characteristics of the vessel should be considered. The vessel should be able to remain in a stable position even in rough weather. Thus, the vessel is required to have a good and stable digital positioning system. The deck size of the vessel should be at least 1000 m<sup>2</sup> to be able to install all of the equipment and to allow sufficient area for the jointing. For instance, a flexible joint can be up to 25 m long.

Personnel are needed to maneuver all of the equipment and perform the repair. Representatives of the supplier, the owner of the cable, and the insurance company should also be present during the repair operation. Thus, the vessel should be equipped with sufficient cabins to host all of the people that must be onboard during the repair operation.

Another important aspect of the planning process is the legal discussion between the client and the insurance company. It is very important to define the liability (and its limits) of each party from the beginning. This discussion can take a long time—up to two years in certain cases.

### The Repair Operation

Once the repair has been planned, the vessel, equipment, and the crew will be mobilized. Once it has arrived, the equipment needs to be installed on the vessel and the layout needs to be certified by the appropriate body. This mobilization phase usually takes 10–15 days.

The vessel is then ready to sail to the fault location. Two repair joints and part or all of the spare cable will be used in the repair operation.

### Typical Duration of Repair Work

As mentioned above, repair operations for submarine cables can vary from case to case. The duration of the repair operation is dependent on many parameters, and any estimate of the duration of this operation is generally inaccurate and misleading, so it is important to carefully consider whether such an estimate should be supplied.

Even when a good repair plan is in place in terms of spare parts management and equipment and jointing team availability, the time required for a repair operation is extremely unpredictable due to various factors

including availability of vessels and crew, time of the year, weather, and environmental restrictions.

### Concluding Remarks on the Maintenance of Submarine Cables

Due to the long lengths, remote locations, and difficulties involved in accessing submarine cables, repair operations for such cables are expensive and time-consuming. Depending on the time needed to locate the fault, the extent of the damage, the time taken to mobilize a suitably equipped ship and crew, and the length of legal discussions regarding liability, a repair can take weeks, months, or even years. Because of the extensive test program performed on submarine cables when they are manufactured and before they are delivered, internal failures due to the cable itself are rare. Most failures in submarine cables are caused by third-party damage, a topic that is addressed by WG B1.21 in TB 398 [10.17]. Furthermore, damage can occur to a submarine cable at a different points in its lifetime, i.e., before or after commissioning.

## 10.10 Upgrading and Uprating

The upgrading and uprating of HV cable systems is addressed in TB 606, published by WG B1.11 [10.65].

The life expectancy of an underground cable system is usually more than thirty years. This makes it difficult to predict changes in the cable environment or how the operating conditions will evolve over time. Increases in demand raise major issues. Replacing a power link or installing an additional circuit incurs a significant investment cost. Some congested areas even prevent the operator from carrying out such an extension. The difficulties involved in obtaining planning permission for new sites also favor extending the lifetimes of existing facilities, often with the additional goal of transmitting higher power with higher reliability to minimize the duration of asset unavailability. The challenge is to upgrade the existing cable system with reasonable and relevant solutions.

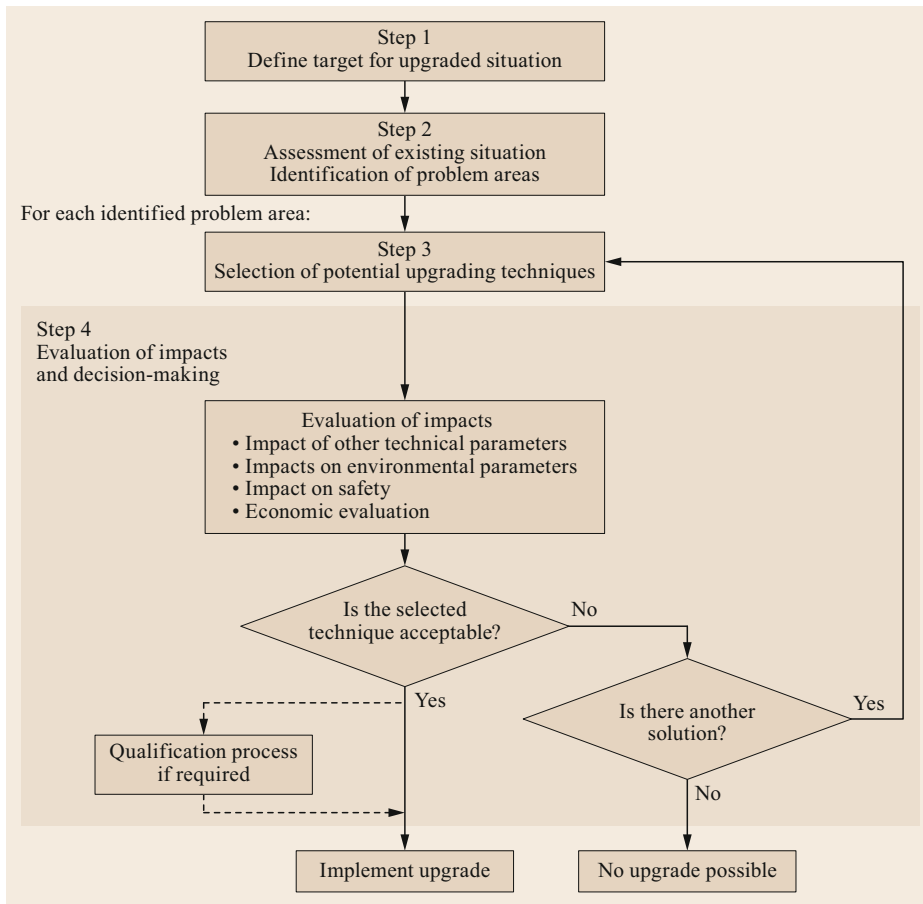

*Upgrading* is generally the process of improving equipment performance by replacing (working) components in order to meet new operating requirements (although other solutions are also discussed in TB 606 [10.65]). This allows the transmitted power, service life, environmental impact, and safety to be improved.

*Uprating* is the process of applying a physical solution that allows the system to be operated at a current level above its rated current, or the process of applying a method or a calculation that allows improved assessment of the performance of the system. In TB 606, uprating is treated as a special type of upgrading [10.65].

A simple step-by-step methodology with flowcharts is proposed in TB 606 to guide the engineer through the upgrading process. The steps involved, from the definition of the target for upgrading to the assessment of the existing situation, the identification of relevant issues, the selection of potential upgrading techniques, the evaluation of their impacts, and the decision-making step, are described.

An assessment of the actual condition and performance of the cable system is the first step in any upgrading process. In a thorough evaluation, a list of the parameters with the greatest influence on the specific aspect of the system to be upgraded (usually the transmitted power) is provided, as well as a list of the many other aspects of the link that could be impacted by the upgrading process.

Increasing the transmitted power is the usual aim of any upgrading process. Possible parameters to ex-

**Fig. 10.116**  
Step-by-step  
methodology  
for upgrading  
a cable (adapted  
from [10.65])

plore include the voltage level, the current rating, and the phase difference between the voltage and the current for AC systems. A fourth possible solution may also be considered: the conversion of the system from AC to DC. A panel of various solutions for increasing the current rating are considered: altering the current capacity (via new overload conditions, new calculation procedures, temperature monitoring), reducing losses, and improving heat transfer (using, e.g., ventilated tunnels, special backfill [10.15], hotspot smoothing, heat pipes, forced cooling, or reconductoring).

Other aspects of the performance of the cable may be upgraded, such as environmental and safety aspects. As an example, transition compounds may require upgrading (in terms of, e.g., audible noise, electromagnetic fields, and fluid leaks). Regarding safety issues, interesting solutions to reduce the risk of fire or an explosion (see also TB 560 published by B1.29 [10.49]) may be implemented. Fault containment should also be

considered in order to limit the consequences of a fault for the environment and people nearby.

Once upgrading solutions have been identified, it is highly recommended that the impact of the upgrade on other system functions should be explored, because changing the existing cable system may interfere with other technical or environmental parameters.

To illustrate possible applications, one chapter of TB 606 provides interesting case studies on upgrading, ranging from a simple reassessment of the current capacity of a link to a more complicated case involving forced cooling and retrofitting of new cable in existing pipes. Other examples can be found in the bibliography of TB 606 [10.65].

### 10.10.1 Proposed Methodology

Engineers design underground cable systems with great care. Since the life expectancy of such a system is often

more than thirty years, the potential evolution of the operating conditions of the power link is accounted for in its specification. The spread of urban areas, the establishment of industrial estates, or changes in the expectations of customers may lead to the need to increase the power transmitted. Some operating rules require circuit redundancy in order to compensate for the loss of a deficient line. In this case, the remaining systems must be able to transmit extra power in an emergency to ensure the reliability and availability of the overall network.

Sometimes the existing power network will become insufficient or inadequate. Replacing a link or installing an additional circuit may involve a substantial investment cost. A reasonable solution may be to improve the existing line or its environment. According to electrical engineering laws, the voltage level and/or the load current must be increased to boost the power transmitted.

It is important to understand that the process of upgrading an existing system involves an assessment of the feasibility of redesigning the cable system that accounts for higher stress levels. This redesign may, for example, include replacing components, modifying the cable environment, or installing monitoring devices.

To identify the most appropriate solution, TB 606 proposes a step-by-step methodology for upgrading

a cable that is illustrated by the chart shown in Fig. 10.116 [10.65].

Techniques for increasing the transmitted power include:

- Increasing the voltage level
- Increasing the current rating by reassessing the current capacity
- Increasing the current rating by assessing lower losses
- Increasing the current rating by improving heat transfer
- Increasing the current rating through forced cooling
- Reconductoring
- Improving the phase difference between the voltage and the current (compensation).

Another solution is to increase the performance by changing from AC to DC with:

- Intrinsic characteristics
- Suitability of the existing cable and its components for DC operation
- Transmittable real power
- Retrofitting of steel pipe when necessary.

## 10.11 Life-Cycle Assessment

WG B1.36 recently published TB 689 [10.66], which discusses the life-cycle assessment (LCA) of underground cables.

Electricity losses have been found to be the most important factor in the life cycle of an underground cable. In order to reduce these losses, the electrical resistance of the cable must be lowered, which can be achieved by increasing the crosssection of the conductor. LCA results can therefore be used in debates about the need to reduce electrical losses.

Based on the conclusions of a LCA, it may also be possible to propose materials and processes that result in a lower environmental impact in manufacturing, installation, and in the end-of-life phase of a cable.

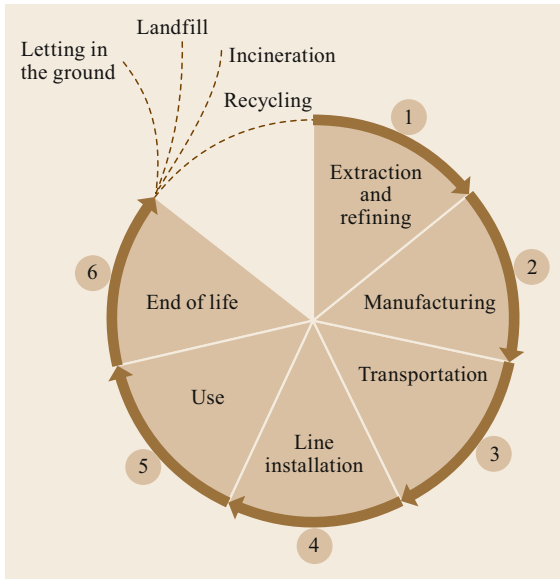

The manufacturing phase may be improved by introducing the use of recycled materials as input materials. This potential improvement should first be evaluated through a sensitivity analysis. For technical reasons that largely relate to recycled material performance, cable manufacturers may only use primary

metals and plastics. However, new technologies that use a thermoplastic insulating material that exhibits similar thermomechanical behavior to crosslinkable materials have recently been developed. Studies to improve the performance of recycled materials should also be carried out. There may be an opportunity to recover cables that have reached the ends of their lives and recycle some of the materials in them to reduce the costs of producing new cables, given that primary materials are becoming increasingly rare and expensive.

The scope of a LCA is from the cradle to the grave. The different steps in the life cycle of a cable that are taken into account are as follows:

- The *extraction, refining, and transportation* of raw materials, including minerals for metals (aluminum and/or copper) and petrochemicals for polymers
- The *manufacture* of intermediate materials, such as plastic granules, wire rods, cables, and accessories

**Fig. 10.117** Stages in the life cycle of an underground cable (adapted from [10.66])

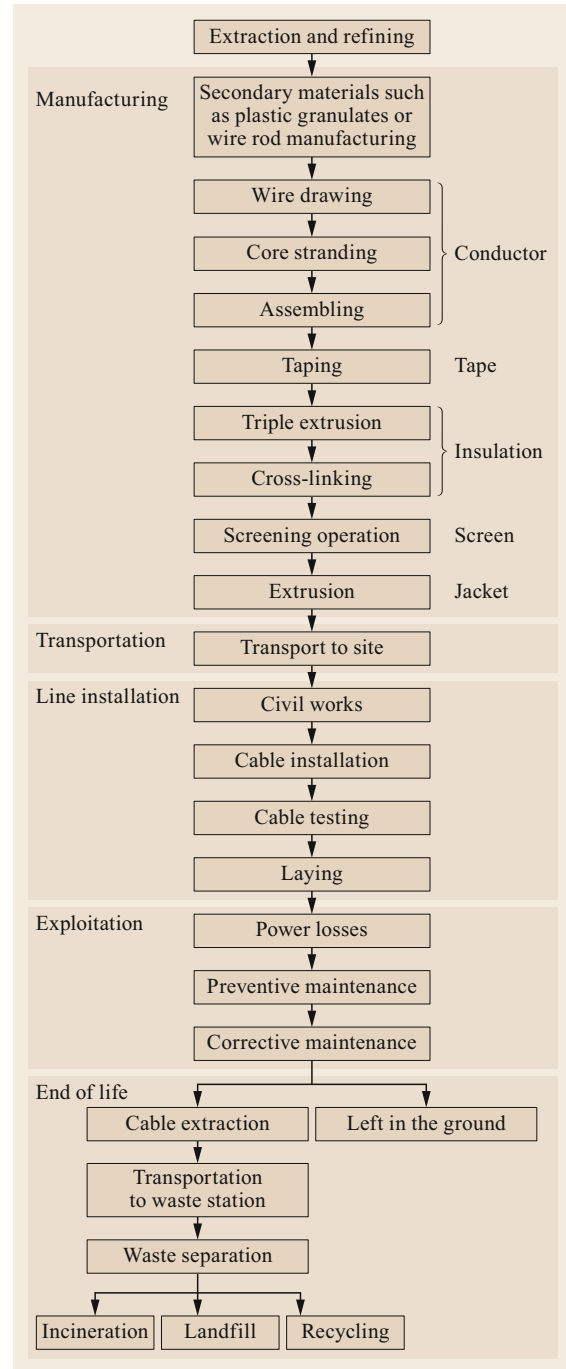

- The *transportation* of the cables and accessories from the construction site to the line installation site
- The *construction and installation* of the line
- The *operation* of the line
- The *end-of-life* phase.

This does not take into account the production, maintenance, and decommissioning processes for facilities and capital goods (such as buildings, machines, and roads) associated with cable manufacture, installation, and operation. This is because these facilities and capital goods are assumed to have a negligible environmental impact.

Figures 10.117 and 10.118 illustrate the life cycle of an underground cable. It is assumed that each cable will be pulled out of the ground after 40 years of operation due to regulatory requirements or for economical motives.

A practical example of a LCA for a 90 kV line is given in TB 689 [10.66].

**Fig. 10.118** Detailed summary of the life cycle of an underground cable (adapted from [10.66]) ▶

## 10.12 Superconducting Cables

Advances in superconducting cable technology [10.67] and in-grid applications of these cables have necessitated the development of an industry testing guideline on the design and performance requirements of superconducting cable systems: TB 538, prepared by WG B1.31 [10.68]. This guideline focuses on the requirements for AC high-temperature superconducting (HTS) cables based on cold dielectric designs. Low-temperature superconducting (LTS) materials, warm dielectric designs, and DC designs are not currently considered in the guideline.

HTS materials and applications of them have attracted considerable interest since the discovery of these materials in 1986. These superconducting materials can be cooled with liquid nitrogen (at  $77\text{ K} = -196^\circ\text{C}$ )—a relatively inexpensive, inert fluid that is easy to manage industrially. Despite this long period of development, HTS cables are still very much a new technology for the power utility industry. The cables covered in TB 538 can be categorized into three general designs:

1. *Single-core designs* (Fig. 10.119). These have one electrical phase per cryogenic envelope. Each phase incorporates a phase conductor, a dielectric, and a concentric neutral conductor. Three single-core cables are required for typical three-phase power system applications. Designs commonly use HTS wires for the concentric neutral layer and may or may not include copper wires to shunt short-circuit currents and protect the HTS wires.
2. *Three-core designs* (Fig. 10.120). These have three single-phase cable cores inside a common cryogenic envelope. This is also called a *triad* design.

**Fig. 10.119**  
Single-core HTS cable (adapted from [10.68])

Each core typically consists of a phase conductor, a dielectric, and a concentric neutral conductor made of HTS wires. The neutral conductor may or may not include copper wires to shunt short-circuit currents and reduce heat generation.

3. *Triaxial designs* (Fig. 10.121). Here, three electrical phases are arranged concentrically around a common core inside a common cryogenic envelope. The dielectric between the phases must withstand the phase-to-phase voltage rather than the typical phase-to-ground voltage. A concentric neutral conductor (HTS or copper) is typically located on the outside of the cable core. This design is used for medium voltages and optimizes the CAPEX (one superconducting screen, one cryostat for the whole system, and one cable to install).

### 10.12.1 Experience with Superconducting Cables

In-grid demonstration projects have shown that superconducting technology works and is technically viable. A list of in-grid demonstrations worldwide is shown in Table 10.10. Other demonstration projects around the world that were installed at test facilities or industrial sites are listed in Table 10.11. Additional development

**Fig. 10.120**  
Three-core HTS cable (adapted from [10.68])

**Fig. 10.121** Triaxial cable (adapted from [10.68])

**Table 10.10** Power grids that include HTS cables (data from 2012)

Country and utility	In-service date	Voltage (kV)	Designed power level (MVA)	Length (m)	Design
Denmark	2001	24	–	30	Warm dielectric, single-core <sup>a</sup>
China, China Southern Power Grid	2004	35	120	33.5	Warm dielectric, single-core <sup>a</sup>
USA, National Grid	2006	34.5	48	350	Three-core
USA, AEP	2006	13.2	69	200	Triaxial
USA, LIPA	2008	138	574	600	Single-core
South Korea, KEPCO	2011	22.9	50	500	Three-core
Japan, TEPCO	2012	66	200	250	Three-core

<sup>a</sup> This design utilizes a conventional extruded dielectric material that is extruded over the cryostat and operated at ambient temperature

**Table 10.11** Laboratory-tested and industrially applied HTS cables (data from 2012)

Country	Date of testing/application	Voltage (kV)	Designed power level (MVA)	Length (m)	Design
Japan, Super-GM	2005	77	133	500	Single-core
US, Carrollton	2000–2006	12.4	27	30	Single-core
South Korea, KEPRI	2007	22	48	100	Three-core
Mexico	2007	23	80	100	Three-core
Germany/Spain	2008	10	17	30	Single-core
Germany/Spain	2010	24	133	30	Single-core
Russia	2010	20	104	200	Single-core
South Korea	2011	154	1000	100	Single-core

and advances are needed in the area of cryogenic refrigeration and in improving the reliability of those systems.

Investments made around the world by various national government agencies and private industry have facilitated rapid advances in HTS cable, accessory, and cooling technologies. This trend is expected to continue, leading to further improvements in performance, efficiency, and ratings in the near future. These advances in HTS cable technology, combined with improvements in the manufacture of materials and components, will enhance the cost-benefit ratio of HTS cable implementation.

The HTS cables in development today are primarily envisioned as a solution to grid constraints in dense urban areas. Following the successful demonstration of the technology and economics needed to support implementation, HTS cables will remain a niche market for the short to mid-term (5–10 years), implying that the number of projects worldwide and the volume of HTS cables installed will remain limited.

### 10.12.2 Cryogenic System Issues

As mentioned earlier, WG B1.31 published TB 538, which gives recommendations for HTS cable testing [10.68]. Annex B of [10.68] provides information on cryogenic system technology that serves as an overview of the technology and the functional parameters associated with HTS cable operation. It also guides the user in key issues for system specifications.

Actual testing requirements and specific performance requirements of cryogenic refrigeration systems are not included.

The specific requirements for the operation and reliability of cryogenic cooling systems vary depending on the overall system design and performance expectations of the HTS cable. For example, the fault-limiting performance depends on different thermal operating parameters of the system. The operational tolerances of parameters such as temperature variation, pressure variation, heat load capacity, and buffer volume (installed to accommodate the expansion of the liquid when warmed above normal operating temperature) can all vary according to the manufacturer's system design philosophy and performance specifications.

TB 538 does briefly address the cryogenic aspects of safety and pressure containment. The piping and cooling system equipment used with HTS cables are commonly classified as high-pressure piping and pressure vessels in the relevant country's laws and specifications. As such, TB 538 does not propose specific requirements for HTS cables, but it does highlight critical issues for the reader.

### 10.12.3 Future Work

There are several key areas that must be addressed in future work on HTS cable testing. These issues represent challenges to the development and commercialization of the technology and will need to be resolved to

achieve the widespread market adoption of HTS cables for a range of applications. For AC cables, these areas of future work include routine/factory testing of completed cable lengths, aging tests of cryostats, and requirements for increased voltage levels.

There is currently no accepted methodology for the factory testing of full lengths of cable after manufacturing. Sample testing is performed at various stages during the manufacturing process and after completion. However, it is impractical to perform high-voltage and high-current tests on a full length of cables. The need to cool the cable to cryogenic temperatures and impregnate the dielectric tapes with the cryogen makes tests on full reels of finished cable impractical. Sometimes the cable reel at the factory does not include the cryostat. In all cases, the thermal contraction of the cable on the reel presents extreme difficulties. Methodologies to enable the factory testing of full lengths of cable in a similar way to conventional cables must be developed to facilitate the widespread adoption of HTS cables by the utility industry.

The cryostat used for HTS cables is typically a double-layer vacuum-jacketed corrugated pipe. Expe-

rience regarding the life expectancy of vacuum-jacketed cryostats is limited, although some cryostats of this type have been used for extended periods in similar applications at scientific and research labs such as CERN.

TB 538 focuses on HTS cables with  $U_m = 170$  kV ( $U = 150$  kV). However, 275 kV AC HTS cables are currently being developed at the time of writing. Testing guidelines will therefore need to be adapted to higher voltage limits in coming years to match research and development efforts around the world.

Some users may request long-term prequalification tests for HTS cable systems, similar to those defined in IEC 62067 or IEC 60840 for XLPE cables, due to the limited experience of HTS cables operating in a grid. The need for a prequalification test and/or its details will need to be discussed, taking into account the opinions of users and manufacturers, by future CIGRE or IEC working groups.

A CD on test methods and requirements for high-temperature superconducting power cables and their accessories with rated voltages from 6 kV ( $U_m = 7.2$  kV) up to 500 kV ( $U_m = 550$  kV), based on TB 538 [10.68], has been prepared by TC 90 and TC 20 of the IEC.

### 10.13 Gas-Insulated Lines

A gas-insulated line is a special type of electric transmission line, i.e., it transmits electric active power (and, in the time domain, electric energy) over a given distance. Gas-insulated lines go by various acronyms. The IEC acronym is GIL, while older acronyms include GITL (gas-insulated transmission line) and CGIC (compressed gas-insulated cable). Regardless of the acronym used, a gas-insulated line consists of a tubular enclosure made of high-conductivity aluminum or aluminum alloy in which each tubular phase conductor (aluminum) is held in a central position by epoxy resin insulators. As described in TB 639 (on factors that impact on the decision to invest in either GILs or cables for AC transmission) [10.7], there are two dif-

ferent kinds of GILs: single-phase (Fig. 10.122) and three-phase (Fig. 10.123) GILs. An example of the internal structure of a GIL is given in Fig. 10.124. The GIL configuration with three conductors in one enclosure suffers from phase-to-phase faults and significant interaction forces between the conductors, so it is generally not used in real-world installations. GILs are not used at the LV and MV levels.

GILs were developed directly from SF<sub>6</sub>-insulated substations (or gas-insulated substations, GISs). However, a GIL differs from a GIS in that the GIL has no switching or breaking functions. In the past, when GILs were called CGICs, they were considered a special type of insulated cable.

**Fig. 10.122** Indicative dimensions of a flat single-phase GIL (rated voltage 420–550 kV); the typical weight of one pipe without gas is 30–60 kg/m and the typical diameter is 400–550 mm (adapted from [10.7])

**Fig. 10.123** Three-phase GIL used in GIS at the lower high-voltage range up to 170 kV (adapted from [10.7])

First-generation GILs were built from standard GIS components using pure  $\text{SF}_6$  as the insulating gas and straight enclosures. In the year 2000, a second generation of GILs was introduced that could be used to transmit power over longer distances and had a reduced environmental footprint. These GILs utilize an insulating gas mixture (such as  $\text{SF}_6/\text{N}_2$ ) and a minimum bending radius of enclosures was introduced (typically 400 m).

It is well known that isolated phase bus ducts have structures similar to those of GILs, but are often used at MV levels to connect generators to step-up transformers in power plants. These MV isolated phase bus ducts are insulated with air at atmospheric pressure and are manufactured to have the same general structure as GILs but have larger diameters (since the dielectric strength of air is one-third that of the gas most commonly used in GILs,  $\text{SF}_6$ , at a given pressure) and increased spacing. The use of  $\text{SF}_6$  in GILs requires the application of welded joint technology to reduce possible gas losses to a minimum. It is also recommended that  $\text{N}_2/\text{SF}_6$  gas mixtures should be employed on long transmission lines to reduce the amount of  $\text{SF}_6$  used. GILs can be supplied as sections that have been assem-

bled and tested in the factory. The factory-assembled GILs are shipped in sections up to 18 m long and are either bolted together with flanges (sealed with O-rings) or welded together in the field. GILs can also be supplied as elements that need to be assembled on-site. For this solution, conductor and enclosure lengths along with support insulators are transported to the installation site, where they are assembled in situ. Various elements, including a straight unit, an angled unit (such units can be angled by up to  $90^\circ$ ), a compensation unit, and a disconnecting unit, are depicted diagrammatically in Fig. 10.125. The shipping lengths of GIL elements may vary from 6 to 18 m depending on the installation and technology used. The maximum shipping length must be transportable to the installation site.

The assembled sections are joined together via plug-in contacts, and the enclosures are linked by on-site welding or bolted flanges. The quality of the enclosure welds is a crucial influence on line reliability, so a special computer-controlled orbital welding machine is used and every welded part undergoes ultrasonic testing to ensure the highest quality. This welding procedure is known to have a high degree of reliability and quality based on experience of its use in nuclear power plants. For bolted flange technology, tightness is ensured by the use of gaskets or seals. These seals can be different shapes, although O-rings are commonly used. The high degree of tightness is achieved by selecting the appropriate gasket (materials and shape) as well as by using the right installation procedures. The tools, equipment, and skilled labor needed to connect the flange-bolted GILs on-site are simpler than those needed for welded GIL technology. This simpler installation also permits many more bolted sections of GIL than welded GIL sections to be installed per day. In addition, when site maintenance or repairs are performed, the bolted technology is simpler to implement than the welded one. It should be noted that the flange-bolted solution would be very difficult to apply for directly buried GILs, so the welded solution is preferred.

**Fig. 10.124** Internal structure of a GIL (adapted from [10.7])

**Fig. 10.125** General overview of the units comprising a GIL: A: straight unit, B: angled unit, C: disconnecting unit, D: compensation unit; also shown are: 1: enclosure, 2: conductor, 3: sliding contact, 4: non-gastight insulator that provides a fixing point for the conductor, 5: sliding post-type insulator, 6: longitudinal thermal expansion compensator (adapted from [10.7])

GIS and GIL manufacturers have made continuous improvements over the last 30 years to ensure that GILs are virtually leak-free. The need for leaktight GIL systems is also driven by environmental concerns. Current standards (from both the IEEE and the IEC) require GIL systems to lose no more than 0.5% (by volume) of their gas per year. Designs for both welded and flange-bolted GIL have both improved to the point where it is straightforward to meet and exceed the required tightness standards. The welded GIL gas tightness easily exceeds these requirements; for instance, the first welded GIL installation, which dates from 1976, is still in service with the original gas fill.

The space between the phase conductor and enclosure is filled with an insulating gas which must withstand the phase-to-earth voltage. This insulating gas can be pure  $\text{SF}_6$  under a pressure of 0.3–0.5 MPa or a more environmentally friendly and less expensive  $\text{SF}_6/\text{N}_2$  mixture (typical ratio: 10–20%) at a higher pressure (up to 1.0 MPa). The insulating gas therefore always contains sulfur hexafluoride ( $\text{SF}_6$ ), an inert, nontoxic, nonflammable gas. More details of the environmental impact of  $\text{SF}_6$  are available in TB 351 [10.69]. The handling of  $\text{SF}_6$  is regulated in IEC 62271-4. The contribution of  $\text{SF}_6$  to global warming is small, and the use of  $\text{SF}_6$  is regulated by several regional directives, chiefly the new EU Regulation No. 517/2014 of 16 April 2014 on fluorinated greenhouse gases.

It is worth noting that the dielectric strength of  $\text{SF}_6$  is approximately three times that of air at a given pressure. This gas is widely used in high-voltage equipment, where its insulating properties permit compact structures. These structures must satisfy the IEC standard 62271-204 (for an insulating gas consisting of pure  $\text{SF}_6$  or a  $\text{SF}_6/\text{N}_2$  mixture under pressure).

With regard to dimensional characteristics, it should be noted that the optimal ratio between the inner diameter of the enclosure and the outer diameter of the conductor to minimize the electric field is 2.72. In prac-

**Fig. 10.126** GIL connection to overhead line via the bushing (800 kV example; adapted from [10.7])

tical applications, however, any ratio between 2.5 and 3 can be adopted since the electric field increases by only 0.5% in this interval.

A GIL enclosure resembles a gas transportation pipeline, which is why GILs are sometimes referred to as *electric pipelines*. So far, all real-world GIL installations have been short runs that were implemented instead of overhead lines or to provide connection points for hydroelectric, thermal, and nuclear power plants. However, the technical features of this electric transmission line indicate that is suitable for long lengths and bulk power transmission, as shown in TB 351 [10.69].

The most widely used laying type for GILs is above the ground inside substations, where they are used to connect overhead lines or transformers with GIS. Steel structures are typically used to hold the GIL above ground. For long-distance transmission, the connection of the GIL to the overhead line is most commonly done via a bushing as shown in Fig. 10.126.

**Table 10.12** Historical development of GILs

1971	First HV installation of a GIL insulated with pure SF <sub>6</sub> (first-generation GIL) in Eastlike, Ohio at a rated voltage of 345 kV (circuit length 122 m)
1972	First directly buried HV installation of a GIL insulated with pure SF <sub>6</sub> (first-generation GIL) at Hudson Switching Station in New Jersey at a rated voltage of 245 kV, 1600 A (circuit length 138 m)
1975	First HV installation of a GIL insulated with pure SF <sub>6</sub> in Ellensburg, Washington at a rated voltage of 550 kV, 3000 A (circuit length 192 m)
1976	First HV European installation of a GIL insulated with pure SF <sub>6</sub> (first-generation GIL) at a hydropump storage plant in Schluchsee, Germany, with a rated voltage of 400 kV (circuit length 670 m)
1981	First HV installation of a GIL insulated with pure SF <sub>6</sub> in Guri Dam, Venezuela at a rated voltage of 800 kV, 1200 A, 1925 kV BIL (total phase length 855 m, 5 circuits)
1997	Longest (phase length) installation (17 010 km) of a GIL insulated with pure SF <sub>6</sub> (first-generation GIL) at PP9, Saudi Arabia, with a rated voltage of 380 kV (circuit length 709 m, 8 circuits, for a total phase length of 17 010 m)
1998	Longest (circuit length) installation (3.3 km) of a GIL insulated with pure SF <sub>6</sub> (first-generation GIL) at Shinmeika-Tokai, Japan, with a rated voltage of 275 kV (circuit length 3300 m, 2 circuits)
2001	First HV installation of a GIL insulated with a SF <sub>6</sub> /N <sub>2</sub> gas mixture (second-generation GIL) in Geneva, Switzerland, with a rated voltage of 220 kV (circuit length 420 m)
2004	First HV installation of a GIL insulated with a SF <sub>6</sub> /N <sub>2</sub> gas mixture (second-generation GIL) in the UK at Hams Hall, with a rated voltage of 400 kV (circuit length 540 m)
2009	First HV installation of a 800 kV, 4000 A GIL (BIL 2100 kV) insulated with pure SF <sub>6</sub> in Laxiwa Dam, China (total phase length 2928 m, 2 circuits)
2012	First directly buried second-generation HV GIL at Kelsterbach substation near Frankfurt, Germany, with a rated voltage of 400 kV (circuit length 880 m)
2013	First installation of a 420 kV GIL with a 80N <sub>2</sub> /20SF <sub>6</sub> gas mixture, a bending radius of 400 m, and all welded joints, which passes under a Bavaria brewery (4 three-phase circuits each 1 km long in one tunnel, each circuit with a rated current of 3150 A)

### 10.13.1 Historical Development of GILs

The historical development of GILs is reported in Table 10.12.

### 10.13.2 Comparison of GILs to Conventional Cables

TB 639, prepared by JWG B3/B1.27 [10.7], was initiated to help clarify if the best solution for a particular transmission line project is extruded cables or a gas-insulated transmission line (GIL). Evaluating the options for a transmission line project is a complex task, and this technical brochure provides the information needed to make solid decisions based on the knowledge of experts in SC B1 (on cables) and SC B3 (on substations).

In TB 639 [10.7]:

- The economic parameters associated with UG cable and GIL installations are identified and the relative cost structures are given.
- Typical transmission solutions for GIL and UG cables are compared.
- Environmental impacts such as health and safety requirements and external electromagnetic fields are taken into account.

Technical definitions of cost factors and drivers are given in TB 639 to permit an informed comparison of solutions. Examples of these cost factors and drivers include

access to and the width of the route, system configuration, rights of way, safety aspects, fire-related aspects, transmission losses, reactive power compensation, aging of equipment, life-cycle costs, service experiences, gas tightness, recycling of the cable/GIL material in the end-of-life phase, CO<sub>2</sub> emissions (during production, installation, lifetime), waste disposal, geographical aspects, construction aspects, O&M, and standards and regulations. Practical applications are shown in TB 639.

The impacts of restoration cost factors in the case of failure and relevant outage durations are also covered in TB 639. Since the publication of TB 639, TB 773 on fault location in land and submarine cable links has also been published [10.64].

It is worth remembering that the aim of TB 639 is not to provide absolute costs but comparative and relative ones. It gives guidelines for case-by-case evaluation. Even though the transmission solutions presented in TB 639 are typical, they are not necessarily representative.

Most of the factors and economic parameters mentioned vary according to local conditions (e.g., civil works) and over time (e.g., the prices of raw materials). As mentioned in the executive summary of TB 639, any relative comparison is inherently insufficient to obtain satisfactory general results.

Section 10.A.1 below is an unbiased Reference Statement from CIGRE regarding AC land power transmission via overhead lines, gas-insulated lines, and

underground cables above 170 kV [10.70]. As noted in the introduction to the Statement, it attempts to explain the fundamentals of these technologies in a manner that can be understood by a nontechnical person or a person

who is not involved in the industry on a day-to-day basis. Of course, more detailed information can be found in previous sections of this chapter or in the chapter dedicated to overhead lines.

## 10.A Appendix

The following CIGRE Reference Paper [10.70], written by M. Marelli, P. Argaut, H. Lugschitz, and K. Kawakita, on behalf of CIGRE Study Committees B1, B2 and B3, is intended to provide unbiased information regarding options for HV and EHV AC transmission lines. The authors and the Technical Council of CIGRE have agreed to include this text in the Chapter 10 of this book, since UG Cables and GIL are covered in this chapter and Overhead Lines are the topic of Chap. 9.

### 10.A.1 Overhead Transmission Lines, Gas Insulated Lines and Underground Cables

There is a considerable amount of highly technical information, specifications and guides available on the transmission of bulk electrical power from one area to another. This information is available from bodies such as CIGRE, IEC (International Electrotechnical Commission), and many National-based organizations. There is, however, very little information that would explain the fundamentals of the technologies in such a manner that it could be understood by a non-technical person or a person not involved on a day-to-day basis in that industry. This paper will attempt to fulfil that need by providing basic information in hopefully a readily understandable manner.

This paper refers to transmission lines exceeding 170 kV alternating current (AC). Direct current (DC) connections and subsea cables are not a part of the scope of this paper (for those, other criteria apply to compare).

#### Technical Basics

Some of the fundamentals of power transmission are the voltage and current levels used to transmit the power from one area to another. Roughly speaking the voltage multiplied by the current is equal to the power. If one thinks of electricity in terms of water flow then voltage is like pressure i.e., it drives the current through the conductor in the same that pressure drives water through a pipe. Current is the flow of electricity through the conductor.

In AC transmission the power is transmitted utilizing a three phase system with three metallic conductors; the size of the conductors govern their thermal capability to carry current i.e., the larger the conductor the more current it can carry. The conductors must be in-

sulated from the ground and from each other in order to be able to withstand the voltage applied; again, the more insulation the higher the voltage that can be used in the transmission circuit.

The three conductors may be assembled in an overhead line circuit (OHL), an underground cable circuit (UGC) or a gas insulated lines (GIL) circuit. Each one will be described below.

One basic technical aspect to be considered is related to routing a transmission line, including:

- *Route availability*: it must be possible to construct the line.
- *Urbanization*: if the line is to be routed through an urban area, then future developments may have an impact on the route and design of the line.
- *Route topography*: if the terrain is very uneven or hilly, the technical challenges and costs increase.

#### Overhead Lines (OHL)

An overhead line circuit is typically composed of lattice steel towers which support the three conductors that make up the circuit. In some lines, tubular poles (pylons) are used instead of lattice structures. The conductors are insulated from the structures by means of insulators, which are made of toughened glass, porcelain or of composite materials.

Typical examples of OHL designs in current use are shown in several CIGRE Technical Brochures and the CIGRE Green Book *Overhead Lines*.

Depending on voltage and terrain, towers are typically 200–500 m apart from each other.

Many OHL designs are fitted with one or several earth wires at the top of the tower. These earth wires have two functions, firstly to protect the conductors from a lightning strike which might cause an outage and secondly in the event of a fault: the fault current will be mainly contained within the conductor/earth wire loop and returned to earth. Earth wires are often fitted with fiber optic elements for communication purpose.

It should be noted that in many cases OHLs have two electric circuits or more on the same tower. Each circuit may have 1–4 conductors in a bundle for each phase (and even more at Ultra High Voltage Lines). These OHLs can carry many times the power of a single circuit line with single conductors.

The design of an OHL depends on many factors including:

- *Conductor size*: the size of the conductor is dependent on the current to be carried. Of course, the size of the conductor also has an impact on the weight the tower must support—currently the standard maximum conductor size used is about 800 mm<sup>2</sup>.
- *Ground clearance*: the conductor must have a safe clearance from the ground and any buildings that may be located underneath it i.e., there must be no possibility of flashover from the conductors to the ground, persons or obstacles.
- *Impact of weather*: very strong winds may exert considerable mechanical loadings on the conductors and the towers; in addition, large ice loadings on conductors can impact on the towers. Of course, the worst loading is the potential combination of wind and ice. The lines are designed for such loadings.
- *Electrostatic/charging effects*: the impacts on metal structures in the proximity of the OHL are eliminated by earthing of such metallic facilities. In some countries, national regulations may apply in addition

to ICNIRP values (International Committee for Non-Ionising Radiation Protection).

- *Magnetic effects*: The current in the conductor produces a magnetic field, and the voltage produces an electric field, both must be considered during the design of the line. There are non-binding, but recommended limit values provided by ICNIRP 1998/2010. The ICNIRP recommendation must be considered taking into account of the costs and benefits and where the time of exposure is significant.

### Underground Cables (UGC)

An underground cable circuit is composed of three power cables (three phases) and normally one communication cable installed in the ground to form one electric circuit. A typical design of a power cable is shown in figure below.

If the power to be transmitted is beyond the capability of one circuit, more parallel cable circuits (or more cables per phase) must be installed. The larger the conductor the more current it can carry and the thicker the insulation the more voltage it can withstand. The cables are manufactured in highly specialized factories and they are normally delivered in drum lengths varying from 500–1000 m. In some cases, delivery cuts can be longer (2000 m and above).

Such a circuit of 10 km route length with drums of 1000 m would have 10 × 3 i.e., 30 drums in total. It would require 27 joints to join the cables together and there would be 3 terminations or sealing ends at each end (Substation, Transition Compound or Equipment installed on towers).

The cables are typically installed in one of the following arrangements:

- Directly in the ground (trench)
- In ducts installed in the ground
- In concrete troughs
- In a tunnel

- In a pipe or pipes drilled into the ground to pass under some obstacle or encumbrance
- On a cable tray attached to a bridge.

The design of an underground cable circuit depends on many factors including:

- *Conductor size*: the size of the conductor is dependent on the current to be carried and the increase of temperature (due to the current flowing through the cable) of the surroundings as allowed by regulations. Of course, the size of the conductor also has an impact on the weight and size of the cable drum being delivered – currently the maximum standard conductor size used is 2500 mm<sup>2</sup>.
- *Soil thermal conductivity*: the conductor size has an impact on the ability of the cable to dissipate the heat, which is created by the current flowing through the cable when it is delivering power. In the case of a cable installed in the ground this heat must travel through the soil surrounding the cable. Therefore the ground thermal conductivity and temperature also have an impact on the cable sizing.
- *Presence and possible impact*: of other services in the soil which may conflict with the cable route either now or in the future (e.g., other cables, heating or cooling pipes, water supply and waste water).
- *Urbanization*: if the cable is to be routed through an urban area future building or road developments may impact on the circuit.
- *Possibility of flooding*: flooding may undermine the installed cable circuit.
- *Cable pulling*: the route and drum lengths and route topography must be such that the cables can be pulled into the selected installation arrangement i.e., trench, duct, tunnel, etc.
- *Electrostatic effects*: underground cables have no electrostatic effects initiated by the cable as the electric field is contained inside the cable and shielded by the screen. Electrostatic effect may come from equipment installed above ground (terminations).
- *Magnetic effects*: the current sets up a magnetic field which must be considered during the design of the underground circuit. As for OHL, the ICNIRP recommendation must be considered taking into account of the costs and benefits and where the time of exposure is significant. It should be noted that underground cables have higher magnetic fields than overhead lines at close distance, but the fields fall off more rapidly with distance.

### Gas-Insulated Lines (GIL)

GIL are generally composed of three parallel aluminum tubes for one three phase circuit. The aluminum tubes

are in sections (typically 12–18 m long and 500 mm enclosure diameter). They are bolted together with flanges (sealed with O-rings) or welded together on site to be gas tight (automated welding process including 100% weld quality control by ultra-sonic test). Inside each enclosure pipe a smaller cylindrical aluminum conductor pipe is supported by cast resin post insulators. The GIL enclosure pipe is filled with a gas mixture of 20% sulphur hexafluoride (SF<sub>6</sub>) and 80% nitrogen at 0.8 MPa pressure to reduce the greenhouse impact from SF<sub>6</sub>.

GIL may have approximately the same transmission capacity as an overhead line and about double the capacity of a XLPE cable system, depending on actual situations. GIL systems are mostly used to EHV voltages (> 245 kV) up to 1000 kV. GIL installation is adapted to pipe line laying technologies and is carried out at local assembly and installation on site. All parts are delivered to the construction site and the laying follows a continuing process. The cost efficiency for this on-site laying process increases with the length of the transmission line to be above 1 km. For shorter length the factory orientated laying process may be more cost effective. This on-site laying process has been verified in many projects world-wide and offers a reliable and safe installation of the GIL. When the outer diameter of the enclosure is enlarged to about 750 mm also a clean air solution of GIL can be offered using Nitrogen and Oxygen only with a GWP (Global Warming Potential) of zero.

GIL are typically installed above ground, in tunnels (phases in vertical or horizontal arrangement) or in underground galleries. Direct buried installations are uncommon today, as it requires additional coatings for passive corrosion protection and cathode corrosion. Experiences with GIL worldwide is constantly increasing with ever larger project sizes (10–20 km route length), higher rated voltages (mainly 400, 500 and 1000 kV) and current ratings (3000, 4000 and 5000 A). The longest installation is the Tokai Line of Chubu Electric in Japan with two three phase systems of 275 kV and 5000 A of 3.3 km transmission route length in a tunnel.

The design of a GIL circuit depends on many special factors including:

- *Presence and possible impact:* of other services which may conflict with the GIL route either now or in the future (e.g., cables, heating or cooling pipes, water supply and waste water).
- *Route considerations:* the given bending radius can be a limiting factor for a route.
- *Urbanization:* if the line is to be routed through an urban area, future building or road development may impact on the circuit, that's why separate tunnels for electric transmission lines may be the best solution.
- *Electromagnetic effects:* GIL circuits have negligible electromagnetic effects as the electric field is earthed through the metallic enclosure. The magnetic field is mostly superposed by the induced current into the solid grounded enclosure pipe.

### Advantages and Disadvantages of Various Technologies

It is very difficult to compare the three technologies as each circuit installation is different with respect to location, importance of the circuit, reputational and financial impact if there is an outage, method of installation, operational and maintenance aspects, environmental impact, planning/licensing, etc. In view of this no general conclusions can be drawn, and each installation must be treated on a case by case basis. For the comparison of GIL and UGC see CIGRE TB 639.

In Table 10.13 we endeavor to compare the three technologies under the listed heading.

The operational and environmental aspects are considered in Sects. 10.A.1, *Operational Aspects*, *Environmental Issues* below.

Each of the above factors needs to be considered specifically for the project being investigated taking the potential installation methodologies into account, which is for UGC and GIL e.g., direct burial, ducting, horizontal directional drilling, tunnelling. Lifetime-costs may give other factors than investment costs. They

also depend strongly on the project and must be calculated case by case.

In order to rank the different possibilities, a scoring system could be developed for each of the above factors. Notwithstanding any scoring system experience and mature technology will always be important in any project as the Line owner will not wish to use unproven technology, as that would constitute a high and unacceptable risk.

### Operational Aspects

In the Table 10.14 the various technologies are compared from an operational point of view.

Each of the above factors needs to be considered specifically for the project being investigated taking the potential installation methodologies into account e.g., direct burial, ducting, horizontal directional drilling, tunnelling, etc.

Due to the very different electrical parameters of the UGC, the application of UGC introduces a series of technical challenges that must be addressed during planning, design and operation stages of the UGC system. In AC networks there normally is an offset between the current and voltage. This is due to the different components and loads in the network. The current will fill up the conductor to a certain degree, but only a part of the current can be used as *real power* because of this offset. The rest is *reactive power*. This reactive power shall be compensated to reduce the losses in the network and to control the voltage.

The exchange of reactive power between the UGC and the power system is significantly higher compared to an equivalent OHL. This reactive power must be compensated and therefore a number of additional components are introduced. This adds complexity to the system both in term of operation and maintenance.

Another complication that must be addressed is the shift in system resonance frequencies introduced by

**Table 10.13** Comparison of technologies

	UGC	OHL	GIL
Investment costs	High	Not so high	High
	There are no general rules for the comparison, as the cost of each technology will depend on how that technology deals with the specific factors that apply on each specific project		
Installation difficulty	Yes	No	Yes
Experience	Yes	Yes	Yes
Mature technology	Yes	Yes	Yes, for short lengths above ground
Competitive tendering	Yes	Yes	Yes, some cases with short length
Reliability	Yes	Yes	Yes
Repair time	High <sup>a</sup>	Low	High <sup>a</sup>
Lifetime	> 40 years	> 80 years	> 50 years
Installation time	Depending on local site conditions and requirements	Faster than UGC or GIL	Depending on local site conditions and requirements

<sup>a</sup> Highly dependent on the availability of spare parts and thus on maintenance policy

**Table 10.14** Comparison of operational issues

	UGC	OHL	GIL
Length limitation	Yes (60–100 km depending on voltage)	No	No theoretical technical limitation
Need for electric compensation	Yes, if longer than above	No	No
Extreme weather effects e.g., mechanical overloading due to ice/snow/wind	No	Possible	No
Can be re-energized if temporary fault	No, as faults that occur are not temporary Experience exist of reclosure for combined OHL-UGC lines	Yes	Yes, auto reclosure is possible
Ease of fault finding	No	Yes	Yes
Ease of fault repair	No	Yes	No
High level of expertise required for repair	Yes	No	Yes
Difficult to store repair material	No	No	No
Limited shelf life time of repair material	Yes	No	Yes
Outage time required after fault	Long	Short	Long
Haul road required for access	Yes, if installed in cross country	No	No

the application of UGC. Experience from several countries shows that amplification of background harmonics (electrical noise) occurs due to interaction between the UGC and the power system. Furthermore, the risk of temporary overvoltages is also increased for the same reasons. Both diminished power quality (due to electrical noise) and temporary overvoltages are serious challenges for which mitigation methods are expensive. A further complication is that study and design for the mentioned issues are still comparable immature and little practical experience exist worldwide. Hence, it can be difficult to quantify the risk to the system when a longer UGC is added.

The capacitive load of GIL is much lower (factor 4–5) than for solid insulated cables. Therefore, a phase angle compensation is only needed with GIL transmission length of 100–200 km length. This is depending on the network conditions and needs to be calculated. In principle the GIL can be operated like an OHL including the auto-reclosure function for short time interruption without any danger to the surrounding.

### Environmental Issues

In the Table 10.15 the various technologies are compared from an environmental impact point-of-view.

### Behavior Under Large Disturbances

The Table 10.16 compares the technologies when subject to large disturbances.

### New Technologies

OHL, UGC and GIL continue to evolve with improvements in the manufacturing and in the installation equipment and technologies.

As far as the technology aspect is concerned for OHL, the adoption of composite insulators has been widely adopted. In addition, the use of high temper-

ature conductors and real-time rating applications has become standard use.

For UGC there have been some developments in polymeric materials for insulation other than the currently used XLPE, but it is not yet clear when they will become commercially used. In addition, sensors are often embedded in UGC thus improving the use of real time monitoring and management systems.

There is little further development in the GIL technology, except maybe the routes can become longer. Insulating gases others than  $N_2/SF_6$  gas mixtures are under development for clean air ( $N_2/O_2$ ).

### Better Use of Existing Lines

One of the areas of interest is about the *better use of existing lines* i.e., the possibility to get more power through the existing lines as this might replace or postpone the need for a new development.

In the case of existing OHL it is possible to replace existing conductors with high temperature conductors or to use real time rating applications or to increase the voltage. Existing AC OHL can be converted to DC, if the design of the line allows this. A remarkable increase of transport capacity can be achieved.

In the case of both UGC and GIL the preferred method to increase the power capacity on existing lines consists in the possible use of real time rating applications and the mitigation of hot spots. For buried systems (typically for UGC) this is associated with the longer thermal transients that may allow for cables overloads.

### Conclusions

The fundamentals of UGC, OHL and GIL technologies have been outlined in Sect. 10.A.1, *Technical Basics*. It is very difficult to compare the three technologies as each installation is different with respect to location, importance of the circuit, costs, reputational and financial

**Table 10.15** Comparison of environmental issues

	UGC	OHL	GIL
Landscape and visual	Maybe, if going across open landscape and need construction access roads	Yes	Limited impact, as the construction site for GIL can be kept short (some 100 m)
Electric field effects (voltage)	No	Yes	No
Magnetic field effect (current)	Yes, limited	Yes	No, because of induced return current.
Noise effects	Yes during construction. No during operation	Yes during construction. Can be during operation at certain weather conditions (corona)	Yes during construction. No during operation
Restricted use of land	If UGC going across fields, the area over the cable may be used for ordinary crops but not for trees. No excavation or deep ploughing is allowed. Restrictions depends on local regulations	Limited to tower footing area and possible restrictions regarding trees and buildings under the conductors	If GIL going across fields restrictions similar to those for UGC are expected—dependent on installation method
Geology and soils	Possible impact during construction	Possible limited impact at tower areas	Possible impact during construction
Water resources	Possible impact during construction	Possible limited impact at tower areas	Possible impact during construction
Ecology and nature	Possible impact during construction	Possible limited impact at tower areas	Possible impact during construction
Cultural re-sources	Possible impact on archeological important areas	Possible impact on archeological important areas at tower areas	Possible impact on archeological important areas
Recreation and tourism	Limited impact	Maybe some impact depending on location	Limited impact
Air quality	Possible impact during construction	Possible impact during construction	Possible impact during construction
Traffic and noise	Possible impact during construction	Possible impact during construction	Possible impact during construction
Requirement for dumping material off site	Maybe, during construction	Limited	Maybe during construction
Acceptance by landowners	Yes	Limited acceptance	Yes
Acceptance by public	Yes	Limited acceptance	Yes

**Table 10.16** Comparison of behavior under large disturbances

Heading	UGC	OHL	GIL
Earthquake	Major damage can occur, but flexible mitigation methods can limit damage	Limited damage to structures can occur	Major damage can occur, but flexible designs important
Tsunami	Damage to exposed ends only	Major damage	Damage to exposed ends only
Storms, hurricanes, tornadoes, typhoons etc.	Minimum damage, only to exposed ends	Extensive damage to lines, if not designed for such events. Falling and blown down trees will be an issue	Minimum damage, only to exposed ends
Flood	No damage except in wash-out areas. De-energise circuit for safety reasons	Structures can be taken out in wash-out areas, but otherwise minimum damage	No damage except in wash-out areas. De-energise circuit for safety reasons
Wild fire and bush-fire	Minimum damage to cable route, damage to exposed ends. Burial depth important	Extensive damage during heavy fires	Minimum damage to cable route, damage to exposed ends. Burial depth important
Landslide	Scouring damage only. Otherwise no damage	Damage to concerned structures	Scouring damage only. Otherwise no damage

impact if there is an outage, method of installation, operational and maintenance aspects, environmental impact, planning/licensing, lifetime, etc. In view of this no general conclusions can be drawn and each installation must be treated on a case by case basis using the headings outlined in Sects. 10.A.1, *Overhead Lines (OHL)*, *Underground Cables (UGC)*, *Gas Insulated Lines (GIL)*.

In order to rank the different development possibilities a scoring system could be used for each of the headings. Notwithstanding any scoring system, some headings will always be important in any project as the Project Engineer will not wish to propose an installation that would be unacceptable to the planners or to proceed with a development that may appear too costly or where the technology is not suitable for the proposed end-use.

### Literature

CIGRE published lot of documents and Technical Brochures (TB) that can help to further understand the technologies available for power transmission. Most relevant are:

- TB 194: Construction, laying and installation techniques for extruded and SCFF cable systems
- TB 218: Gas insulated transmission lines (GIL)
- TB 250: Technical and Environmental issues regarding the integration of a new HV underground cable system in the network
- TB 351: Application of long high capacity gas-insulated lines in structures
- TB 498: Guide for application of direct real-time monitoring systems
- TB 583: Guide to the conversion of existing AC lines to DC operation
- TB 601: Guide for thermal rating calculations of overhead lines
- TB 606: Upgrading and uprating of existing cable systems
- TB 639: Factors for investment decision GIL vs cables for AC transmission
- TB 680: Implementation of long AC HV and EHV cable systems
- TB 695: Experience with the mechanical performance of non-conventional conductors
- TB 748: Environmental issues of high voltage transmission lines in urban and rural areas
- TB 756: Thermal monitoring of cable circuits and grid operator's use of dynamic rating systems
- CIGRE Green Book *Overhead Lines*
- CIGRE Green Book *Substations*.

## 10.C CIGRE Technical Brochures to be Published

The following Technical Brochures will be published by CIGRE in the near future (note that when a Technical Brochure is published, it is announced at [e-cigre.org/](http://e-cigre.org/)):

- B1.38: *After Laying Tests on AC and DC Cable Systems with New Technologies*
- B1.54: *Behavior of Cable Systems Under Large Disturbances*
- B1.56/B1.72: *Cable Ratings Verifications*
- B1.57: *Update of Service Experience of HV Underground and Submarine Cable Systems*
- B1.58: *Asset Management in MV Cable Networks*
- B1.60: *Maintenance of HV Cable Systems*
- B1.61: *Installation of HV Cable Systems*
- B1.62: *Recommendations for Testing DC Extruded Cable Systems for Power Transmission at a Rated Voltage Up to and Including 800 kV*
- B1.63: *Additional Recommendations for Mechanical Testing of Submarine Cables for Dynamic Applications*
- B1.64: *Evaluation of Losses in Armoured Three Core Power Cables*
- B1.66: *Recommendations for Testing DC Lapped Cable Systems for Power Transmission at a Rated Voltage Up to and Including 800 kV*
- B4/B1/C4.73: *Surge and Extended Overvoltage Testing of HVDC Cable Systems*
- C4/B4/38: *Network Modelling for Harmonic Studies*
- D1.54: *Basic Principles and Practical Methods to Measure, to Establish Recommendations for Measurement of AC and DC Resistance of Conductors of Power Cables and Overhead Lines*

### Pierre Argaut

Hericy, France  
[pierre.argaut@laposte.net](mailto:pierre.argaut@laposte.net)

Pierre Argaut graduated as an electrical engineer from IEG Grenoble in 1971. He has worked for Delle Alstom (Head of R&D/GIS), for the South European Pipeline (Operation Manager), and for SILEC Cable (Senior VP/R&D). As well as holding various positions within CIGRE, he has received the TC Award (2000) and Distinguished Member Award (2002) from CIGRE, and was appointed CIGRE Honorary Member in 2016.

# Substations

## 11. Substations

Terry Krieg 

This chapter presents an overview of aspects of engineering associated with high-voltage substations, providing the reader with information on the use and application of substations, a description of the various primary, secondary and auxiliary components, and the planning and design of substations through to construction and commissioning. Substations are long-lived assets, and the chapter provides information on the management of substations throughout their life cycle. Information on future trends for substations is also included. Parts of this chapter refer to sections of the Springer Substations Greenbook published in 2018 [11.1].

Substations such as the one shown in Fig. 11.1 from Australia are important parts of the overall power system that includes the generation, transmission and, finally, the distribution of energy to end consumers. Since the first power stations and networks were established across the globe in the 1800s, the sources of generation have changed, the functionality and performance demands of the system have evolved, and customer expectations for reliability have increased, but the important role of substations within the overall power system remains.

## 11.1 Overview and History

When substations were first installed, they were considered to be directly associated with a single generating *station*; hence the name *substation* was used, and the name remains to this day.

The first power generators in the 1870s and 1880s were direct current (DC) systems; transmission of electricity over long distances was therefore not feasible, and generation was generally placed within a short distance of the load. In the 1880s, the first alternating current (AC) transmission was installed, and the era of the substation began. Technical development rapidly followed.

In 1884, a single-phase 2000 V, 130 Hz AC line, 34 km long, was built for the International Exhibition of that year in Turin, Italy.

The first three-phase generator and motor is believed to have been built by Mikhail Dolivo-Dobrovolsky in Germany in 1888 [11.2].

The first three-phase AC line was installed in 1891 for the Frankfurt Electro-Technical Exhibition, a 15 kV, 175 km line between Lauffen am Neckar and Frankfurt am Main (Fig. 11.2).

This 40 Hz system is widely considered to be the world's first demonstration of long-distance three-phase AC power, finally proving superiority over Edison's DC and Tesla's two-phase AC systems. Siemens and General Electric began work on three-phase generators the same year as the Frankfurt Exhibition, and General Electric built its first hydroelectric power station in Redlands, California in 1893.

The first large-scale hydroelectric generators were installed in the United States in 1895 at Niagara Falls by Nikola Tesla and George Westinghouse [11.3], pro-

viding electricity to Buffalo, New York via transmission lines and substations built by General Electric. The development and evolution of substations has continued to this day.

### 11.1.1 Function and Purpose of a Substation

The overall function of a substation within a network is to transform voltages from one level to another and also to provide switching functions, providing a connection between the sources of energy and the ultimate consumer, at the same time providing protection and security for the grid and its components. In a power network (Fig. 11.3), substations can be considered as *nodes*, enabling connection between transmission and distribution lines and the safe connection and disconnection of lines, generators and loads to and from one another.

**Fig. 11.2** The Lauffen powerhouse and dam (Courtesy Historisches Museum, Frankfurt)

**Fig. 11.3** Generalized power system

In the modern network, substations play a key role in ensuring network stability and safety by providing sensing and switching functions to detect line faults, and then rapidly isolating these faults to maintain overall network stability, so that for any fault, the actual faulted section (usually the line) is switched out of the network, isolating the faulted section and limiting the impact on the overall grid.

With the rapid expansion of renewable energy sources within the power network, the functions of parts of the network are changing. Where previously energy was supplied from centralized power stations remote from load centers, the increase in renewable, intermittent and dispersed generation means that energy may be produced at any point and in any voltage level within a network. The direction of energy flow in any line may also be different from the top-down (large centralized generators to loads) flows for which the network was originally designed. In the future, power networks will be more dynamic, responding to active and more intelligent loads and smart devices and the changing nature of generation and customer demands.

### 11.1.2 Substation Types

The different types of substations in the power network are generally categorized as:

- Substations attached to power stations
- Interconnection substations providing switching functions
- Step-down substations
- Distribution substations
- Converter substations linking DC transmission lines with AC loads.

Each of these substation types may exist in different combinations, and any substation may perform more than one of these functions. For example, a switching station may include a distribution substation function providing local supply for auxiliaries inside the main station or to nearby customer loads. A step-down sub-

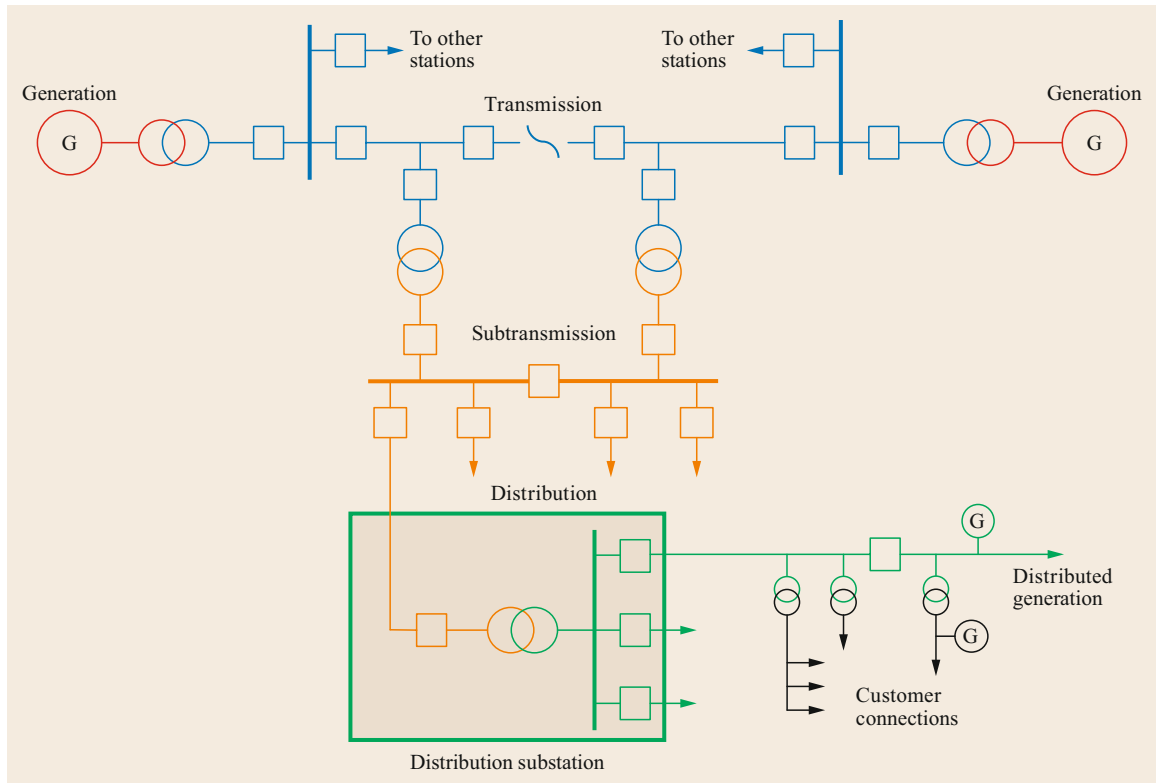

**Fig. 11.4** 1200 kV Bina National Test Substation, Madhya Pradesh, India (Photo: Krieg)

station may incorporate an interim transformation of voltage level, connecting adjacent parts of networks and lines, or the substation may connect to the distribution system providing a final link to the end consumer. However, each of these substation types has a range of common components.

### 11.1.3 Transmission or Distribution Substations

The topic of substations covers a wide range of forms, technologies and voltage levels. Much of the focus in general substation engineering and also in this chapter is on transmission substations with voltage levels typically from 60 up to 1200 kV (Fig. 11.4). Distribution substations are typically designed for the voltage range of 1–60 kV and connect to lines that feed customers directly or to transformers that convert to voltage levels used in industrial and residential premises, usually 110–600 V. A transmission substation can be described as providing interconnection between generation sources, while a distribution substation connects the consumer to the power network. Fig. 11.5 shows the different parts of a typical power network including both transmission and distribution.

**Fig. 11.5** Single-line diagram illustrating major components of the power system

**Fig. 11.6** Typical ground-level suburban 6.6 kV, 100 kV distribution substation in Nagoya, Japan (Courtesy Chubu Electric)

Typically, a distribution substation is physically smaller than a transmission substation (an example is shown in Fig. 11.6), although comprising many of the same basic primary and secondary components.

Distribution substations may also be constructed using pole-mounted equipment such as the example in Fig. 11.7 from Japan.

**Fig. 11.7** Pole-mounted 6.6 kV substation in Nagoya, Japan, comprising switches, surge arresters, and 50 kVA and 75 kVA transformers (Courtesy Chubu Electric)

### 11.1.4 Substation Components

The components of a transmission or a distribution substation include primary equipment such as circuit breakers and switches, busbars, conductors and connections, transformers and measuring devices with associated secondary protection, control, metering, monitoring and

auxiliary systems. All of these components must work together in a safe and effective way to meet the objectives of asset owners and the needs of the overall grid. An important aspect of the substation is the civil engineering associated with its design, the impact of the substation on the environment and local community, and the impact of the environment on the substation itself.

## 11.2 Planning

Substations are important parts of the overall power network and a significant investment for network owners and operators. The need for new or modified substations is usually identified as part of the long-term planning of the power grid. The substation needs to meet the present needs of the grid and, as far as can be determined, the future requirements of the grid, providing sufficient allowance for future expansion.

### 11.2.1 Network Planning

Power networks are designed to transport energy from the sources of generation to loads. The aim is to achieve this transfer of energy safely and efficiently, minimizing losses and with the design of the network providing adequate consideration of redundancy in the event of failures. The power network (a small network model is shown as an example in Fig. 11.8) comprises power stations, substations, transmission and distribution lines, and cables. Substations typically consist of transformers and reactors, capacitors, switching devices, and associated control and protection equipment.

Networks are inherently interconnected on a regional, state, national or international basis. Long-distance transmission allows for generation that may include renewable intermittent sources such as wind and

solar, enabling connection to load centers that might be some distance from the generator.

Historically, long-distance transmission was achieved using three-phase AC systems (50 or 60 Hz), but with the development of power electronics, high-voltage DC (HVDC) lines and networks are increasingly part of the transmission system, enabling asynchronous interconnection and large energy transfer between different parts of the transmission system.

Network planning is required to ensure that networks are able to provide a reliable energy supply to meet all customer load requirements, and planning therefore includes a number of interrelated functions:

- Generation planning, which includes load and capacity forecasting and capacity resource planning
- Transmission planning to ensure that supply loads can be achieved from the most economical sources of generation, allowing flexible operation of generation and overall system reliability and stability
- Distribution system planning including load forecasting, achieving reliability for customer loads and the required connection capacity.

Network (or system) planning is a coordinated process that uses historical data to predict and plan for fu-

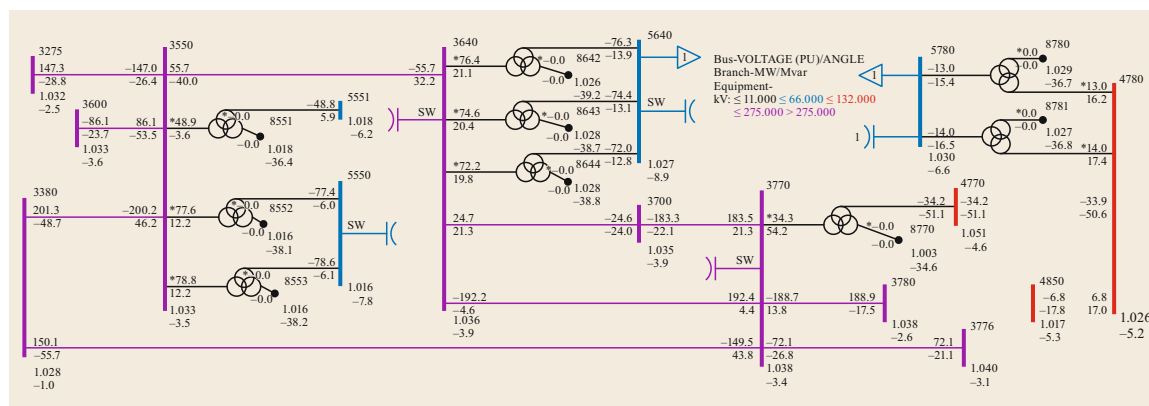

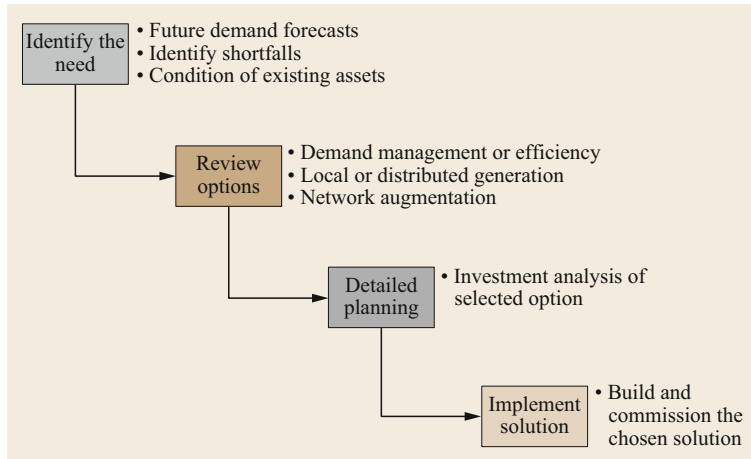

Fig. 11.8 Example of a small network model showing load flows

**Fig. 11.9** Typical transmission utility planning steps

ture requirements. Network planners face considerable challenges in the planning and development of modern power networks due to rapid load growth and changing demand characteristics, changes in the economic and regulatory environments in many countries, climate change, the availability of new technologies and changing customer expectations.

The common stages in network planning for a typical transmission utility are shown in Fig. 11.9.

Substation planning cannot be done in isolation from the requirements of the grid; it is essentially a derivative and an outcome of the overall network planning functions. System studies are carried out regularly by network planners to ensure that the network is capable of satisfactorily fulfilling the above functions, and these studies will indicate when the network needs to be augmented and whether this augmentation requires the construction of a new substation, a capacity increase or the extension of existing ones. Planning may also indicate that a substation needs to be adapted to meet changing requirements, downgraded or bypassed, and this may also be a driver for substation modification such as removing feeders or line exits, reducing site size or decommissioning of a substation. Once the need for a new substation, capacity increase, or modification or extension of an existing substation has been established and the range of requirements and key attributes are determined, then the more detailed planning of the substation can commence.

Typical broad requirements for substation planning may include:

- General physical location within the network
- Required maximum capacity (the loading) for both the present and future
- The fault clearance time required to maintain network stability

- Fault current levels at the proposed point of connection
- The type and characteristics of the earthing system to be employed to suit the proposed section of the network
- Number and type of lines or cables to be connected
- Primary circuit availability, redundancy and security requirements that will affect the choice of substation bus configuration
- General control and protection requirements such as the method of control and the degree of automation, whether manned or unmanned, and the degree of secondary system redundancy required
- Type and availability of communications
- General requirements such as the type of site (urban or rural), local requirements such as aesthetics and environmental controls required
- Design life required (50 years is typical, but shorter design times are also feasible for specific applications).

Some of these factors will be governed by overall network planning criteria, local standards and regulatory requirements; in other cases, consideration of all factors will be required.

### 11.2.2 Site Selection

One of the first decisions in the detailed planning of a new substation will be the physical site location. Broadly speaking, the location will be influenced by the planning carried out at the network level and the presence or absence of existing generation, transmission or distribution infrastructure. A switching station, for example, may be built at a site where multiple lines intersect. A generator substation will obviously be located near or adjacent to the actual generator, although

there may be situations where a site is chosen so that the substation is located away from sources of pollution such as dust or sea spray that might be adjacent to a power station and detrimental to future substation performance.

Site selection is important and needs to balance future risks and substation objectives to determine a suitable site location in the required general area defined in planning.

The substation site should be in a *protected* location to minimize hazards and risks, and should be capable of providing a stable surface for the construction of a substation to meet the requirements detailed below, including during and after the specified disaster incidents.

The location of the substation site should not expose the future substation or workers to hazards (worker safety). In particular, the following locations should be avoided:

- Sites located close to the outside of a bend in a road—risk of vehicle impact
- Sites located close to the ocean, forests, agricultural fields or heavy industries, where there may be a risk of salt spray, fire or windblown debris and contamination from pollutants
- Sites located close to hazardous industries such as petrol service stations or chemical plants, due to the risk of explosion, fire and contamination from pollutants.

In addition to worker safety needs, the chosen site should not expose the substation infrastructure to high levels of risk during service life. The following locations should be avoided in order to minimize risk:

- Sites located close to waterways, dams or wells—risk of pollution of drinking water sources from the substation in the event of a spill
- Sites located in close proximity to underground services and to residential and commercial buildings—risk of transferred potential electrocuting humans or animals
- Sites located close to schools, parks or playgrounds—sensitive areas, risk to children and from vandalism and unauthorized entry
- Sites close to heavily populated areas—prudent avoidance of electromagnetic field (EMF) exposure or noise complaints
- Sites located downwind of any heavy industry with airborne pollution that could be hazardous to personnel and potentially impact on the design life of the substation

Some of the other factors that may be considered in choosing a suitable site include the following:

- *Sufficient area for present and future needs*  
The substation site should be of sufficient size to accommodate the complete substation, including the substation itself, access routes for high-voltage and medium-voltage feeders, access routes for various services, and areas for driveway access, vehicle parking and landscaping, including a suitable buffer zone on the sides and rear of the substation.
- *Avoidance of adverse environmental conditions*  
The performance of the substation should not be unfavorably affected by the substation site condition during adverse environmental conditions (including defined disasters) specified for the substation. This includes secondary effects such as soil erosion and scouring during severe ice, snow, rain and flooding, and increased earth resistance during droughts. In addition, the site should not be located such that the substation may have an adverse impact on sensitive environmental zones.
- *Adequate access during construction and future operations and maintenance*  
Site access should enable access by staff, equipment and vehicles required for construction, operations and maintenance and plant replacement during substation design life. This access requirement should cover all aspects of the substation's operation, including for personnel and light and heavy vehicles. The access should be available in all weather conditions. Access roads, feeder routes and services access through private property must be covered by a suitable registered easement.
- *Allowance for vehicular traffic*  
The selected site should avoid potential adverse effects from road traffic. It should not be located on the outside bend of a heavily trafficked or high-speed road. The site should have at least one suitable vehicle access point from a public road. This access point should provide safe vehicle exit and entry to the public road. Access points on blind curves, close to the crest of hills and other locations with restricted vision or acceleration areas should be avoided. The access point should be suitable for development as a roadway for vehicles, including low loaders and cranes (to enable heavy plant such as power transformers to be transported to and from the substation). Relevant local government or road authority approval should be obtained for access if necessary.
- *Provision for vehicles*  
The site should be provided with adequate parking for maintenance vehicles immediately adjacent to

the substation building and outside the substation security enclosure. Sites with limited load-bearing capacity soils should be fitted with concrete pads for crane-stabilizing legs adjacent to the two power transformer locations.

- **Landscaping**  
The substation construction program should include landscaping the site. This should be arranged in agreement with the local authorities and may involve community consultation. Landscaping should incorporate aesthetic and security aspects. In some cases, land may be set aside for planting of flora or positioning of an architecturally designed substation building to limit the view and noise of outdoor high-voltage (HV) plant. On completion of the substation, the design and finish of the site should meet local council and community expectations with respect to aesthetics.
- **Avoidance of the risk of flooding**  
A typical requirement is that the substation site be located at least 300 mm above the *100-year* flood line and above the local tidal surge and tsunamis levels.
- **Avoidance of nearby cliffs**  
The site should be located away from cliffs and steep rocky slopes so that the risk of damage from slides, avalanche and, potentially, vandalism are reduced to an acceptable level.
- **Rock layers**  
Any site rock layers should be assessed to allow for the installation of standard foundations, stormwater drains, earthing, cables and other underground substation components.
- **Site security**  
consideration of nearby residential or industrial zone to reduce the risk of vandalism or unwanted intrusion.

In practice, no potential site is perfect, and a compromise is often required in the choice of the ideal location for a new substation.

### 11.2.3 Primary Equipment Layout

Many design decisions for substations are influenced or dictated by local standards, historical design approaches and past local practices [11.4]. There is good reason for conservatism in the design of layouts as operations and maintenance staff and designers become familiar with particular types of substation configurations. Any change to an alternative arrangement needs to be considered carefully, including consideration of the impact on operations and maintenance staff and contractors.

The basic objective of the primary plant layout is to facilitate the operational requirements of the substation within the overall electrical network. The key switching functions within the substation are carried out using circuit breakers, and in the past the types of technology used meant that frequent routine, preventive and corrective maintenance was required. Oil-filled breakers, air-blast breakers and the different types of operating mechanisms required regular and sometimes frequent maintenance. This maintenance requirement remains a key element of substation layout design.

Disconnectors were required to facilitate the safe performance of maintenance activities, allowing circuit breakers to be isolated from the network for maintenance. This requirement for disconnectors has had a strong influence on the design of historical substation layouts and many standard layouts include a proliferation of unnecessary disconnectors. Circuit breaker design has evolved so that maintenance requirements are significantly less than that required historically, but the *standard layout* adopted has remained unchanged in many utilities. In many utilities, disconnector maintenance is now the dominant driver of substation maintenance programs.

Substations are nodes or hubs for interconnections between regions, countries, etc., in the network, and also transform power between networks of different voltages and at infeed (generation) and load points of the network. The network characteristics together with a particular substation type lead to consideration of a range of different primary equipment layouts.

Primary equipment layouts are also called circuit arrangements, switching arrangements, circuit configurations or busbar schemes, busbar switching arrangements or busbar configurations, among others. The substation single-line diagram (SLD) provides an overview of the substation circuit arrangement and generally shows all switching and non-switching high-voltage equipment. It is the basic document required to begin the design of the remainder of a high-voltage substation.

The primary equipment layout defines the relative arrangement of required busbars and busbar sections, circuit breakers, disconnector/earthing switches, power transformers, instrument transformers and surge arresters. The choices made at this early stage of the design process have a major influence on the final operability, maintainability, flexibility of switching arrangements and other factors related to the primary functions of the substation. The equipment layout influences the design of the secondary and auxiliary systems for control and protection, and ultimately the reliability and availability and the whole-of-life cost of managing the substation.

The main broad requirements to be considered when choosing a primary equipment layout are as follows:

- **Security and redundancy**  
The capability of a power system at a given moment in time to perform its supply function in the case of a fault [11.5]
- **Maintainability**  
The ability of an item under given conditions of use to be retained in, or restored to, a state in which it can perform a required function when maintenance is performed under given conditions and using stated procedures and resources [11.6]
- **Flexibility**  
The ability for the substation to be reconfigured to meet operational requirements during credible contingency events.

Choosing an optimal layout for a particular substation situation requires consideration and comparative analysis of a range of factors specific to the application of the circuit breaker, its function within the network and local standards, and there are various multi-criteria analysis methods available to compare different options for a particular project. CIGRE Technical Brochure 585 [11.4] provides a simple method for comparing different layout options based on overall design requirements and preferences.

Apart from those mentioned previously, some additional considerations that might affect the final choice of layout for a particular substation may include:

- Extendibility of the layout for future needs
- Consideration of credible contingency events
- Existing operational familiarity with a particular layout used historically
- Physical arrangement, direction and location of incoming or outgoing lines or feeders
- The number of busbars and busbar sections required
- Physical location of busbars to avoid a single fault affecting two or more busbar sections
- Maintenance capability and equipment
- Environmental and aesthetic requirements.

Options for the layout of the substation can be analyzed and various factors considered depending on the application and location in the network of the substation. For example, substations designed for direct power station connection may have different layouts and arrangements because of the different emphasis (and analysis weightings) on the key criteria of security and redundancy, maintainability and operational flexibility when compared with

other substation applications such as in switching stations or step-down applications. CIGRE TB 585 [11.4] provides a method for conducting this analysis.

#### 11.2.4 Service Security, Redundancy and Reliability

One of the key drivers in the design of the primary substation layout is the requirement for network security and redundancy, and some explanation is given here. For the substation to achieve its functional objectives, it must be capable of effective operation following different credible contingency events, such as failure of a single or multiple network or substation components. This concept of substation design is referred to as service security and redundancy. Service security is defined as the analysis of the substation's configuration in terms of availability of supply to the network after internal (busbar side of circuit breaker) and external faults (line side of circuit breaker), assuming otherwise normal system configuration.

The service security or redundancy is commonly characterized by the terminology  $N-1$  criteria and  $N-2$  criteria (some jurisdictions use the terminology  $N+1$  and  $N+2$ ), defined as:

- $N-1$  security means that the security of supply to all connected customers is maintained in the event of failure of a single primary network element or associated secondary system.
- $N-2$  security means that the security of supply to all connected customers is maintained in the event of the failure of two primary network elements or associated secondary systems in the same event.

While these terms ultimately apply to overall network security, they can also be applied to the consideration of options and the arrangements of components within the substation.

Another key aspect of substation design is its inherent reliability. The functions of the substation are defined by the circuit arrangement comprising the various components including circuit breakers, disconnectors, busbars, transformers, and related control and protection systems. The failure rate and the typical repair rate of individual devices or the *mean time between failure* (MTBF) can be summated mathematically to determine an expected outage time per year for the overall substation by considering the interrelationships of the individual components in the substation. This enables a statistical approach and probabilistic calculations of overall substation reliability for comparison of various primary substation layouts.

Reliability analysis studies of the proposed substation layout can be undertaken using *failure mode and effects analysis* (FMEA) techniques.

Various references [11.7] are available to provide expected failure rates of different circuit arrangements and voltage levels. These values can be used to mathematically analyze the overall substation design reliability, including consideration of the reliability of modern high-voltage devices and switchgear components. In addition, maintenance strategies and philosophies should be taken into account, as these practices will influence the MTBF value of components and the reliability of the final substation design.

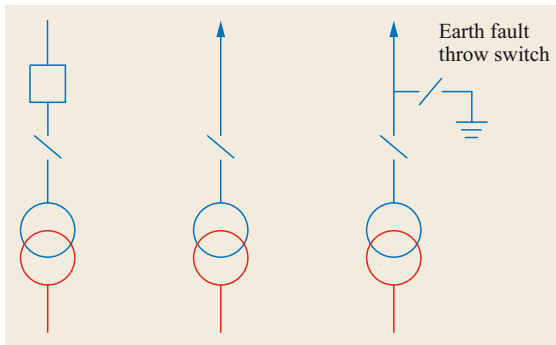

Fig. 11.10 Typical *no-busbar* substation layouts

### 11.2.5 Typical Substation Layouts

Utilities and regions often use a range of different primary layouts, and these layouts are often adopted as standard practice within that utility or region. Some of the more common layout options are listed in the following sections.

#### No Busbar

The most basic substation layout includes no high-voltage busbar at all. This type of layout may be considered for remote or end-of-line substations feeding a single consumer such as a mine site. If no circuit breaker is fitted, then high-speed communications may be required to trip the remote circuit breaker at the feeder substation in the event of a substation or transformer fault. Alternatively, an earth fault throwing switch may be used to deliberately apply a single-phase earth fault to the incoming line in the event of a transformer or other substation fault that requires the remote end to be tripped.

A *no-busbar* layout (Fig. 11.10) may be used as an interim substation development step, with a bus to be added at a later date as load grows or the security of supply becomes more important. In that case, space should be allocated in the yard layout to allow future expansion to add a circuit breaker or a single bus. This is an impor-

Fig. 11.11a–c Single-busbar variations. (a) No bus section, (b) bus section disconnector, (c) with bus section circuit breaker

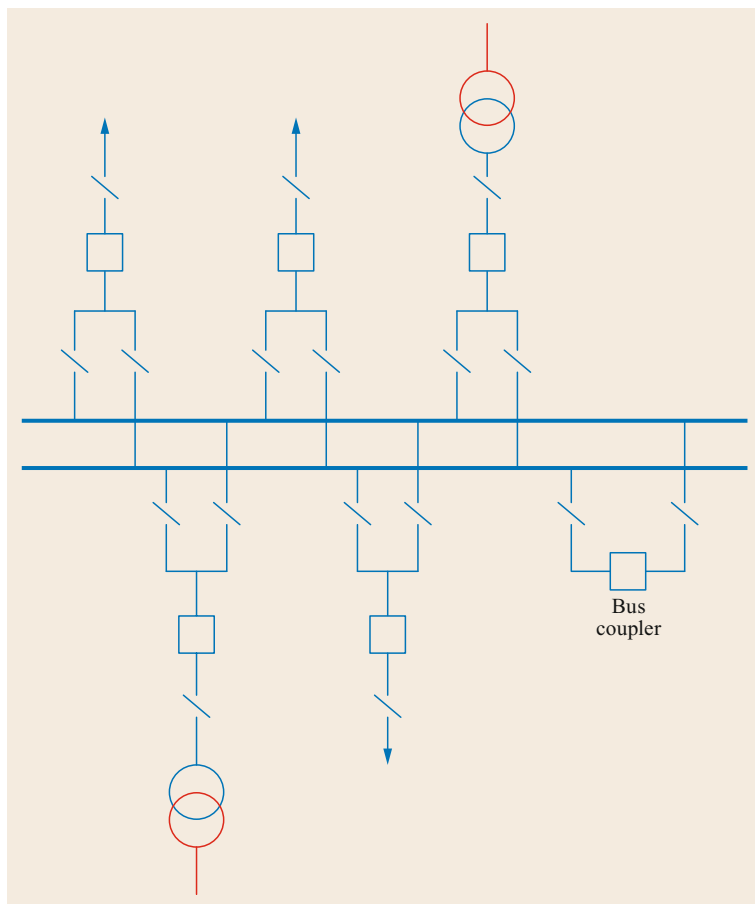

Fig. 11.12 Double-busbar layout

tant consideration to allow a low-cost initial design with allowance for future needs. It may be extremely difficult to add additional components if insufficient space is allocated at the initial design and layout stage.

### Single Busbar

Apart from the direct connection of the transformer to a line as described in the preceding section, the single-busbar layout is perhaps the simplest of substation layouts that can be selected. This is also called an *H-configuration*. There are a range of possible variations (some examples are shown in Fig. 11.11) depending on the level of security and flexibility that is required and the number of incoming and outgoing feeders or lines.

The single-busbar layout is generally the lowest-cost and easiest design option, providing a simple layout for operations. However, a fault on the busbar will generally cause loss of the entire substation unless a section circuit breaker is fitted. Maintenance of busbar disconnectors will typically require a complete substation outage (Fig. 11.11a,b). Using a single, sec-

tionized bus (Fig. 11.11c) offers benefits in terms of security and flexibility, enabling load to be transferred from one transformer to the other for maintenance.

### Double Busbar

In the double-busbar arrangement, lines and transformers may be connected to one of two busbars. This arrangement is often used in higher-security applications in well-interconnected networks, allowing for additional switching flexibility. The coupler circuit breaker provides the ability to join (or split) the two busbars, enabling a faulted line or a component being maintained to be isolated from the network. Circuits (lines or transformers) can be switched to either bus without interruption of supply.

In the double-busbar arrangement (Fig. 11.12), if the bus coupler is not closed, a single bus fault will most likely cause loss of the connected feeders but not the entire substation as in the single-bus layout. Feeders can be quickly switched to the healthy bus to restore the connection.

**Fig. 11.13** Double-busbar layout with transfer bus

A variant of the double-busbar arrangement provides a *third transfer bus* to enable circuits to be temporarily connected to a bus so that circuits can remain in service during maintenance or repair of the line circuit breaker (Fig. 11.13).

#### Triple Busbar

In a triple-busbar layout (Fig. 11.14), the connected lines and transformers can be switched to one or more of three busbars using disconnectors. This is used in some situations where reliability, security and flexibility are very important.

#### Breaker-and-a-Half

A *breaker-and-a-half* layout (or 1.5 breakers) is based on a double-busbar layout but is arranged so that two circuits (lines, transformer connections or generation source) share three circuit breakers (Fig. 11.15). This means that three circuit breakers connected between the two busbars (called a *diameter*) connect to two circuits

(line, transformer, generator). This provides a very flexible substation layout that is often used where there are a number of incoming lines and where the network requires a high degree of interconnectivity. This layout allows a single circuit breaker to be isolated for maintenance without affecting customer loads or transmission lines.

The normal state for this layout is for all circuit breakers and disconnectors to be closed at all times. The connection of various lines and transformers often depends on the physical layout of the site and the spatial position of the incoming lines in relation to the substation site.

The advantage of this layout is that a busbar fault in the substation will have only limited impact on reliability and may not cause loss of connection of any lines or transformers. A single line fault trips two circuit breakers in the diameter, but the other circuit remains connected via the remaining circuit breaker. If only two diameters are initially installed, the layout is similar to

Fig. 11.14 Triple-busbar layout

the ring layout (see later section). If the initial development is only a small number of lines, the substation may be laid out geographically to suit a *breaker-and-a-half*, with some circuit breakers missing from the layout, to be added at a later date as new circuits are added in future years.

One of the disadvantages of the breaker-and-a-half layout cited by some designers is the added secondary circuit and protection complexity. Also, there are some protection considerations required to address possible protection *dead zones* within parts of the primary layout due to the relative position of current transformers (CT) and overlapping of CT summation zones.

#### Two-Circuit-Breaker Layout

Using two circuit breakers per circuit between busbars offers additional flexibility but with the disadvantage that additional primary components are required, adding to substation cost (Fig. 11.16).

#### Ring and Mesh Layouts

A Ring or mesh bus substation layout is a single-busbar station with a closed loop formed by each connected circuit breaker (Fig. 11.17). Circuits (lines or transformers) are connected between any two circuit breakers. The number of circuit breakers fitted equals the number of circuits (lines or transformers), and all circuit break-

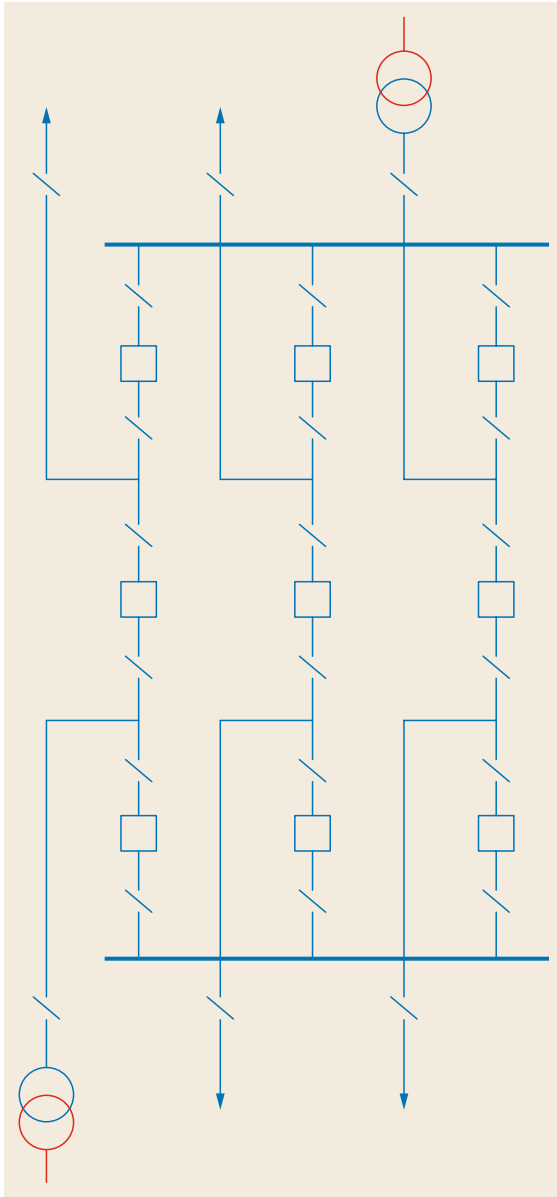

ers must be rated for the combined load current of each circuit with allowance for busbar current.

The ring or mesh bus layout may be used as a first step in the development of a breaker-and-a-half substation, and this may dictate the physical layout of the primary plant.

The preceding section does not cover all possible layout options for any particular project. There are many combinations of the basic and most common layouts that are represented here. The choice of layout for a new substation depends on the preferences of the utility and local standards and also the degree of weighting that the utility owner places on the criteria of security, redundancy, maintainability and flexibility for the substation application. The choice of layout will also be influenced by budget and future plans for the substation project.

#### Choosing the Right Substation Layout

Choosing the *right* substation layout for a new project is not a precise science. In some cases, the layout will be preselected based on regional standards or regulatory requirements. Where the layout is not predetermined, various methods of multi-criteria analysis can be used to compare the relative advantages and disadvantages of each proposed layout. The final decision will be based on the intended application of the substation (i.e., generator substation, interconnection, step-down, etc.), the

**Fig. 11.15** Three-diameter, breaker-and-a-half layout

cost involved and an acceptable balance of the criteria of security, redundancy, maintainability and flexibility as discussed in the previous section. CIGRE Technical Brochure 585 [11.4] provides a simple way to compare different layout options [11.8].

### 11.2.6 Primary Design Layout

Using the chosen busbar configuration, the chosen equipment and technology types and the construction

**Fig. 11.16** Two-circuit-breaker layout

method enables the designer to prepare the substation primary layout drawings, the primary design of the substation. Fig. 11.18 shows the typical layout of a 1.5-breaker (breaker-and-a-half) substation (one diameter shown). Fig. 11.19 shows a breaker-and-a-half layout under construction at Port Augusta, South Australia. Layouts can be difficult to identify from ground level.

### 11.2.7 Technology Types

Another important decision made at the planning or concept design phase of a substation project is the type or technology of primary equipment that will be used. The types can be broadly classified as either:

- *Air-insulated switchgear (AIS)*  
AIS is defined as switchgear and other high-voltage equipment where the insulation to earth and between phase conductors is provided mainly by air at atmospheric pressure and where some live parts are not enclosed.
- *Gas-insulated switchgear (GIS)*  
GIS comprises metal-enclosed switchgear and other high-voltage equipment where the insulation is obtained, at least partly, by an insulating gas other than air at atmospheric pressure. This gas is usually SF<sub>6</sub>

**Fig. 11.17a,b**  
Ring bus layouts considering later development into either a two-CB (a) or breaker-and-a-half CB layout (b). Future components shown as dotted lines

or an SF<sub>6</sub> mixture with other gases such as nitrogen, although a range of other alternative gas types are being considered [11.9]. IEC 62271-203 [11.10] provides requirements for substation design using GIS.

- **Mixed-technology switchgear (MTS)**  
MTS equipment has been developed from AIS or GIS into one of the combinations of AIS in compact and/or combined design GIS in combined design. Mixed technology may sometimes be referred to as hybrid-insulated switchgear (HIS), where bays are made from a mix of AIS and GIS technology components.

Choosing the type of technology for the primary equipment to achieve the configuration required in a substa-

tion project requires consideration of a range of factors. Some of these factors are related to the choice of site, the characteristics and size of the site, and the project economic factors.

AIS has the significant advantage that the equipment is generally initially the cheapest to purchase. However, its disadvantages include the requirement for more site space than other technologies to allow for the electrical clearances required in air. In addition, the primary equipment is exposed to the environment and subjected to animals and pollution. Where space is available and land cost is not prohibitively high, AIS will be the most suitable first solution for an extra-high-voltage (EHV) substation. AIS also has the advantage that it is relatively easy to extend and modify as the needs of the substation develop with time.

**Fig. 11.18a–c** Single diameter of a 1.5-breaker substation layout shown as (a) single line diagram (SLD), (b) plan view, (c) elevation

**Fig. 11.19** The author inspecting a 275 kV transmission substation extension (1.5-breaker layout) under construction, Port Augusta, South Australia (Courtesy Peter Burnell)

GIS equipment is usually initially more expensive to purchase than equivalent AIS substations but may have a lower overall whole-of-life cost if all

factors, including land cost, are considered. The substation will take up much less space than a comparable AIS substation with the same functionality. In locations where the cost of land is high, it may be necessary and advantageous to build using GIS technology that can be safely incorporated into an urban building design or even underground, avoiding large urban space requirements, pollution and other risks. GIS may also be advantageous from a safety perspective, with fewer exposed high-voltage components.

MTS (or HIS) shares some of the advantages of the compactness of GIS but with some AIS components, combining multiple functions and technologies. This design can enable a solution that is small in size while still generally cheaper than GIS, with some compromises. MTS can be used where the land costs are moderate and pollution is not a major issue, providing a compact and cost-effective solution. MTS can be used for new substations or the extension of existing AIS substations where space is limited, avoiding the need to procure more land.

CIGRE Brochure 390 [11.11] more fully describes the evaluation of different technology types and how these various factors can be compared.

### 11.2.8 Specifications and Contracting

There are many ways that a new substation may be acquired by the utility or asset owner. In some cases, in-house design and construction capability can be used, but often the design and construction, or the construction only is outsourced to another organization. In both the in-house and outsourcing situations, there is a need to specify the requirements for the new substation beyond the layout and technology type discussed above. This preparation of specifications, together with the required commercial terms and conditions, is used to procure the substation or to specify for internal design.

Specifications can be prescriptive (conventional), or they can define only the key functional requirements (functional). A function specification procurement method can be useful as a strategic approach to assist in the introduction of new technology and designs, but each specification style has both advantages and disadvantages.

#### Conventional Specifications

Using the conventional, generally more prescriptive approach to substation specification usually requires that all of the relevant information related to the site and the incoming circuits be predetermined and provided for the design and construction tender process. This information will most often include the following:

- *Site location details*  
The precise location and site constraints, usually in the form of a drawing or GPS (Global Positioning System) location.
- *Electrical and connection information*  
This includes the characteristics (voltage, current ratings), number and type (underground or overhead) of circuits to be connected to the substation. In the case of cable connection, this information may include the size and type of cables to be connected.
- *System parameters*  
This includes the nominal, highest and lowest system voltages together with the required basic impulse level (BIL) and switching impulse level (SIL). An important system characteristic is the short circuit level at that network location and the type of neutral earthing required.
- *Power transformers*  
including the open circuit voltage ratio, rating, cooling method, vector group (including tertiary if required), impedance, tap changer (on load, off load,

off circuit), tapping range and steps, noise level requirements termination details and capitalized value for losses.

- *Auxiliary supplies*  
Including the voltage and rating required for the low-voltage AC (LVAC) auxiliary supply and, importantly, the survival time and voltage level for DC batteries and any redundancy and segregation requirements.
- *Substation environmental conditions*  
This is to allow the designer to select appropriate equipment, design appropriate fittings, supports and buildings, and ensure adequate rating and plant performance.
- *Civil design constraints*  
This may include soil characteristics such as minimum ground-bearing pressure for footing design, and the earth resistivity and thermal resistivity of the soil for the earthing and electrical design, together with any site investigation reports and borehole results. The finished levels at the site and whether they are level, sloping or terraced may be included. The existence of contamination and any requirement for post-construction treatments may be included. The fencing and security requirements to be applied, together with necessary interface points with roads, water supplies and drainage. The detailed requirements for any buildings on the site including the dimensions of the rooms, heating, ventilating and air conditioning requirements as well as the finishing requirements. The locations of any known buried services existing within the site boundaries.
- *Secondary system requirements*  
This may include the details of the control center system to which the substation will interface, including the manufacturer and the protocol and software that will be used. In addition, the level of automation and control, both local and remote indications, and other control requirements.
- *Protection requirements*  
Including the requirements for each circuit, especially the required fault clearance time. Required redundancy and the protection philosophies to be applied for each circuit together with breaker failure and other requirements. Requirements for local test and other requirements to meet local maintenance requirements. Integration with remote end protection systems will need to be specified.
- *Communications requirements*  
Including the method communication available or to be supplied. This may be power line carrier (PLC), microwave radio, telephone line, pilot cable or optical fiber, or a combination. Communications will include a mix of voice, telephony, data and me-

tering, protection signaling and intertripping, and may include a mix of digital and analog signals to be communicated. The speed, redundancy and security of communications will usually be specified.

- **Standards and regulations**  
These may include local standards or other national or international standards and regulations applicable to the asset owner or to the site.
- **Health, safety and environmental requirements**  
This may include a range of local utility requirements. Environmental requirements may be local or regional regulations or standards including noise, EMF or EMC (electromagnetic compatibility) requirements, oil discharge limitations for the site, aesthetic requirements, and archaeological or other site constraints and considerations [11.12].
- **Other design requirements**  
These may include design life and the method for evaluating the design such as whole-of-life costing minimization and *safety in design* requirements.

Conventional prescriptive specifications are generally considered to have a lower level of commercial risk for the contractor and the owner.

### Functional Specifications

Increasingly, asset owners are finding that a conventional approach to specification delivers conventional outcomes, and many utilities have introduced a form of functional specifications that are aimed at defining the key outcomes required from the substation, without specifying the detail of *how* these outcomes might be achieved by a designer or builder. This type of specification is more appropriate when both design and construction are to be outsourced. Often, the aim for utilities who use this approach is to introduce new approaches to the design and introduce innovation that would not be possible using a conventional specification approach.

The principle of a functional specification is to specify the broad requirements (the *what* that is required, rather than the detail) and the objectives of the substation without specifying *how* this is to be achieved, leaving that to the designer. In some cases, this approach can be coupled with a contracting arrangement between the owner and outsource organization that provides a way to share the benefits (and penalties) if the overall objectives of the project can be achieved.

Functional specifications come with some commercial risk for both parties, and the associated terms and conditions are therefore important and must be aligned with the business requirements of both parties.

One approach for the specification of substations used in Australia and detailed in reference [11.13] involved articulating and documenting:

- The *design philosophy* for the new substation  
This is a relatively short document that establishes the key policies and philosophies that the design must adhere to.
- The *functional specifications* of the substation  
Including the key limitations and performance requirements. Present and future requirements should also be specified.
- The *concept design* detailing key design elements as a guide or template for the detailed full substation design documentation.

Using this three-stage approach, the asset owner can have more confidence that the new substation will meet present and future requirements, aligned with broader corporate objectives, without preparing detailed specification that might contain errors and inconsistencies.

### Standardization

One of the criticisms that manufacturers and suppliers have leveled against utilities is that they are often resistant to change and that the prescriptive procurement specification processes traditionally used by utilities limit the ability for suppliers to present new approaches and introduce new technology. The reader may wish to read [11.13] for more discussion on this issue.

On the utility side, there is good reason to be conservative in new projects and to avoid making substantial design changes that might ultimately cause reliability issues or add to whole-life costs in future years, long after the builder has completed the project and moved on. One fundamental factor is the capability of existing operations and maintenance staff and their ability to adapt to a change in design of controls, layouts or equipment. It is vital that any designer include a consideration of operations and maintenance staff capability and their opinions and preferences in designing new substations. There are safety and reliability as well as industrial risks in ignoring the corporate knowledge and capability of staff and operating equipment that will be required to operate and maintain the station. There are also considerations of the type and mix of spares kept, so there is often good reason to restrict the level and number of changes to primary equipment.

Utility standards often incorporate national and regional legislation and regulations regarding health and safety, environment and security, and can also extend to incorporating common standards to assist in reducing construction errors, outage time and cost, improving safety, ensuring knowledge sharing and simplify operating and maintenance procedures.

Utilities normally select standardized substation configurations using prescribed equipment for each substation layout together with the agreed method of

protection and control for each arrangement. High-value substation components, substation cables and other material may be predetermined according to corresponding procurement contracts in place.

However, for corporate strategic reasons, many utilities have an interest in exploring new technologies, not just repeating the same designs. Using the functional specification approach described in the previous section is one way to achieve this, but there are other ways to identify and incorporate innovation in new substation design.

The regulatory and commercial environment for many utilities means that there is often a need to reduce cost of delivery of new infrastructure, and rapid load growth may also mean that new infrastructure needs to be delivered more quickly than traditional processes have been required to deliver.

The utility needs to preserve the important aspects of past practices in relation to maintainability and operability, and to do this at lower cost and faster delivery times. There is often a corresponding strategic objective to not *lock out* new ideas and new approaches that might be available in the future and that align with the utility aims and objectives. One strategy that some companies have used to introduce innovation is to change from conventional, prescriptive approaches to substation specification by using a functional specification approach. That step change process can allow suppliers the freedom to introduce new technological approaches to an otherwise conservative organization. The processes associated with that change can be significant, involving change management among managers, designers, operations and maintenance staff. This process of change requires the utility to ask internally, *what is it that we really need to meet our corporate objectives*. The answer to that question is often much less than previously defined in prescriptive specifications and existing design standards.

Another approach that can be taken to address the need for faster delivery and lower costs is for the utility to determine a set of *standard designs* that can be adopted for future substations. These standard designs can be prepared as a concept design that articulates as much of the design of the future substation as is feasible, without the final step of a detailed design. The adoption of a standard design involves deciding upon the key elements that will be standardized for the future designs. These key elements may include limiting the range of transformer sizes, limiting the switchgear fault levels or technology types to be considered, and even developing standard primary and secondary drawings that can be tailored once the actual site and the specific design parameters for a specific project have been determined. In this way, significant savings can be achieved

in the development of the design for a new substation. The approach is compatible with a traditional design approach, and often previous design drawings may be adapted by a designer for a new substation design project. This process of adopting a *standard design* for use in future substations can have significant benefits, and from a utility standards perspective allows the important aspects of design to be standardized, predetermined and aligned with operations and maintenance needs, and spares and procurement requirements, with reduced project design time.

There is another major advantage to the adoption of standard designs to standardize the design approach, and that relates to staff knowledge and experience. Traditionally, a utility or organization's substation standards were developed over a longer time period and were intended to document key corporate requirements based on experience and knowledge with key design requirements, but with the need to capture every future application requirement. This type of standard development requires considerable expertise and usually long-term experience in order to understand the rationale for different design approaches and also future needs. The type of skill required to develop an organization's design standards is becoming increasingly difficult for many companies to secure, and in any case, the approach often lacks the ability to innovate and adopt new technologies as they emerge. However, the process for preparing a standard design does not require the same level of experience and is not so different from the effort and knowledge required for a single design project.

A *standard design* approach enables more precise specification and contracting and reduces the potential misunderstanding that may develop between the utility and its substation builder. Design time can be significantly reduced using a *standard design* approach through the development of concept design drawings that need only to be tailored to the specific requirements of a particular project, rather than the designer starting from a blank slate, and with basic design parameters.

*Case Study*—In 2005, Ergon Energy, a transmission and distribution utility in Queensland, Australia, was faced with the challenge of delivering a significantly increased and prolonged capital program requiring lower costs and shorter delivery times. The company decided on a *standard design* approach with more functional specifications and achieved significant savings in design and delivery times for a number of key projects. The targeted 80% reduction in design time was achieved for some substation design projects. The process of changing the standards approach from prescriptive to functional design achieved significant innovation and new technologies that had never been used before by that utility. The project to make the necessary internal

changes involved communication and consultation with staff across the organization, carried out over a 2-year period. A new range of internal processes was introduced to ensure that future innovation was not locked

out, while still aiming to achieve the design savings and the procurement and spares holdings benefits. The basic designs that were adopted during that period are still in use by that utility today.

## 11.3 Design

Design of substations [11.14] involves a range of considerations, from site selection, to substation layout with adequate redundancy, electrical clearances, insulation coordination, structural and civil design, and secondary and auxiliaries design.

Once a suitable site has been defined that provides adequate access and security, considering issues such as soil types and the risk of flooding, and with a design that is acceptable to the local community, the design of the actual substation can commence. Substations operate in harsh environmental conditions, and earthing and lightning protection is a major design consideration. The impact of the substation on the environment and the environmental footprint of the substation must be considered when designing a new installation and also in ongoing life management.

Substations can be built using a range of insulation technologies, each with their own advantages and disadvantages. The most common technology for primary equipment is air-insulated switchgear (AIS) although the use of gas-insulated switchgear (GIS) using either SF<sub>6</sub> or any of a range of other gases has evolved and has become common in many regions, particularly where limited space may be an issue. The use of overhead connections, underground cables and gas-insulated lines (GIL) may also be part of the consideration for substation designers.

In some cases, substations are built for offshore applications requiring particular design considerations. For mobile and modular substations, the risks associated with transportation and relocation are a consideration.

The substation is required to operate reliably and to require minimal maintenance, meeting the required performance objectives over a long lifetime. These design aspects necessitate a range of electrical, mechanical, civil and structural engineering skills.

The design process varies from organization to organization, but some common elements can be defined. Fig. 11.20 provides a summary of the key steps and interdependencies for a typical greenfield substation design. Addition, more detailed information is available in other references, including CIGRE Technical Brochure

740—Contemporary solutions for low cost substations in developing countries [11.15].

### 11.3.1 Sustainability

Sustainability is a key area of concern for the power network and for substation designers today. This chapter does not discuss sustainability in general, but some aspects of sustainability directly affect substation design and are discussed briefly in this section. Sustainability can be considered to be about people, planet and profit (3 Ps). The following sections consider some of these aspects in relation to substation design.

### 11.3.2 Designing for Safety

Design is often influenced by local codes, design standards and legislation. Experience with safety incidents and accidents has led many countries to adopt health, safety and environmental protection laws or rules with mandated requirements for designers of electrical infrastructure [11.16].

The aim of these rules is to protect employees, the public and the environment from harm over the life of the installation. These rules or legislation may be referred to as health safety, environment and quality (HSEQ) or occupational safety and health (OHS) guidelines. In some cases, specific legislation requires designers to follow a defined process to ensure that applicable safety and environmental considerations are addressed during the design process.

In general terminology, designing for safety involves the integration of hazard identification and risk assessment within the design process to eliminate or minimize the risk of injury throughout the life of a product being designed.

One of the design challenges for infrastructure such as substations is considering what hazards might exist over the life of the installation, and that may mean considering what may occur over more than 50 years of installation life. The design process (Fig. 11.20) refers only to the key steps, but any requirements for HSEQ considerations are embedded into the design process and design decision-making.

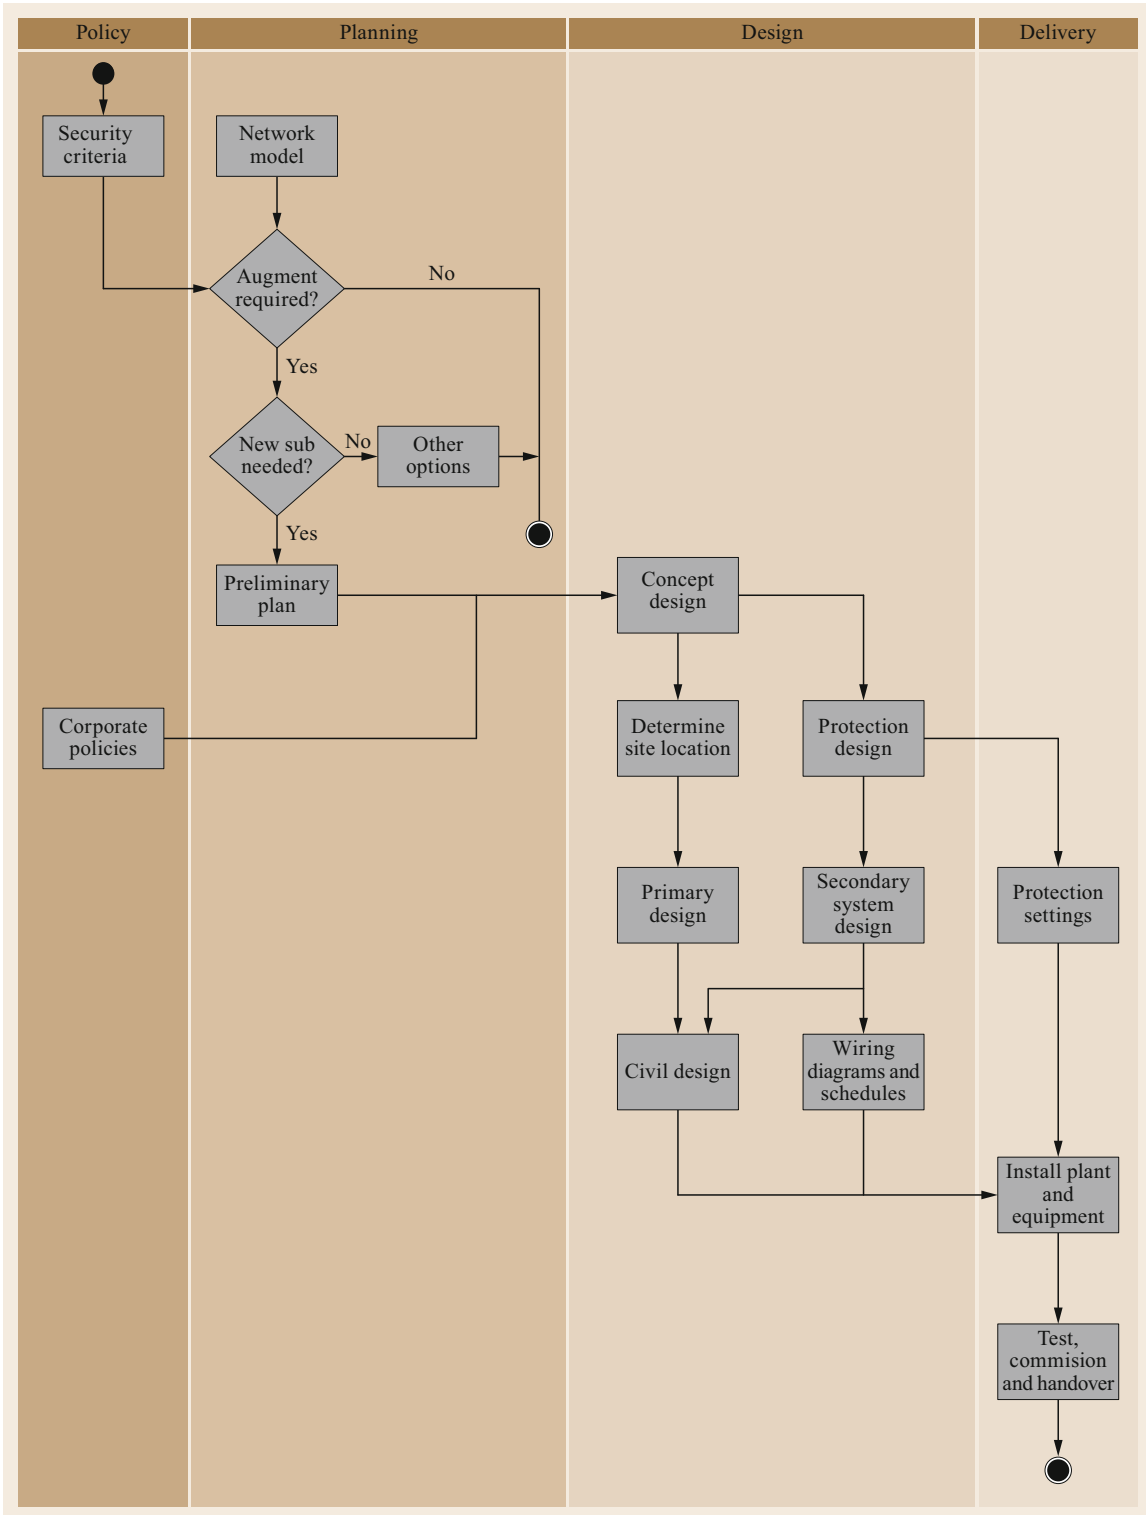

Fig. 11.20 Typical basic substation design process steps (summary only)

It is estimated that building inherently safe plant and equipment would save between 5–10% of their cost through reductions in inventories of hazardous materials, reduced need for protective equipment and the reduced costs of testing and maintaining the equipment.

The direct costs associated with unsafe design can be significant, for example retrofitting, workers' compensation and insurance levies, environmental cleanup and negligence claims. Since these costs have a greater impact on parties downstream in the life cycle who buy and use the product, the incentive for these parties to influence and benefit from safe design is also greater.

A safe design approach results in many benefits including:

- Prevention of injury and disease
- Improved usability of products, systems and facilities
- Improved productivity
- Reduced costs
- Better prediction and management of production and operational costs over the life cycle of a product
- Compliance with legislation
- Innovation, in that safe design demands new thinking.

Safety and environmental consideration is one of the fundamental requirements for all designers, whether it is legislated or not, for the particular utility or client.

### 11.3.3 Substations and the Community

Substations are designed to fulfill a set of functions within the electrical network, but they are often built adjacent to residential, business or industrial areas and other infrastructure, and are therefore required to meet community expectations for visual aesthetics, noise control and other factors, and in some cases mandatory regulatory requirements. In the past, substations could be designed to simply achieve their core electrical and mechanical functions, but increasingly utility owners need to consider the needs of the community in relation to electrical infrastructure. To this end, designers have often taken considerable effort to reduce the impact of the infrastructure on the community (Fig. 11.21). This can be justified on the basis that the utility can ultimately be shown to be a better community citizen, even if these measures add to the cost of the installation, which must be passed on to the shareholders and other stakeholders.

In some utilities, it is common practice to consider screening of the substation with trees, shrubs or other vegetation or by semi-sinking the substation into the ground, located behind a natural hill or artificial earth bank (Figs. 11.22 and 11.23) [11.17]. While from

**Fig. 11.21** The night lighting and facade of the Laura 110 kV Substation in Russia (Krasnaya Polyana—Sochi) is an example of design for aesthetics (Courtesy Electra)

**Fig. 11.22** Prinsenhage high-voltage substation in Breda Substation in the Netherlands (Courtesy TenneT/Movares)

**Fig. 11.23** Anneberg 400/220 kV Substation, Swedish National Grid (Courtesy Tennet/Movares)

a purely functional perspective the ideal substation location may be on the top of a prominent hill to achieve the best line approach direction and design, this would normally not be considered by the substation designer. One of the conflicting considerations for the designer in designing visual screening is to consider the needs of the substation security and to avoid creating locations where an intruder might be hidden from view.

A substation may also be located in a more urbanized area. In these cases, the landscape elements will often have an environmental added value as an urban recreation area. For example, the substation may have elements that serve as a visual or acoustic buffer, parking strip or cycling route.

**Fig. 11.24** Technical facilities with an attractive outer shell or fence in Dronten, Rotterdam, Liedsche Rijn, Utrecht (Courtesy Tennet)

**Fig. 11.25** 3-D visualization showing a proposed new substation in a suburban street in North Queensland, Australia (Courtesy Ergon Energy)

In some cases, attractive screening can be added to the substation façade (Fig. 11.24).

Three-dimensional visualization techniques can be used by the design team during a community engagement process to demonstrate how the design will integrate into the streetscape.

The example shown in Fig. 11.25 from Australia demonstrates how architectural additions to the substation can be used to modify the appearance of the substation building to adapt to the local street environment.

None of the examples above completely hide the substation, and ultimately the only way this can be achieved is by building the substation underground, as in the example from Japan in Fig. 11.26.

Increasingly designers need to consider how to integrate substations into the community. In some cases, mandatory requirements are enforced by local authorities as part of a project approval process, but in others these measures are to ensure that the substation gains community acceptance. There are many examples of practices around the world, and the requirements for the substation to be an accepted part of the local community should never be ignored.

#### 11.3.4 Key Components

Substations can be constructed with a number of different layouts and using a number of construction methods including indoor, outdoor, overhead or underground, on ground, on pylons or floating on the sea, and may be built using AIS, GIS or hybrid technologies or

**Fig. 11.26** Meijou Underground Substation design in Japan (Courtesy Chubu Electric)

a combination. Whatever the type and method of construction, a substation includes some or all of a number of high-voltage and low-voltage components that can be classified as:

- Primary power lines or cables
- Busbars and overhead conductors
- Instrument transformers including voltage and current transformers
- Disconnectors or isolating switches
- Circuit breakers
- Surge or lightning arresters
- Power transformers
- Reactive compensation devices including reactors and capacitor banks
- Support insulators and bushings
- Control buildings to house protection and control equipment
- Secondary control and protection systems
- Earthing system
- AC and DC auxiliary systems that may include an on-site emergency generator
- Environmental control systems
- Security fences
- Civil and structural supports.

### 11.3.5 Preliminary Design

The first step in the design of a substation is to confirm the busbar layout, often determined at an early planning stage. The busbar layout is usually defined by overall network requirements and the required substation function as described in Sect. 11.2. This design process step defines the single-line diagram of the substation and the key primary components that will be required.

The preliminary design, (or concept design), is part of the early stages of the overall design process and involves the development of the single-line diagram together with the chosen primary and secondary philosophies and technology decisions into a more coherent document that articulates how the substation will look and fit onto the selected site. The concept design normally considers the actual selected site characteristics. In most cases, the site will be predetermined because it has been already forward-purchased or allocated or otherwise defined, and so the concept design will incorporate those details.

Good practice approaches in design often include a collaborative approach to development of ideas for the concept design phase, as decisions made at the concept phase often have a major impact of the final design. Collaboration at this early stage with operations, maintenance and commissioning staff, as well as representatives from the various engineering disciplines

including primary, secondary, protection and civil design, can be a useful input to the design process.

The design standards of the organization or utility may define many of the key parameters that need to be addressed in the physical and electrical layout of the substation, but the concept design must include reference to:

- Primary design including maintenance access and electrical clearance requirements
- Insulation coordination requirements including lightning protection
- Structural and civil design including seismic requirements
- Earthing and lightning protection
- Reactive plant requirements
- Control and protection philosophy and automation
- Auxiliary system requirements
- Environmental requirements including the effects of the environment on the substation and the substation on the environment.

Many of these design aspects are interrelated and may require an iterative approach during the design process, particularly in the early stages. For example, the size of the site available may restrict the types of technology or the actual physical layouts that may be considered. It is unusual for a designer to have the luxury of first deciding on a bus layout, then defining a required space, and then finding suitable land or space.

A range of aspects of the design phase are discussed in the following sections.

### 11.3.6 Electrical Clearances

Electrical clearances (or safety clearance distance) [11.18] are required to ensure adequate safety for operations, maintenance and other staff by establishing adequate distances between high voltages and accessible locations within the substation fence. Clearance distance is defined as the minimum distance to be maintained between live equipment or conductors in order for work to be safely carried out in the substation. These distances are used by the designer to arrange the equipment within the substation.

These standard clearance distances vary around the world and have been derived in many different ways, and not always logically in relation to the nominal voltages. Different methods have been adopted in each country or region to establish electrical safety clearance, based on the nominal voltage level of the substation. It should be noted that these safety distances are in air and do not relate to insulator length or creepage distance.

**Fig. 11.27** Typical human dimensions for determining safety clearance charts (Adapted from [11.19], © IEEE)

This *safety distance* is initially defined by the impulse withstand voltage rating of the substation, but is also intended to account for the expected physical size and movements of operations and maintenance staff within the substation. The design intention is always to reduce the risk of inadvertent contact by staff with live equipment during typical maintenance and operations tasks within the substation.

In most cases, safety clearance distances are defined by regional standards or legislation and are incorporated into the design by referring to tables and charts. However, in formulating such tables of safety clearance, the following are considered:

- The basic value aimed at ensuring no flashover from high voltage under the least favorable conditions. This basic value usually incorporates a safety factor.
- A safety zone is established to account for typical human activities.

The average dimensions of operations staff are used to determine an appropriate safety zone to be incorporated into the clearance distance. Fig. 11.27 shows typical human dimensions and activities that might be expected during substation operations and maintenance.

One of the difficulties in using *typical* dimensions is that no two individuals are the same, and the size of staff may vary considerably.

If there are no guards or safety screens in place, then the safety distance must allow for the free movement of staff beneath the high-voltage equipment. Based on the typical dimensions, the minimum distance to live equipment from ground access may be considered as 2.25 m; however, for simplicity and additional safety, a minimum of 3.0 m is commonly recommended, even though the impulse withstand distance for voltages under 380 kV may be much less than this distance.

The minimum safety distance from the ground is considered as that measured from the highest accessible point on or near the ground level (without climbing supports or structures in the normal course of activities) and the nearest live conductor. Insulators are considered to be live conductors for the purposes of safety clearance measurement, even though the lower parts of the insulator may be at earth potential.

If safety clearance distances cannot be achieved by placement and design of support structures, then appropriate guards or screens will be required to prevent or limit free access by staff from the ground.

Safety clearances are also required to allow maintenance work on live components in relation to adjacent circuits. Similar principles to those used for ground clearance can be applied to determine horizontal and vertical distances to be added to the basic clearance distances to ensure adequate safety margins for maintenance staff using tools. To determine an appropriate clearance, the normal distance that a worker could be expected to reach (with light tools) is added to the basic non-flashover distance, with an appropriate safety margin. Typical values that may be used, in addition to the non-flashover distance, are:

- 1.75 m horizontally corresponding to a worker with arms outstretched
- 1.25 m vertically above the working plane corresponding to that part of the worker passing above the plane when their arms are outstretched.

Permanent visual means of identifying the defined safety zone may be incorporated into the design. Vehicle access barriers, for example, may be used to restrict movement of vehicles under live equipment where the vehicle height may encroach beyond the safe zone. When work is required within the substation, it is normal practice that a safe working area is defined using

**Fig. 11.28** Typical substation elevation showing different heights for conductors

ropes, chains, flags or other markers according to local safety regulations.

There is no design that can be made completely safe for all work tasks. For example, the common use of elevating work platforms and scissor lifts means that maintenance staff have significant reach within, above and outside the work area that is difficult to control by screens or guards. Training and adequate safety procedures are required to ensure that there is minimal risk of staff being injured during maintenance activity in a live substation by reaching outside the defined safe working area. The designer should aim to minimize risk to a level as low as reasonably practicable (ALARP) by ensuring adequate safety clearances and avoiding known risks such as *oversailing conductors*, which have been the cause of death in some countries. Appropriate screens and barriers should be used where appropriate.

### 11.3.7 Primary Design

The layout of the substation is driven primarily by the choice of busbar configuration allowing for the required clearances, the insulation type and voltage level, and the technology type allowing for the ongoing maintenance and security of the site [11.14]. The substation layout defines the disposition of the various items of high-voltage equipment (line or cable entry, switchgear, transformers, etc.) and their connection to achieve the busbar configuration within the site size and shape that has been chosen. Once a basic layout has been determined, the type of connection and busbars must be chosen to finalize the primary design.

For an air-insulated substation, different parts of the substation are usually arranged at different heights to

achieve adequate distance between parts of the circuit (Fig. 11.28).

Busbars and connections between the busbars and other components may be either rigid or flexible, or a combination of both. Often the choice of conductor type will depend on local practices and standards, but it is also dependent on the type of switchgear that will be installed. For either choice, the issues of safety, final layout complexity, ease of erection, short circuit forces, aeolian vibration/resonance and cost should be considered by the designer. Effective design solutions can be determined for either flexible or solid conductors.

The final layout must allow for adequate phase-to-phase and phase-to-ground (or other equipment) distances and provide adequate access for typical maintenance activities.

There are other considerations involved in finalizing the substation layout, including:

- Future expansion—consideration of the ultimate layout requirements and ease of extension and any future uprating requirements
- The direction of approach of incoming lines and feeders
- The risk of failure of flyover spans and overheads wires
- Physical security
- Storage, parking and laydown areas
- Environmental requirements.

Historically, substations have been designed to allow frequent circuit breaker maintenance, and consequently disconnectors are a major part of the primary design. Consideration may be given to the use of disconnect-

ing, rotating or withdrawable circuit breakers to reduce or even eliminate the need for disconnectors. The lower maintenance frequencies of modern circuit breakers means that electrical isolation for maintenance may be achieved by flexible leads with disconnectable links rather than actual disconnectors. The use of hybrid switchgear can also simplify substation layouts and reduce the physical dimensions required for bays.

Another considerations for the primary designer is visual impact and aesthetics. A low-profile layout may be preferred in order to reduce the visual impact of the site.

### 11.3.8 Insulation Coordination

Insulation coordination involves a series of design process steps to select the appropriate dielectric strength of substation equipment and to match this with appropriate protective measures to be incorporated into the substation design. It can be a complex subject, and only general considerations are given in this section [11.19–21].

Insulation coordination considers the expected overvoltages generated in the external network that affect the substation and overvoltages from within the substation itself. These overvoltages may consist of external overvoltages due to lightning, switching operations and other transitory conditions, and also overvoltages due to circuit resonance. There are some particular considerations for GIS substations including DC and AC voltage stressing and very-fast-front overvoltages.

The aim of insulation coordination is to reduce the risk of dielectric failure and to coordinate the insulation within the substation by considering:

- Equipment voltage ratings including lightning impulse withstand, switching impulse withstand and power-frequency voltages
- Insulation withstand levels
- Creepage distance of external insulators
- Clearances in air of various components
- Footing and earth resistances
- Ratings and energy dissipation characteristics of selected surge arresters.

Externally generated overvoltages are generally controlled by the use of overvoltage-limiting devices such as surge arresters and rod gaps. Internally generated overvoltages are controlled by the design of primary equipment and other precautions. The aim for the designer is to reduce the probability of insulation failure due to overvoltages, whether generated internally or externally. The risk cannot be totally eliminated, and

the objective is to achieve an economically and operationally acceptable risk level.

The majority of lightning overvoltages affecting substations enter as traveling waves on the overhead lines. Where a transmission line is shielded and its tower footing resistances are low (generally considered to be  $10\Omega$  or less), a lightning stroke to a shield wire or a tower will normally discharge safely to earth on the tower and not enter the substation. If the tower footing resistances are high or if shielding is not effective, a stroke to a shield wire or tower may raise the potential of the tower far above that of a phase, and depending on the current of the stroke may result in a *back flashover* from the tower to the phase conductor. This could result in accompanying power-frequency earth fault current in the ionized path formed, flowing in the opposite direction to that of the surge current.

A back flashover will typically initiate a traveling overvoltage wave of extremely high rate of rise on the phase conductor that travels along the conductor and ultimately enters the substation. Similarly, lightning strokes that occur close to the line may induce sufficient overvoltage in the phase conductor to generate a traveling wave.

This type of induced overvoltage is usually not an issue at transmission voltages, but can have a severe impact on distribution equipment.

Traveling waves travel along the line in both directions away from the point of strike or back flashover, but are attenuated by the resistance of the phase conductor and so dissipate with distance. A strike or a flashover within 2–3 km of a substation is generally considered to be close enough to cause potential problems that must be considered in the insulation coordination study.

The main task in insulation coordination is to coordinate the expected overvoltage stress in the substation from various sources with the insulation strength of the insulating components of equipment installed in the substation.

Two methods can be used to assess the adequacy of insulation coordination. These are basically classified as:

- *Deterministic* method, which can be applied if there is little or no statistical information available. In this case, a set of values is determined or assumed and coordinated so that no breakdown will occur under this assumption. A safety factor is applied to allow for statistical scatter in assessing the expected level and frequency of occurrence of transient overvoltage.
- *Statistical* method, which can be used if the risk of failure can be fixed at an acceptable value and calcu-

**Fig. 11.29** Surge diverter fitted to incoming line in a 132 kV substation (Courtesy CPP, Australia)

lated using an overvoltage probability distribution and the breakdown probability of the insulation.

#### Achieving Adequate Insulation Coordination

The process of insulation coordination will usually result in the need for metal-oxide surge arresters fitted at each overhead line or cable entry point and at GIS, transformer and reactor interface points (Fig. 11.29).

For small, compact substations in moderate-risk lightning regions and with voltages up to 300 kV, surge arresters on the entry points are normally sufficient for protecting the substation and adjacent high-voltage equipment. For physically large substations in high-risk lightning regions or in substation arrangements with long busbars or bus ducts and for voltages higher than 300 kV, extra surge arresters mounted close to the transformers or reactors may be required.

#### Surge Arrester Selection

The selection of a surge arrester is a compromise between temporary overvoltage capability, level of protection and energy dissipation capability of the surge arrester. The surge arrester must be stable under system conditions and under short-duration power-frequency overvoltages. When these conditions are not known, a sufficient safety margin should be selected. The protection level should be selected as low as possible in order to achieve an economically sufficient margin between the protection level of the surge arrester and the insulation level of the equipment. The energy dissipation capability of the surge arrester must match the stress that the surge arrester will endure during switching and lightning overvoltages. Simpli-

fied calculations are normally sufficient to select the correct temporary overvoltage capability, protective level and energy dissipation capability of surge arresters.

The overvoltage protection of a substation is not only a question of which arrester to choose. For protection against lightning surges close to the station, it is even more important that the arrester be installed in the most effective way. The surge arrester should always be placed as close as possible to the equipment to be protected. An important aspect of all surge arrester mounting (especially in the vicinity of GIS) is that the length and inductance of the earth connection of the surge arrester should be minimized. The use of a normal stranded earthing conductor is not recommended for any GIS earthing, especially surge arresters, due to self-inductance of the conductor. The use of a flat square-, rod- or rectangular-section solid conductor is the preferred method of earthing in situations where fast rate-of-rise transients may be expected (such as lightning- or GIS-induced transients).

In addition to considering very-fast-front overvoltages, insulation coordination should also consider ferroresonance phenomena. Ferroresonance is a resonance between nonlinear inductance and some form of series capacitance associated with parts of the substation such as capacitive voltage transformers, long line connections, cables or capacitive coupling. It may occur where a transformer is lightly loaded and during single-pole switching procedures and can result in equipment damage under some circumstances.

### 11.3.9 Earthing and Lightning Protection

The substation earth mat or grid is an important aspect of the overall design of the substation, particularly in relation to the safety of personnel.

A substation earth grid has two main functions:

1. *Operational*  
Providing a path for current to the general body of earth in normal and fault conditions.
2. *Safety*  
For personnel, animals or equipment within the environs of a substation or in remote locations to avoid dangerous voltages during the flow of earth fault currents in the earth grid.

The earth grid also provides for the discharge of lightning and switching surges to earth and for the earthing of high-voltage equipment during maintenance.

The earth grid and the connections to it from the transformer neutral points must be rated for the most onerous prospective earth fault currents that might be

expected under worst-case conditions. The grid resistance to remote earth should be low enough to limit the earth fault current below a minimum value necessary for correct operation of the protective relays.

The earth grid and the connections to it from equipment, housings and structures should be such that touch and step voltages within or in the vicinity of the substation and transferred from the earth grid to external locations over telephone circuits or low-voltage power circuits or by any other means, are maintained within safe limits [11.22].

It is common practice to also connect the shield wires of overhead conductors and any metallic bare conductors entering or leaving the substation to the substation earth grid. This has the effect of further reducing the impedance of the earthing system to ground, particularly for smaller substations, but care must be taken so that the earth grid potential rise under fault conditions is not transferred to water pipes or telecommunications circuits or other metallic conductors that might be contacted by persons.

During earth-fault conditions, the flow of current to earth will produce voltage gradients within and around a substation, and it is therefore important that persons within the substation or in the vicinity are not exposed to dangerous voltage gradients.

There are a number of different types of hazardous potentials that may arise when an earth fault occurs:

- *Rise of earth potential or grid potential rise (GPR)*  
Due to a rise in voltage of a part of the earth system above true earth.
- *Step voltage*  
The voltage occurring between the feet of a person walking (or stepping) across the earthed system at the time a fault occurs.
- *Touch voltage*  
Between the hand of a person touching equipment (such as a metal support or an operating panel) at the time a fault occurs. Touch voltage can be considered the most serious because the expected path of the current may be through the heart from hand to feet, potentially causing ventricular fibrillation.
- *Mesh voltage*  
Voltage that occurs within the earth grid when a fault occurs.
- *Transferred voltage*  
Voltage that is transferred from a site with an earth fault to a remote location by conduction through screens, pipes or other conductors.

The effects of electric current passing through the parts of a human body depend on the physiology of the person and the duration, magnitude and frequency of the

current. The most dangerous consequence of such an exposure is a heart condition known as ventricular fibrillation, which may result in damage to the heart and loss of blood circulation.

The earth mat or grid is designed to limit these hazardous potentials to values that are not dangerous to personnel, animals or equipment. The supports and metallic frames of all high-voltage equipment within the substation are permanently connected to the earth grid.

### General Earth Grid Design

The typical substation earth grid is composed of suitably sized earthing conductors (usually copper) laid approximately 500 mm below the surface of the ground and covering the whole extent of the site. The fence may be connected to the substation earth mat, but may be earthed separately for a range of reasons. Earthing conductors are placed within the grid based on the calculation of expected hazardous voltages under fault conditions. It is important that earthing conductors are not subject to corrosion due to chemical interaction with the surrounding soil.

The size of conductors and the spacing of the earth grid is determined during the earthing design process.

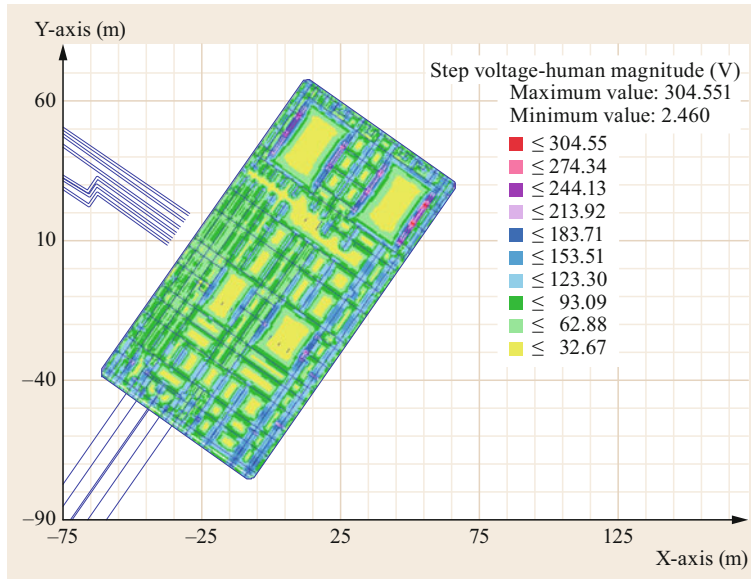

Calculations of expected hazardous voltages consider a range of factors including:

- Substation physical layout
- Soil characteristics including thermal and electrical resistivity
- Earth return paths via overhead line earth wires or cable sheaths
- Earth fault level due to network characteristics and the expected duration of faults based on protection design.

During earth-fault conditions, the flow of current to earth will produce voltage gradients within and around a substation. Because of this rise, there are voltage gradients across the earth grid and around the substation, which may be represented as surface voltage contours.

Calculations of earthing gradients and other earthing calculations are usually carried out using specialized earthing analysis software packages (e.g., the SES-CDEGS [11.23] or similar software packages). A typical outcome of a substation earthing design package for step voltages in a small substation is shown in Fig. 11.30.

Connection of the equipment frames to the earth mat should be made so that connections will not be physically damaged or easily removed as part of normal maintenance activities and are able to withstand expected fault current without damage. Often two con-

**Fig. 11.30** Typical output of a substation earthing design step voltage analysis in the form of a heat map showing expected transient human step voltages under fault conditions

ductors per structure are used to provide a level of redundancy and safety in case of removal or damage. Earth grids are designed to carry the maximum earth fault current for the duration of the expected earth fault. For the purpose of conductor sizing, fault durations are usually assumed to be one second for voltages in excess of 170 kV and three seconds for voltages below this, to allow for the unexpected failure of primary protection devices. Alternative worst-case clearing time assumptions may also be used as a design parameter for calculating the conductor size required.

#### Earth Grid Resistance Value

The earth grid resistance to remote earth should be kept as low as reasonably possible in order to fulfill the operational function of the earth grid. The earthing system should be designed to achieve safe touch and step voltages within the substation property for any person within the substation.

Maximum step and touch voltages are set to levels which will limit the current flowing through an exposed person to the safe current level.

The following factors influence the earth grid resistance:

- Soil resistivity
- Area covered by the earth grid
- Shape of the earth grid
- Mesh size of earth grid
- Burial depth of earth grid.

The characteristics of the earth grid conductor, including the cross-sectional area of the conductor and its

burial depth, also have a small effect on the earth grid resistance.

The equation is simplified from IEEE 80-2000 [11.24] and can be used to calculate approximate earth grid resistance

$$R_g = \frac{\rho}{4} \sqrt{\frac{\pi}{A}} + \frac{\rho}{L_T},$$

where  $R_g$  is the substation ground resistance ( $\Omega$ ),  $\rho$  the soil resistivity ( $\Omega \text{ m}$ ),  $A$  the area occupied by the grounding grid ( $\text{m}^2$ ), and  $L_T$  the total length of the conductors (m).

This equation assumes a simple grid arrangement and homogeneous soil resistivity, which is rarely the case in practice. This equation can be used to obtain an approximation of the earth grid resistance. In almost all cases, more complex analysis is needed.

The use of a suitable software package such as *SES-CDEGS* [11.23] or similar software is generally required to more accurately calculate grid resistance.

#### Soil Resistivity

Modeling of the expected performance of a substation earthing system requires knowledge of the soil characteristics and the determination of an equivalent electrical model of the surrounding soil and rock. This is achieved using the results of soil resistivity measurements in the vicinity of the site being studied and through careful interpretation of the results of such measurements.

Typically, soil resistivity measurements are taken using the *Wenner method* [11.25]. This method, which

**Fig. 11.31** Soil resistivity results for a large urban construction site

involves four measurement probes, enables the measurement of soil resistivity for different electrode spacing. Analysis by computer-aided methods is recommended to develop a soil model for the substation site. Typical soil model results are shown in the diagram below (Fig. 11.31).

In many cases, in analyzing the soil resistivity measurements it is possible to arrive at a simplified horizontally layered model of the soil structure around and below the earthing system. Occasionally, however, a more complex model will be required. Uniform or horizontal two-layer soil models can be used with manual calculations to determine the performance of an earthing system, but more complex soil models can be used only with computer-aided design.

#### Design for Touch and Step Voltage Limits

Design for touch and step voltage safety limits can be calculated using appropriate proprietary software or by simplified equations given in IEEE 80-2000 [11.24] and shown here based on a 50 kg body mass, 50 Hz frequency, a fault clearance time equal to the design earth fault clearance time selected and topsoil resistivity as

**Table 11.1** Typical soil resistivities—selected soil types

Soil type	Resistivity ( $\Omega$ m)
Clay, soft	50
Clayey sand	50–100
Soil, chalky	100–300
Limestone, fissured	500–1000
Granite	1500–10 000

indicated.

$$E_{\text{touch } 50} = (1000 + 1.5C_s\rho_s) \frac{0.116}{\sqrt{t_s}},$$

$$E_{\text{step } 50} = (1000 + 6C_s\rho_s) \frac{0.116}{\sqrt{t_s}},$$

$$C_s = 1 - \frac{0.09(1 - \frac{\rho}{\rho_s})}{2h_s + 0.09},$$

where  $E_{\text{touch } 50}$  = touch voltage in V,  $E_{\text{step } 50}$  = step voltage in V,  $C_s$  = surface layer derating factor,  $\rho_s$  = resistivity of the surface material ( $\Omega$  m),  $\rho$  = resistivity of the earth beneath the surface material ( $\Omega$  m),  $t_s$  = duration of shock current (s),  $h_s$  = thickness of the surface material (m).

In the absence of site-specific measured surface layer resistivity data, typical resistivities (as shown in Table 11.1) and thicknesses of surface layers can be assumed as a starting point for the calculation of the safety limits. However, it is always preferable to have actual site-specific data on soil characteristics available prior to the design.

The typical thickness of surface layers is 0.1–0.2 m for crushed rock or 0.05 m of tarmacadam. These materials can be used to reduce the risk of excessive or dangerous levels of step potentials within substation boundaries.

#### Transferred Voltages and Hot Zones

High ground potential rise (GPR) may cause problems outside the substation property, including:

- Hazardous step voltages
- Hazardous transferred touch voltages at fences and other metallic objects
- Equipment damage to infrastructure belonging to other utilities such as telecommunications cables and junction boxes.

Hazardous transferred touch voltages may occur where a metallic object, such as a fence, is earthed at a location and then traverses areas of different voltage levels. The metallic object is then at a different voltage from the ground over which it travels. A person touching such

**Table 11.2** Typical admissible voltages from ITU-T K.33 (International Telecommunications Union, 1996) [11.26]

Fault duration (s)	Admissible limit (V)
$t \leq 0.1$	2000
$0.1 < t \leq 0.2$	1500
$0.2 < t \leq 0.35$	1000
$0.35 < t \leq 0.5$	650
$0.5 < t \leq 1.0$	430

a metallic object is exposed to voltage difference in the form of a touch voltage.

Voltages may be transferred along the following metallic paths:

- Fences
- Shield wires
- Cable sheaths/screens
- LV neutrals
- Railway lines
- Gas pipe lines
- Other long metallic structures.

It is not always possible to model all of the mentioned metallic objects as part of an earth grid calculation. However, if any of the above are in the vicinity of the substation site, they should be tested using a current injection test.

Surface voltage contours are also used to define the *hot zone* of a substation or specific surface voltage safety limits agreed upon with the local authorities concerned.

A simplified calculation of the dimensions of specific surface voltage contours is given in IEEE 80-2000 [11.24] as

$$\varphi_e = \frac{\rho I_e}{2\pi d},$$

where  $\varphi_e$  = voltage on the surface of the earth (voltage level),  $\rho$  = soil resistivity,  $I_e$  = earth fault current,  $d$  = distance from the center of the grid.

This equation assumes a simple grid and uniform soil resistivity, which is rarely the case. This equation can be used to gain an approximate idea of the size of the hot zone contour. In nearly all cases, more complex analysis is needed.

One way of determining the extent of the hot zone is to use the voltage levels given in Table 11.2. These are the relevant voltage levels for different fault clearance times, and illustrate that the extent of the hot zone is dependent on fault clearance time.

Special design considerations may be required for transfer voltages associated with:

- Telephony and data cables entering the substation
- Distribution power cables for auxiliary or other supplies
- Adjacent traction or other power circuits
- LV systems and cables entering the substation
- Water and gas pipes.

### Earth Conductor Sizes

The earthing system comprises earth conductors, both underground and aboveground, including risers to connect aboveground equipment. Earth conductor size can be calculated using the Onderdonk formula or by consulting charts issued by conductor manufacturers

$$A = I \sqrt{\frac{t_c \alpha_r \rho_r 10^4 / \text{TCAP}}{\ln[1 + (T_m - T_a) / (K_0 + T_a)]}},$$

where  $A$  = area of the conductor ( $\text{mm}^2$ ),  $I$  = RMS current (kA),  $t_c$  = fault clearing time (s),  $\alpha_0$  = thermal coefficient of resistivity at  $0^\circ\text{C}$ ,  $\alpha_r$  = thermal coefficient of resistivity at reference temperature,  $T_m$  = maximum allowable temperature for the conductor type ( $^\circ\text{C}$ ),  $T_a$  = ambient temperature ( $^\circ\text{C}$ ),  $T_r$  = reference temperature for material constants used (typically  $20^\circ\text{C}$ ),  $\rho_r$  = resistivity of the earth conductor at reference temperature  $T_r$  ( $\mu\Omega/\text{cm}^3$ ),  $K_0 = 1/\alpha_0$ , TCAP = thermal capacity factor ( $\text{J}/(\text{cm}^3\ ^\circ\text{C})$ ).

### Earthing System Design

Earthing system design is an important aspect of the overall substation, and various analytical methods have been used in the past to achieve a safe earth system design. Previously, designers have generally used a deterministic approach to earthing design, but this often results in costly design solutions. Earthing design, as for other aspects of the substation, is a compromise between safety, risk and cost, and this balance can be optimized using quantified risk analysis techniques. CIGRE Working Group B3.35 surveyed the various analytical approaches in common use and examined the ways that designers could demonstrate due diligence in meeting their duty of care through risk and cost-benefit analysis using quantified risk techniques.

### Safety Earths or Portable Earthing Devices (PEDs)

Safety earthing is used to provide for personnel safety while working on otherwise live equipment. Typically, portable temporary earthing is applied on conductors on either side of the work area for protection of operating personnel against any improper re-energization of the work area due to error, transient effects, or induction from adjacent live circuits or from any other source.

Portable earthing devices must be rated for the maximum expected fault level and duration for that substation. Appropriate connection points and methods of connection are provided as part of the substation design.

In some cases, permanently installed earthing switches are provided to facilitate earthing of lines or other parts of the substation. Where ferroresonance of power transformers is likely, specially designed earthing switches may be installed to enable the quenching of the ferroresonance before re-energizing the circuit.

In designing the placement of portable earthing connection points, the designer should consider the height and the ability of the operator to apply the earth using operating sticks. Earthing connection points should be placed in the expected locations necessary to undertake typical maintenance activities. In applying earths, the normal operating procedure is to first prove that the circuit is dead, and then apply the earthing conductor. In applying earths, the operator will connect the earthed end first, before making the final connection to the device or conductor.

Special earth connection points or earthing spigots are fitted at the high-voltage end and connection points on the structures at the earth end. These points are designed to enable the type, size and number of portable earth connections required to carry the fault current to be easily attached.

### Earth Grid Testing

The earth grid at every substation should be checked and tested periodically to ensure that the performance of the earth grid is always capable of meeting the overall design requirements and the safety levels required for personnel in the vicinity of the substation.

Testing is important to verify the design calculations and to ensure that there have not been changes that might adversely affect the earthing system performance. Changes may include a change in fault level, removal of earth conductors (e.g., copper theft), degradation or damage due to corrosion, changes in soil characteristics and other changes.

Typical substation earthing system test frequencies are:

- Visual inspection annually
- Earth continuity testing every 5–7 years
- Remote injection testing every 12–15 years.

The test frequency for individual utilities depends on local policies and risk management practices.

### Lightning Protection

One of the issues for substations in some parts of the world is protection against lightning. Protection against

lightning can be problematic, as there are no measures that will provide 100% protection, and lightning itself is unpredictable. It is a phenomenon that has caused severe damage to life and property. Direct hits may cause structural failure, whereas indirect hits, through inductive or capacitive coupling, may affect the reliability and integrity of electronic equipment within the substation. Lightning can even affect substations built underground.

Although surge arresters are used to protect the substation against the effects of lightning striking lines and overvoltage surges entering the substation, it is also important to take steps to protect the substation against direct lightning strikes that may cause insulation flashover. The aim of the protection is to reduce the risk of injury to staff and equipment damage, and to prevent major outages. Even smaller lightning strikes that may not result in actual flashover have the potential to cause damage to substation equipment such as transformers.

The risk of lightning is defined by the frequency of the lightning strikes and by the ground flash density (GFD) or the keraunic level at the substation site. GFD is defined as the average number of strokes per unit area per unit time at a particular location. The keraunic level is defined as the average number of thunderstorm days or hours for a given locality. Maps are available in most regions that define the expected number of thunder-days per year and the expected severity.

Protection from lightning can add significant costs to the substation, and a risk assessment is recommended to determine whether the cost versus risk is justified based on the criticality of the substation and the risk of lightning at that location. Three methods are typically used by designers for the analysis of lightning protection systems:

1. Classical empirical curves design approach using fixed protection angles and empirical curves
2. Electro-geometric model method (EGM), usually implemented as the rolling sphere method (RSM) as shown in Fig. 11.32
3. Collection volume method (CVM).

There are a range of other methods, but these three are the most commonly employed. The classical empirical approach was initially developed in the 1940s but is not recommended for higher-voltage substations.

Using the electro-geometric approach, an imaginary sphere of fixed radius is assumed to represent the risk of lightning strike distance and is *rolled* over the structure of the substation. Equipment that does not intersect with the rolling sphere is considered to be in the protection zone.

The radius of the sphere ( $S$ ) as shown in Figs. 11.32 and 11.33 represents the strike distance of the lightning

**Fig. 11.32** Rolling sphere method (Courtesy CPP, Australia)

stroke and is determined by the surge impedance and the allowable stroke current. Unlike the classical approach, the EGM takes account of the basic impulse level of the equipment being protected. However, one of the assumptions of this method is that the method assumes a fixed striking distance, regardless of the structure height.

The collection volume method, also known as Eriksson's attractive radius model, takes into account the physical features of the structure being protected. Based on this and on the intensification of the electric field created by different points of the structure, the CVM provides recommendations for the optimal placement of lightning rods or air terminals.

Protection against direct lightning strokes in the substation is carried out using either overhead earth wires or lightning rods, or a combination of both these protection methods. If overhead earth wires are to be used, then attention must be paid to the elimination of the risk of earth wires falling down onto busbars or other substation equipment. Overhead earth wires can be difficult to inspect and maintain in a live substation. Lightning rods may be mounted on freestanding structures or on vertical extensions of substation support structures.

As for earthing, lightning protection analysis is usually undertaken using specialized software and 3-D design methods.

For additional information about lightning protection and analysis methods for substations, see IEEE 998—Guide for Direct Lightning Stroke Shielding of Substations [11.18], IEC 62305-1 Protection against

Lightning [11.27] and IEC 61936-1 Power Installations exceeding 1 kV AC [11.28].

### 11.3.10 Reactive Plant

Reactive plant may be included in a substation for the purpose of network reactive compensation or voltage control. Network voltage and var control requirements may include both steady-state and dynamic system conditions, and will be dependent on the generation capabilities and the load characteristics of the network.

Reactive compensation is generally applied at the point in the network that is causing the effect, so that the substation affected will be the one that includes the new device. This means that a long line which would normally give rise to increased voltages (Ferranti effect) will normally be fitted with a line reactor at the receiving end to reduce the voltage. The line reactor may be switched or may be permanently connected to the line. Series capacitors can also be used to compensate for line inductance and to increase the power transfer capability of a line.

The most common forms of reactive plant in a typical substation are shunt-connected capacitor banks or line reactors. Shunt-connected capacitor banks are commonly used to control network voltages and are generally switched using an associated circuit breaker.

Reactive circuit breaker switching can be onerous, and the reactive switching capability of the circuit breaker should be considered in the design process.

Dynamic compensation or fast-acting reactive compensation such as static var compensators (SVCs) may be used to improve overall network stability, reduce harmonics and provide voltage and power factor correction. An SVC is a static device and generally comprises a switched capacitor element combined with a thyristor-controlled reactor to provide variable reactive compensation that is essentially stepless and fast-acting.

### 11.3.11 Substations and the Environment

One of the fundamental design considerations for a new substation is the environment. The environmental conditions that exist at the new site must be considered in designing the infrastructure, but the designer must also consider the impact of the new substation on the environment once built. This is often referred to as the substation *environmental footprint*. The objective for many utilities is to ensure that the substation has minimal impact on the local environment from any aspect of the design.

The environment in which the new substation is to be built is a major design consideration. Ambient tem-

**Fig. 11.33** Typical small substation lightning coverage 3-D model (Courtesy CPP, Australia)

perature, solar radiation, wind, rain, snow, ice and the likelihood of pollution all affect the selection of equipment supports, housing and insulation, and the design of the substation components, particularly where the substation is outdoors. Ambient temperatures have a major impact on loading and must be considered in equipment selection. Sporadic environmental conditions or risk factors such as floods, bushfires, hurricanes, earthquakes, volcanic eruptions and lightning all need to be taken into account by the designer.

The impact of the substation on the environment usually comprises a range of factors including:

- Spoil from construction activities
- Noise
- Visual amenity
- Archaeological or cultural heritage issues associated with the site
- EMF
- Oil and cleaning agent pollution of soil and in runoff
- Release of SF<sub>6</sub> and other gases into the atmosphere
- Water and other liquid site runoff.

Some of these factors can be controlled as part of the design; others are a matter of consultation, safe work practices and community awareness.

### Physical Environment

The design ratings of the substation are based on the expected operating environment of the site. This operating environment is sometimes referred to as the *physical rated environment* and can be derived from the service conditions used in the various high-voltage equipment specifications and reproduced in national and international standards. Typical rated physical environment specifications for a site in Australia are shown in Table 11.3.

### Animals

Another aspect of the substation physical environment is the effects of wildlife on substation reliability. The types of animals that typically cause reliability problems in substations are rodents, reptiles and small animals that are able to enter the substation through the fences or walls, and birds and bats, but frogs and snakes may also be a hazard in some regions. Snakes in particular may be not only a hazard to maintenance workers but also a danger to insulation.

Various forms of protection and barriers can be used to prevent bird, small animal and reptile damage, while appropriate baiting can be used to deter small rodents.

The use of composite insulators can cause problems in certain areas, especially on de-energized lines.

**Table 11.3** Typical rated physical environment specifications, Australia

Factor	Minimum	Maximum
Shaded air temperature (no solar radiation) (°C)	-5	+50
Solar radiation (horizontal surface) (W/m <sup>2</sup> )	Nil	1200
Wind speed (m/s)	0.7	50
Monthly rainfall (mm)	Nil	360
Maximum rainfall—100 years (mm/h)	-	347
Relative humidity—outdoor (%)	25	100
Altitude (m)	< 1000	
Ambient ground temperature at 900 mm (°C)	+20	+35
Soil thermal resistivity (K m/W)	1.0	1.5
Isokeraunic level	Up to 50 thunder days/year	
Minimum pollution severity	Level II—medium	

Certain parrot species peck the silicon rubber in de-energized composite insulators and can completely destroy a composite insulator in extreme cases, as in Fig. 11.34.

One solution is to place a protective sleeve over the composite insulator during installation. This sleeve is removed by pulling a cord at ground level before energization. Although sensitive to electric fields, birds in some cases will damage energized insulation, and this is much more difficult to combat. In extreme cases, some utilities have reverted to glass and/or porcelain insulators to avoid the issue.

#### Environmental Control Measures

Once the substation is constructed, the main environmental issues are oil/water control and noise control.

Generally, a substation site will be chosen to avoid the risk of damage to the surrounding environment, es-

**Fig. 11.34** Bird damage on a composite insulator (Courtesy TransGrid, Australia)

pecially to permanent watercourses and underground aquifers.

Utilities will generally ensure that care is taken during construction and during the life of the substation to avoid leakage of oil or other substances into groundwater or outside the substation boundary. Oil leaks from power and instrument transformers, switchgear, capacitors, coils, etc., are generally safely contained on-site. Oil retention pits are sometimes used for on-site storage of oil (or other contaminants) and also as a fire control measure. A central underground tank may be used to retain oil and contaminants on-site. The tank must be sized to contain the volume of the largest oil-filled equipment plus a margin that allows for rainwater and water from fire protection or control systems (where used).

The probability of an oil spill occurring in a substation is generally considered to be very low. However, when substations are located near sensitive areas such as lakes and reservoirs or wetlands, depending on the quantity of oil on-site, the consequences of discharge outside the substation are higher, requiring special attention.

Solutions that are required by regulation or legislation will vary from region to region, and specific solutions will be determined by the risk identified for a particular site and the type of equipment installed. Some common control methods include:

- Oil spill containment on-site using bund walls around power transformers, ditches around the substation, pits, dams or tanks. Adequate allowance for rainwater and fire control water should be included in the design. Care should be taken to ensure that overflow is managed so that there is no unwanted discharge from the site.
- Oil/water separator systems—there are a number of methods that are commonly used and a range of commercial products that separate water from the contaminated liquid. Generally, these systems rely on the difference in specific gravity between water and oil in order to separate contaminants from water.
- Oil-blocking systems—allow liquid to pass unless oil is detected, blocking the flow of oil and water.

CIGRE Technical Brochure 221 [11.28] contains more detailed information on this subject.

Noise from substations can be a significant issue for residents near the site. While at the design stage the distance to nearby residences may be large and the noise control adequate, housing built near the substation after construction and heightened awareness of acoustic noise can cause issues for the asset manager.

### 11.3.12 Structural and Civil Design

Civil and structural design is an important aspect of the overall substation design project. Civil and structural components include:

- Buildings
- Equipment and conductor supports
- Footings and ducts
- Drainage and oil control
- Noise control
- Fire barriers
- Security and fencing.

In a substation, a range of structural materials may be used, including wood, concrete, steel and aluminum. Structures are required to support high-voltage equipment, meeting the loads and forces imposed by the environmental conditions such as wind and the electrical forces associated with short circuit forces under fault conditions.

Substations have design lives of typically more than 40 years, and measures need to be taken so that corrosion is managed in order to ensure the life of steel and concrete supports and structures. Generally, steel used for supports is treated with hot-dip galvanizing, but other treatments and coatings may need to be considered in extremely hostile environments.

#### Foundations

Foundations or footings are required for the mounting of high-voltage equipment, and comprise a considerable proportion of the civil works for a substation. Footings are designed to the applicable national or regional standards by a civil engineer in conjunction with the substation primary designer, and some level of iteration between the two may be required to determine the most economical design solution to meet the required design loads. The design calculations will be based on the site geotechnical report detailing soil characteristics including the soil properties in relation to moisture content.

Based on the soil characteristics, different foundation designs may be used to achieve the required outcome, including shallow raft foundations, block foundations, rock anchors or deep foundations with pillars to mount the equipment. Selection can be based on factors such as ground conditions, installation cost for the different approaches or selected utility standard design approach.

Depending upon the type of soil and the loads, the foundation construction material is generally concrete, with or without steel reinforcement. In some cases, piles may be needed to achieve support requirements.

The finished level of the footings is used to align high-voltage equipment, which is usually fixed a small distance above the finished level to allow a degree of adjustment in aligning components. The space between the footing and the equipment is usually grouted or sealed to prevent water lodging in the interface, causing corrosion.

Equipment is mounted on the prepared footings using either cast-in threaded fixings or alternatively chemical or expansion anchor bolts. Chemical anchors have the advantage that the support structure can be located and the holes in the baseplate used as the drilling template. Cast-in bolts require considerable care during foundation installation to ensure that the anchor bolts are in the correct location. Some types of cast-in bolt do allow a degree of play in the position of the bolts, which can then be grouted into place when the support structure is in place.

Foundation design must also allow for the later installation of earth conductors and control cables to avoid the need for cutouts after the foundation is installed. In addition, ensuring that steel reinforcement is adequately connected to the substation earth grid and does not result in earth current loops in normal or fault conditions may be important in some installations, particularly in the vicinity of air-core reactors, where strong magnetic fields may exist.

Power transformers require a foundation to adequately support the static load plus oil containment and fire control facilities. Firewalls may be required between adjacent transformers, and in some cases may also act as noise control devices.

#### Buildings

Substation buildings are designed to applicable building codes or national standards. The main role of the substation control building is to provide physical protection for equipment, including control and protection equipment, SCADA (supervisory control and data acquisition) equipment and substation auxiliaries. In some cases, high-voltage switchgear may be located inside a building to provide environmental protection and security for the primary equipment, including AIS, GIS and hybrid (mixed technology) switchgear.

Although substations are generally designed to be unmanned on a continuous basis, some human amenities and workshop facilities may be required for periodic attendance by inspectors or operations and maintenance personnel.

Similar to other buildings, there are a range of approaches that can be used to design a substation building. The substation building may be a permanent brick or concrete construction, but there is a trend toward the use of modular, prefabricated and transportable build-

ings that have the advantage of off-site construction, including fitment of control and protection equipment, to reduce project cost and commissioning time.

While initial and lifetime costs for the particular country or individual location are the main basis for the construction type selected, security concerns must also be taken into account, which may result in requirements such as minimal or no windows (or protected windows), reinforced nonflammable roofs or reinforced doors.

The local climate and the environmental requirements of the installed equipment will determine the degree of climate control required in substation buildings. A common practice is to use a two-stage climate control system that maintains temperatures for the short times of worker occupation at one set point and reverts to a lower (or higher, depending on the climate) setting when unattended to reduce energy consumption. Some electronic equipment items generate heat and also have a limited environmental range, requiring some degree of continuous climate control. This also applies to batteries, where some types have an optimal temperature range and which also have ventilation requirements due to the emission of gases during charging.

Appropriately zoned security and fire alarm systems should be provided and connected to the SCADA system or local fire authority. A risk assessment should be used to determine the degree of security and fire detection and suppression to be provided.

#### Cable Trenches and Ducts

Cable trenches are a common method of providing adequate protection for secondary control cables between the individual items of HV equipment and for connection to the control building. Some equipment-to-equipment connections will typically be made by providing conduits for the necessary control cables, but for the connections to the control room, surface ducts with reinforced lids are the customary approach in substations. The advantage of surface ducts (although this may be the most expensive option) is the ease of access for later changes during the life of the substation. It is important that the choice of duct cover is carefully considered to ensure that the lid is strong enough to support vehicle loads in the substation during operations and maintenance.

#### 11.3.13 Seismic Considerations

Earthquakes can occur in any part of the world but are most common in the area described as the *Pacific rim*. Substations can be vulnerable to earthquakes, both from the risk of physical structural and equipment damage and from unwanted maloperation of equipment such as relays and other mechanical devices in the substation.

In areas where earthquakes are considered a foreseeable risk, a range of methods can be used to reduce the impact on reliability and to ensure that the power network can be rapidly restored following a major earthquake.

Different techniques can be used to model the expected behavior of equipment under earthquake conditions. A common approach is to use a shake table to simulate different earthquake scenarios and to validate design solutions. One of the most obvious areas of weakness in high-voltage electrical equipment is porcelain insulators, and various methods can be used to brace or strengthen structures with porcelain insulation.

Other measures to counteract earthquake issues in substations include:

- Removal of transport wheels on power transformers and solid fixing to avoid shifting in earthquakes
- Additional mechanical bracing and stiffening on support frames for conservators, piping and radiators on transformers
- Insulating rubber damper mountings used for sensitive relays and control devices.

Whatever procedures and solutions are adopted to reduce the risk of damage from earthquakes, it is important that the solutions are aligned with the earthquake risk for the particular substation and that region, and the expected characteristics of earthquakes in that location. The solutions adopted by the designer must be cost-effective and must not have an adverse impact on substation reliability, severability or maintainability.

#### 11.3.14 Fire Control

Fire in a substation is generally considered a rare occurrence, and the measures for the detection and suppression of fires in a substation vary depending on the risk appetite of the asset owner, the criticality of the substation, local standards, the type of construction and the equipment used. The most common approach for managing fire risk is to design layouts that ensure adequate physical separation between equipment such as power transformers to reduce the risk that a fire on one transformer will affect an adjacent unit.

The general objective in substation fire protection is to minimize the hazard, limit the damage and reduce the impact on overall substation reliability. When designing any aspect of the substation, including fire protection systems, the final design is a balance between risk and cost.

One of the most common fire suppression systems used in substations is a water spray system on power transformers. The key aim of such a system is to limit the conflagration, to cool the fire and to reduce the risk

of the fire spreading to other parts of the substation, particularly adjacent units. Gas systems including  $N_2$  or  $CO_2$  may also be used to attempt to smother the flames in the event of a transformer fire. An important aspect of the design of fire suppression for transformers is the need to contain the resulting oil/water mix from pollution of groundwater. Oil containment is designed to accommodate the transformer oil volume plus an allowance for rainfall collected in the containment and from firefighting.

Fires in substation control rooms are considered even more rare than transformer fires. However, it is common, usually due to building standard requirements, to have some type of fire detection system, and in some cases to have fire suppression in control rooms and switch rooms. Fire suppression may be some form of gas release or hypoxic system where oxygen levels are kept lower than normal. Any suppression system requires consideration for maintenance worker access and staff safety.

Fire detectors in substations are typically connected to control centers via SCADA systems to alert operations personnel to the fire, and may also be connected to local fire authorities. Local fire authorities who are not experienced in high-voltage substations and who enter to fight a fire may present a safety issue to be managed by the asset owner. There are cases where inexperienced firefighting personnel have entered substations to fight a fire, gaining access by cutting gate locks, without proper awareness of the hazard of high-voltage equipment. This type of issue is best managed by training and awareness and by adequate levels of consultation between the substation owners and the local fire authorities.

Fire control measures in substations vary depending on local standards, fire regulations, and the risk and criticality of the substation. Some utilities manage the risk by accepting that a substation fire is a risk but that the fire cannot be contained, and the loss of part of the substation is inevitable.

### 11.3.15 EMF and EMC Design

Substation equipment can be the cause but also may be susceptible to electromagnetic interference and electrical disturbances. Sources of disturbance include a range of electrical transient phenomena that might affect substation equipment:

- Electrical transients from high-voltage device switching of circuit breakers and disconnectors
- Electrical transients from some form of insulation breakdown
- Power-frequency electrical and magnetic fields

- Transient earth potential rises during faults
- Lightning and switching transients from outside the substation
- Geomagnetic disturbances.

Each of these potential sources of electrical disturbance can have a major effect on components within the substation, requiring special attention on the part of the substation designer and during the construction of the substation, to layout, shielding, earthing and screening practices in the substation.

#### Disconnecter-Induced Disturbances

Switching of a disconnector occurs when the load current has been removed and disturbances result from the voltage collapse and multiple restrikes at the point of interruption of the primary arc. Typically for air-insulated substations, the transients that result are tens to hundreds of kilohertz; however, in the case of GIS, the transients have a far higher frequency, up to thousands of megahertz. The initial value of the peak current of these transients is proportional to the change in voltage at the arc point ( $\Delta V$ ) and the surge impedance, which is dependent only on the geometry and characteristics of the surge path. In general, this phenomenon can be significantly worse in substations where the rated voltage is 100 kV or higher. The effects can be a much more serious issue for GIS than for AIS, and can generally be observed as short-duration, steep-fronted transient pulses.

Fig. 11.35 shows a typical measured transient, although the reader should note that the measured waveform is limited by the capability of the measuring equipment, and the observed waveform may not be an accurate measure of the actual frequency or the level of the signal that is being generated. The actual signal frequency and rate of rise is likely to be much higher than can be measured by conventional measuring equipment.

While these transients are generally not a human safety issue (although some operators have reported shocks during manual operation), this transient phenomenon is observed in substations as short-duration electrical transients during disconnector switching that can have significant effects on electronic equipment. Although related transient phenomena can be observed during circuit breaker switching, the more serious (in terms of control systems) generally result from disconnector switching.

Power-frequency electric and magnetic fields are also a potential source of concern. However, as the field levels originate from high-voltage conductors, the typical distances from such conductors are usually sufficient for human safety and short-term exposure.

Insulation breakdown can also be a source of electrical disturbances and transients, and often these can be

**Fig. 11.35** Transient waveform (bus current) measured during opening of a 500 kV disconnector (Adapted from [11.29], © CIGRE)

detected with RF (radio frequency)-sensitive measuring equipment and used as a method for general condition assessment of a substation.

All of these disturbance sources can have a significant effect on electronic devices, causing maloperation and failure of components, and the proper design and treatment of cable screens and general substation earthing practices are important control methods.

### Geomagnetic Disturbances

Geomagnetic disturbances can have a serious effect on substations and the power system. Currents induced in power lines flow to ground through substation transformers, which can cause saturation of the transformer core and a variety of consequential problems. Increased heating due to geomagnetic interference has caused transformers to fail in the past. Increased harmonics generated in the transformer can result in unwanted relay operations, causing unwanted tripping of power lines.

Geomagnetically induced currents (GIC) are driven by the electric fields produced by the variation in the earth's magnetic field that occurs during a geomagnetic disturbance. These variations are driven mainly by solar activity, particularly solar flares and solar storms. Because of their low frequency compared with the AC frequency, the geomagnetically induced currents appear to a transformer as a slowly varying DC current. GIC flowing through the transformer winding produces extra magnetization which, during the half-cycles when the AC magnetization is in the same direction, can saturate the core of the transformer. This results in a non-sinusoidal, distorted AC waveform with increased har-

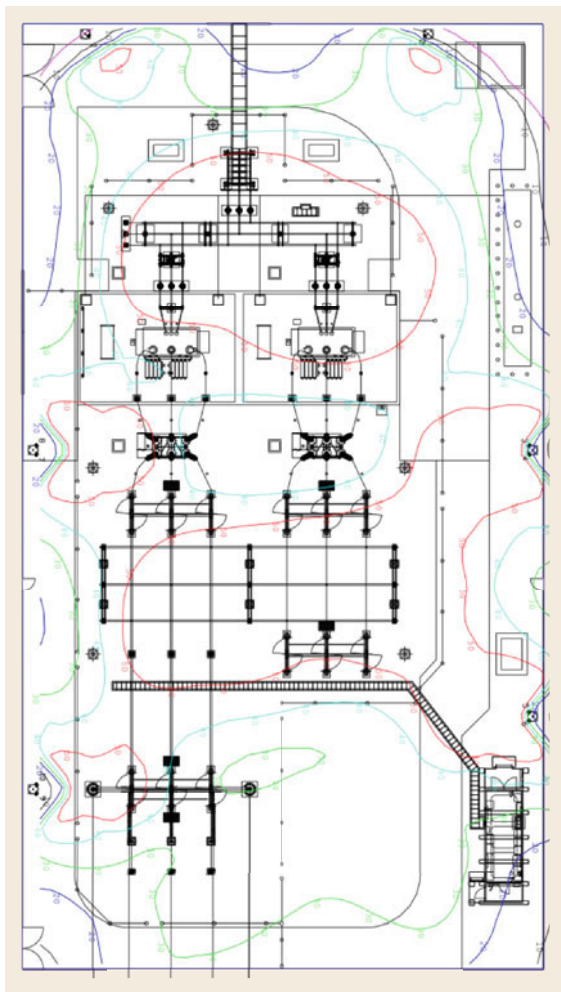

monic levels that can cause maloperation of relays and other equipment on the system. Transformers may be damaged thermally.

Saturation of the transformer core produces increased eddy currents in the transformer core and structural supports heating the transformer. The large thermal mass of a high-voltage power transformer means that this localized heating may not produce a major change in the overall transformer temperature but can cause damage to parts of the transformer windings.

### EMC Control Methods

In most cases, there is no treatment to eliminate the actual generation of electrical transients and geomagnetic disturbances, which are inevitable within a high-voltage substation environment. However, there are steps that can be taken by the substation designer to minimize the effect of the transients and other disturbances typically observed in substations, and this is commonly managed by earthing practices and secondary cable screening. Unlike conventional practice for power-frequency screening, the recommended practice for the earthing of most substation control cables is generally to earth all secondary cable screens at both ends of the cable (sending and receiving ends, with the screen suitably sized for fault current flow) or, ideally, double-screen cables with the inner screen earthed at one end and the outer screen or sheath at both ends. The exception to this practice of double-end screen earthing is small signal cables. This practice is sometimes accompanied by the installation of a large-diameter parallel earthing conductor in the same trench as the control cables to provide an alternative low-impedance path under fault

**Fig. 11.36** Lighting contours for a small substation, with contours showing lighting levels in lux (Courtesy CPP, Australia)

conditions. The latter measure is to bypass any circulating current that might occur due to transient potential rise in parts of the earthing system due to system or substation faults.

The other aspect of the control of transients is to ensure that there is a low-inductance path for transients to earth. A stranded earthing conductor may have significant self-inductance, presenting a high impedance to high-frequency or fast-rate-of-rise transients. The use of a flat bar, rod or zero-inductance cable should be considered for all major equipment earth connections to provide a low-impedance path for electrical transient pulses into the earthing system.

The reader should be aware that the information provided in this section is a summary only, and the topic of transient disturbance and EMC in substations is a specialized topic. CIGRE Technical Brochures 124 [11.30] and 535 [11.14] provide much more detailed information and coverage of this topic.

### 11.3.16 Lighting Design

The objective of substation lighting design is to provide sufficient light both within and outside the substation building for normal and emergency work activities, including operations and maintenance. Another consideration for the designer is the security aspect of substation lighting, which may include photoelectric cell or motion sensing.

Typically, a designer will work with lighting levels from local standards specified for internal surfaces and external work areas. External lighting must be adequate for the typical work activities that might be undertaken, with consideration for luminance level at key locations, glare rating, color rendering, spill and *sky glow* rating. DC emergency lighting, driven from substation auxiliary batteries, may be provided in case of system power outage.

Specified design light levels will vary from one region to another, but typical values are:

- Inside buildings: 160 lux at floor level
- Outside: 10 lux for operational or walking areas, 5 lux other areas.

These levels are typical requirements and may vary on a case-by-case basis or based on local standards.

A lighting study is usually undertaken using specialized lighting software to prepare a lighting contour plan based on the selected luminaires, selected location and mounting heights. An example of the outcome of a lighting study is shown in Fig. 11.36. Particular attention should be paid to light spillage to neighboring properties and shadows in operational areas. Color rendition can also be an issue for operations and maintenance. Generally, white color (color rendition index of 50 or higher) is considered preferable for substations.

Outside lighting should be mounted in a way that facilitates maintenance, reduces glare outside the substation, and does not require an outage of the high-voltage plant or the use of ladders or other equipment for access to lamps for replacement. This often requires the installation of separate swing-down light fittings rather than mounting on high-voltage structures and supports.

## 11.4 Construction and Commissioning

Once the design has been completed, there are various methods and contracting arrangements that can be used to facilitate the construction and commissioning of new substations or the enhancement of existing facilities. Each of these methods has challenges, advantages and disadvantages for the utility. Construction involves a range of challenges in ensuring that the works are adequately managed from the perspective of quality control and site logistics, to ensuring site safety. Commissioning the substation involves suitable testing and validation of the design to enable connection of the substation into the overall grid. Finally, training for operations and maintenance staff and documentation are vital functions for any new substation.

### 11.4.1 Methods

Construction of a new substation or major modifications can be undertaken in a number of ways, depending on the preferences of the owner. In some cases, the owner has internal staff who are able to specify, design, procure, construct and commission a new substation, but frequently, any part of that process may be undertaken by external contracted organizations. In some countries, this practice of outsourcing is common, while in others it is observed as an emerging trend.

The substation may be fully supplied by an external organization or different combinations of delivery retained in-house. In some cases, the owner organization will retain engineering in-house and construction services will be obtained from an external contractor. In others, the entire process is managed by external parties, apart from specifying the initial requirements.

All of these approaches can be managed with effective controls and delivery processes, and each has attendant commercial and operational risks, advantages and disadvantages. Whatever the method adopted, it is important that the construction process is managed methodically, using project management principles, to ensure that the work sequence is logical and aimed at minimizing delays and optimizing costs.

### 11.4.2 Site Logistics

The process of construction begins with site preparation and benching as required by the civil design. The delivery and storage of materials and equipment on-site will commence soon after the site is prepared, and should be coordinated so that the equipment is delivered in time for erection or appropriately unloaded and stored on or near the substation site. Transport delivery ideally should be arranged to deliver the equipment as it is

needed for construction, as storage on-site has attendant risks. For example, the largest items are usually power transformers, and these should be delivered only when the site is adequately prepared and when the arrival does not interfere with other works.

Each substation site and transport route is unique, and the challenges for the construction crew in logistics and transportation are different. A transport and logistics plan may be useful to ensure coordinated, just-in-time delivery of equipment and materials.

### 11.4.3 Quality Control

Quality control is one of the most important aspects in substation construction projects, and key to successful execution of the project. Contractors and suppliers should be required to submit a quality control plan that documents all the necessary procedures and steps to be undertaken for delivery of equipment, installation and construction work.

Once the layout has been established and footings are installed, the first task is usually heavy steelwork installation, followed by major primary equipment items and bus-work. In some cases, preassembly of equipment in the workshop in a controlled environment is advantageous, saving time on-site.

A good site construction manager is able to foresee issues and uses experience to ensure that works are coordinated and that appropriate quality control is applied for equipment delivery and at early construction and erection stage.

Although the early-works stages of substation construction are largely physical erection of plant, one of the important requirements at this stage is to ensure that the underground components of the earth grid are installed according to required specifications. This is difficult to assess once trenches are covered and conductors buried.

### 11.4.4 Documentation

Manuals, drawings and other documentation are an important aspect of substation construction and life management. The level of documentation is often related to the contracting approach (turnkey or in-house) and the degree of design standardization adopted by the utility. If substation design is highly standardized, then the level of design documentation may be less than that required for a new design supplied by an external supplier. It is important that various manufacturers' manuals are collected as the construction progresses for later documentation of the entire substation. The other

aspect of design documentation is ensuring that any departures from the design drawings are documented in *as-built* drawings, so that the final substation drawings reflect the actual installation on-site and not just the design intent.

Any test results related to tests carried out on equipment should be retained as a base for future condition monitoring and lifetime trending.

### 11.4.5 Commissioning and Testing

Substation commissioning is the process that takes the substation from construction and connects it to the power network to achieve the network function specified for the substation. It is an important process, as it represents the start of the life of the substation as an asset in the network. The records of the testing undertaken at commissioning become the base level for lifetime condition monitoring and trending.

The overall process of commissioning a new substation is usually considered a two-stage process:

- Precommissioning
- Connection of the substation to the network.

The commissioning process typically starts with workflow planning and determination of the required final connection date. The commissioning tasks are then assembled into a project workflow that ends at that date. Commissioning tasks are coordinated with construction activities to ensure that tasks are completed as soon as possible within the construction program, and sequenced logically to avoid overlap, interruption to construction, and waiting time. Commissioning a large substation is not a task for a graduate engineer and takes a degree of experience often gained working with other commissioning personnel or after long experience on smaller projects. The knowledge required to effectively commission a substation covers a wide area of substation design and plant technology, and an understanding of control and protection systems.

Commissioning activities are documented and the process controlled using preprepared *inspection and test plans* (ITP) and *test reports* that detail the key tasks completed and testing results obtained. This plan is used and the test results, when complete, become the main documentation of the commissioning process. ITPs and test plans are the main quality control documents specifying the testing.

#### Precommissioning

The general objective of precommissioning is the identification of drawings and equipment, confirmation of proper primary connection, correct orientation of equip-

ment, and functional testing of the assembled equipment to confirm correct operation of circuitry and components. Precommissioning assumes that the equipment installed has been previously type-tested in the factory or laboratory, and the tests carried out on-site for precommissioning are to confirm that the equipment is undamaged, functional, correctly assembled and erected, aligned and fully operational. Precommissioning generally does not involve the whole substation as an assembly, but treats the various components and circuits separately.

**Identification and Location of Equipment and Components.** The first step in precommissioning is to identify and locate all the primary components, check correct erection and orientation, check that design details on drawings are correct, and record serial and other information that might be required later.

**Preliminary Testing—General.** Pretesting is carried out at this stage to ensure that instrument transformers are undamaged in transport, have the correct polarity and that ratios are correct, and switchgear auxiliaries and mechanisms are working according to manufacturer's instructions. Pretesting is carried out before the primary circuit is connected to the network. Ideally, the entire substation is not connected, but in some case parts of the substation may be live, and extra care needs to be taken to avoid operational or safety issues during testing.

Switchgear is checked to ensure that fluid levels, settings and all adjustments are as per requirements, and functional testing is carried out to ensure that the disconnect or circuit breaker is fully operational. Timing tests on circuit breakers may be carried out at this stage.

Power transformers are often set up by the manufacturers who install the coolers, bushings and other auxiliary systems, fill the unit with oil, commission auxiliary systems and carry out basic testing. For power transformers, it may be useful to take an oil sample at this final setup stage, well before energization, to provide base levels for gas concentrations and to confirm oil quality and dryness.

Generally, all equipment can be tested in some way to make sure it is operational; however, full type testing generally will not be feasible on-site, and it is assumed that this is carried out before arrival. Factory test certificates should be reviewed and collected at this stage for later inclusion in the substation commissioning document set.

Instrument transformers are often tested on-site using a primary injection test set to confirm that available ratios are correct, leaving the selected ratio finally connected at the end of the pretesting ready for the next stage of testing.

Pretesting can be carried out on unconnected equipment, but it is important to carry out functional testing after all physical erection activities are completed. An important aspect of this first stage of precommissioning is to ensure that wiring within devices and between the devices and the control room is installed and labeled correctly according to the design drawings. This is typically carried out before DC or AC auxiliaries are switched on. A common technique before any energization of even auxiliary voltages is to first *bell-test* wiring to ensure correct connection as per the schematic wiring diagrams. It is important to confirm using both positive and negative testing, i.e., that low-resistance circuits exist where intended and that there is no path to adjacent cores. This can be difficult in some cases. Often visual inspections alone are used to identify correct wiring and the connection of the right cores of cables on terminals. Secondary cable insulation resistance to earth should be checked once all cables and connections have been confirmed.

Other aspects of precommissioning include:

- Checking the tightness of connections
- Inspection and validation of earthing and correct connection to all equipment
- Validation of cable screen earthing according to design
- Validation of drawings and asset records with nameplates
- Energizing and testing of AC and DC auxiliary circuits.

Pretesting is carried out in a sequential manner, so that testing occurs after erection and wiring, but once tested, equipment wiring is left undisturbed where possible. Generally, the first stage of pretesting is focused on the equipment itself, then the wiring and interconnections, and gradually as the equipment itself is confirmed as correctly wired, the assembly and the overall primary and secondary circuit functionality can be tested.

Finally, once all mechanical primary connections have been checked for tightness, and micro-ohm tests carried out on joints or sections in busbars or in flexible connections, high-voltage testing should be carried out on primary equipment to check for insulation problems. This high-voltage testing is typically not carried out to full working voltage level, but is rather used to identify any gross errors and problems as a last test before energization. Once resistance testing on conductors and insulation is complete, it is important that these connections are not disturbed again for other testing; hence planning for a proper sequence of tests is important.

In the pretesting stage, control and protection relay testing can commence. As for primary equipment, it is assumed that the relay has passed type testing in

the laboratory, and the site testing is focused more on the settings to be applied, confirming that these are correctly applied and that the relay performs as expected at those settings.

Records are kept as the pretesting progresses to indicate which circuits and equipment have been pretested. This may be in the form of notes, but a good approach is to retain a set of *commissioning drawings* that are colored or otherwise marked as the pretesting proceeds. This becomes a record of progress for the commissioning team. Documentation is maintained to the level agreed upon with the asset owner for eventual handover after commissioning is completed.

The following is a list of the generic checks and tests in the recommended order:

- Inspection of the plant and nameplate data
- Confirmation of basic plant operation where applicable
- Insulation resistance and polarization index testing of primary plant
- High-voltage pressure tests of primary plant
- Resistance measurements of primary circuit connections
- Insulation resistance testing of AC and DC control and protection circuits
- Secondary circuit insulation tests.
- CT and VT (voltage transformer) ratio and polarity tests by primary injection and wiring loop resistance or secondary burden tests
- CT magnetization tests
- Relay secondary injection tests
- Checking of control circuitry wiring
- Functional tests of local and remote control, closing, tripping and protection including intertripping
- Electrical and mechanical interlocking checks
- Functional tests of SCADA, controls, alarms, indications and analogs
- Testing of trip and blocking circuitry
- Final pre-energization checks.

**Building Services and Auxiliary Systems.** The building itself should be commissioned as early as possible and any auxiliary power and light circuits switched on and tested as required.

AC supply will be required as a first step, and so this is often tested and commissioned at the first stages of the commissioning or even construction phases. Automatic and manual changeover and interlocking should be checked together with diesel and other standby functionality.

DC supplies including batteries and chargers should be commissioned ready for progressive energization of secondary circuitry and further substation testing.

**Circuit Breakers.** Each circuit breaker should be tested after erection to ensure that it is fully operational. Primary, secondary and earthing connections should be checked. Primary insulation resistance and contact resistance tests should be carried out using a suitable test set. Any discrepancies should be investigated and corrected. The operation of any circuit breaker alarms, mechanisms, pumps, compressors, switches or interlocks should be verified. Gas pressure lockout circuitry and settings should be verified and set as required.

Once adjustments have been made and the circuit breaker proven operational, timing tests should be carried out to ensure the unit meets specified values, and any discrepancies, including differences between phases, investigated.

The mechanism energy storage capability should be verified on-site by simulating the O–CO–t–CO sequence according to specification. This is recommended for each unit in case of specific installation issues. The value of t, the recovery time between operations, will vary depending on the type of mechanism and the specification.

**Gas-Insulated Switchgear (GIS).** GIS needs to be considered carefully from a commissioning perspective. GIS cannot be fully assembled off-site, and the process of GIS erection on-site carries the risk of contamination of the gas spaces. High-voltage testing on the constructed sections is typically performed once they are assembled on-site. A one-minute power-frequency test or a longer operational voltage soak test are both commonly used and can be effective in checking that the sections have been cleaned and assembled without contamination by dust or metallic particles. Functional operation, timing tests and checks on the gas monitoring relays, lockout and alarms should also be undertaken.

**Power Transformers.** Following delivery on-site, one of the first checks undertaken is to check the shock recorder for any evidence of impact during transportation. Once the transformer is located on its foundation, then the oil filling/filtering process should be commenced. Samples of the oil should be taken and tested until a satisfactory moisture level and oil withstand test voltage is obtained (e.g., in excess of 50 kV across a gap of 2.5 mm). When the oil handling process is completed, the following checks should be done:

- Check that all oil levels are correct in conservator, diverter switch tank, bushing, etc.
- Check the operation of low-oil-level alarms
- Check that all valves are in the correct position—open or closed as required
- Check that thermometer pockets are filled with oil.

Insulation resistance (IR) and polarization index (PI) values should be checked preferably before the transformer connections are made so that the values can be compared with those taken in the factory. The insulation resistance of the core ground should be measured as well, as this can also give an indication of any damage in transit.

A ratio and vector group test will normally be carried out to verify that the phasing is correct for the network.

The following tests should be carried out at every tap:

- Ratio
- Winding resistance.

A magnetization current check can be carried out using an appropriate test set or by connecting an LV supply to the transformer HV terminals with the LV open circuit. The measurements should be carried out using an analog ammeter, and it should be confirmed that there is no break in current as the tap changer moves from one tap to another. If there is a short break, this can be seen when using an analog meter (rather than a digital instrument).

Other checks on the tap changer are manual operation, local electrical operation, remote electrical operation and automatic parallel operation, and a check of the limit switches at the ends of the range. Secondary injection of the automatic tap change scheme should be carried out to verify that settings and dead bands are operating correctly.

The cooling system should be checked by setting and confirming the temperature for operation of the fans and pumps and the winding temperature alarm and trip values. It must be confirmed that the pump filters are fitted correctly and the pump flow is in the correct direction. The winding temperature indicator should be checked by secondary injection and the oil temperature also checked.

The Buchholz alarm and trip should be tested by injection of air and operation of the relevant flag relays verified. Explosion vent functionality should be simulated to verify correct operation and connection of all associated secondary wiring.

On larger transmission system transformers, it is good practice to perform a frequency response analysis (FRA) test and a swept frequency response analysis (SFRA) test during the commissioning of the transformer. These tests are carried out using specialized test sets, applying a voltage to one end of a winding and analyzing the output voltage at the other end of the winding, the other windings being open circuit during the test. The voltage is kept the same, and the frequency of the applied

voltage is swept through a range of frequencies and the output voltages recorded and plotted on a graph. This effectively creates a *fingerprint* for the winding that can be compared against the result obtained in the factory. A change in the *fingerprint* will indicate any movement of the windings that may have occurred during transport. The commissioning *fingerprint* can also be used for comparison with later tests during the life of the transformer to detect whether any damage has occurred to the transformer while it has been in service.

**Power Cables.** Power cable testing is a specialized area and generally outside the scope of normal substation commissioning, but a series of visual checks can be undertaken to ensure correct connection to bushings and surge arrestors and phasing and connection of screens. Cable screens may be grounded at either both ends or a single end, but this should be according to the design requirements.

Insulation resistance (usually 15 kV), cable and screen continuity, and path resistance testing can be undertaken. Other testing that may be undertaken includes:

- Polarization index
- AC or DC testing (depending on cable type)
- Very low frequency (VLF) testing
- Oscillating wave test
- Partial discharge testing.

**Earthing Systems.** One of the most important aspects of substations and the safety of persons and equipment is the earthing system. Generally, the testing carried out on earthing systems can be summarized as follows:

- *Earth conductor resistance*  
Measurement of all joint resistances.
- *Earth bonding tests*  
Verification that all plant, towers and structures are correctly connected to the earthing system, and measurement of bonding resistance.
- *Earth grid resistance* to remote earth  
Verification that the design levels are achieved on-site.
- *Verification of separation* where applicable  
Checking that separately earthed structures or other earthing systems are isolated from the earth grid as per the design. A common example is the substation fence, which may or may not be connected, according to the particular earthing design requirements.

Much of the earthing system is buried and installed as part of the site initial works. It is good practice that the substation commissioning process include inspection of

earth grid trenching and installation to ensure adequate trench backfill.

**Instrument Transformers.** Current transformer ratio and polarity can be easily checked on-site. Polarity is checked using an instrument or a simple DC *flick test* and small battery. Where ratios match, differential current transformer connections (bus zone or similar) can be tested by current injection across the substation bus work to confirm correct connection of each of the CTs. Magnetization curves should be carried out using specialized test equipment. Finally, insulation resistance tests should be carried out and results recorded before connection of secondary wiring. Any earthing links should be temporarily removed during testing to ensure that a single earth is wired to the circuit.

The voltage transformer ratio can be checked by injection and measurement, and each secondary circuit insulation resistance measured and recorded, before secondary wiring connection. Checks of any deliberate circuit earths should confirm the single point of secondary earth connection.

**Reactive Compensation.** Reactors and capacitors are tested by measuring capacitance and inductance and also insulation resistance where applicable. All values are recorded for commissioning records.

**Surge Diverters.** Surge diverters are generally not able to be fully tested on-site, and simple functional tests should be carried out to ensure that the units are serviceable and have not been damaged in transit to site or in erection.

**Protection Relays.** As for other substation plant, the full functionality and type testing of protection relays is assumed to be undertaken off-site, and the philosophy for precommissioning is to verify the operation of the relay and the application and verification (by testing) of the assigned protection settings. The increasing complexity in functionality of relays means that full testing or even testing of the settings may be a major exercise, and automated test sets are useful to reduce testing time.

The verification of protection logic settings is important, as there are parts of the logic and in-service conditions that the protection engineer may not have considered when determining required settings, causing possible maloperation in service. Unused functions should be verified as disabled or isolated from basic functions.

Before applying DC auxiliary voltages, testing of the basic insulation resistance of the relay and the associated secondary circuits should be performed. This includes VT, CT and DC circuits, ensuring appropriate levels of insulation resistance.

Once DC is applied, secondary injection tests should be undertaken to measure the relay and the secondary wiring burden, and there are several ways that this can be done, depending on the circuitry and the CT secondary windings. Ideally, the burden applied to the CT should be measured with the rated nominal current injected. Secondary injection can be arranged and measured at the CT secondary terminals to ensure that the entire secondary circuit and the burden of the relay itself is included. In some cases, the CT may be constructed with an additional injection winding to enable secondary injection.

Secondary injection is also used to verify the operation of the relay at the required settings. The most basic injection test measures pick-up and drop-off levels, and these should be compared against the required settings. Specialized and automated test sets can be used to verify that the relay operates according to the selected settings. Testing should generally be carried out in accordance with the manufacturer's instructions and aimed at verification of the selected setting and the functionality selected for the application, rather than trying to test all relay functions and verify all setting ranges.

The correct operation of all output trips, alarms, and input and output signals should be verified using the associated initiating relays or contacts in the substations where possible. In some cases, testing of relay output trips or associated isolating points may require a large number of primary circuit breaker operations. The use of a *dummy circuit breaker*, simulating the CB characteristics, is recommended in order to reduce the wear and tear on the primary equipment, but final testing of the circuit breaker is essential to ensure that the protection scheme is fully operational. In all cases, where isolating links or switches are fitted, these links should be verified by both positive and negative testing. *Positive* and *negative* testing checks the conditions for both operation and non-operation when required.

An important part of secondary injection and relay testing is to verify operation, test functionality and settings, and record operating times for all relays.

**Overall Checks and Tests.** The earlier stages of pretesting described above are carried out mainly on individual equipment items, circuits and bays, and once these tests have been completed, additional overall tests can be undertaken that cover sections of the substation or even the entire substation. Examples of such testing include circuit breaker failure systems that trip multiple devices on failure of a single breaker, hard-wired interlocking systems that include multiple primary equipment items, bus protection circuits and other hard-wired protection circuits.

Overall testing of these types of systems may involve primary injection across large parts of the substation or functional tripping of several circuit breakers. Ideally, these types of tests are carried out when the entire substation is disconnected from the network. Extreme care from a safety and network reliability perspective is required when parts of the substation are live and the commissioning is being undertaken on a new bay or line.

**Final Commissioning Tests.** The testing undertaken in the precommissioning stage verifies that the equipment is set up and connected correctly and ready for energization. All testing is designed to identify and rectify problems, to enable the substation to be energized. However, there are a number of protection tests that can only be carried out by energization and loading. Before the next stage of commissioning commences, all test leads and temporary connections should be checked and removed. The substation should be placed in a condition ready to energize. All workers on-site should be briefed in regard to site safety prior to energization.

Typically, there are local administrative procedures required for this pre-energization stage, and documentation may be required to prepare for the substation's connection to the network.

A switching program will be prearranged and authorized in conjunction with the commissioning team to provide the necessary steps to finally confirm VT phasing or current transformer summation as required by the particular configuration of the network. It is important that the mind-set of the commissioning team changes at this point, and the substation is from this point considered to be energized.

The energization process will be managed using the defined switching steps and under the control of the network controller. Energizing the substation is carried out step-by-step to allow sufficient time to identify any issues and for safety in the event of primary equipment failure. At various steps, secondary voltages, currents and phase rotation are checked at relay terminals to ensure correct connection from the primary system. In some cases, commissioning may involve synchronizing parts of the network interconnected for the first time, and it is important that the commissioning team understand any identified differences in phase or voltage levels.

In some cases, temporary secondary connections may be made to verify CT balance in differential circuits or to verify the correct connection of directional relays. Soak testing is recommended for major equipment such as transformers, and staff should remain indoors and protected from any catastrophic equipment failures that might occur. It may be useful to take additional oil samples at various stages of the transformer

energization to assist in identifying any latent issues. Immediately after energization, after soak testing and after loading are typical points where additional samples are taken.

Thermographic inspection may also be useful to identify any hot spots in equipment or connections.

As the various tests are successfully completed, the temporary settings are removed and the final settings applied. Test connections and instruments are removed and the substation configured for full service.

Following successful commissioning and energization, the final documentation of the commissioning process, the various factory test certificates, manuals, as-built drawing set and test results can be finalized for handover to the network owner, completing the main commissioning process.

#### 11.4.6 Training

Substation training requirements depend on the training policies and practices of the asset owner and organizational philosophies. There are a range of employee interactions with substations, and this implies a range of training levels and requirements to support different activities. One of the more important aspects of training for substations follows from the commissioning process, and it relates to training for operations and maintenance staff who should be trained in the particular requirements of the new substation. Often, a commis-

sioning team will provide familiarization training for operators and inspection and maintenance staff at the time a new substation is connected to the system.

Other general training may include:

- Safety induction for visitors or nonaccredited staff
- General substation awareness training for new staff
- Specific training on new substation equipment for operations and maintenance staff

Some of the training on specific new substation equipment may be undertaken by the supplier as part of a procurement agreement.

In general, university and technical training for engineers and technical staff is more difficult to obtain. General industry courses are available in most countries, but with the diversity in skills required for the range of aspects of substation planning, design, asset management, maintenance, operations and other asset aspects, there is no simple solution for the provision of substation training. Manufacturers may be able to supply courses on their own products, but general training is more difficult to obtain. This book is aimed at addressing some of the training needs for the general industry.

In some countries, industry organizations have recognized the lack of appropriate university training and are working with universities to improve power sector and substation training for undergraduates.

## 11.5 Substation Asset Management

Substations are long-lived assets, and an operating substation site may exist for 100 years or more, with equipment, components and systems changing and evolving to meet the ongoing and changing needs of the grid.

Since the 1990s there has been more awareness within the power industry of the value of asset management, which has now been developed as a recognized discipline to become an agreed-upon global standard.

Asset management for substations includes the complete asset life cycle and includes risk management and the balancing of often conflicting objectives for asset owners. Asset management is applied to all aspects of the substation life cycle, including planning and design, construction, operations and maintenance, environmental management, performance and condition monitoring, security, spares management and, ultimately, decommissioning of the substation at end of life.

A formalized asset management process provides a means for asset owners and operators to demonstrate

to shareholders, regulators and a range of other stakeholders that assets are being managed in a way that is consistent with the highest level of objectives defined for the organization.

### 11.5.1 Asset Management Fundamentals

Asset management has various definitions, but is an important aspect of the management of inherently long-lived-asset high-voltage substations. Many of the preceding sections of this chapter have focused on the delivery of new substation infrastructure, but a network comprises mostly older substations, some reaching ages of over 80 years in certain regions of the world.

Successfully managing a large population of substations requires the interaction of many individuals within the owner's organization and a range of suppliers and service providers. Asset management invariably involves all levels of the business, from senior management through all levels of asset management activities.

While there are many definitions, asset management generally involves balancing risks, costs and performance to achieve agreed-upon asset objectives. These objectives are often defined at a high strategic level but involve activities at the lowest level of the organization. An important aspect of asset management is the asset life cycle, from conception to disposal.

Asset management is not new, and organizations have been managing all types of assets, including substations, for many decades. In the 1980s, however, the discipline of *asset management* began to be discussed, particularly in the UK, USA, Australia and New Zealand, and rapidly spreading to many other countries. Since that time, there has been significant development in international understanding of the best practice principles that underlie good asset management practice.

In 2004, the British Standards Institute (BSI), in collaboration with the Institute of Asset Management, released Publicly Available Specification (PAS) 55 in two parts, considered to be the first internationally recognized specification for asset management.

In 2014, the ISO 55000 series of standards [11.31] were issued, defining accepted global understanding of asset management principles. These standards detail agreed-upon best practice principles that have relevance for many assets, including high-voltage substations.

This section discusses some of the key principles that are part of the practice of asset management for substations.

### 11.5.2 Stakeholders

One of the reasons for the development of the discipline of asset management was the difficulty in providing assurance to stakeholders that an organization was effectively managing its assets. The introduction of PAS 55 in 2008 was driven by the need to demonstrate that privatized utilities and transport organizations in the UK were effectively managing their assets. In particular, there were concerns regarding the asset management systems in place to ensure the longer-term integrity and safety of the privatized assets.

Successful asset management requires the active participation of many individuals within an organization and its supply chain. It requires the understanding and support of internal and external stakeholders, such as shareholders and regulators, who may wish to exert influence on the utility.

### 11.5.3 Risk Management

Risk management a foundational principle of asset management. Risk is related to uncertainty but can be assessed in relation to the likelihood that an event may occur and the consequence of that event.

Risk management can be considered as a coordinated set of practices to identify and define hazards and inherent asset risk, to assess the risks and the consequences and compare these against other risks to determine priority, consider feasible mitigation methods for that risk, and determine and implement a solution.

Risk management often aims to reduce risk to a level *as low as reasonably practicable* (ALARP), particularly for safety-related risks. Many organizations develop an internal risk policy that defines what the organization accepts as tolerable risk, referred to as the organization's risk appetite. This is often represented as a risk–consequence matrix that includes several risk criteria, including:

- Safety
- Financial implications
- Reliability
- Market efficiency
- Relationships
- Organization and people
- Environment.

The matrix then defines the levels of consequence in each of those criteria to provide guidance for asset decision-making and prioritizing.

Risk management is an essential task for the asset manager, particularly in relation to optimizing the costs and reliability of infrastructure. The goal of risk management is to find the optimal solution from several options meeting broader organization objectives.

Broader organizational objectives may include:

- *System*: reliability and quality of supply
- *Equipment*: technical condition of the equipment to meet performance, regulatory and legislative objectives
- *Financial*: capital investment and whole-of-life costs
- *Societal*: public opinion, reputation, community acceptance.

There are many references to the practice of risk management, and the reader is encouraged to search for those to find more information on this topic.

### 11.5.4 Reliability

The reliability of substations is obviously a key concept and is related to risk management. The concepts of risk and reliability together can be used to develop an appropriate maintenance strategy for the organization. Consideration of risk in assets such as substations invariably involves a third concept, that of criticality. The introduction of criticality provides another way to prior-

itize activities including maintenance, replacement and refurbishment works.

### 11.5.5 Maintenance

Similar to risk management, there are many texts and references available on the topic of maintenance management.

Maintenance is defined in IEC 60300-3-14: 2004 [11.32] as

the combination of all technical, administrative and managerial actions during the lifecycle of an item intended to retain it in, or restore it to, a state in which it can perform the required function.

Part of the range of activities broadly described as asset management is maintenance management, and that is defined as

all the activities of management that determine the maintenance objectives or priorities, strategies and responsibilities, and implement[ing] them by means such as maintenance planning, maintenance control and supervision, and several [improvement] methods including [economic] aspects.

Maintenance management can be complex and may involve a range of disciplines within a company, including operations, engineering, information technology, economics, safety, risk, engineering and accounting.

A maintenance strategy can be broadly divided into two approaches:

1. Corrective maintenance (or defect maintenance)
2. Preventive maintenance.

There is no right or wrong approach, and different maintenance strategies may be appropriate for different components of the substation.

*Corrective maintenance:* Corrective maintenance can be otherwise described as a *run-to-failure* maintenance approach. Assets are repaired when they fail, either immediately or in some prioritized fashion. Repairs based on unpredictable equipment failure are inherently unplanned, and it is generally accepted that unplanned repairs can be up to ten times as expensive as planned and scheduled repairs carried out in a planned and scheduled manner. However, corrective maintenance may be appropriate for some asset types and may even be necessary if there is no feasible or cost-effective preventive maintenance that can be applied.

*Preventive maintenance:* Preventive maintenance is maintenance that is regularly performed on a piece of

equipment to maintain its condition and reduce the likelihood of failure. Preventive maintenance may be performed while the equipment is in service in order to avoid an unplanned failure. Preventive maintenance is generally time-based but can also be condition-based. Traditionally, substation maintenance was carried out by periodic preventive maintenance, but many utilities have progressed to a condition-based protocol, where maintenance is carried out when the condition of the equipment is such that maintenance is required. Condition-based preventive maintenance is generally considered the optimal approach in terms of cost and risk.

Maintenance that is initiated and triggered on the basis of time periods (time-based maintenance, TBM) is relatively easy to implement with modern maintenance management information systems. Work orders are issued at predetermined time intervals, allowing for forward resource planning and scheduling.

*Condition-based maintenance:* Condition-based maintenance (CBM) relies on the known condition of the asset and may be more difficult to implement than TBM unless a clear picture of the asset condition can be obtained and there are sufficient resources, skills and knowledge for the more complex planning of maintenance activities. Forward planning of the required resources is more difficult with CBM. Condition assessment often relies on inspections unless suitable condition monitoring techniques are available for the asset type.

In some asset types, the condition of the asset may be obtained by diagnostics, and some may be suitable for online condition monitoring techniques. However, in all cases, the speed of decay or the gestation period of typical faults from the first signs of a change in condition may be difficult to predict.

Condition monitoring is a well-accepted concept in substations, and a range of techniques for both offline and online monitoring can be employed. A number of techniques have been adopted by the power industry to enable the development of an optimized maintenance management approach, including:

*Reliability-centered maintenance (RCM)* is a structured approach that considers reliability in high-risk asset types and was originally conceived within the aircraft industry. It is a step-by-step approach that can yield good results, but its implementation can be time-consuming and resource-hungry.

*Risk-based maintenance (RBM)* is aimed at minimizing cost and risk in order to achieve an optimal maintenance solution using aspects of RCM, CBM, TBM and CM.

*Total productive maintenance (TPM)* is often considered to be more appropriate for the manufacturing industry. TPM aims at the most efficient and effective use of equipment (overall equipment effectiveness, OEE).

This method considers a range of factors including human and technical aspects; however, like RCM, it can be time-consuming and resource-hungry to implement.

Ultimately, the maintenance approach used by any organization depends on the nature and the condition of the assets and the risk appetite of the asset owner. The important progression for any utility is from a reactive to a proactive and preventive maintenance approach. The choice of technique to determine the optimal maintenance approach will be best determined by the broad objectives of the organization.

### 11.5.6 Strategy and Policy

The establishment of an asset management model in an organization is a common response to external drivers of better business performance including improved asset decision-making. Effective asset management provides the opportunity to align asset decision-making with broader organizational objectives. Optimizing asset decision-making usually relates to reliability, risk, and operational and capital investment costs.

The asset manager is required to meet corporate objectives including legislative and regulatory requirements.

This combination of potentially conflicting objectives requires the establishment of organizational policies and strategies to articulate how the various, and often conflicting, requirements will be balanced.

A powerful feature of good asset management practice is the alignment of asset activities throughout the organization, from the corporate objectives right through to the smallest asset inspection or maintenance task.

The establishment of appropriate policies and strategies becomes a tool for utilities to demonstrate this whole-of-business alignment. Examples of key asset management policies include:

- Risk management policy
- Safety policy
- Environmental policy
- Quality of supply and security policy
- Financial policy
- Procurement policy
- Employee conduct and equal opportunity policy.

Asset managers must be familiar with relevant internal company policies and understand how these affect asset management decision-making. In some cases, there may be specific asset management policies defining the approach to asset decision-making, maintenance and condition monitoring.

The usual definition of asset strategies is that they are high-level plans of action to achieve an objective

or asset policy. The development of strategy is often the responsibility of the asset manager (as is sometimes the development of policy). An asset strategy may contain the overall approach and may be complemented by more detailed asset action plans; such a strategy is important in articulating a plan for achieving a higher-level organizational objective.

### 11.5.7 Environmental Management

The general aim of substation environmental management from an asset management perspective is to reduce the environment footprint of the substation during its service life. Some of the environmental control measures are built in at the design stage and include oil/water separation systems, drainage measures and buffer zones. Other measures include ongoing site management, maintenance and operations in relation to conservation of natural resources, protection of habitats and control of hazards.

One of the challenges for substation asset owners may be older substations and equipment built to different standards than would be acceptable today. CIGRE Technical Brochure 221 provides a guide to reducing the environmental impact of substations at the design phase [11.33].

The broader movement toward the concept of sustainability means that a whole range of aspects of substation management may need to be considered, depending on organizational policy.

### 11.5.8 Whole-of-Life Management

The lifetime of a substation is typically considered to be more than 50 years, during which the substation can be expected to undergo significant changes with new (particularly secondary) equipment and expansion with new circuits and additional transformers. The substation becomes a mix of various technologies, and the age of installed equipment will range from brand-new to over 50 years.

Whole-of-life management and decision-making is an important aspect of asset management and affects the way maintenance is carried out, including refurbishment and replacements.

#### Life-Cycle Factors

A range of lifetime factors are considered when making asset decisions (such as life extension options) for substations and other assets, including:

- *Future needs*: Is the substation due for decommissioning or even complete substation replacement at some stage in the foreseeable future?

- *Fault levels:* Is the substation capable of managing current or predicted fault levels, and is the current equipment rating suitable?
- *Asset health and performance:* This usually entails a detailed assessment of the plant condition compared with network requirements.
- *Safety:* Is the equipment safe? Can life be extended safely according to current standards?
- *Costs and risk:* Are the costs and risk of life extension or refurbishment well understood?

### Asset Life-Cycle Phases

Asset life cycle includes all aspects of managing assets, from the initial concept to disposal. The substation life cycle can include up to seven phases:

1. Identification of need
2. Design
3. Construction
4. Commission
5. Operation and maintenance
6. Decommission
7. Manage residual liabilities.

Clearly, not all of these activities involve the same length of time, with the *operate-and-maintain* phase the predominant activity in terms of proportion of substation asset life. In many utilities, the aspect of substation life that attracts the most attention is the early stages of *design and construction*.

### Life-Cycle Cost Analysis

Life-cycle costing (LCC) is the most effective means of considering the financial aspects of asset management decisions. Consideration of not only the initial purchase cost but also the implications for the asset lifetime provides a more accurate picture of the value of a decision, whether a new substation purchase, implementation of new technology or a change in maintenance strategy. The general understanding of life-cycle costs is that the initial purchase price is only part of the cost of an item or project.

Life-cycle cost  
 = purchase cost  
 + installation and commissioning cost  
 + cost during asset life (including losses)  
 + cost of disposal at end of life .

The cost of operations and maintenance is a major component of the ownership cost of a long-lived substation asset. Refurbishment costs, maintenance costs including labor, tools and equipment, and spare parts and

consumables, and costs for outages, including costs associated with unavailability when an asset is out of service for maintenance or following a failure, must all be taken into account for a lifetime assessment. The initial purchase cost is relatively easy to assess and compare, whereas the lifetime and disposal costs may be more difficult to assess, particularly considering a 50-year time horizon.

The substation lifetime is also a matter of debate for any utility. There is usually a financial lifetime, typically 40–45 years determined for accounting purposes, whereas the technical lifetime may be much longer (or shorter) depending on the technology and the care taken during the life of the asset. Life-cycle cost analysis is strongly influenced by the organization's accounting approach and by the regulatory environment and the various strategies that are employed by the organization to achieve its objectives.

**Net Present Value Calculations.** Life-cycle costs can be analyzed and different options compared using discounted cash flow techniques based on the time value of money. Typically, each organization has an approach mandated by financial policies for such analysis. One common technique is to use the net present value (NPV) to analyze and compare option costs. This technique applies simple mathematics to account for the time value of money. The NPV technique can be applied in different ways. In the formula below, an initial purchase or capital investment can be compared with the savings that accrue from year to year.

$$NPV = \sum_{n=0}^T \frac{C_n}{(1+i)^n} - C_0 ,$$

where  $n$  = the year of the cash flow,  $T$  = total number of years being analyzed,  $i$  = the discount rate (determined by the organization, typically 5–10%),  $C_n$  = the net cash flow, benefit or cost in year  $n$ , and  $C_0$  = the total initial investment cost (at year 0) if applicable.

The costs should include all costs, including any disposal costs at the end of the period. If NPV is positive (or  $> 0$ ), this means that the investment adds value to the organization and the project may be justifiable from an accounting perspective. Another application for this formula is to compare a capital purchase with a lease cost, where the capital purchase is  $C_0$  and the lease costs are the costs per year ( $C_n$ ). If the NPV result is positive, it may be better financially to lease the asset rather than purchase outright.

This is an important technique for the asset manager and enables the comparison of long-term options and whole-of-life costing. There are many references

available on the application of NPV techniques for decision-making, including CIGRE TB 354 [11.34].

### 11.5.9 Condition Monitoring

One of the fundamental functions of asset management is the need to *manage risk* associated with assets. Achieving that function and actually *managing the risk* requires the manager to *understand* the level of risk, and this requires *knowledge* of the asset health or condition and taking appropriate actions in response (management) to achieve an overall objective. Condition monitoring is therefore an important function of asset management that must be undertaken for assets of any kind, and particularly in substations.

#### Goals of Condition Monitoring

One of the goals of condition monitoring is to reduce the likelihood of unplanned failure by applying tools and techniques to assess the ongoing condition of the asset and to detect changes to enable remedial actions in a timely manner. Other goals for condition monitoring include:

- Cost savings by reducing inspections or periodic monitoring
- Better utilization of staff (or working with reduced staff numbers)
- Asset risk reduction
- Better asset utilization by getting more performance out of the asset with better knowledge of the condition with time
- Asset life extension.

Condition monitoring can be periodic (diagnostic testing when needed or at predetermined intervals) or continuous, and there are now many techniques and devices available to cost-effectively monitor the condition online in a continuous manner.

#### Diagnostic Testing

The basis and the foundation of condition monitoring involves carrying out some type of diagnostic test that is appropriate for the asset type (e.g., an oil test on a power transformer). The results of this test may indicate the asset condition at the time the test was undertaken, if properly selected for that type of asset, but may require expert interpretation. An important aspect of condition monitoring is the process of taking diagnostic test results and using those results to provide an indication of asset condition and any changes with time. The condition may then be used as a trigger for remedial actions on an individual asset level (i.e., a repair or refurbishment) or to assess a group of assets to assist

decision-making for the entire population (e.g., deciding that the population needs to be replaced).

Effective condition monitoring enables the asset manager to take a more proactive rather than reactive role in managing the asset.

#### Information Management

Typically, an asset manager will manage not just one but a large number of substations, each substation with a large number of equipment items, and the condition information required to be managed effectively is extensive. Understanding the risk of the assets overall requires knowledge of the condition of all those components. The added complexity is the need to manage that information on a time basis so that a change in condition over time can be identified and action taken to avert a failure. This complexity requires the application of appropriate information management systems and business processes to manage the numerous data sources and to provide and present information so that asset decisions can be made. Information management is therefore core to an effective condition monitoring strategy for an organization. The processes of managing that information and using the information for asset decision-making are also important parts of effective asset management.

#### Capital Investments

One important aspect of condition monitoring is that online monitoring usually requires some capital investment for equipment up-front. This often includes the purchase, installation and ongoing maintenance of some type of electronic device, appropriate for the type of asset, measuring a quantity that is indicative of the asset condition or performance and fitted permanently to the asset. The NPV techniques described in the previous section may be useful for comparing options or evaluating benefits versus cost for such investment.

However, in some cases, condition monitoring can use already existing condition data sources without any new capital investment. An example of this is the use of applications such as *PI Historian* to access existing SCADA information and provide longer-term information on asset performance.

#### Condition Monitoring Strategy

A common mistake in investigating new technologies and implementing condition monitoring is failing to first consider the objectives of the organization and to establish adequate processes and systems to manage the outcomes after a decision to trial new technology is made. Some organizations have been slow to adapt to the availability of new technology and have failed to transition the organization to a new approach with

new online platforms and devices, new monitoring techniques and new information management processes. Industry best practice suggests the consideration of a *condition monitoring strategy* that articulates what the condition monitoring approach aims to achieve in terms of organizational objectives and how these processes will be implemented to achieve those objectives.

### Conclusions

Condition monitoring is core to effective risk management and ultimately to overall substation asset management. Whether continuously online, or offline and periodic, condition monitoring is necessary to fully understand the risk and performance associated with the asset fleet. A range of appropriate techniques are available for all key substation asset types, and many organizations have had good experiences with the introduction and application of online methods of continuous condition monitoring of substation equipment.

### 11.5.10 Substation Security

Substation owners have a responsibility to prevent unauthorized access to sites within their control, both to protect the infrastructure from harm and to ensure the safety of personnel who may deliberately or unwittingly attempt to enter the site. Security for substations must necessarily consider relevant local legislation, regulations, national standards and any other relevant documentation, including past legal proceedings. Physical security is fundamentally a risk management issue, and the particular security measures applied to each site will be managed according to the organization's risk assessment processes.

Physical security of substations is usually considered as three levels of control:

1. *Primary controls*  
The physical security such as fences, gates and equipment layouts to control or prevent access or contact with high-voltage equipment
2. *Secondary controls*  
Used to assist in the identification of persons, the detection of intrusion and generally to support primary control methods
3. *Procedural controls*  
Support primary and secondary controls to ensure ongoing effectiveness of controls including security policies, procedures, risk assessments, inspections and auditing.

Security for substations and other infrastructure is often considered based on the principle of *defense in depth*. The *defense-in-depth* principle is the consideration of

layers of protection to secure an asset from an external attack, with the rationale that these security layers provide an increasing barrier to penetration.

Physical security measures for new buildings and major refurbishment projects should be considered as early as possible in the predesign phase of the project.

Security risk assessments should be carried out early in the overall design process for greater effect and cost efficiency. The location and proximity of substation buildings may warrant special consideration regarding the placement of doors, locks and windows. Grounds design and vegetation can also have an impact on security.

When siting substations near roads, the likelihood of impact by vehicles should be assessed. Siting installations away from curves in roadways or behind natural vehicular barriers or the use of protective bollards will minimize the likelihood of unauthorized access following damage by vehicles.

The general security measures for the outer layer of substation security are often considered to be the substation fencing and gates, but natural barriers such as plants, rocks, moats and gullies may also provide an outer barrier to substation entry. Additionally, consideration should be given to *natural surveillance*, or the exposure of an individual trying to access the outer barrier of a substation. It is important to avoid providing natural hiding places adjacent to the substation boundary. Other measures include providing an outer lower fence and inner security fence to assist in observing unauthorized individual access in the space between the two fences (referred to as a *sterile* security space).

Fencing or walling are the primary means for preventing unauthorized access to high-voltage substations, and the design of the fence and the materials used for construction can have a major impact on the effectiveness of the fence as a security measure. An intruder-resistant fence should provide a degree of resistance to climbing or otherwise breaching by an opportunistic intruder. Obviously, a determined intruder with tools can breach any fence, and the security value may be measured by the amount of time such an intruder might take to breach the fence. Typically, the chain mesh fence with barbed wire that was often used in the past is being replaced by high-tensile-strength welded mesh or security-rated fencing materials, brick or masonry to resist unauthorized intrusion.

Fence height (including topping) is typically a minimum of 2.9 m. Tops should be barbed wire, barbed tape or razor wire with a concrete footing to limit the ability to dig underneath the fence. Electric fences with detection sensing may be considered in high-security applications. Various commercial fence types such as

palisade are available that are resistant to all but determined entry using tools.

Security measures to control the issue of locks are important, as is the selection of appropriate durable, high-security key systems and lock hardware.

Primary security may be reinforced with electronic detection systems as a secondary control measure at the substation boundary and for buildings within the substation. Closed-circuit TV, alarms and monitoring systems and various types of detection systems can be installed to detect intrusion attempts and enable a response. Adequate levels of lighting are also an important deterrent and may assist in positive identification of intruders for visual detection methods.

Public awareness of the risks of substation entry and the need to report unauthorized entry is an important aspect of substations security. Warning signs should be fitted at the boundary as a deterrent to less-determined intruders.

This section is intended to provide the reader with a general introduction to substation security, and more in-depth information is available from a variety of sources. An independent security consultant and an assessment of site security is often a useful tool in assessing the adequacy of existing security measures.

### 11.5.11 Spares Management

The effective management of risks associated with power system assets requires consideration of the level and availability of suitable spares. The spares strategy

affects the way the network and the substation are designed, particularly in regard to the level of redundancy to be included in the design.

Spares management is not just managing data and ensuring that there is a spare unit for every plant item in the substation. Substation spares management should be carried out at the network level and derived from the basic asset and risk management policies of the organization. Stock levels of essential spares should be based on the number and types of assets in the network, and must consider the strategic significance and criticality of the unit in the network, failure rate, procurement lead time and cost of the item.

Power transformers are arguably the most important and critical items within a substation. Sufficient spare transformers should be retained as spares in case of transformer failure in any substation within the network. The spare needs to be compatible with the range of locations for which it is applicable, with the appropriate fittings (bushings, connection type, shape and size) to enable replacement of a failed unit within the required replacement times.

One aspect of spares management that can be overlooked is the need to ensure that the spare equipment is adequately stored and maintained. In the case of spare power transformers, this may include periodic inspection and testing to ensure that the transformer is in good condition, and storage measures to prevent the ingress of moisture. Consideration may be given to keeping the spare energized to assist in managing moisture ingress.

## 11.6 Secondary Systems

Secondary systems are an important aspect of the overall substation performance and operations, and are used to control and monitor the operation of primary equipment, whether AIS, GIS or MTS technology. Secondary systems provide the intelligence that enables the substation to react to system demands and to safely isolate network faults external to the substation, as well as faults within the substation itself. Protection, monitoring and diagnostic functions provide ongoing assurance that the substation is healthy and operating effectively. Important functions of secondary systems include voltage and reactive plant control. Communications systems provide the necessary ability to send and receive data for control, metering and monitoring purposes.

Auxiliary systems in substations provide reliable and secure power supply in the event of extended network outages.

Condition and performance monitoring is also facilitated by secondary systems and is an important aspect of the ongoing management of the substation, especially as the majority of substations are unmanned and fully automated.

### 11.6.1 Auxiliary Systems

Auxiliary systems include the various low-voltage AC and DC power supplies required to power all of the substation equipment. The auxiliary supplies generally provide power for building and cabinet heating, lighting, battery chargers, transformer cooling fans and pumps, while the DC supplies are used for the control and protection of the plant and for tripping and closing of switchgear to clear faults. These systems need careful design to ensure reliable operation of the substation

and the ability to allow for future expansion of the substation.

### AC Auxiliary Systems

AC auxiliary systems in a substation typically consist of a transformer either connected to an external distribution system or from the tertiary of the main substation transformers. In high-criticality substations, a diesel backup generator is sometimes fitted to provide AC auxiliary in the event of a system outage. Typical AC auxiliary loads include:

- Building power and light and external switchyard lighting
- Battery charging
- Transformer tap-changer drives, cooling fans and pumps
- Cabinet heating
- Fire pumps.

The AC switchboard may be segregated to provide a more secure supply for *essential loads*, with appropriate changeover systems to allow for automatic changeover in the event of an outage of one or more incoming supplies.

### DC Auxiliary Systems

One of the most critical loads on the AC auxiliary system is the station battery chargers supplying the DC auxiliary systems. The majority of the control and protection systems within the substation are powered by the DC auxiliary system, which is designed to provide the appropriate levels of reliability and redundancy consistent with the criticality of the substation.

Battery bank nominal voltages vary according to local standards, but 50, 110, 125 and 220 V are commonly used within substations. Batteries are selected and sized to meet the *survival time* requirements of the substation. *Survival time* is defined as the length of time that the substation can perform its function in the absence of AC auxiliary supplies. Typically, this survival time is 10–12 h but may be 24 h or more in remote regions at long distances from maintenance workshops.

In smaller substations, one battery bank may be fitted, but the usual practice in most transmission substations is to install two completely separate battery banks with separate chargers and associated changeover systems. Each of these batteries feeds different sets of protection and control equipment to provide the appropriate level of redundancy for the substation. Transmission-level substations will typically have two battery banks for control and protection functions and possibly two more for communications equipment.

The most common technologies for batteries in substations are lead-acid or nickel-cadmium. Nickel-cadmium types are generally more expensive initially but have a longer life expectancy than the equivalent lead-acid types. The most common technology type currently used in new substations is *sealed* lead-acid (SLA) batteries or valve-regulated lead-acid (VRLA) batteries. Absorbed glass mat (AGM) batteries refer to a specific type of SLA/VRLA battery. Batteries are usually installed in separate battery rooms where temperature and ventilation can be controlled. The advent of sealed battery technology has meant that batteries can be safely installed in a control room and bay cabinets, but even with sealed batteries, adequate allowance for ventilation is required.

### DC Distribution in Substations

Substations can be physically large, with long DC auxiliary cable lengths, and one of the important considerations for the DC system designer is voltage drop. The nominal voltage of the bank is not the normal battery float voltage, and the designer needs to consider the rating and operating range of control and protection equipment, the effects of loss of AC power and the voltage drop during DC equipment operation at substation extremities. Typically, the DC system is arranged as a *floating* system, and neither the positive nor negative side is directly earthed, with relays arranged to detect unintentional earth faults and to raise an alarm. This isolation from earth provides a measure of safety for staff working on equipment in the substation.

Appropriate segregation of adjacent circuits is an important aspect of the planning for DC auxiliary cable routes within the substation.

## 11.6.2 Protection and Control

Protection systems are essential in ensuring that substation and external faults are detected and cleared in a discriminative manner and rapidly enough to ensure safety, maintain overall network stability and minimize equipment damage.

The design and provision of adequate protection to detect and isolate faults quickly and with discrimination is an integral aspect of the substation and, in turn, the overall power network. Protection systems incorporate many of the primary and secondary components of the substation including the instrument transformers, circuit breakers, DC auxiliary systems and the protection relays themselves.

### Basic Principles

Discrimination in protection means that when a fault is detected, the appropriate circuit breakers trip to clear

a fault, but only those necessary to isolate the fault. Appropriate discrimination in protection systems is achieved by one (or a combination) of three basic methods:

1. *Current-graded protection*  
Relies on the fact that current values under fault conditions will vary depending on the location of the fault because of the impedance between the source and the fault.
2. *Time-graded protection*  
Where relay operation may be time-delayed to allow other protection to operate first to clear the fault.
3. *Unit protection*  
Faults are detected within zones by comparison of two or more current quantities or phase angles. Unit protection does not need time grading to discriminate and can be fast-operating.

Protection systems and schemes are designed to ensure that the system will operate under all required conditions, but will *not operate* under conditions when not required to do so. Generally, this means that protection is designed to *not operate* for faults outside the protected zone. In designing a protection scheme, consideration must be given to the type and expected frequency and duration of faults that are likely, all relevant parameters of the power system and the characteristics of the protection equipment to be used. An appropriate grading margin is applied to allow for calculation and measurement errors and other variations.

Protection schemes are also designed to ensure a level of redundancy so that failure of a single protection element does not cause failure of the entire protection scheme. This can be achieved by duplication and the use of multiple sets of protection relays or overlapping zones of protection or a combination of both approaches.

The main types of protection in a substation broadly depend on the type of substation but generally include:

- Transformer protection including differential protection, thermal and other protection such as explosion and gas detection
- Busbar protection
- Feeder, line or cable protection.

An important aspect of protection schemes is current summation, where the secondaries of multiple current transformers are summated to represent the out-of-balance current (in magnitude or phase), a direct application of Kirchhoff's first law. In a busbar differential scheme, current balance is achieved when the current

into the busbar is equal to the current out. Any imbalance indicates a system fault. In other cases, the imbalance between two current transformers in a bay of a  $1\frac{1}{2}$  breaker substation may represent the line current of the circuit connected to that bay.

A direct example of current summation is power transformer differential protection. Current transformers on the primary and secondary sides of the protected transformer are usually connected to form a circulating current system. Imbalance between the primary and secondary currents, indicating a transformer fault, causes operation of the relay. Differential protection schemes are designed to allow for the transformer ratio differences between the primary and secondary, tap changer range and the vector arrangements of the transformer. Filtering is applied to unbalanced currents to allow for transient DC offset and harmonics due to transformer inrush current.

### Line Protection

Line protection schemes may also use the current summation or differential approach using current references from either end of the cable or line, although distance impedance protection is commonly used. Distance protection is a form of non-unit protection. Voltage and current references can be used to determine the apparent impedance of a line or cable as seen by voltage and current references, thus providing an indication of the location of a fault and its direction in relation to the relay. If the measured impedance is less than the reach setting and in the correct *direction*, this may indicate a fault on the protected line.

In distance protection, operating time varies depending on the apparent location of the fault providing discrimination in the protection scheme. By providing communication signals between remote ends of the line, in different scheme arrangements, high-speed relay operation and fault clearance can be achieved for line faults over the entire line section.

Typically, distance to fault (relay reach) is classified in zones, with a fault within the first 80% of the line generally considered to be in zone 1. Zone 2 reach may include the line and the remaining section of the line and beyond the next substation, or typically 120% of the protected line impedance. Zone 2 tripping is normally time-delayed to allow appropriate time discrimination for remote-end protection on adjacent lines to clear the fault.

Zone 3 is typically set to detect faults 120% beyond the second line section and is further delayed in relation to zone 2. Zone 1 tripping time is usually instantaneous, aimed at achieving overall fault clearance times as low as 1–2 cycles if possible.

**Fig. 11.37** Application of line protection between two substations (zone 1 only)

Distance relay setting can be complex, and modern relays have a large number of features and settings to be considered in each application. Protection schemes may include a number of arrangements incorporating remote-end intertripping and communications. For example, in a blocking distance protection scheme, the local relay may be set to detect distance faults beyond the remote-end substation, but a blocking signal initiated from the remote end if the fault is detected beyond the remote-end relay (seen as a fault *behind* the remote-end relay), is sent to block operation of the local relay.

In a permissive underreach transfer tripping scheme (referred to as PUP or PUTT), the relays for a line from substation A to substation B may be arranged so that a fault detected in the right direction in the remote-end relay (substation B detects a fault in the A direction) but in the zone 2 reach of the local relay (in Substation A) results in a permissive (or acceleration) signal to be sent from the substation B relay to the substation A relay giving *permission* to trip immediately, effectively accelerating the operation of the substation A relay. In Fig. 11.37 the relay at sub A has zone 1 reach set to 80% of the distance to sub B. A line fault at 90% of the line distance is within the zone 2 reach of the sub A relay, and a relay trip signal would normally be time-delayed. Using a PUTT scheme means that the relay at sub B operates when it *sees* the fault within its zone 1, trips in zone 1 time and sends a permissive signal to the relay at sub A to also trip.

This section is not intended to be a protection text, and the reader is encouraged to refer to many references for a more complete explanation of substation and line protection schemes.

### 11.6.3 Voltage and Reactive Control

Voltage on a transmission network is normally controlled by the dispatching of reactive power from generators connected to the network. Injecting more reactive power increases the system voltage, while reducing the injection or even absorbing reactive power reduces the voltage. Additional local steady-state voltage control is mainly achieved using either automatic tap changer

control on power transformers or automated reactor switching.

Automatic tap-change control schemes (ATCC) are used to control the voltage on the low-voltage side of transformers, using the busbar voltages on the low-voltage side of the transformers as a reference. Voltages outside the preset voltage limits (dead-band) initiate the operation of the transformer on-load tap changers, adjusting taps to bring the voltages within the specified limits. Tap-change timing is often coordinated using time delays to ensure that there is no interaction with other automatic tap changers, as that may cause *hunting* as multiple devices interact with each other.

Line drop compensation (LDC) may be incorporated into the automatic tap changer control system to control the voltage at the other end of a line by compensating for the voltage drop in the line.

ATCC was traditionally performed by dedicated schemes and relays. With the increasing use of computerized control systems, the ATCC function can be integrated into the control system by the use of suitable software, significantly reducing the amount of cabling on the site.

As networks become more complex, it is becoming increasingly necessary to install additional reactive plant at substations remote from major generation sources in order to control the voltage. This reactive plant may be either of the dynamic type, such as static var compensators (SVC) or static synchronous compensators (STATCOM), synchronous condensers or passive devices such as shunt capacitors or shunt reactors. When both dynamic and passive devices are connected, they are coordinated such that the steady-state voltage control is carried out by the passive devices, and the dynamic plant is kept in reserve to respond to incidents on the network such as tripping of circuits or load rejection.

### 11.6.4 Metering

Metering can be largely divided into two categories: operational metering and tariff metering. Operational metering provides the measurement of analog values such as voltage, current and frequency, and active and reactive power for the purpose of system operations,

while tariff metering ensures that the sale of electricity between different parties within the network can be performed. These two categories of metering are normally provided by separate measurement transformers and subject to different regulatory and operational requirements. In addition, there are many other monitoring functions that may be applied to improve the performance of the system including fault locators for overhead lines, fault recorders to give analog traces of fault conditions to aid in the analysis of faults, and event recorders to understand the sequence of events upon the occurrence of faults. In addition to these functions, there are cables, self-supervision of the devices and specialized condition monitoring equipment to optimize maintenance and indicate incipient faults before they become full-blown faults. Based on the measurement

scanning frequency, these monitoring functions can be divided into three categories: plant performance monitoring, fault recording and system dynamic monitoring.

### 11.6.5 Communications

The substation is part of an interconnected system for power system operations, and so there must be a means of communicating to and from the substation both between substations and to control centers. The types of information that need to be communicated include telephony for giving switching and permit information to the operators, data for providing the relevant information to the central control point, and signaling to enable the correct operation of protection. The speed and security required for each of these functions may differ.

## 11.7 Special-Purpose Substations

There are myriad different substation types used in the power industry, but there are some special design cases that have been introduced in recent years that are briefly discussed below.

The types of substations include transmission and distribution, switching stations, collector substations used for wind farms, DC substations or converter stations and traction substations. Within those broad classifications, a number of special-purpose substations have evolved to meet the needs of the industry. These include offshore substations associated with oil and gas or offshore wind farms. The remoteness of the locations for these substations and the associated difficulties in operations and maintenance means that special attention to design is required. Mobile and modular substations have been developed for fast deployment within networks or in mining or similar situations. The growth in demand and the development of megacities has led to the development of ever-increasing transmission voltages, and now UHV (ultra-high-voltage) AC and DC (> 800 kV) substations have been successfully developed and commissioned to meet the growing demand in some countries. All of these special-purpose substations require careful consideration in design and construction and in ongoing operations and management.

### 11.7.1 Mobile Substations

Mobile substations were initially developed in the mining industry. Electrical machinery for mining is often electrically driven and sometimes at high voltages. As the mining progressed, electrical loads including electrically supplied excavators, crushing equipment and

dump trucks moved to new areas of the mine. Frequently mines were depleted and the infrastructure relocated to new sites. A range of technologies were developed over time to provide the necessary portability, extending to mobile substations for the mining industry. It is believed that one of the first mobile substations was developed as early as 1937 in Italy.

Mobile substations can be broadly considered to be any transportable substation, but in this section, *mobile* refers to substations with permanently attached wheels and the ability to be towed on roads. Other types of substations that may be considered mobile are skid-mount substations and prefabricated substations.

Transmission and distribution utilities typically design networks to allow for relatively slowly changing network loads compared with the mining industry. Load forecasts enable the development of plans for new infrastructure, including new substations. If that planning is effective, then the substation is built just in time to meet the load growth requirements in a particular region. Substations are designed to provide redundancy or facilities for maintenance, so that customers are not unduly affected when a transformer or other substation plant item is removed for maintenance purposes. However, in some cases there is insufficient warning of load increases, and temporary augmentation of substation capability is required. There may not be sufficient justification or funding to permanently increase the transformer capability to allow for sufficient redundancy on a permanent basis. Also, it may be necessary to allow for emergency failures and a way to rapidly respond to an unplanned failure. In a single-transformer substation, there may be insufficient time or funding for a second transformer to provide

**Fig. 11.38** 66 kV substation using multi-voltage transformer and GIS switchgear (Courtesy Ergon Energy, Australia)

redundancy, and many utilities have implemented mobile substation technology.

A mobile substation such as the one shown in Fig. 11.38 is designed to match the requirements of the network and to provide the ability to be rapidly inserted into the substation to replace a transformer or a circuit breaker or switchboard. The design of a mobile substation requires consideration not only of the basic electrical requirements or road authority requirements for road transport, the ability of the supporting vehicle to be able to access the site within the appropriate response time. Consideration must also be given to how the mobile system will be connected, the transport restrictions and the effect of vibration and shock. A further challenge is the integration of the mobile substation into the existing substation control and protection system.

In some cases, mobile substations are built in multiple parts that must all be transported and connected on-site. In other applications, transformers are designed with multiple voltage ranges to suit a variety of substation applications, such as the one in Fig. 11.39. Mobile substations may be built using AIS, hybrid or GIS tech-

**Fig. 11.39** NOMAD mobile substation in Australia in 2006 (Courtesy Ergon Energy, Australia)

nologies. One of the significant challenges for a mobile substation designer is road authority weight and size restrictions. Mobile substations may be designed as containerized or *skid-mount*, or as fully articulated towable vehicles with permanently attached wheels, either for road or for rail. Mobile substations may also be designed for transport on planes, barges or ships.

The application of mobile substations can have significant benefits for restoration after catastrophic weather or disaster events, with the ability to rapidly replace damaged substation components. In addition, the ability to transfer customer load to a mobile substation to allow maintenance on a substation transformer may allow a utility to defer capital investment in enlarging an existing substation capability permanently or meeting temporary regional load increases.

One important aspect of the application of mobile substation design is the required connection time. If a very short connection time is required, then the site is often prepared by establishing defined connection points and spaces to allow quick installation. This may extend to the inclusion of plug and socket arrangements to enable fast connection and switched protection arrangements to readily integrate the mobile unit into the substation and the site.

### 11.7.2 Offshore Substations

The development of renewables, and wind power in particular, has spurred growth in offshore wind farms and the corresponding need to introduce more offshore substations and other transmission and distribution infrastructure. Wind farms are often located some distance from shore, and collector substations may be required to provide voltage transformation and switching to enable a reliable shore connection.

The design of offshore substations has some additional challenges for any designer beyond the basic electrical requirements that need to be addressed. The

**Fig. 11.40** A typical containerized substation being lifted off shore (Courtesy CIGRE [11.28])

most common shore connection is cable, and this may be AC- or DC-connected, often depending on the relative distance to shore and load centers.

In an offshore application such as the containerized substation module shown in Fig. 11.40, the substation is built on a platform that may be floating or fixed to the sea bottom. The designer needs to consider a range of additional issues including:

- Transport of the substation to its final resting place at sea.
- Transport of operations and maintenance staff to and from the substation—including how staff can access the site from boats.
- Emergency evacuation requirements—in the event of fire, explosion, accident or damage due to storms.
- Maintenance requirements—the frequency of maintenance may be dictated by how often staff can access the site. Daily inspections may not be feasible.
- Environmental issues associated with a marine location—marine environments have a range of hazards such as corrosion and salt spray. Potential pollution from substation operations, equipment failures and maintenance should also be considered.
- Navigation, security and other hazards associated with the remote location.

In an offshore application, the designer generally aims to reduce the size of substation assemblies, and in some cases, confined space issues may arise requiring special attention during maintenance and operations.

The remoteness of the substation and the difficulty in accessing for maintenance may create the need to consider inclusion of more condition monitoring equipment to provide early warning of problems and

planning or repairs. Further guidance on the development of off-shore substations can be found in CIGRE Technical Brochure 483 [11.35].

### 11.7.3 DC Substations

HVDC has seen an increased focus in electricity networks as the need for large power transmission grows within the interconnected power grid worldwide. New technological developments have enabled the development of higher-voltage DC systems, and more cost-effective HVDC transmission is now a feasible option along with traditional AC solutions. More substations around the world now incorporate both AC and DC; typically this has been for linear applications between two different transmission or distribution systems. The future challenge is the development of an HVDC grid and substations with DC buses or multi-circuit DC solutions.

#### Design Issues

Many of the basic substation design fundamentals are valid for both AC and DC technologies. However, the safe operation of the substation requires consideration of switching, isolation and making equipment safe for maintenance, considering issues such as management of DC current and associated electric and magnetic fields and trapped charge in DC conductors. New methods and strategies are needed to detect and clear faults, to achieve faster clearance time for DC systems (compared with AC) in order to prevent large system collapse events.

#### Standards

Work is under way on establishing standard voltages, electrical and safety distances for DC systems. This is necessary so that there is some consistency among different designs, and in the longer term, multi-vendor solutions can be safely operated together. This will also encourage competition and reduce costs, making DC more accessible and viable as a network choice.

This should also enable agreement on type tests, which will reduce the need for repeating type tests, leading to reduced costs over the longer term.

### 11.7.4 Modular Substations

Substations are traditionally built on-site using high-voltage and secondary components that are assembled, mounted, connected and tested on-site. This type of construction requires a construction team to undertake a range of on-site activities during the construction period. For remote sites, this often means that field personnel are required to live away from home in suitable accommodations, incurring attendant living and other costs. The industry is increasingly striving to achieve

**Fig. 11.41** Skid-mount substation example (Courtesy Ergon Energy, Queensland, Australia)

lower delivery costs for substations and faster delivery time, and there is a trend toward the use of modular, preassembled and tested components to reduce project costs and delivery times. Modularity is essential in some situations, such as offshore substations where it is not feasible to assemble components in the final site location, but the use of modular substations can also apply for tradition distribution and transmission scenarios in urban and rural locations.

The use of modular substation assemblies (e.g., pre-built switch rooms, switchgear bays, control rooms) and even entire substation solutions can reduce project delivery risks with respect to project management and such aspects as coordination of skilled resources and interfacing, reducing project costs. Modularity in substation design provides benefits in standardization of designs, saving design and installation time, and reducing spare parts requirements. Maintenance may also be simplified through the use of similar configurations and standardized components.

In the past, the concept of modular substations was seen as an acceptable emergency approach, but one that provided a less permanent or inferior design solution in the long term. However, with advanced design and modern materials and manufacturing techniques, modular substations can be designed to be situated in the most extreme environments, offering significant advantages over traditional construction methods, particularly in remote or challenging locations such as the skid design substation shown in Fig. 11.41.

Building substations or major parts of substations in a factory environment may eliminate many construction-related risk factors including weather, availability of skilled labor, remote access and the need for worker accommodations. Modular substations such as the one shown in Fig. 11.42 can be designed to suit a range of physical environments that may be applica-

**Fig. 11.42** Prefabricated substation example (Courtesy Ergon Energy, Queensland, Australia)

ble in high-wind, fire-risk or earthquake-prone regions. Substation components can be preassembled, prewired and pretested prior to transport to site, saving on-site assembly and testing time.

The use of modular components allows the designer to consider the application of *plug-and-play* solutions that provide the ability to add primary and secondary components as needed in future years. This may be achieved by replacing switch rooms with larger capacity on the same footprint or adding sections of preassembled components, such as a new control room with secondary equipment preinstalled, requiring only reconnection of external cabling that may be assembled using plug-and-socket connection.

A further advantage of the use of preassembled modular substations is the suitability of this method for single-supplier arrangements. Rather than dealing with a range of equipment suppliers, the use of a modular approach means that a utility can contract with one supplier for a complete turnkey solution.

Modular substations will not be suitable for every situation or voltage class, but for smaller substations, particularly distribution stations, complete substations in modular form are feasible. In larger transmission-level substations, sections such as switchgear bays or capacitor banks, control rooms or relay rooms may be suitable for this type of construction and delivery method. The modular construction and delivery approach is particularly well suited for remote and difficult locations.

### 11.7.5 UHV Substations

Ultrahigh voltage is defined as voltage levels greater than 800 kV (AC). UHV transmission has been in use to some extent since the 1980s, but mainly in research applications. The first commercial UHV transmission lines were installed in the former USSR in 1985

**Fig. 11.43** 1200 kV Bina National Test Substation, Madhya Pradesh (India), in 2013

(500 km line from Ekibastuz to Kokchetau, 400 km line from Kokchetau to Kostanay), but were later discontinued because of reliability and partial discharge issues. Further application of UHV has been carried out in China, and in 2009 the 1000 kV line between Jindongnan, Nanyang and Jinmen was placed in service. India successfully commissioned a 1200 kV substation and transmission line in 2012. Fig. 11.43 shows part of the 1200 kV Bina test station under construction.

The application of higher voltages and UHV AC and DC has been driven by an ever-increasing demand for electricity, and in some cases the development of megacities with high population densities. UHV transmission provides the ability to transmit high levels of electrical energy power efficiently over large distances using a minimum number of lines and substations.

#### Advantages and Disadvantages

UHV lines have some advantages, generally requiring less right of way to be approved for construction when compared with the equivalent energy capability and lower voltage levels. UHV has the ability to transmit large amounts of energy from one part of the electricity system to another, and this may have broad advantages as regards overall network stability, particularly in areas with a large proportion of intermittent or renewable energy sources.

However, there are also some disadvantages to be considered. For example, an air-insulated UHV substation requires a large site, and the space requirements are generally significantly higher than for lower voltages. The use of gas-insulated or hybrid insulation systems is common in UHV applications to reduce space requirements. The cost of a UHV substation is higher than that for the more conventional and common EHV, and so careful cost analysis is required to evaluate the whole-of-life cost benefits in using UHV.

#### Design of UHV Substations

One of the considerations for the design of UHV infrastructure is the need for reliability. As the UHV is used to transmit comparatively large amounts of energy, failure of a UHV component may have a significant effect on the substation and the overall network. And because UHV equipment is relatively new, there is limited experience with equipment failure and few global reliability statistics. Failure statistics for EHV equipment can be used to provide an indication of the expected reliability of UHV, enabling an assessment of the reliability of UHV equipment to assist the design process.

The UHV substation designer needs to consider adequate levels of redundancy to avoid a single failure causing a total system outage. The spares policy for the substation should consider the possible long replacement times for components that may not be *off-the-shelf* items.

The UHV substation may be designed using either AIS, GIS or some form of hybrid component insulation. Each of these options will need to be considered in relation to available land, the reliability and redundancy required, and the total project budget.

#### Transport and On-Site Testing

The components for a UHV substation are physically large, and transport to remote sites may be a challenge in the construction and installation stages of the project. Power transformers are generally the largest substation component, and a UHV transformer needs to be able to be transported to site using available roads and handling equipment. The mass and physical dimensions need to be considered.

Because of the size of the components, preassembly and pretesting of components is not feasible, as might be considered for lower voltages with comparatively small components. This means that on-site erection is required, and subsequent on-site testing is important to verify that assembly is complete and there is no transport damage.

#### Conclusions

The growth in demand for energy is expected to continue, together with a higher proportion of renewable generation sources. These trends will lead to increased application of UHV in more countries, to provide large energy transfer over greater distances.

#### 11.7.6 Railway Substations

Electric train traction systems require substations that may incorporate converters for DC traction or rotary converters for non-system frequency applications. These substations are often at distribution voltages (less than 50 kV), and apart from the AC-to-DC or

variable-frequency converters have comparable primary and secondary components to transmission and distribution substations.

A railway company may operate its own transmission and distribution network specifically to service its own power requirements for traction applications including substations, overhead lines and cables. The

nature and size of railway substations means that the application of modular buildings is feasible and is commonly used.

Protection systems and general earthing may be different from that used in traditional transmission and distribution substations, due to the nature of the power supply, the load and the rail system.

## 11.8 Trends in Substations

Substations will continue to evolve to meet changing needs. Growth in the use and application of digital techniques in substations will continue, eventually leading to better integration of components, improved reliability, higher functionality and, ultimately, lower costs. Higher levels of monitoring, artificial intelligence and increased automation will lead to *smarter substations*.

The availability of novel materials means that the design of insulation systems will continue to evolve. The advent of robotics will mean improvement in substation management and better utilization of limited human resources in managing the increasing complexity of the modern substation.

Ultimately substations are an investment for the community and still today there are many parts of the world that have no access to electricity. One of the more recent trends is to consider ways in which lower cost solutions, suitable for remote or rural communities can be implemented.

### 11.8.1 Digital Substations

One of the significant trends in substation development in recent years is the evolution from traditional substation design to the use of digital technologies. Substations are critical nodes in the overall transmission and distribution system, providing a link between generation sources and the consumers of energy. The entire network, and substations in particular, must be not only reliable but also adaptable to changing requirements as the network expands and develops to meet the needs of energy consumers. Although the lifetime of a substation site may be more than 100 years in some cases, the components inside the substation itself will change and will be replaced during that lifetime. Some components will be changed many times. In some cases, these changes will include increasing capacity to meet higher demand or increased fault levels, but changes will also include adding capability to meet new protection, automation and control requirements as the network itself becomes ever more complex.

One of the largest obstacles to the complete transition of substation design to a fully digital model is not the technology itself and the availability of expertise; it is the legacy of existing, older substations. Slow adoption of a radical new approach means that a hybrid approach is needed, with many old substations being gradually replaced with newer digital components integrated with the older technologies, and this can be challenging for designers and for ongoing operations and maintenance activities.

The advantages of digital substation technology include:

- Significantly reduced copper wiring and simpler installation
- Reduced design time and the use of design standardization
- Interoperability between devices from various suppliers
- Improved reliability
- Improved measurement accuracy and recording
- Simplified commissioning and testing
- Ease of future expansion.

Each utility is managing the transition to digital substations at their own pace and based on strategic and commercial objectives that are often different for each utility.

### Digital Components

Traditionally, substations have been constructed using individual components such as circuit breakers, instrument transformers and protection relays wired together with copper cabling. Using a digital approach, the components can be interconnected digitally using optical fiber as a communications path. IEC 61850 *Communication networks and systems in substations* [11.36] is a set of international standards governing communications, SCADA and automation systems within substations, and is the backbone and framework around which a digital substation may be built.

**Low-Power (LPIT) and Nonconventional Instrument Transformers (NCIT).** One of the most important parts of the digital substation is optical VTs and CTs used to directly convert analog primary quantities (volts and amperes) to digital signals. These are often referred to as low-power instrument transformers (LPITs), sensors or nonconventional instrument transformers (NCITs). Digital signals are not subject to secondary cabling voltage drop or to electromagnetic interference. Optical transducers may also have improved linear performance and frequency response compared with conventional instrument transformers, providing more accurate measurement of the characteristics of the primary signal. Conventional VTs and CTs can also be used in a digital substation, and a merging unit is used to convert the analog signals to digital.

**Intelligent Electronic Devices.** The core principle of a digital substation is a system of primary and secondary devices connected using optical fiber communications. In a digital substation, primary devices such as circuit breakers, tap changers, instrument transducers and secondary human-machine interfaces (HMIs), bay controllers and protection relays are all implemented as intelligent electronic devices (IEDs). IEDs communicate with each other via the 61850 communications network within the substation.

**GPS Time Clock.** An important aspect of the digital substation is accurate time synchronization between different devices and between substations. This ensures that protection functions operate correctly as part of the overall protection scheme and that event and alarm logs accurately report event timings. Time synchronization is achieved using a GPS clock transmitting time synchronization signals to all IEDs.

**Merging Units.** Merging units are used to combine signals from different measurement sources for transmission to other devices. They provide the interface between conventional analog measurement transducers and bay controllers and control and protection devices.

#### IEC 61850

The digital substation can be achieved using the principles embodied in various parts of International Standard IEC 61850 *Communication networks and systems in substations* [11.36]. This standard and its various parts defines the protocols for communications, SCADA and automation systems within substations, providing a framework from which to build the digital substation. IEC 61850 is designed to enable interoperability between different manufacturers and types of IEDs. It defines requirements for data that include protection,

automation, communication and condition monitoring functions within the substation.

#### Generic Object-Oriented Substation Event (GOOSE).

The IEC 61850 optical network within the digital substation operates using an Ethernet protocol in which traditional high-priority, time-sensitive digital signals (status, value) are transmitted (broadcast) in the form of generic object-oriented substation event (GOOSE) messages. GOOSE is a specific formatting of data enabling the fast transmission of protection status signals (less than 4 ms). The consistent high-speed transmission of signals is essential to ensuring the reliable and timely operation of interconnected IEDs (relays or circuit breakers).

#### System Architecture.

The initial implementation of IEC 61850 in the 1980s was mainly concerned with the station bus, which provided a way for various IEDs to communicate with each other. Primary devices under this scenario still used conventional instrument transformers, hard-wired to the protection relays. In 2005, IEC 61850 was enhanced to include what is referred to as the *process bus* to provide the connection between primary devices and bay controllers.

More recent standardization work within IEC 61850, in particular the harmonization with utility communications architecture (UCA), showed that this was not the only architecture that could be used. IEC 61850 therefore provides no specifications with regard to communication topology. As a consequence, IEC 61850 does not restrict any physical communication interfaces; it only specifies communication services that may be combined on a (physical) communication link according to requirements.

IEC 61850 is unique and is not a former serial link protocol adapted to TCP/IP-Ethernet. IEC 61850 was designed to operate over modern networking technologies and delivers significant levels of functionality not available from legacy communications protocols. These characteristics of IEC 61850 provide a benefit in relation to the cost to design, build, install, commission and operate power systems. IEC 61850 enables fundamental improvements in the substation automation process that is simply not possible with a legacy approach, with or without TCP/IP-Ethernet.

#### Conclusions

The technology to implement digital solutions is mature and available in the market, and will be the dominant trend in future digital substation designs. It can be expected that more manufacturers will offer primary equipment with embedded sensors and transducers. The challenge for designers is to harness

this trend economically and effectively while retaining the dependability and reliability required for a substation, and to find effective ways of integrating older technology as the transition to digital substations occurs.

There is vast potential to be realized from the existing capability of devices that form the digital substation to enable improved management of substation information and functionality, and wide area monitoring and control functions between network substations. The implementation of digital substations will provide higher reliability and enable better utilization of information regarding plant status and condition. Digital substation technology will assist in reducing the cost of infrastructure and will form an important part of the future Smart Grid.

### 11.8.2 Novel Materials

Significant step changes have occurred in the substation automation and communication aspects of substations, but the pace of change in basic primary equipment technologies has been slower. Utilities are often reluctant to be the first to try new technologies, and there must be a clear business objective in implementing changes to existing approaches.

There have been significant improvements in substation equipment technology that have come from the manufacturing industry, such as the improved reliability of circuit breakers. The key areas for future development of substations are expected to be in power electronics and energy storage.

Some of the key new technologies influencing substation equipment development are listed in the following sections.

#### Composites

Composite insulation materials in high-voltage equipment provide the opportunity to reduce weight and increase mechanical strength with more efficient fabrication techniques. This means that equipment can be safer and lower-cost, while still offer performance similar to that of *traditional* materials such as porcelain, glass, steel and concrete. A key driver for the use of composite insulation rather than porcelain is safety.

The lower mass of composite materials means that support insulators, bushings and prefabricated buildings are easier to handle and transport, resulting in faster construction times.

There is still a lack of experience with the longer-term issues associated with some types of composites, including whole-lifetime performance such as losses, maintenance burden, failure modes and effects, and compatibility with other substation materials.

#### Nanomaterials

Using nanomaterials, designers are able to optimize insulation design by eliminating unnecessary equipment components, reducing the physical footprint and reducing overall stress in service.

The use of nanomaterials provides the opportunity to enhance material performance to distribute current more effectively to reduce heating or losses, or profiling of the voltage grading to reduce the electrical stress seen on different parts during operation, enabling an overall reduction in the size, weight or functionality of the equipment. One of the earliest applications of nanomaterials was GIS spacers.

#### Superconductivity

The need to provide costly specialized auxiliary systems to support cryogenic cooling has slowed the adoption of superconductivity in mainstream electricity delivery when considered against alternative conventional technologies.

The application of superconductivity in substations worldwide has been largely associated with transformers, energy storage and fault current-limiting applications.

New risks associated with personnel handling and maintaining cryogenic material in terms of training, safety and work processes around handling will need to be considered.

### 11.8.3 Alternatives to SF<sub>6</sub>

Sulfur hexafluoride, or SF<sub>6</sub>, has been used extensively in the power industry since the 1960s in transmission and distribution systems [11.37]. SF<sub>6</sub> is a unique gas with exceptional electrical insulation and arc interruption capability. However, it also has high global warming potential (GWP) of 23 500 (100-year time horizon), and the industry has searched for alternatives, driven by environmental concerns.

The search for alternative gases [11.9] began with the establishment of the Kyoto Protocol in 1997. The characteristics of these alternative gases include:

- Lower GWP than SF<sub>6</sub>
- Low toxicity
- Nonflammable, high heat dissipation
- High dielectric strength and arc-quenching capability
- Stability and compatibility
- Availability and low cost.

The most promising naturally occurring alternative was found to be CO<sub>2</sub>, but with switching and dielectric per-

**Fig. 11.44** Patrol robot in Liantang 1000 kV Substation, China (Photo: Krieg)

formance far below SF<sub>6</sub>. Field experience has been obtained using CO<sub>2</sub>-filled switchgear, and units are commercially available for some voltages.

The most promising alternative gases appear to be fluorinated gas mixtures such as C5 perfluoroketone (CF<sub>3</sub>C(O)CF(CF<sub>3</sub>)<sub>2</sub> or C5-PFN) or iso-C4 perfluoronitrile ((CF<sub>3</sub>)<sub>2</sub>-CF-CN or C4-PFN). These gases are mixed with CO<sub>2</sub> or air as a buffer gas to achieve a sufficiently low boiling point for low-temperature requirements.

These gas mixtures appear to offer dielectric performance below that of SF<sub>6</sub> but may be feasible with derating and design modifications for use in switchgear.

An important aspect of gas alternatives is the toxicity of breakdown products. This is an issue with the

management of SF<sub>6</sub> and is also likely to be an issue for these alternative mixtures, although there is limited knowledge available to date.

The search for alternative gases as an insulating medium will continue. The identification and selection of a suitable alternative, without the disadvantages of SF<sub>6</sub>, is important to the power sector.

#### 11.8.4 Robotics

Traditional substation patrol, inspection and manual operations in substations require significant manpower, and there are issues with efficiency, consistency and quality. There are also potential safety problems for workers in severe climatic conditions such as rain, snow, fog, storm, heat and cold. With increasing demand for more intelligence in substations and unattended operation, new technologies have been developed for substation inspection and operation.

The development of robotics and drone technology in general industry has made it possible to apply this technology in the electric power industry. The robot may be used to replace or supplement human workers to complete security and equipment inspections, analysis and diagnosis, remote control, supplementary maintenance and live-line working, and other functions, to improve effectiveness and safety and thus reduce the cost and risk associated with operations and maintenance of in-service substations.

In the 1980s, a number of countries including Japan, Canada and China began research into the application of robotics in substations, and since that time there have been significant developments in robotics technology. Robots for substation inspection have become commercialized, and currently more than 900 substations in China are using robots to replace or assist human inspection (Fig. 11.44).

Given the current global business environment and heightened risk awareness, robots used in substations must meet many requirements, including functionality, environmental adaption, reliability and safety. The development of relevant standards in IEC and ISO is anticipated in the coming years, and the use of robots is expected to become more mainstream.

Terry Krieg was appointed Chairman of SC B3 (Substations) from 2012–2018. He received his Bachelor degree in Electrical Engineering from the University of South Australia, and is a Fellow of the Institute of Engineers Australia (FIEAust) and Registered Professional Engineer Queensland (RPEQ). A graduate of the Australian Institute of Company Directors (GAICD), he manages his own international consulting company, Power Network Consulting.

# HVDC and Power Electronics

Mohamed Rashwan, José Antonio Jardini

High voltage direct current (HVDC) is an economic alternative to alternating current (AC) transmission to transmit power over long overhead lines when the transmission distance exceeds 500–1000 km. It is practically the only solution for transmitting power with long underground/submarine cables or to connect two nonsynchronous systems.

Two types of converter technologies are available: the line-commutated converter (LCC) utilizing thyristor valves and the voltage-source converters (VSCs) utilizing insulated gate bipolar transistors (IGBTs).

In this chapter, these technologies are introduced together with the corresponding system architectures. Also direct current (DC) grids are introduced. DC grids will facilitate the interconnections between systems and the expansion in renewables integration in the grid.

## 12.1 History of Power Transmission

Electric power transmission was initially based on a DC system. Thomas Edison designed the world's first central electric station, which began operation in 1882 in New York. It supplied the region of the city within a radius of approximately 1.6 km from the station with DC power.

However, DC was soon replaced by AC for electricity generation and transmission because AC generators were considered to be simpler to use and it is easy to step AC up or down from one voltage level to another. These advantages made AC very convenient for trans-

mission and distribution. The development of three-phase AC further encouraged the widespread adoption of AC for power transmission.

In spite of this, some engineers remained convinced that DC could play an important role in power transmission. Those engineers soon realized the advantages of DC; for instance, the need for just one conductor instead of three simplifies the transmission line. In 1883, the French engineer René Thury developed and designed a high-voltage DC transmission system using DC generators connected in series at the sending end and a comparable number of DC motors connected in series at the receiving end. The DC motors drove low-voltage AC generators.

The most famous of Thury's plants was the Mouties to Lyon DC system. This system, commissioned in 1906, had a power rating of 4.5 MW, which was transmitted for a distance of 180 km at a DC voltage of 60 kV. The system was expanded around 1912 such that it transmitted 19.3 MW at a transmission voltage of 125 kV. The Thury system remained in operation until the mid thirties.

In 1922, a link across the Skagerrak between Norway and Denmark was discussed for the first time. A Thury system was considered for this link, at a rated power of 42 MW and a transmission voltage of 110 kV DC.

Research into HVDC transmission continued. Even though the principle of the Thury system had been proven, the conversion of AC to HVDC and vice versa was considered to be the most desirable approach.

Mercury arc valves for low-voltage applications became available in the late 1920s. In the early 1930s, Uno Lamm developed a mercury arc valve for high-voltage applications. This development led to the construction in 1954 of the first converter-station-based HVDC link, the Gotland HVDC link, which was rated at 100 kV DC.

The development of HVDC based on this converter technology led to an expansion in the use of HVDC. Between 1954 and 1972, eleven systems were constructed with a highest rating of 1800 MW and  $\pm 450$  kV in a bipolar configuration, all of which utilized mercury arc valves.

The first HVDC system using thyristor valves was constructed in 1972 between Hydro Quebec and New Brunswick (the Eel River back-to-back HVDC link) in Canada. The valves were air cooled and the scheme was rated for 320 MW. In 1978, the first water-cooled thyristor valve was introduced in the Nelson River HVDC system in Canada, with a DC voltage of  $\pm 500$  kV.

The introduction of thyristor valves encouraged the application of HVDC in power transmission projects. Since 1972, the DC voltage of a single bipolar HVDC link has increased to  $\pm 800$  kV, and the power rating to 8000 MW. Recently, HVDC at  $\pm 1100$  kV and 12 000 MW was introduced.

Until 1997, HVDC converter stations were based on line-commutated converter (LCC) technology. This technology utilizes the features of high-power, high-voltage thyristors, which do not have the ability to be

**Table 12.1** Characteristics of LCC and VSC systems

Function	LCC	VSC
Semiconductor device	Thyristor devices are presently 4, 5, and 6 inches in size, and have a rating of 8.5 kV and 6300 A	IGBTs with an antiparallel freewheeling diode and an ability to be turned off when desired. Current rating 4.5 kV and turn-off current of $\approx 2000$ A
DC transmission voltage	$\pm 1100$ kV with an overhead transmission line and up to $\pm 600$ kV with a mass impregnated polypropylene laminate (PPL-MI) cable	Up to $\pm 500$ kV with an overhead transmission line or a cross-linked polyethylene (XLPE) cable
DC power	Up to 12 000 MW on a single bipole and a DC voltage of $\pm 1100$ kV [12.1]	Up to 2000 MW at $\pm 500$ kV
Reactive power requirements	Consumes up to 60% of its rating reactive power at each terminal	Does not consume any reactive power, and each terminal can independently control its reactive power
Filtering	Requires large filter banks	Requires moderately-sized filter banks or no filters at all
Black start	Limited application	Capable of black starts and feeding passive loads
AC system short-circuit level	Critical to the design	Not critical
Commutation failure performance	Commutation fails in the event of AC and DC disturbances in a bipolar system	No commutation failure
Load rejection overvoltage	Large, and has to be mitigated because of the large reactive power support	Not large due to the small size of the filters (if required)
Footprint	Large due to the size of the filtering and reactive power support equipment	40–50% of the size of a LCC system with a similar rating
Power losses	Approximately 0.65–0.7% of the station rating	Approximately 0.85–0.9% of the station rating

turned off on demand. However, in 1997, the voltage-source converter (VSC) was used for the first time (in the Hellsjön experimental project, at a moderate rating of 10 kV and 3 MW). In contrast to thyristors, VSCs are semiconductor-based devices that can be turned off on demand, which has distinct advantages for certain ap-

plications. The VSC device of choice is presently the insulated-gate bipolar transistor (IGBT).

Therefore, the HVDC industry currently has two technologies to choose from: LCC and VSC systems. Each has its own characteristics that makes it suitable for specific applications, as shown in Table 12.1.

## 12.2 Applications of HVDC

There is a continuous debate in the industry whether to utilize HVDC or AC for a specific project. It is important to choose the most appropriate technical and economic solution (AC or HVDC) for a particular application [12.2]. We now consider some important applications of AC and HVDC.

### 12.2.1 Long-Distance Transmission Using an Overhead Line

This application can involve either the connection of two AC systems or the transmission of bulk power over a long transmission distance. AC and DC transmission systems are competitors for this application, and the transmission distance plays an important role in the analysis and selection of the most suitable technology.

A HVDC line utilizes only two conductors at plus and minus polarities for a bipolar system and is therefore cheaper to construct than an AC line of the same capacity, which requires three conductors. In HVDC, there is a need for converter stations at each end of the transmission line, so the total cost of the scheme consists of the cost of the transmission line plus that of the converter stations. Even at a transmission distance

of zero, the cost of the converter stations must still be factored in for HVDC; however, due to the lower cost of the HVDC line than the AC line, the cost of the HVDC system does not increase as rapidly with transmission distance than the AC system. This is because the HVDC has less conductors and the AC lines require compensation elements when the transmission distance is sufficiently large, and these elements must be factored into the costs of the system. Therefore, HVDC will begin to be economically advantageous compared to AC beyond a certain distance, referred to as the breakeven distance (Fig. 12.1). This distance depends on the cost of the line in a particular jurisdiction. The comparison is even more complicated if the AC line needs to be series and shunt compensated, as depicted in Fig. 12.1.

The CIGRE technical brochure TB 388 (published in 2009), which discusses the impacts of HVDC lines on the economics of HVDC projects, is a valuable document in this regard [12.3].

Figure 12.2 shows a comparison of the tower dimensions of a 500 kV HVDC bipolar line with those of a 500 kV double-circuit AC line.

When utilizing HVDC to transmit bulk power from a remote isolated generator that has no local load connected to its busbar, it is possible to select the generation frequency independent of the typical system frequency. In addition, larger frequency excursions can be accepted at the generating station. Such a system is shown in Fig. 12.3.

Fig. 12.1 Cost comparison of AC versus DC systems

### 12.2.2 Transmission via Cables

Due to the structure of an insulated cable, it exhibits a high capacitance and low inductance compared to an overhead line. Under AC conditions, this high cable capacitance results in an increased reactive charging current that increases with the transmission voltage. Obviously, the cable capacitance also increases with transmission distance. All of these factors limit the power that can be transmitted by cables.

HVDC has the advantage that there is no further charging current once the cable capacitance is charged.

Fig. 12.2 Tower dimensions

Fig. 12.3 Point-to-point transmission

Fig. 12.5 Connecting systems with different frequencies

Fig. 12.4 HVDC transmission using cables

This means that there is no limitation on either the voltage or the transmission distance (Fig. 12.4).

### 12.2.3 Transmission Between Nonsynchronous AC Systems

When it is necessary to connect two nonsynchronous AC systems (e.g., a 50 Hz system to a 60 Hz system), the only technical practical way to achieve this is via HVDC, as shown in Fig. 12.5.

### 12.2.4 Integration of Renewable Offshore Wind Resources

There seems to be a drive to position wind power plants further offshore (Fig. 12.6) [12.5]. This means that increasingly long power cables are being used to connect these offshore wind power plants to the shore. As described earlier, long AC cables are not a practical solution. Therefore, HVDC is a practical alternative for bulk power transmission from offshore wind plants. There are challenges in this regard relating to the efficient use of space on the offshore platforms (Fig. 12.6) as well as the interactions of the HVDC controls with the wind farm controllers. Further, special measures are needed to deal with mechanical stresses caused by the sea conditions, wind, and corrosion out on the open water. Having said that, many projects based on offshore platforms have been already implemented.

Fig. 12.6 Offshore arrangement [12.4]

## 12.3 HVDC System Configuration

Both LCC and VSC HVDC systems can be configured in many ways depending on the application and the economics involved.

### 12.3.1 Bipolar System

In this configuration, a positive pole and a negative pole are connected to a bipolar transmission circuit [12.6]. The transmission circuit can be an overhead line, a HVDC cable, or a combination of both. The bipolar configuration can use LCCs or VSCs. It can also be implemented with one LCC pole and one VSC pole. In a bipolar configuration, the high-voltage (HV) terminal of each converter is connected to the transmission circuit, and the neutral terminal is connected to an electrode via an electrode line or a low-voltage metallic return conductor.

The electrode can be a ground electrode or a sea or shore electrode, as shown in Fig. 12.7. Another alternative is to connect the neutral (N) terminal to a dedicated metallic return (DMR) conductor, as shown in Fig. 12.8. Such an arrangement is considered if electrodes are not an acceptable solution either technically or for environ-

mental reasons. In a typical bipolar scheme, the DC current is the same at the two poles. Therefore, no DC current will flow in either the electrodes or the DMR. When the currents at the two poles are unbalanced, the difference in current will flow in the electrodes or the DMR.

Obviously, if only one pole is in operation, the other pole can still operate at full DC current and DC voltage capacity, and the DC current return path involves either the electrodes or the DMR. This is referred to as monopolar operation.

During monopolar operation of a bipolar HVDC system with electrodes, the full DC current will flow continuously in the electrodes. This mode of operation was allowed in many early HVDC systems, but monopolar operation with DC current flowing in the electrodes for a prolonged duration is avoided in most modern HVDC systems. This is achieved by adding a switching arrangement at the neutral end of the bipole to divert the DC return current to the other pole conductor. This is referred to as metallic return operation.

The switching arrangement is shown in Figs. 12.9 and 12.10. Figure 12.9 depicts normal bipolar opera-

Fig. 12.7 Bipolar HVDC system with ground return

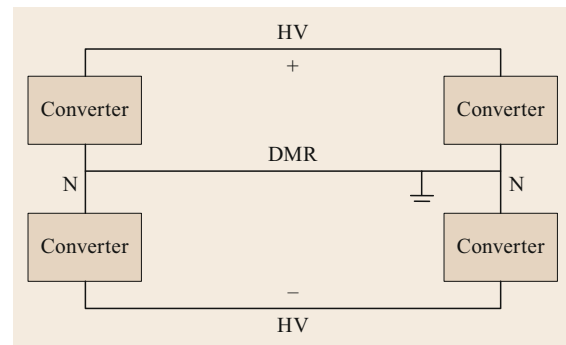

Fig. 12.8 Bipolar HVDC system with metallic return

Fig. 12.10 Monopolar transmission

Fig. 12.13 Open MRTB. Monopolar transmission with metallic return

tion with equal DC currents at the two poles, whereas Fig. 12.10 shows bipolar operation with just one pole and DC current flowing in the electrodes.

The additional switches required to shift from monopolar operation with electrode return to monopolar operation with metallic return are shown in Fig. 12.10. Two types of switches are required, the metallic return transfer breaker (MRTB) and the ground return transfer switch (GRTS). These two switches are not DC breakers but commutating switches, as shown in Fig. 12.11. In principle, when the switch is closed, a DC current  $I$  is flowing through breaker  $S$ . When the switch is commanded to open, breaker  $S$  opens and draws an arc that excites the series combination of  $L$  and  $C$  into oscillation at a specific frequency and forces the current in  $S$  to zero. The current is diverted to the absorber  $Z$  (ZnO), which must dissipate the energy.

Upon closing the GRTS, the metallic conductor at the pole is connected in parallel with the electrodes, and

Fig. 12.11 Metallic return transfer breaker (MRTB)

the DC current is shared according to the relative resistances (Fig. 12.12).

Upon opening the MRTB, the full DC current at the pole flows in the metallic return at the pole (Fig. 12.13).

### 12.3.2 Monopolar System

In this configuration, the system contains only one pole of either polarity. The transmission circuit can be an overhead line, a HVDC cable, or a combination of both. This configuration can be used with LCCs and VSCs. In this configuration, the HV terminal of each converter is connected to the transmission circuit and the neutral (N) terminal is connected to an electrode via an electrode line (Fig. 12.14). The electrode can be a ground electrode or a sea or shore electrode.

Fig. 12.14 Monopolar transmission with earth return

## 12.4 Converter Pole Configuration

There are many ways to arrange the converters in a HVDC station. The choice of a particular converter arrangement is dictated by the rating of the HVDC system as well as reliability and availability requirements.

### 12.4.1 Single Converter Per Pole

Here, in principle, there will be only one converter per pole at each end of the transmission. This converter can be either a LCC or a VSC. This configuration can also be realized with a LCC at one station and a VSC at the other station. The single converter per pole concept is utilized in many LCC- and VSC-based HVDC systems. It is clear that, in such a configuration, any converter outage will result in a pole outage. However, this issue can be overcome by utilizing the built-in capacity for converter overload at the healthy pole in a bipolar system.

### 12.4.2 Two Converters in Series Per Pole

In this case, two converters in each station are connected in series at each pole, as shown in Fig. 12.15. The typical arrangement is that the two converters in series have the same voltage rating, but unequal voltage ratings are also possible. The DC current is the same in the two converters; therefore, in the equal voltage rating case, each converter is rated for half the pole power, and in a bipolar system it represents 25% of the bipole rating. An outage of a converter at any pole will cause the pole to operate at only 50% of the DC voltage. In an arrangement with converters in series, additional equipment (such as bypass switches) is needed to allow the operation of a single converter at the pole. Such an arrangement is utilized in ultrahigh-voltage direct current (UHVDC) to achieve the high DC voltage;

**Fig. 12.15** Two converters connected in series per pole

for example, at  $\pm 800$  kV, each converter will be rated for 400 kV [12.7–9]. It is also utilized in some HVDC systems at lower voltages ( $\pm 500$  kV) when the contingency of a pole outage based on a single converter per pole design is not acceptable. In addition, this type of arrangement can be utilized to construct a HVDC project in several stages in order to spread the development costs or if the full rating is not required from the start. The converters connected in series can be LCCs, VSCs, or a LCC and a VSC.

The bypass switches employed in series converters are not DC circuit breakers; they are typically high-speed switch with no DC current interruption capability. Therefore, a special control process to allow the bypass switch to open at zero DC current is required when starting up the series-connected converters.

### 12.4.3 Two Parallel Converters Per Pole

In this arrangement, two converters in each station are connected in parallel at each pole, as shown in Fig. 12.16. The two converters will have the same DC voltage rating but can have equal or unequal DC current ratings. In this configuration, an outage of the converter will lead to a loss of only 50% of the pole power or 25% of the bipole rating in the equal ratings scenario.

An outage of a converter at a pole will lead to the pole operating at full voltage but reduced DC current. Such an arrangement is utilized in UHVDC to achieve high DC current ratings at the maximum possible DC voltage if the current required is higher than the rating of a single converter per pole. High-voltage, high-speed switches (HVHS) are typically connected in series to each converter to enable the rapid isolation of one converter and continued pole operation with a single converter.

**Fig. 12.16** Two parallel converters per pole

This type of arrangement can be also utilized to construct a HVDC project in several stages to spread the development costs or if the full rating is not required from the start. In this case, each stage is operating at the nominal pole voltage. The parallel converters can be LCCs, VSCs, or a LCC and a VSC.

#### 12.4.4 Staging

One advantage of HVDC is that the project can be constructed in stages. Staging is useful if there is no need

for the full HVDC rating from the start. Typical staging options are as follows:

- In a bipolar HVDC system with a single converter per pole, one pole is constructed first and the second pole is added at a later stage.
- There are many options for a bipolar system with series- or parallel-connected converters at each pole. For example, a single converter could be used per pole initially, and other converters could then be added to the poles in stages.

### 12.5 Line-Commutated Converter (LCC) Fundamentals

In Fig. 12.17, the DC current in the circuit is only a function of the difference between the two DC voltages  $U_{d1}$  and  $U_{d2}$  of the rectifier and the inverter, respectively, as well as the ohmic resistance of the line  $R$ . Thus,

$$I_d = \frac{U_{d1} - U_{d2}}{R}.$$

The DC power  $P_r$  at the sending end (rectifier) =  $I_d U_{d1}$ .

The DC power  $P_i$  at the receiving end (inverter) =  $I_d U_{d2}$ .

The difference between  $P_r$  and  $P_i$  is the loss in the transmission circuit.

It will be shown later that neither  $U_{d1}$  nor  $U_{d2}$  are dependent on the frequency or the phase angle between the two AC systems, which is a significant advantage when connecting two asynchronous systems.

Reactive power cannot be transmitted over the HVDC link. Therefore, one AC network does not contribute short-circuit power to the other AC network.

#### 12.5.1 LCC Operation (Rectifier Operation)

LCC technology is based on the six-pulse bridge shown in Fig. 12.18 [12.2, 10].

As shown in Fig. 12.18, there are six controlled thyristor valves in the bridge. These valves can be turned on but not off, and they act as unidirectional switches. Each valve can only turn on if its anode is more positive than its cathode and a trigger pulse is ap-

Fig. 12.17 Electrical circuit of a LCC

plied to the thyristors. There are two valves for the R phase and two for each of the other two phases.

The valves are arranged in two groups. The cathodes (C) of three of the valves are connected together and are referred to as the cathode valves; the other three have their anodes (A) connected together, and are referred to as the anode valves.

In this six-pulse bridge, the valves are turned on (triggered) sequentially, with two valves conducting at any particular moment in time to complete the current path, as shown in Fig. 12.19. The six valves are

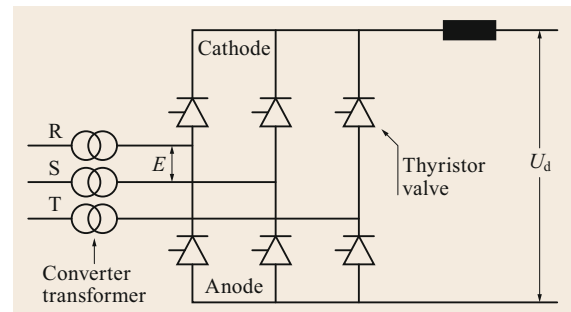

Fig. 12.18 Rectifier operation

Fig. 12.19 Two of the valves (1 and 2) in the six-pulse bridge conducting at a particular instant

**Fig. 12.20** Commutation of valve 1 to valve 3

**Fig. 12.21** Valves 2 and 3 conducting

triggered once per fundamental frequency cycle, which means that the six-pulse bridge operates at a frequency of six times the fundamental frequency of the AC system. One valve is triggered every  $60^\circ$ . This means that if we start with valve 1, valve 2 will be triggered  $60^\circ$  later, and so on. Each of the valves will carry the current for  $120^\circ$ .

The current for the cathode valves shifts between valves 1, 3, and 5. The current for the anode valves shifts between valves 2, 4, and 6. Under normal operating conditions, no two valves in the same phase (e.g., valves 1 and 4) can conduct at the same time, as this would produce a short circuit at the DC terminals and result in  $U_d = 0$ .

When valve 1 is conducting, the current is flowing in the R phase to the load. It returns through valve 2 to the T phase, and the voltage RT is applied to the DC line. When valve 3 is triggered, the current is passed as shown in Fig. 12.20. The sharing of the current between valves is referred to as the commutation process.

When the current in valve 1 is completely commutated to valve 3, valve 3 carries all of the current, as shown in Fig. 12.21. Note that the voltage in the DC line is then ST.

The same commutation process occurs between valves 2 and 4 and the remaining valve.

By controlling the moment that a valve is triggered relative to the zero crossing, the DC voltage  $U_d$  can be

**Fig. 12.22** Commutation instants at phase-to-phase zero-voltage crossings

controlled. As shown in Fig. 12.22, zero voltage crossings occur for each valve as follows:

- Valve 1 is connected between phases R and T
- Valve 2 is connected between phases S and T
- Valve 3 is connected between phases S and R
- Valve 4 is connected between phases T and R
- Valve 5 is connected between phases T and S
- Valve 6 is connected between phases R and S.

Therefore, individual valves can be triggered at zero crossings. If valve triggering is delayed by a time (also known as a firing or delay angle)  $\alpha$ , as shown in Fig. 12.23, the average voltage (taking  $I_d = 0$ ) on the DC side is

$$U_d = \frac{3\sqrt{2}}{\pi} E \cos \alpha = 1.35E \cos \alpha,$$

where  $E$  (Fig. 12.18) is the line-to-line AC voltage applied to the valve.

It is clear that the DC voltage can be modified by changing  $E$ ,  $\alpha$ , or both. The maximum DC voltage is obtained at  $\alpha = 0$ , and the average DC voltage is zero at  $\alpha = 90^\circ$ .

The term  $(3\sqrt{2}/\pi)E$  is referred to as the ideal no-load direct voltage or the open circuit voltage of the converter  $U_{dio}$ .

Earlier in the discussion, we introduced the commutation process, which was assumed to occur instantaneously. However, this is not realistic, as it would disobey the laws of physics due to the inductance in

Fig. 12.23 Commutation instants with a firing angle of  $\alpha$

Fig. 12.24 Overlap and firing angles for rectifier DC voltages

the circuit. Because of the inductance in the commutation path, the commutation of the current from, say, valve 1 to valve 3 will take a finite amount of time. There will then be an overlap where the current will decay to zero in one path (for valve 1) and rise to its steady-state value in the other path (for valve 3). This period is referred to as the overlap angle  $\mu$  (Fig. 12.24).

This angle depends on the inductance in the circuit. There are several inductances in the circuit, but the transformer reactance dominates. The inductance in the circuit is referred to as the commutating reactance  $X_C$ . Naturally, the overlap angle  $\mu$  is also a function of the value of the DC current. The higher the DC current in the circuit, the longer it takes to commutate from one valve to another.

The impact of the commutation process and the overlap angle  $\mu$  is to reduce the output DC voltage  $U_d$  of the converter, as shown in Fig. 12.24. If  $\mu$  is zero, which means that  $X_C$  is zero too, the DC voltage only depends on  $\alpha$  in Fig. 12.24.

From Fig. 12.24, it is clear that during the period  $\mu$ , the voltage at the upper pole is

$$\frac{\dot{V}_R + \dot{V}_S}{2} = -\frac{\dot{V}_T}{2}.$$

The commutation process and the resulting  $\mu$  reduces the DC voltage of the converter during rectifier operation according to the following

$$\begin{aligned} U_d &= \frac{3\sqrt{2}}{\pi} E \cos \alpha - \frac{3I}{\pi} X_C \\ &= \frac{1}{2} U_{\text{dio}} [\cos \alpha + \cos (\alpha + \mu)], \end{aligned}$$

$$U_d = U_{\text{dio}} \cos \alpha - \frac{3I}{\pi} X_C.$$

The above equations can also be written as

$$U_d = U_{\text{dio}} \left( \cos \alpha - d_x \frac{I_d}{I_{dN}} \frac{U_{\text{dio}N}}{U_{\text{dio}}} \right),$$

where  $N$  refers to rated values and  $d_x$  is the commutation reactance (p.u.)

$$d_x = \frac{3I}{\pi} X_C \frac{I_{dN}}{U_{\text{dio}N}}.$$

### 12.5.2 LCC Operation (Inverter Operation)

As discussed earlier, the DC voltage is zero at a delay angle of  $90^\circ$ . If we increase the delay angle  $\alpha$  beyond  $90^\circ$ , the resulting DC voltage will be negative.

During inverter operation, both  $\alpha$  and the overlap angle  $\mu$  have the same definitions as before, but there is another angle  $\gamma$ , the extinction angle, that is important too. In order to define this angle, it is necessary to understand phenomena associated with the valve conducting current.

The valve turns off when the current in the thyristors falls below a critical level referred to as the holding current. The anode current falls at a certain  $dI/dt$  to zero and then continues to move to a negative value in the reverse direction by the application of a reverse voltage. A reverse current will continue to flow until all of the excess stored charge is removed from the thyristors. If a forward voltage is reapplied to the valve soon after the current has passed zero, the thyristor will turn on again. However, if sufficient time is allowed for all of the stored charge to be removed by the reverse voltage, the forward voltage can be reapplied. It is important to note that the voltage distribution across the series-connected thyristors is not ideal under such conditions. The turn-off time is defined as the time taken for the voltage across the thyristor to turn positive after the anode current has passed through zero. For defining the extinction angle  $\gamma$  it is necessary to take into consideration the turn-off time of the thyristors and any sudden

**Fig. 12.25** Firing, overlap, and extinction angles during commutation from valve 1 to valve 3

**Fig. 12.26** Inverter operation and the resulting DC voltage of the converter

increase in the DC current as well as any sudden drop or shift in the AC voltage due to AC disturbances.

The angle between the end of the current in the valve and the start of the voltage going positive is referred to as the deionization period or extinction angle  $\gamma$ . The angles  $\alpha$ ,  $\mu$ , and  $\gamma$  are related in the following manner

$$\alpha + \mu + \gamma = \pi,$$

and  $\gamma + \mu = \beta$ , as shown in Fig. 12.25.

The following inverter equations can be defined in a similar way to the rectifier equations

$$\begin{aligned} U_d &= \frac{3\sqrt{2}}{\pi} E \cos \alpha - \frac{3I}{\pi} X_c \\ &= \frac{1}{2} U_{dio} [\cos \alpha + \cos (\alpha + \mu)], \\ U_d &= \frac{3\sqrt{2}}{\pi} E \cos \alpha - \frac{3I}{\pi} X_c \\ &= \frac{1}{2} U_{dio} [\cos \alpha + \cos (\alpha + \mu)], \\ U_d &= \frac{1}{2} U_{dio} \{ \cos [\pi - (\mu + \gamma)] + \cos (\pi - \gamma) \} \\ &= \frac{1}{2} U_{dio} [\cos (\gamma) + \cos (\mu + \gamma)], \\ U_d &= \frac{3\sqrt{2}}{\pi} E \cos \gamma - \frac{3I}{\pi} X_c = U_{dio} \cos \gamma - \frac{3I}{\pi} X_c. \end{aligned}$$

Or

$$U_d = U_{dio} \left( \cos \gamma - d_x \frac{I_d}{I_{dN}} \frac{U_{dioN}}{U_{dio}} \right).$$

The rectifier and inverter DC voltage equations are similar except that  $\alpha$  is replaced with  $\gamma$  (Fig. 12.26).

### 12.5.3 Application Example and Basic Control

The equations used to determine the conditions in a LCC HVDC system were listed earlier but are repeated here for the sake of clarity.

#### Combined Equations

For the rectifier,

$$U_{dR} = U_{dioR} \left( \cos \alpha - d_x \frac{I_d}{I_{dN}} \frac{U_{dioN}}{U_{dioR}} \right).$$

For the inverter,

$$U_{dI} = U_{dioI} \left( \cos \gamma - d_x \frac{I_d}{I_{dN}} \frac{U_{dioN}}{U_{dioI}} \right).$$

For the line,

$$I_d = \frac{U_{dR} - U_{dI}}{R}.$$

Additional equations to determine other values are now presented.

For the overlap angle,

$$\begin{aligned} \mu_R &= \arccos [\cos (\alpha_R) - 2d_{xR}] - \alpha_R, \\ \mu_I &= \arccos [\cos (\gamma_I) - 2d_{xI}] - \gamma_I. \end{aligned}$$

For reactive compensation,

$$\tan (\varphi_R) = \frac{2\mu_R + \sin (2\alpha_R) - \sin (2\delta_R)}{\cos (2\alpha_R) - \cos (2\delta_R)},$$

$$\begin{aligned} \delta_R &= \alpha_R + \mu_R, \\ Q_R &= P_R \tan (\varphi_R), \end{aligned}$$

$P$  and  $Q$  represent the active and reactive power, respectively, while the subscripts R and I correspond to the rectifier and inverter, respectively.

The remaining variables are the same as those described previously

$$\tan(\varphi_I) = \frac{2\mu_1 + \sin(2\gamma_1) - \sin(2\delta_1)}{\cos(2\gamma_1) - \cos(2\delta_1)},$$

$$\delta_I = \gamma_1 + \mu_1,$$

$$Q_I = P_I \tan(\varphi_I).$$

### Example

Consider the following example based on the Brazilian Rio Madeira HVDC project:

- Power per bipole: 3000 MW (in the rectifier)
- One 12-pulse bridge per pole
- Rated voltage:  $\pm 600$  kV
- Rated rectifier angle:  $\alpha = 15^\circ$
- Minimum rectifier angle:  $\alpha = 5^\circ$
- Rated inverter minimum angle:  $\gamma = 17^\circ$
- $d_x = 0.09$  p.u.
- Line resistance:  $15 \Omega$
- AC system voltage: 500/550 kV (both sides)
- Rated current:  $3000/(2 \times 600) = 2.5$  kA

The aim is to calculate the rated condition values.

In a point-to-point LCC system, one converter (generally the inverter) controls the DC voltage, and the other controls the DC current.

On the rectifier side, for a six-pulse bridge, the values are

$$U_{dR} = U_{dioR} \left( \cos 15 - 0.09 \frac{1}{1} \right),$$

$$U_{dioR} = 342.5 \text{ kV} = 1.35 E_R,$$

$$E_R = 253.7 \text{ kV}.$$

The nominal ratio of the transformer should therefore be 500/253.7.

Note that an on-load tap changer (OLTC) should be included to take care of loading variation at the high-voltage side of the transformer. This should have an appropriate tap range, which can be achieved using a small step:

The overlap angle  $\mu = 23.19^\circ$ .

The reactive power is 1606 MVAR.

The voltage in the inverter and other values are as follows

$$600 - 15 \times 2.5 = 526 \text{ kV per pole},$$

$$P_I = 2812 \text{ MW},$$

$$U_{dioI} = 324.7 \text{ kV},$$

$$E_I = 240.5 \text{ kV}.$$

The overlap angle  $\mu = 22.08^\circ$ .

The reactive power is 1583 MVAR.

### Working Principle

In a point-to-point LCC system, one converter controls the DC voltage (typically the inverter) while the other (the rectifier) controls the DC current. The general principle is shown in Fig. 12.27.

In the steady state, the insertion of  $I_{\text{margin}}$  ( $\Delta I_d = 10\%$ ) into the inverter loop control leads to the requirement that  $\gamma_d$  is larger than  $\gamma_{\text{min}}$ . The value of the latter is chosen and thus defines  $U_{dI}$ . Consequently, the inverter voltage can be controlled.

Now, suppose that the AC voltage of the rectifier is reduced for any reason. This will cause a reduction in  $U_{dR}$ , so  $\alpha_r$  will decrease to compensate provided that it is not below  $\alpha_{\text{min}}$ , in which case the OLTC will act to increase the AC voltage in the rectifier, pulling  $\alpha_r$  up to the rated value.

Conversely, suppose that the AC voltage in the inverter drops. The value of  $U_{dI}$  will then decrease, so  $I_d$  will tend to rise and  $\alpha_r$  will increase to maintain the current.

These two operational assumptions are just examples, and it should be noted that the LCC control system has other features that will be described later.

### 12.5.4 Peak Rectification

Peak rectification, also referred to as amplitude rectification, occurs in any converter with no load [12.10]. The ideal no-load voltage was defined earlier as  $U_{dio} = (3\sqrt{2}/\pi)E$ . However, the true no-load voltage will be higher because the converter can charge the circuit capacitance on the DC side during an open circuit. While it is being charged, the capacitance will also discharge through the high leakage resistance in the DC circuit. If the time constant for the discharging of the capacitance is longer than the time between converter voltage peaks, the circuit capacitance will recharge to a higher value, which explains why this behavior is referred to as peak or amplitude rectification. The circuit capacitance discharges in an exponential manner.

Peak or amplitude rectification will occur in any open-circuited converter, even at firing angles that are slightly higher than  $90^\circ$ . This phenomenon is utilized in HVDC systems during open-circuit testing of the converter station or DC transmission circuit. It can also be used for the precharge function in multiterminal HVDC systems.

### 12.5.5 Changing the Power Direction in LCC Converters

In LCC technology, the DC current direction is always the same because thyristor valves can only carry cur-

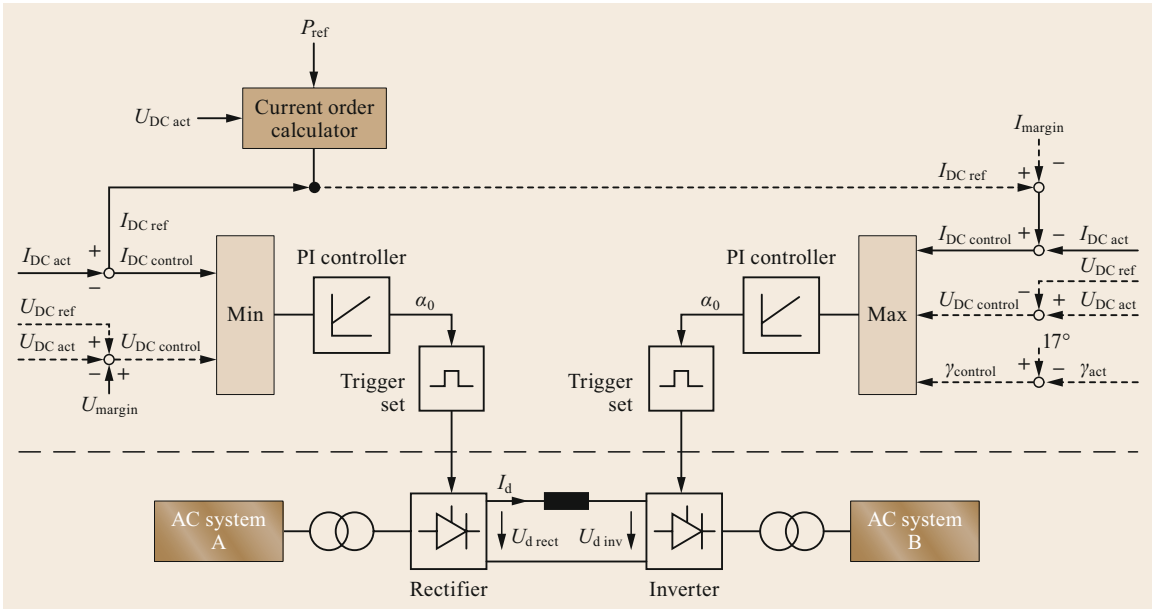

Fig. 12.27 Working principle of a point-to-point LCC HVDC system

Fig. 12.28 Reversing power to the negative pole in an intermediate converter. During the reversing process, the  $S_1$  switches are closed while the  $S_2$  reversing switches are open; the  $S_1$  switches are then opened and the  $S_2$  reversing switches are closed

rent in one direction. Therefore, in order to reverse the power direction in a two-terminal HVDC system, the DC voltage polarity is reversed but the direction of the DC current remains the same. In a multiterminal HVDC system, if all of the terminals reverse their power directions, then the direction of the current remains the same but the voltage polarity is reversed.

However, if only one terminal in a multiterminal system changes its power direction, it must still change its voltage polarity [12.11]. Since it is connected to a pole of opposite polarity, reversing switches are required, and the converter will have full insulation at both of its terminals, as shown in Fig. 12.28.

### 12.5.6 Harmonics

#### Characteristic Harmonics

Cyclic triggering of the valves in a six-pulse bridge produces harmonics [12.2, 10]. Both the output DC voltage and the currents that appear in the valve-side phases of the transformer contain certain characteristic harmonics that are produced whether the converter is operating as a rectifier or an inverter.

#### AC Current Harmonics

Assuming that the AC system is perfectly symmetrical, there is no imbalance in the commutating reactor  $X_C$ , or equidistant triggering (firing) of the valves. For a six-pulse bridge, the harmonics produced in the current on the valve side of the transformer are of order  $6n \pm 1$ , where  $n$  is an integer that takes values from 1 to  $n$ . Therefore, the current harmonics are as follows:

- 5th and 7th harmonics for  $n = 1$
- 11th and 13th harmonics for  $n = 2$
- 17th and 19th harmonics for  $n = 3$
- Higher harmonics for higher values of  $n$ .

The magnitude of the  $n$ -th harmonic current is given by

$$I_n = \sqrt{6} \frac{I_d}{n\pi},$$

where  $I_d$  is the DC current.

### Voltage Harmonics

Assuming that the AC system is perfectly symmetrical, there is no imbalance in the commutating reactor  $X_C$ , or equidistant triggering (firing) of the valves. The six-pulse bridge harmonics produced in the DC voltage are of order  $6n$ , where  $n$  is an integer that takes values from 1 to  $n$ . Therefore, the voltage harmonics are as follows [12.12, 13]:

- 6th for  $n = 1$
- 12th for  $n = 2$
- 18th for  $n = 3$
- Higher harmonics for higher values of  $n$ .

### Twelve-Pulse Bridges

The previous discussion considered the characteristic harmonics of a six-pulse bridge. However, we can take advantage of the design and winding configuration of a converter transformer to eliminate some of these harmonics.

In a converter consisting of two six-pulse bridges connected in series on the DC side (one with a wye–wye transformer and the other with a wye–delta transformer) the voltages of the bridges will be  $30^\circ$  out of phase, so that their harmonics will also be out of phase. Since  $30^\circ$  of the main frequency correspond to half a cycle of the 6th harmonic, the 6th harmonic will be in phase opposition in the two bridges, and the two bridges will be in phase for the 12th harmonic.

A similar effect is also seen for the AC current harmonics (Fig. 12.29). These harmonics will be of order  $12n \pm 1$ ; in other words:

- 11th and 13th harmonic for  $n = 1$
- 23rd and 25th harmonic for  $n = 2$ .

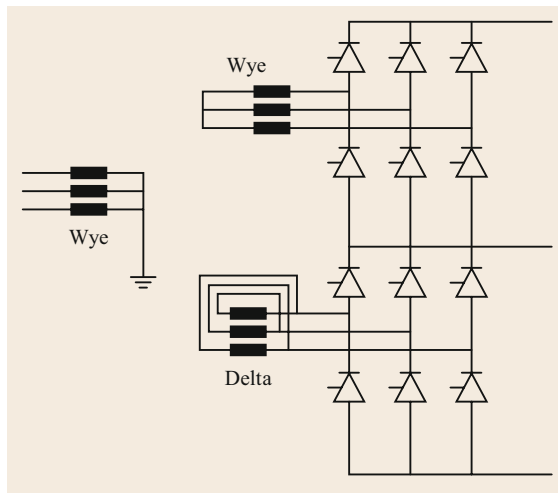

Fig. 12.29 Arrangement of a twelve-pulse bridge

The DC voltage harmonics will be of order  $12n$ , implying:

- 12th harmonic for  $n = 1$
- 24th harmonic for  $n = 2$ .

Thus, it is clear that the use of a twelve-pulse bridge eliminates certain harmonics.

### Noncharacteristic Harmonics

As mentioned earlier, the characteristic harmonics are based on ideal conditions. In reality, however, the following issues will influence the harmonics [12.2]:

- Firing error
- AC voltage unbalance or distortion
- Direct current modulation from the remote station
- Imbalance between converter components
- Imbalance between the applied voltages of the wye–wye and wye–delta transformers
- Imbalance between the firing angles of the wye–wye and wye–delta transformers
- Induced harmonics due to parallel AC lines sharing the same right-of-way as the DC line or in some cases both the DC and the AC lines on the same tower.

This will result in the generation of noncharacteristic harmonics of all orders. Such harmonics should be taken into consideration when designing the equipment, especially the AC and DC filters.

### 12.5.7 Reactive Power

The operation of the converter results in a phase angle between the fundamental component of the currents and the phase voltages. In principle, this phase angle is similar to a power factor. This means that the converter (a rectifier or an inverter) will consume reactive power. A rule of thumb is that a typical converter at nominal firing angles will consume approximately 50–60% of its rating in reactive power. More precisely, the reactive power consumption is a function of the delay angle  $\alpha$ , the overlap angle  $\mu$ , and the converter power at that point of operation.

The converter power factor

$$\cos \varphi = \frac{U_d}{U_{dio}},$$

$$\cos \varphi \approx \frac{1}{2} [\cos \alpha + \cos (\alpha + \mu)].$$

$$P_{dc} = U_d I_d = EI \cos \varphi,$$

where  $U_d$  is the DC voltage of the converter and  $I_d$  is its DC current

$$EI = \frac{P_{dc}}{\cos \varphi},$$

$$Q = EI \sin \varphi = P_{dc} \tan \varphi.$$

The consumption of reactive power by the converter is compensated by using either shunt capacitor banks or a combination of shunt banks and shunt AC filters. This is the typical approach that is used to provide reactive compensation for a converter. However, the reactive power compensation must be managed together with the reactive power consumption of the converter as well as the filters needed to meet the harmonic performance of the DC system.

In practice, as the DC power of the converter is ramped upwards, its consumption of reactive power increases. Therefore, shunt elements must be switched on to avoid excessive reactive power consumption from the AC system. Reactive power exchange with the AC system should be controlled. The magnitude of the steps due to the switching of the shunt bank are a function of the robustness of the AC system and are determined through system studies. Figure 12.30 shows how reactive power exchange with the AC system can be maintained in a band between  $+Q$  and  $-Q$  using this approach.

As the DC power of the converter is increased, the reactive power requirements of the converter  $Q_{\text{Converter}}$  will also increase. If the reactive power demand of the converter minus the reactive power supplied by the shunt banks  $Q_{\text{Shunt}}$  exceeds  $+Q$  (i.e.,  $Q_{\text{Converter}} - Q_{\text{Shunt}} > +Q$ ), then another shunt element must be switched on to ensure that the reactive power remains between  $+Q$  and  $-Q$ .

Similarly, as the converter DC power is reduced, its reactive power requirements will also decrease. If the reactive power demand of the converter minus the reac-

Fig. 12.30 Reactive power management in a conventional converter

tive power supplied by the shunt banks falls below  $-Q$  (i.e.,  $Q_{\text{Converter}} - Q_{\text{Shunt}} \leq -Q$ ), then a shunt bank must be switched off. For all the bank switchings one should take into consideration the harmonic performance specified.

### 12.5.8 Capacitor Commutated Converter (CCC)

In this circuit, series capacitors are connected between the converter and the AC bus on the valve side of the converter transformer (Fig. 12.31) [12.14]. It is clear that the capacitors are insulated at the full DC voltage from ground. Because of the presence of the capacitors on the valve side, the CCC typically has higher voltage applied at the valve side than a conventional converter, resulting in higher stress design requirements for the snubber circuits and an increased voltage rating for the arrester. Depending on the design, and considering a typical capacitor size of 20–25% of the rating, the increase in the voltage stress is around 10%. On the other hand, the short-circuit current due to a valve short circuit is lower than that for a conventional valve. This is due to the fast charging of the capacitors, which produces a counter voltage that limits the peak value.

The typical protective process applied during a valve short-circuit fault is to block the valves with no bypass action. However, it is standard in such a design to assume that the blocking may fail and that three or four loops of fault current will continue, depending on the speed of the circuit breaker trip. The capacitor counter voltage will certainly reduce the loop peak. The capacitor counter voltage will also reduce the blocking voltage seen by the valve involved in the short circuit.

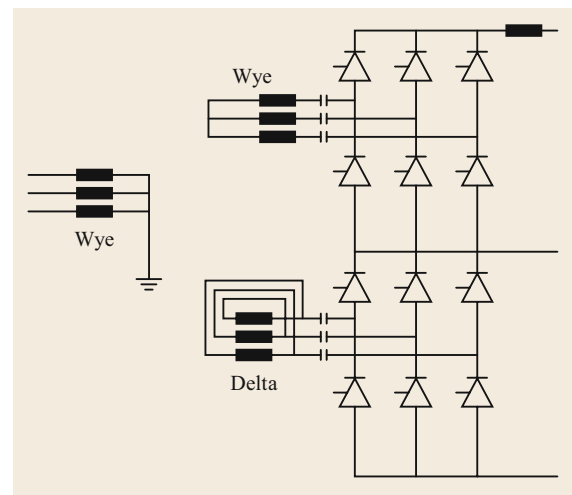

Fig. 12.31 Capacitor commutated converter (CCC)

The phase currents of a CCC are very similar to the phase currents of a conventional converter. The only difference is that the currents during the overlap interval include not only the sine wave of fundamental frequency but also a component with the natural frequency of the capacitor/inductor circuit. As explained earlier, because the capacitor voltage supports the commutation of current from one valve to another, the overlap angle is reduced. This reduction will lead to a slight increase of 1–2% in the AC harmonics.

In a CCC, the rating of the converter transformer is reduced because the reactive power that flows through the transformer is reduced. The no-load losses of the converter transformer are lowered by the reduced rating of the unit, but the load losses are increased due to increased harmonic currents and commutation jumps.

The presence of the capacitor provides an additional commutation margin proportional to the direct current. This results in improved commutation failure performance.

### 12.5.9 AC System Strength

The strength of the AC system—the short-circuit MVA—plays an important role in the operation of a HVDC system. The interaction between the DC and AC systems is a very important consideration in the system studies performed before implementing a HVDC project [12.15].

Such interactions and the overall stability of the system can only be determined through studies carried out during the planning stage, the design phase, and when the system is operational (as the AC system changes). Such studies can determine the viability of integrating a HVDC into an AC network, as well as any enhancement that may be required to achieve this. Figure 12.32 shows how an inverter is typically connected to the AC network.

The inverter supplies DC power ( $P_{dc}$ ) to the AC system and consumes reactive power ( $Q_C$ ). Most of the reactive power is supplied by the shunt banks ( $Q_S$ ).

Fig. 12.32 Connecting an inverter to the AC network

We now need to define some very important quantities

Short-circuit ratio (SCR)

$$= \frac{\text{System (short circuit) MVA } (S)}{\text{DC power } (P_{dc})}$$

Effective short-circuit ratio (ESCR)

$$= \frac{\text{System MVA } (S) - \text{Capacitor MVA } (Q_s)}{\text{DC power } (P_{dc})}$$

Both the SCR and the ESCR are quantities that can be utilized to explore the difficulties that may be encountered. An ESCR of less than 2.5 is often said to indicate a weak network that may require some mitigation measures to overcome any performance issues.

### 12.5.10 Power Voltage Instability

HVDC systems, especially those utilized for bulk power transmission, are operated with constant DC power control [12.16].

The principle of constant power control means that, for a given operating point, the system is set to transmit a certain power order  $P_{dc}$ . The DC current reference is calculated as

$$I_{dref} = \frac{P_{dc}}{U_d}$$

where  $U_d$  is the DC voltage.

This means that  $I_{dref}$  would be expected to be constant at any operating point since both  $P_{dc}$  and  $U_d$  are constant. However,  $U_d$  is dependent on the AC system voltage. If the AC system voltage  $V$  decays due to problems relating to voltage control in the AC network, the output of the shunt capacitors connected to the converter bus bar will fall in proportion to  $V^2$ , which will in turn lead to a further decline in the system voltage  $V$ . Thus,  $U_d$  will also decrease and, based on the above equation,  $I_{dref}$  will increase, resulting in greater demand from the converter for reactive power. This will prompt a further reduction in  $V$ , and in some cases will lead to a complete collapse of the system.

The power voltage instability depends on:

- The operational control mode of the DC system (e.g., constant power control or constant current control)
- The AC system strength ESCR
- The AC system operating bus voltage criterion
- The method of regulating the voltage at the inverter bus
- The inverter control mode.

The maximum available power (MAP) of a HVDC is the maximum power that the system can transmit without incurring a system collapse. This can be evaluated by considering all of the above factors in system studies.

### 12.5.11 Multi-infeed

In the above analysis, the ESCR is based on the use of one HVDC link to feed an AC system. However, in many situations, there are several HVDC links that terminate in close vicinity (electrically speaking) in an AC system. Therefore, the performance of each HVDC link (inverter) will be affected by the presence of the other DC links. Such interactions are referred to as multi-infeed interactions. The degree of interaction will depend on how close the AC buses are to where the DC links terminate. The following phenomena associated with multi-infeed interactions are discussed in detail in CIGRE TB 364 [12.17], published in 2008:

- Transient overvoltages
- Commutation failures
- Harmonic interaction
- Power voltage instability and control interaction.

Although tuning the control system can help to mitigate these interactions, it is first necessary to study and determine such interactions.

CIGRE TB 364 introduces a first-level indicator of the degree of interaction between two HVDC links, which it terms the multi-infeed factor (MIF). This is defined mathematically for AC systems  $e$  and  $n$  as

$$\text{MIF}_{e,n} = \frac{\Delta V_e}{\Delta V_n},$$

where  $\Delta V_e$  is the observed voltage change at bus  $e$  for a small induced voltage change at bus  $n$ . A MIF value of zero implies that the buses are far apart and there is no interaction, whereas a MIF of 1 means that the two buses are very close and there will be an interaction. The brochure suggests that a MIF of more than 0.15 is indicative of a possible interaction. It also states that for interactions between AC systems with many HVDC systems, a matrix of MIF values can be derived. MIF values can be evaluated using transient stability or short-circuit studies.

### 12.5.12 LCC Control and Protection

The control and protection of an LCC HVDC is achieved using various functions. These can be categorized into:

- The HVDC controls
- The measurement system

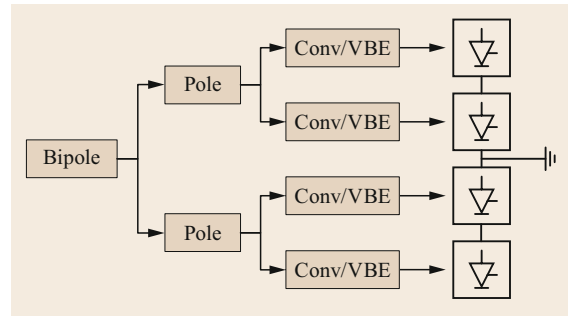

Fig. 12.33 LCC control system hierarchy

- The sequence controls
- The slow control functions (tap changer control)
- The protection.

The steady-state DC voltages of the rectifier and the inverter were presented in Sects. 12.5.1 and 12.5.2. It is clear that the DC voltages are dependent on the converter delay angle/extinction angle and the line-to-line AC voltages applied to the converter valves. The valve voltages are governed by the AC system voltage and the turns ratios of the converter transformers. However, the valve voltage can be regulated via the on-load tap changer. Therefore, LCC converter control can be achieved by controlling either the delay angle  $\alpha$  or the AC voltage of the valve  $E$ . Delay angle control is fast and can be relied upon to respond rapidly, whereas  $E$  control is slow and is typically used to keep the delay angle within certain margins.

The following control loops are used in a LCC control system:

- DC power control (an open or closed loop)
- DC current control
- DC voltage control
- Minimum extinction angle  $\gamma$  control
- Reactive power control
- AC voltage control.

The control strategy used for a particular terminal is not chosen in isolation; the aim is to identify the most suitable and reliable way of operating the entire HVDC system. Indeed, several modes of control are actually assigned to each terminal, with smooth transitions between them.

A typical LCC control system hierarchy is shown in Fig. 12.33.

Different control functions may be assigned to the different levels. This assignment process is part of the design strategy of any supplier.

To understand the concept of LCC controls, it is important to note that the aim is to translate a power

**Fig. 12.34**  
Equipment used and measurements performed in a bipolar system

demand into control pulses that are supplied to the thyristor valves.

Before we examine the control system, we should consider where measurements are performed in a typical converter station, as shown in Fig. 12.34.

The quantities and the measurement locations indicated are typical and can therefore vary for different projects. The following quantities are measured:

- The DC line current at each pole,  $I_{dL}$
- The DC line voltage at each pole,  $U_{dL}$
- The DC pole current at each pole,  $I_{d1}$
- The DC pole voltage at each pole,  $U_{d1}$
- The neutral DC bus voltage at each pole,  $U_{dN}$
- The neutral bus DC current at pole 1,  $I_{dN1}$
- The AC currents in the converter transformers on the valve side,  $I_{acb1}$  and  $I_{acb2}$ .

In Fig. 12.35, the DC reference power (power order)  $P_{ref}$  is an input for the power controls. Dividing  $P_{ref}$  by the sum of the two DC pole voltages  $U_{d1}$  and  $U_{d2}$  in a bipolar HVDC system yields  $I_{ref1}$ . This equation still applies if the system is monopolar (i.e., there is only one  $U_d$ ) and if one pole in a bipolar system is not in service (i.e.,  $U_{d1}$  is equal to zero). This is an important feature of bipolar HVDC systems, as the remaining pole can compensate for the loss of power at one pole up to its rating plus any overload.

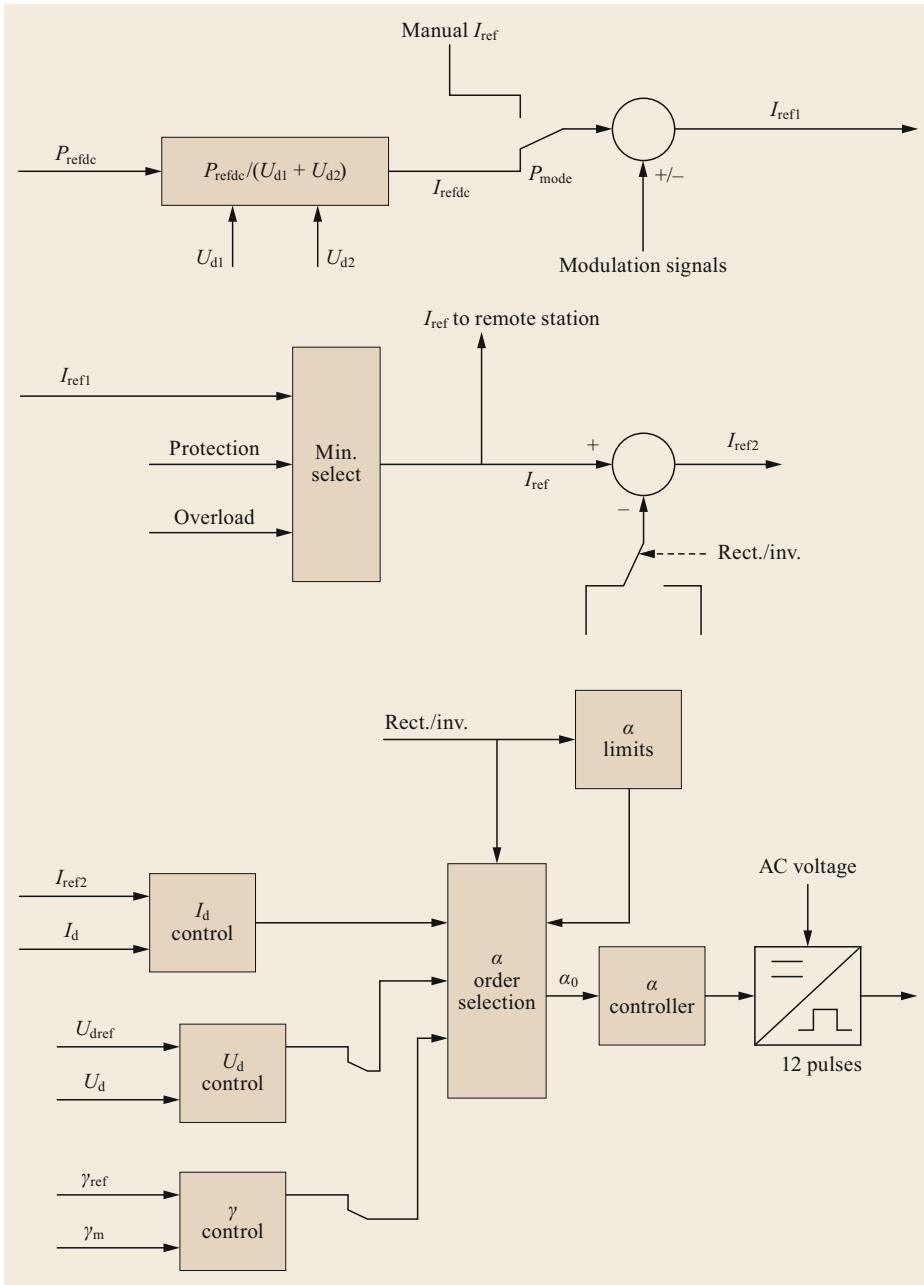

If power modulation controls are needed for damping purposes in the AC systems, the relevant inputs and signals are taken into consideration as modulation signals to the current reference. The current reference  $I_{ref1}$  is sent to both the local station and the remote station

via the communication system. To prevent any interaction between the DC current controllers for the two stations, a small current margin (typically 10% of the rated current) is subtracted from the current reference at the inverter station. The signal  $I_{ref2}$  is fed to the DC current controller. Depending on the control strategy applied, other controllers such as a DC voltage controller ( $U_d$  control) and a gamma controller ( $\gamma$  control) may also be active or inactive. However, only the firing angle ( $\alpha$  order) of a particular controller is selected at a given time, which in turn affects the output of firing pulses during the final stage. Controllers are selected and deselected dynamically, and the transition or control mode switchover must be smooth.

### 12.5.13 LCC Converter Startup (Deblock)

The term *deblock* refers to converter startup. In the configuration with a single converter per pole, as shown in Fig. 12.36, deblocking is very straightforward. The firing pulses for the converter are released at a firing angle ( $\alpha$ ) of  $150^\circ$ , which is referred to as force retard. The inverter is typically deblocked before the rectifier. Because the inverter starts first, it needs to send a signal to the rectifier via the communication system. Thus, the rectifier is released after a telecommunication time delay. Following successful deblocking, the firing angle for the converter ( $\alpha$ ) is determined by the appropriate controller at that station, e.g., the gamma ( $\gamma$ ) controller at the inverter or the DC current ( $I_d$ ) controller at the rectifier.

The deblocking of series-connected converters per pole is a little more involved than for a single converter

**Fig. 12.35**  
Converter control loops

per pole. There are many possible scenarios. Converters in series are shown in Fig. 12.37.

If pole 1 is out of operation and pole 2 is in operation, the bypass switches at pole 2 will be in the open position and the DC current will pass through the converters at pole 2. On the other hand, the converters at pole 1 are in the blocked state and the bypass switches at pole 1 will be in the closed position, so DC current will flow through the bypass switches at pole 1. This DC current is referred to as the spill current from pole 2,

**Fig. 12.36** Single converter per pole

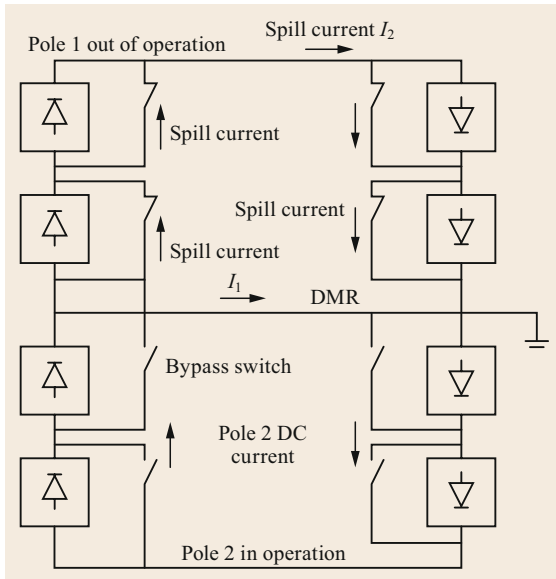

Fig. 12.37 Configuration of converters in series

and is divided between the DMR and pole 1 according to the relative resistances of the DMR and the pole 1 DC circuit, which includes the DC line or cable.

Bear in mind that the bypass switches are normal breakers with no ability to interrupt the DC current. Therefore, zero current must be present in the bypass switch before it will open and extinguish the arc. In a typical sequence, the converter is allowed to deblock at a delay angle  $\alpha$  in the rectifier region. By deblocking at such  $\alpha$ , the converter will produce a current opposite to the spill current, leading to zero current in the switch, which in turn extinguishes the arc. The value of  $\alpha$  is dependent on the switch characteristics as well as the speed of separation of the contacts. Delay angles  $\alpha$  of between  $45^\circ$  and  $75^\circ$  have been utilized.

The second mode of operation involves deblocking the second converter at a pole. In this case, one converter is deblocked and the second converter is blocked with a closed bypass switch. Therefore, the closed switch will carry the actual pole current. This current can be the full load current of the pole, which is much higher than the spill current. However, the same sequence described above for deblocking with a spill current will also apply.

There are several variations of the above sequence, but the aim is always to create zero current in the switch.

#### 12.5.14 LCC Converter Faults and Disturbances

Although there are a wide variety of converter faults and disturbances that can occur in a HVDC converter station, we only discuss some of them here.

Fig. 12.38 Turn-off process

#### Inverter Commutation Failure

Inverter commutation failures can occur due to [12.18]:

- AC system faults and disturbances
- DC faults or disturbances
- Equipment failure.

Among the above causes, equipment failure can usually be excluded due to the redundancy built into the control equipment. Therefore, we will concentrate here on AC faults and disturbances. An AC fault at the converter busbar will lead to a commutation failure. The severity of the converter AC bus fault will determine how fast the inverter will recover from a commutation failure. A remote AC fault that results in either a reduction, a phase shift, or a distortion of the inverter commutating voltage will also induce a commutation failure. A drop in the valve voltage to approximately 80% for one of the phases will typically lead to a commutation failure. However, it is expected that the control system will help the inverter to recover and resume normal operation at a reduced AC bus voltage. The stronger the AC system, the lower the probability that a commutation failure will occur due to a remote AC fault.

A commutation failure occurs due to the physical characteristics of the thyristor valves in a LCC. Therefore, in order to understand commutation failures, it is necessary to examine the turn-off process for thyristors (Fig. 12.38).

Thyristor turn-off occurs when the current drops below a certain value (known as the holding current). During the commutation process, the current falls to zero, but current will continue to flow in the reverse direction in the thyristors when a reverse voltage is applied to them. This reverse current will continue to flow until all of the excess stored charge is drained from the thyristors.

Fig. 12.39 Normal commutation

Fig. 12.41 Commutation failure

Fig. 12.40 Commutation of valve 1 to valve 3

Fig. 12.42 Recovery from commutation failure

If a forward voltage is reapplied before this excess reverse charge is removed, the thyristor will turn on again. The turn-off time is defined as the time from the point at which the current reaches zero to the point at which the thyristor voltage turns positive.

The reverse recovery charge  $Q_{RR}$  is an important parameter of thyristors.

The impact of the AC system fault/disturbance is that insufficient charge is removed from the thyristors before a positive voltage is reapplied. Since it is a statistical phenomenon, some thyristors will be more affected than others. However, even if only a few thyristors turn on because of this phenomenon, the whole valve will be triggered to turn on to protect the thyristors. This results in out-of-turn conduction and thus a commutation failure. Commutation failure is therefore related to a lack of time for the outgoing valve to fully deionize following an AC disturbance.

In principle, this is due to a decrease in the extinction angle  $\gamma$ . Because of the statistical nature of thyristor characteristics, the  $\gamma$  of the whole valve is set to be larger than the actual time needed to deionize the thyristors.

When a commutation failure occurs, it creates a bypass at the DC terminals of the bridge, which results in an increased DC current and an average DC voltage of zero, so the DC power during the commutation fail-

ure is momentarily zero. In Fig. 12.39, valves 1 and 2 are conducting normally. When valve 3 is prompted to fire, the commutation process starts, as shown in Fig. 12.40.

If an AC fault or disturbance occurs, valve 1 may not have enough time to fully turn off after commutating the current to valve 3, so it can conduct current as soon as a positive voltage is reapplied to it. This out-of-turn conduction of valve 1 causes valve 3 to extinguish. When valve 4 is commanded to fire, a short circuit develops on the DC side, as shown in Fig. 12.41.

When valve 5 is commanded to fire (Fig. 12.42), the bypass is extinguished and recovery takes place so long as faults do not continue to occur.

If the commutation failure persists, the converter is removed from service. The commutation failure protection usually commands a block of the converter.

#### Valve Short Circuit

This type of fault can be the result of a flashover across any valve that is not conducting at the time. This will cause a short circuit between two AC phases of the transformer on the valve winding side.

Let us suppose that a flashover occurs between the terminals of valve 3 in Fig. 12.43 while valve 1 is conducting. This results in a short circuit between the R and S phases.

**Fig. 12.43** Valve short circuit

The valve short-circuit current is calculated based on the following:

1. The maximum short circuit level of the AC system
2. The minimum commutating reactance
3. The minimum frequency
4. The maximum DC voltage
5. The minimum permissible delay angle  $\alpha$ , which is typically  $5^\circ$ .

Two calculations are performed. The first is for the single loop (pulse) of short-circuit current. Because the converter is blocked, the valve must withstand the AC voltage, including the overvoltage resulting from the load rejection due to the blocking of the converter. The second is for multiple loops (typically three loops) in which the AC breaker trips and clears the fault. This multiple loop scenario will occur if converter blocking fails. However, no forward voltage is reapplied to the valves in the multiple loops.

### 12.5.15 Thyristors and Thyristor Valves

The backbone of HVDC LCC technology is the high-voltage, high-power thyristor. Active silicon thyristors that are six inches in diameter and have a current rating of 6.3 kA per device (Fig. 12.44) are currently available [12.19]. Thyristors with a flat-pack design are the

**Fig. 12.44** 6-inch light-triggered thyristor with a DC current rating of 6.3 kA (© Siemens/Infineon Bipolar)

**Fig. 12.45** The four layers and three terminals of a thyristor

norm in HVDC valve applications. This type of device is easy to manipulate mechanically within the valve and easy to cool. In principle, a thyristor should be sandwiched between water-cooled heat sinks.

A thyristor is a semiconductor device with four layers and three terminals, as shown in Fig. 12.45. The anode is connected to the P1 layer, the cathode to the N2 layer, and the gate to the P2 layer.

In the forward blocking mode, when the anode is positive with respect to the cathode, the thyristor will conduct a small leakage current, as shown in Fig. 12.46. If the forward voltage is increased beyond a specific value, referred to as the breakover voltage (VBO), the thyristor will turn on. However, this kind of activation is not desirable as it is not a gated turn-on and it is not possible to control how the current spreads in the device. This type of activation can lead to thyristor failure.

In the reverse blocking mode, when the anode is negative with respect to the cathode, a small leakage current will flow. However, if the voltage is increased above the breakdown voltage  $V_R$  of the junction between P1 and N1 (see Fig. 12.46), the current increases rapidly. This breakdown is due to avalanche effects.

The leakage current that flows in both forward and reverse blocking is temperature dependent, and when a temperature of  $125^\circ\text{C}$  is exceeded the leakage current can increase rapidly and failure can occur.

**Fig. 12.46** Current–voltage characteristic of a thyristor

Fig. 12.47 500 kV thyristor valves (© Siemens)

When a gate pulse is applied to a thyristor and the anode is positive with respect to the cathode, the thyristor is turned on. Thyristor gating can be achieved using either an electrical pulse (i.e., an electrically triggered thyristor, ETT) or a light pulse (i.e., a light-triggered thyristor, LTT).

The power dissipation is high during turn-on. The allowable rate of increase in the anode current  $dI/dt$  is a critical parameter. If the anode current increases too rapidly it will lead to high power loss in a small area and the device may fail due to localized heating. This is mainly due to the increased current density: the current increases very quickly, meaning that it does not have sufficient time to spread.

### Thyristor Valves

Modern thyristor valves (Fig. 12.47) have the following features:

- A modular design with stacked thyristors and heat sinks
- Deionized water cooling of the thyristors, valve reactors, and snubber resistors
- The use of fiber optics for signal transmission between the thyristor levels and the valve control via the valve base electronics (VBE).
- On board thyristor protection, either electronic or integrated.

A thyristor valve consists of multiple thyristor levels, where a thyristor level consists of a thyristor, its heat sinks, snubber circuits, DC grading resistors, and the associated electronics (see Fig. 12.48) [12.20].

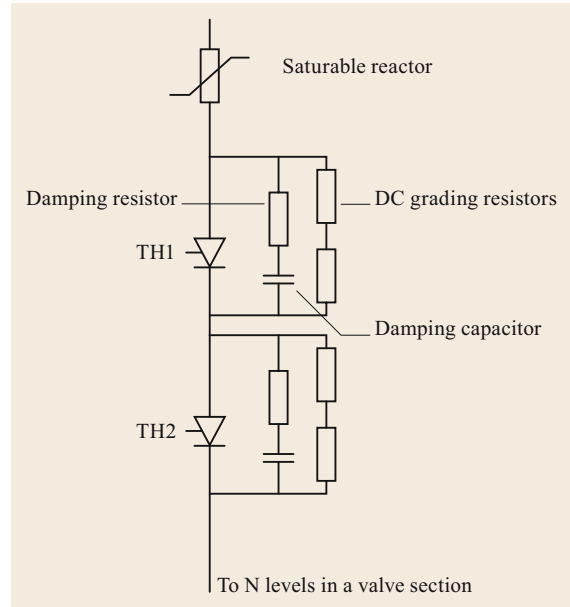

Fig. 12.48 Typical thyristor levels

There may be one saturable reactor per thyristor level, or a saturable reactor may serve multiple thyristor levels in series. The thyristor levels are connected in series, which is achieved mechanically by including a number of levels in a module or valve section together with the necessary cooling manifold and piping. The valve sections or modules are assembled into a valve structure together with fiber optic cables, cooling pipes, and insulators. The valve structure can include a single valve, a double valve, or a quadruple valve.

For thyristor valves that use ETT (Fig. 12.49), each thyristor level is equipped with thyristor electronics that are termed the gate electronics. The gate electronics receive trigger pulses in the form of light pulses from the VBE. These pulses are converted into electrical pulses that are processed by the gate unit and delivered to the thyristor gate as electrical signals. The status and condition of each thyristor level are also reported by the gate electronics to the VBE, and the gate electronics protect the individual thyristors against forward overvoltage and steep front voltages  $dv/dt$  that may occur during the thyristor recovery period.

Forward overvoltage can occur during faults or due to the loss of a firing pulse. Forward overvoltage protection is referred to as breakover diode protection (BOD). In most designs, this is a passive element that triggers the thyristor into conduction based only on the forward voltage of the forward thyristor. The gate electronics require power, which is obtained from the voltage across the thyristor in the off state.

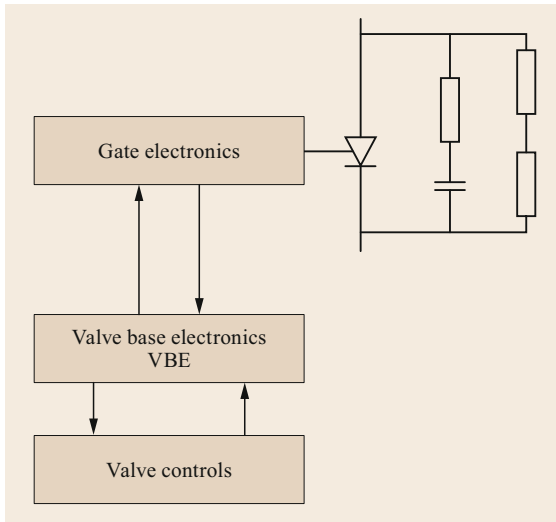

Fig. 12.49 Thyristor level concept for an ETT

For a light-triggered thyristor (Fig. 12.50) with integrated self-protection (LTT), the trigger pulses are transmitted from the VBE as light pulses. Since the thyristor is triggered by light energy there is

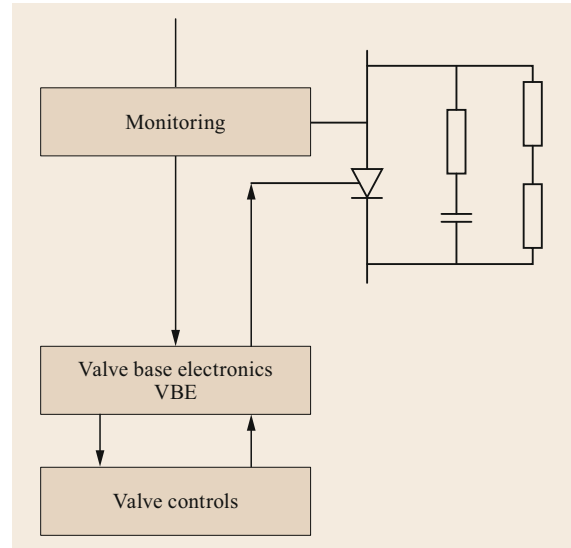

Fig. 12.50 Thyristor level concept for a LTT

no need to convert the pulses to electrical signals, so the need for gate electronics is eliminated.

## 12.6 Voltage-Source Converter (VSC)

The voltage-source converter was introduced in 1997, when it was used at a very low rating ( $\pm 10$  kV and 3 MW) in the Hellsjön project, together with a HVDC XLPE cable. However, this does not mean that VSC technology can only be used with HVDC XLPE cables. VSCs can also be applied to overhead lines, mass-impregnated (MI) cables, or combinations of HVDC cables and overhead lines. The semiconductor device usually employed in VSCs is the insulated gate bipolar transistor (IGBT). A VSC can control the active and reactive power exchanged with the AC system separately.

### 12.6.1 IGBTs

The IGBT is a three-terminal, four-layer (p-n-p-n) semiconductor (Fig. 12.51) device with a metal oxide

Fig. 12.51 The symbol for an IGBT

semiconductor (MOS) gate structure and a high input impedance. It has a very low on-state voltage drop due to conductivity modulation, and has superior on-state current density.

It has a wide safe operating area (SOA), which is the current-voltage region within which a power switching device can be operated without destructive failure. For the IGBT, this region is defined by the maximum collector-emitter voltage  $V_{CE}$  and collector current  $I_C$  below which the IGBT must be operated to protect it from damage.

An IGBT can be easily turned on or off. To turn it on, a positive signal is applied between the gate and the emitter, and to turn the device off, the signal between the gate and the emitter must be zero or

Fig. 12.52 Wire-bonded IGBT [12.21]

**Fig. 12.53** Stakpak module [12.22]

slightly negative. When a positive voltage is applied from the collector terminal (C) to the emitter terminal (E), the device is in the forward-blocking mode. Applying a positive voltage of sufficient level to the gate (G) will then cause the device to conduct. On the other hand, when a negative voltage is applied from C to E, the device becomes reverse biased.

A very important feature of an IGBT is the ability to limit the short-circuit current that passes through the device when a short circuit occurs at its terminals. The IGBT collector current  $I_C$  is a function of the gate-emitter voltage  $V_{GE}$  and the temperature. The device will have to be turned off to protect it.

Two types of IGBTs are currently available for HVDC applications: wire-bonded IGBTs (Fig. 12.52) with low losses and press-pack IGBTs (Fig. 12.53). The type of IGBT used in a HVDC converter will impact the converter design.

### 12.6.2 VSC Design

VSCs for HVDC applications include many IGBTs connected in series. Many issues must therefore be considered during VSC design:

- The mechanical design of the converter valves
- The cooling requirements within the valve
- The control of many IGBTs in the same valve
- Minimizing losses
- Equipment reliability
- The voltage distribution under both transient and steady-state conditions.

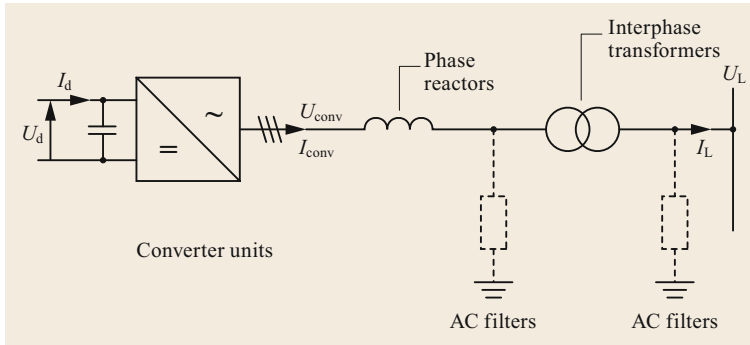

Following the introduction of VSCs for HVDC applications, a number of converter topologies were utilized in early HVDC projects. All of these topologies (Fig. 12.54) utilized two- or three-level converters with pulse width modulation (PWM) [12.24, 25].

As shown by Fig. 12.55, the VSC generates an AC waveform that has a fundamental frequency and harmonics. The harmonics can be filtered.

The converter controls the angle of the voltage by starting with square waves, and it controls the mag-

**Fig. 12.54** (a) Two- and (b) three-level VSCs [12.23]

**Fig. 12.55** Simplified circuit diagram for a VSC. Here,  $U_{conv}$  is the rms line-to-line AC voltage of the converter unit(s) including harmonics,  $U_{conv-ph}$  is the rms phase-to-phase AC voltage of the converter unit(s) including harmonics, and  $I_{conv}$  is the rms alternating current of the converter unit(s) including harmonics [12.23]

nitude of the voltage by controlling the pulse width. Therefore, a VSC can be represented as the simple circuit depicted in Fig. 12.55. The VSC electrical circuit can also be represented as shown in Fig. 12.56.

The rms value of the fundamental frequency component of the phase voltage  $U_{conv-ph}$  on the valve side of the interface reactance for the VSC in square-wave operation can then be defined as

$$U_{conv-ph(1)} = \frac{\sqrt{2}}{\pi} K_{\gamma} U_d e^{-j\delta},$$

where:

$\delta$  is the phase angle between the converter voltage  $U_{conv}$  and the AC voltage  $U_L$   
 $K_{\gamma}$  is the voltage ratio factor [0 ... 1].

Ignoring the resistance, the corresponding phase current in phase (a) can be expressed as

$$I_{conv-a(1)} = \frac{U_{conv-ph(1)} - U_{L(1)}}{Z}$$

$$= \frac{\frac{\sqrt{2}}{\pi} K_{\gamma} U_d e^{-j\delta} - U_{L(1)} e^{-j0}}{jX};$$

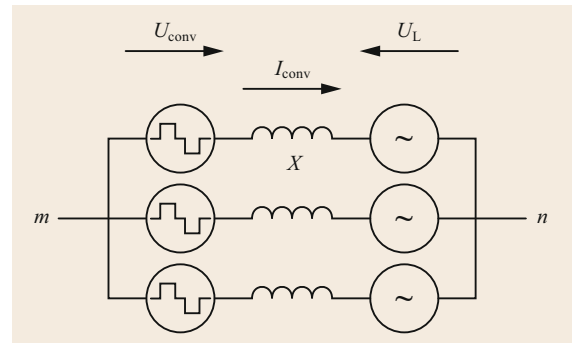

$$P = \frac{U_{conv(1)} U_{L(1)}}{X} \sin \delta,$$

$$Q = \frac{U_{L(1)} (U_{L(1)} - U_{conv(1)} \cos \delta)}{X}.$$

The direct current of the converter bridge  $I_d$  can also be derived using the equality of power on the AC and DC sides

$$I_d = \frac{\sqrt{6}}{\pi} \frac{U_{L(1)}}{X} \sin \delta.$$

As can be seen from the  $I_d$  equation, the active power is mainly determined by the phase angle between  $U_{L(1)}$  and  $U_{conv(1)}$ . At any given operating point, an increase

**Fig. 12.56** Representation of a VSC circuit [12.23]

in the phase delay of  $U_{conv(1)}$  would decrease the active power delivered to the AC system. Similarly, at any given operating point, a decrease in the phase delay of  $U_{conv(1)}$  would increase the active power delivered to the AC system.

The reactive power is defined by the converter voltage magnitude ( $U_{con(i)}$ ).

### 12.6.3 Modular Multilevel Converter

Although the solution discussed above certainly works, converter losses are high due to the switching losses from the IGBTs at a PWM frequency of 1260 Hz (using the Cross-Sound Cable project as an example). However, in 2006, the modular multilevel converter (MMC) was introduced. The advantages of the MMC are as follows [12.26, 27]:

- Low converter losses as there is no high-frequency switching
- No AC filter requirements
- Low  $dv/dt$  upon switching due to small switching steps.

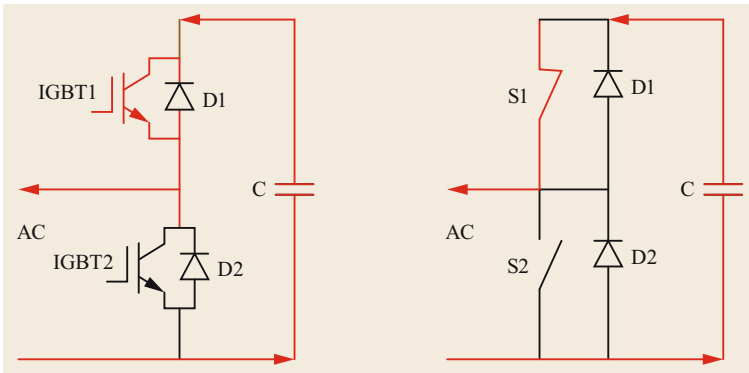

The smallest block in a MMC configuration, which is referred to as a submodule (Fig. 12.57), contains two main components:

**Fig. 12.57** MMC submodule (half bridge)

**Fig. 12.58** IGBT1 and IGBT2 in the off state

**Fig. 12.59** IGBT1 triggered into conduction

- A DC capacitor
- Two IGBTs connected across the capacitor.

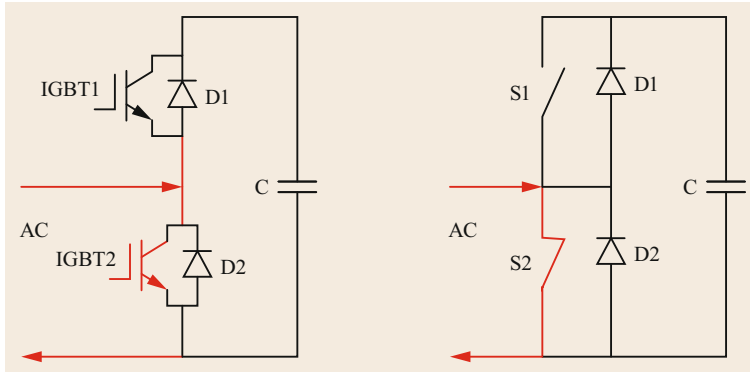

The AC connection is located at the midpoint of the two IGBTs, IGBT1 and IGBT2, which are similar to the controlled switches S1 and S2. When IGBT1 and IGBT2 are in the off state, capacitor C is charged through diode D1, as shown in Fig. 12.58.

When IGBT1 is triggered into conduction (similar to S1 being closed), capacitor C will discharge through IGBT1 to the AC side, as shown in Fig. 12.59.

**Fig. 12.60** AC voltage using a MMC

The resulting AC voltage is as shown in Fig. 12.60. Basically the output voltage consists of many capacitor voltages inserted when IGBT1 is conducting.

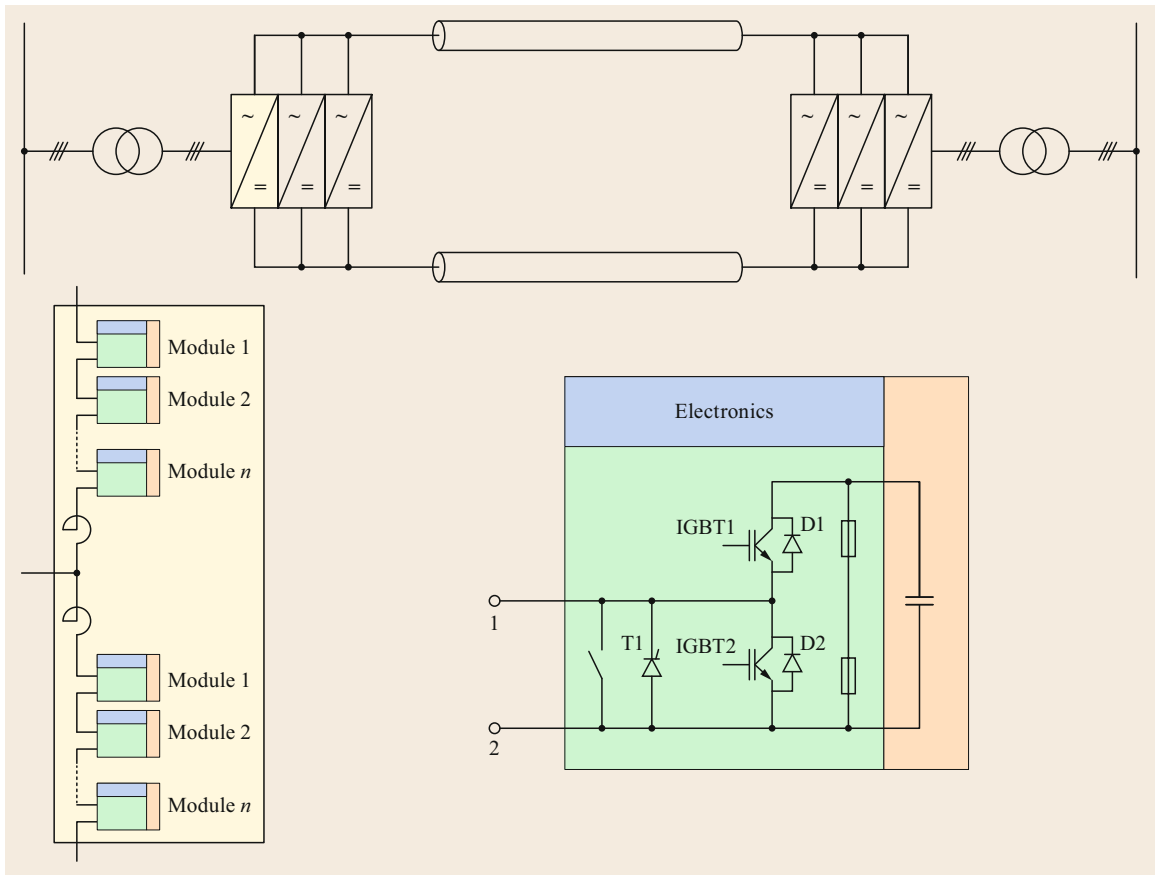

**Fig. 12.61** IGBT2 triggered into conduction

If IGBT2 is switched on (i.e., switch S2 is closed), then the submodule is bypassed and no voltage builds up on the capacitor, as shown in Fig. 12.61.

It is important to define the terminology of a multi-module VSC:

- A *submodule* is the smallest single phase unit; it consists of two IGBTs and their associated equipment
- A *phase module* is obtained by connecting  $N$  sub-modules in series along with one phase reactor to form either the positive or the negative side of an AC phase, as shown in Fig. 12.62
- A *phase arm* is obtained when two phase modules are connected to obtain a complete phase, as shown in Fig. 12.63
- A *converter* comprises of three phase arms.

**Fig. 12.62** MMC concept (© Siemens)

Fig. 12.63 Power module (courtesy of ABB) [12.28]

Fig. 12.64 VSC converter (courtesy of Siemens)

Some photos of physical parts of a VSC converter are depicted in Figs. 12.63 and 12.64.

If more than one submodule, for example  $N$  submodules, are connected in series, then each submodule can be either:

- Off, where IGBTs 1 and 2 are both in the off state
- On, where IGBT1 is conducting (on state) and the capacitor voltage is applied at the terminals
- Bypassed, where IGBT2 is conducting (on state).

In principle, a voltage is generated in steps (which depend on the number of submodules connected in series and the individual status of each submodule) at the terminals of the phase arm. The switching process of a submodule is not performed at high frequency, so the switching losses of the IGBTs are reduced, as are the total losses of the converter. Figure 12.65 shows the resulting waveform of the MMC VSC converter. From the VSC electrical scheme, it is apparent that the phase voltages are built from the positive and negative terminals with the addition of a variable source, the capacitor voltages (Fig. 12.65). Increasing the number of capacitors leads to a better and smoother AC waveform.

A back-to-back VSC converter is shown in more detail in Fig. 12.66. In Fig. 12.66a the single line diagram of the back-to-back system is shown. In the Fig. 12.66b the back-to-back alone is shown with the details of the modules. The positions of the switches at a particular instant are presented in Fig. 12.67. Note that six arms with six capacitors per arm are depicted in Fig. 12.67. Some capacitors are inserted and some are bypassed. Taking as an example the two arms in series on the right-hand side of Fig. 12.68, it is clear that the voltage  $V_c$  is obtained through both arms: one (the lower arm) includes half the DC voltage plus the voltage of six capacitors and the other (the upper arm) includes half of the DC voltage plus the voltage of zero capacitors.

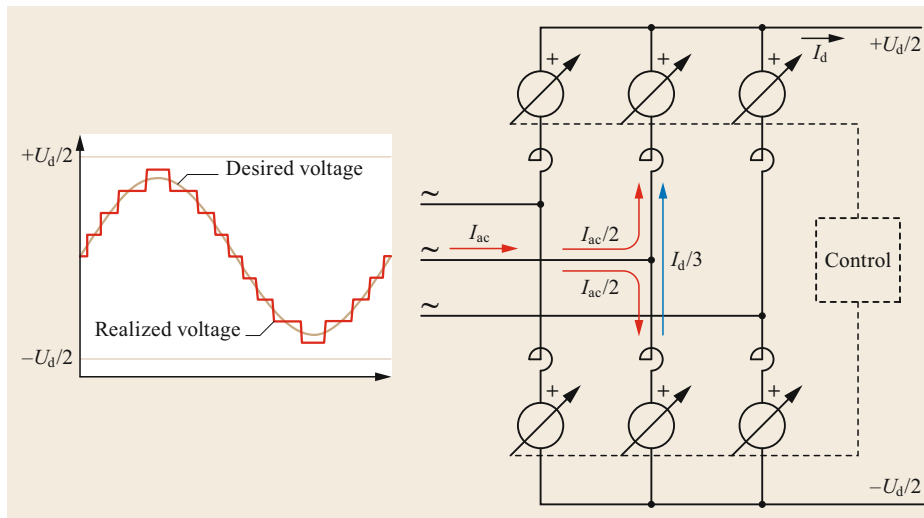

Fig. 12.65 Overview of the MMC concept by CIGRE [12.29]

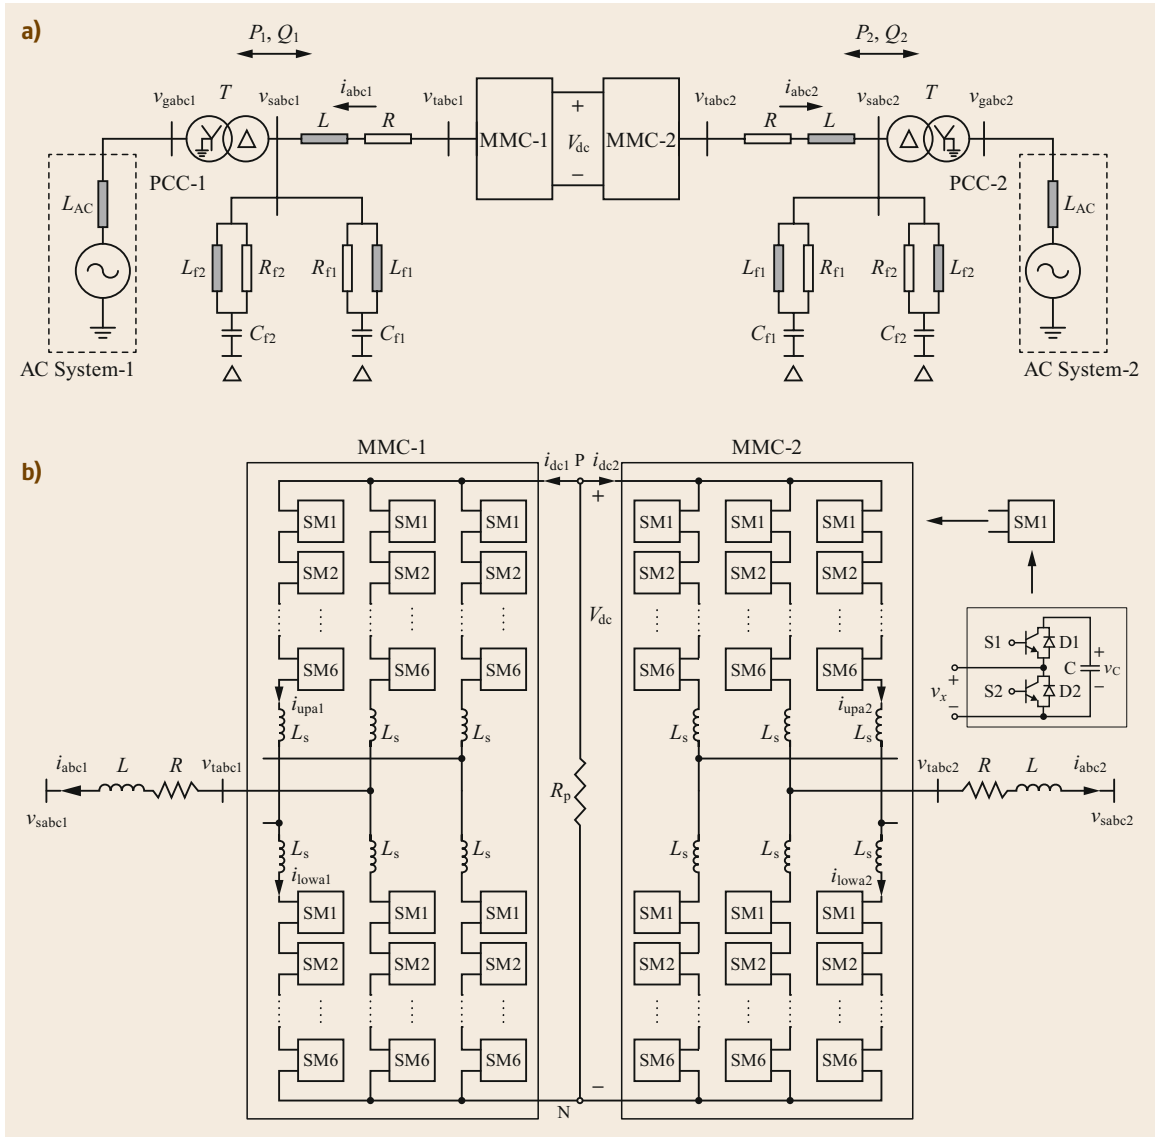

Fig. 12.66a,b Back-to-back VSC [12.27]

Therefore,

$$V_{tc} = -\frac{V_{dc}}{2} + nlV_{cap} = \frac{V_{dc}}{2} - nuV_{cap} ,$$

where  $nl$  and  $nu$  are the number of capacitors in the lower and upper arms, respectively.

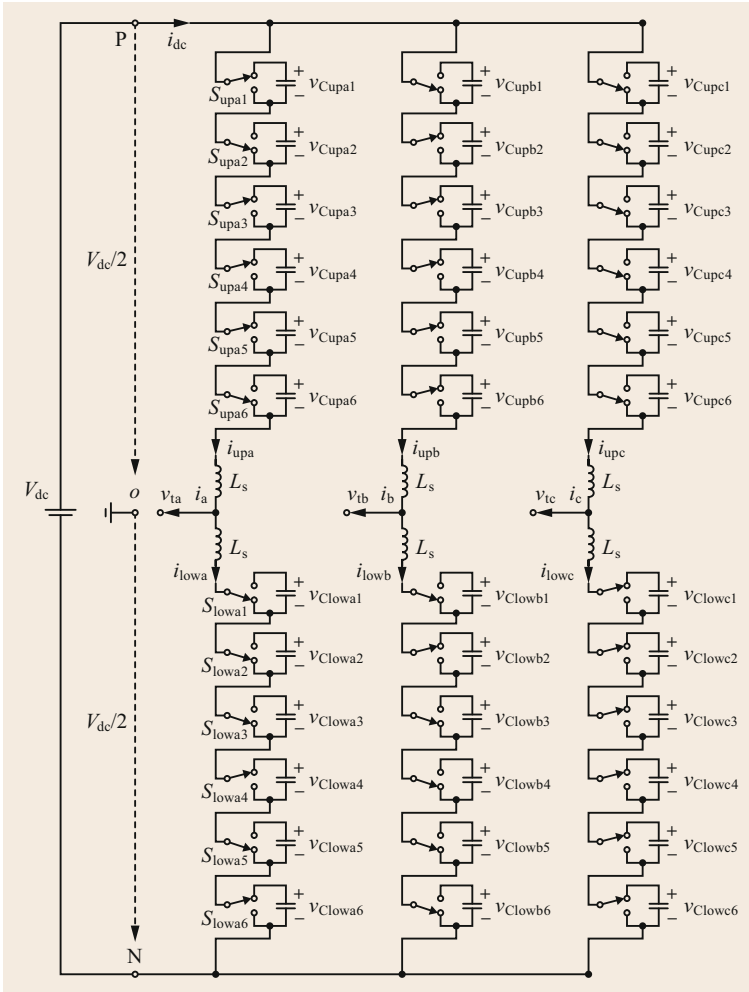

Note that Fig. 12.67 indicates that there are  $nl + nu = 6$  voltage components in each of the three voltage pass. The voltage of each capacitor is  $V_{dc}/6$ .

### 12.6.4 Active and Reactive Power Control

As mentioned earlier, a VSC converter can independently control active and reactive power and exchange them with the AC system (Fig. 12.69) [12.23].

The converter can control the output power by modifying the magnitude and phase of the generated voltage.

The VSC can control the active power or  $U_d$  using  $\delta$  or the AC voltage, and the reactive power can be controlled via  $\lambda$  (Figs. 12.70 and 12.71).

**Fig. 12.67** Positions of the switches in a MMC at a specific instant [12.27]

**Fig. 12.68** Voltage build-up

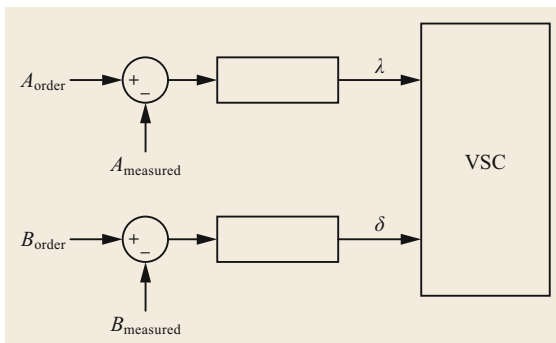

**Fig. 12.69** Converter control components [12.23]

Consider a VSC converter that has an output of  $U_C$  (or  $U_{conv}$  in Fig. 12.55) and is connected through an impedance  $X$  to the AC system. This converter will supply or absorb reactive power based on whether the converter voltage  $U_C$  is higher or lower than the system voltage  $U_S$  (or  $U_L$  in Fig. 12.55), as shown in Figs. 12.72, 12.73, and 12.74.

The active power is a function of the angle  $\delta$  between the converter voltage  $U_C$  and the system voltage  $U_S$ , as shown in Figs. 12.75 and 12.76.

### 12.6.5 Full-Bridge Converter

In the preceding discussion, the converter was arranged in a half-bridge configuration. Such an arrangement works adequately in most VSC applications, but in a bipolar DC system configuration, where there is a ground connection on the DC side, large short-circuit currents are driven to the DC side through the diodes during a DC-side ground fault (similar to a pole-to-pole fault in a symmetrical monopole). Such currents can-

**Fig. 12.70** Direct control of  $\lambda$  and  $\delta$  using parameters  $A$  and  $B$  [12.23]

not be controlled by a half-bridge converter, so a full-bridge converter (see Fig. 12.77) can be utilized instead. In a full-bridge converter, the current can be controlled in four quadrants, as shown in Fig. 12.78. The AC side voltage of the full bridge is basically symmetrical, as shown in Fig. 12.78.

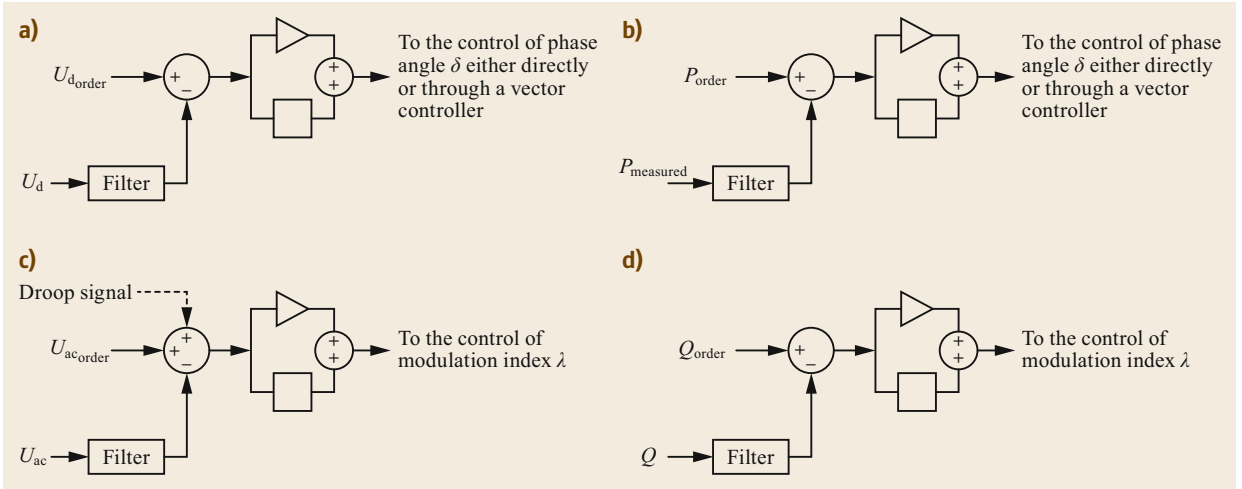

During a DC fault (pole to ground in a bipolar system or pole to pole in a symmetrical monopole system), the module capacitors in both half- and full-bridge converters can discharge, producing very large DC currents. The rate of change in these currents can be very large, so fast detection and interruption of fault currents is needed to protect converters. Fast detection of DC faults is possible by measuring the rates at which DC currents and voltages increase. Once a fault has been detected, the fault currents can be interrupted in several ways in full-bridge MMC converters [12.30].

#### DC Fault Current Interruption Through Blocking

The most popular DC fault-current interruption mechanism used in full-bridge MMC converters is blocking. As soon as the converter is blocked, all of the converter module capacitors are inserted via freewheeling diodes in the direction opposite to that of the fault current. This can momentarily yield voltages of opposite polarity that are more than 2 p.u. at the faulted DC pole, which quickly reduce the fault current.

#### Active DC Fault Current Control

One of the main advantages of full-bridge converters over half-bridge converters is the ability to control both the AC internal voltage and the DC voltage independently (i.e., an extra degree of freedom) over the full range of DC voltages. If required, the DC pole voltage can be instantly reversed by inserting the modules in the opposite direction while maintaining the AC voltage.

**Fig. 12.71a-d** VSC controller. (a) DC voltage controller, (b) active power controller, (c) AC voltage controller, (d) reactive power controller [12.23]

**Fig. 12.72** Single-line scheme

**Fig. 12.75** The converter is absorbing active power

**Fig. 12.73**  $U_s > U_c$ : the converter is absorbing reactive power

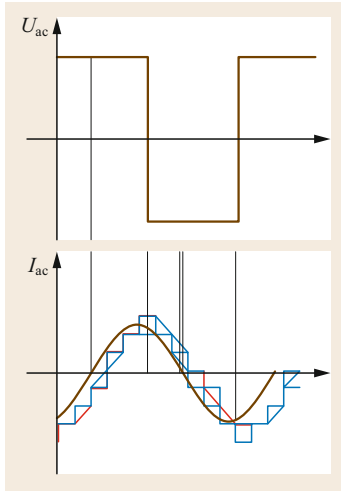

**Fig. 12.76** The converter is supplying active power

**Fig. 12.74**  $U_s > U_c$ : the converter is supplying reactive power

**Fig. 12.77** Full-bridge converter

**Fig. 12.78**  
Current path in four quadrants

- It can be built from half-bridge converters, as described earlier. It can be also constructed with full-bridge converters, although there is no technical advantage to doing so if it is a cable-based application (the probability of a pole-to-pole fault is small).
- Since the system is floating with no intentional ground connection in a symmetrical monopole, the DC voltages of the two poles may drift. However, leakage currents due to the high resistance to ground (e.g., the DC voltage dividers) on the DC side prevent excessive DC voltage drift.
- Another approach that is used to address the problem is to connect a high impedance (a reactor plus a resistor) between the transformer and the converter at one station, as shown in Fig. 12.80. Under normal conditions, the current in the L1 reactor is negligible. The stress during a DC-side ground fault should be considered when selecting R2 (Fig. 12.80).

### 12.6.6 Symmetrical Monopole

The symmetrical monopole (Fig. 12.79) is one of the configurations used in VSC converters.

In this configuration, the VSC converter is connected to the positive and negative poles but not to ground. The main features of this configuration are as follows:

- The transformer is not exposed to DC voltage, so it is a regular AC power transformer.
- It is implemented with two XLPE cables in most applications.
- A DC ground fault does not result in short-circuit currents, but it does expose the healthy pole to very high voltages that can be as high as twice the rated voltage.
- There is no power transfer during any outage.

### 12.6.7 Bipolar Arrangement

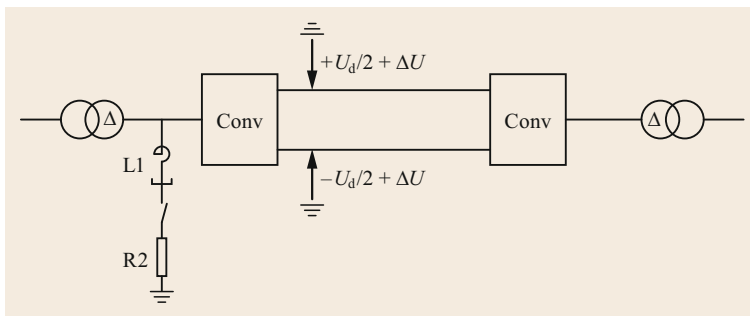

In a bipolar arrangement, just as in a LCC, there are two independent poles arranged in a bipolar configuration with either a ground return or a dedicated metallic return (Fig. 12.81).

In a bipolar arrangement:

- The transformer is a converter transformer subjected to DC stress.
- A ground fault on the DC side is characterized by high short-circuit currents that impact the AC system. These occur because, in addition to the DC current, an AC current component feeds the fault through the diodes from the AC side.

**Fig. 12.79** Symmetrical monopole

**Fig. 12.80** Control of voltage drift

Fig. 12.81 Bipolar arrangement

- Half-bridge or full-bridge converters can be utilized. However, in the event of a DC-side fault in either the cable or the overhead transmission line, a half-bridge converter requires the breaker on the AC side to be tripped. This is not a problem if cable-based transmission is used. However, in the case of an overhead line (which can frequently suffer weather-induced DC line faults), AC breaker tripping is problematic. This is because a restart is performed following a DC line deionization period in HVDC. A full-bridge converter is capable of deionizing the DC line without the need to trip the AC circuit breaker.

### 12.6.8 Converter Charging

In a typical MMC, the capacitors and (if present) DC cables are charged through the diodes before the converter is started. The capacitors and the cables are charged as soon as the AC breaker is closed. A preinsertion resistor (charging resistor) is utilized to limit the charging current. When a half-bridge converter is used, the capacitors and the cables are charged to approximately the peak of the line-to-line-to-line voltage.

## 12.7 DC Grid

As converter technologies (especially MMC technology) are now mature, researchers are considering a configuration in which converters are connected via a meshed grid. This would increase the reliability of the HVDC transmission system. Studies of this configuration have been carried out by CIGRE, which has created specific working groups to discuss issues such as:

- HVDC feasibility [12.31]
- The preparation of connection agreements or grid code for multiterminal schemes and DC grids [12.32]
- The development of HVDC converter models for a HVDC grid [12.33]
- Control methodologies for direct voltage and power flow in a meshed HVDC grid [12.34]
- Protection and local control of DC grids [12.35]
- The design of HVDC grids for optimal reliability and availability performance [12.36].

The aim is to bring knowledge of DC grid technology up to the same level as that for AC grids.

Figure 12.82 shows an example of the CIGRE test system, which integrates offshore and onshore renewable generation into AC power systems [12.33].

The test system consists of two onshore and four offshore AC networks (the buses labeled Ba) and three DC systems (DCS1, DCS2, and DCS3). System DCS1

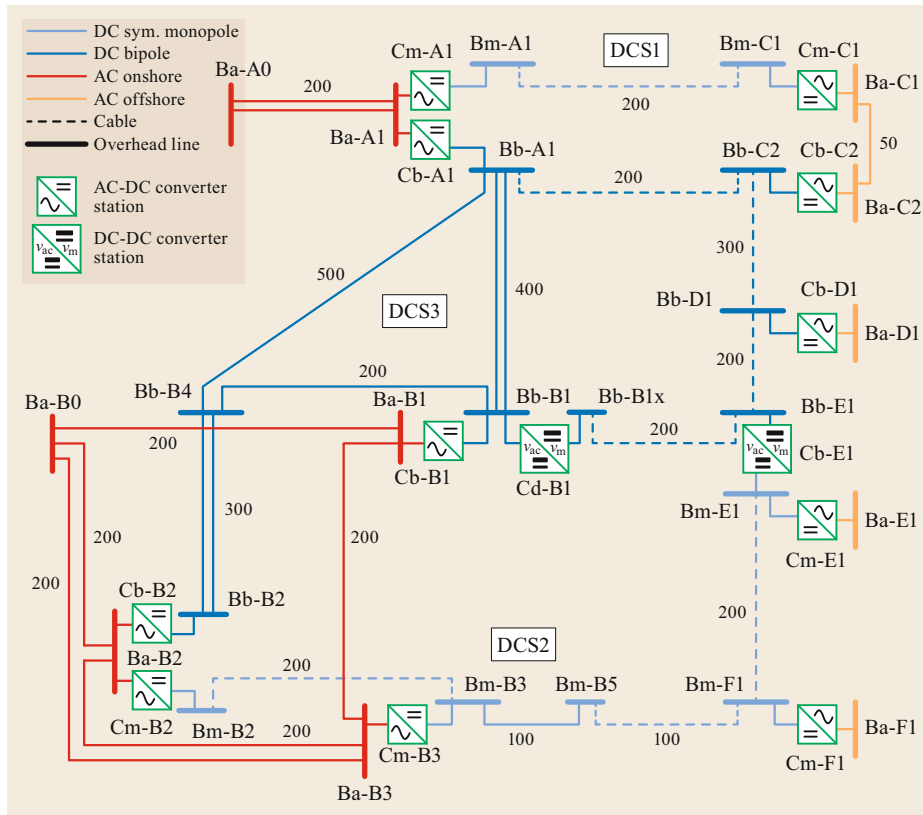

utilizes point-to-point cable transmission,  $\pm 200$  kV, and employs a symmetrical monopole configuration. System DCS2 is a  $\pm 200$  kV multiterminal system with symmetrical monopoles. System DCS3 is a DC meshed grid,  $\pm 400$  kV, that uses a bipolar configuration, overhead lines, and cables.

There are many VSC AC/DC converters and two DC/DC converters in the test system. One of the DC/DC converters (Cd-B1) causes small changes in the Bb-B1x bus to control the power in the Bb-B1x to Bb-E1 circuit. The other DC/DC converter (Cd-E1) connects the 400 and 200 kV DC systems.

In a symmetrical monopole configuration, the need for or the occurrence of an outage in one pole (converter or line) causes both poles to disconnect. In a bipolar configuration, the system can remain in operation with only one pole; this type of operation is usually termed an asymmetrical configuration.

The interconnection of systems (AC and DC) is achieved through converters (controllable devices), which allows the systems to be independent. Therefore, the power flow can be calculated separately for each system.

There are many challenges that must be overcome in order to develop a system like the one described. For instance, as of 2018, the capacity of a VSC was below 2000 MW, whereas the capacity of a LCC was about 6000 MW at  $\pm 800$  kV. Also, a DC cable with ethylene-

**Fig. 12.82** CIGRE DC grid test system [12.33]

propylene-rubber (EPR) insulation is limited to 320 kV, although 500 kV cables may become available soon. Indeed, some 500 kV high-capacity oil-filled cables are already on the market.

DC/DC converters (buck–boost configuration) are in use in industrial systems with low power ratings. The use of a combination of components (DC/AC converter, transformer, and AC/DC converter) in DC/DC converters such as Cd-E1 has been proposed. The transformer may be single-phased and designed for a specific frequency (not necessarily 50 or 60 Hz).

The main challenge, however, is to develop fast-acting DC breakers. Some engineers believe that, if the transient current capability of an IGBT is taken into account, the fault clearing time (i.e., the time from the instant the fault is detected until the current is interrupted) should be less than about 5 ms to avoid system collapse. A protection relay in an AC system can detect a fault in 8–15 ms, and the breaker will open in about 20–40 ms. Thus, new devices (based on power electronics) will need to be developed for DC grid applications [12.31].

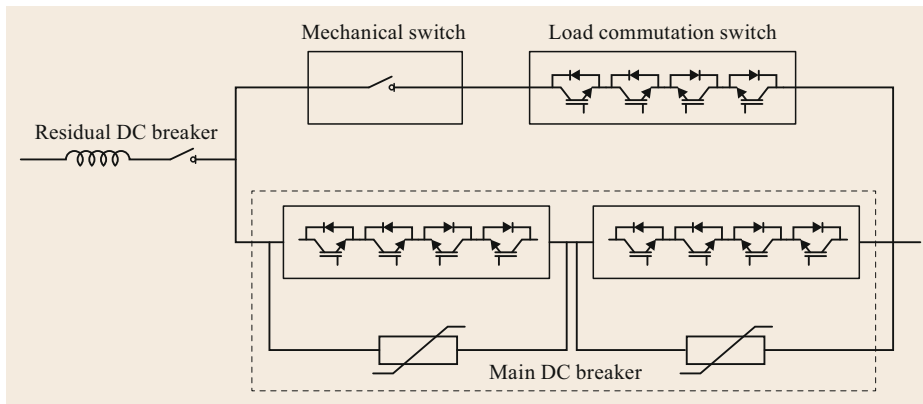

Some manufacturers have, however, developed prototypes of a hybrid DC breaker; see, for example, Fig. 12.83. During steady-state operation, the mechanical and load commutation switches are closed. When

a fault is detected, the commutation switch opens and the current is rerouted to the main DC breaker. The mechanical switch also opens (there is no arcing). The main breaker then trips and the current is rerouted to the varistor branch. The current decreases to zero and the residual DC breaker is opened. To reconnect the line, the reverse procedure is carried out. Note that mechanical and load commutation switches are also employed to reduce losses, which are high in the main circuit breaker.

Other manufacturers believe that for DC grid applications, a full-bridge architecture must be used in the VSC. A half-bridge architecture is generally used in the bipolar configuration. When a pole-to-ground fault occurs, the short-circuit current circulates through the diodes (see Fig. 12.57), which may damage the converter. In a point-to-point transmission system, this threat (damage) is prevented by opening the AC breaker sufficiently rapidly (this approach is used in the Caprivi Link HVDC Scheme). Although the use of the full-bridge architecture may result in greater reliability, it is also more expensive.

One of the CIGRE working groups (B4-72) is considering possible applications of DC grids and is producing benchmark models that include VSCs, LCCs, breakers, and other related devices.

**Fig. 12.83** Hybrid DC breaker

Finally, it is important to mention that the increasing generation of renewable energy will have an impact on new HVDC systems. Some wind power plants (specifically those that use type 4 wind turbines) employ the full converter architecture to connect them to AC feeders. Photovoltaic power plants generate DC voltage and are connected to AC feeders through inverters. In

all of these cases, a voltage and frequency transient ride-through capability is required, and this is easily obtained with VSC converters. Offshore wind farms located far (e.g., 100 km) from the shore must be connected to the grid via DC cables.

All of these factors will enhance the application of DC grids in a meshed configuration.

## 12.8 Future Trends

As discussed above, future developments in this field are likely to include (among others):

- EPR insulated cables with a voltage rating of 500 kV or more.
- VSCs with high power rating capacities.
- The development of economic full-bridge converters.
- The development of fast DC circuit breakers based on power electronics.
- Offshore DC grids. When developing an offshore DC grid, it is important to identify the required converter characteristics, determining the operating points, DC voltage level, amount of reserve, DC grid fault behavior, type of testing, and the DC grid behavior during AC faults.

Sao Paulo, Brazil  
jose.jardini@gmail.com

José A. Jardini received a PhD from São Paulo University in 1973. He has worked for Themag Engineering and São Paulo University. His work focuses on power systems and electrical system automation, and he has participated in many important Brazilian AC and DC system studies. He is a Fellow of IEEE and a member of CIGRE, and contributes to the CIGRE Transmission Line and HVDC System Working Group.

# Power System

## 13. Power System Protection

Peter Schegner

A protection system is an essential requirement for the safe and reliable operation of an electric power system. An electric power system is part of an infrastructure that covers a large area and in which faults cannot be avoided in general. The protection system must guarantee that faulty equipment is disconnected from the system as quickly as possible in order to ensure the continued operation of the rest of the electric power system.

At the beginning of this chapter, the general requirements for a selective protection system and its basic concepts are presented. This is followed by a description of the criteria that can be used to detect faults in electric power systems. Current and voltage transformers are required to measure high voltages and currents. The selection and dimensioning of these are described in the following. The basic selective protection functions are explained and their implementation is described in the following section. Additional functions that are used to increase the performance and selectivity of the protection system are also presented. At the end of this chapter, some examples are presented to illustrate the structure of the protection system for selected electric equipment.

### 13.1 Background

Fault and hazard conditions cannot be avoided in broadly distributed electric power systems, so their impact on the electric power system has to be minimized by using a selective protection system. The essential task of the protection system is to switch off faulty equipment very quickly and selectively [13.1]. The objectives are to significantly reduce the damage to the faulty equipment, to protect equipment exposed to short-circuit currents from overloading, and to ensure the safety of people and animals against step and touch voltages. The protection system must ensure that the fault does not extend and that the function and stability of the entire electric power system are guaranteed.

#### 13.1.1 General Requirements

In addition to the requirements applicable to all technical systems, such as small size, low maintenance, easy operation, and reasonable price, the following additional requirements must be met by protection systems:

##### Selectivity of Protection

According to [13.2], selectivity is the ability of a protection system to identify the faulty section and phase of an electric power system. The term *selectivity* includes the identification of the faulty equipment and its position inside the electric power system, as well as the detailed

state of the fault, characterized by its type and behavior. The requirement for selectivity is of fundamental importance to ensure that only faulty equipment is disconnected from the electric power system and that the actions of the protection system are appropriate for each fault situation.

#### Sufficiently Fast Response Time

The requirement for a sufficiently fast response time of the protection system results from two important facts: on the one hand, the amount of damage depends on the duration of the fault, while on the other hand, the stability of the overall electric power system is also directly affected by the duration of the fault. This applies, for example, to arc faults, which lead to a rapid increase of the temperature in the surroundings of the arc. This may result in an explosion of encapsulated equipment as well as thermal and mechanical overload of all current-carrying components. In addition, loss of stability of generators and other consequences could arise.

When determining the response time, a trade-off must be achieved between technical requirements and economic expenditure. In practice, the response time required for a protection system depends on the electric equipment to be protected, ranging from a few milliseconds (e.g., for trolley wires of electric railways) to a few minutes for overload protection (e.g., for transformers).

#### Reliability of Protection

Reliability is an important feature of any technical system. Commonly, reliability requirements are subdivided into different aspects, as the technical approaches used to improve reliability in different fields can vary greatly and even be contradictory. Often, reliability is divided into dependability and security. In order to increase the dependability (functional reliability), i.e., to reduce the probability of outage of the technical system, several redundant and diverse devices may be operated in parallel at the same time. Finally, a one-of- $n$  decision is implemented. On the other hand, to increase the safety against malfunctions, several devices may be connected in series, meaning that  $n$  devices must reach the same decision to cause a response of the technical system. This illustrates the contradictory solutions to increasing the reliability of any technical system. The objective must be a technically reasonable solution.

The reliability of a protection system is strongly related to the definition of incorrect operation of protection. In [13.2], incorrect operation of protection is defined as the failure to operate or an unwanted operation. Failure to operate means that there is a fault in the

electric power system but the protection system does not operate or misoperates. An unwanted operation of the protection system is the activity of the system during normal network operation or during a fault in the energy system that lies outside the zone of the protection system.

For protection systems, any unnecessary intervention in the form of switching off fault-free primary equipment is an undesirable event. A malfunction, i.e., the misoperation of the protection system during a primary fault, is extremely critical. In any case, the protection system must be, in principle, more reliable than the protected system, i.e., the primary equipment of the electric power system.

#### Accuracy and Sensitivity of Protection

These requirements are related to the implementation of the protection function, including both its measuring accuracy and timing.

The timing is important for the selectivity of the protection system. In modern numerical protective devices, the timing depends only on the runtime of the software. Therefore, nowadays there are in general no timing problems associated with aging of hardware or other environmental effects such as temperature.

However, timing may still vary, even for numerical protective devices. This variation depends on the software implementation and the calculation time of the protection algorithm, which defines the cycle time of the software. These fluctuations should lie in the range of a few milliseconds.

An additional challenge is the measurement accuracy of the protection system. On the one hand, currents in the range of 10% of the rated current have to be measured with high accuracy in order to start, for example, impedance calculations. On the other hand, the short-circuit current could be more than 50 times the rated current, and this high current should also be measured with high accuracy. The measurement range of the current path should be 1–100, with an error below 1%.

Only if these requirements are fulfilled is selective and accurate fault location realizable.

#### Economic Adequacy of Protection

The costs of the protection system must be reasonable in relation to the value and importance of the primary equipment to be protected; for example, the protection system for a low-voltage network with a small number of customers should be simpler and cheaper than the protection system for a transmission transformer. As a rule of thumb, the price of the protection system should lie in the range of 2–5% of the value of the primary equipment.

### 13.1.2 General Protection Concepts

The protection system is part of the secondary equipment of any electric power system. The main parts of the secondary equipment are the control and protection systems [13.3]. One of the special challenges faced by the protection system is that it must function automatically in critical network conditions without support from operating personnel. Furthermore, it is expected that the protection system will work properly even if extreme voltage and current conditions are present in the electric power system.

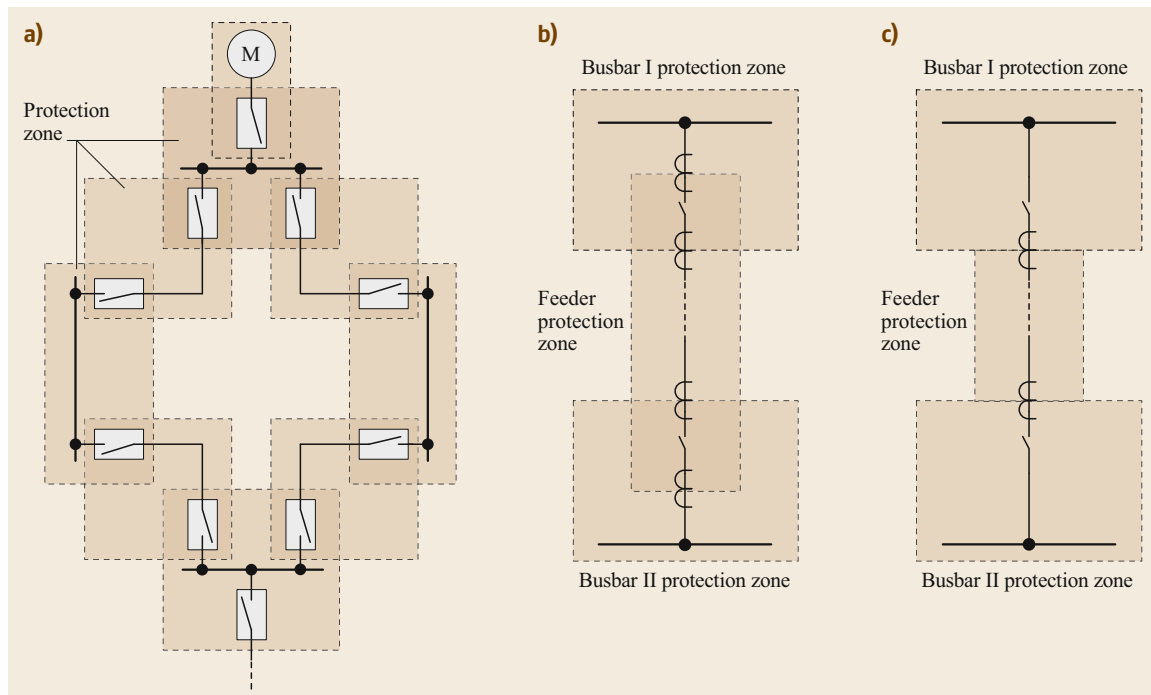

#### Protection Zones

In order to meet the general requirements described above, the entire electric power system is divided into so-called protection zones. Figure 13.1a shows an example of an electric power system, which is divided into several protection zones. The borders of the protection zones are defined by the current measurements, i.e., the position of the current transformers installed in the electric power system. Theoretically, each piece of electric equipment should be assigned to a separate protection zone. Therefore, to achieve overlapping of the protection zones, theoretically, two current measurements should be carried out at the interface between protection zones. This is shown in Fig. 13.1b. However, this

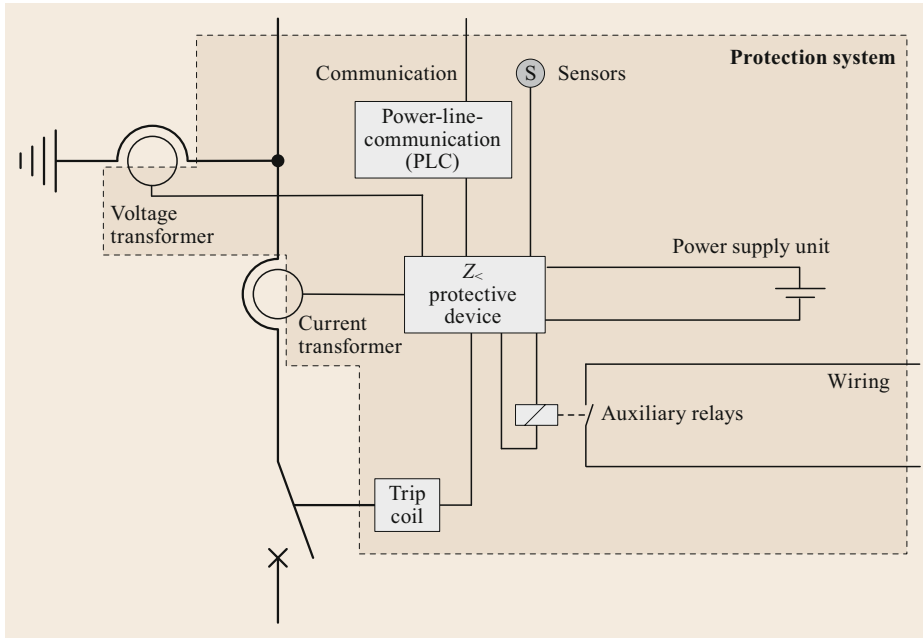

theoretical requirement of overlapping protection zones is not implemented in practice due to the high costs involved; rather, the current measurement is carried out at only one place. In order to implement two independent protection systems for adjacent protection zones, two separate secondary windings of the current transformer are used, resulting in the arrangement shown in Fig. 13.1c. The adjacent protection zones no longer overlap, but only touch each other. In the event of a fault in the small area between the current transformer and circuit-breaker, the busbar is switched off unnecessarily while the fault will still be transmitted via the line. The fault is switched off by the backup protection system, which is explained below. The small, nonselective area described above is therefore acceptable.

#### Backup Protection System

In order to achieve the necessary reliability of the protection system, a backup protection system is provided for each protection zone. A backup protection system is a fully redundant protection system. According to [13.2], a protection system consists of at least a protective device, a separate secondary winding of the instrument transformer, independent wiring, independent tripping circuits, its own auxiliary supply, and where provided its own communication system. The circuit-breakers are excluded. This is illustrated in Fig. 13.2.

**Fig. 13.1a–c** Layout of protection zones. (a) Electric power system with protection zones, (b) ideal protection zone, (c) real protection zone

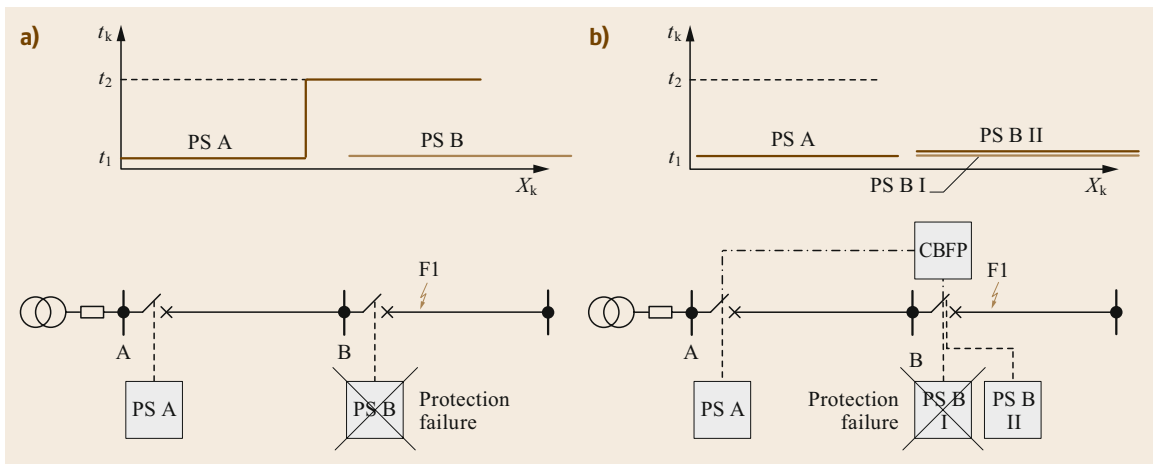

**Fig. 13.2** Elements of a protection system (adapted from [13.2])

In the past, there was a distinction between the so-called main and backup protection systems. However, today, there is no such prioritization between the two protection systems, indicating that both work on an equal and independent basis.

It should be noted that the possibility of a failure of the circuit-breaker must also be taken into account when designing the backup protection, although by definition the circuit-breaker is not part of the protection system.

There are two fundamentally different concepts for implementing backup protection systems, viz. remote backup protection and local backup protection.

In the case of remote backup protection, the faulty equipment is switched off by the protection system of an adjacent protection zone, as illustrated in Fig. 13.3a. To achieve this, all the protection systems in the electric neighborhood of the fault should also detect faults in adjacent protection zones. If the fault is not switched off within a specified time, the reach of all the protection zones is extended. These extended protection zones now also include the electric equipment of the neighboring protection zones. If the short circuit is located in this extended protection zone, a trip is triggered. When using this type of backup protection, a malfunction of the protection system leads to a nonselective

**Fig. 13.3a,b** Backup protection schema. (a) Remote backup protection. (b) Local backup protection with additional circuit-breaker failure protection (CBFP)

trip with an additional time delay. Remote backup protection covers the malfunction of both the protection system and the circuit-breaker. The concept of remote backup protection is typically used in distribution networks.

In contrast, local backup protection is characterized by the local duplication of the entire protection system. According to Fig. 13.3b, this duplication affects not only the actual protected device but also the complete wiring and power supply up to the tripping coil of the circuit-breaker. To prevent systematic faults in protective devices from failure to operate, devices from different manufacturers are normally used, and

optimally different protection principles should also be used.

Since the malfunction of the circuit-breaker is not included in this concept, circuit-breaker backup protection must always be installed in addition. This can be achieved, for example, by an additional communication link to the next circuit-breaker with corresponding logic. Such local backup protection is used in high-voltage and extrahigh-voltage networks. The expense is considerably higher, but significant shorter fault clearance times can be achieved in the event of protective or power switch malfunctions [13.4], which is necessary for the stability of such networks.

## 13.2 Protection Criteria

In this section, physical quantities that can be used to identify faults in electric power systems, i.e., so-called protection criteria, are presented. These protection criteria should be able to discriminate between operating, fault, and hazard status in the electric power system. In the simplest case, a physical quantity (e.g., current, temperature, or pressure) is compared with an adjustable threshold value. In addition, a special tripping characteristic (depending on a physical quantity) or sets of tripping characteristic (e.g., depending on several physical quantities) can be used to classify the network status.

These protection criteria can be divided into electric and nonelectric categories.

### 13.2.1 Electric Protection Criteria

The voltage and current, as well as values derived therefrom, can be used as protection criteria. Such derived values can include, for example, the impedance, admittance, and active, reactive, or apparent power. In addition, the phase angle between the voltage and current can also be used as a criterion for the fault condition of an electric power system. Not only the voltage and current of the natural system (e.g., line currents and phase-to-earth voltage or phase-to-phase voltages) but also the voltages and currents of the symmetrical components are evaluated. In addition, dielectric and magnetic fields or electric charges can also be used as protection criteria for special applications.

Selected electric protection criteria are described in more detail below. For this purpose, the measuring circuits are shown schematically, the typical range of values is explained, then a statement on selectivity is made.

### Overcurrent Criterion

Figure 13.4a shows the basic measuring diagram for the overcurrent criterion. The overcurrent protective device is typically connected by a current transformer. The tasks of the current transformer are explained in the following section. In the simplest case, the circuit-breaker is actuated when a preset current threshold is exceeded.

In order to guarantee reliable and secure discrimination between operational and failure status based on the overcurrent criterion, the following conditions must be observed

$$I_{\text{pi}} < c I_{\text{sc min}}; \quad c < 1, \quad (13.1)$$

$$I_{\text{do}} < \frac{1}{c} I_{\text{o max}}; \quad c < 1, \quad (13.2)$$

with:

$I_{\text{pi}}$	pick-up current
$I_{\text{do}}$	drop-off current
$I_{\text{sc min}}$	minimum short-circuit current
$I_{\text{o max}}$	maximum operation current
$c$	constant factor.

This relation between the different current levels is additionally illustrated in Fig. 13.4b. The necessary difference between the pick-up and drop-off current is explained at the end of this chapter.

For the overcurrent criterion, the following conditions must be observed:

The security factor  $c$  takes into account the measurement accuracy of the current transformers and the protective device itself, as well as the inaccuracy in determining the current settings. It must be considered that the maximum operating current at particular times,

**Fig. 13.4a,b** Overcurrent criterion with the connection to the primary system. (a) Measurement diagram, (b) range of application

e.g., during start-up processes, may be significantly higher than the rated current of the equipment. The calculation of the minimum short-circuit current must take into account, in addition to the specifications of [13.5], the most unfavorable switching condition (weakest supply) and the most critical fault location, as well as the most unfavorable fault conditions (high equipment temperature, fault transition resistance).

Selective short-circuit clearing based on the overcurrent criterion can only be achieved by introducing an additional delay time. This may lead to conflicts between the requirement for short fault clearing time and the selectivity of the protection system. In addition, the maximum fault clearing time prescribed by the upstream network operator must be observed.

Depending on the application, the overcurrent criterion can be applied directly to the line currents as well as the positive-, negative-, and zero-sequence currents of the symmetrical components. In some cases, the levels of single harmonics of the current are used as criteria.

In addition, it is important to consider whether the rms value, the maximum amplitude, or only the fundamental value of the current will be rated. Especially in critical borderline cases, this choice can lead to very diverse reactions of the protection system.

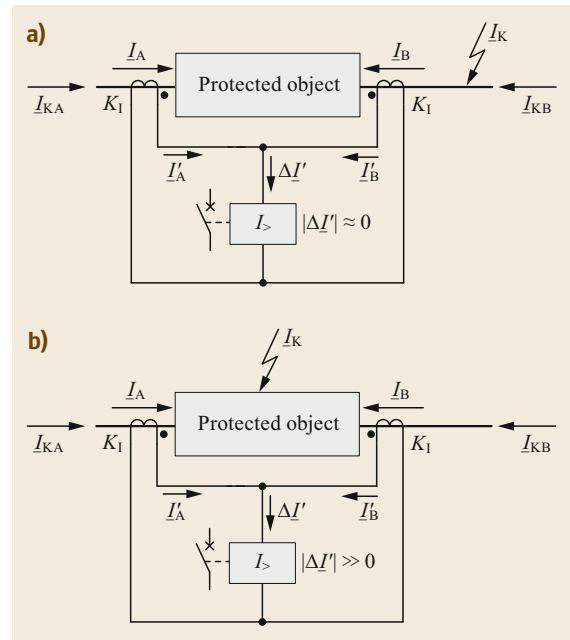

### Differential Current

The basic principle of differential protection has been known for a long time. In differential protection, the measured values are compared according to their magnitude and phase position. This can be done, for example, by a direct comparison of instantaneous values. It is also possible to compare the magnitude and phase angle of the current.

Differential current protection is the simplest and most commonly used form of differential protection. From a theoretical point of view, the procedure is based on Kirchhoff's circuit law, which states that the geometric sum of the currents at a node must be zero at all times.

The principal circuit used for unstabilized current differential protection is shown in Fig. 13.5.

Current transformers are connected at the ends of the protected object, thereby defining the differential

**Fig. 13.5a,b** Basis of the unstabilized current differential criterion. (a) Current differential protection with an external fault, (b) current differential protection with an internal fault

protection zone. The measuring direction of the current transformers is of great importance here. Usually, the measuring direction is oriented towards the protected object. This is indicated in the figure by the points on the current transformers and the counting direction of the current arrows. However, the direction of the current arrows on the current transformers thus does not correspond to the physical direction of the current, which depends on the position of the fault and of the power source. This representation of the principle is based on the assumption that the current transformers have an identical ratio.

The secondary windings of the current transformers are connected in series. The following relationship applies to the differential current

$$|\Delta I'| = |I'_A + I'_B|, \tag{13.3}$$

with:

$|\Delta I'|$  absolute value of the differential current on the secondary side

$I'_{\underline{A}}$  secondary current from side A  
 $I'_{\underline{B}}$  secondary current from side B.

The current split for an external fault is shown in Fig. 13.5a. In this case, the measured currents and the differential current are as follows

$$I'_{\underline{A}} = K_I I_{\underline{A}} = K_I I_{\underline{K}A}, \quad (13.4)$$

$$I'_{\underline{B}} = K_I I_{\underline{B}} = -K_I I_{\underline{K}A}, \quad (13.5)$$

$$|\Delta I'| = |K_I I_{\underline{K}A} + (-K_I I_{\underline{K}A})| = 0, \quad (13.6)$$

with:

$K_I$  transformation ratio of the current transformer

$I_{\underline{A}}$  primary current from side A

$I_{\underline{B}}$  primary current from side B

$I_{\underline{K}A}$  short-circuit current from side A.

It can be seen that, if a fault occurs outside the protected object, the measured currents cancel each other and no differential current flows via the differential branch.

Figure 13.5b illustrates a fault within the protected object, resulting in the following current distribution

$$I'_{\underline{A}} = K_I I_{\underline{A}} = K_I I_{\underline{K}A}, \quad (13.7)$$

$$I'_{\underline{B}} = K_I I_{\underline{B}} = K_I I_{\underline{K}B}, \quad (13.8)$$

$$|\Delta I'| = |K_I I_{\underline{K}A} + K_I I_{\underline{K}B}| \neq 0, \quad (13.9)$$

with:

$K_I$  transformation ratio of the current transformer

$I_{\underline{A}}$  primary current from side A

$I_{\underline{B}}$  primary current from side B

$I_{\underline{K}B}$  short-circuit current from side A.

The short-circuit current components ( $I_{\underline{K}A}$  and  $I_{\underline{K}B}$ ) of both sides depend on the short-circuit power of the respective connected networks. If no feeding network is connected to one of the sides, this portion of the short-circuit current may become zero. However, it is important that none of the short-circuit current components be negative in relation to the defined counting direction. This ensures that, in the case of a fault within the differential protection zone, a differential current always occurs.

As explained above, this principle is referred to as unstabilized current differential protection. This criterion is applicable to all spatially concentrated protected

Fig. 13.6 Basis of the stabilized current differential criterion

objects. In this basic form, current differential protection is not used, since even the slightest inaccuracies in the current transformers can lead to considerable differential currents in the event of high short-circuit currents outside the protection zone, in which case nonselective tripping could occur.

In practice, the so-called stabilized differential protection function is used, as shown in Fig. 13.6.

In addition to the differential current, the through current or stabilizing current  $I_{stab}$  is also measured in this case. According to Fig. 13.6, this current can be simply determined using the following relationship

$$I_{diff} = |I'_{\underline{A}} + I'_{\underline{B}}| n, \quad (13.10)$$

with  $I_{diff}$  is the secondary differential current,  $n$  is the ratio of the secondary current transformer,

$$I_{stab} = |I'_{\underline{A}} - I'_{\underline{B}}| m, \quad (13.11)$$

with  $I_{stab}$  being the secondary stabilizing current and  $m$  the ratio of the secondary current transformer.

In modern numerical protective devices, other definitions of the stabilizing current are also used, for example,

$$I_{stab\ alt} = |I'_{\underline{A}}| + |I'_{\underline{B}}|. \quad (13.12)$$

Based on this definition, the stabilizing current can be calculated more easily, and the definition is also applicable for three-winding power transformers.

Figure 13.7 shows a diagram of the differential and stabilizing current for various faults and network situations. All currents are referred to the rated current  $I_r$  of the primary terminal of the power transformer. The stabilizing current is estimated according to (13.11).

Curve (a) shows the resultant correlation between the differential and stabilizing current for a short-circuit

**Fig. 13.7** Basis of the stabilized current differential characteristic

outside the protection zone. It is assumed that the two current transformers on both sides of the protected object work without measuring errors. Curve (b) results if it is assumed that the current transformers have a relative measurement error of  $\pm 2.5\%$ . This measurement error is still within the accuracy definition of the current transformer. It can be seen that a significant differential current already occurs.

Curve (c) is obtained in the case of a short circuit within the protected object that is supplied from both sides with identical short-circuit power. If only one network feeds the fault, the curve (d) applies.

This results in the tripping characteristic for stabilized differential protection shown in Fig. 13.7. Such a multistage tripping characteristic is used very often and can be applied to achieve high sensitivity for low short-circuit currents and increased stability for high through currents due to short circuits outside the protected zone.

The principle of stabilized differential protection is state of the art today. Differential protective devices differ in their definition of the differential and stabilization currents.

#### Further Current Criteria

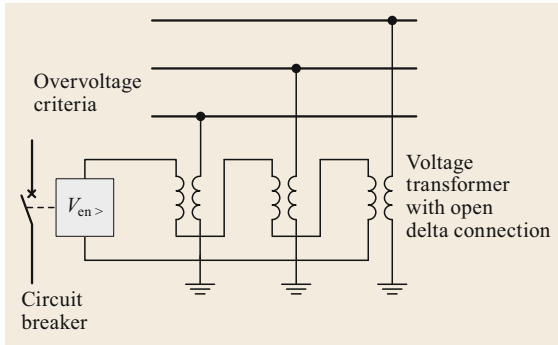

In addition to the overcurrent criterion described above, the current rise can also be used as a criterion. In mathematical terms, the derivative of the current  $di/dt$  is

monitored. In this way, the maximum current value can be determined before it reaches its maximum value. This is a very fast method, but it is not a fault location selective criterion. An additional delay time to achieve a selective reaction does not make sense, because it reduces the fast operation time of this criterion. Therefore, this criterion can only be used for clearly spatially delimited electric equipment that requires a very fast fault clearing time. A typical application for this criterion is the protection of the contact wire of electric railway systems.

A further criterion is the so-called off-system current. This criterion can only be applied to clearly spatially delimited electric equipment that is completely isolated from the earth potential. Via a coupling device, such as a capacitor, an external current is injected with a frequency that does not match the system frequency. The external current circuit is closed via the parasitic capacitance of the primary electric equipment. If a galvanic connection appears between the primary electric equipment and earth, e.g., when an earth fault occurs, the current in the external circuit increases. This off-system current criterion is very sensitive. In Germany, it is used to monitor the windings of large generators.

#### General Voltage Criteria

Figure 13.8 shows the basic measuring diagram of the zero-sequence voltage. The open-circuit voltage at the

**Fig. 13.8** Zero-sequence overvoltage criterion with the connection to the primary system

delta winding of the three voltage transformers is proportional to the zero-sequence voltage. If this voltage exceeds a defined threshold, there is an earth fault in the electric power system. This can be used for signaling or disconnection, depending on the type of star point treatment of the electric power system.

This criterion cannot be used to determine the location of the earth fault, which implies that it can only be used in a nonunit protection schema. This criterion is used in conjunction with other criteria for the detection of earth faults in all electric equipment.

#### Further Voltage Criteria

In addition to the aforementioned overvoltage criterion, there are also undervoltage criteria. Both types of voltage criteria are often used together with other criteria.

The phase-to-earth and phase-to-phase voltages as well as the positive-, negative-, and zero-sequence voltages can be used as inputs for the voltage criteria. For special applications, single harmonics of the voltage may also be used as criteria.

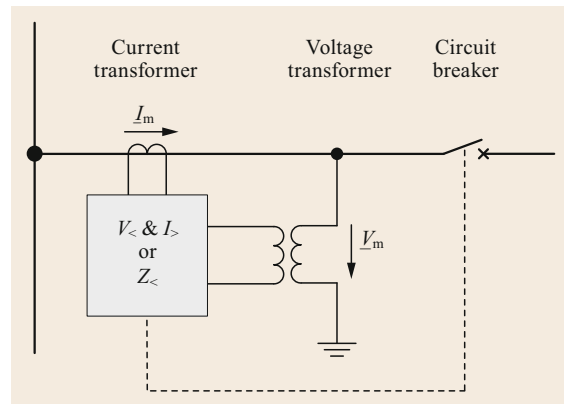

#### Derived Characteristic Criteria

Both the voltage and current can be used as input signals for the mentioned criteria. These electric signals are used to calculate the impedance, admittance, but also the active, reactive, or apparent power. In addition, the angle between the current and voltage can also be calculated as a criterion. The simplest case is a logical combination of an undervoltage and overcurrent criterion.

The basic connection for measuring voltage and current is shown in Fig. 13.9.

The undervoltage/overcurrent derived criterion is a logical combination of voltage and current thresholds. It can be formulated as

$$[(|V_m| < V_<) \wedge (I_m > I_b)] \vee [ |I_m| > I_> ], \quad (13.13)$$

**Fig. 13.9** Measurement of voltage and current for derived characteristic criteria

with:

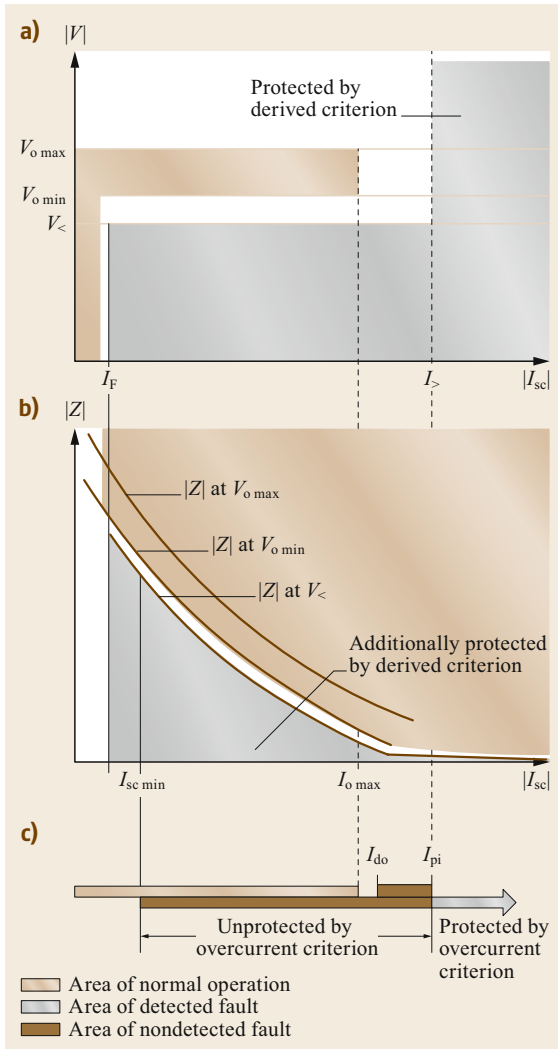

- $|V_m|$  absolute value of the measured voltage
- $|I_m|$  absolute value of the measured current
- $V_<$  threshold for minimum operational voltage
- $I_b$  threshold for base point current
- $I_>$  threshold for overcurrent.

Figure 13.10a illustrates a situation in which the maximum operating current  $I_{o,max}$  is greater than the minimum short-circuit current  $I_{sc,min}$ . In this case, the relations defined in (13.1) and (13.2) cannot be fulfilled. Therefore, the pick-up and drop-off current must be set above the maximum operation current. The lower part of the figure clearly shows that there is a wide current range in which a fault will not be detected by the overcurrent criterion.

The logical combination of the undervoltage and overcurrent criteria according to (13.13) is illustrated in the top of Fig. 13.10. The value of the base point current could be 10% of the rated operation current. Based on the logical operation, the fault situation is identified. It can be clearly seen that, based on this logical operation, faults with current below the rated current can also be detected.

Figure 13.10b additionally illustrates the corresponding fault detection area in the impedance versus current diagram. The three curves in the middle represent the absolute value of the measured impedance at the maximum and minimum operational voltage ( $V_{o,max}$  and  $V_{o,min}$ ). The lowest curve shows the lowest acceptable impedance during normal operation as a function of the current; this corresponds to the  $V_<$  threshold. The area below this curve represents the additional protected impedance region.

Another derived criterion is the underimpedance criterion. The basis of this criterion is the assumption

**Fig. 13.10a-c** Discrimination between fault and normal operation by derived electric criteria. (a) Derived criterion: undervoltage and overcurrent criterion, (b) resulting fault detection area, (c) simple criterion: overcurrent criterion

that there is a correlation between the impedance measured during a short circuit and the distance to the short circuit. In this way, the location of the fault can be calculated directly from the impedance value, if the impedance per length of the electric line is known. The single line diagram in Fig. 13.11a illustrates this situation. The second part of this figure shows the electric circuit. It can be clearly seen that the impedance measured at the start of the line indicates the distance between the measurement and the fault location.

Based on the voltage loop in Fig. 13.11b, the fault impedance can be calculated from the measured voltage  $\underline{V}_m$  and current  $\underline{I}_m$  as

**Fig. 13.11a,b** Relation between fault impedance and fault location. (a) Single line diagram, (b) electric circuit

$$\underline{Z}_m = \frac{\underline{V}_m}{\underline{I}_m} = (R'_1 + jX'_1) l_{sc} \quad (13.14)$$

with:

$\underline{Z}_m$  complex value of the calculated impedance

$\underline{V}_m$  complex value of the measured voltage

$\underline{I}_m$  complex value of the measured current

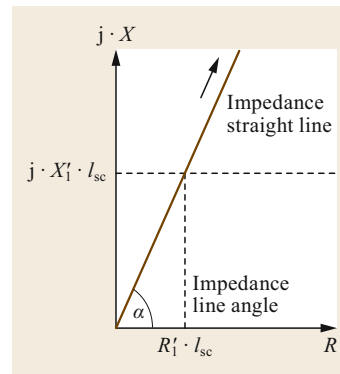

$R'_1$  length-related positive-sequence resistance of the line

$X'_1$  length-related positive-sequence reactance of the line

$l_{sc}$  distance between measurement point and fault location.

Figure 13.12 illustrates (13.14) in the complex  $X/R$ -plane. The impedance straight line represents the constant  $X/R$ -ratio of the transmission line. The position along this straight line changes depending on the fault distance  $l_{sc}$ .

Figure 13.12 illustrates how either the reactance or resistance of the fault loop can be used to deter-

**Fig. 13.12** Fault distance in the complex plane

mine the fault distance. This is only valid for an ideal fault without additional contact or arc resistance. In real applications of this criterion, the fault distance is determined based on the reactance. The mentioned contact resistance does not considerably disturb the reactance. The underimpedance criterion is used to protect overhead transmission lines, cables, transformers, and generators. It is a universal criterion.

### 13.2.2 Nonelectric Criteria

The following list presents the numerous nonelectric physical variables that can also be used to detect faults in electric power systems:

- **Temperature**  
Temperature measurements are used for transformers, electric machines, generator cables, and overhead lines. Such temperature measurements are partly carried out using simple sensors (e.g., PT100 resistance thermometers), but also with the help of infrared temperature measurement instruments.
- **Gas pressure**  
The pressure of the gas can be used as a fault indicator for air- and gas-insulated switchgear (GIS) or gas-insulated lines (GILs). Very different techniques for measuring the pressure of the gas are available, including simple pressure equalization flaps up to modern temperature-compensated pressure sensor technology.
- **Light**  
Light is often used for the identification of arcs in closed or encapsulated switchgear. Either simple point-based light sensors or fiber-optic cables can be used as sensors.
- **Structure-borne noises**  
Noise can be used to detect partial discharges in gas-insulated switchgear. Special microphones for structure-borne sound can be used for this purpose.
- **Oil flow rate and oil level**  
The oil flow rate is often used for oil-filled electric equipment. The oil flow rate between the electric equipment and oil storage is measured. During normal operation, this flow rate is determined by the thermal behavior of the equipment. If a fault occurs, the resulting decomposition of the oil results in a very high flow rate.

This list presents only a small selection of the nonelectric criteria, which are often used as additional diverse criteria for the protection of electric equipment.

### 13.2.3 Notes on Protection Criteria

Below, general information related to the protection criteria is given. First, a classification of the protection criteria is presented, based on the underlying characteristics of each which define the overall behavior.

All set points must include hysteresis in order to achieve a stable and predefined response according to the chosen protection criterion. Before implementation of such criteria in hardware, this behavior was achieved based on the physical effect itself. In modern software implementations, this behavior must be implemented as a software function. Additionally, general information about the treatment of the settings of protective devices are given. The final note relates to the determination of direction.

#### Classification of Protection Criteria

In general, protection criteria can be categorized into absolute selective criteria (unit protection) and relative selective protection criteria (nonunit protection).

Absolute selective criteria are characterized by the fact that faulty equipment can be identified unambiguously. Absolute selective criteria enable fault location determination without additional information or equipment. When using these criteria, faults outside the considered protection zone cannot be detected, thus these criteria are not suitable for remote backup protection.

Relative selective criteria detect a fault in the electric power system but identify the faulty equipment only ambiguously. As a rule, a time delay is used to achieve selective identification of faulty equipment. These criteria are always suitable for remote backup protection.

Table 13.1 illustrates the different types of protection criteria and provides additional examples.

#### Hysteresis of Set Points

All set-point values or tripping characteristics are executed with hysteresis, as shown in Fig. 13.13. In this regard, a so-called disengaging ratio is defined. This disengaging ratio is necessary to ensure stable operation of the protective device (without *chattering*). In the case

**Table 13.1** Comparison of absolute and relative selective protection criteria

Type of protection criteria	Example	Remote backup protection	Supplementary measures to achieve selectivity
Absolute selective	$\Delta I, \Delta \varphi$	Not suitable	Stabilization
Relative selective	$Z <, I >$	Suitable	Time graduation

**Fig. 13.13**  
Threshold with hysteresis

of electromagnetic protective devices, this function is included in the design. In the case of modern numerical protective devices, this function must be implemented in the software.

The disengaging ratio is defined as

$$f_{dr} = \frac{x_{do}}{x_{pi}}, \quad (13.15)$$

with:

$f_{dr}$  disengaging ratio  
 $x_{pi}$  pick-up value  
 $x_{do}$  drop-off value.

The disengaging ratio  $f_{dr}$  is smaller than 1 for all protection criteria that monitor the exceeding of a threshold, e.g., the overcurrent threshold. Depending on the application, this disengaging ratio should lie between 0.75 and 0.99.

When monitoring whether a quantity falls below a threshold, the disengaging ratio must be higher than 1, e.g., for undervoltage monitoring.

### Settings of Protective Devices

Protective devices, with rare exceptions, are designed as so-called secondary devices, meaning that they are connected to the electric power system via current and voltage transformers. For this reason, protective devices are always set in relation to these secondary values.

With the introduction of numerical protective devices, it becomes possible in principle to carry out the setting using primary values, if the ratio of the voltage and current transformers is specified. However, in order to be backwards compatible and to avoid confusion, the setting of protective devices remains based on secondary values today.

This results in the following setting calculation for current values

$$I_{s\text{set}} = \frac{I_{srCT}}{I_{prCT}} I_{p\text{set}} = \frac{1}{w_{rCT}} I_{p\text{set}}, \quad (13.16)$$

with:

$I_{s\text{set}}$  secondary set value of the current  
 $I_{srCT}$  secondary rated current of the current transformer  
 $I_{prCT}$  primary rated current of the current transformer  
 $I_{p\text{set}}$  primary set value of the current.

Here, the currents  $I_{prCT}$  and  $I_{srCT}$  are the primary and secondary rated values of the current transformers, while the calculated secondary set value is  $I_{s\text{set}}$ . In practice, the setting is often determined based on the nominal input value of the protective device.

The secondary impedances are calculated as

$$Z_{s\text{set}} = \frac{\frac{I_{prCT}}{I_{srCT}} Z_{p\text{set}}}{\frac{U_{prVT}}{U_{srVT}}} = \frac{1}{w_{rCT} w_{rVT}} Z_{p\text{set}}, \quad (13.17)$$

with:

$Z_{s\text{set}}$  secondary set value of the impedance  
 $U_{srVT}$  secondary rated voltage of the voltage transformer  
 $U_{prVT}$  primary rated voltage of the voltage transformer  
 $Z_{p\text{set}}$  primary set value of the impedance.

The voltages  $U_{prVT}$  and  $U_{srVT}$  are the primary and secondary values of the voltage transformer.

### Directional Decision

All relative selective protection criteria generally require a directional decision in meshed electric power systems or electric power systems with changing flow directions. In these cases, it must be determined whether the fault is in the direction of the protected object or not.

In addition to the current, the voltage is also required to determine the short-circuit direction. The short-circuit direction is derived from the angle between the current and voltage. Such directional determination can be negatively influenced by numerous factors, including, for example, the resistance/reactance ratio of the short-circuit loop, the level of the load current, and the compensation of overhead lines. The following description illustrates only the general principles of directional estimation; for detailed information, see [13.6].

In principle, the short-circuit direction could be determined from the sign of the short-circuit impedance or admittance. However, this method is not used, because this information is not reliable in critical short-circuit situations, e.g., nearby three-phase fault conditions. Therefore, a separate directional determination function is always implemented.

There are different technical solutions for determining the direction. In Europe, short-circuit loops in the natural system are usually evaluated. This means, for example, that in the case of a single phase-to-earth fault, the phase-to-earth voltage and the phase current of the faulty conductor are compared. However, this method becomes problematic with very small fault voltages, which is typical of nearby faults.

To determine the fault direction correctly even in these cases, the directional decision is often based on nonfault voltages, particular in overcurrent protection devices. In this case, the voltage of a loop, which is not affected by the fault, is used as a reference. An additional angle correction must be applied. It should be noted that, for all protection devices in electric power systems, the selection of the nonfault voltage must be made according to the same principle, which is normally the set point of each protective device.

In the case of a nearby three-phase fault, all voltage loops will have very low values. Therefore, the above-described procedure based on the nonfault voltage cannot be used. With the introduction of numerical protective devices, a so-called voltage storage function can be implemented. In this case, the shape of the voltage before the fault is repeated periodically. The prerequisites for this are, on the one hand, a high-precision frequency measurement, and on the other hand, that the network frequency changes only slightly

during a short circuit. The use of the voltage storage function has been tested in modern numerical selective protective devices and is state of the art today. This function correctly determines the direction of the short circuit, even if there is no voltage at all.

If the fault direction cannot be determined, for example, in the case when the voltage storage is empty and this function is not available, a preorientation is usually specified. This preorientation is typically set to the protected object, which normally leads to tripping.

Fault direction estimation in Anglo-American countries is often based on the direction evaluation of the symmetrical components. In the simplest case, the short-circuit direction is calculated based on the positive-sequence system. Since it is necessary to increase the reliability of directional estimation in the case of critical faults, procedures which additionally consider the directional decision in the negative- and zero-sequence systems can be applied.

## 13.3 Requirements on Current and Voltage Transformers

Only a few primary protective devices directly analyze the primary voltage and current values. These are usually limited to low and medium voltage levels.

Due to the huge amplitudes and high potentials of the voltage and current signals, they cannot be directly processed by secondary protective devices. The signals must therefore be adapted by voltage and current transformers or corresponding dividers.

The main tasks of the current and voltage transformers are:

- conversion of standardized primary values to standardized secondary values
- electric insulation of the protective devices against the high-voltage potential of the protected object
- exact instantaneous transformation of the primary values of current and voltage over the entire working range of the protective device
- supply of auxiliary power for transformer-powered protective devices.

A distinction is made between transformers for protection or measurement applications in terms of their accuracy and transformation characteristics. The following information is focused on the requirements for protection applications.

### 13.3.1 Inductive Current Transformers

Inductive current transformers are inductive transformers that are operated in short circuit. The primary side

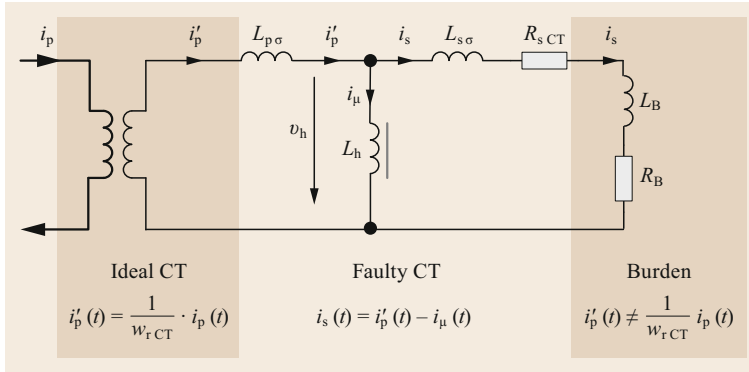

has only a few turns (in extreme cases only one), while the secondary side has a large number of turns. The primary side is operated in series with the electric power system, thus the current is impressed. With an ideal current transformer, the secondary current is therefore completely independent of the load. The secondary side acts as a theoretically ideal controlled current source. If the short circuit on the secondary side of the current transformer is opened during operation, large and dangerous overvoltages can occur.

A fundamental distinction is made between current transformers for measuring and protection purposes. Current transformers for measuring purposes must exhibit very high accuracy up to their rated current. These types of current transformers are used for billing. If the flowing current exceeds the rated value, the current transformer should saturate to protect the connected secondary devices. Current transformers for protection purposes must have a very wide measuring range, i.e., from 1% up to 100 times the rated current. The ratio of the measurement range is 1–1000.

The characteristics of current transformers for protection purposes are explained in more detail below. The international standard [13.7] specifies a number of standardized nominal values for the primary and secondary rated currents of such current transformers.  $I_{sT} = 1 \text{ A}$  has become established worldwide as the standardized secondary rated current, although sometimes the value  $I_{sT} = 5 \text{ A}$  is used.

Due to the necessary magnetizing current and the nonlinear behavior of the iron core, real current trans-

**Fig. 13.14** Simplified equivalent circuit of an inductive current transformer

formers do not exhibit ideal transfer behavior [13.8]. Measurement errors occur, depending on the one hand on the load (burden) and on the other on the setup of the iron core. A current transformer is dimensioned by the manufacturer for the rated burden, but in normal operation, it is loaded with a different burden. In addition, the exponentially decaying part of the short-circuit current at the installation site must also be taken into account. Therefore, it is necessary to dimension current transformers for each installation site.

As the stationary and transient magnetic flux can be superimposed in the magnetic circuit, the sizing of current transformers can also be divided into a stationary and transient dimension step. This requires that current transformers must always be dimensioned for the stationary and transient short-circuit current, taking into account the operational burden of the current transformer when connected.

Such dimensioning is achieved by calculating a stationary dimension factor  $K_{ost}$  and a transient dimension factor  $K_{tfdc}$ . The maximum secondary short-circuit current that can be transferred for an accuracy limit time of  $t'_{al}$  by the current transformer without saturation can then be calculated using the equation

$$I_{s\max} = \frac{K_{ost}}{K_{tfdc}} I_{sr} \tag{13.18}$$

$$I_{p\max} = \frac{K_{ost}}{K_{tfdc}} I_{pr} \tag{13.19}$$

with:

$K_{ost}$  stationary dimension factor

$K_{tfdc}$  transient dimension factor

$$w_{rCT} = \frac{I_{prCT}}{I_{srCT}} \tag{13.20}$$

is the rated transformation ratio of the current transformer.

The method for dimensioning of current transformers relies on the equivalent circuit diagram shown in Fig. 13.14, divided into three parts. The first part is an ideal current transformer with a theoretical ideal transformation ratio. This means that all further currents, voltages, and impedances are referred to the secondary side of the current transformer. The second part represents the nonlinear behavior of the real current transformer. This includes the leakage inductance of the primary and secondary winding, the resistance of the secondary winding, and the nonlinear and stray magnetization impedance. The third part is a model of the burden of the current transformer at the installation site. This burden includes both the wiring and the input impedances of the connected protective devices or other secondary equipment.

The nonlinear physical behavior is very difficult to describe, so simplifications are necessary. First, hysteresis is neglected and the magnetizing characteristic is simplified to the original curve with saturation [13.9], as shown by the dashed line in Fig. 13.15. In the next step, the linear part of this curve is represented by a single, constant inductance  $L_h$ , corresponding to the slope of the magnetizing curve in Fig. 13.15. In this case, the saturation is neglected too.

**Fig. 13.15** Simplified model of the nonlinear inductance  $L_h$

**Fig. 13.16** Phasor diagram of current transformer in the linear range

With this simplified linear analytical model, the magnetic behavior is only described correctly for a demagnetized current transformer. There should be no remanence present in the iron core, therefore the current transformer should be slotted to significantly reduce the remanence. This model is only valid up to the first saturation of the iron core, the so-called accuracy limit time  $t'_{al}$ .

**Stationary Dimension**

For steady-state dimensioning of current transformers, it is assumed that both the primary and secondary currents are sinusoidal. The current transformer is only operated up to the saturation limit. The error occurs due to the magnetizing current of the inductance  $L_h$ . Based on some assumptions, the resulting measurement error is illustrated as a vector diagram in Fig. 13.16, revealing that the measurement error of the current transformer results from the magnetizing current  $i_\mu$ . The secondary current is obtained by phasor subtraction of the magnetizing current from the ideally transferred primary current. The resulting secondary current has an error on the absolute value and angle in the linear operating range of the current transformer.

The magnetizing current is very small compared with the nominal current of a current transformer in this range. The accuracy of the current transformer for protection purposes is defined by the accuracy classes presented in Table 13.2. The calculation of the magnitude of errors at the rated current and at the rated

accuracy limit current are calculated according to [13.7] in two different ways. The first calculation method assumes a sinusoidal primary and secondary current. Therefore, this calculation is based on rms values. The second method assumes a small distortion of the secondary current. The calculation of the accuracy is carried out in the time domain.

Assuming that the current transformer is operated in the linear range, there is no saturation and all currents and voltages are sinusoidal. In this case, the calculation for an inductive current transformer represented by the equivalent circuit diagram shown in Fig. 13.14 can be carried out using phasors.

To a first approximation, the main field voltage  $V_h$  in Fig. 13.14 is identical to the voltage on the burden and the voltage on the secondary winding. If this main field voltage  $V_h$  at the magnetizing inductance  $L_h$  exceeds the so-called knee-point voltage  $V_{h\,sat}$ , the current transformer leaves its linear range, causing an abrupt increase of the magnetizing current. The current transformer goes into saturation and can no longer be described using phasors. From the equivalent circuit diagram, it is immediately visible that, with a lower burden (lower resistance), a greater current can flow until the knee-point voltage is reached. There are different approaches for determining the knee-point voltage. Unfortunately, these also give different results, so the method used to determine the knee-point voltage must always be known.

The manufacturer designs the current transformer in such a way that it reaches the saturation point at the rated accuracy limit current, when the rated burden is applied to the current transformer. According to standards, the rated burden occurs at  $\cos(\varphi) = 0.8$ , resulting in

$$V_{h\,sat} = K_{rst} I_{sr} |(R_{sCT} + R_{rB}) + j\omega (L_{s\sigma} + L_{rB})|, \tag{13.21}$$

with:

- $R_{sCT}$  resistance of secondary winding
- $L_{s\sigma}$  leakage inductance of secondary winding
- $R_{rB}$  rated resistance of the burden
- $L_{rB}$  rated inductance of the burden
- $I_{sr}$  secondary rated current
- $K_{rst}$  rated stationary accuracy limit factor
- $U_{h\,sat}$  saturation voltage of magnetizing inductance.

**Table 13.2** Accuracy classes of current transformers for protection applications according to [13.7]

Accuracy class	Measurement error at the primary rated current (%)	Phase displacement at the primary rated current (min)	Measurement error at the primary rated accuracy limit current (%)
5P	1	60	5
10P	3	–	10

Normally, the current transformer is not operated at its rated burden, as the burden in the application depends on the wiring and the connected protective devices. Normally, the operational burden is lower than the rated burden, but the knee-point voltage is the same. The following equation is therefore valid for the operation mode

$$V_{h\text{sat}} = K_{\text{ost}} I_{\text{sr}} |(R_{\text{sCT}} + R_{\text{oB}}) + j\omega (L_{\text{s}\sigma} + L_{\text{oB}})|, \quad (13.22)$$

with:

- $R_{\text{oB}}$  operation resistance of the burden
- $L_{\text{oB}}$  operation inductance of the burden
- $K_{\text{ost}}$  operation stationary accuracy limit factor.

Combining (13.21) and (13.22), the stationary accuracy limit factor can be calculated as

$$K_{\text{ost}} = K_{\text{rst}} \frac{|(R_{\text{sCT}} + R_{\text{rB}}) + j\omega (L_{\text{s}\sigma} + L_{\text{rB}})|}{|(R_{\text{sCT}} + R_{\text{oB}}) + j\omega (L_{\text{s}\sigma} + L_{\text{oB}})|}. \quad (13.23)$$

The leakage inductance of the secondary winding is very small and can be neglected, thus

$$K_{\text{ost}} = K_{\text{rst}} \frac{|R_{\text{sCT}} + \underline{Z}_{\text{rB}}|}{|R_{\text{sCT}} + \underline{Z}_{\text{oB}}|}. \quad (13.24)$$

The impedance angle of the operating burden is often not known, therefore only the resistance of the operating burden is used. To avoid oversizing, the absolute value of the rated burden is simply used. This leads to the following simplified equation for the calculation of the stationary operational accuracy limit factor

$$K_{\text{ost}} = K_{\text{rst}} \frac{R_{\text{sCT}} + |\underline{Z}_{\text{rB}}|}{R_{\text{sCTs}} + R_{\text{oB}}}. \quad (13.25)$$

### Transient Dimension

Depending on the inception time of a short-circuit fault, an exponentially decaying direct-current component results in the primary short-circuit current. This short-circuit current can be expressed as (13.26)

$$i_{\text{p}} = \sqrt{2} I_{\text{SC}}'' \left[ e^{-\frac{t}{T_{\text{p}}}} \cos(\theta) - \cos(\omega t + \theta) \right], \quad (13.26)$$

with:

- $T_{\text{p}} = L_{\text{p}}/R_{\text{p}}$  primary time constant
- $\theta = \gamma - \vartheta$  fault angle
- $\gamma$  switching angle or fault inception angle
- $\vartheta = \arctan(X_{\text{p}}/R_{\text{p}}) = \arctan(\omega T_{\text{p}})$  phase angle of the short-circuit impedance.

**Fig. 13.17** Primary and secondary currents of current transformer with exponentially decaying direct-current component

The primary time constant of the short-circuit current  $T_{\text{p}}$ , also referred to as the network time constant, is determined by the  $R/X$  ratio of the primary network at the installation point of the current transformer. This time constant depends mainly on the voltage level and the structure of the network. It can take values from a few tens to several hundreds of milliseconds. This time constant must be determined by the network operator.

Figure 13.17 shows the transient transfer behavior of a current transformer. The primary short-circuit current has a time constant of  $T_{\text{p}} = 100$  ms. This is typical for medium-voltage networks. The secondary time constant of the converter is  $T_{\text{s}} = 300$  ms. The second curve shows the current transformer's transfer behavior. In this case, the current transformer saturates after 12 ms.

On the secondary side of the current transformer, the time constant of the short-circuit current and the time constant of the current transformer  $T_{\text{s}}$  itself superimpose.

The magnetic flux resulting in the current transformer is the integral of the main field voltage over time. For a purely sinusoidal main field voltage, the magnetic flux reaches its maximum after a half-wave, since the current transformer is magnetized with opposite polarity in the next half-wave. This balance is lost due to the direct-current (DC) component of the short-circuit current. The current transformer is additionally magnetized by the DC component until the saturation flow is reached.

In addition, the duty cycle must be taken into account. If the short-circuit current is only a switch-off, viz. the so-called C-0 cycle, there is no additional magnetization. In combination with the auto-reclosing function, the duty cycle would be C-0-C-0. After a short interruption, the short-circuit current could flow again, and an additional magnetization would occur.

**Table 13.3** Different types of current transformers for protection according to [13.7, 10]

Type of current transformer	Threshold for remanence flux	Description
P	No	Definition of the accuracy by rated accuracy factor for symmetrical short-circuit current
PR	Yes	
PX	No	Definition of current transformer behavior by parameters of the magnetizing curve
PXR	Yes	
TPX	No	Closed-core current transformer for specified transient duty cycle
TPY	Yes	Gapped (low-remanence) current transformer for specified transient duty cycle
TPZ	Yes	Linear current transformer (no remanence)

This leads to additional requirements on current transformers.

In the following, a C–0 cycle is assumed. The calculation of the transient dimension factor is based on the differential equation for the simplified equivalent circuit of an inductive current transformer shown in Fig. 13.14. The transient factor is obtained from the ratio  $K_{tf}(t)$  between the time-dependent magnetic flux and the peak value of the sinusoidal component

$$K_{tf}(t) = \frac{\psi(t)}{\hat{\psi}_{\text{sinus}}} = \frac{L_h i_{\mu}(t)}{\hat{\psi}_{\text{sinus}}}, \quad (13.27)$$

with:

- $K_{tf}(t)$  time-dependent ratio of the magnetic flux
- $\psi(t)$  time-dependent magnetic flux
- $\hat{\psi}_{\text{sinus}}$  peak value of the sinusoidal magnetic flux.

The calculation of this time-dependent factor is illustrated in detail in [13.11]. Taking into account some simplifications and the worst-case assumption, the following equation published in [13.10] results

$$K_{\text{tf dc}}(t'_{\text{al}}) = \frac{\omega T_P T_S}{T_P - T_S} \left( e^{-\frac{t'_{\text{al}}}{T_P}} - e^{-\frac{t'_{\text{al}}}{T_S}} \right) + 1, \quad (13.28)$$

with:

- $K_{\text{tf dc}}(t'_{\text{al}})$  transient dimension factor as a function of the accuracy time
- $t'_{\text{al}}$  accuracy limit time.

The entire dimensioning of the current transformer for the C–0 cycle can now be carried out according to (13.28).

For the dimensioning of a current transformer for a C–0–C–0 cycle, the demagnetization during the idle period and the remanence of the current transformer must be taken into account. It is assumed that the short-circuit current after the reclosing maintains the same polarity as immediately before switching off, i.e., the

worst-case situation,

$$K_{\text{tf dc}}(t'_{\text{al}}, t''_{\text{al}}) = \left[ \frac{\omega T_P T_S}{T_P - T_S} \left( e^{-\frac{t'_{\text{al}}}{T_P}} - e^{-\frac{t'_{\text{al}}}{T_S}} \right) + 1 \right] e^{-\frac{(t_{\text{dt}} + t''_{\text{al}})}{T_S}} + \left[ \frac{\omega T_P T_S}{T_P - T_S} \left( e^{-\frac{t''_{\text{al}}}{T_P}} - e^{-\frac{t''_{\text{al}}}{T_S}} \right) + 1 \right], \quad (13.29)$$

with:

- $t_{\text{dt}}$  dead time during auto-reclosing
- $t''_{\text{al}}$  accuracy limit time for the second current flow.

The remanence is taken into account by the definition of different types of current transformers, as listed in Table 13.3 according to standards [13.7] and [13.10].

### 13.3.2 Inductive Voltage Transformers

Inductive voltage transformers are inductive transformers that are operated in almost no-load condition. The primary side has a large number of windings, while the secondary side has a small number of windings. A short-circuit on the secondary side of the voltage transformer can lead to overload and thermal damage of the voltage transformer. Therefore, voltage transformers must be protected against overload.

The standard [13.12] specifies a number of fixed values for the primary and secondary rated voltages.  $V_{\text{sr}} = 100 \text{ V}$  has become established as the secondary rated voltage in many countries. The standard [13.12] defines different accuracy levels for voltage transformers depending on their application. This includes not only the accuracy levels but also the ranges of the nominal voltage at which these accuracy levels apply. Table 13.4 lists the requirements for voltage transformers for protection applications. The given accuracy values must be guaranteed in the voltage range from 5% of the rated voltage up to the rated voltage multiplied by the rated voltage factor to be selected by the customer (typically 1.2, 1.5, or 1.9). A range of burdens

**Table 13.4** Different types of voltage transformers for protection applications according to [13.12]

Accuracy class	Measurement error at the primary rated voltage (%)	Phase displacement at the primary rated voltage (min)
3P	3	120
6P	6	240

over which these values must be guaranteed is also defined in the standards.

In contrast to a current transformer, no further dimensioning is required for a voltage transformer with

regard to the transfer behavior as long as it is burdened with a load identical to or below its rated burden. A small burden for a voltage transformer implies a small current at a large voltage, which corresponds to a large impedance on the secondary side.

Because voltage transformers must not be overloaded, they must be protected with a fuse or voltage transformer automatic fuse. It is important that the tripping of this automatic fuse be signaled to the protective devices, in particular to distant protection; otherwise, there is the danger of overfunctioning, as zero impedance will be calculated in the absence of a voltage.

## 13.4 General Protection Functions

This section illustrates the three main and most widely used protection functions. When implementing these protection functions in devices, there are minor differences between manufacturers. These minor differences are not illustrated, but only the basic functional concept. In order to obtain an understanding of the detailed differences, manufacturers' manuals must be studied in detail.

Initially, the protection function was implemented using mechanical relays. Therefore, even today, protective devices are often called protection relays. However, modern protective devices are based on microprocessors, and the functions are implemented using highly complex signal-theoretical algorithms. For this reason, the term *protective device* is increasingly being used.

### 13.4.1 Introduction to Protection Functions

#### Function Numbers

Individual protection functions are often identified using the ANSI device number system [13.13]. Device numbers are used to identify the functions of devices shown on a schematic diagram. Some examples of device numbers are shown in Table 13.5. One physical device may correspond to one function number or may have many function numbers associated with it, as is the case with new, numerical protective devices.

**Table 13.5** Example ANSI device numbers according to [13.13]

Device number	Description
50	Instantaneous overcurrent relay
51	AC time overcurrent relay
51N	AC time neutral overcurrent
51P	AC time phase overcurrent
59	Overvoltage relay
59N	Neutral overvoltage
59P	Phase overvoltage

A suffix letter or number may be used with the device number; for example, the suffix *N* is used if the device is connected to the neutral (e.g., 59*N* indicates protection against neutral voltage displacement), whereas the suffixes *X*, *Y*, and *Z* are used for auxiliary devices.

#### Starting

As illustrated above, a distinction is made between absolute and relative selective protection criteria. It has been illustrated that relative selective protection criteria need a time delay for selective fault clearing and the back-up functionality. To implement this time delay, a common time base for all protective devices in the same network is needed. This is achieved by the so-called starting element.

The main task of the starting element is to detect short circuits in the electric power system, independent of their location, aiming to detect short circuits in not only its own but also distant protection zones.

The starting element has the task of starting the internal time base for all protective devices. In this way, the starting element defines a common reference time point for all protective devices. There are also protective functions where the starting element has additional functions.

Depending on the protection criterion applied, different methods can be used to implement the starting element. In some cases, the procedures are very simple, to ensure the starting of the protective devices and avoid the requirement for additional setting parameters. However, there are also very complex algorithms. The individual methods for implementing the starting elements are explained in detail when the respective protective function is described.

#### Release Characteristic

Special release characteristics apply to achieve a defined behavior of protective devices in case of repeated

**Fig. 13.18a,b** Function of the independent reset time: **(a)** Immediate release after switch-off command, **(b)** delayed release after switch-off command (adapted from [13.14])

intermittent faults or faults occurring in rapid succession. A fundamental differentiation is made between instantaneous, independent, and dependent release behavior.

**Instantaneous Release.** If no intended delay is foreseen, the protective device must release itself when the

drop-off value  $I_{do}$  of the input quantity is reached. This applies for both types of overcurrent protective devices described below.

**Independent Release.** With this method, the protective device must remain active for a fixed reset time after the value of the characteristic quantity falls below

**Table 13.6** Examples of inverse time characteristic functions (adapted from [13.14])

Typ	Trip time			Release time		Description
	$t_{TT} = T_P \left[ \frac{k}{\left(\frac{I}{I_S}\right)^\alpha - 1} + c \right]$			$t_{RT} = T_P \frac{t_r}{1 - \left(\frac{I}{I_S}\right)^\alpha}$		
	$k$ (s)	$c$ (s)	$\alpha$	$t_r$ (s)	$\alpha$	
A	0.14	0	0.01	a	a	Inverse
B	13.5	0	1	a	a	Very inverse
C	80	0	2	a	a	Extremely inverse
D	0.0515	0.1140	0.02	4.85	2	IEEE moderately inverse
E	19.61	0.491	2	21.6	2	IEEE very inverse
F	28.2	0.1217	2	29.1	2	IEEE extremely inverse

<sup>a</sup> To be defined by the manufacturer

the drop-off value; the starting element is set to zero. All other internal functions of the protective device remain at the reached operating states, but without being reset. This also applies to the time delay counter of the time zones, which remain active and stop counting, but are not set to zero.

The basic behavior is shown in Fig. 13.18. If the characteristic quantity, e.g., the current, exceeds the pick-up value, the protective device is triggered after an internal response time. The starting signal and the active status are set. If these two signals are active, all functions of the protective devices work; in particular, the internal time zones are started. If the characteristic quantity falls below the drop-off value, the starting signal is reset after an internal release time, and the adjusted reset time  $t_{RT}$  is started. Only the active status is now present. The internal protection functions are stopped but not reset. After the release time has elapsed, the internal active state and thus all internal protective device functions are reset  $t_{re}$ . It is assumed that the adjusted delay time to switch off the circuit-breaker  $t_{tripp}$  has not yet been reached. As seen in the first part of Fig. 13.18a,b, the actual release time consists of the internal response time and the adjusted release time setting.

The second part of Fig. 13.18a,b explains the behavior when a starting signal occurs again within the release time. Whenever the starting signal is set, all internal protective device functions continue to run from the previously stored state, since the starting and active signal are present. This applies in particular to all time zones. If the adjusted delay time to switch off is reached, the protective device issues the switch-off command.

If the characteristic quantity falls below the drop-off threshold after the switch-off command, the starting signal is reset after an internal response time. The manufacturer of the protective device can now specify in which way the protective device behaves: either the adjusted release time is started again, as shown in Fig. 13.18b, or as shown in Fig. 13.18a, the protective device is immediately released.

**Dependent Release.** The logic of dependent release is identical to that of independent release. The difference is that the release time does not correspond to a fixed adjusted time value but is dependent on the value of the time delay counter and the current flowing after the reset of the starting element. The time delay counter will be integrated upward while the starting element is active and downward after the reset of the starting element. The speed of these upward and downward integrations depends on the actual flowing current and the selected delay function according to Table 13.6. The logic is shown in Fig. 13.19. Again, there are the two different behaviors after a switch-off command, which is explained in the independent release function.

The release time can be calculated using

$$\int_0^{t_p} \frac{1}{t_{TT}(G)} dt - \int_0^{t_{RT}} \frac{1}{t_P(G)} dt = 0. \tag{13.30}$$

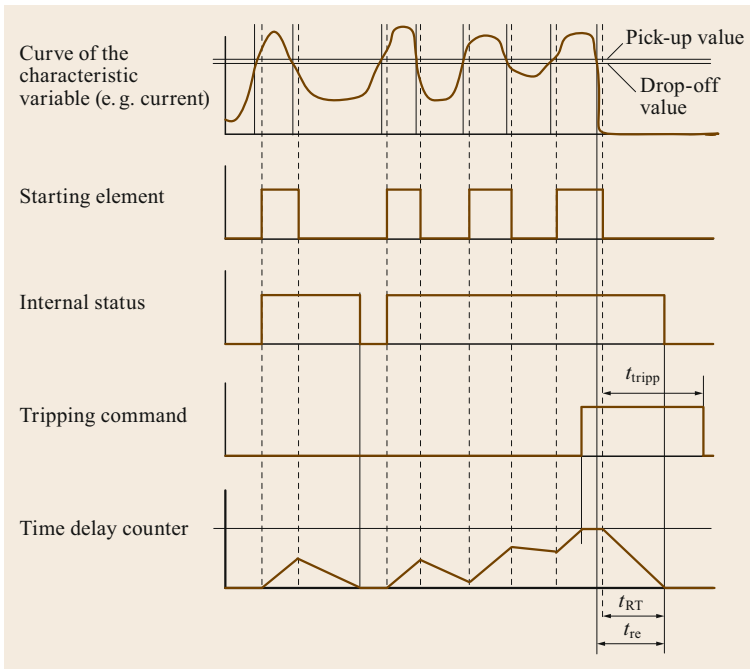

In this case,  $t_p$  is the time during which the starting signal is active. It is assumed that this time is shorter than the switch-off command time  $t_{tripp}$ . The resulting release time is  $t_{RT}$ . These relations are very easy to understand for two constant currents during and after the starting signal.

**Grading Time**

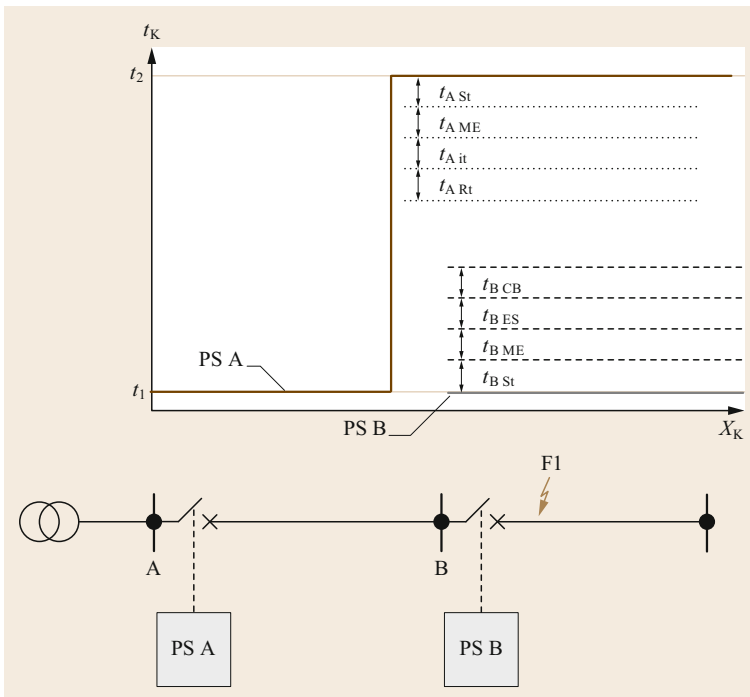

All relative selective protection criteria require a delay time to achieve selectivity. The aspects to be taken into account when determining the delay time are explained below.

Figure 13.20 shows two protective devices in neighboring protection zones. The short circuit is to be switched off by protective device B, whereas protective device A supplies backup protection for protective device B.

Protective device B requires the following times until the short circuit is cleared:

**Fig. 13.19** Function for the dependent reset time (adapted from [13.14])

**Fig. 13.20** Explanation of definition of the grading time

- $t_{B St}$  is the internal starting time of protective device B. This time depends on the implementation of the algorithms used.
- $t_{B ME}$  is the delay time caused by the error of the internal time measurement of protective device B. This value is particularly critical for electronic and electromechanical protective devices.
- $t_{B DI}$  is the adjusted delay time of protective device B. This delay time is assumed to be zero to estimate the grading time.
- $t_{B ES}$  is the delay time due to external switching relays for controlling the circuit-breaker.

- $t_{BCB}$  is the circuit-breaker opening time. This is the time from the switch-off command to the interruption of the current. This includes not only the time to open the power switch contacts but also the arc extinguishing time.

In addition to the delays caused by protective device B, the delays caused by protective device A must also be taken into account:

- $t_{ASt}$  is the internal starting time of protective device A. This time depends on the implementation of the algorithms used.
- $t_{AME}$  is the delay time caused by the error of the internal time measurement of protective device A. This is particularly critical for electronic and electromechanical protective devices.
- $t_{Ait}$  is the internal release time of protective device A. This time depends on the implementation of the algorithms used.
- $t_{ARt}$  is the additional adjusted release time of protective device A.

The required grading time  $\Delta t_{gt}$  is estimated as the sum of the times listed above. The worst-case times, meaning the maximum times, must always be selected

$$\Delta t_{gt} = t_{BSl} + t_{BME} + t_{BES} + t_{BCB} + t_{ASl} + t_{AME} + t_{Ait} + t_{ARt} \quad (13.31)$$

The required grading time thus depends largely on the technology used. Numerical protective devices have considerably shorter starting times than electromechanical protective devices. Additionally, the accuracy of the internal measurement time is considerably higher and independent of the temperature and age of the protective device. This also applies to circuit-breakers.

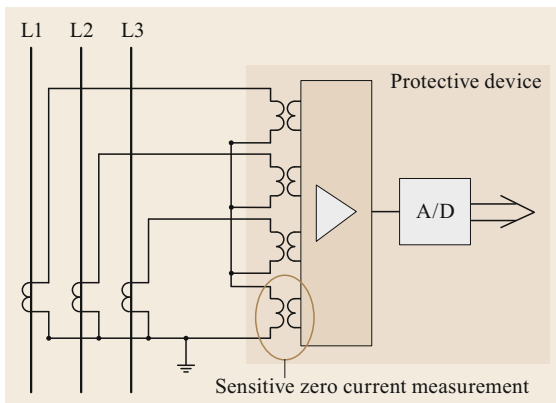

Fig. 13.21 Connection schema for overcurrent protection

Modern circuit-breakers have a short opening time. In addition, the variation of the switch-off times, depending on the temperature, is considerably smaller.

Typical grading times range from 200 to 600 ms. The shorter time applies exclusively to stations which are equipped with numerical protective devices and modern circuit-breakers. The longer times apply to stations with electromechanical protective devices and old circuit-breakers.

Usually, grid operators consider the issues described above only once when calculating the grading time. A grading time that is valid for the entire network is then defined and applied, with modifications being made only in exceptional cases.

### 13.4.2 Overcurrent Protection

In the case of overcurrent protection, a basic distinction is made between independent and dependent overcurrent protection.

As shown in Fig. 13.21, overcurrent protective devices are connected in the same way regardless of the type of overcurrent protection function. Overcurrent protection devices have at least three current inputs for the phase currents. Often, a fourth current input is used for the zero-sequence current measurement. The zero-sequence current can theoretically also be calculated internally from the measured phase currents, but direct measurement is always more accurate. Therefore, overcurrent protective devices often have these fourth current inputs. In distribution networks with isolated star point or resonance star point earthing, a ring-type current transformer with a more sensitive transformation ratio is often used. Therefore, versions of overcurrent protective devices with a fifth current input are also available.

The inputs of all types of protective devices are completely galvanically isolated. Different technical solutions are available to achieve this, such as the use of current transformers inside each protective device. The feasible measuring ranges of protective devices are specified in the standard [13.15], with 1 A and 5 A being typically preferred.

#### Instantiations of Overcurrent Protection

The instantaneous overcurrent (IOC) or definite time overcurrent (DIOC) function is typically used by European electric distribution network operators. Modern DIOC devices offer multistage overcurrent protection functions. Figure 13.22 illustrates a four-stage overcurrent function. There are four independent settings for the current thresholds and related delay times. The smallest current threshold automatically gives the

**Fig. 13.22** Current–time characteristic of four-stage definite time overcurrent device

threshold for the starting function. There is no additional setting for the starting function. This results in simple handling for this type of protection function. If the flowing current is above this smallest threshold, almost all the internal timers are started.

Modern numerical DTOC protective devices have up to six overcurrent stages. On the one hand, this large number of overcurrent stages makes it possible to implement short tripping times for high-current faults within their own protection zone, while on the other hand, it is possible to implement multistage backup protection. This large number of overcurrent stages can be easily and cheaply implemented in numerical overcurrent protective devices, since the same programming code is called for each stage. The number of useful overcurrent stages depends on the topology of the electric power system.

The calculation of the flowing current from the sampled values can be achieved using different types of algorithms. It is possible to estimate the rms value, the amplitude of the fundamental value, or the peak value. Depending on the manufacturer, different solutions are offered. There are overcurrent protective devices where one of the above-mentioned algorithms is fixed, but also devices where the customer can select the calculation algorithm.

In addition to the analysis of the phase currents, overcurrent protective devices also include the zero-sequence and negative-sequence current. The evaluation of the zero-sequence current is used for the detection of single phase-to-earth faults, whereas the evaluation of the negative-sequence current is used for the detection of an imbalance in the network.

In addition to the classic overcurrent functions, modern numerical overcurrent protective devices now offer other functions that improve the selective short-circuit detection. These include, for example, trans-

former inrush detection and power-on stabilization for protection of capacitor banks.

To achieve selective short-circuit clearance in networks with ring structures, the short-circuit direction is additionally required. To determine the short-circuit direction, voltage information is also needed. Therefore, overcurrent protective devices that are additionally equipped with voltage inputs are also available. Based on the voltage information, various further functions, such as overvoltage protection, are implemented.

The focus of the further explanations presented below will be on the basic function of overcurrent protection. Further information on the mentioned additional function is available in the book [13.16].

### Inverse Time–Delay Overcurrent Protection

Inverse time-delay overcurrent protection or inverse definite minimum time (IDMT) devices are typically used in North and South America for the protection of distribution lines [13.17]. With this overcurrent function, the tripping time is inversely proportional to the short-circuit current. Numerous different tripping time characteristics and reset time characteristics are defined in different standards, the best known being [13.14].

The basic parameters of these current–time characteristic curves are the so-called reference setting current ( $I_S$ ) or pick-up current and the time factor  $T_P$  or time multiplier setting (TMS). The current–time characteristic is always defined in relation to the reference setting current. In addition, the starting signal is seeded when the reference setting current is reached, implying that the overcurrent device starts operating. The TMS factor defines the general behavior of the overcurrent device. When this multiplier is adjusted to below 10, an inverse time characteristic is obtained. Multiplier factors between 10 and 20 result in a DTOC-like time characteristic. In Table 13.6, the most often-used inverse-time characteristics according to [13.14] are defined.

The time-dependent characteristic curves must be observed by the protective devices in a range from  $I_T$  to  $I_D$ .  $I_T$  is the lowest current value at which the protective device is guaranteed to operate. The determination of the delay time starts from this value. The ratio  $I_T/I_S$  must be less than 1.3. This implies that the protective device must operate correctly at a maximum of 30% above the reference value  $I_S$ .

All protective devices with a dependent characteristic curve must guarantee a shortest tripping time starting from a current value  $I_D$ . From this current onwards, the protective device can operate with a constant tripping time. This means that, from this current value onwards, dependent overcurrent time protection becomes

**Fig. 13.23a,b** Examples of current–time characteristic of inverse time–current protective devices (adapted from [13.14]).  
**(a)** Tripping time, **(b)** release time

independent overcurrent time protection. The shortest guaranteed tripping time must be calculated using

$$t_c(I_D) = T_P \left[ \frac{k}{\left(\frac{I_D}{I_S}\right)^\alpha - 1} + c \right], \tag{13.32}$$

with:

- $k$  parameter of the IDMT function [13.14]
- $\alpha$  parameter of the IDMT function [13.14]
- $c$  parameter of the IDMT function [13.14]
- $I_D$  highest current value at which the IDMT function is guaranteed to operate
- $I_S$  reference current value of the IDMT function
- $T_P$  time factor of the IDMT function.

For clarification, the different time dependences are represented graphically in Fig. 13.23a,b. In Fig. 13.23a, the three IEEE [13.14] inverse time tripping curves are shown. The TMS is set to 1 for this illustration. Depend-

ing on the flowing short-circuit current, the tripping time lies in the range from 100 s down to a few milliseconds. The advantage is that faults with a very high short-circuit current will be switched off in a very short time. This reduces the damage to the faulty equipment and the mechanical and thermal stresses on the devices carrying the short-circuit current. This figure shows the limits for the currents  $I_T/I_S$  and  $I_D/I_S$ . It can be seen that, from the current ratio  $I_D/I_S$  onwards, the protective device operates with a constant time delay.

Figure 13.23b illustrates the dependence between the current and the release time according to IEEE [13.14]. If the current ratio  $I/I_S$  is near 1, then the release time is above 100 s.

Just as for the DTOC function, not only the phase currents but also the zero- and negative-sequence currents are evaluated.

The right of Fig. 13.23 illustrates the reset time for the IEEE inverse time characteristic. Again, the TMS is set to 1. It can be seen that, for small fault currents, the reset time could be in the range of 100 s. This feature

stabilizes the protection function against intermittent faults with weak currents.

### 13.4.3 Transformer Differential Protection

The basic principle of differential protection was explained in Sect. 13.2. As described above, only the stabilized differential protection function is used today. In order to achieve a reliable and stable behavior of the differential protection, each modern differential protective device has a number of additional functions, as explained below.

#### Saturation Discriminator

High short-circuit through currents can cause the saturation of one of the two current transformers. This results in a differential current and will lead to tripping of the differential protective device. This should be avoided by correct dimensioning of the current transformers. In addition, it is generally required that identical current transformers be used on both sides of the protected object, where possible. Since, despite the above-mentioned measures, one-sided current transformer saturation can occur, a saturation discriminator is used to stabilize the differential protection.

The principal function of the saturation discriminator is based on the assumption that all current transformers operate saturation free in the first milliseconds. In this case, the differential current  $I_{\text{diff}}$  will be small but the stabilization current  $I_{\text{stab}}$  will be high.

This behavior is illustrated in the bottom of Fig. 13.24. From the starting operating point (P1), the

Fig. 13.24 Explanation of the saturation discriminator function

differential/stabilization current trajectory jumps to P2. This point indicates a high stabilization but low differential current. If one of the current transformers starts to saturate, the trajectory moves from point P2 to P3 inside the tripping zone, because the differential current increases. In this case, the switching off is blocked. If the saturation of the current transformer drops, the trajectory moves in steps back to point P2. If the external fault is switched off, the trajectory jumps back to the operational point P1.

In the case of an internal fault, the differential/stabilization current trajectory jumps directly from the operation point P1 to the fault point PF. In this case, switching off by the circuit-breaker is initiated.

This saturation discriminator analysis explains the movement of the differential/stabilization current trajectory. In this way, any external or internal fault with saturation of the current transformer can be discriminated.

#### Inrush Detection

A high transient current can occur when switching on transformers or other electric equipment with an iron core. The reason is the saturation of the iron core, which depends on the remanence and the switching instant. These so-called inrush currents with amplitude up to 10 times the nominal current can occur for several 100 ms. This is illustrated in Fig. 13.25.

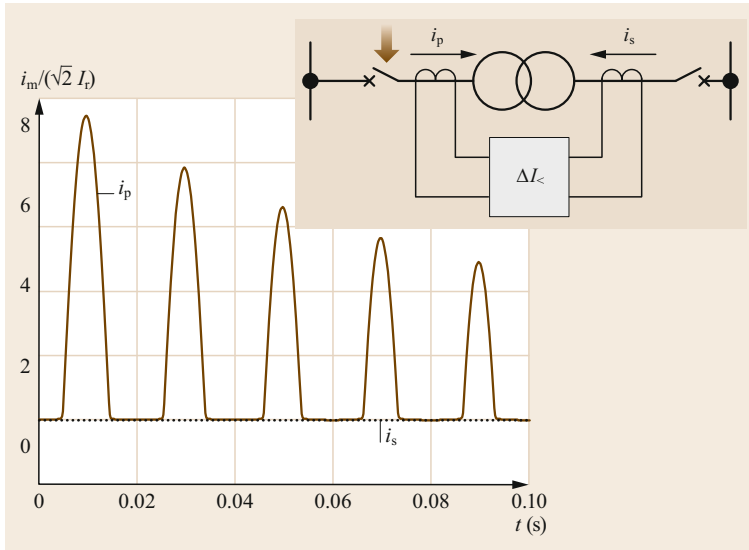

The unsymmetrical inrush current leads to an unsymmetrical voltage drop across the long connection lines. This results in an unsymmetrical voltage at the connection point, which is comparable to a small DC voltage offset. This DC voltage offset leads to saturation of other electric equipment with an iron core that has not been switched, an effect called sympathetic inrush.

The inrush current only flows from one side into the electric equipment. From the point of view of the differential protection function, this current therefore always indicates an internal fault. To avoid malfunction, the inrush stabilization function is necessary for the differential protection function.

Inrush stabilization is based on an analysis of the frequency spectrum of the differential current. Figure 13.26 shows a typical frequency spectrum for an inrush current. The second harmonic reaches values up to 50% of the fundamental current. A typical threshold to identify the inrush current is 20–30% of the fundamental current. During normal operation, the second harmonic will never reach this level.

#### Additional Functions for Power Transformers

Additional functions are required to provide differential protection for transformers. Very often, the rated cur-

**Fig. 13.25** Example of an inrush current

**Fig. 13.26** Frequency spectrum of an inrush current

rent of a power transformer and a current transformer are not identical. In addition, three-phase transformers may exhibit a phase shift between the different terminals of the transformer. Both effects have to be considered for the application of a differential protection schema.

#### Normalization of the Measured Currents

The rated current at each terminal of a power transformer is determined by the rated voltage at this terminal and the rated power of the winding of the terminal. Therefore, the values of the rated current of a power transformer are not compatible with the standard values for current transformers according to [13.7]. In order to reduce the reserve requirement, grid operators some-

times use selected values of the rated currents defined in the standard. There is always a mismatch between the rated current of the power transformer, current transformer, and protective device.

Previously, an adjustment transformer was used to interconnect the current transformer and protective device. This adjustment transformer was individually dimensioned and built, and this approach was not very flexible and was prone to errors.

Normalization of the measured currents includes two steps. First, all the currents are transformed to the primary terminal of the power transformer, taking into account the transformer ratio of the current transformers and the power transformer itself. In the second step, these currents are referred to the rated current of the primary terminal of the power transformer. Today, modern numerical differential protective devices calculate an internal adjustment factor  $k_x$  based on the parameters of the power and current transformers. The measurements of the protective device are then scaled internally using this adjustment factor. The superscript symbol (") is used to indicate that the current is normalized.

The calculation of the adjustment factor is explained below.

To estimate the currents at each terminal of the power transformer, the measured currents must be multiplied by the current transformation ratio of the used current transformers. The current on the primary terminal of the power transformer can be calculated as

$$I_{pPT} = I_{pm} \frac{I_{prCTP}}{I_{srCTP}}, \tag{13.33}$$

with:

- $I_{pPT}$  current at the primary terminal of the power transformer  
 $I_{pm}$  measured current at the primary terminal of the power transformer  
 $I_{prCTP}$  primary rated current of the current transformer on the primary terminal of the power transformer  
 $I_{srCTP}$  secondary rated current of the current transformer on the primary terminal of the power transformer.

A related calculation can be done for the secondary terminal of the power transformer using

$$I_{sPT} = I_{sm} \frac{I_{prCTS}}{I_{ssCTS}}, \quad (13.34)$$

with:

- $I_{sPT}$  current at the secondary terminal of the power transformer  
 $I_{sm}$  measured current at the secondary terminal of the power transformer  
 $I_{prCTS}$  primary rated current of the current transformer on the secondary terminal of the power transformer  
 $I_{srCTS}$  secondary rated current of the current transformer on the secondary terminal of the power transformer.

The calculations of the differential and stabilizing currents are carried out at the primary terminal of the power transformer. Therefore, all the currents must be converted to this side of the power transformer. The current transformation ratio of the power transformer can be calculated as

$$u_{vpsPT} = \frac{V_{prPT}}{V_{srPT}} = \frac{S_{prPT} \sqrt{3} I_{srPT}}{S_{srPT} \sqrt{3} I_{prPT}}, \quad (13.35)$$

with:

- $u_{vpsPT}$  voltage transformation ratio between the primary and secondary terminal of the power transformer  
 $V_{prPT}$  rated voltage at the primary terminal of the power transformer  
 $V_{srPT}$  rated voltage at the secondary terminal of the power transformer  
 $S_{prPT}$  rated apparent power at the primary terminal of the power transformer  
 $S_{srPT}$  rated apparent power at the secondary terminal of the power transformer  
 $I_{prPT}$  rated current at the primary terminal of the power transformer  
 $I_{srPT}$  rated current at the secondary terminal of the power transformer.

Usually, the apparent powers of the primary and secondary terminal of a power transformer are identical. However, power transformers with three terminals often have different apparent powers at each terminal. Therefore, this general equation is selected to calculate the transformation ratio of a power transformer.

The secondary current referred to the primary side of the power transformer is calculated as

$$I'_{sPT} = I_{sPT} \frac{1}{u_{vpsPT}} = I_{sPT} \frac{S_{srPT} I_{prPT}}{S_{prPT} I_{srPT}}, \quad (13.36)$$

with:

- $I'_{sPT}$  secondary current referred to the primary side of the power transformer

Normally, the currents are scaled by the rated current of the primary terminal

$$\begin{aligned} I''_s &= I_{sPT} \frac{1}{u_{vpsPT}} \frac{1}{I_{prPT}} = I_{sPT} \frac{S_{srPT}}{S_{prPT}} I_{srPT} \\ &= I_{sm} \frac{I_{prCTS}}{I_{srCTS}} \frac{S_{srPT}}{S_{prPT}} I_{srPT} = I_{sm} k_s, \end{aligned} \quad (13.37)$$

with:

- $I''_s$  normalized secondary current on the primary terminal of the power transformer  
 $k_s$  internal adjustment factor for the secondary terminal.

This results in the general internal adjustment factor  $k_x$ ,

$$k_x = \frac{I_{prCTx}}{I_{srCTx}} \frac{S_{rxPT}}{S_{prPT} I_{rxPT}}, \quad (13.38)$$

with:

- $k_x$  general internal adjustment factor, where x stands for s (secondary), p (primary), or t (tertiary)  
 $I_{prCTx}$  primary rated current of the current transformer on terminal x of the power transformer  
 $I_{srCTx}$  secondary rated current of the current transformer on terminal x of the power transformer  
 $S_{prPT}$  rated apparent power at the primary terminal of the power transformer  
 $S_{xPT}$  rated apparent power at terminal x of the power transformer  
 $I_{xPT}$  rated current at terminal x of the power transformer.

Depending on the design of the numerical differential protective device, the adjustment factor can only be calculated for a defined ratio of the rated currents.

If there is a large mismatch between the rated current of the power transformer and the rated primary current of the current transformer, the signal at the input of the protective device will be very low and noisy. This inaccuracy would be increased by multiplication with a huge adjustment factor, so depending on the manufacture, the adjustment factor is limited.

### Vector Group Adjustment

Power transformers are built with different types of connection of the windings. Typical winding connections are delta and star connection. Depending on the connection type and winding scheme applied, a phase shift appears between the currents at the terminals of the power transformer. This is defined by the vector group of the transformer.

Previously, phase adjustment transformers were interconnected between the current transformer and protective device to eliminate this phase shift. However, the phase adjustment transformer must be individually dimensioned and built. This was not very flexible and was prone to errors.

Modern numerical differential protective devices use a so-called vector group adjustment matrix. The structure and calculation of this matrix are explained below.

The calculation of the transformer differential current is based on the winding currents. The winding currents are calculated by means of the measured terminal currents. It is assumed that all the terminal currents are normalized. For windings with star connection, the measured terminal currents are identical to the winding currents. For windings with delta connection, it must be considered that the voltage ratios and winding ratios are not identical. For delta winding, the currents can be calculated by

$$\underline{I''_{s a W}} = \frac{1}{\sqrt{3}} \underline{I''_{p a}}, \quad (13.39)$$

$$\underline{I''_{s b W}} = \frac{1}{\sqrt{3}} \underline{I''_{p b}}, \quad (13.40)$$

$$\underline{I''_{s c W}} = \frac{1}{\sqrt{3}} \underline{I''_{p c}}, \quad (13.41)$$

with:

- $\underline{I''_{p a}}$  normalized primary terminal current of phase a
- $\underline{I''_{p b}}$  normalized primary terminal current of phase b
- $\underline{I''_{p c}}$  normalized primary terminal current of phase c
- $\underline{I''_{s a W}}$  normalized secondary winding current of the delta winding phase a
- $\underline{I''_{s b W}}$  normalized secondary winding current of the delta winding phase b
- $\underline{I''_{s c W}}$  normalized secondary winding current of the delta winding phase c.

Fig. 13.27 Example for the calculation of the vector group adjustment matrix

According to Fig. 13.27, the measured terminal currents do not correspond to the winding currents. There is one branching point (node) between these two currents. The following current equations result at these branching points, where the calculation is performed using the currents whose values have already been adjusted to the rated current of the current transformers

$$\text{Node I: } \underline{I''_{s a}} = \underline{I''_{s a W}} - \underline{I''_{s c W}}, \quad (13.42)$$

$$\text{Node II: } \underline{I''_{s b}} = \underline{I''_{s b W}} - \underline{I''_{s a W}}, \quad (13.43)$$

$$\text{Node III: } \underline{I''_{s c}} = \underline{I''_{s c W}} - \underline{I''_{s b W}}, \quad (13.44)$$

with:

- $\underline{I''_{s a}}$  normalized secondary terminal current of phase a
- $\underline{I''_{s b}}$  normalized secondary terminal current of phase b
- $\underline{I''_{s c}}$  normalized secondary terminal current of phase c.

Using this equation system alone, the winding currents cannot be calculated; An additional equation is needed:

Node I minus node II results in

$$\underline{I''_{s a}} - \underline{I''_{s b}} = \underline{I''_{s a W}} - \underline{I''_{s c W}} - \underline{I''_{s b W}} + \underline{I''_{s a W}}, \quad (13.45)$$

$$\underline{I''_{s a}} - \underline{I''_{s b}} = 2\underline{I''_{s a W}} - (\underline{I''_{s c W}} + \underline{I''_{s b W}}) + \underline{I''_{s a W}} - \underline{I''_{s a W}}, \quad (13.46)$$

$$\underline{I''_{s a}} - \underline{I''_{s b}} = 3\underline{I''_{s a W}} - (\underline{I''_{s c W}} + \underline{I''_{s b W}} + \underline{I''_{s a W}}). \quad (13.47)$$

The sum of the three winding currents corresponds to three times the zero-sequence current in the transformer of the rate current adjustment and normalized currents. Due to the rate current adjustment and normalization of all currents, the current in the secondary winding is equal to the current in the primary winding, yielding

$$\begin{aligned} \frac{1}{3} (\underline{I''_{s a}} - \underline{I''_{s b}}) &= \underline{I''_{s a W}} - \underline{I''_{0 W}} \\ &= \frac{1}{\sqrt{3}} (\underline{I''_{p a}} - \underline{I''_{0}}). \end{aligned} \quad (13.48)$$

This calculation is repeated also for node II minus node III and node II minus node I.

Finally, the following matrix equation results

$$\underbrace{\begin{pmatrix} I''_{pa} \\ I''_{pb} \\ I''_{pc} \end{pmatrix}}_{\mathbf{i}_p^{''*}} - I''_0 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & -1 & 0 \\ 0 & 1 & -1 \\ -1 & 0 & 1 \end{pmatrix} \underbrace{\begin{pmatrix} I''_{sa} \\ I''_{sb} \\ I''_{sc} \end{pmatrix}}_{\mathbf{i}_s''}. \quad (13.49)$$

This equation can be written as

$$\mathbf{i}_p^{''*} = f_{vs} \mathbf{S}_s \mathbf{i}_s'', \quad (13.50)$$

with:

- $f_{vp}$  winding factor of secondary terminal
- $\mathbf{S}_s$  vector group adjustment matrix
- $\mathbf{i}_s''$  vector of the measured and normalized current of the secondary terminal
- $\mathbf{i}_p^{''*}$  vector of the measured and normalized current of the primary terminal without the zero-sequence current.

#### 13.4.4 Busbar Differential Protection

Different protection criteria (Sect. 13.2.1) are used for busbar protection. For applications in distribution networks, only the binary starting signals from other protection devices, e.g., for overcurrent protection of the feeders, are logically linked to detect busbar faults. For a single-busbar substation with only a single feed-in and a small number of outgoing feeders, without feed-in, so-called backward interlocking is used. This is an effective, fast, and inexpensive busbar protection solution for simple busbar systems [13.18]. In general, no additional equipment is required. As described above, a definite direction of the energy flow—from the transportation to the distribution network—is necessary.

In the past, power differences or phase shifts of the currents between all the feeders of a busbar were used to detect busbar faults [13.19]. In addition, so-called high-impedance differential busbar protection devices are also used outside of Europe [13.20]. This type of busbar protection is usually recommended for small busbar systems with few feeders. The advantage of this technology is its good performance, immunity to current transformer saturation, and relatively low cost [13.21]. With the introduction of numerical protection devices, the significance of this type of busbar differential protection has decreased.

In modern low-impedance differential busbar protection, the currents are digitized immediately at the current transformers and then processed numerically. This principle is a lot more flexible [13.22]; for example, current transformers with different transformation ratios and transmission behavior can be used. In addition, it is much easier to extend the protection system [13.23]. Such low-impedance differential busbar protection is described in detail below.

Modern busbar protection devices are based on the stabilized current differential principle (Sect. 13.2.1). For larger busbar substations with several busbar sections or reverse busbars, a subdivision into discriminating zones is implemented [13.24]. The current sum is calculated for each independently operated discriminating zone and is zero under normal operation conditions or if a fault occurs outside the discriminating zone. The described procedure is physically based on Kirchhoff's current law, which states that the currents flowing into a node must be equal to the current flowing out of it. This means that the sum of all the currents flowing into a node is zero if the direction of the currents is taken into account. This natural law is valid for alternating currents at any time or to the complex current phasor with the correctly calculated phase.

The principle of low-impedance differential busbar protection is illustrated in Fig. 13.28, which shows a double busbar system. The number and structure of discriminating zones are defined by the position of the disconnectors. Ideally, the discriminating zones should correspond to the protection zones (Sect. 13.1.2). However, this is not feasible technically, since the protection zones are bordered by the current transformers and not by the disconnectors and circuit-breakers. If a short circuit occurs between the current transformer and circuit-breaker of an outgoing feeder, it is no longer located within the protection zone but lies in the corresponding discriminating zone. Nonselective tripping occurs for this small area of the busbar system.

The equations presented below apply to the protection zones within the two discriminating zones (DZs) of the double busbar substation considering the position of the disconnectors illustrated in Fig. 13.28. During normal operation, the following sum of the primary currents applies to each discriminating zone

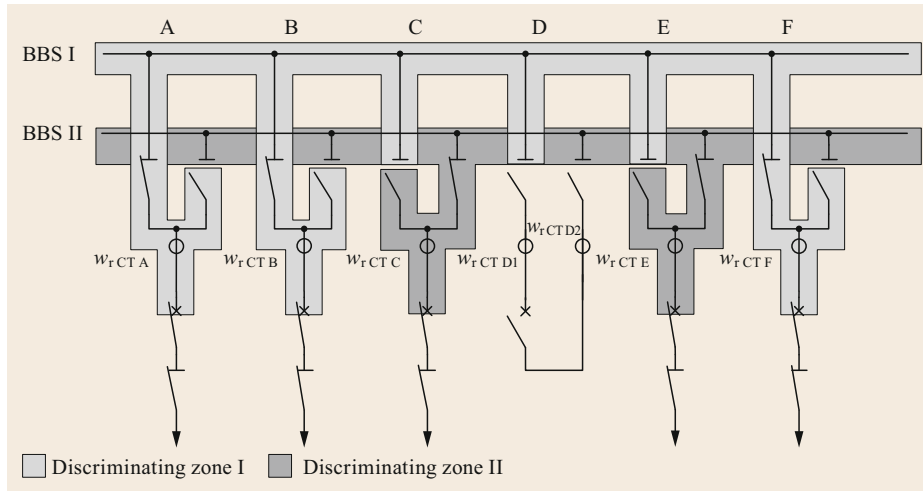

DZ I (normal operation):

$$I_{pDZIA} + I_{pDZIB} + I_{pDZIF} = \Delta I_{pDZI} = 0, \quad (13.51)$$

DZ II (normal operation):

$$I_{pDZIC} + I_{pDZIE} = \Delta I_{pDZII} = 0. \quad (13.52)$$

**Fig. 13.28** Double busbar substation with two busbar sections (BBS I and BBS II) and two discriminating zones (DZs)

The total primary current for the entire busbar substation can be calculated for normal operation as

$$\text{Total busbar system (normal operation):} \\ \Delta I_{p,DZI} + \Delta I_{p,DZII} = 0. \quad (13.53)$$

A prerequisite for the correct calculation of the primary current sum is a standardized measuring direction for the current transformers. This must be ensured during the installation of the current transformers. It could be decided, for example, that currents flowing into the busbar are positive while currents flowing out of it are negative.

If one of (13.51)–(13.53) is not fulfilled, there is a fault within the busbar system. These simple relations form the basis for low-impedance busbar differential protection. Theoretically, only the current sum can be used to differentiate between the faultless and faulty states within the discrimination zone. The current sum can be calculated by using either the instantaneous values of the currents or the complex current phasor, mentioned above. In these equations, the representation of the current phasors is used. In numerical busbar differential protection systems, the current sum is calculated on a phase-selective basis. In the event of a short circuit within a discrimination zone, all the circuit-breakers assigned to this discrimination zone are selectively opened. The goal is to disconnect from the faultless network only the part of the busbar that is affected by the fault.

However, numerous inaccuracies in the measurement system must be taken into account when implementing busbar protection systems, e.g., the deviations of the transmission ratio of the used current transformers within their fault tolerances, the stationary and dynamic transmission behavior of the current

transformers, and the measurement errors of the entire measurement chain.

### Normalization of the Measured Secondary Currents

In this straightforward form, the calculation of the current sum applies only to the primary currents in the substation. Like all protective devices, the busbar protection system is connected to the primary system via current transformers. The current transformers reduce the currents according to their transmission ratio true to scale. The phase angle of the currents is retained. The following equation corresponds to the current sum of discriminating zone I (DZ I) for the secondary measured currents, where the nominal transmission ratios of the current transformers are considered (Sect. 13.3.1)

$$I_{sIA} w_{rCTA} + I_{sIB} w_{rCTB} + I_{sIF} w_{rCTF} = 0. \quad (13.54)$$

The equation for the current sum calculation based on the currents measured on the secondary side of the current transformers and their nominal transformation ratios is mathematically accurate, but can suffer from numerical problems if implemented in numerical protection devices. For this reason, manufacturers of protective devices internally convert the current to a fictitious uniform busbar reference current, similar to the implementation in transformer differential protection devices.

### Stabilization of Busbar Differential Protection

If a busbar protection algorithm were to be based only on the calculation of the current sum, measurement errors in the current transformers, for example, could already lead to unwanted tripping. If the short circuit occurs near the busbar, the outgoing short-circuit cur-

rent is divided between several feeders. These parts of the short-circuit currents are considerably smaller. Due to the percentage errors of the current transformers, this can result in significant residual currents. For this reason, busbar differential protection also works with stabilization. Further details can be found in Sect. 13.2.1. This implies that, for busbar differential protection, a stabilization characteristic similar to that for transformer differential protection must be set.

#### Synchronized Data Acquisition

Due to the spatial extent of large busbar systems, the current signals cannot be transmitted as analog values to a central data acquisition system. Therefore, modern busbar protection devices work with decentralized data acquisition units. In addition to the analog signals, the feeder-related binary input and output are also recorded there. For the current sum calculation explained above, however, it is a precondition that all analog information be acquired synchronously. Today, manufacturers of busbar protection devices use proprietary communication protocols to guarantee this. Physically, fiber-optic connections to the central device are often used. These enable very high data rates and can ensure electromagnetic compatibility at the same time.

#### Discriminating Zone

As explained above, large busbar systems will be divided into discriminating zones. The discriminating zones are defined by the position of the disconnectors within the topology of the busbar system and the current position of these disconnectors. When the disconnectors are switched on, the downstream circuit-breakers form the physical border of the discriminating zone. The discriminating zone defines which measured current values are merged to become a current node. The structure of the discriminating zone can be determined by logical operations or by a topological calculation algorithm. Both methods are used in practical applications.

Due to the long operation times of disconnectors, which can extend several tens of seconds, the following states of the disconnector have to be taken into account: switched on, switched off, and fault/intermediate position. There are different strategies for handling the fault/intermediate position of a disconnector. The discriminating zone can be completely blocked. A busbar fault occurring at that time results in a complete switch-off of all circuit-breakers of this busbar system by the comprehensive check zone. Alternatively, the fault/intermediate position of the disconnector can be substituted by a predefined switch position. This substitute value is selected such that reliable tripping occurs in an extended discriminating zone. Within very large busbar systems with a large number of discriminating

zones, this prevents the protection system from completely switching off the whole busbar system if a short circuit occurs during this transition period.

#### Check Zone

In the check zone, the actual positions of the disconnectors are not taken into account. The sum of all the measured currents of the entire busbar substation is calculated. In the case of an internal short circuit, this leads to a nonselective switch-off of the entire busbar system. The check zone acts as a backup function for when an internal short circuit in a busbar is not detected within the associated discriminating zone.

The check zone could also be used to stabilize the operation of the busbar protection device. If an internal short circuit is detected in one of the discriminating zones but not within the check zone at the same, the tripping is blocked. Such miscalculation of the current sum within the discriminating zone could be caused, for example, by an incorrect assignment of a feeder to this discriminating zone.

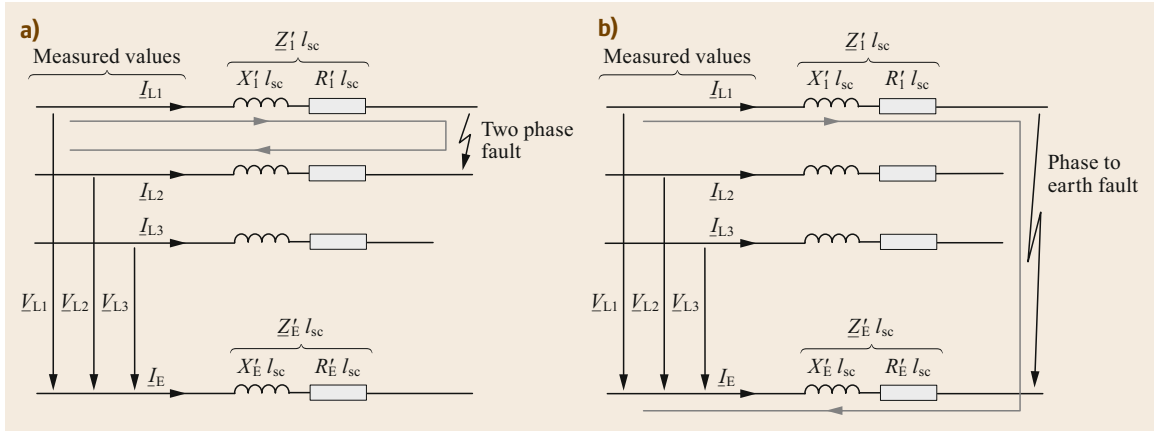

#### Saturation Discriminator

In the event of a high-current short circuit near the busbar substation, current transformer saturation may occur. A saturation discriminator is used in order to achieve a stable behavior of the busbar differential protection system, similar to the one used in transformer differential protection systems. The functionality of the saturation discriminator is explained in Sect. 13.4.3. The detailed technical realization of the saturation discriminator depends on the manufacturer of the busbar protection device. In addition, it depends on whether the current sum is calculated using instantaneous values or phasors.

#### Additional Functions

The busbar protection device records a large amount of information from the whole busbar system. It is aware of the current switching status of disconnectors and circuit breakers and can respond very quickly. Therefore, a number of additional functions are integrated into numerical busbar protection systems today; these are not busbar protection functions in the strict sense, but they improve the selectivity and reaction time of the overall protection system.

**Circuit-Breaker Failure Protection.** If a fault occurs within the discriminating zone, all circuit-breakers which border this discriminating zone receive the switch-off command. The circuit-breaker failure protection function checks whether the current flowing through these circuit-breakers is very small within an adjustable time after a trip command. If the current does

**Fig. 13.29a,b** Illustration of calculation loop depending on the fault type. (a) Phase-to-phase calculation loop, (b) phase-to-earth calculation loop

not drop below a minimum value, a trip signal is sent to the circuit-breaker at the other end of the connected line. This enables quick identification of a busbar fault in case of a malfunction of the circuit-breaker of a busbar feeder. This function improves the stability of the electrical power transmission system.

**Direct Tripping of a Discriminating Zone Through External Signals.** This fallback function is used in the case of a circuit-breaker malfunction in the event of a short circuit on the line. The short circuit on the line is detected by the line protection device. The line protection device sends an off command to the corresponding circuit-breaker. If this circuit-breaker malfunctions, the short-circuit current can only be interrupted by opening all of the circuit-breakers which belong to the same discriminating zone. An external trip signal at the corresponding feeder is used to notify the busbar protection system that all circuit-breakers assigned to this discriminating zone should be switched off. As this is a very critical function—as a major part of a busbar system is switched off—this function is ensured by secondary information, which can be either an additional binary enable signal or an internal current threshold. The external trip signal is only accepted if the current threshold is exceeded or a binary enable signal is present at the same time. In addition, the time sequence of the trip and enable signals is usually monitored to avoid overfunctions.

### 13.4.5 Distance Protection

The distance protection criterion was explained in Sect. 13.2.1 based on a single-phase example. Real distance protection devices have at least three current inputs for the phase currents and three voltage inputs

for the phase-to-earth voltages. Further technical specifications are described in [13.25]. Depending on the additional functions, for example, a sensitive earth fault detection or so-called zero-current compensation for double circuit lines, additional current and/or voltage inputs may also be present. However, only the three current and voltage inputs mentioned above are required for the basic distance protection function. For the connection and dimensioning of the current transformers, the information given for overcurrent protection and the current transformer apply.

#### Calculation of the Loop Impedance in a Three-Phase System

Depending on the type of short circuit, different calculation loops have to be used. Figure 13.29 shows an example of a single-phase fault and a two-phase fault. The first case results in a single phase-to-phase calculation loop, for which the following equation can be applied

$$I_{L1}Z'_{sc} - I_{L2}Z'_{sc} = V_{L1} - V_{L2} \quad (13.55)$$

The equation for calculating the fault impedance of a phase-to-phase calculation loop can thereby be obtained. To calculate the fault distance, only the positive-sequence reactance per unit length has to be known

$$\frac{V_{L1} - V_{L2}}{I_{L1} - I_{L2}} = Z'_{sc} = R'_{sc} + jX'_{sc} \quad (13.56)$$

A phase-to-earth fault results in a phase-to-earth calculation loop, for which the following equation can be applied

$$I_{L1}Z'_{sc} - I_E Z'_E = V_{L1} \quad (13.57)$$

The positive-sequence reactance per unit length and the earth reactance per unit length have to be known for the further calculation. The goal is to obtain identical equations to calculate the fault distance independent of the fault type. Therefore, the equation is converted and the so-called complex  $\underline{k}_E$ -factor introduced

$$\begin{aligned} \underline{Z}'_1 l_{sc} \left( I_{L1} - I_E \frac{\underline{Z}'_E}{\underline{Z}'_1} \right) &= \underline{Z}'_1 l_{sc} (I_{L1} - I_E \underline{k}_E) \\ &= \underline{V}_{L1} . \end{aligned} \quad (13.58)$$

This results in

$$\frac{\underline{V}_{L1}}{I_{L1} - I_E \underline{k}_E} = \underline{Z}'_1 l_{sc} = R'_1 l_{sc} + jX'_1 l_{sc} , \quad (13.59)$$

$$\underline{k}_E = \frac{\underline{Z}'_E}{\underline{Z}'_1} = \frac{\underline{Z}'_0 - \underline{Z}'_1}{3\underline{Z}'_1} . \quad (13.60)$$

From (13.60), it can be seen that the complex factor  $\underline{k}_E$  can be interpreted as a weighting factor for the earth return current, which is constant for specific cables or overhead line arrangements. It should be pointed out that the factor  $\underline{k}_E$  depends on the zero-sequence impedance. This includes not only the conductivity of the earth itself, but also all conductive material in the earth. The calculation of this impedance is therefore problematic, especially in cities, and it has to be measured.

There are different definitions for the  $\underline{k}_E$  factor depending on the manufacturer. However, all the definitions are based on (13.57); For example, this equation can be split into real and imaginary parts to get a real  $k_R$  factor for the resistance and a real  $k_X$  factor for the reactance. A common feature of all the methods is that the positive-sequence reactance per unit length is always used to calculate the fault distance.

Functionally, a distinction is made between a switched or full distance protection schema. In the case of a multiphase fault, the fault distance can be calculated in all fault-affected phase-to-earth and phase-to-phase loops. In the case of a two-phase-to-earth fault (Fig. 13.30), there are two phase-to-earth loops and one phase-to-phase loop, for which the fault distance can be calculated. In the case of the switched distance schema based on complex logic, one of these loops is selected. This should be the same loop for all the distance protection devices in a physically connected electrical network. In Europe, the switched distance protection schema is typically used in medium- and high-voltage networks [13.26]. The full distance protection schema is applied worldwide in extrahigh-voltage networks. A mixture of the two different distance protection schemas should be avoided, as complex short-circuit sequences may result in nonselective tripping.

Fig. 13.30 Illustration of switched and full distance protection schemas

The differentiation between switched and full distance protection schemas has its origin in electromechanical and analog protection devices. When using these technologies, each measurement loop was implemented in separate hardware. For the switched distance protection schema, only one measurement unit and simple switching logic were needed.

Figure 13.31 shows the main functions of a switched distance protection system. In comparison with overcurrent protection, significantly more subfunctions must be configured by the user. This increases the complexity of distance protection applications.

Switch distance protection calculates the fault direction and distance, then selects a distance zone based on the selected calculation loop.

#### Distance Measuring System

The concept of distance protection was explained in Sect. 13.2.1. The measured reactance is used to determine the distance between the measuring point and the short-circuit location. This is done because the measured resistance could be biased by a short-circuit resistance at the fault location and additionally, in the case of an arc fault, by the arc fault resistance. The realization of the impedance measurement function by electromechanical relays or analog circuits does not allow separate evaluation of the resistance and reactance, as should be done ideally.

The tripping characteristic of electromechanical or analog technology-based distance protection [13.27] in the complex  $R$ - $X$  plane results in circles or a so-called mho characteristic (admittance circle) [13.6]. This is illustrated in Fig. 13.32. The introduction of modern numerical protection devices enabled an optimized design of the tripping characteristic. The goal was to achieve

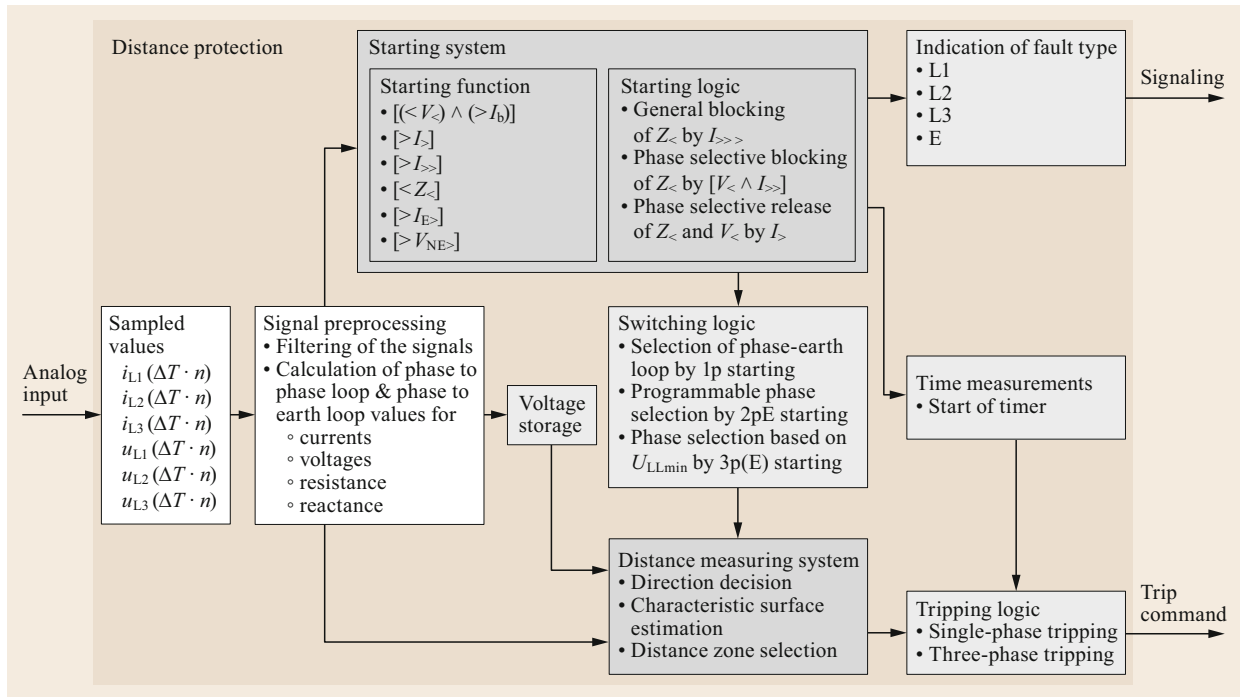

Fig. 13.31 Functions of a switched distance protective device

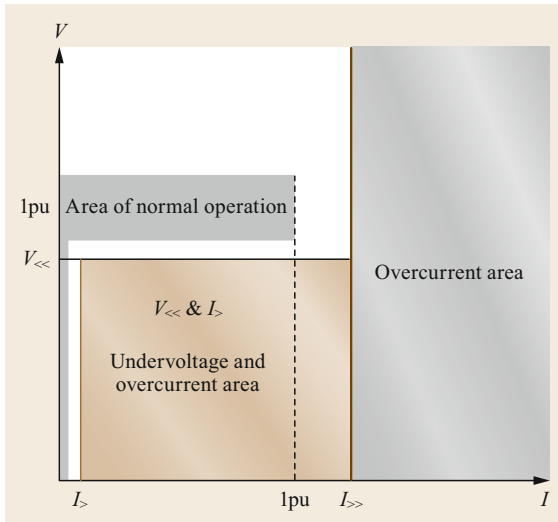

Fig. 13.32a–c Illustration of various tripping characteristics. (a) Tripping characteristic of an electromechanical device. (b) Mho characteristic (admittance circle). (c) Polygonal tripping characteristic

the largest possible and user-adjustable arc resistance reserve or compensation. This leads to the polygonal tripping characteristic curves which are typical today. The mixed use of distance protection devices with mho and polygonal tripping characteristics is possible, but problematic. In Europe, the use of the polygonal tripping characteristic curve has been established on all voltage levels due to its many advantages.

#### Starting System

The goal of the starting system is to differentiate between the fault condition and the normal operation

status. In contrast, the focus of the described distance measuring system is only on the protected object, e.g., an overhead line, and not on the overall electrical energy system. This starting function should detect all abnormal states in the complete electrical energy network. A distinction from the permitted load range has to be made. In general, a distinction is made between the overcurrent, undervoltage, and underimpedance starting functions. Numerical distance protection devices today work in parallel with all three types of starting functions. In detail, these functions can have different specifications depending on the manufacturer.

**Fig. 13.33** Illustration of the overcurrent and undervoltage starting function

#### Overcurrent and Undervoltage Starting Function.

The overcurrent and undervoltage starting function is illustrated in Fig. 13.33. The permissible operating range is marked in the current–voltage plane by a gray area. This operation range is limited by the permissible voltage range and the maximum permissible operating current, taking into account a temporary overload. It has to be considered that the switched-off line is also a permissible operating state. Here, the voltage and current are zero, or very small for measuring reasons. These effects result in the gamma-shaped permissible operating range displayed.

It can be seen that a simple overcurrent starting threshold  $I_{\gg}$  does not optimally adapt to the permissible operating range. In the case of a weak in-feed, the voltage drops below the permissible operating voltage but the short-circuit current does not reach the overcurrent starting threshold, so the fault would not be detected.

The undervoltage starting function ( $V_{\ll}$ ) with an additional enabling current threshold ( $I_{\gg}$ ) provides a much better adaptation to the permissible operating range. The enabling current threshold is necessary to identify the switched-off status. This is illustrated in Fig. 13.33.

**Underimpedance Starting Function.** In the case of underimpedance starting, the actual measured impedance is compared with the permissible load impedance. The principle is shown in Fig. 13.34. It is assumed that the permissible load always has a very large ohmic component. A pure reactive load is not regarded as a permissible operating condition.

In the case of electromechanical and electronic distance protection devices, the shape of the starting char-

acteristic in the  $R$ – $X$  plane is often a technology-based circular characteristic or one of its variants, similar to the distance measurement system.

With today's numerical distance protection devices, the characteristic of the starting area depends on the manufacturer. Different variants are shown in Fig. 13.35. The goal is to approximate as closely as possible the impedance characteristic of the permissible load.

**Starting Logic.** The different presented starting functions must be logically combined to reach an overall decision. Among other features, the type of neutral point treatment of the electrical network has to be taken into account. In addition, its function should eliminate implausible decisions of the underimpedance, overcurrent, or undervoltage starting functions. Such implausible decisions of these functions may result from incorrect settings. The goal of the starting logic is to ensure a clear identification of the fault type and the faulty phases.

One of these logical criteria is explained in the following. Figure 13.36 shows a phase-to-earth fault. The underimpedance starting function does not know which type of fault occurred. Therefore, the impedances of all three phase-to-earth calculation loops are calculated by

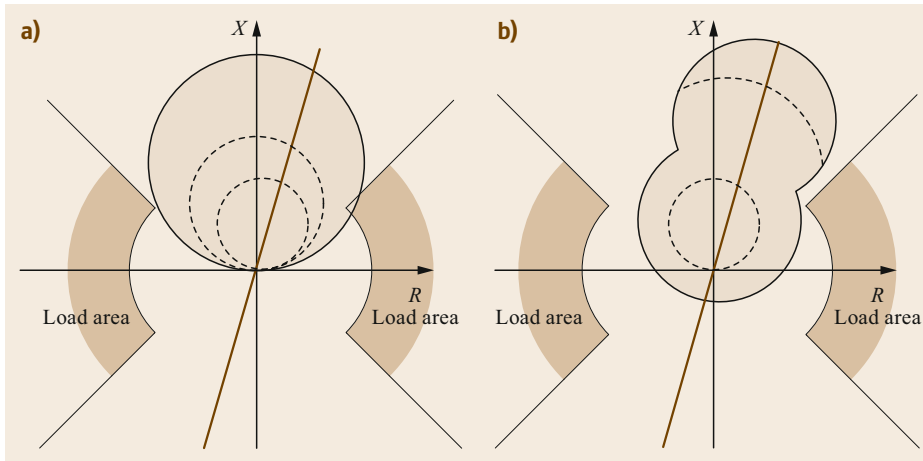

$$\frac{V_{L1}}{I_{L1} - I_E k_E} = Z'_1 I_{sc} = Z_{L1-E}, \quad (13.61)$$

$$\frac{V_{L2}}{I_{L2} - I_E k_E} = Z'_1 I_{sc} = Z_{L2-E}, \quad (13.62)$$

$$\frac{V_{L3}}{I_{L3} - I_E k_E} = Z'_1 I_{sc} = Z_{L3-E}. \quad (13.63)$$

The impedances calculated in phase-to-earth loop L2–E and phase-to-earth loop L3–E do not make sense physically. Since the earth return current is included in (13.62) and (13.63), small impedances are calculated. For a selected situation, the calculated phase-to-earth impedances are given in Fig. 13.36. It can be seen that there are two phase-to-earth loop impedances (L1–E, L2–E) within the underimpedance starting characteristic. To avoid a wrong decision of the starting function, the starting logic selects the smallest phase-to-earth loop impedance and rejects all loop impedances that are 1.5-times higher. The result is a correct detection of the single phase-to-earth fault in the phase L1–E.

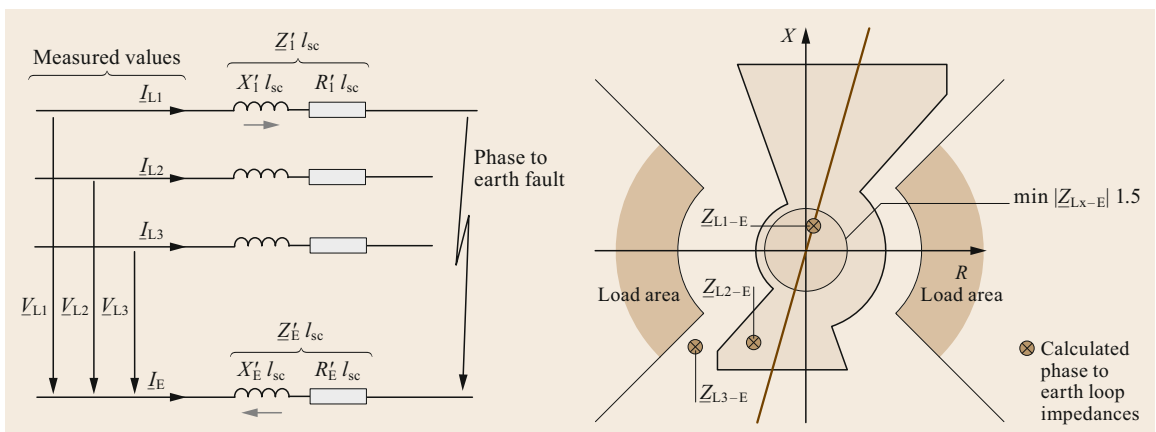

**Switching Logic.** The switching logic is only necessary for switched distance protection schemas. Based on the final decisions of the starting logic and on given rules, which have to be selected by the user, the measuring loop is determined. This measuring loop is used by the distance measuring system to calculate the fault distance.

### General Information on the Application of Distance Protection

These illustrations show that the complexity of distance protection is considerably higher in comparison with overcurrent protection. On the other hand, distance protection significantly improves the quality of short-circuit detection and clearing. Especially in critical fault situations, e.g., weak in-feed situations, the distance protection still ensures a high degree of selectivity in the clarification of short circuits. This is the reason why distance protection is very often used in extrahigh-voltage networks. In these networks, distance protection is the standard protection schema.

Due to the growing number of decentralized generation plants in the distribution network, it will become necessary to use distance protection at this voltage level increasingly as well. One challenge here is the high parameterization demands mentioned above.

#### 13.4.6 Additional Functions

With the aid of so-called additional functions, the command time of the protection system should be reduced, its selectivity increased, and the interruption time shortened. In addition, there are special functions for detecting critical conditions of selected equipment or the entire electric power system that are not directly caused by a short circuit, e.g., overloads, earth faults, power swings, and frequency deviations. The most important additional functions are briefly described below.

##### Auto-Reclosing

A large fraction of the short circuits that occur in an overhead line network are arc faults, caused by atmospheric or switching overvoltages. After the fault has been switched off, these arcs extinguish themselves and the overhead line can be reconnected. Especially at the extrahigh-voltage level, more than 90% of faults that occur can be eliminated immediately in this way.

In principle, the automatic reclosing (AR) function gives the circuit-breaker an on command at the end of the dead time. However, additional requirements must be met before this function can be implemented; For example, the drive of the circuit-breaker must be able to operate the switching sequence off–on–off, it must be ensured that the type of fault is suitable for automatic reclosing and that the short circuit has been completely switched off. Depending on the length of the dead time, it may be necessary to check the synchronicity of the power system before switching on.

One-, two-, or three-pole automatic reclosing can be carried out in high- and extrahigh-voltage networks.

A precondition is that each pole of the circuit-breaker has its own drive.

##### Signal Comparison

Signal comparison methods are used for the following applications:

- protection of the total line length of an overhead line or cable within the time first zone
- protection of short transmission lines with distance protection (where the impedance of the line is smaller than the smallest possible setting)
- reduction of the operation time for a fault near the far-end station (reducing stability problems).

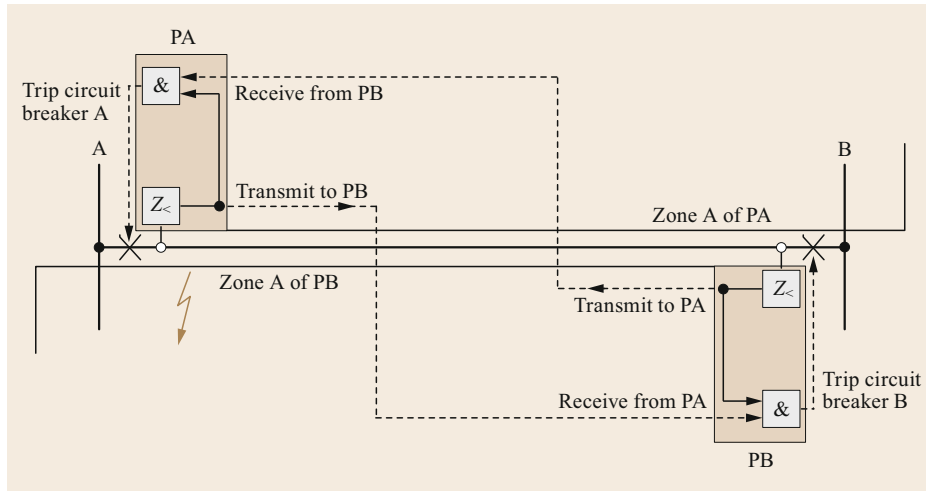

In general, the selectivity and response time of the protective device are increased with the help of such signal comparison methods. For this purpose, binary information is exchanged between the protective devices installed at both sides of the protection object, which could be an overhead transmission line or transformer but also switchgear. There is no exchange of measured values or other analog information.

To avoid the unwanted operation of a protective device, the received binary information is always linked to local information, to give permission or block a local decision. The advantage of signal comparison is that the requirements for signal transmission in terms of speed and bandwidth are very low.

Regarding signal comparison methods, a fundamental distinction is made between unblocking and blocking methods. The unblocking methods are more oriented towards avoiding unwanted operation. If, for example, the expected binary signal is not received due to a transmission fault, there is no unblocking and the backup function of the protective device is activated, leading to delayed but selective fault tripping. This type of signal comparison is often used in Central Europe. The basic decision of the blocking method is based on local information, e.g., an impedance measurement. If no blocking signal arrives within a short delay time, the protective device trips the fault. These methods guarantee a short fault clearing time, albeit with the danger of unwanted or unnecessary tripping. This method is often used in the USA.

The permissive overreach distance protection schema is now explained. This schema belongs to the unblocking methods. It is illustrated in Fig. 13.37. The line is protected by a distance protective device. The so-called overreach zone A is set between 120–150% of the total line length on both sides of the line. A binary signal is transmitted if a fault is detected within this overreach zone A. There is no direct tripping of

**Fig. 13.37** Example of signal comparison with permissive overreach distance protection (adapted from [13.28])

the line, because a short circuit in this zone will also be signaled if a real fault occurs beyond the next station.

When the distance protective device receives a binary signal, a logical link to the local decision of zone A will be performed. If both conditions are fulfilled, the

circuit-breaker will be tripped. This method guarantees a short operation time independent of the location of the short circuit. The permissive overreach distance protection schema is often used for the protection of short transmission lines. A reliable communication channel is necessary.

## 13.5 Outlook on Protection Systems

The development in the field of selective protection systems is characterized by the changing requirements of electrical power systems and by developments in the fields of communications and computer technology.

### 13.5.1 Changes in the Electrical Power System

Due to the increased integration of small and decentralized generation units into the electrical power system, new requirements for protection arise.

#### Reduction of Short-Circuit Current

Small and decentralized generation units, e.g., wind power plants or photovoltaic systems, are often connected to the grid via power electronics. The maximum short-circuit current of these devices is restricted by the thermal limits of the electronic components and normally lies in the range of the rated load current. Therefore, overcurrent protective devices can no longer differentiate between the normal load and the fault situation. Thus, additional criteria are needed. One solution could be the application of distance protection. The drawback is the high complexity and price of this protection schema. Due to the increasing availability of

high-speed communication links, differential protection schemas could be implemented more easily. The disadvantage of this solution is the lack of a backup function and its high dependency on the reliability of the communication link.

#### Changing Short-Circuit Current Direction

Decentralized generation units are often based on renewables, thus the in-feed is heavily feature dependent [13.29]. This results in a high dynamic in the magnitude and rapid direction changes of the short-circuit current. This makes it very difficult to determine the settings for protection devices. Today, one option is to adapt the settings of protection devices remotely, depending on the load situation. Generally, precalculated settings are used. Another idea is so-called adaptive protection [13.30], where each protection device estimates its own settings automatically based on the actual situation of the electrical grid [13.31].

#### Heavily Loaded Transport Lines

Another challenge is the transportation of huge amounts of electrical energy over long distances. In some cases, so-called high-temperature low-sag (HTLS) conductors are used to increase the transmission capacity. The clear

distinction between the load and the short-circuit areas shown in Sect. 13.4.5 is then often no longer possible. It may happen that the maximum permissible transmission power is limited by the protection system and not by the physics of the overhead line. This is not acceptable, so new protection schemas have to be developed.

### Overall System Protection

The protection system was originally designed to detect faulty equipment in the electrical system based on locally available information (e.g., voltage, current) and to switch off faulty equipment as fast as possible. Due to the presented challenges in secure and reliable detection of faults in electrical networks, this equipment-based approach of classical protection schemas is critically discussed. The idea is to complement the equipment-based approach by an overall system protection schema. Such concepts are technically possible today due to the availability of fast communication links and powerful computers.

The advantage of overall system protection is that not only equipment-based faults but also critical system status (e.g., power swings, resonances) can be detected and eliminated. New algorithms must be developed for this purpose.

### 13.5.2 Technological Drivers

In the case of electromechanical protective devices, the individual functions of a protection system were usually separate boxes. With the introduction of analog circuit technology, the protective functions were implemented on printed circuit boards. In numerical protection devices, the protection functions are only software modules. To date, protective devices remain

individual, dedicated pieces of equipment; they fulfil all the necessary protection functions related to [13.13].

### Common Protection and Communication Devices

The increased use of communications technology also within switchgear, for example, to transmit sampled values from current and voltage transformers, enables new system architectures for protective devices. One approach that has been discussed is thus to implement the protective function as a subfunction on the communication controller, where the necessary local information (e.g., voltage, current) is already available. The reliability and availability of the protective function based on such a concept must be critically evaluated.

### Protection in the Cloud

Another idea is the implementation of virtual protective devices in the cloud. New communication technologies such as 5G guarantee low latency. Therefore, this standard will be used in industry automation. The possible application of this technology for protection systems is also being investigated in initial research projects. The very high computing power required for 5G technology meets the requirements for protection technology.

### 13.5.3 General Requirements

As described above, protection technology is developing very rapidly. However, it has to be taken into account that protection systems play an essential role in the safe and reliable supply of electrical energy. Compliance with the basic requirements for protection systems outlined in Sect. 13.1.1 must be critically reviewed before new technologies can be introduced in this field.

Peter Schegner studied electrical power engineering, then worked as a system engineer in power system control and joined the scientific staff at Saarland University, receiving his PhD with a thesis on earth-fault distance protection. He then worked as Head of the Development Department of Protection Systems at AEG, Frankfurt, later becoming Full Professor and Head of the Institute of Electrical Power Systems and High Voltage Engineering of TU Dresden.

# 14. Information Systems and Telecommunications

# Information

Carlos Samitier 

Since the very beginnings of the power grid, telecommunications has been a necessary component to operate the system. The evolution of information technology and the improvement of its capabilities open new opportunities to improve system operation, which evolved from a manual operation to a more automated one and is presently a fully automated system that is paving the way to the deployment of smart grids and the future use of artificial intelligence. This chapter depicts the working principles and technologies used to manage and operate the power grid. The first part is devoted to operational applications. These are the *brain* of the system and gather information from the field and make decisions to automatically control the grid and take the required actions to protect its components from fault or other events that may impair the stability of the system. The most important applications and analyses of their telecommunications requirements are identified. These requirements will be the input for telecommunications technology selection and network design. The second part of this chapter is focused on telecommunications technologies and networks. A review of telecommunication technologies used to implement power utilities operational services is given. Telecom services are classified, and their attributes are described in order to give an understanding of further classifications and their operational applications. Network design is introduced in order to highlight the key differentiated aspect of power-system automation telecom networks. Finally, cybersecurity aspects are introduced, providing key aspects and a reference to international standards that should be applied. Smart grid architecture and components are also briefly described.

## 14.1 The Role of Information and Communication (ICT) in a Power Grid

As explained in previous chapters, a power grid is a complex distributed system, whose main function is the supply of electricity to customers distributed in over a wide area, the technical difficulty being the requirements for maintaining almost constant voltage and frequency. To achieve this, a balance between generation and consumption must be maintained. As the consumption changes continuously, generation must be accommodated in realtime.

This functionality is implemented by a number of applications, some of them working at the system level, several supporting grid nodes functionality, substations, generation plants, etc., and others directly related to primary equipment and other field devices.

As these applications require data interchange between them, as well as remote data access, telecommunications is required, thus becoming a necessary component to assure grid functionality. Applications and telecommunications infrastructure form a distributed system, whose key function is to maintain the stability and continuity of the system by providing services to operate and protect the grid. This system can be considered

as the brain and nervous system of a power grid. Without its functionality, a grid cannot maintain its operation.

Figure 14.1 shows the main ICT components. Control centers gather field information, process it, and provide the interfaces for human interaction. To implement such functionality, a telecommunications infrastructure providing specialized operational services is required, as shown in Fig. 14.1.

This generic structure is replicated in every site, so every substation or generation plant is equipped with a site control application that allows operations to be carried out on site. Similarly, every substation bay has a local controller with similar functionality to supervise and operate the bay's primary devices. Substations and generation plants require a local communications infrastructure that is, nowadays, implemented using a local area network (LAN) that connects intelligent electronic devices (IED) that carry out operation functions in the local environment. Their communications capabilities together with the wide area network (WAN) allow local information to be consolidated by control center applications.

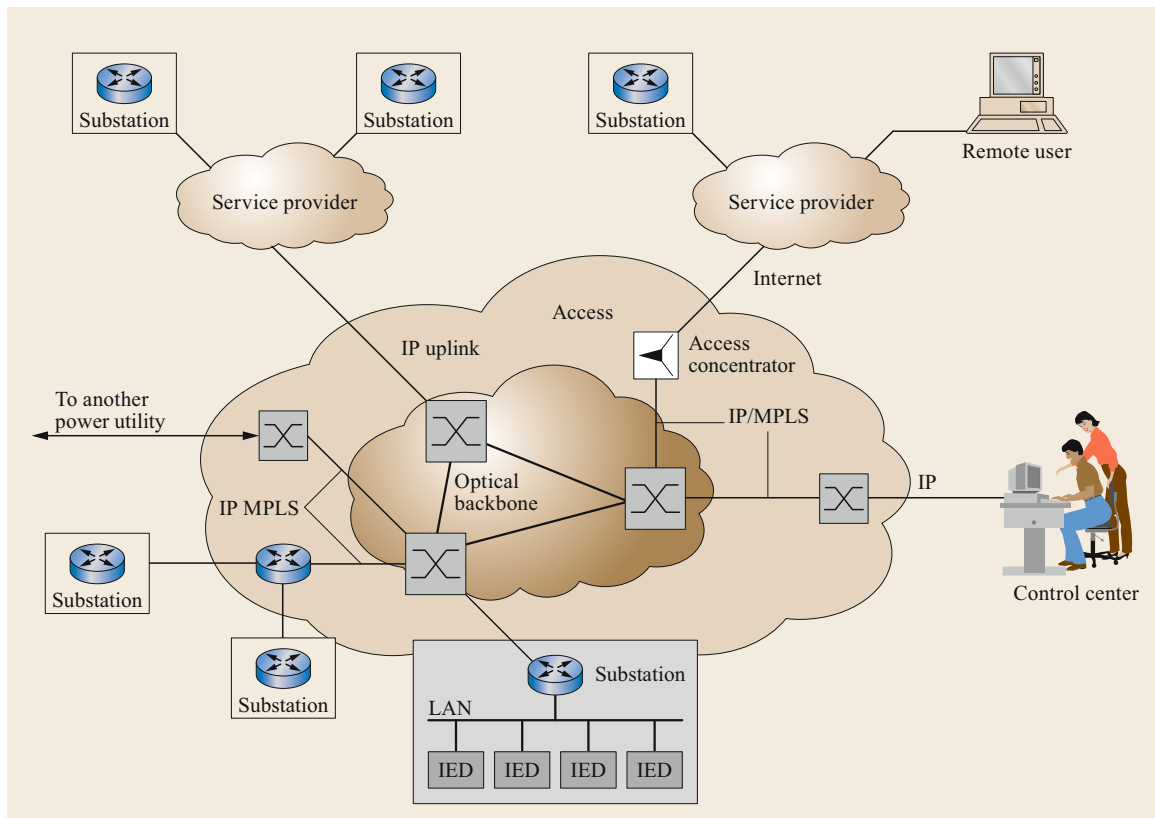

Fig. 14.1 ICT overview

ICT provides a logical view of the power grid. Primary devices components, values, status, etc., are stored and processed by local operational applications and transmitted to control centers

Both applications and telecom infrastructure need to fulfil very demanding performance requirements, the most critical being the realtime response together with a very high availability and dependability.

The term *realtime* has a specific meaning for operational applications; it applies to service latency or application response time. It can be understood in different manners, and it is not only matter of time but also of the reliability of the response time. That is to say, performance measurements based on statistics cannot be used for critical functions, as once the maximum delay is exceeded, the operation is considered faulty. In the operational environment, every operation has to be carried out before the maximum accepted delay.

The maximum response time depends on every operational application and can range from 1 s to 3 ms. The requirements for time synchronization functions are expressed in functions of the synchronization error. Some precision time synchronization applications require a synchronization error lower than a tenth of a microsecond.

Some applications require a quite deterministic latency, whereas others accept some latency variation, but all of them require a bounded delay. Consequently, mission-critical applications and telecom services will need to be implemented to achieve these operational requirements.

These application requirements impose tough design conditions for the telecommunications infrastructure. Telecommunications networks as well as internal substation communications should be as reliable as operational application requirements. Due to this, even using the same technology as telecom operators, design, configuration, and operation are rather different, as is explained later in the telecommunications section (Sect. 14.3).

The aforementioned characteristics of operational applications made them quite different from the information technologies used in business applications, not only in the way technologies are used but also with respect to the application design. The main differences are:

- IT systems are focused on information, whereas operational applications are focused on the process. Their functionality is to optimize and maintain the operation of the process; information is only required to achieve their functionality.
- IT reliability and dependability requirements are not as high as for operational applications, which can

be considered mission critical, as their reliability and dependability requirements are several orders of magnitude higher than IT applications.

- Short service interruptions used to be accepted for IT applications, but service interruption of some critical operational applications may lead to catastrophic situations, so these applications should be designed to be fault tolerant.

The operation of the power grid is carried out using a number of collaborative applications, some working in a centralized way, and others being distributed along the grid. Applications working at system level are normally located at control centers. These applications interact with operational applications located at every site using the telecommunications services provided by a telecommunications infrastructure.

Primary ICT goals have evolved over time. The first use of operational applications was focused on the remote control of field devices. Simple telecom services using point-to-point telecommunications channels were used to support this functionality.

This approach evolved towards the control of the power grid as a system. New applications were developed to provide a view of the grid and optimize its performance. This approach required enhancing the telecommunications infrastructure both to improve communications with grid sites and also between applications at control centers.

The next step was focused on business performance, that is to say, how grid operations, asset-management, condition monitoring of primary equipment, other field devices, etc., impact on business performance. New applications were developed, and interchange of information with IT applications became a must. This led to the development of new control center architecture and data modeling requirements, which paved the way to the latest development, the smart grid concept.

Smart grid implies *total interoperability*, which is achieved by standardizing the following key concepts:

- Information modeling. Object modeling and standardized semantics are applied to every component of the power grid.
- Information services. Information interchange is standardized considering data modeling properties.
- Communications services. Object communications, which is implemented using message interchange, is defined using abstract communications services, which provides isolation from actual telecom technology. Consequently, many different telecommunications technologies can be used, thereby allowing optimization of cost and performance.
- Application interface allowing integration at the business level.

Following this trend, modern applications model all primary equipment in a standardized way, thereby simplifying information interchange between applications, and use standard communications interfaces. This new architecture is defined by the IEC 61850 series of standards and is the foundation of modern operational ICT systems.

The use of standard protocols and the increased need for information interchange between operation and IT systems, the use of public telecommunications

infrastructures, and the Internet introduced a number of opportunities for cybersecurity attacks. The number of attacks are growing day by day. Therefore, there is a need to take protection measures to reduce the risk of successful cyberattacks.

Cybersecurity is a necessary component in all modern operational systems. Cybersecurity protection measures must be considered from the design phase throughout the system's life cycle, as explained in the cybersecurity section (Sect. 14.4).

## 14.2 Operational Applications

This section identifies operational applications, shows its functionality and develops architectural details, and describes information interchange. The focus of this section is on identifying operational applications' functionality, and how they interact each other to support power-grid operations.

Therefore, architecture, data modeling, information interchange, interfaces, and interoperability are of primary interest to understand how they form an integrated system. Furthermore, these subjects are a primary source of information to define telecommunications requirements.

These applications are implemented using proprietary algorithms; consequently, they are different for each system supplier. Nevertheless, data modeling semantics and protocols are standard in order to assure interoperability, as will be explained in following sections. The description and working principles of these algorithms are out of the scope of this chapter, since our focus is on information structure and the required telecommunications services. Operational applications are distributed along the grid forming subsystems, systems, and systems of systems.

Legacy ICT technologies were based on a set of independent applications unable to share information; due to this, the same piece of information acquired in the field was coded in different ways and transmitted to different applications using different protocols. The use of object-oriented technologies paved the way to the implementation of a common information bus that enables application integration. This evolution started in two parts, at control centers for enterprise application integration and at fields for substation automation systems.

In a modern grid, including the smart grid, applications are designed using standard data modeling and communications services, so they can share and interchange information, thereby forming an integrated system that provides the functionality to operate, man-

age, and maintain the grid and its relations with IT applications and the energy market.

Operational applications provide operational services implemented using the following components:

- Applications running on servers and other devices with communications and processing capabilities called intelligent electronic devices (IEDs).
- Operator interfaces implemented by terminals that provide the human-machine interface (HMI) or by IEDs displays.
- Communications infrastructure providing telecommunications services. These services can be based on internet protocol (IP) connectivity or merely on bit transport services to connect legacy devices.

The most important system used to operate the grid are the energy management system (EMS) and the distribution management system (DMS). EMS and DMS include a number of operational applications, each with its own application domain with specific working modes and performance requirements.

### 14.2.1 Energy Management System

The energy management system (EMS) is a realtime high-performance distributed set of applications and tools used by the operators of a power grid to monitor, control, and optimize the performance of the generation and transmission system.

EMS is composed of the following applications.

#### Realtime Supervisory Control and Data Acquisition (SCADA)

SCADA provides data acquisition and supervisory control of field information and devices. It includes alarm and event logging, control operation, and other facilities to operate the grid. Further information and architecture are provided later on.

### Generation Dispatch and Control

This provides the functions required to dispatch generators according to the criteria settled by grid operator with the aim of maintaining grid stability.

### Energy Scheduling and Accounting

This provides the functionality to interact with the energy market, including interchange scheduling, accounting, and weather demand forecast.

### Transmission Security Management

This provides facilities and advanced functions to analyze and optimize the use of grid assets in a reliable and secure manner. State estimation is the most important function. The state estimator (SE) uses data provided by SCADA and other field devices to create a realtime model of the grid, which is used to optimize power flows. The reliability of SE depends to a great extent on the precision of phasor measurement units (PMU). Modern PMUs take 30 or more samples of the current and voltage values and time stamp them with a common reference clock synchronized with the global positioning system (GPS) universal clock. This provides time-coherent information of the values in all the grid nodes. The higher the number of samples, the higher precision and realtime performance of the calculation results. Nevertheless, this introduces a considerable traffic load on the telecommunications infrastructure and an increasing processing strain on the data processing infrastructure.

### Operator Training Simulator

This provides a number of functions to check different network operations using a realistic interface with the same models, icons, and functionality as the real EMS application. This application allows testing the effect of different operations on the functioning of the network status.

## 14.2.2 Distribution Management System

A distribution management system (DMS) is a set of applications that provides services to monitor and control the distribution grid in a reliable and efficient manner.

The key advantages brought about by DMS are:

- Reduction in the duration of outages
- Improvement of the operational efficiency
- Determination the resources required to restore faults quickly and efficiently
- Improvement of outage communications to customers with more accurate information and estimated restoration time

- Improvement of service reliability by reducing the outage effect through a more accurate grid configuration and state.

DMS uses the services and information provided by SCADA to implement a number of functions described in following paragraphs.

### Network Connectivity Analysis

Distribution grids usually include a large number of customers and field equipment with changing configurations, so it may be difficult for the operator to identify functionality from a graphical connectivity display. Network connectivity analysis is a function that provides connectivity information obtained from the information of the position of switches and breakers, which determine the feeding point of a due load. Network connectivity function informs the operator about the operating state of the distribution grid, indicating working schemes such as radial mode, loops, or parallel configurations.

### Maintenance Schedule and Safety Management

Safety measures to protect field personnel is a key issue for power utilities. Grid operators schedule grid reconfiguration to isolate a section of the network to make it safe before work can be carried out. Schedules must be validated before implementation to verify their suitability and effect on network stability. Switching operations can combine telecontrol commands with manual operations of nonautomated apparatus. When a section has been secured, a working order is issued. Once the work has been finished, this function will facilitate the restoration of the working configuration by controlling the order of commands and manual operations.

### Power Flow

Power flow, or load flow, is an application that calculates voltage and currents at different parts of the power grid in normal steady-state conditions. It is very important to know the working conditions of grid elements in order to analyze whether they can withstand stress without any damage or degradation of their life span. Furthermore, from economical point of view, losses should be kept as low as possible when considering system constraints and the risk that the system falls in an unstable mode should be limited.

Power-flow calculation is carried out from the voltages of every power bus of the grid. As power-flow calculation is a nonlinear problem, numerical methods are employed. Market products implement proprietary algorithms.

Modern power flow algorithms consider nonlinearities and a set of constraints to determine the optimal power flow. Operational limits can also be calculated using these algorithms. Limits such as active or reactive power of a generator, current and voltage upper limits, tap position of a power transformer, etc., can be determined by power-flow algorithms.

### Voltage and Reactive Power Control

Voltage and reactive power control application manage voltage levels and reactive power throughout the grid. There are two primary mechanisms to control voltage across the grid, load tap changers in power transformers and capacitor banks. Voltage and reactive power control applications interact with tap changers and capacitor bank local controllers to maintain voltage levels in selected power bus. This interaction is normally implemented using SCADA, which gathers voltage information from the field and issues control commands to field devices, as explained in the following sections. In fact, regulation of apparatus to achieve the set point level sent by the control center application is implemented by a local automatic control system that modifies the working point of the apparatus to achieve the desired voltage level. Ampacity of power lines and feeders can also be controlled by this application, with the advantage that the effect of the reactive power is considered in the calculation of the current flow.

### Load Balancing

Load balancing using feeder configuration is essential to manage load-congested areas. A load-balancing application monitors the status of the distribution grid, identifies overload areas, and allows the operator to reroute the loads to other parts of the network. Load balancing can also be used for loss minimization. The load balancing application uses optimal power-flow algorithms and switching plans to minimize losses.

### Distribution Load Forecasting

A load forecast is essential to the operation and planning of a distribution grid. The load forecasting application helps the grid operator make important decisions with respect to grid configuration planning and load switching, as well as identifying the need for future grid development.

Load forecasting is carried out both in the short term – up to one day – and in the long term – up to one year to forecast the load in the long term; external factors such as weather, holidays, etc., should be considered.

Several mathematical models have been developed for load forecasting based on different techniques such as multiple regression, exponential smoothing, stochas-

tic time series, fuzzy logic, neuronal networks, and knowledge-based systems. None of them have been standardized, so each power utility requires that algorithm that better suits its topology and operation modes.

### Fault Location and Restoration

The reliability of the power supply depends to a great extent on the number of outages and their duration. Reducing the outage time duration is, therefore, important to fulfil reliability requirements.

The fault locator and system restoration application reduces outage time by helping the operator locate the fault and suggesting a switching plan or, in some cases, automating service recovery. SCADA provides the information to locate the fault. Once located, a switching action plan is implemented. The switching operation can be carried out manually or automatically. In any case, switching is implemented using SCADA services.

### Load Shedding

Unexpected changes in network conditions may lead to instabilities and critical failures. A load shedding scheme detects predetermined network conditions and performs a predefined set of control actions to re-establish normal conditions.

Load shedding is a component of a wide area protection scheme, the remedial action scheme (RAS). Consequently, it may act by tripping loads in response to some condition detected in the wide area protected by RAS or due to some condition detected in the distribution network.

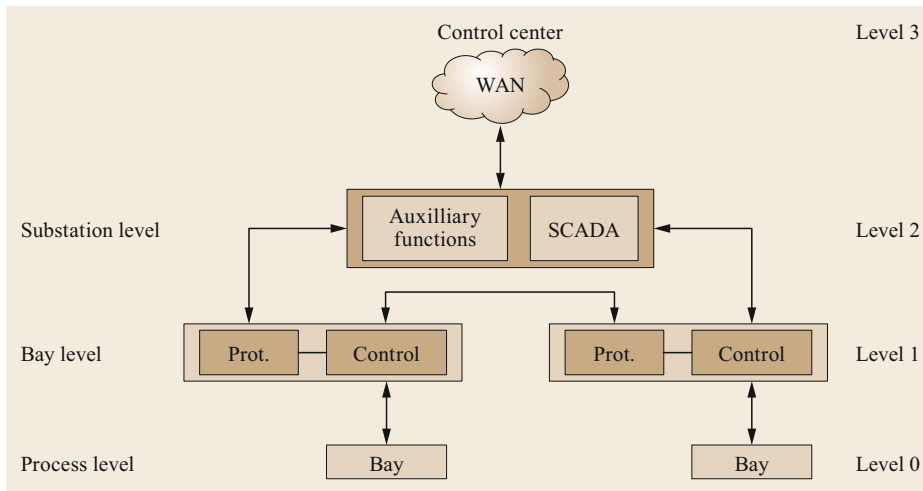

## 14.2.3 SCADA

Supervisory control and data acquisition is a distributed control system that uses intelligent electronic devices (IEDs) and networked data communications to supervise and control different aspects of a power grid. SCADA services and functionality are provided through a graphical operator interface that shows the grid status of supervised elements and allows process commands to be issued.

SCADA architecture and implementation evolved from monolithic proprietary solutions to distributed systems using standard communications protocols to the latest architecture based on IEC 61850 series of standards, which defines protocols, communications services, data models, and object semantics.

Figure 14.2 shows the SCADA architecture. The SCADA system is structured as levels that perform different processes.

Level 0: field level. This includes primary equipment and other field apparatus. This level provides field information such as voltages, current, status, alarms, etc.

**Fig. 14.2** SCADA architecture

**Level 1: bay level.** This comprises bay control and supervision functionality. These functions are carried out by an IED, the bay control unit, which gathers field information, and execute commands whether issued locally or remotely. It can also perform logic functions related to bay operation.

**Level 2: substation level.** This includes all the functions to supervise and control the whole substation or plant. These functions are implemented by a substation controller, which in fact is a local SCADA system that gathers substation information, execute commands, log system activity, carry out logical functions, and provide a graphical operator interface that allows local supervision and operation of the substation, as well as the substation information display.

**Level 3: control center level.** The SCADA application located at control center servers provides supervision and control services of the power grid and gathers grid information and shares it with other control center applications.

SCADA typically uses a database that contains data elements called *points*, which represent each specific field element. Points may hold field values such as analogue magnitudes or status, or can be used to issue commands. Modern architecture based on IEC 61850 standard uses objects instead of points. Objects provide a powerful functionality and a richer information structure, which enables interoperability with other applications, as explained in following sections.

SCADA functionality at substation level works in a similar way. It gets all the information from the substation field and filters and groups this information before sending it to the control center. Furthermore, using this information implements some local logical functions related to supervision of the operation and status of substation devices. Substation SCADA is configured

to filter and process field information before send it to the control center. Some legacy SCADA implementations use different protocols inside the substation and from substation to control center. Modern approaches unify protocols and data models at all SCADA levels.

The man-machine interface (MMI) or the human-machine interface (HMI) provides the view of the system and the interaction interface to the SCADA operator. Grid and substation information is presented to operating personnel in a graphical way in the form of mimic diagrams, which are a schematic representation of the grid or a particular site. Alarms, status, values, etc., are presented in realtime on the MMI display.

Mimic diagrams consist of line diagrams, symbols, and icons that represent the grid structure and process elements. Status and values of mimic elements are updated in realtime.

MMI is also used to host the graphical interface of other SCADA functions, such as the historian that stores time-stamped data, events, and alarms in a database. Historian database information can be retrieved to analyze faults or unusual events. This information can be shown as a text list or in a graphical way. Alarm handling is a very important SCADA functionality that uses MMI to present its events. It classifies alarms according to their severity and provides facilities for alarm management according to the operator's criteria.

SCADA monitors field values to determine when an alarm condition is present. Once an alarm or other event occurs, actions will be taken depending on the logic implemented at any SCADA level from 0 to 4. This event can be generated directly by a change in the status of a field signal or indirectly when is the result of a calculation carried out from several signals, like in

the case of analogue ones or a result of a logic function. The activation of an alarm rises and an indicator generates an alarm report, etc. This event can be presented and processed at any SCADA level, but in any case, it is presented to the SCADA operator using the MMI. Alarms can be classified into different levels of severity and can have a different status, such as pending, recognized, and cleared. The level of severity and the status are clearly identified by color codes, font type, blinking text, etc.

SCADA provides services to other control center applications. Data interchange was formerly proprietary, later based on generic standards, and finally, fully standardized in an open and distributed power utility architecture, as described in following sections.

To perform all the above-mentioned functions, SCADA requires a telecommunications infrastructure that becomes a key component to guarantee system performance and reliability. Two different types of communications infrastructure are required: local communications inside substations and plants and wide area network communications to connect substations to the control center. The most important requirements for SCADA communications are availability and reliability. Nowadays, SCADA uses standard communications protocols that have been specifically designed for this application, efficiency and reliability being its most important characteristics. Details on communications technologies and SCADA protocols can be found in the telecommunications section (Sect. 14.3).

#### 14.2.4 Asset Management and Condition Monitoring

Asset management applications provide the functionality to guarantee the service level of physical assets in the most cost-effective manner with an acceptable and manageable risk. Although the concept includes the entire life cycle of the asset, from design to disposal, asset management applications are focused on operating conditions, maintenance, repair, and refurbishing.

Asset management is a centralized application that provides functionality to support risk-based management decisions. The decision process is rather complex due to the fact that both short-term and long-term decisions should be supported on the grounds of a holistic approach.

The decision-making process must consider aspects such as:

- System development plans
- System performance impact
- Economic aspects such as price, cost, and benefit
- Impact on safety and society.

An asset management application should integrate data related to primary equipment, secondary equipment, and IT infrastructure. This integration simplifies the two key challenges, the integration and correlation of heterogeneous operational systems and integration with other business applications such as enterprise resource planning (ERP), customer relationship management (CRM), etc. A new power-system operational architecture and associated technologies make this integration possible, as will be explained later in this section.

Using the information provided by SCADA and other field devices, an asset management application extracts key information from the huge amount of data gathered from the grid. These data are linked with other relevant information related to economic aspects, social and environmental information, etc., to make decisions to improve asset management.

Condition monitoring is a complementary tool of asset management. Condition monitoring is the process that monitors parameters that provide information about the working condition of an apparatus in order to identify a significant change that is indicative of a developing fault. Condition monitoring is a key component of predictive maintenance and provides very relevant information to the asset management application.

Condition monitoring information allows maintenance to be scheduled and other actions be taken to prevent failure and avoid its consequences. Condition monitoring is normally applied to primary equipment such as power transformers, breakers, rotating machines, etc. Traditional architecture consists of specialized equipment associated with the primary device and located in the same location. This device processes specific parameters such as pressures, gases, etc., to identify anomalous conditions. A summary of the findings is transmitted to the asset management application. Nowadays, modern implementations based on IEC 61850 architecture models this monitoring function in a standardized way, so most sophisticated applications able to correlate information of different nature can be implemented. For further details, see Sect. 14.3.9.

#### 14.2.5 System Protection Schemes and the Protection Management Center

Protection of power system is a very important function to detect and isolate faults in order to protect the equipment and limit their effect on the grid. Chapter 13 has already presented different protection schemes that are specialized in clearing faults related to substation equipment, power lines, or cables.

In addition to these schemes, there are other schemes specialized in protecting the system as a whole. These

schemes combine protection and control functionality and rely on telecommunications services to perform their task.

A system protection scheme (SPS) is defined according to the North American Electricity Reliability Council (NERC) as follows.

An automatic protection system designed to detect abnormal or predetermined system conditions, and take corrective actions other than and/or in addition to the isolation of faulted components to maintain system reliability. Such action may include changes in demand, generation or system configuration to maintain system stability, acceptable voltage, or power flows.

SPS is normally designed to cope with the following phenomena:

- Transient angle instability
- Small signal angle instability
- Frequency instability
- Short-term voltage instability
- Long-term voltage instability
- Cascaded tripping.

A vast number of SPS are in operation worldwide; the most common actions are:

- Adaptive protection – changing protection settings based on system conditions
- Generator control and rejection
- Actions on automatic generation control
- Load shedding due to both underfrequency or undervoltage
- Out of step protection
- Load rejection – transmission line removal
- Reactive power compensation
- System split/separation
- Tap changer blocking.

SPS architecture can be local or system wide. Local implementation involves field information and control devices located at a substation or generation plant. System wide SPS involves collecting information from multiple sites. Decision-making and logic functions can be performed at one location or distributed among several places. Telecommunications facilities are required in all the cases to collect information and to initiate remote corrective actions. System wide SPS can encompass an area or the whole grid. Telecommunications service is a key component of a SPS system. Latency and service reliability have a direct influence on SPS performance. In fact, internal SPS algorithms

should consider telecom service performance and failure modes.

SPS can be deployed with different scopes namely:

- *Substation*: Information obtained locally within the substation and used to control substation devices
- *Regional area*: Information gathered from several nearby substations which have a greater but limited impact on power system
- *Wide area*: Information gathered from most of network sites to monitor the network with a complete geographical span having the greatest impact on power system.

The working principle of the SBS is based on a centralized working mode, that is to say, information is obtained from the field and transmitted to a central point where it is processed and analyzed to obtain relevant information about power system status. The result of this evaluation can be passed to an operator for manual action according to the operator's criteria, or a command can be automatically issued to start an automatic action in the field. Every scheme has different telecommunications requirements in terms of bandwidth, reliability, and latency. The telecommunications network is a critical component of every SPS. Therefore, the telecommunications service used by any SPS application should be tailored accordingly to application requirements, as will be discussed later in this chapter.

The use of Ethernet-based telecommunications with a large bandwidth capacity allows IEC 61850 GOOSE (generic object-oriented substation event) and sample values messaging to be used to transmit data from the field back to the central control application. This approach will simplify implementation while reducing the response time of SPS, thus improving its performance. Most SPS applications can provide a better accuracy when measurements coming back from different parts of the system are synchronized.

Current implementations use phasor measurement technology to correlate information obtained from different network locations, as this method can be synchronized using different precise-time synchronization methods to improve accuracy. Due to this, control actions can be taken faster and with more accuracy. Phasor measurement units (PMUs) provide synchronized vectors using GPS time synchronization. This information is transmitted to processing units using standardized protocols such as IEEE C37.118 or IEC 61850-90-5.

### 14.2.6 Energy Market

As was already explained in previous chapters, the energy market, or the electricity market, is a system that

enables electricity to be traded through bids to buy and offers to sell. Bids and offers are cleared by the market operator, which is an independent entity. Trade clearing considers internal market rules, load forecast, and grid conditions in order to maintain generation and load balance.

Power utilities, whether generators, transmission, or distribution ones, are actors in the electricity market. Therefore, they have to be connected to market operators to send offers, receive generation orders, etc. This connection must be implemented using standard data modeling and protocols with a near realtime performance. Consequently, deregulated markets should be implemented using communications standards. IEC has developed the IEC 62325 set of standards, which defines an energy market framework that includes semantics, data modeling, market operations, and application messaging process. IEC 62325 is an extension of the common information model (CIM); it defines the business process and operations, as well as semantics and data modeling. The most relevant functions required to interact in the energy market are:

- Auctioning. Sending bidding and buying offers.
- Acknowledgment. Functional and technical acknowledgment of documents.
- Scheduling. Process of exchanging information related to generation schedules, load schedules, and other schedules supported by the market.
- Settlement. Interchange of information to settle the electricity market such as differences between scheduled energy and meter values.
- Managing reserves. The process of managing spare generation units and dispatchable loads for balancing purposes.

Participation in the energy market requires the integration of operational applications in a common framework, since interaction with operational applications are required to implement scheduling actions and manage reserve assets. Therefore, EMS, DMS, and SCADA applications should share information using standard data models, as is discussed in Sect. 14.3.8

Cybersecurity is an issue of most concern for energy-market actors. Market transactions should be protected against cyberattacks, as these operations can compromise system stability and may involve important economic losses. IEC 62351 is the set of standards recommended to protect energy-market information. Cybersecurity details are discussed in Sect. 14.5.

### 14.2.7 ICT Management and Maintenance

As we saw in the previous section, ICT infrastructure has a capital role in the operation of a power grid.

Therefore, it is very important to manage and maintain it properly to assure service reliability and availability, as these have a direct impact on power-system reliability.

The scope considered does not only include the telecommunications networks, but also information processing platforms and system components, as well as IEDs implementing substation automation systems. Managing such a complex infrastructure is a challenge due to the need for integration of different technologies to provide a system view.

The following aspects must be considered:

- The need for a unified view of ICT systems. This can only be achieved by implementing a network management center.
- The technology integration challenge. Many different technologies working together to support operational services. Monitoring them is difficult due to the need for information integration, as every technology uses different semantics, data modeling, and protocols.
- Information presentation. The challenge here is how to present information in such a way that it becomes useful for the customer, that is to say, other operational applications.

These challenges should be overcome by the network management center, which provides both a console-supporting HMI, as well as a middleware layer that allows information to be interchanged with other applications. HMI provides the interface for day-to-day operation, administration, maintenance, and security monitoring of the network. These facilities are provided by management services that are implemented using a distributed infrastructure that involves every single device and application participating in the support of operational services and applications. On the other hand, middleware provides information and services to high-order management and business applications. Details on management architecture and functionality can be found in Sect. 14.3.9.

### 14.2.8 Control Center Application Architecture

We have seen how a power grid is operated and managed using quite a large number of applications, some local and some distributed, which gather information from the field to provide services and facilities that guarantee electricity delivery with the required level of quality and reliability. These applications should share information with business management IT applications to empower business management. They must support a number of different user groups and organizational

functions, including operators, supervisors, operator training, operation planning, and maintenance tasks.

Legacy systems were implemented in such a way that each application gathered field information using its own data format and protocol. For this reason, the same piece of information was coded in different ways and transported to the central application using different protocols and stored in different data bases with different formats. It was really difficult to share information between applications, so information interchange was very limited. Therefore, system view was poor and rather limited, which prevented an optimal use of grid resources.

This architecture was not scalable, so new technologies and system architecture have been developed and adopted. Nowadays, the goal is to implement integrated systems, that is to say, systems formed by applications able to share information and be fully interoperable.

Integrated systems require a high level of interoperability between applications. This implies that interoperability must be guaranteed at different levels:

- Connectivity. An open and standard communications interface must be used. Ethernet technology is the communications interface used in control centers.
- Protocols. A suite of protocols including all the layers needs to be defined. Not only the protocols, but also the profile or selected options must be standardized to guarantee interoperability at protocol level. Manufacturing message specification (MMS) and transport control protocol (TCP)/IP is the protocol stack used in modern control centers.
- Middleware. This is a software layer that supports transparent communications between distributed applications. Different technologies can be used to implement this functionality; all of them provide the facility of distributing applications in different servers in a transparent way.
- Application interface. This provides communications services with other applications.
- Object modeling and semantics. These specify data format and properties, as well as naming.

Integration technology should fulfil the following requirements:

- Open communications. These allow system components to exchange any kind of information of arbitrary complexity.
- Technology independence.
- Provide an information exchange model.
- Publishing independence. Any subscriber should be able to be configured to receive a message without modifying the publisher configuration.

- Open expansion. New publishers and subscribers can be deployed regardless of existing ones.

As we saw before, the two key aspects to implementing an integrated system is to use a common data model and semantics, as well as a common application interface able to provide communications services between distributed applications. This application interface is implemented using middleware that provides those services required to support what may be seen as the *application bus*, that is to say, a communications bus that provides transparent communications between any application connected to this bus.

This new architecture was designed to fulfil a key requirement: interoperability between applications. Consequently, two generic components have been standardized, the application programming interface (API) that defines communications services and data interchange methods, and a common information model (CIM) that unifies semantics and data object modeling.

This architecture facilitates application integration. Several scenarios can be envisaged:

- Integration of applications developed by different suppliers running on the same system
- On-line data exchange between independent systems
- Sharing of engineering data between different systems
- Exchange of data between the similar applications working in different systems.

This new architecture is defined by the IEC 61970 standard series for EMS and IEC 61968 series for DMS. Two fundamental components are defined by these sets of standards; the API is referred to in these standards as the component interface specification (CIS) and the common information model (CIM).

### CIM Architecture

The common information model is an abstract model that represents every power utility object related to grid operation. It provides a standard way of representing devices and resources as object classes and their attributes. CIM also defines a common language including semantics and syntax, so data can be published and interchanged independently of how it is represented inside the applications.

Due to the huge number of objects defined by CIM, the object classes are grouped into logical packages containing a set of objects related to a specialized function. The CIM model is described using the Unified Modeling Language (UML). Figure 14.3 shows a class diagram of top packages' dependencies.

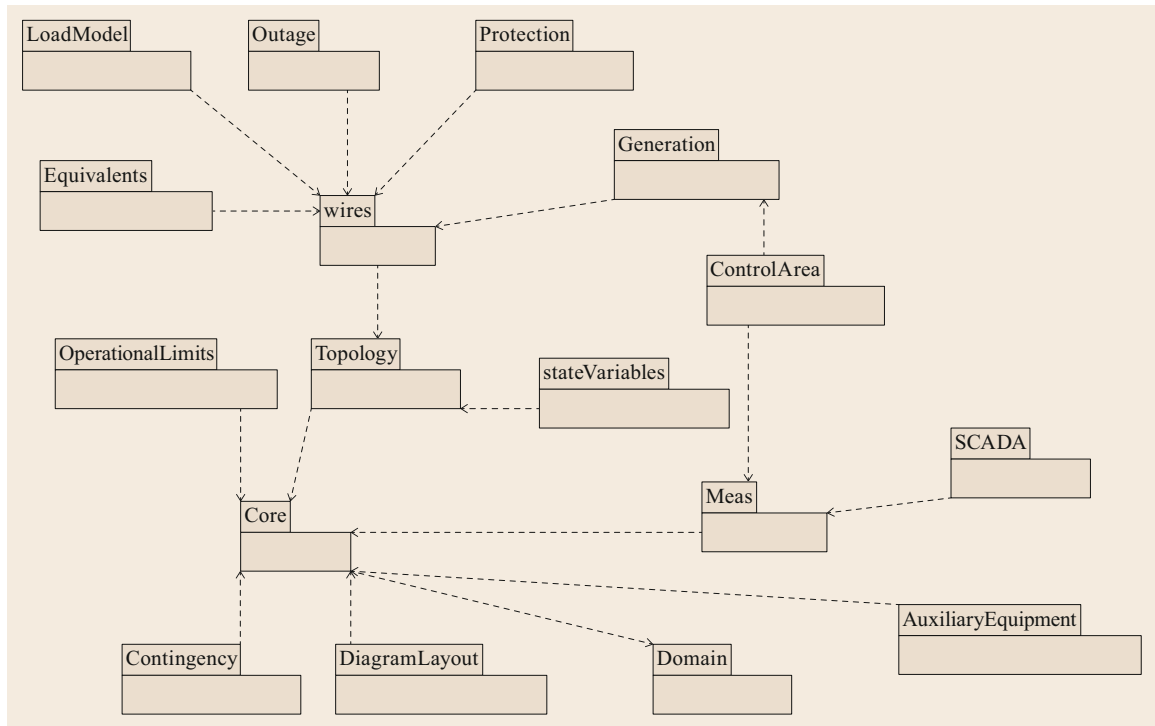

Fig. 14.3 CIM class diagram showing dependencies

The package *Domain* defines data types used by classes in other packages. The following types are defined (Fig. 14.3):

- *CIMDatatype*. A data type that contains a value attribute and optional unit of measure and multiplier.
- *Primitive*. The most basic data type such as Boolean, integer, etc.
- *Enumeration*. A list of constant values.
- *Compound*. A set of data of any of previous types.

The package *Core* contains the models of power-system resources including conducting equipment. This package only depends on the *Domain*, but most other packages have associations that depend on it.

The package *Diagram Layout* describes how objects are arranged to form a coordinated system.

The package *Operational Limits* models the working limits of operational system devices.

The package *Topology* describes how equipment is connected and models grid topology, which is the result of the state of switches and breakers.

The package *wires* models the electrical characteristics of transmission and distribution networks. This package is used by several applications, such as the state estimator, load flow, etc.

The package *Generation* contains other packages that model load forecasting, automatic generation control, economic dispatch, and unit commitment.

The package *Load Model* is responsible for modelling energy consumption and system load. Related information that may affect load, such as seasons and day types, are also included.

The package *Outage* is an extension of the packages *core* and *wires* and models current and planned network configuration.

The package *Auxiliary Equipment* models other types of equipment that is not related to topological connections such as sensors, fault locators, etc.

The package *Protection* is an extension of the packages *core* and *wires* and models protection equipment. It is also used by fault location applications.

The package *Equivalents* models equivalent networks that are the result of network reduction, considering actual connectivity in the functioning of switches and breaker position.

The package *Meas* describes data exchanged between applications. Data types for measurements can be:

- Control information
- Set points
- Analogue information
- Digital information, such as position, alarms, etc.

The package *SCADA* models information used by SCADA applications, including communications status.

The package *Control Area* models the operational specification of a grid area including actual generation,

actual area load, load forecast, and power flow. A control area gathers generators, loads, and a set of tie lines for the connection to other areas to implement different functionalities such as automatic generation control, power flow area interchange, etc.

The package *Contingency* models information related to contingency situations, including equipment status and contingency plans.

The package *State Variables* models variables for analysis solutions, including short circuits, power injection, power flow, voltages, and conducting equipment status.

### API Architecture

The application programming interface (API) is the tool used by applications to interchange information. API provides communications services to applications. In the context of CIM/CIS standards, these services should be independent of the implementation of the components supporting them and of the underlying protocols. This approach is aligned with service-oriented architecture (SOA). The SOA paradigm provides a uniform means to offer, discover, and interact with capabilities provided by other applications. Its central concept is *service*, which is defined as a mechanism to enable access to capabilities, where the access is provided by an interface used according to constraints and policies specified by the service description.

An integrated system should be based on services with the following characteristics:

- Explicitly defined interfaces. Interfaces should be declared and known using a formal and clear definition.
- Loosely coupled. Service should have dependency to standard interfaces only but never with internal interfaces or any other dependency.
- Use abstraction. Services should be independent of implementation technology.
- Reusability. Services should be reusable in different business contexts. This is very important, as it has a direct impact on cost and improves system consistency.
- Autonomy. Services should have control of their environment in order to be able to provide the required service level.
- State control. Services should be able to control their internal state. Services should always be in a known state that can be requested by a third party.
- Self-descriptive. Services should be understandable and can be found at design and run time.
- Manageable. A service can be started and initialized by a well-defined interface.
- Testable. Services should be testable without the use of the rest of the system.

In order to understand interface concept and implementation, it is broken down into its components. This component-based approach also facilitates the use of systems and software of different sources. It is important to mention that this approach is independent of any particular middleware services or technology. Consequently, service interface does not depend on middleware technology just uses it internally.

The reference model is shown in Fig. 14.4. Rather than showing the functional layer, the model shows the components required to create a reusable framework.

The model is intended to be applied to control center environments, which are typically based on a number of servers connected by a local area network (LAN). Since a control center includes a variety of systems to support operational applications, it is important that applications can be used in multiple contexts. This is achieved due to the properties associated with each component interface.

A component is a reusable building block. It shall provide a standard interface that allows other applications to invoke its functions and to access internal data component. Components expose methods, properties, and events. The model of a component defines its basic architecture and specifies the structure of the interface and the way it interacts with other components. Components are executed within a *container*. A container provides an operating-system process in which the component can be executed. The container isolates the component from the runtime platform. The component adapter is a piece of software that links the component and its container. The adapter can implement protocol and data translation. The component

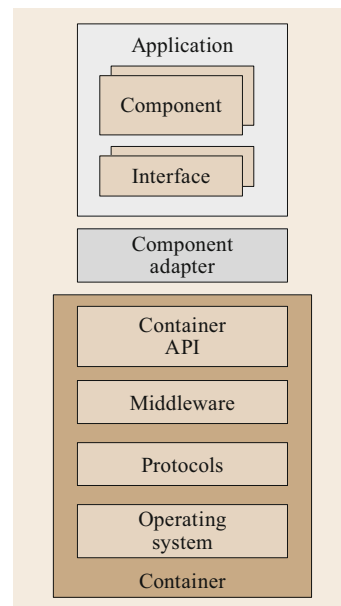

Fig. 14.4  
Functional layers

adapter deals with the differences between component interfaces and container technologies. The application interface is completed with two more components, the middleware and the communications protocol stack.

There are several technologies and different middleware implementations, as is described in technology section. The power utility should select the technology and define a middleware implementation profile, as well as a communications profile. Profiling is a necessary step to guarantee interoperable solutions, as standards are normally opened so they offer many implementation approaches.

### Hardware Architecture

Although every supplier implements different solutions, the most common approach is the use of a redundant fault-tolerant architecture implementing a layered model.

The computing platform comprises the following components:

- Local communications implemented using an Ethernet LAN
- Servers hosting applications
- Storage units built into servers and external ones holding a backup image of the system
- Backup units
- A user interface.

The hardware architecture should provide the following features:

- *Fault-tolerant architecture.* This implies the use of two disjoint LANs and, in general, redundant communications and cyber-protection infrastructure. The connection with the WAN is normally implemented through two routers and two firewalls, each connected to a different LAN. Every device has two Ethernet ports each connected to one LAN.
- *Server redundancy.* This includes data storage and power supply redundancy.
- *Resiliency.* The architecture should assure continuous operations in spite of local anomalies and planned maintenance, including installation of updates and patches.
- *Disaster recovery.* In the case of major failure or local disaster, a minimum functionality should be guaranteed.

Layering architecture implies that communications, applications, and data are supported by different servers that can only communicate through firewalls. The minimum architecture comprises the following layers:

- *Communications layer.* Supported by the front-end servers that have IP connectivity with field IEDs through a firewall and a wide area network. These servers implement communications protocols and data conversion when needed.
- *Application layer.* Control center applications are installed in servers allocated to the same layer. Sub-layering is also possible.
- *Data layer.* Data are stored in a different layer to protect their integrity.

The number of servers and layers depends to a great extent on the size of the system. Regardless of the number of servers, data modeling and API should be implemented according to the above-mentioned standards.

### Service Continuity

Control center host-operational applications are capital to guarantee electrical supply continuity. Consequently, business continuity and disaster recovery plans should be implemented. The implementation of these plans affects not only every aspect of both hardware and software architecture, but also the fact that a complete backup control center is usually implemented in a different location.

To support these specific requirements, control center platform architecture has to be designed to provide redundancy to support continuous operations while providing flexibility to react to system component failures or disaster scenarios. This performance has to be maintained even during maintenance or system upgrades.

The most relevant requirements related to business continuity are:

- *Flexibility of operation.* The architecture should support different operation modes between the main and redundant system:
  - Main–main. Both systems are active and synchronized.
  - Split mode. Some functions are segregated to one of the systems during maintenance or upgrades.
  - Main–backup. One system acts as primary and becomes synchronized with the other.
- *Synchronization.* Functions and services must be synchronized between systems. The transfer time of applications and services should be optimized.
- *Storage.* Data backup facilities must be provided.
- *Maintenance facilities.* System architecture should support the upgrade or maintenance of applications, the operating system, and hardware components carried out in one of the system images.

Continuity of operations is closely related to the continuity of telecommunications services, both inside the control center and at the wide area network, since communications between system images will usually require telecommunications services. Consequently, a contingency and business continuity plan should embrace all ICT aspect and components. Business continuity and disaster recovery techniques are developed in the telecommunications section (Sect. 14.3.10).

### The User Interface

The user interface is a very important functionality in a control center, since it supports the interaction between system operator and operational applications. A control center user interface is not limited to a screen to present data but a complete framework that provides flexibility and enables integration and expansion of multivendor solutions into a system that looks like a large, single application. Visualization devices are the primary interface between the control room operator and grid operational application. Typically, they consist of operator consoles and electronic wall displays.

Consequently, the most important requirement for a user interface framework are:

- *Common look and feel.* Common presentation and navigation perspective, regardless of the underlying applications.
- *Task-oriented displays.* Capabilities to define user displays according to business rules regardless of the origin of the data.
- *Flexibility.* The ability to customize the user displays consistently with the enterprise business practices and style guides.
- *Technology independence.* Capability to define user displays regardless of application technology and data format.
- *Multi-vendor console management.* The ability to enable displays from multiple vendors within a shared user interface framework.
- *CIM support.* The display process should be integrated in the CIM data model.
- *Cybersecurity support.* User interface must implement cybersecurity measures in accordance with IEC 62351 to implement access control to applications and data.

The user interface framework includes the components:

- *Visualization environment.* The control-room visualization environment controls visualization devices that are the primary interface between the control-

room operator and the grid. Typically, they consist of operator consoles and electronic wall displays.

- *Visualization management.* This implements the visualization of several applications on the same display at the same time.
- *Display editor.* This includes the tools for display configuration.
- *Rendering engine.* This generates the display content from the application data.

Although the display format and content can be configured, displays shown on user interfaces can be classified into three major categories:

- *Operator displays.* These present the state of the power grid and allow the operator to operate the system. They include one-line diagrams, geographic displays, alarms, etc.
- *Engineer displays.* These are used for engineering and maintenance tasks. They are nonoperational displays and so less critical than operator displays.
- *Management displays.* These dashboard-type displays are used by management or nonoperator personnel. They may also be available externally to the operational environment.

### 14.2.9 Substation Applications Architecture

IEC 61850 architecture and technology is the cornerstone of modern power-utility operational systems. The first edition of the IEC 61850 series was focused on the substation automation system (SAS), which includes all the functions implemented by IEDs to control, monitor, and protect the substation equipment and its power supplies. In addition, there are other functions that maintain the SAS, such as system configuration, IEDs management, and communications monitoring, or software management and cybersecurity.

This section is focused on understanding the way IEC 61850 models devices, and the way IEDs communicate to implement an automation function. This has an important impact on the way Ethernet and IP are used in the application domain which, correspondingly, affects the design and configuration principles.

#### Relevant Aspects of the IEC 61850 Standard

The fundamental goal of the IEC 61850 standard (Communications Networks and Systems in Substations, Edition 1) – published at the end of 2004 –, which applies to SAS, is to standardize the communications between intelligent electronic devices (IEDs) from different manufacturers inside the substation. In other words, the objective is to define a substation automation

system (SAS) which allows interoperability between IEDs from different manufacturers; or more precisely, between functions that are carried out by equipment installed in the substation. In this scenario, interoperability is the capability for two or more IEDs of interchanging information, and of using that information for a correct cooperation regardless of the model or manufacturer of the devices. Interoperability should not be confused with *interchangeability*, which corresponds to a wider concept and is out of the scope of the standard. It is important to highlight that the standard does not have as an objective to achieve interchangeability between IEDs nor the complete configuration of the equipment in a substation, but just interoperability with respect to the communications between devices.

To achieve this, the standard defines:

1. A *suite* or set of well-proven protocols and the way to use them to fulfil operational requirements.
2. Data models and semantics that will be used to interchange information between SAS functions.
3. Communications services specified in such a way that they become independent of the communications protocols.
4. The language and format used to describe IEDs and SAS configuration and capabilities.

Due to these features, a very important capability is achieved; the specification is not related to its implementation. That is to say, a SAS can be specified using IEC 61850 architecture and features, and the final performance of the system is independent of its implementation. This provides a very high degree of flexibility and reutilization of proven solutions regardless of their final implementation.

Another relevant feature introduced by IEC 61850 is the standardization of IEDs configuration files using the common language Substation Configuration Language (SCL) that is used to interchange IEDs configuration information files among the different engineering tools and from these tools to IEDs.

After some years of positive experiences using IEC 61850 technology, it was proposed to extend this technology and concepts outside of the substation. By the end of 2012, most of the IEC 61850 Edition 2 was approved. This new edition extends the use of this technology to the whole power system from the control center to every single device of the power grid. In 2017, some parts are still under discussion. A summary of related standards and their status is summarized later in this section.

Historically, in order to carry out these functions, serial protocols have been used in point-to-point or point-to-multipoint configurations. These approaches needed to differentiate services or subsystems in differ-

ent networks, and for this reason, the communications architecture, although being simple, ended up becoming inflexible and complicated to maintain topology. Furthermore, nowadays, more and more substation devices have communications capabilities, so legacy solutions are not appropriate, as they do not provide flexibility or scalability. Consequently, Ethernet technology has become the standard communications interface due to its flexibility, as it can carry any protocol or data format, and its scalability that ranges far higher than what is required by power automation systems.

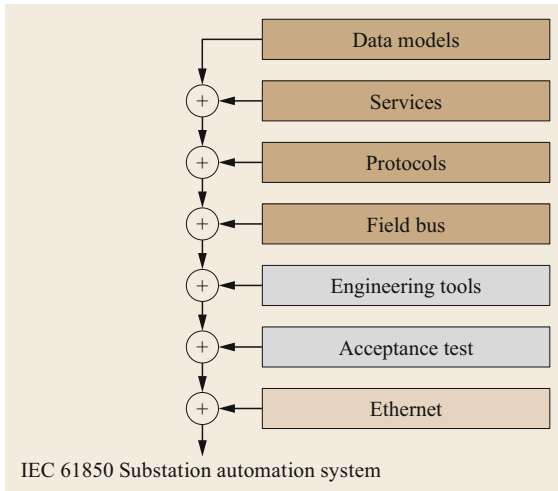

The scope of the IEC 61850 series is not limited to interoperability, but it is much broader, as it proposes not only a new concept of automation of substations – based upon a new architecture for communications – but also defines models of information and configuration languages based on the Extensible Markup Language (XML). Likewise, IEC 61850 standardizes the use of Ethernet networks with priority, and it defines the interchange of critical messages called generic object-oriented substation events (GOOSE), as well as sampled value (SV) messages, for the transmission of the measurements of current and voltage transformers. These measurements can be carried out by means of new models of measuring transformers whose output values are digital, or by means of specific units that convert the conventional analog measurements into digital information, called *merging units*.

The models of information and the communications services are independent of the protocol, and the use of the manufacturing message specification (MMS) protocol in the application and Web service layers will allow the growth and validity of this standard, as they make the use of new technologies of communications feasible.

Edition 1 of the standard is made up of 14 parts; it was a great innovation not only with regard to the approach of using object-oriented modeling techniques, but also with respect to communications modeling that allows services to be isolated from the protocols supporting them. Edition 2 is made up of a larger number of parts, as it covers the whole power utility grid from control centers to customer premise devices. For further details of both editions, see the standards section (Sect. 14.2.10).

Figure 14.5 shows the components that make up an IEC 61850 substation automation system. The most generic component is data modeling; this part models every substation device and in Edition 2 also every power grid device. Models use services that have been defined in an abstract mode, so they are independent of underlying protocols. Protocols used by IEC 61850 are well known and proven, e.g., MMS and IP. The standard defines protocol profiles to ensure service performance.

A field bus or process bus defines how primary equipment with communications capabilities can send

**Fig. 14.5** IEC 61850 components

and receive their status, as well as voltage and currents in the form of samples.

The definition of the Substation Configuration Language (SCL) based on XML defines the format of configuration files, and how these file can be interchanged between configuration tool and IEDs. Finally, the standard includes the specification of conformity test procedures. All the above-mentioned components rely on Ethernet as the communications interface and technology to implement a communications network inside the substation. Communications outside substations can be implemented using Ethernet or IP according to the service and application. Therefore, to fully understand this technology and to make the most of it, technologies involved in every component must be well understood; namely, Ethernet, IP, XML, and object-oriented technology, including UML.

### IEC 61850 SAS Architecture

Legacy technologies had fewer resources to implement a well-structured SAS. Communications were not as widely used as in modern systems, so it was difficult to implement redundant systems, and consequently, they were less reliable and had poor flexibility.

IEC 61850 defines a hierarchical SAS architecture made up of four levels using the same concept shown in Fig. 14.2. Although the concept is similar to the legacy architecture, the big difference is that it is fully implemented using communications devices.

Level 0 comprises the process level, which includes primary equipment with communications capabilities and any other associated IED. Communications between this level and upper levels is implemented using process bus technology, which uses fast messages to transmit status and sample values.

Level 1 comprises IEDs that implement protection, control, and measurement at the bay level. This level obtains information from level 0, processes it, and generates information to the field level, upper levels, and to other bays. Edition 2 of the standard includes the interaction with bays of other substations, mainly for protection and automation functions.

Level 2 is the substation level. This level includes the functions related to the whole SAS, such as substation automation logic, local SCADA, and gateway or proxy devices. Level 2 communicates with the bay level and gathers information to be interchanged with the control center.

Level 3 is the control-center level. This level was out of the scope of Edition 1 but was included in Edition 2. Control-center communicates with substation level 2 IEDs to update the status of LN objects and map them to CIM objects, which are, in fact, accessed by control-center applications.

In order to avoid the legacy SAS limitations introduced by several of the above factors, the new IEC standard suggests building the automation system on top of an Ethernet-based LAN. This allows virtualization of a large number of peer-to-peer connections over the same physical infrastructure, ensuring a high degree of redundancy, bandwidth, very low latency, and higher reliability.

A number of different network topologies are possible using Ethernet technology; this standard can integrate over the same network, multiple communications services, and protocols, such as MMS, GOOSE, FTP, SNMP, etc., ensuring redundancy and reliability. Furthermore, Ethernet can provide several mechanisms to implement fast and even bumpless communications recovery, as is described in the communications section (Sect. 14.3.5).

### Function Modeling

SAS is implemented by several functions, such as protection, control, automation, etc. IEC 61850-5 defines each SAS function and depicts how it can be implemented and how information is interchanged. The implementation of every function is expressed by means of the LNs and the messages interchanged between them.

The concepts involved in function modeling are:

- Functions are implemented using *logical nodes* (LN). A LN is the most basic function with communications capabilities. It is defined by means of an object class.
- LNs are grouped into *logical devices* (LD) that model the functionality associated with a device. This concept is no longer used in most IEC 61850 device implementations, as LD is a mere LN container.

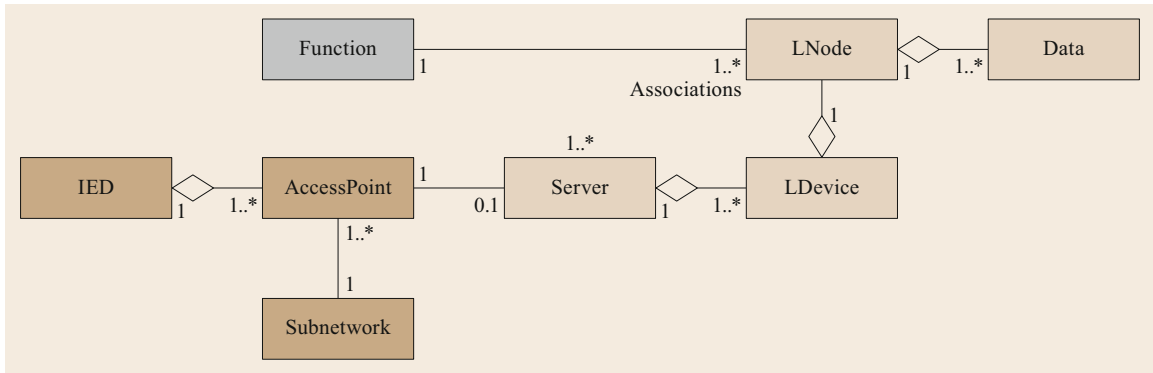

Fig. 14.6 UML diagram of a function

- LDs are contained in a *server* that is associated with a communications access point, which is implemented using an Ethernet interface.

Figure 14.6 shows the UML diagram of a function.

This diagram shows the composition of an IEC 61850 IED and the relation of its internal components from the communications interface to LNs. It is important to mention that SAS functions are only related to LNs.

#### Data Structure

A very important aspect introduced by the IEC 61850 standard is the structure of the data. While classical protocols typically operate under the concept of numerical and linear addressing and data coding, IEC 61850 works with a structured data model based on the object principle. Linear approximation is simple is difficult to maintain; it is not scalable and does not provide interoperability. With the old approach, each control point requires an arbitrary and individual address.

The IEC 61850 standard models substation devices using object modeling techniques. In fact, modeling is not limited to physical devices as it also includes SAS functions.

Object-oriented techniques provide three important features:

- *Abstraction*. An object is the abstraction of a real device. It represent the features required to implemented SAS functions. These features are expressed by means of a data structure and a communications interface that support the interaction with other objects and define how to use object functionality.
- *Encapsulation*. Every object performs an internal function using its own data and algorithms. These internal data and algorithms are hidden from other objects, so every implementation can be differ-

ent yet still compatible, as they all use the same standard communications interface that is used to transmit messages with information related to the public part of the object.

- *Inheritance*. Hierarchical relations between object can be defined in order to establish relationships between the most general objects to other more particular ones that provide details. Inheritance enables that a class receives or inherits the properties and methods of another class. This creates an object class hierarchy, so the *children* class inherits features and properties from the superclass. This feature allows detailed object classes to be reused in the definition of more complex ones.

Consequently, the IEC 61850 standard is based on the following hierarchy of concepts that are expressed as objects:

- *FUNCTION*. Every SAS basic function that is implemented using objects that interchange messages to execute the action of the function.
- *LOGICAL NODE (LN)*. A logical node is the most basic function. It is implemented as an object form by data, internal methods that implement its functionality, and a communications interface that allows messages to be interchanged with other LNs and expose the service supported. Methods are encapsulated and can only be used through interface communications services. LN data are objects, so its content is not a simple value but an object that has a complex structure.
- *COMMON DATA CLASS (CDC)*. Data included in LNs are modeled using CDC objects. A CDC is an object that models data and – as any other data – is formed by data that are attributes of the CDC and are expressed using basic data. Attributes contain values and properties of the generic data concept expressed by the CDC.

- **BASIC DATA.** These define the coding format of the attribute information.

This data modeling methodology is based on a structured information format that, together with standardized object semantics, provides self-descriptive objects so any application can interact without previous knowledge of the data structure. This provides flexibility and expandability, facilitating future retrofitting.

### Logical Nodes – General Concepts

A logical node is the abstract representation of a specific functionality for substation automation. Its main feature is that this function cannot be decomposed into more basic functions. It can be said that it is an atomic function.

LN are modeled using object classes. This is a concept used in object-oriented programming, which allows real objects to be modeled and thus implemented in a program in such a way that this program resembles the properties of the real object.

An object class is defined by:

- **Name.** This identifies the class. IEC 61850 identifies LNs by four capital letters.
- **Data structure.** This is the information content in the class. In IEC 61850, data are object classes named common data class (CDC) with the structure of an object class.
- **Interface.** This is a communications service that supports the interaction with other class by means of messages.
- **Methods.** These implement the services offered by the interface.

Methods and private data are encapsulated, which means that they are hidden to other objects and, consequently, not specified by the standard. The scope of the standard is limited to public parts, name, public data, and interface. For this reason, each implementation can be different and still compatible.

LN classes, as any other object class, are specified by means of a table that contains the LN name, data objects, and services. Data objects contained in LNs are defined using CDC object classes. The CDC data structure is formed by attributes. Each attribute contains the following fields:

- **Name.** This identifies the attribute. Names are standardized by IEC 61850-7-3.
- **Type.** This defines the data type of the attribute.
- **Functional constraint (FC).** This defines the use of the attribute, as described later this section.

- **Trigger options.** These specify whether this attribute can generate a trigger condition. Three conditions may generate a trigger: data change, quality change, and data update. Triggers are used to generate spontaneous messages, such as GOOSE and reports.
- **Value.** This contains the value of the attribute.

The FC defines functionality associated with the attribute. As specified by IEC 61850-7-3, FC types are coded with two letters with the following use:

- **ST** refers to attributes related to a *status* information, whose value may be read, substituted, reported, and logged, but not written. It can also be included in a dataset.
- **MX** refers to an analogue *measure* information, whose value may be read, substituted, reported, and logged, but not written. It can also be included in a dataset.
- **CO** refers to *control* information the value of which can be operated using the control model service and read.
- **SP** refers to a *set-point* information, whose value can be operated using the control model service and read.
- **SV** refers to a *substitution*, whose value can be written.
- **CF** refers to a *configuration* information, whose value can be written and read.
- **DC** refers to a *description* information, whose value can be written and read.
- **SG** refers to a *setting group* and identifies the active setting group. It cannot be written.
- **SE** refers to *setting group editable* and uses the setting group control block service.
- **EX** identifies *extension* information providing a reference to the namespace.

FC relates attributes to services. That is to say, an attribute can be accessed using the service identified by its FC. This provides an extra verification of the coherency of the use of LN objects and attributes. LN classes are defined by IEC 61850-7-4. CDCs are defined by IEC 61850-7-3 and the service interface is specified by IEC 61850-7-2.

### IED Structure

An IED is a physical device, a physical entity with specific properties like serial number, status, health, etc. An IED implementing server functionality should have a data structure in accordance with the UML diagram of Fig. 14.5. This implies that the access point must have at least one logical device that contains LNs. An IED may contain multiple logical devices. A logical device must

contain at least two logical nodes that support generic IED functions.

**LLN0:** logical node zero. This logical node contains information about the logical device and its communications control blocks that configure how GOOSE, SV, reports, and log messages will be constructed. Usually, it also contains the data sets associated with control blocks. Therefore, it is a container for all the information and data necessary for the operation of the LN included in its LD. LLN0 also controls local/remote working mode and testing facilities. LLN0 configuration of these features affects all LNs inside the same LD.

**LPHD:** contains information about the physical device. Serial number, description, health, etc.

### Naming

LN objects and attributes are addressed according to the structure

```
<IEDName>/<AccessPoint>/<LDName>/
<LNName>.<DataObject>.<DataAttribute>
```

IEDName, Accespoint identification, and LD name are not defined by the standard.

The LN name is formed by three fields:

- **Prefix:** Optional identifier.
- **LN class name:** A four-letter code that identifies its functionality.

- **Instance:** Optional ordinal number used when more than one instance of the same class is included in an LD.

Finally, in order to exchange communication information between different devices, configuration file content and syntax are defined by an XML schema. This file contains naming of objects, specification of mandatory and optional parameters, data types of every attribute, and value ranges. Since naming and object content rules are defined by this file, it can be used to validate other SCL files, such as IED configuration files and substation configuration files.

### Communications Interfaces

IEC 61850 defines the communications interfaces between substation levels. Figure 14.7 shows the reference architecture of an IEC 61850 substation including communications interfaces shown as numbers in circles.

The numbers in Fig. 14.7 identify different types of interfaces, which support different services and, therefore, have different communications requirements. Interface types are:

1. Protection data between station level and bay level
2. Protection data between bay level and remote protection device
3. Data exchange between bay level devices

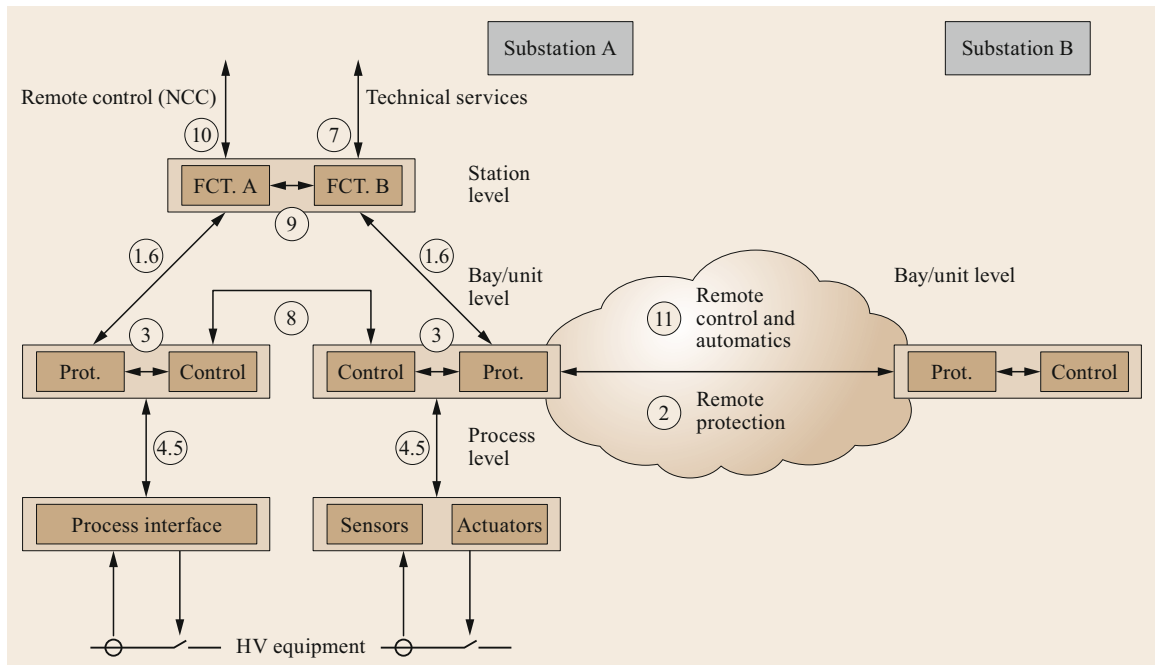

Fig. 14.7 Logical interfaces. (Adapted from IEC 61850-1)

4. Data exchange between process level and bay level of instantaneous samples of current and voltage
5. Control data between process level and bay level
6. Control data between station level and bay level
7. Remote configuration and monitoring data
8. Direct data exchange between bays for fast functions, such as protection and interlocking
9. Internal control data in the substation level
10. Control data between station level and control centers
11. Control data exchange between different substations.

IEC 61850 Edition 1 did not implement interfaces 2, 7, 10, and 11, whereas Edition 2 includes all of them.

It is important to explain the interface concept. In this context, every interface is related to a specific communications service that has a performance requirement. Several interfaces can share the same physical interface but use it in a different way with different protocols and settings.

As shown in Fig. 14.7, by using a wide area network – typically an IP network – the remote system can be connected to several control centers or engineering facilities. For those legacy facilities that typically communicate using IEC 60870-5-101, IEC 60870-5-104 (TCP/IP), or DNP 3.0 protocols, information interchange between control center and substations a *protocol interpreter* or *gateway* must be provided to *translate* the information from IEC 61850 to the protocols and formats used by the control center. The standardization of this communication involves not only communication between the two levels but also an adaptation of the data models used in the control center. IEC 61850-80-1 specifies the mapping of IEC 60870-5 series, whereas IEC 61850-80-2 the mapping to DNP 3.0.

Information interchange with modern control centers can be implemented using the new standard IEC 61850-90-2. This standard defines two communications models, the direct information interchange and the use of a proxy device. The first model allows control centers to access any object of the SAS. This approach provides transparency and flexibility but puts heavier workload on the control center. The second model uses a proxy to mirror the information required by the control center. Proxies do not modify information or protocols.

#### Communication Between LNs

As LNs are modeled using object classes; their communication is implemented using messages sent and received through their communications interface. There are two types of communications, client–server and peer-to-peer messaging. Client–server communications are based on the connection-oriented paradigm us-

ing MMS protocol over TCP. This kind of messages is mainly used for SCADA applications. Peer-to-peer messages are instantaneous multicast messages that, in fact, do not use any protocol, as the information is encapsulated in multicast Ethernet frames. There are two type of messages, event oriented and sampled values of current and voltages. Event information is transmitted using generic object-oriented substation events or GOOSE messages.

The IED sending GOOSE messages is called the *publisher*, and the IEDs listening to GOOSE messages are called *subscribers*. There is no protocol or communication between publisher and subscribers. Configuration of this messaging communication is carried out at configuration time before the system is in operation and can only be modified by changing configuration.

IEC 61850-5 defines seven different types of messages. Each message is associated with a service, to one or several interfaces, and to a protocol:

- *Type 1A*. Trip. Used for protection applications. Associated with interfaces 2, 3, 5, 8, and 11. Implemented by a GOOSE message carried over a multicast Ethernet frame.
- *Type 1B*: Used for protection automation applications not related to direct tripping. Associated with interfaces 2, 3, 5, and 8. Implemented by a GOOSE message carried over a multicast Ethernet frame
- *Type 2*. Medium-speed SCADA messages, such as status and tripping information. Associated with interfaces 1 and 6. Implemented using MMS over TCP/IP.
- *Type 3*. Low-speed SCADA messages, such as alarms and measured values. Associated with interfaces 6, 10, and 11. Implemented using MMS over TCP/IP.
- *Type 4*. Raw data. Associated to process bus sample values. Associated with interface 4. Implemented by an SV message carried over a multicast Ethernet frame.
- *Type 5*. File transfer. Associated with interfaces 6 and 7. Implemented using FTP over TCP/IP
- *Type 6*. Time synchronization. Used for IED time synchronization and phasors and sample-value time stamping. Associated with all the interfaces. It can be implemented using SNTP over IP for IEDs time synchronization or IEEE 1588 over Ethernet for phasors and sample values.
- *Type 7*. Commands. Used to issue control commands. Associated with interfaces 6 and 10. Implemented using MMS over TCP/IP.

To adapt to different requirements of different applications message types are subdivided into performance

classes. Different groups of performance classes are specified for control and protection and for time synchronization. Control and protection classes identified as TT0 to TT6 specify the maximum transfer time that ranges from 3 ms to 1 s. Time synchronization classes identified as T0 to T5 specify synchronization accuracy that ranges from 1  $\mu$ s to 1 ms. IEC 61850 specifies two types of communication requirements: static and dynamic. Static requirements refer to properties not related to latency or transmission capacity. Static requirements are:

- *Ubiquity*. Any function or LN may be allocated in any IED without limitations imposed by communications.
- *Abstraction*. SAS function and their characteristics must be specified without referring to their implementation and the communications infrastructure.
- *Standardization*. Interaction between functions should be described using logical interfaces. Those interfaces must be independent of their physical implementation.

Dynamic requirements refer to latency or transfer time. In this context, latency refers to the maximum transmission time. The average latency should be used in the context of operational realtime services. Transmission time refers to the time required by an LN to transfer a message to another application or an LN located in a different IED. Therefore, it includes not only the communications latency in the LAN but also the processing time in both IEDs required to convert this message in an Ethernet frame and decode it at the receiver side. Latency is specified by performance classes as explained above.

#### Communications Methods

Legacy SAS were implemented using the master–slave communication method. This method is neither flexible nor scalable, so it has been abandoned in modern operational communications. IEC 61850 is based on the client–server paradigm, which is complemented with peer-to-peer messaging communications for fast information transfer.

*Client–Server*. By definition, a server is a device that offers a service using internal data, and a client is a device that requests a service that interacts by getting or interchanging data with the server. As a typical example of a client we can mention an Internet browser that connects to a Web server to get information or interchange data. This communications principle is connection-oriented, which implies that client and server should establish a connection prior to information interchange.

A server can accept a connection from any client without previous configuration and from several clients at the same time, the maximum number of clients being limited by hardware capabilities. For this reason, this method provides flexibility and scalability. LNs can be associated with a client or a server functionality. An IED can have server or client functionality and in some cases both functionalities, client and server, at the same time. In any case, it is only the client the one that gathers information from other IEDs.

As IEC 61850 servers support directory services, which implies autodescription and discovery functionality, clients can discover server data structure and functionality, and consequently, they can interact with any server without previous knowledge of the server capabilities. For this reason, an object's database is no longer required, as clients can dynamically create the internal image of the server's data structure. Furthermore, as explained later this section, IEC 61850 specifies how a substation configuration file can be created. This file contains the data model and services of all the IEDs of the SAS. Clients can also use this file to learn server's information structure.

*Control Command Service*. Control commands can be executed in different ways. The supervision of the expected state change produced by a command is the factor used to differentiate command types. Commands can be classified as normal or not monitored and with enhanced security when the status change is monitored to inform of the result of the command and with or without the previous selection of the device.

Then there are four different types of commands:

1. Direct commands with normal security
2. Select before operate (SBO) commands with normal security
3. Direct commands with enhanced security
4. SBO commands with enhanced security.

The best choice is probably the last one due to the following:

1. Data integrity requirements: As specified by IEC 60870-4, commands require integrity class 3, which under certain conditions can only be reached by using a SBO procedure.
2. The standard IEC 61850-80-1 specifies the mapping of IEC 60870-5-101 and IEC 60870-5-104 to IEC 61850; only enhanced security commands are supported.

It must be considered that an SBO control command is a completed process that starts when the device

is selected and has finished delivering the result of the process, so it is not necessary to read the status of the device afterwards, as the command delivers complete information about the result.

**Origin of Commands.** The hierarchy of control command is implemented using the origin attribute. This attribute is used to identify the origin of commands in order to enable or disable command execution considering their origin and the status of the local mode data attribute value.

The philosophy is that commands can be generated manually or automatically whether from any automatic process or application. In any case, the command source can be:

- A control center
- Local SCADA
- A bay.

IEC 61850 local control model is hierarchical. This means that when a local mode is active within a SAS level commands are only accepted from the same level.

Note that in order to apply the behavior of local command, it is necessary to distinguish between commands coming from an automatic process or from an application. Commands from automatic processes may not be subject to local command blocking.

The different command origins types are:

- *Bay control.* The command comes from a bay-level device.
- *Station control.* The command comes from a station-level device.
- *Remote control.* The command comes from the control center.
- *Automatic bay.* The command comes from a bay-level automatic process.
- *Automatic station.* The command comes from a station-level automatic process.
- *Automatic remote.* The command comes from an automatic process from the control center.
- *Maintenance.* The command comes from maintenance tools.
- *Process.* The command comes from spontaneous state change.

**Remote/Local Mode.** With regard to local modes, the generic working principle is as follows: each level – station, position, and process – has its own local mode attribute. When a level is in local mode, it only accepts commands from that level and not from upper levels. Local mode is controlled by the attribute *Loc* in LNs related to control functions. LLN0 also has this attribute;

consequently, as for other functionality, setting LLN0 in local mode automatically sets all LNs inside the LD to local mode too.

### Proxies and Gateways

Proxy functionality is required when not every piece of information of the SAS needs to be available for some external clients. In this case, a proxy device gathers information from different SAS servers and presents it in the form of LNs. By doing this, a summary of SAS information is available for any client, whether internal, such as local SCADA, or external, such as a maintenance center.

When the external client does not support IEC 61850, a gateway device is required to map the information and translate to the client's protocol. A gateway is a device that works at the application layer. This means that has to decode all the information interchanged in one side and map it to an internal database and process this information to adapt it to the format and protocol of the other side. Typically, a gateway is installed at the substation level for translating from IEC 61850 protocols at new substations and IEC 60870-5-101 or IEC 60870-5-104 in current control centers.

The recommendations to implement a device of this type are included in the technical specification IEC 61850-80-1. Basically, it is a guide that addresses the information-exchange model based on CDC data using IEC 60870-5-101 or IEC 60870-5-104 and includes the following items [14.1]:

1. Conceptual model of the gateway.
2. Command mapping to IEC 60870-5-104 IEC 61850.
3. Mapping of CDC (common data classes) of IEC 61805 to ASDUs (application service data unit) IEC 60870-5-104.
4. Mapping of data attributes to CDC data types in IEC 60870-5-104. An example can be seen in Fig. 14.8.
5. Mapping from IEC 61850 services to IEC 60870-5-104 services.
6. Extension of SCL file syntax in private sections in order to include the association between IEC 61850 data attributes and IEC 61870-5-101/104 information object addresses (IOAs).

### Communications Interface ACSI

LNs communicate using the abstract communications service interface (ACSI). The term *abstract* means that the interface is specified without implementation details, so it is not related to a particular application interface and, therefore, it can be used over any application protocol. Actually, ACSI can be implemented using MMS protocol or Web services without any change in the LN interface being required.

Services provided by ACSI are listed here:

- *Directory services.* These provide the capabilities to browse the content of an IEC 61850 server. By using this service, a client can obtain all the information trees of a server. This includes a list of LDs on the server; in every LD, LNs include a list of data objects and their attributes included in every LN. This service provides an autodescription of the IED data model.
- *Get, set, and substitution.* This group of services implements read and write operation over data, attributes, or datasets. Substitution is a more complex service, which includes two actions. First, write the value to be shown when substitution is activated. Second, activate substitution, so that when a client reads data or an attribute, the delivered value provided will be the substitute instead of the value read from the field. The substitution state is indicated when providing a substituted value in a reading operation.
- *Select active setting group.* This service allows the selection of a particular setting group among those previously loaded into LLN0.
- *Report control subscribe.* This service establishes the relation between a client and a report control block already configured on a server. When the client subscribes to a report, the report is sent to the client using this service. Transmission of a report as well as its content depends on the configuration of the report control block. It can be event driven or periodic.
- *Query log control.* This service allows querying the content of the log. It can also be used to clear log content.
- *Control.* This service issues control commands. It includes the entire process of selection and execution, as well as getting the final result of the command.
- *GOOSE.* This service supports GOOSE message publication and subscription.
- *Sampled values.* This service supports publication and subscription of sample values.

ACSI services are mapped to the application protocol using the specific communication service mapping (SCSM). There is one SCSM for each application protocol, including Ethernet encapsulation for GOOSE and SV messages. SCSM specifies how every abstract service is defined depending on the application protocol. Details are included in following sections.

#### IEC 61850 Protocol Stack

The IEC 61850 standard defines a LAN Ethernet as the physical communications technology to implement

a SAS. The LAN architecture and topology are not specified by the standard. In fact, every solution can adopt the topology required to achieve performance and availability objectives. The telecommunications section (Sect. 14.3) discusses the aspects that affect performance and topologies, and features that may improve availability.

*Message Types.* In an IEC 61850 substation, there exist two different ways of communicating for the different types of messages involved. One way is vertical, from the substation controller to the IEDs and vice versa; and the second way is horizontal, between IEDs. In the case of vertical communication, a client-server is used. In the case of horizontal communication, the transmission is based on the peer-to-peer principle.

In any case, the standard distinguishes between different types of messages depending on the intrinsic characteristics of their nature and classifies them into performance classes, as was already introduced in previous section.

As has been mentioned, there are messages whose transfer time must be very fast, such as GOOSE messages, for which the standard defines a simplified protocol stack or *shortened* path, in comparison with that of the full OSI/ISO reference model. The principle followed by these messages that circulate through a *shortened* path is, in certain way, similar to that used in the protocols of the IEC 60870-5 series, which make use of the EPA model (enhanced protocol architecture), based only upon three layers or levels with the aim of reducing the times required for communication between two devices. It is in this way that *peer-to-peer* messages or GOOSE do not pass through the different levels in the model but are delivered directly to the link layer.

*Suite of Protocols.* The IEC 61850 standard adopts a set of existing protocols widely used in order to carry out the different functions that implement ACSI services. Figure 14.8 shows more specifically different approaches according to the type of messages and the service supported. Messages with high requirements regarding transfer time, by virtue of their *mission-critical* nature, are directly mapped to the data-link layer as this procedure reduces message processing workload.

*Profile for Peer-to-Peer Communications.* In *GOOSE* (generic object-oriented substation event) messages, the information published is defined by the dataset content. Trigger conditions of dataset components generates the event. Please note that former generic substation status event (GSSE) messages that only support fixed state information has been deprecated by Edition 2. GOOSE messages are sent

Message type	Events	Samples	Synchronization		SCADA
	1, 1A	4	6	6	2, 3, 5
	GOOSE	SV	PTP	SNTP	MMS
				UDP/IP	TCP/IP
Ethernet ISO/IEC 8802-3					

Fig. 14.8 IEC 61850 protocols

Fig. 14.9 GOOSE message transmission procedure

periodically with a cadence that can be configured independently for every GOOSE message. When an event associated with a trigger condition is generated, a burst of messages is generated. This mechanism improves dependability because if a message is lost, the following one will be processed. Figure 14.9 shows the transmission pattern of a GOOSE message.

$T_0$  indicates the retransmissions cadence of messages when there is no event that produces a trigger condition. This is the rest condition. The continuous retransmission of messages is also used to check that publisher IED and LAN are working properly.

$T_1$  is the smallest retransmission time of an event. As can be appreciated, the message is immediately sent after a trigger condition.

$T_2$  and  $T_3$  are the retransmission times that become duplicated until the rest retransmission time ( $T_0$ ) is reached.

*Sampled-value* messages use the same protocol profile but a different transmission mechanism, as these messages are sent periodically. SV messages are not related to trigger conditions. They carry a dataset containing time-tagged samples of voltage and/or current. The cadence of transmission depends on the sampling rate and the number of samples contained in the dataset. For these messages, latency is not as critical as with GOOSE, but it must be bounded. What is more critical in this case is the delay variation that is a specific requirement, since if not bounded, it may affect relay performance.

**Profile for Time Synchronization.** In the substation bus, time synchronization is implemented by means of the Simple Network Time Protocol (SNTP). The SNTP protocol is transported over UDP connectionless transport protocol. SNTP is generated by an IED that acts as a master clock. This IED uses a global positioning

system (GPS) receiver to synchronize its internal clock. SNTP can provide a synchronization accuracy better than 1 ms, which is adequate for SCADA time stamping.

The process bus requires a more accurate time synchronization. IEC 61850-9-3 specifies that the process bus should be synchronized using the IEEE 1588v2 or Precision Time Protocol (PTP). PTP can provide a synchronization accuracy better than 1  $\mu$ s. Details of PTP applications can be found in Sect. 14.2.

**Profile for Client–Server Communications.** For client–server communication mode, an MMS application protocol together with the profile of the transport type or the  $T$  profile is used. As mentioned, the IEC 61850 standard adopts widely spread standardized protocols, which as a consequence are very well tested, on the several levels of its model – this being structured and presented in a similar way to how the OSI/ISO model of reference is conceived and usually presented –, as is explained in more detail in the telecommunications section (Sect. 14.3).

#### Manufacturing Message Specification (MMS) Protocol

The specification of messages for manufacturing consists of the application-level specification of the services and procedures necessary for the purpose of interchanging information between devices of the type of those installed in production chains. MMS is an application protocol that was initially defined for industrial process control that later found application for realtime SCADA. Its first use in this field was as the application protocol for ICCP/TASE.2 IEC 60870-6 for interconnection of control centers. Later, it was adopted by the utility communications architecture and finally by IEC 61850.

One key feature of MMS particular architecture is its capability of simultaneously providing client and

server functionality. This feature is supported by the *virtual manufacturing device* that implements the following functionalities:

- Access to object contained on the server
- Services used by the client to access those objects
- Server behavior.

Basically, the services that can be performed by MMS are writings, readings, and descriptions of variables (directories), which in our case will consist of sets of attributes of logical nodes and of files or folders (transparent transfers of blocks of bytes without specifying their sizes). These services, taken to our particular case, can be translated into alarm reports, control and instructions executions, autodescription of the objects, and transfers of files.

The MMS standard was published in 1986. It is considered a very reliable and extremely secure protocol. Nevertheless, its technology is becoming cumbersome for some lightweight applications, so other middleware solutions and application protocols based on XML, such as XMPP, will gradually replace MMS. Consequently, we will not develop any further detail of the MMS architecture.

The MMS application protocol is transported using the so-called *T* profile, which is based on TCP for connection-oriented transport and IP. Further details of this profile and protocols' working principles can be found in the telecommunications section (Sect. 14.3).

### Configuration

Legacy SAS lack the concept of the *legacy system*; each device performs a function depending on the values of its input without any knowledge of internal process of other devices. For this reason, the configuration of every device was carried out using proprietary vendor tools that do not need information from other devices to create the configuration. Consequently, it was not possible to share that configuration information between the different engineering tools, and IEDs have no information about the configuration of other IEDs of the SAS.

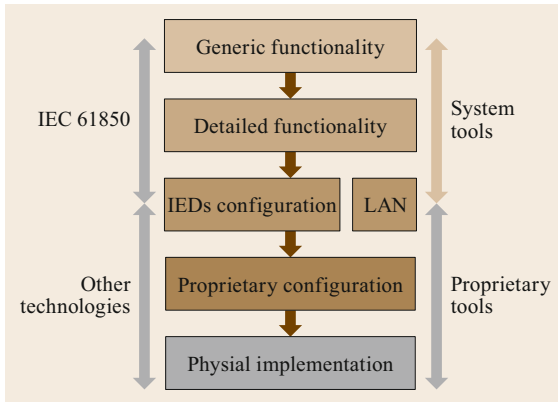

IEC 61850 defines a method for SAS configuration with a system view approach, so every device has the configuration information of other IEDs required to perform their functions, so that they can collaborate to implement more complex tasks. IEC 61850-6 defines the Substation Configuration Language (SCL). This language allows the interchange of specification and configuration files between system configuration tools, IED configuration tools, and IEDs. Due to this, it is possible to automatically create a SAS configuration file that contains data models, service capabilities, communication information, and private data.

The standard defines the following file types. The content and use of the files is identified by the file extension:

- *System specification description. File type .ssd.* This file contains an XML description of the single line diagram of the substation and the LNs associated with every primary device, bay, voltage level, or substation level. It also includes the data model of LNs. It is used to specify SAS projects.
- *IED capability description. File type .icd.* This file describes the functional and engineering capabilities of and IED type. The IED name is the *TEMPLATE*. The file describes services supported by the IED as well as its data model. It can contain a communications part with preconfigured information. There is one icd file per every IED model.
- *Instantiated IED description. File type .iid.* This file contains all the information of a single instance file of an IED preconfigured specifically for a project. Configuration data may not be completed and may change during the engineering process.
- *Configured IED description. File type .cid.* This file describes the final configuration of an IED in a project. There is an icd file for each IED in a project. This files contains all the information needed by the IED to perform its function. In Edition 2, the cid file is a subset of the scd file.
- *System configuration description. File type .scd.* This file contains all the IEDs of a project, including communication and data flow information.
- *System exchange description. File type .sed.* This file describes the interfaces of one project to be used by other project. It is a subset of the scd file containing all the information required by other project to connect external information. This file is required to automatically configure GOOSE subscriptions between substations.

IEC 61850 defines a novel configuration process that is very flexible and well structured. As shown in Fig. 14.10, the configuration process starts from the most generic specification to construction details. SCL language and the files described above are used in most parts of the process both to create the files and also to interchange files between tools, and to download the cid configuration files to IEDs.

The process starts using a *system tool* that is able to generate the *ssd* file, and from this file the rest of the process, including the specific IEC 61850 engineering process. As an IEC 61850 SAS is a distributed system made of basic functions, it is important to star design the SAS from the system view. From this information further details can be added, and when the actual im-

**Fig. 14.10** Configuration process

plementation level is reached, proprietary tools must be used, as information and configuration that are out of the scope of the standard must be defined.

### Specification Process

The main goal of an IEC 61850 specification is to assure functionality and interoperability. The specification process comprises the following steps:

- *Data profile definition.* This is a key step to achieve interoperability. A formal definition of the data model removes any ambiguity and select which options will have to be implemented to guarantee SAS functionality and performance.
- *SAS functions.* Selection of required functions.
- *Logical node selection.* List of logical nodes required for the implementation of SAS functionality.
- *LN communications.* Logical nodes interchange information by means of messages that are specified using the concept of PICOM (piece of information for communication). This process provides detailed information on how logical nodes interact to implement every SAS function.

Once the whole process is completed, a generic specification that guarantees functionality is obtained. It is important to mention that this specification guarantees the functionality regardless of how SAS will be implemented. Any specification tool is able to generate the *ssd* file according to the standard, but as this file does not include all the required specification information, only advanced tools can complement this file with the rest of the specifications, such as *picoms* or even wired signals. Implementation constraints can also be defined in the specification. For instance, it can be defined that some logical nodes should be included in the same device. By doing this, we can obtain a generic

specification of the devices that will implement the project.

Finally, by gathering logical nodes in a specification IED, a specification *scl* file is automatically created. This file specifies the IED data model and capabilities in very similarly to how an *icd* file does it for real devices. The specification file can be checked against a real IED *icd* file to verify compliance.

### IEC 61850 Engineering Process

A completed IEC 61850 engineering project should not only contain IEC 61850-related information, such as logical nodes and how they interchange information but also wired signals and legacy devices. As the main function of an engineering tool is to describe functionality, it is very important that the tool seamlessly relates wired signals with IEC 61850 functionality providing a clear view of system functionality regardless of the technologies used to implement it. As IEC 61850 includes a number of facilities that allow SAS functionalities to be implemented in different ways, the system tool should support all of them, providing the required capabilities to choose the working mode freely. Namely, some functions can be implemented whether by using sequential interrogations or by means of trigger conditions and reports, or GOOSE messages.

Figure 14.11 shows the engineering process step by step. The engineering tool provides the required functionality to assure coherency of the process. The results of the process are *scl* files according to the standard, as well as drawings, connection lists, and other documents not shown in the figure.

The use of signals based on reports or GOOSE messages requires some specific functions to support the generation of a list of signals, as well as the generation of drawings showing the implemented functionality in a classical way.

### Configuration

The configuration process is different depending on the edition of the standard. Edition 1 lacks many functionalities and information in the configuration files, so it is not possible to directly configure an IED from the files defined by the standard and, therefore, the IED configuration tool of the IED manufacturer has to be used. On the other hand, Edition 2 included these missing data, so IED can be directly configured from the system tool by downloading the *cid* file.

This is possible due to the definition of a new type of file, the *iid*, which includes settings and other private parameters. Nevertheless, there are a number of parameters that are not included in *scl* files yet, being the most important logical functions configuration and relay setting.

### 14.2.10 Standards

The International Electrotechnical Commission (IEC) is the standardization body in charge of the preparation of international standards in the electrotechnical field. Its Technical Committee 57 (TC57) is in charge of the set of standards related to operational systems, including the smart grid. This section names the different families of standards with the aim of providing a relation of the standards that should be considered when specifying or designing an operational system. The applications and the key concepts included in these standards are developed throughout the entire chapter.

#### Control Center Standards

Control centers comprise a set of applications that are specified by the following standards.

**IEC 61968.** Application integration at electrical utilities – system interfaces for distribution management.

The IEC 61968 series is intended to facilitate integration of distributed applications that communicate each other using middleware.

- IEC 61968-1. Interface architecture and general recommendation.
- IEC 61968-2. Glossary of terms.
- IEC 61968-3. Interface for network operation.
- IEC 61968-4. Interface for records and asset management.
- IEC 61968-5. Interface standard for operational planning and optimisation.
- IEC 61968-6. Interface for maintenance and construction.
- IEC 61968-7. Interface standard for network extension planning.
- IEC 61968-8. Interface standard for customer support.
- IEC 61968-9. Interface for meter reading and control.
- IEC 61968-11. Common information model (CIM) extensions for distribution.
- IEC 61968-13. CIM resource description framework (RDF) model exchange format for distribution.
- IEC 61968-100. Implementation profiles.

*IEC 61970.* Energy management system application program interface (EMS-API). The IEC 61970 series develops a set of guidelines and standards to facilitate distributed application integration and information interchange with systems external to the control center.

- IEC 61970-1. Guidelines and general requirements.
- IEC 61970-2. Glossary of terms.
- IEC 61970-301 Edition 6. Common information model (CIM) base.
- IEC 61970-302. Common information model (CIM) for dynamics specification. Extension of IEC 61970-301 to specify exchange models representing the dynamic behavior of power-system components to facilitate system simulation studies for system dynamic assessment and planning.
- IEC 61970-401. Component interface specification (CIS) framework.
- IEC 61970-402. Common services.
- IEC 61970-403. Generic data access.
- IEC 61970-404. High-speed data access (HSDA).
- IEC 61970-405. Generic eventing and subscription (GES).
- IEC 61970-407. Time-series data access.
- IEC 61970-452. CIM static transmission network model profiles.
- IEC 61970-453. CIM-based graphics exchange.

- IEC 61970-456. Solved power system state profiles.

### OASIS

The Organization for the Advance of Structured Information Standards (OASIS) is a nonprofit consortium that drives the development, convergence, and adoption of open standards for the global information society. OASIS promotes the development of industrial

standards for security, the Internet of Things, cloud computing, energy, content technologies, emergency management, and other areas. OASIS has defined the SOA framework that is used in control centers to implement CIM architecture. The OASIS reference model for service-oriented architecture 1.0 standard was released in 2006.

#### IEC 61850 Standards Series

As we saw before, IEC 61850 has become the common technology and architecture for the power grid. This technology allows a common platform for all the operational applications to be established, thereby finding applicability in the whole power system. The standards that specify this new architecture are shown in the following list.

*IEC 61850 Edition 1.* Comprises the following parts:

- IEC 61850-1. Introduction and overview. Technical report, 2004.
- IEC 61850-2. Glossary of terms, 2003.
- IEC 61850-3. General requirements, 2002.
- IEC 61850-4. System and project management, 2002.
- IEC 61850-5. Communication requirements for functions and models, 2003.
- IEC 61850-6. Configuration description language for communications in electrical substation related to IEDs, 2004.
- IEC 61850-7-1. Basic communication structure for substation and feeder equipment – Principles and models, 2003.
- IEC 61850-7-2. Basic communication structure for substation and feeder equipment – Abstract communication service interface (ACSI), 2003.
- IEC 61850-7-3. Basic communication structure for substation and feeder equipment – Common data classes, 2003.
- IEC 61850-7-4. Basic communication structure for substation and feeder equipment – Compatible logical node classes and data classes, 2003.
- IEC 61850-8-1. Specific communication service mapping (SCSM) – Mappings to MMS (ISO 9506-1 and 9506-2) and to ISO/IEC 8802-3, 2004.
- IEC 61850-9-1. Specific communication service mapping (SCSM) – Sampled values over serial unidirectional multidrop point to point link, 2003.
- IEC 61850-9-2. Specific communication service mapping (SCSM) – Sampled values over ISO/IEC 8802-3, 2004.
- IEC 61850-10. Conformance testing, 2005.

Edition 1 was deprecated by Edition 2.

*IEC 61850 Edition 2.* Comprises the following parts related to SAS:

- IEC 61850-1. Introduction and overview. Technical report, 2013.
- IEC 61850-3. General requirements, 2013.
- IEC 61850-4. System and project management, 2011.
- IEC 61850-5. Communication requirements for functions and models, 2013.
- IEC 61850-6. Configuration description language for communications in electrical substation related to IEDs, 2009.
- IEC 61850-7-1. Basic communication structure for substation and feeder equipment – Principles and models, 2011.
- IEC 61850-7-2. Basic communication structure for substation and feeder equipment – Abstract communication service interface (ACSI), 2010.
- IEC 61850-7-3. Basic communication structure for substation and feeder equipment – Common data classes, 2010.
- IEC 61850-7-4. Basic communication structure for substation and feeder equipment – Compatible logical node classes and data classes, 2010.
- IEC 61850-7-410. Hydroelectric power plants – Communication for monitoring and control, 2007.
- IEC 61850-7-420. Basic communication structure – Distributed energy resources logical nodes, 2009.
- IEC 61850-7-510. Basic communication structure – Hydroelectric power plants – Modeling concepts and guidelines. Technical report, 2012.
- IEC 61850-8-1. Specific communication service mapping (SCSM) – Mappings to MMS (ISO 9506-1 and 9506-2) and to ISO/IEC 8802-3, 2011.
- IEC 61850-9-2. Specific communication service mapping (SCSM) – Sampled values over ISO/IEC 8802-3, 2011.
- IEC 61850-9-3. Precision Time Protocol profile for power-utility automation, 2015.
- IEC 61850-10. Conformance testing, 2012.
- IEC 61850-80-1. Guidelines to exchanging information from CDC-based data models using IEC 60870-5-101 or IEC 60870-5-104. Technical specification, 2016.

### 14.2.11 Technologies

Control centers and substation automation systems are designed using specific application design methodologies and architecture. Furthermore, IT and telecom technologies are configured in a specific manner. This section is focused on the solutions commonly used by power utilities to implement their operational services. Both control center and SAS are built using distributed applications running in different devices that are connected in the same LAN or through a WAN with IP connectivity. For this reason, application architecture has to fulfil two key requirements: scalability and ubiquity. To achieve this, middleware and application architecture are very important. This section explains the working principles and properties of different middleware solutions, as well as the distributed application solution currently used for control center implementation.

#### Middleware

Middleware is a software layer that enables communications and management of data among distributed applications. It is typically a layer above the transport layer and below the application layer. Using a middleware layer, distributed applications interact as if they were running on the same computer. Middleware is used to provide other facilities such as object location and service description. CORBA and Web services are examples of middleware solutions.

#### CORBA

Many industries face the need to integrate distributed processes. Different technologies have been developed to respond to these requirements. The common object request broker architecture (CORBA) was the first to have a wide acceptance and is still used in many power utility distributed applications.

The deployment of TCP/IP networks simplifies data interchange between computers, paving the way to the implementation of distributed systems. Nevertheless, data communications are not enough to implement an open distributed system, the location to distributed processes and objects, as well as the access interface, must be standardized in order to achieve interoperability. Furthermore, in order to support mission-critical applications real-time constraints must be considered.

As we saw in the previous sections, power system operation has evolved from a centralized system to a distributed one able to integrate any kind of information. This evolution started when IP technology was adopted, since it provides open connectivity, the following step being the implementation of distributed systems using the concept of a middleware layer. A middleware layer provides services to the applications.

These services implement access to data, applications, and objects that are connected through a TCP/IP networks, thus hiding the fact that these objects are not located in the computer where the application is running. CORBA became the first standard middleware architecture. It simplifies information interchange and interaction between applications and processes developed by different manufacturers. CORBA was formerly used in network management systems and later adopted in other process applications, mainly at high-level applications. Nowadays, CORBA is being replaced by other technologies, as is explained in this section.

The CORBA environment opens the door to a distributed object environment able to host any kind of application. CORBA technology is being developed and standardized by the object management group (OMG). CORBA 2.0 was introduced in 1994 and is still evolving, since the latest technologies of objects are being incorporated to it. Despite this evolution, there is a stable nucleus based on an open and standard set of services that allows distributed application to be implemented in heterogeneous environments, with the advantage that the objects defined in this architecture can be reused. For these reasons, it has been adopted by the ITU-T (International Telecommunication Union – telecommunication standardization sector) as the basis of the management system of the telecommunications networks and by IEC as a middleware technology to implement operational applications based on CIM/CIS architecture.

The communications between the client application and the objects in a CORBA implementation is supported by the object request broker (ORB) bus. The main function of the ORB is to provide transparency over the infrastructure that provides communications between the clients or users and the objects. The functionality provided by ORB comprises:

- *Object location.* There is no need to know where an object is located to invoke it.
- *Object implementation.* There is no need to know how the object is implemented, nor the operating system or the hardware platform in which the object is executed.
- *Object execution state.* There is no need to know the actual object state before using it.
- *Object communication mechanisms.* There is no need to know how the communication with the object is implemented, shared memory, a LAN, an IP WAN, etc.

The connection between the client and the ORB and the object and the ORB is carried out by means of a standard interface implemented using the Interface Definition Language (IDL). Since the ORB manages

the location of objects and applications solving all the issues related to the network layer, it is possible to move an object or an application without introducing any modification of the elements that interact with it. Hence, CORBA is the first step to achieve mobility, ubiquity of a server, or an object collection, thereby simplifying the implementation of distributed processing and data gathering systems.

CORBA standards define how objects are invoked and how clients send requests to servers. Due to the use of the IDL, it is possible to modify the actual implementation of a server without notifying any of its users of this change. This is a great help in achieving modern architecture requirements, as was stated in previous sections.

The services provided by the ORB are directly available at the network domain, where the objects and clients are located by simply using the IDL interface. The integration of two ORB buses of two different domains requires the use of the Inter-ORB Protocol. For the specific case of IP networks, the Internet Inter-ORB Protocol (IIOP) is used.

The CORBA application programming interface (API) has been updated with a quality of service (QoS) parameters definition, so that it is possible to request a quality service level to the ORB in the interaction with any object. Since the specification is quite open, the key issue is to design an ORB able to process QoS requests and map them into the QoS architecture of the underlying IP network. The use of static priorities to map QoS requests and differentiate services with higher priority is the simplest approach to achieve a level of QoS bounded into the limits required by control systems. Nevertheless, to achieve a bounded delay, which fulfils the requirements of the protection systems, will require further research that follows out of the scope of the present project but that will have to be implemented in order to obtain a platform able to support both control and protection in the substation environment.

The details of how an IP network provides QoS are described in the telecommunications section (Sect. 14.3.6). The key issue in this case is how to assign the right QoS parameters to every user, since they are not hosts or IEDs but objects and clients using objects. In other words, when an application invokes a certain remote object, this invocation and all the related information must experience a determined QoS. The way to achieve this dynamic QoS assignation is by using the Lightweight Directory Access Protocol (LDAP). LDAP is an Internet standard originally developed to simplify the ITU-T X.500 directory service recommendation that allows a tree-like directory to be implemented in a distributed way amongst several servers located at different sites. By using LDAP, it is possible to define the user profile of every service and even define the QoS

required by a transaction like the use of certain object, application, or server. Hence, by defining the service directory, different QoS will be defined for every object invocation in such a way that it is possible to adapt the network performance to the requirements of a particular object, even in the case when several objects with different requirements have been installed in the same object repository. The use of a communications protocol based on TCP/IP extends the *ORB object bus* to remote platforms in such a way that they can be controlled and executed remotely without limitations.

The use of CORBA or any other middleware technology changes the concept of a control center as a system confined into a building, as by using a middleware the scope of the control center is only limited by IP connectivity. These technologies represent the first step towards virtualization.

### Web Services

One of the latest advances in Internet applications standardization is the Web services architecture. Web services are modular applications that can be described, located, and invoked using standard Internet protocols and XML messaging. The entire new architecture is a new industrial standard defined by the Web Consortium W3C.

The use of the Web services allows a standard and distributed application environment to be deployed using common Internet technologies. This is the component that was missing in a management system to be able to integrate new and existing devices under a common management environment.

A Web service application is self-contained, self-describing, modular, and can be published, located, or invoked across the IP network that connects clients and application repositories. This is achieved due to the standardization of objects and services using standard specification and description languages, UML and Web Services Description Language (WSDL), and the provision of an application discovery service, the Universal Description Discovery and Integration (UDDI) service to implement directory-like application discovery agencies and the use of the Simple Object Access Protocol (SOAP) to access distributed objects.

Web services provide an advanced Web middleware where services can be distributed, legacy data and database information can be accessed using standard interfaces, service provision is independent of network topology and architecture, and the user interface is unified for all the applications. When using the proper implementation architecture, scalability and fault tolerance can be obtained, thus configuring the right approach to support operational power system services.

The SOAP protocol specifies how two processes running on different devices or containers interchange

structured information through an IP network. SOAP is a message-oriented protocol; information is interchange using messages coded in XML.

SOAP consists of three parts:

- The SOAP envelope construct is the root of the message. It describes *what* is in a message, *who* should process it, and *whether* it is optional or mandatory. It contains the *header* and the *body*. The header is optional, it can contain ancillary or complementary information, as well as advanced control directives. The body is mandatory and contains the XML message.
- The SOAP encoding rule defines a *serialization mechanism* that should be used to exchange instances of objects.
- The SOAP RPC defines *procedures* to use remote procedure calls (RPC) and their responses.

These parts are fully decoupled, which provides the following advantages:

- Extensibility
- Protocol independence
- Programming language independence.

### Service-Oriented Architecture (SOA)

SOA is way of implementing distributed applications based on distributed components that provide capabilities and functionalities to others that use them. The SOA principle is independent of the technology or the product implementing it. SOA is not a programming technology or a middleware, it is a paradigm or a guideline to design a system from a set of distributed applications able to provide services and collaborate with each other to perform their task. SOA is based on a central concept – the service. The service concept can be defined as *the performance of a function or work by one entity for another*. The service concept embraces the following ideas:

- The capability to carry out work for another entity.
- The specification of the work offered to another entity.
- The need for work to be carried out by another entity.

SOA is a powerful framework that matches needs and capabilities, including the combination of capabilities to fulfil a complex need. It facilitates scalability and interoperability.

A service is used or accessed by means of its service interface. It defines how to access the functionalities provided by the service. Invoking a service may pro-

vide information as a response to a request or change the internal status of the entity providing the service or both things at the same time.

Visibility, interaction and effect or outcome are key concepts describing SOA framework.

*Visibility* refers to the capacity for those that need a service and those with capabilities to provide it to see each other. *Visibility* requires *awareness*, *willingness*, and *reachability*. In other words, the service requester must be aware of service availability, the provider must be willing to provide the service, and parties must have connectivity to interchange messages.

To implement the visibility description of service functionality, technical requirements, constraints, use policies, and access and response mechanisms must be provided. The service description must be implemented with a self-description syntax and semantics language such as XML, for instance.

*Awareness* of service offerings requires discovery mechanisms. The service provider must be able to describe its service and its policies. Service awareness requires that service description and policy be available to potential consumers.

*Willingness* is the act of initiating and participating in a service interaction.

*Interaction* is the actual use of a service. This is implemented by exchanging messages. A prerequisite for interaction is reachability.

*Outcome* is the result of using a service. The result may imply a state change that may produce a returned information to be sent to the service requester.

The information model is an important characteristic of a service. It determines which information can be exchanged when using the service. The information model has a structure that defines data coding, format, and structure data included in the model. Another important property of the information is the semantics. A critical issue is the interpretation of data, as it must be consistent between the participants in a service interaction. A formal description terms and their relationships provides the basis for the definition of semantics and ontology that in turn facilitates the correct interpretation of information exchanged.

The behavioral model is the other aspect that has to be known to successfully use a service. It defines the sequence of actions and temporal aspects of interacting with a service.

Nowadays SOA is implemented using Web services, but in fact it is independent of technology and implementation, so any other solution can be used in the future. SOA can be seen as the evolution of object-oriented technology. The trend is to evolve SOA to a virtualization of services, as is explained in Sect. 14.6.

## 14.2.12 Design Principles

The way applications and their functions are distributed will determine their performance and telecom requirements. Therefore, it is important to define design principles that may optimize cost and performance of the overall system. This section will focus on application and control-center architecture, telecom network design issues will be covered in the subsequent section.

### Control-Center Architectural Objectives

The main architectural requirements are the following:

- *Lower total cost of ownership (TCO)*. The deployment of a new control center is a big investment, where the cost of the product is not the only aspect to be considered. TCO includes the following concepts:
  - Project implementation costs
  - Multivendor integration costs
  - Model development and maintenance costs
  - Graphical interface development and maintenance costs
  - Migration costs
  - Training and skill requirements.
- *Improved business continuity*. This includes minimizing the impact of outages for any reason, including cyber-attacks.
- *Improved user interface*. This establishes a common, role-based, and customizable task-oriented interface independent of underlying applications, thus eliminating multiple application-specific user interfaces.
- *Improved standardization*. Absolute compliance with IEC standard series.
- *Interoperability*. This includes the straightforward integration of multivendor solutions.
- *Reuse of software components*. This implies the ability to share components in multivendor solutions.

The control-center architecture can be evaluated according to its architectural qualities, which describe the degree of achievements of the above-mentioned architectural objectives. Although these qualities are difficult to evaluate, it is important to consider them during specification and design phases. The most relevant qualities are:

- *Scalability*. This is the ability of a system to grow several orders of magnitude in response to increased work load or expansion of its functionality. Scalability is a very important quality, since it will extend the lifespan of the system as long as it can keep being upgraded. Scalability may involve adding more servers, increasing bandwidth, etc. It is, therefore, important to check the scalability of all technology, as well as of the system architecture.

- *Flexibility*. This is determined by the capacity of a solution to adapt to business requirement changes. Flexibility may impact the system performance.
- *Platform independence*. This includes the following aspects:
  - Operating system independence
  - Middleware independence
  - Management system independence.
- *Maintainability*. This determines the effort required to identify and isolate problems, replace components, and implement system modifications. It has a direct influence on TCO.
- *Security*. Protection against cyber-attacks is a capital quality of a system. The system architecture must be designed to minimize vulnerabilities. Security design principle should be aligned with the IEC 62351 series of standards, as is explained in Sect. 14.4.
- *Availability*. This is the percentage of the total up-time during which the system is available to the users performing according to its operational requirements. Availability is related to the service not only to hardware; consequently, software quality has a relevant impact on system availability.
- *Business continuity*. This is the ability to recover from a system failure. It is closely related to availability. Business availability requirements together with components' failure rate determine the degree of redundancy of the system and the algorithms that should be implemented to use them efficiently.
- *Usability*. This measures how well the human-machine interface responds to business functions and activities that should be carried out by the system operators. A user-friendly interface and consistent look and feel are common usability requirements.

## 14.3 Telecommunications Services

We have seen in previous paragraphs that different operational applications require sharing information to perform their tasks. Communications between distributed applications is supported by communications services. A service represents a set of functions offered to a user by a provider. The service is made available through service access points (SAP). In fact, the qualities and capabilities of a service are completely defined by the interface of the SAP. Consequently, the provider becomes an abstract entity, whose implementation is hired from service users. For this reason, a service provider may be composed of smaller entities that may be using underlying services providers. This implementation concept is known as *layering*. A service can be upgraded by using underlying services that are more powerful. This process can be nested until the desired service functionality is achieved. Services provided by a SAP are invoked using service primitives. These primitives, which are similar to programming sentences, are issued by the user to ask the service to perform some action. The result of the action is reported to the user.

Three different types of interactions can be distinguished:

1. **CONFIRMED SERVICES**. These involve a handshake between the user requesting the service and the remote user accepting the interaction. This type of service provides sequence control, and it is normally used for connection-oriented communications; it involves four primitives:
  - **Service.REQUEST**, invoked by the requesting user

- **Service.INDICATION**, delivered to the remote accepting user
  - **Service.RESPONSE**, an answer sent by the remote accepting user
  - **Service.CONFIRMATION**, delivered to requesting user.
2. **UNCONFIRMED SERVICES**. This type of service does not require a handshake. It does not provide sequence control or information synchronization; it is normally used for connectionless services. They involve two primitives:
    - **Service.REQUEST**, invoked by the requesting user
    - **Service.INDICATION**, delivered to the remote accepting user.
  3. **PROVIDER-INITIATED SERVICE**. This service is generated by the service provider due to an internal condition. It is used by the service provider to inform its users about changes in service conditions; it involves a single primitive:
    - **Service.INDICATION**, sent to both users upon an internal condition of the service.

From the above list we can identify two types of services, connection-oriented services and connectionless services. Connection-oriented services are implemented through three phases:

- **Connection establishment**. During this phase, user and service provider negotiate the service working mode and requirements. If successful, a connection is established.

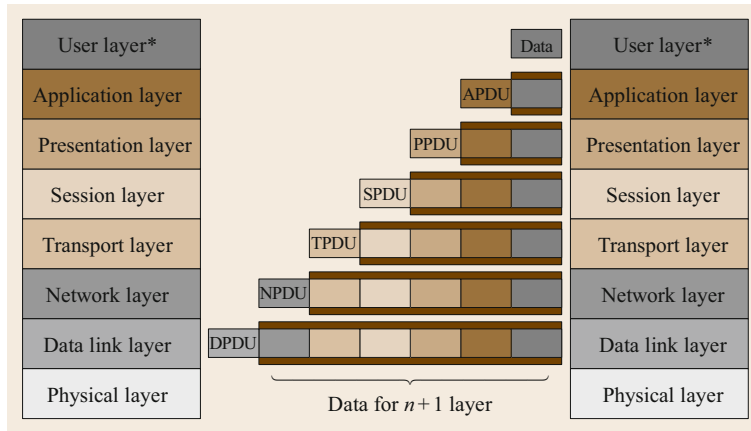

Fig. 14.13 Seven-layer model

- Data transfer. During this phase, data is transferred, since the service is operative as agreed in previous phase.
- Connection release. The service is terminated and users binding is released.

A connectionless service has one phase, data transfer. Each time data is transferred, different options may be requested to the service provider. There is no explicit relationship between service users.

Service information interchange is implemented using protocols. A protocol defines a sequence of messages called protocol data units (PDU) and a finite state machine that implement the way a service is used. When an application wants to transfer some data to a remote user, the service interface must be used. Data to be transferred is called *service data unit* (SDU). The service provider attaches protocol control information (PCI) to form the PDU. PCI identifies the data and their nature. When the service is implemented using the layering concept, that is to say, using an underlying service, the original PDU becomes the SDU of the underlying service interface.

In order to clarify these abstract concepts, we can establish the following association to clarify the above-mentioned terms:

- SDU can be understood as user data.
- The PCI concept can be associated with the protocol header.
- The PDU concept can be associated with a packet.

The open system interconnection (OSI) reference model defines communications tasks in terms of seven functional layers. Altogether, they implement the communications service offered at the application SAP.

The seven functional layers perform the following functions:

- *Application layer*. This provides the SAP to applications and implements information transfer using the underlying services provided by the rest of the functional layers.
- *Presentation layer*. This adds structure to SDUs in order to assure a common understanding of the information exchanged.
- *Session layer*. This adds control mechanisms to information exchange.
- *Transport layer*. This is responsible for the reliable end-to-end data transfer across the network.
- *Network layer*. This is responsible for the delivery of data to the remote user regardless of the network topology.
- *Data link layer*. This is responsible for the transmission, framing, and error control over a single link.
- *Physical layer*. This implements the physical interface to the communications media.

As shown in Fig. 14.13, every functional layer implements its service using its own protocol. The transmission of every functional layer PDU is implemented using the services provided by the underlying layer. For this reason, every layer establishes communications with its peer to implement its service. This process is repeated until the physical layer generates a physical signal suitable for transmission through a communications medium.

It is important to note that each layer introduces its own protocol header, which means a considerable overhead. This effect must be considered when a critical realtime service must be implemented. For this reason, some realtime operational services use a simplified protocol stack to optimize response time and overhead. The functional layers are divided into two blocks. The upper three layers provide the information transfer service to applications. The four lower layers provide end-to-end data transfer service.

Services provided by the application layer are structured into application service elements (ASE) that are specialized in specific service formats like remote connection, file transfer, etc. Every ASE has an association control service element (ACSE) that implements the task related to the relation establishment and releases with the peer application layer. An association is a binding between two entities, the initiator and the responder. The primary task of the ACSE is to bind to application processes.

Every ASE uses the service provided by the presentation layer to implement its service. ASE PDUs are abstract in nature, which means that every implementation is free to code them in their preferred format, depending on the programming language and the operation system. The presentation layer unifies these formats, defining a concrete representation that results in an unambiguous format that can be understood by any receiver. The presentation layer uses the abstract syntax notation one (ASN.1) (ISO/IEC 8825-1). ASN.1 uses the basic encoding rules (BER) to define how information has to be coded.

BER is based on the *tag-length-value* paradigm. That is to say, every object is coded using this principle, so that three fields are generated for every object, the tag that defines the type of data, the length of the data, and the value. The tag is a code that identifies data types such as boolean, integer, real, string, etc. ASN.1 is the common encoding method or presentation layer used in operational applications, including control centers and IEC 61850.

The session layer controls and synchronizes data transfer during the binding of the processes. Unlike the transport layer that provides a reliable communications circuit, the session layer supervises data stream transmission and establishes and maintains the connection with the peer session entity.

The application profile is usually embedded into the application, whereas the transport profile can be included in the operating system or become a specialized library. Telecommunications network design is focused on the transport profile or T-profile. The application profile must match application service requirements. These requirements are mainly focused on functionality but may also include quality of service and performance issues. In fact, performance requirements are transferred to lower layers that are control the working modes that can fulfil those requirements. Telecom service provision is based on the T-profile. From the point of view of telecommunications implementation, the SAP is provided by the transport layer. The transport layer provides end-to-end transport services. The most important task of the transport service is to provide transparency over network topology and

the changing reliability conditions of the underlying infrastructure.

Two types of transport services can be distinguished, connection-oriented and connectionless. The connection-oriented transport service provides a reliable end-to-end data transport. The service is implemented in three phases: connection, data transfer, and release. This service is normally implemented using the TCP protocol. TCP provides data segments' fragmentation and reassembly, end-to-end flow control, and errored or lost-frame retransmission.

The connectionless service provides unreliable transport. It only comprises the data transfer phase. The connectionless service is normally implemented using the UDP Protocol.

The network layer service is responsible for data transfer regardless of the network topology and transmission media. Consequently, it provides transparency over the topology of the network and transparency over the transmission media of every traversed link. To achieve this, the network layer must include the following functions:

- *Addressing*. This is a uniform mechanism to identify nodes, and users must be provided. Addressing should be independent of network topology and from any media-specific addressing scheme.
- *Routing*. The process of finding the shortest route between origin and destination is the key routing functionality. To achieve this, connectivity and topology discovery are required.
- *Quality of service*. Different applications may have different performance requirements. This information must be considered when applications' binding is established. The network layer should provide the functionality to guarantee performance requirements.

The link layer service is responsible for the reliable transmission of data over point-to-point links. To achieve this, error detection or correction codes may be added, and frame retransmission may be used, depending on the technology of the link. For multicast links, a specific link layer address may be required, as in the case of Ethernet. In those cases, a mapping between network layer and link layer addresses must be provided. The physical layer service adapts the bits of the messages to the physical interface generating the signal required by the telecommunications media.

Due to the diversity of telecommunications media and the different performance requirements of operational applications, it is important to define a detailed profile. The profile defines the specific configuration of every layer required to fulfil specific service require-

ments and considers the capabilities of the underlying layers. Further details on the working principles of the T-profile layer are given in the following sections. Section 14.3.5 is focused on depicting operational telecom requirements and suitable technologies supporting operational services, including how networks should be designed to achieve those requirements.

### 14.3.1 Basic Concepts

As presented in the previous sections, power-system operation requires the interaction of multiple applications distributed through the system. The implementation of a telecommunications network to support operational services must consider quite a large number of aspects, both internal to the network such as size and architecture and others external due to the requirements and specific working modes of the applications using its services.

The internal network factors to be considered are geographical scope, infrastructure availability, site locations, etc. External requirements that impose design constraints are normally associated with the criticality of operational applications and the volume, type, and scope of information exchange across the power system.

Figure 14.14 shows the interaction model between application and telecommunications infrastructure. Applications have telecommunications service requirements that are expected to be offered at the service access point (SAP). The telecom infrastructure has a set of service capabilities that are a function of the technology and implementation of the telecom infrastructure. A match must be achieved between requirements and capabilities. This agreement is expressed by means of a so-called service-level agreement (SLA), as is explained later in this section.

When a match between requirements and capabilities cannot be found, a redesign of the telecom

infrastructure is the only solution due to the criticality of operational applications. Telecommunications service can be implemented using a dedicated telecom infrastructure or using a service provided by an external telecom operator. The former provides an easier match between requirements and capabilities, whereas the latter does not allow specific service matching, as it is normally based on services implemented using a limited number of standard levels of quality and performance. Communications service requirements are related to the applications they serve (e.g., SCADA or protection communications services). We will focus on operational application telecom requirements that are defined considering application-specific working modes and the degree of criticality.

There are other applications related to maintenance and support of the power system, such as voice and data communications for field maintenance staff, which have an indirect impact on the operation, so they should be also treated as *operational*, even if their service performance requirements are not so demanding.

The criticality of communications services in the power-utility environment can be assessed through the consequences of service loss and degradation. The operation-support services are the most critical ones, and so financial consequences of a loss of communications in utility business and market activities can be much higher. *Nonoperational* communications are, however, more tolerant of transient or programmed service unavailability, allowing IT-type procedures for service restoration and maintenance to be used.

Power-utility operational applications can be grouped into different categories according to their information exchange scope:

- *Substation-to-substation applications.* These applications comprise fast automation systems providing

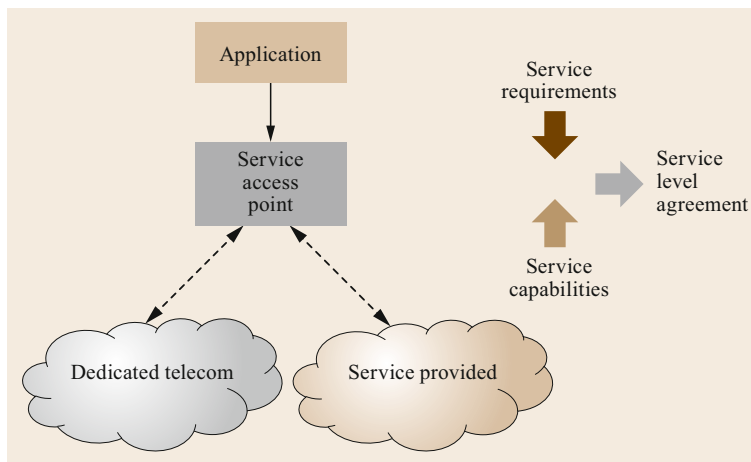

Fig. 14.14 Application and telecom interface

protection and control of power-system primary assets and prompt detection and isolation of electrical faults. The most critical requirement is latency, the limits of which may range from 200 to 10 ms. These applications are also used in bulk generation plants, energy farms, and energy-related process sites. These applications have critical requirements that constitute one of the main drivers for implementing dedicated telecommunications infrastructures in electrical power utilities.

- *Field device-to-control center applications.* These applications present status and measurement data from the grid or bulk generators to control center applications. SCADA and wide area monitoring systems are realtime mission-critical applications, but their latency requirements are not as high as those of protection applications, since their latency requirements are in the range of 1–5 s.
- *Interplatform applications.* These applications comprise the synchronization or coordination of databases in geographically remote platforms, whether for redundant processing or to gather information in a hierarchical architecture, such as between regional and national levels, or in a functionally distributed system implementing monitoring and control platforms. They generally require a sporadic transfer of much larger volumes of data. The time constraints here are around a few seconds. It should, however, be noted that cybersecurity constraints in this case become more severe, in particular when more than one company and one dedicated network are concerned.
- *Office-to-field applications.* These can be considered as *IT-to-OT* applications. They cover the access requirements from an engineering office located in the corporate enterprise environment of the power utility to devices, data, or staff located on field sites. Remote configuration, maintenance, and parameter settings of intelligent devices in the substation, as well as field worker mobile data access to support platforms are among these types of applications. Cybersecurity of remote access is of major concern here.

One of the most relevant characteristics of operational applications are their sensitivity to time delays. Deterministic and controlled time behavior is one of the major requirements that drives utilities to deploy and maintain dedicated telecommunications networks. In these networks, the time performance, as well as availability and fault tolerance, can be adapted to the requirements of each application through the appropriate choice of technologies and proper topological structuring. On the other hand, when public telecom services are used, bounded latency is rarely part of the service-level agree-

ment (SLA) of the service provider. Generally, the service provider cannot commit contractually to anything better than an *average communications delay* and is, therefore, to be excluded when time-sensitive applications are to be carried, as this kind of service performance cannot guarantee a bounded delay.

### 14.3.2 Service Classes and Applications

The concept of service classes was introduced to allow quality of service (QoS) requirements to be broadly determined for each application type. This reduces the number of different service types as one class can be used by several applications. From the generic point of view, service classes can be associated with two generic groups: nonelastic and elastic. The nonelastic service class is used to support those applications that are not tolerant to uncontrolled delays and/or losses. Elastic applications are those that can control the traffic flow that they are offering to the network and can, therefore, tolerate some changes in delay and throughput.

In order to better understand application requirements, they can be classified as elastic and nonelastic according to their tolerance to delay variation and packet losses. This classification is rather generic, as several different subcategories can also be identified. However, it is very important to understand application behavior and requirements in order to identify the proper service model, as this will determine the protocol stack to be used and will also influence the choice of technology.

#### Nonelastic Applications

Nonelastic applications are an important class of realtime applications they are also called *playback* applications, such as voice, video, or circuit emulation services over packet networks, as well as the delivery of IEC 61850 sample value messages. These applications must deliver information at a constant rate, so they should be able to cope with delay variations introduced by packet networks and reduce or compensate them.

These kind of applications handle information that is changing continuously. The source processes and packetizes the information and sends the packets to the network, normally at a constant rate, generating a continuous flow of packets. Packet networks, whether Ethernet or IP, introduce a variable delay, so packets are delivered to the destination with a continuously changing latency. The receiver must deliver the information at the same bit rate as it was generated, so it must include some mechanism to compensate the delay variation introduced by the network. This is implemented by buffering the incoming packets and delivering the packets with a fixed offset delay, which corresponds to

the average delay, whereas the size of the buffer is related to the maximum delay variation introduced by the network. The total offset delay of the service is related to the buffer size and, therefore, this is a key requirement to be considered when designing a network, as this kind of application requires a service with reduced delay variation.

Some applications like video playback are not affected by offset delay, others like video or voice conferencing can accept some average delay variation due to network overload, as they can measure the actual delay and dynamically modify their behavior. Nevertheless, other applications like sample value messages offset delay directly, which affects their functionality, as some protection application are not able to measure delay and, in any case, this delay will be added to the tripping time. Network design must consider performance requirements and delay variation tolerance of the application using telecom services. This is a very limiting requirement that may affect the choice of network architecture and the technologies used to implement it. The implementation of a service providing guaranteed upper bound delay implies having a quite deterministic one that requires the use of network technologies able to reserve bandwidth and with the proper queue scheduling procedures.

### Elastic Applications

While nonelastic realtime applications do not wait for late packets to arrive, elastic applications have a greater tolerance, which is a function of the transport protocol and the application itself. The fact that elastic applications can wait for a packet to arrive does not mean that the application's performance will not be affected. There is a direct relation between service latency and application performance but unlike nonelastic applications, a packet arriving too late is not a lost packet.

Elastic applications process packets as they arrive. The application will wait for received packets rather than continue execution without the information. IT applications such as Web browsing, file transfer, etc., do not require service characterization but protection-related application, i.e., different types of teleprotection schemes require a guaranteed bounded delay. Packets arriving later than this bound will be considered lost and thus also the associated command. The teleprotection service is an example of an elastic service with some constraints similar to nonelastic applications. That is to say, delay variation does not affect application performance if it is lower than the upper bound. A delay higher than the bound implies a loss of information. Other elastic applications does not have this constraint but, in fact, there is always a limit on the accepted packet delay. For IT applications, if the delay

is higher than session or application timeout, the application will consider that communication to have been lost. Upper bound delay requirements vary from very demanding ones, such as teleprotection that requires a few ms, or SCADA applications that require a few seconds to the less demanding requirements of IT applications. An appropriate service model for interactive burst elastic applications requires throughput commitment provision, whereas other service, like file transfer, can be supported by a best-effort service.

Now that we have discussed the generic application requirement types, we will analyze specific communications service requirements for every operational application.

### IEC 61850 Service Classes

As we saw in the previous section, IEC 61850 functionality is implemented using different services with different performance requirements, the most critical being time transfer or latency and availability. The standard distinguishes three types of performance classes that apply to sample values, control and protection signals, and time synchronization. The service used by sampled values should introduce a delay so small that it does not influence the operation time.

Table 14.1 shows IEC 61850 transfer-time classes. A communications network must be designed to guarantee the required performance for every application type.

Time synchronization is an important service to obtain a correct sequence of events and be able to process sample values of different sources in a coherent way. Table 14.2 shows IEC 61850 time-synchronization service classes.

The time class determines the synchronization protocol to be used. For instance, to achieve T1 requirements, SNTP can be used, whereas for T4, the Precision Time Protocol IEEE 1588V2 must be used.

### Teleprotection Signaling

Protection application services require the most demanding performance of telecom services. Their key function is to improve the performance of protection

**Table 14.1** Transfer-time requirements

Transfer-time class	Transfer time (ms)	Application examples: Transfer of
TTO	> 1000	Files, events, log contents
TT1	1000	Events, alarms
TT2	500	Operator commands
TT3	100	Slow automatic interactions
TT4	20	Fast automatic interactions
TT5	10	Releases, status changes
TT6	3	Trips, blockings

**Table 14.2** Time synchronization classes

Time-synchronization class	Accuracy ( $\mu$ s) synchronization error	Application
TL	> 10 000	Low time synchronization accuracy – miscellaneous
TO	10 000	Time tagging of events with an accuracy of 10 ms
T1	1000	Time tagging of events with an accuracy of 1 ms
T2	100	Time tagging of zero crossings and of data for the distributed synchrocheck. Time tags to support point on wave switching
T3	25	Miscellaneous
T4	4	Time tagging of samples and synchronized sampling
T5	1	High-precision time tagging of samples and highly synchronized sampling

devices by sending information of the remote end of the power line. The term *teleprotection* refers to the communications interface of the protection system. Teleprotection signaling transforms the state information transmitted by the protection relay into a signal suitable for transmission over a telecommunications channel and restitution to the remote protection relay or remote circuit breaker in a secure and prompt manner. It may be integrated into the protective device, into the telecommunications access equipment, or more generally, it may constitute a stand-alone device. This often supplements locally available data, confirming that a fault detected by at least one end, is, in fact, internal to the line, such that otherwise time-delayed operations may be accelerated.

In accordance with previously defined protection performance parameters, the operational performance of a teleprotection signaling system can be defined through the following parameters:

- *Security* is the ability to prevent communications service anomalies from issuing a command at the remote end when no command has been sent. Security is expressed as the probability  $P_{uc}$  of *unwanted commands*. Security is related to the communications service integrity (error performance) and the teleprotection signaling system's error detection capability.
- *Transmission time* is the maximum time ( $T_{ac}$ ) for the delivery of the command at the remote end, after which it is considered as having failed to be delivered. This is a constraint to the time performance of the communications service, not only in terms of nominal value but also as a guaranteed limit.
- *Dependability* is the ability to deliver all issued commands at all times. It is expressed as the probability  $P_{mc}$  of *missing commands*. This sets a very severe constraint on the availability and error performance of the communications service, challenging such telecom service concepts as *errored seconds* and *degraded minutes* being counted in the available time of a communications service.

In this context, *security* is not related to cybersecurity, as is explained by its definition. Cybersecurity attacks may impair any of the three parameters that determine teleprotection performance. The term *command* refers to a tripping or blocking order that is a binary signal. Teleprotection services can be used to transmit *state* information or analogue information. Teleprotection services can be understood as specialized telecommunications services used by some protection schemes, as is described in the following paragraphs.

#### State Comparison Protection Schemes

State comparison protection schemes use communication channels to share logical status information between protective relay schemes located at each end of a transmission line. This shared information permits high-speed tripping for faults occurring on 100% of the protected line. The logical status information shared between the relay terminals typically relates to the direction of the fault, so the information content is very basic and, generally, translates into a *command* requiring very little communication bandwidth. Additional information such as *transfer tripping* of a remote breaker to isolate a failed breaker and block recloser function may also be sent to provide additional control. The *command transmission time* is of great importance because the purpose of using communications is to improve the tripping speed of the scheme. Transmission-time variation is tolerated when it is below the maximum transmission time. Commands received later than the maximum transmission time are considered lost.

Communication-channel security is essential to avoid false signals that could cause incorrect tripping, and communication-channel dependability is important to ensure that the proper signals are communicated during power system faults, the most critical time during which the protection schemes must perform their tasks flawlessly.

Communications for state-comparison protection schemes must, therefore, be designed to provide safe, reliable, secure, and fast information transfer from one relay scheme to another. The communications scheme

must – for the vast majority of protection schemes – also be able to transmit information in both directions at the same time. The amount of information required to transfer between relay schemes depends on the relay scheme logic.

The terminology used to describe these state comparison protection schemes is presented below:

- Directional comparison blocking schemes (also called blocking overreach, BO)
- Directional comparison unblocking schemes (DCUB)
- Permissive overreaching transfer trip schemes (POTT)
- Permissive under-reaching transfer trip schemes (PUTT)
- Direct transfer tripping (DTT).

#### Current Differential Protection Schemes

Current differential protection, extensively used on high-voltage transmission lines, compares the amplitude and phase of the local terminal currents with the amplitude and phase of the currents received from the remote terminal through a communications channel. The currents at each line terminal are sampled, quantified, and transmitted to the remote end of the protected line for comparison. Current samples collected from a remote point must be compared with those measured locally at the same instant of time. An error in the delay compensation mechanism results in a differential current measurement error that increases the risk of unwanted tripping.

Delay compensation in differential protection relies on the existence of a common time reference. Originally, and still in the great majority of installed and operational devices, this is achieved using a *ping-pong* technique to evaluate the *round-trip* transfer time and performance delay compensation assuming equal send and receive path delays. This creates a great sensitivity of the system to latency asymmetry and variability and, therefore, and has become a very important communications requirement.

Modern protection systems can receive an external time reference such as a GPS clock to provide global time-stamping of samples, enabling them to tolerate

switched networks. Once the system is synchronized, a loss of GPS signal can be tolerated on a switched communications network using various techniques provided that the communications path does not change too often. There is, however, some reticence to render the protection system dependent upon an *externally provided* synchronization service such as a GPS satellite.

New-generation current differential relays using the IEC 61850 network interface and Precision Time Protocol (IEEE 1588v2) are expected to receive self-provisioned time coherence through the network, which will perform the necessary ping-pong action from switch to switch to determine the travel time from relay to relay. It is expected that precision time distribution will itself become a critical *substation-to-substation* service in future utility telecommunications networks.

Due to latency variation and symmetry requirements of existing relays, fixed path and nonqueued communications are used. Direct fiber and multiplexed communications are frequently employed. Packet-switched Ethernet communications with deterministic routing and time delay are presently being tested. It must be emphasized that the availability of current differential relays depends upon the availability of the communications channel. Consequently, it is required to have the capability of quickly detecting any loss of communications or inadequate quality of a channel in order to disable the differential scheme and employ another means of protection, such as distance and over-current backup. Path delay increases tripping time. For very high voltage levels, the overall communication-path delay should be lower than 6 ms. Table 14.3 summarizes the teleprotections service requirements.

#### System Protection Schemes

As described in the previous section, system protection schemes (SPS) involve a number of wide area protection schemes, the function of which is to maintain power-system stability. SPS requires telecommunications services to carry out their tasks. SPS perform its functions by comparing data acquired across the controlled system. Telecom service requirements involves a high-resolution capture and tight time imperatives which imply high bandwidth and low latency deterministic communications requirements. The completeness

**Table 14.3** Summary of line protection schemes and their communications requirements

Protection scheme		Main communications attributes
Directional comparison blocking (blocking overreach)	BO	High dependability (on healthy lines), very low transfer time
Permissive overreaching transfer trip	POTT	High dependability, controlled time
Directional comparison unblocking	DCUB	(Special case of POTT)
Permissive underreaching transfer trip	PUTT	High dependability, controlled time
Direct transfer tripping	DTT	Very high security, high dependability, controlled time
Current differential protection	CDP	Time synchronization of samples, bandwidth for transport of samples

**Table 14.4** Telecom requirements of system protection schemes

Factor	Reporting rate range	End-to-end latency	Measurement timing error ( $\mu$ s)	Sensitivity to message transfer delay variations	Sensitivity to lost packets	Currently covered in 61850
Sync-check	$\geq 4$ 1/s	100 ms	50	Medium	High	SV service
Adaptive relaying	$\geq 10$ 1/s	50 ms	50	Low	Medium	SV service
Out-of-step protection	$\geq 10$ 1/s	50–500 ms	50	Medium	Medium	SV service
Situational awareness	1–50 1/s	5 s	50	Low to medium	Low to medium	Periodic reporting, SV service
State-estimation and security assessment	1/300–10 1/s	5 s	50	Low	Medium	Periodic reporting, SV service
Data archiving	Any	N/A	50	Low	Medium	All as needed
Wide area control	$\geq 10$ 1/s	50–500 ms	50	Medium	High	SV service

of data sets is to be assured through the reliability and integrity of the communications system. This cannot be fulfilled by an acknowledged exchange and retransmission upon error detection due to time imperatives of the closed-loop system. IEC 61850-90-5 describes the communications requirements for many protection schemes based on synchrophasors. Table 14.4 summarizes these requirements.

### 14.3.3 Service Attributes

The performance of a telecommunication depends on a set of attributes that have a direct impact on its capability to fulfil operational services performance requirements. These attributes cover three main aspects: connectivity, capacity, and timing.

#### Connectivity

Every operational site needs to have access to telecom services. Substation and power plants can be connected to telecom facilities using optical fibers over power lines or power line carriers for some applications that can work over narrow band channels. Utility offices that are located in urban sites cannot be accessed using the dedicated telecom network. Connection to a utility site can be achieved using microwave links, which is not always feasible. The most common solution is to use telecom services offered by a public telecom operator.

The topology of the network infrastructure also has direct influence on the performance and fault tolerance that can be expected from the communications service. The number of switching nodes to be crossed determines the dependability of the connection; consequently, direct links based on dedicated fibers are preferred for critical applications such as teleprotection or other protection applications. Mission-critical applications require fault-tolerant telecommunications infrastructure. To achieve this, two physically independent routes between ingress and egress points are required. This imposes some constraints on the network

topology design, as will be explained later in this section.

#### Throughput (Capacity)

The term *throughput* refers to the service or channel capacity, that is to say, the amount of information, bits, or packets per second that can be transferred using this channel or service. This is a major criterion for selecting a telecom solution. Throughput is, indeed, related to an overall communications system capacity, which itself is related to the allocated bandwidth across the telecom media. However, throughput is not directly related to the channel bit rate, since there are other factors, such as protocol overhead, information coding, among others, that may reduce the effective transfer capacity of a communications interface. Service throughput is also related to other factors, such as application traffic profiles, transport protocols, and network dynamics, as will be explained in subsequent sections.

#### Latency (Delay)

Latency is the absolute delay introduced by the communications network into an application. Time latency is an important constraint for applications requiring a bounded delay. Time latency also matters where a bidirectional exchange is to be established with limited response waiting time. Service latency is a critical requirement of protection applications. Transfer time across the communications infrastructure or latency is added to the fault clearing time, so it is important that latency be bounded to a quite low limit. From 8 to 10 ms is the maximum allowed latency for protection applications, be they analogue or state comparison schemes. Although SCADA is a realtime application, its latency requirements are less strict, as delay in the range of seconds can be tolerated. On the other hand, voice communications can be seriously degraded by latency higher than 150 ms. Absolute time-latency problems may be avoided through appropriate topology design and proper selection of technologies, minimizing the number of nodes

crossed to reduce the delay introduced by store-and-forward and traffic queues. It is important to consider that bounded delay is not an average value but a maximum absolute one that has to be guaranteed in all cases.

### Delay Variation

Delay variation is produced by a lack of determinism in the telecommunications service. That is to say, the information is delivered to the remote end with a latency that changes continuously. This effect can be produced by the queues of a packet network and by a change of propagation delay. The amount of variation depends on the number of nodes crossed and the presence of interfering traffic that shares some communications links, thus increasing the traffic load in some parts of the path. Time predictability is achieved by imposing constrained routing (e.g., maximum number of hops, predetermined backup route, etc.) and adding a jitter buffer to absorb delay variation at the expense of adding an extra absolute delay. This mechanism is normally used to emulate a constant bit-rate connection over a packet network.

Time-division multiplexing (TDM) networks are deterministic. Delays tend to be constant and depend on the propagation delay of the signal and the number of hops. Delay variation in TDM systems can only occur after a route change following an automatic restoration. Transmission-delay variation can affect the performance of current differential relays. An excess of variation may block or even produce a false trip. Teleprotection services can accept delay variation if the total delay does not exceed the maximum transmission time.

### Delay Asymmetry (Path Asymmetry)

Delay asymmetry may be caused by two factors, path symmetry and different traffic load in the go-and-return path. The former is the most relevant factor, which may appear both in TDM and packet networks. Services supporting applications sensitive to delay asymmetry need to be configured with routing or connection establishment algorithms that guarantee path symmetry.

### Service Recovery Time

Mission-critical operational applications require a fault-tolerant service provision, which implies that in the event of a service outage, it can be restored in a very short time. In fact, most operational applications require a bounded restoration time, and for some critical services hitless, even switching is required, which implies no loss of service during the switchover from the faulty channel to the backup one.

Restoration time depends upon the communications technologies and network topology employed. Different methods can be used to implement service

restoration. The selection of any of the above methods depends on the criticality of the service:

- End-to-end alternate route switch-over for each critical service is very fast but not scalable.
- Ring protection across an SDH network can restore a connection in less than 50 ms.
- Ethernet Rapid Spanning Tree Protocol (RSTP) has a convergence time that depends upon the complexity of the network and can range from few to some hundred ms.
- Routing in an IP network is based on different algorithms that re-establish the routing table in each node after any network configuration or status change. Typically, RIP-based routing requires less than 1 min to restore communications, while an OSPF-based system can restore communications in 5–10 s.
- Transport profile multiprotocol label switching (MPLS-TP) enables the network to restore services using pre-established alternate paths for each data tunnel and can, in this way, provide restoration times similar to SDH.

### Service Integrity and Data Loss

Service integrity is the aptitude of the communications network to deliver the transmitted information without degradation, without loss, and without on-purpose alteration. The present section deals with degradation and loss of information due to channel impairments, on-purpose alteration being covered in the cybersecurity section (Sect. 14.4).

Service integrity depends on the performance of every one of the lower layers. Consequently, it depends on the channel integrity as well as the network and transport layers, which may produce loss of packets. We will focus our analysis on aspects that may impair operational service performance.

Focusing in the transmission aspects, data-channel integrity is characterized by its error performance. This is the capability of the network to deliver error-free data between network user interfaces. Error performance depends upon the error-generating behavior of the network, generally characterized by an average bit error rate (BER) measured over a 24 h time period, excluding 1 s intervals where the BER is worse than  $10^{-3}$ .

Long-term average BER, however, does not contain any information regarding the distribution of errors in time and is, hence, meaningful only if we assume a fully random distribution of errors, which is normally far from being the case. It is, therefore, useful to specify different thresholds of error behavior (e.g., BER) measured over shorter time intervals and then to

characterize the communications channel through the statistical distribution of these error behaviors.

Three parameters are defined by ITU-T G.821 to describe the error performance of a 64 kb/s connection:

1. *Errored second (ES)* is a 1-s period that contains one or more errors. For data services, the information is commonly transmitted in blocks containing error detection mechanisms. Blocks received with one or more transmission errors are subject to retransmission. In order to have a high throughput, it is necessary to minimize the number of errored blocks. The 1-s period was historically adopted as a compromise value for data block size.
2. *Severely errored second (SES)* is a 1-s period where the short-term bit error rate evaluated over 1 s exceeds  $10^{-3}$ . An SES can lead to a loss of synchronization, and it is considered that the connection is unusable during the time interval.
3. *Degraded minute (DM)* is a 1 min period where the short-term error ratio exceeds  $10^{-6}$ . The degraded minute was devised principally for digital telephony for which the mentioned error rate is the subjectively perceived boundary of virtually unimpaired transmission.

These parameters are to be derived from averaged data over at least a 1-month period. However, in practice, channels are tested for 4 h to assess ITU-T G.821 compliance.

The network and transport layers work in packet mode. Packets may be lost at the network layer for several reasons:

- Packets are discarded due to transmission errors detected by the link layer error-detection mechanism.
- Packets are discarded by the network protocol due to undetected errors that corrupt the network protocol format.
- Packets are lost due to queue overload because of network congestion.

The packet-loss rate is the addition of these three effects. Errors are not recovered by the network layer.

The transport layer recovers errors by packet retransmission when the TCP transport protocol is used. The Fletcher checksum added to the TCP information segment allows undetected network layer errors to be detected and corrected using retransmission procedure. UDP connectionless transport protocol does not provide a correction mechanism, so the application should take care of error detection and correction when required. A marginal amount of transmission er-

**Table 14.5** Availability objectives

Availability objective	Service down-time in min/y (h/y)	Example of service
99.999%	5.25 ( $\approx 5/57$ )	Protection communications
99.99%	52.5 ( $\approx 5/5.7$ )	SCADA, operational voice
99.9%	525 ( $\approx 5/0.57$ )	Data service

rors, called *residual errors*, are undetected by the error detection mechanism and handed over to the user. Operational applications may have a specified objective for the *residual error probability*;  $10^{-12}$  is the most common figure whatever be the channel bit error rate for control commands. Furthermore, an information packet that arrives with a delay outside the application time constraints is considered as lost information.

### Availability and Dependability

Availability is a service-related statistical parameter that can be defined as the probability of proper operation of the network for a given information exchange. It is normally quoted as a percentage of *up* time of the service, or the percentage of time that the network can effectively forward traffic (e.g., 99.999%). It can be estimated theoretically and measured practically on a network-wide or per-circuit basis.

Service availability can be expressed as

$$A_{\text{Service}} = 1 - \left( \frac{\text{Mean.Time.To.Restore.Service}}{\text{Mean.Time.Between.ServiceOutages}} \right).$$

Some currently used values are given in Table 14.5.

However, this statistical parameter, widely used in public telecommunications, in computer systems and networks, and in defining SLAs, must be used with precaution when applied to operation-critical services with an extremely low *service-to-idle* time ratio.

As an example, consider a managed service with an apparently high contractual availability of 99.999%. This gives an unavailability figure of  $10^{-5}$  and an unavailable time of 311 s/y.

**A protection relay system sending 50 trip commands in 1 year can be unavailable during 6 s each time a trip must be transmitted and still respect 99.999% availability!**

For low-duty cycle operation-critical services, it is more appropriate to use *service dependability* defined as the conditional probability of a service being available when it is solicited. It is important to consider the correlation between power faults and service availability. In fact, there is a correlation between them due to the fact that a power-system fault is a situation that ini-

tiates an extensive exchange of information, but it also induces impairments in the operation of the communications system.

### Electromagnetic and Environmental Constraints

Most access points are located at high voltage sites, so communications equipment should work under harsh electromagnetic conditions. Consequently, wired-access interface must be adequately protected to avoid disturbances that may produce errors, loss of information, or even interface damage that will downgrade service availability. It should be noted that adopting services provided by a public telecom operator does not remove the need for taking these measures, since access equipment must be installed at utility sites.

### Service Survivability

*Survivability* is defined as the ability of the communications service to continue during and after a disturbance (network infrastructure fault). Many operation-critical communications services do not tolerate service interruption and downtime. In addition to the statistical concept of availability, it is essential to assure that, as a minimum, no single fault in the reliability chain will jeopardize the application. The concept of service survivability perceived at the user end translates into *resilience* in the telecom service provider's infrastructure. Resilience is the ability to provide and maintain an acceptable level of service in the presence of faults.

This is achieved through a multilevel resilience model comprised of the following:

- Fault tolerant network elements with duplicated core components and duplication of access equipment at critical sites
- Survivable topology (e.g., ring and mesh structures allowing alternate routing)
- Disruption-tolerant end-to-end transport through protection switching and service restoration mechanisms like SDH MSP ring protection, Ethernet Spanning Tree Protocol (RSTP), MPLS alternate paths, IP routing mechanisms (e.g. OSPF), etc.
- Fault-tolerant and adaptive applications and overlays
- Adapted management strategy and system supervision through appropriate fault management tools dedicated to the operational services.

Some points need to be kept in mind concerning service survivability and the design of resilience:

- *Service restoration time.* Different levels of network resilience operate at different time scales that may

or may not be compatible with different applications' maximum acceptable outage duration.

- *Routing control.* Designing resilience into the network generally signifies injecting a degree of uncertainty into the routing of information and the resources that are used for delivering the service. This in turn, impacts the absolute time latency of the network and generates delay variation. In the most time-sensitive applications, resilience is restricted to the application itself (main/backup end-to-end routes). The two communication channels for these applications must be disjoint, that is to say, they should not have any common path, common node or common equipment, in order to avoid a single failure disrupts the application. To achieve this, a controlled routing algorithm is required.
- *Underlying infrastructure.* Where the telecom service provider network employs a contracted lower layer infrastructure, it becomes difficult or impossible to guarantee the independence of main and backup routes. Tracking the full routing of connections can become extremely difficult.
- *Coordination of resilience.* Applying different layers of resilience in the network to the same service without adequate coordination may cause unnecessary cost and complexity. As an example, main/backup end-to-end application-level fault-tolerance, spanning tree protection on the Ethernet connectivity, and ring protection in the underlying SDH network may all operate on the same network fault with different time scales to switch the traffic from the same topological path to another unique topological path.
- *Dormant faults.* An important issue in assuring service survivability is the capability to detect latent faults in the backup routes. A classical strategy adopted in power system telecommunications networks, is the crossover of main and backup routes for different applications. This approach uses each of the two paths and its associated resources for one main and one backup route, and, therefore, continuously checks each path to detect any anomalies.

### 14.3.4 Service Provisioning and Service Level Agreement

It is important that operational services used by time-sensitive applications be contractually committed through a service-level agreement (SLA) to assure that every aspect of the service will comply with critical operational requirements, such as time constraints and dependability. Whether the service be provided by a public operator or internally provided using power-utility telecommunications infrastructure, the SLA is

useful to formally specify requirements and assess capabilities of the service to be provided.

The electrical power utility's decision on the way a communications service is implemented depends upon several factors, the most important of which are listed here:

- Service quality and reliability requirements
- Service accessibility at sites where communication is required
- Cost of deployment and maintenance of the service during the required operation period
- Commercial availability (or nonavailability) and cost
- Number and dispersion of sites to cover and their communications traffic
- Company policy and regulatory issues concerning capital and operation expenditure (CAPEX/OPEX)
- Disaster recovery/business continuity and security constraints
- Company policy and regulatory position on recovering investments through nonoperational telecom services (e.g., recovering the cost of optical infrastructure through leasing of dark fibers)
- Organizational issues including in-house availability of skilled staff.

Service provisioning can be performed through a public multicustomer operator, in which case the power utility effort is mainly focused on adequately defining the service, contracting the provider's agreement on the quality of the delivered service, and assuring that the provider delivers the contracted service level.

The power utility can also decide that the most adequate manner to provision the service is to use a dedicated telecom infrastructure through its own service delivery process and organization, in which case the network is generally shared with other utility communications services in order to optimize the investment.

Different intermediate solutions may exist between the purely procured and fully in-house service provision using different extents of outsourced operations, field intervention, or maintenance support. Moreover, services of different kinds or in different parts of the network may be provisioned through different modes.

The performance objectives and the quality of service are also different among these different service types. Many operational services, such as protection relay applications, have extremely severe time delay and communication-integrity constraints, whereas the other communications service types are mainly transactional with less severe time sensitivity. On the other hand, business and market communications services implicate access beyond the perimeter of the

power company and may raise more severe security issues.

Considering the organizational diversity of electrical power utilities and their different sizes, activities, and regulatory constraints, the exact perimeters can vary to some extent and may evolve with organizational changes. Some of the factors that influence service provisioning are:

- *Security policy.* The definition of separate security domains across the company and the consequent allocation of applications to these different security domains can result in communications infrastructure segmentation.
- *Organization.* The organizational entity in charge of a group of applications may require exclusive usage of a service or a same group of communications services.
- *Company strategy.* Grouping of communications services may depend upon the company's strategy, for example to merge corporate and operation-related IT and telecoms, or to merge corporate and market related applications' communications provision, etc.
- *Regulatory issues.* Regulation authorities may prevent operational applications to share communications services with nonoperational ones.

When the telecom service-providing entity is tightly related to the *service user* entities, there is a one-to-one correspondence between applications and communications services resulting in an *application-oriented* definition of the communications service (e.g., SCADA or protection circuits). The communications service provider is assumed to be sufficiently familiar with the applications to apply the necessary precautions in the delivery of the required service. However, when a new application is introduced or the requirements of an application change in time, then the user and provider must seek a new common understanding of the service requirements.

On the other hand, where communications service is provided by an external telecom operator, then the service provision contract defines the service attributes according to the provider's *service catalogue* (interface type, throughput, availability, delay, etc.). In this case, the utility user must decide upon the suitable service category for his application *out of the provider's catalogue*.

The service provision contract is known as a *service-level agreement* (SLA), which can be explicit in the case of externally provisioned services or implicit, based on common understanding, for internally provisioned services. SLA is an essential mechanism to ensure the successful provision and operation of net-

work services from an external provider. SLA expresses application requirements in terms of service parameters. The most important parameters that should be included in an SLA are:

- *Service availability.* The frequency, duration, and timing of service failures need to be determined for each service.
- *Bandwidth.* This is the bandwidth available to the different services and may include some flexibility in how this is applied.
- *Delay and delay variation.* It will be necessary to specify this for each application.
- *Data security.* Again, this will be specific to different applications.
- *Power fault correlation.* For services that are critical during power system disturbances, it may be important that specific additional precautions be specified.
- *Penalties.* While penalties may not compensate for loss of critical services, they do focus a service provider's attention on the need to monitor SLA guarantees.
- *Mean time to repair (MTTR).* It is important that there is adequate confidence in the service provider's ability to respond to service failures and carry out the necessary repairs in an acceptable time.
- *Service isolation guarantees.* This refers both to isolation between internal and external traffic, as well as between different internal services.
- *Physical redundancy check (reliability).* This may specify the level of redundancy required, for example, at a network level, an equipment level, or at specific locations.
- *Power backup.* This is critical for those services required during power-system disturbances. It is important to ensure that rural switching locations have sufficient standby arrangements.
- *Performance reports specification.* It is important that meaningful and comprehensible information is provided in a timely fashion. There is very little use in providing vast amounts of data but very little information.
- *Qualified workforce availability.* Obtaining and holding on to qualified personnel is an increasing difficulty for service providers. It is important to ensure that a potential service provider has sufficient depth in their workforce. It is also worth examining that they have the right number of personnel in the right locations in order to ensure that response time guarantees are realistic.
- *Reporting.* This pertains to how service performance will be evaluated including measurement methods, parameters to be controlled, and reporting frequency and format.

Adopting a particular telecom service-provisioning model is not an irrevocable decision. It is often re-examined and reviewed in the light of new situations, some of which are:

1. New company policy and orientation
2. New regulatory issues and requirements
3. Emergence or abandonment of adequate telecom services to be procured
4. New applications or change of scale incompatible with the present provisioning model
5. Lack of satisfaction from the services obtained through the existing provisioning mode
6. Major capital investments and running costs required for refurbishment and extension of existing facilities
7. Technological changes in telecommunications and in power-system technology
8. Lack of qualified staff and the ageing of the technical workforce concerned.

### 14.3.5 Telecommunications Technologies

Operational telecom networks are built using a variety of technologies. The focus of this section is to introduce working principles and specific ways telecom technologies are used. A detailed analysis of the working theory can be found in a quite large number of publications and books.

In order to optimize investment, telecom resources are usually shared by several services. This is accomplished through the use of multiplexing techniques, which will be presented later this section.

Telecom working principles can be grouped into three categories associated with different working modes:

- *Transmission technologies.* Their function is to deliver bits at the remote end of the link. This concept applies mainly to point-to-point links, although some wireless technologies can provide point-to-multipoint transmission services.
- *Transport technologies.* Their function is to deliver bits to a far end, crossing several intermediate nodes. These technologies are able to establish a point-to-point link over a digital network providing bit transparency. They can use a mix of transmission technologies in every one of the point-to-point links used to establish the path.
- *Networking technologies.* Their function is to transport packets between two access points. Packets delivered at the ingress access point can be delivered to any egress access point of the network, so they can establish multiple virtual links using the same access interface.

From the working modes described above, we can summarize that communications can be implemented using the *circuit* or the *packet* paradigm. Both have advantages and disadvantages, as is shown later in this section. Although most existing communications networks are based on circuit technology, power utilities are migrating towards packets due to their higher flexibility, scalability, and cost-effectiveness. Furthermore, the IEC 61850 family of standards specify the use of Ethernet and IP to implement operational communications services form control centers to the other power grid actors. This means that in the near future, the packet paradigm will be the only technology considered to implement operational services. Nevertheless, we will analyze existing technologies, as the migration to a packet-only system will take many years.

Considering the way physical communications links are used, most technologies allow communication-resource sharing or information multiplexing. Multiplexing is normally used to optimize the use of communications resources by integrating operational and sometimes nonoperational services over common infrastructure. This includes multiplexing of dedicated frequency bands, optical wavelengths, time intervals in a high-speed data stream, or dedicated packets in a high-capacity data link.

Circuit technology uses a fixed path or a *circuit* through the network. This path – once established – offers a fixed bandwidth and a fixed and deterministic latency to the service. For the simultaneous transmission of a multitude of services (i.e., many data, voice, or video signals) sharing the same medium, these signals are combined using *time-division multiplexing (TDM)*, where each signal is cyclically allocated a time slot with a time gap short enough to be unnoticed by the user.

The disadvantage of this technology is that the network resources are inefficiently used by sporadic burst traffic, like voice or video. For example, the bandwidth allocated to a voice channel is permanently occupied even during speech pauses or when not used at all. The advantage is that each service receives its dedicated network resource with fixed bandwidth and stable end-to-end delay. The PDH and SDH technologies described in the following sections are examples of TDM networks.

The disadvantage of poorly exploiting network resources has been tackled by the so-called *packet switched* technology. Simply speaking, the data to be transmitted is split into packets (which can be of various sizes) and are labeled with a source and destination address. The packets enter a queue at the ingress of the network, and as network resources become available, the packets are forwarded by switches and routers through the network, normally following the shortest or

the fastest available path. This technology is employed in wide area networks (WAN) based on Ethernet or IP packets.

Marketization, queuing, and competing for network resources like bandwidth, inherently generate the risk of a nondeterministic service delivery that is a potential problem for time-critical signals such as protection. Bandwidth overprovisioning combined with advanced techniques, such as service prioritization, traffic engineering and bandwidth reservation, time distribution protocols, data buffering, and synchronous Ethernet contribute to gradually overcoming or reducing most of the undesired statistical behavior of packet-switched technologies.

*Frequency division multiplexing (FDM)* is a multiplexing technique used at the transmission level. It is based on using separate frequency bands for each service, as is done in power-line carriers or in radio systems. The same principles apply to *wavelength division multiplexing (WDM)*, which is employed over optical fibers. In these systems, the interaction between different services is only through potential crossband interferences. It should be noted that resource allocation through TDM and FDM – or WDM – may be simultaneously used in different hybrid configurations.

Optical communications is the most reliable and powerful transmission technology available nowadays. Optical fibers are widely deployed in power-utility communications networks and constitute the preferred communications medium between substations, as well as for the substations' internal automation networking. Fibers can be dedicated to a single application (e.g., protection relays) or may be shared for the use of many applications.

Power-utility communications networks employ single-mode (SM) fibers due to their better transmission characteristics, such as attenuation, dispersion, and bandwidth. Multimode (MM) fibers are limited in their application to short distances inside the substation (protection relays, actuators, metering devices, etc.), to assure galvanic isolation at low installation and maintenance costs.

Power-utility optical fiber cables are generally deployed along overhead, underground, or undersea power lines. The fibers are illuminated by laser emitters and can be used in single-wavelength or multiple-wavelength modes. In the latter case, every wavelength acts as an independent carrier of information, increasing the fiber capacity or reinforcing service separation. Many optical cable technologies are presently in use, depending on the nature and voltage level of the power transmission lines. In the case of overhead power transmission lines, the optical cable may be incorporated into the protection ground wire, OPGW, or wrapped around it.

Alternatively, the optical cable may be *self-supported*, attached to transmission towers or distribution poles. All-dielectric self-supporting (ADSS) optical cables are generally used for existing line retrofitting when the line voltage is below 150 kV, and where the line is not equipped with protective ground wires with full continuity. This is often the case of medium-voltage distribution lines.

However, above 150 kV, the presence of electric fields affects the transmission characteristics of the fiber, increasing its birefringence effects. Moreover, at higher voltages, ADSS is generally not employed due to the effects of the electrical field on the dielectric sheath. For these systems, the preferred technology is OPGW with the optical fibers placed inside steel, aluminum, or plastic tubes to protect 12, 24, 48, and 96 optical fibers, according to different cable designs.

The available capacity of optical fibers is often assumed to be almost limitless based on advances in optical communications although factors such as temperature change, mechanical stress, and strong electrical fields may limit these capabilities at very high communication speeds far higher than required by operational and IT services.

Wavelength division multiplexing (WDM) is increasingly in use in power-utility communications networks to provide separation between different types of services (operational and corporate networks, legacy and new-packet core networks, fiber-based protection relays, and other communications, etc.). This is particularly true where extra fibers are not available or cannot be provisioned economically. WDM allows multiple optical beams from different optical communications systems, each at a different optical wavelengths, to be combined through an optical multiplexer and injected into the same fiber. At the reception side, the different wavelengths are separated by a passive optical filter bank and treated by different optical receivers. WDM provides full isolation of telecom services that only share the fiber and possible optical amplification.

Coarse-wavelength division multiplexing (CWDM) is defined by the ITU-T Rec. G.671 standard. It allows implementing reliable and cost-effective systems, through a combination of uncooled lasers, relaxed laser wavelength selection tolerances, and wide pass-band filters. CWDM systems can be used in transport networks for a variety of architectures, delivering a very cost-effective solution. Figure 14.15 presents the channeling structure for CWDM together with fiber attenuations.

It is worth noting that the water absorption peak around 1400 nm is no longer present in more recent fiber designs (ITU-T G.652-C or G.652-D) in which the OH ions inside the crystal structure have been removed through a modified manufacturing process.

The dense-wavelength division multiplexers (DWDM) on the other hand, is a technology used to further increase the capacity of the fiber by adding more channels (ITU-T G.694.1). DWDM systems, mainly used by public telecom operators, can multiplex from 32 to more than 100 channels in the range of 1530–1624 nm. With a channel spacing of 1 nm (or below), DWDM operation requires extremely precise optical sources with laser-temperature stabilization resulting in significantly higher complexity and cost. With a channel spacing that is ten times larger, CWDM systems tolerate temperature drift over the whole industrial temperature range of the laser emitters without leaving their allocated channel. This ruggedness, in addition to a considerably lower cost, constitutes significant advantages in the utility communications network where wavelength multiplexing is not often used to attain maximum bandwidth but rather to separate networks. For the use of optical amplification systems in long spans, CWDM systems should be limited to four channels (C- and L-bands) to make them compatible to the limited bandwidth of these devices.

#### Time-Division Multiplexing (PDH and SDH)

*Time-division multiplexing (TDM)* was the prevailing transport technology of power-utility telecom networks, but nowadays it is being replaced by Ethernet and IP technologies. Nevertheless, we will include a brief description of its working principles. Historically, the *elementary digital stream* was fixed at 64 kb/s (56 kb/s in North America) corresponding to 8000 analogue samples/s with each sample coded over 8 bits (8000 sample/s required to convert a 4 kHz analogue voice signal to digital and reconvert back to analogue after transmission across a link without loss of information).

In order to exploit a much higher digital-transmission capacity of transmission systems, the digital bit-stream was used to continuously transport cyclic frames of fixed length, which are partitioned into equal *time slots (TS)*. Using the same TS in each frame, one can transport an elementary digital stream, time-domain multiplexed with other digital streams. A frame header sequence allows synchronizing both ends of the link and, therefore, to separate multiplexed characters at the receiving end.

Time-multiplexing of 32 elementary digital streams (30 useful streams plus slot 1 for header sequence and slot 16 normally reserved for signaling) has yielded a multiplex system with an aggregate bit rate of 2048 kb/s (currently referred to as 2 Mb/s or *E1*). A slightly different constitution in North American and Japanese systems gives a 24-channel multiplex at 1544 kb/s (referred to as *T1 and J1*).

Fig. 14.15 WDM channeling. (Adapted from [14.1])

The E1 system is byte-multiplexed (8 bit per time interval), has a frame length of 256 bit, and a periodicity of 125  $\mu$ s. This system is referred to as a *primary multiplex system* (ITU-T G.703) and can carry voice or legacy data at speeds ranging from 0.3 to  $N \times 64$  kb/s. A primary multiplex system is purely synchronous: at the receiving end, the system must reconstitute clocks from the received signal for bit reception and for frame synchronization. Frame synchronization is performed through initial searching of the frame-header sequence and multiple successive reception of the same pattern at the right time. Synchronization is lost when the pattern is not found at the right place a determined number of times, and a new search for headers is initialized. The loss of synchronization and the consequent time of resynchronization can lead to periods of unavailability, which can affect the performance of certain utility-operational applications, such as protection signaling if no special measure is taken.

However, when multiple E1 streams from different primary multiplexers are to be combined together to use a higher capacity transmission resource, the clocks of the different primary multiplex systems, although at the same nominal frequency, are never identical. Clocks at the same nominal frequency are called *plesiochronous*.

Higher-level combination of primary multiplex data streams is performed through bit multiplexing (com-

binning four 2 Mb/s to constitute an 8 Mb/s stream and then combining by four to constitute a 34 Mb/s, etc.). Successive multiplexing produces a *digital hierarchy* known as a *plesiochronous digital hierarchy* (PDH).

PDH multiplexing was devised – and was well suited – for the connection of telecom switching centers (central office, CO). It is not appropriate for adding and dropping of *containers* at intermediate stations across the network. This means that the whole load of channel groups in the hierarchy need to be *unfolded* whenever some load needs to be *dropped or added*. This method results in unreasonable time delay, complexity, costly equipment, and excessive crossconnect wiring. This drawback has been overcome by the implementation of *synchronous* digital networks. *Synchronous digital hierarchy* (SDH) was designed to deploy digital transport networks able to establish digital channels of different bit rates between any two points of a wide area network. This was achieved by implementing a synchronous digital network that provides intrinsic cross connections and add-drop facilities. The synchronous digital hierarchy is composed of multiplexed digital rates of 155 Mb/s (STM-1), 622 Mb/s (STM-4), 2.5 Gb/s (STM-16), and 10 Gb/s (STM-64). Power-utility telecom networks employ currently STM-1, STM-4, and STM-16.

Unlike PDH, SDH is a network-based system using *add-drop multiplexers* (ADM) at each node loading and

unloading data streams in previously reserved *virtual containers (VC)* to connect to different destinations. The data capacity available is partitioned into a pointer domain and a payload domain. Each VC in the SDH payload corresponds to a specific pointer indicating the location of the VC in the payload. The VCs in the same payload can have different sizes (the number of reserved bytes in the payload), depending on the capacity of the data stream (2, 34 Mb/s, etc.). The minimal size of the VC is 2 Mb/s (VC12) allowing the transport of an E1.

Different levels of overhead (segment, path, etc.) allow more elaborate management and end-to-end recovery of connections across the network. In particular, the *SNCP (subnetwork connection protection)* protects each tributary data stream in a differentiated manner through an alternate path around a ring.

Transport of data across an SDH network is performed through previously reserved capacity and centrally controlled deterministic routing, thus leading to a highly predictable transmission delay. Furthermore, the management information accompanying each virtual container enables very fast data-traffic recovery on network fault conditions (< 50 ms). However, the self-healing mechanisms of SDH are not implicitly bidirectional and may lead to different go and return paths and, consequently, delay differences causing anomalous operation of differential line relays or other devices using an echo method for time synchronization. Precise network design or specific mechanisms are required to avoid such asymmetry in the network.

The SDH systems deployed in the 1990s were focused on the transport of circuit-switched traffic (E1, etc.) with only limited and proprietary facilities for Ethernet packet transport. New-generation SDH (NG-SDH) has since been completed with a set of standards for optimized mapping and control of Ethernet traffic (*Ethernet over SDH or EoS*), as is described in Sect. 14.3.6. This allows power utilities to combine at a control bandwidth granularity, the more efficient and flexible bandwidth sharing packet networks with the deterministic behavior, low delay, and fast healing of SDH.

### Layer 2 Networks – ETHERNET Technology

As we already introduced, Ethernet has become the standard telecommunications interface. Ethernet technology implements the physical layer and link layer functionality, which allow layer 2 networks to be implemented using this sole technology. A layer 2 network is network formed by a limited number of physical devices connected by means of a communications medium able to provide full connectivity. The communications media can be formed by a bus implemented by physical wires, a point-to-multipoint radio, a satellite

system, or an Ethernet LAN. A layer 2 network based on Ethernet technology is a network formed by Ethernet switches and bridges able to forward Ethernet frames to its destination host, thus providing Ethernet service in all of its access ports.

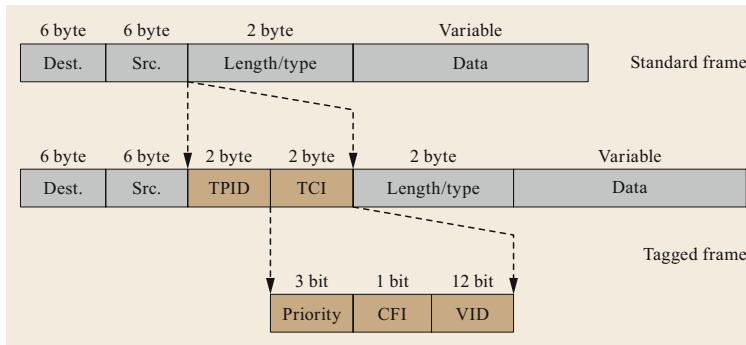

Layer 2 networks do not have routing procedures. There is no need, since layer 2 networks provide broadcast to all their members. Nevertheless, Ethernet switches provide mechanisms to find where every host is connected and, therefore, deliver the frames to its right destination without using broadcast forwarding. This mechanism is not based on the routing principles but on dynamic the Address Resolution Protocol (ARP) table built from the switched traffic. Frames addressed to unknown destinations are broadcasted to all the destinations. Every time an Ethernet switch receive a frame with a new address, this address is automatically added to the ARP table, so as traffic is forwarded, spontaneous broadcast decreases.

Layer 2 addresses are unique and randomly assigned. Unlike layer 3 addresses, they do not identify the location where the host is connected. They are just used to identify the host. Due to the random distribution of Ethernet addresses, the address of every host must be stored in every Ethernet switch and, therefore, it is not possible to implement a routing procedure like in layer 3. Layer 2 networking is a cost-effective approach that presents some scalability limitations mainly due to the random address allocation and the lack of routing procedure. For this reason, large WANs usually require a backbone and more scalable assignment capability.

The concept of *virtual networking* can be applied to both the link layer or LAN and the network layer. In order to segment traffic and improve scalability, mechanisms to implement virtualization of local-area networks have been defined. Virtual networking allows network connections to share common physical media with other data while remaining logically isolated to and from other users. Virtual networking can be set up at different levels in the OSI layer model, from layer 1 to layer 3.

Virtual LANs or VLANs (IEEE 802.1Q) are the mechanism used over Ethernet networks. Upper-layer technology virtual private networks (VPN), such as IPSec, are used at the network layer. The main advantages are the following:

- *Expandability.* Once the network is in place, it can be easily expanded to other sites or higher capacities just contracting new capacity from public network operators.
- Lower cost compared to private or leased communications means, as infrastructure maintenance costs are much lower.

**Fig. 14.16** VLAN frame format. (Adapted from [14.2])

- *Simplified network topology.* Virtually connected LANs can be seen as a single network from the end user/application perspective.

A VLAN defines a logical segment that comprises several LAN resources, including cables, equipment, and some of their ports. Each VLAN becomes a new broadcast domain. Since the broadcast domain defines the scope of a LAN, any host attached to a VLAN can only reach other hosts of the same VLAN due to the limitation of broadcast messages. This provides traffic isolation and a very powerful security mechanism, as there is no way two hosts of different VLANs send information directly. In order for hosts of different VLANs to communicate, a router must be added. In this case, the router controls traffic flows and set communication rules between VLANs.

The IEEE 802.1Q standard defines a 4-byte extension to the Ethernet frame header that allows traffic from one VLAN to be distinguished from another VLAN, as is shown in the following Fig. 14.16.

The tag includes a 12 bit field used as VLAN identifier (VID). VID allows 4096 different VLANs to be defined in a LAN. Whereas trunk ports that interconnect switches carry tagged frames, edge ports can accept tagged or untagged frames. In fact, there are two generic types of VLANs, the ones generated by the switches, normally associated with a set of ports, or a MAC address, IP network, etc., and the ones generated by the IEDs, like in the case of IEC 61850 GOOSE and sample-value messages, where the IED generate the tagged frame. The simplest way to implement Ethernet connectivity with local or limited coverage is to use unshielded twisted-pair (UTP) copper wires or optical fibers through the appropriate Ethernet transceivers incorporated into the Ethernet LAN switches. Due to the harsh electromagnetic environment of power plants and substations, the use of copper interfaces should be limited to connections between equipment located in the same cabinet. Currently, Ethernet has many different interface types; copper interfaces can run from 10

to 1000 Mb/s, whereas fiber interfaces can run from 0.1, 1, 10, and even 40 and 100 Gb/s. Optical Ethernet interfaces – in particular gigabit Ethernet – can be implemented over a wavelength, this way sharing the fiber capacity with other traffic through wavelength division multiplexing (WDM).

Although fiber optic variants of Ethernet were initially designed to connect devices in different floors of a building or even between nearby buildings, the extremely long range of optical interfaces ranging up to 180 km at 1 Gb/s without repeaters allows a LAN to be extended outside the substation becoming a single distributed LAN that works like a LAN but without being local. The implementation of a WAN using Ethernet is simply the interconnection of Ethernet switches using medium and long-range optical interfaces. Furthermore, the increased capacity of new Ethernet standards ranging up to 10 Gb/s allows the capacity of the optical fiber to be used, thus providing a simpler alternative to other transport technologies. Nevertheless, despite its broadband performance, these new Ethernet standards maintain the same working principle, which means that they also suffer from the same technical limitations. In particular, the lack of native quality of service support, routing limitations, and lack of traffic engineering control.

### Radio Communications

Radio communications covers a very large spectrum of systems and solutions used in power utilities to various extents. In general, they present the advantages of fast deployment, where no existing wires can be used and the potential mobility of the communicating peers. On the other hand, they have implicit limitations in service availability (propagation conditions, obstacles, fading due to multipath propagation, etc.), bandwidth limitations compared to wired solutions, frequency allocation and licensing issues, as well as their associated tower and mast infrastructures to assure long coverage.

Some particularly useful applications of radio communications in the power utility are as follows:

- Line-of-sight microwave radio systems (2–13 GHz) are often used to complete optical networks to cover spans that are impossible or difficult to implement in optical fibers (e.g., crossing main motorways, rivers, etc.) or connecting the network to nonelectrical sites (e.g., control centers, office buildings, etc.). Frequency bands are increasingly difficult to obtain in the low end and are constantly pushed to 10–13 GHz or higher, with increased difficulty in assuring path clearance (Fresnel zone clearance) and, hence, requiring more costly tower infrastructure (when not installed on the top of a building) whose height is proportional to line-of-sight constraints. Microwave links, through their high frequency and high directivity are allocated large bandwidths, enabling them to transport high-capacity data flows (e.g., 155 Mb/s TDM or 100 Mb/s Ethernet). However, unlike fiber systems, their capacity cannot be increased with growing requirements beyond the allocated frequency bandwidth. WiMAX technology, defined by IEEE 802.16x standards, is still in use mainly in North America and provides a point-to-multipoint microwave solution with around 70 Mb/s capacity. Line-of-sight radio systems are also used in UHF radio bands with lower capacity (according to different national frequency regulations) but lighter infrastructure (less directional antenna systems, partial clearance of Fresnel zones leading to lower antenna heights). These are frequently used in industrial radio systems deployed in distribution grids.
- Broadband packet-based wireless network IEEE 802.11 (WiFi) is mainly used in the distribution grid to provide a high-throughput network to cover the emerging smart distribution applications. IEEE 802.11, in particular, enables the implementation of broadband wireless mesh infrastructures with ad-hoc network configuration algorithms to cover a distribution network perimeter. A network capacity of around 400 Mb/s can be attained through aggregating multiple channels. Powerful encryption algorithms overcome the security issues often associated with the usage of wireless technology to support operational networks applications.
- Narrowband industrial UHF radio systems provide up to around 20 kb/s over 12.5 kHz allocated frequency bands. These systems are widely used in distribution grid automation and SCADA applications. In some countries, allocated bandwidths of 25 kHz or more allow higher link rates.
- Private mobile radio (PMR) systems also known as land mobile radio (LMR) systems are UHF/VHF radio systems allowing the communications of the utility mobile work force. One or several radio

channels are shared among multiple mobile terminals. Different trunking protocols, such as TETRA or MPT-1327, are used by a central station to control channel access, network signaling, and some specific closed network functions. Implementing an adequate coverage through a PMR is costly compared to public alternatives, considering the area to cover (number of base stations) and, generally, small number of mobile terminals using the network. The major advantage over public cellular service is the higher availability.

- Private cellular radio systems cover different technologies, such as GSM-R (used mainly in transportation), and LTE (4G) are trunked cellular solutions that can be implemented in a private utility operations network to provide very high communication capacities. These technologies can find their place in the future smart distribution network integrating a large number of bandwidth-consuming applications (large-scale realtime metering and demand response), although procuring frequency licenses may be hard to justify for a power utility.
- Satellite communications is radio communications that uses an artificial satellite located in a geostationary orbit to relay and amplify radio signals using a transponder. This is commonly used for TV or any other type of signal broadcasting. A special type of satellite communications is the very-small-aperture terminal (VSAT). This system uses a very small dish antenna and implements a point-to-multipoint bidirectional communications channel. Its use is common for operational applications that can tolerate rather high latency such as data acquisition or even SCADA applications to remote places, where deploying radio or fiber communications is not possible or very expensive. In most cases, the data rate can range up to 16 Mb/s or even higher. Modern implementations use the  $K_a$  band ranging from 26.5 to 40 GHz.

#### Power-Line Carrier

Narrowband power-line carriers (PLC) allows the transmission of communications signals, in particular protection relay communications, over power transmission lines. This technique, which has been in use for a long time, still provides a dedicated infrastructure fully incorporated into the substation with a signal path that implicitly follows substation-to-substation connections over long distances without any repeaters (> 500 km) and, therefore, an interesting solution for transmitting small bits of information such as teleprotection signaling, low-speed data, and speech over long distances. Channels for different applications are aggregated together through frequency multiplexing (FDM)

and transposed to a carrier frequency (roughly 25–500 kHz) or time-multiplexed to construct a digital data stream that is translated in frequency through digital modulation schemes.

Power-line carriers are used when no fiber is available or as a second path to secure the operation of a protection system. The availability of the communications channel being strongly correlated with power transmission line fault conditions, PLC is unsuitable for transmitting current differential protection, coded-sampled values (e.g., IEC 61850), or digital stream teleprotection signaling (due to potential synchronization loss on line faults). They are employed to transmit voice-frequency command type teleprotection, speech signals, and data.

Power-line communications are also used in power distribution grids for building advanced metering infrastructure (AMI) covering smart meters in customer premises, public lighting control, and different distribution automation and SCADA applications. These systems range from lower bandwidth PRIME, G3 and IEEE 1901.2 solutions with a capacity below 120 kb/s, to broadband power-line (BPL) solutions allowing building a packet network over medium-voltage or low-voltage distribution network conductors. Different techniques are used to cross open breakers, eliminate band-limited noise and disturbances, and to operate over variable grid topology and signal transmission characteristics. The system can typically provide 10–100 Mb/s capacity with a span of 3–4 km between nodes. BPL solutions can integrate multiple applications, each of which allocated a distinct VLAN, and may be used for higher data volume and resolution metering applications (e.g., for demand response), backhauling of smart metering, grid automation, SCADA, and other distribution grid applications.

### 14.3.6 Networking Technologies: The Network Layer

The network layer is implemented using the datagram paradigm that offers a connectionless packet service using the Internet protocol, IP. The IP protocol is widely known, so we will not explain its working details. IP has been used for SCADA applications for many years, since the beginning of this century. In 2004, IEC 61850 was approved and, as was previously explained, it is based on IP. Furthermore, in 2012, Edition 2 of the IEC 61850 standard was released, which extends the use of Ethernet and IP to every application involved in power-system operation. Basic IP technology does not provide quality of service (QoS). An IP QoS architecture was defined providing bounded delay, but this architecture was focused on multimedia services and was not specialized in

specific operational requirements. The provision of committee QoS over and IP networks was a problem until the advent of multiprotocol label switching technology, as is explained in the following paragraphs.

#### Multiprotocol Label Switching (MPLS)

Multiprotocol label switching (MPLS) is a packet forwarding technique that was specified by the Internet engineering task force (IETF) in the 1990s in order to implement IP over ATM in a scalable way. This also simplified the provision of IP quality of service and allowed a symmetric path to be established. In fact, it converts connectionless IP into a *connection-oriented* service one, thus simplifying traffic-engineering procedures.

MPLS operates through the insertion of a label at the ingress port of the network and associates a forwarding equivalence class (FEC) to the label. Each FEC defines the manner in which the packet is to be treated in each MPLS node. The label is removed at the egress port of the network. A connection established this way is called a label-switched path (LSP). Labels are swapped at intermediate nodes according to a plan defined through a distributed control plane using a Label Distribution Protocol (LDP). This exchange of control information between the network nodes, each of which takes part in the definition of paths, is a great force giving scalability to very large systems but is also a source of substantial complexity, which may often be found unnecessary in the scale and size of an electrical power utility dedicated network.

The MPLS labels are replaced at each switching node. This provides high flexibility and a dynamic routing capability but it requires network-wide intelligence, implying permanent exchange of control information across the network. This is known as a *distributed control plane*. Moreover, in order to enable each node to allocate capacity for each traffic stream, some traffic rule or policy must be given to the node. A distributed control plane generates critical control traffic across the network, and traffic engineering implies some prior knowledge of traffic classes and attributes. The IP protocol control traffic is transported using a resource reservation protocol, RSVP. Such an operation is suitable for extremely large networks with large variations of traffic volumes and source-to-destination paths, but well characterized traffic models. This is typically the case for telecom operator networks. Adjusting traffic engineering parameters in such a system is complex but far less laborious than configuring thousands of predetermined data paths, which, moreover, can change with time-of-day and with seasons according to network users' bulk movements. The technique is known as MPLS-TE, where TE stands for traffic engineering.

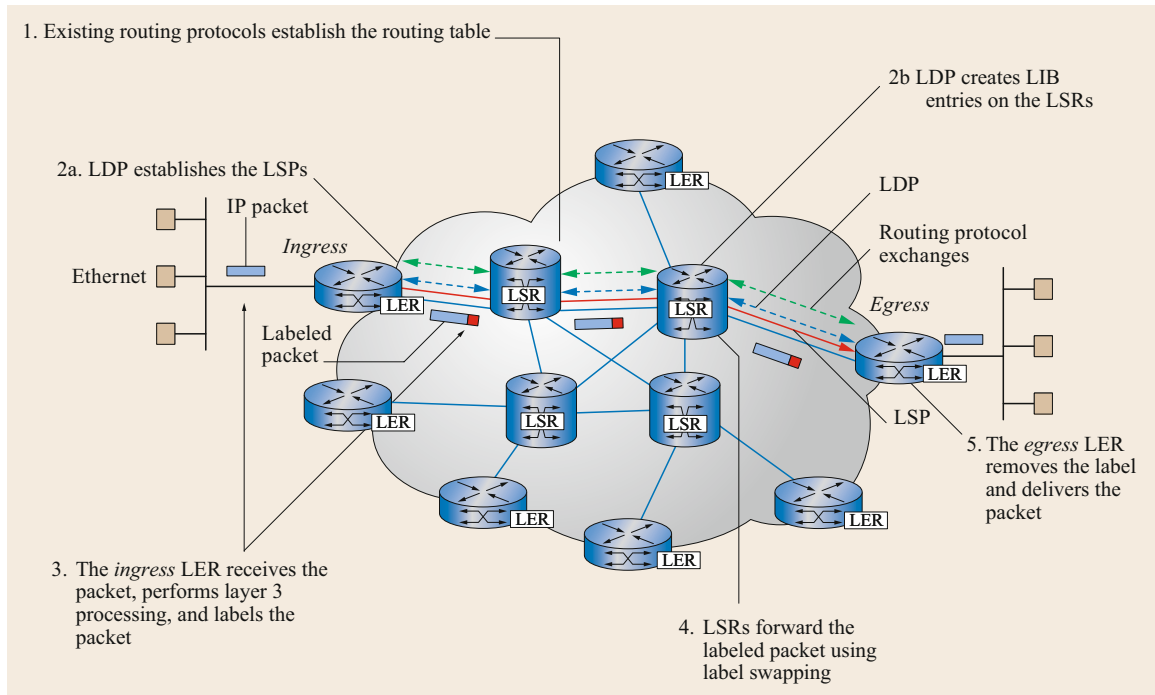

Fig. 14.17 MPLS working principle. (Adapted from [14.3])

IP-MPLS, in its simplest form, uses no traffic engineering but simple priority assignment, as in native Ethernet. The most time-sensitive traffic will only have a better delay variation than lower priority traffic. Such a system provides the traffic isolation advantages of MPLS, dynamic routing through a distributed control plane, but no guarantee on resource allocation to each service (except for the control plane exchanges using RSVP). It suits multisite enterprise networks such as utility nonoperational networks with no tight time and quality of service imperatives.

Transport profile MPLS, or MPLS-TP, is a variant of the MPLS technology simplified for transport-type networks providing predefined tunnels between service access points. It is an adaptation of MPLS to support traditional transport network requirements, such as high availability and QoS support, presently fulfilled by SDH transport technologies. MPLS-TP data traffic is forwarded across the network according to labels, which are added at the network ingress and removed at the network egress point without being changed at intermediate switching nodes. This provides a predetermined tunnel with no *distributed control plane*.

Packet forwarding tables at each node are provided by a central control platform in the same way as in SDH. The centralized control, moreover, allows predetermined end-to-end alternate routes and simple resource allocation. The control platform can allocate

a maximal capacity (peak information rate or PIR) and, if necessary, a minimal capacity (committed information rate or CIR) to each data stream, hence assuring SDH-like quality of service for time-critical services and IP-type flexible bandwidth for non-time-critical services.

MPLS-TP decouples the *end user-to-end user* network into distinct segments of the customer network (application network) and transport network. The latter segment essentially requires point-to-point services known as *pseudowires* (PW) transporting Ethernet (E-line or E-LAN carrier Ethernet services) and legacy TDM circuits upon the packet switched network. Moreover, the focus on transport domain allows MPLS-TP to use only a subset of MPLS, removing nonrelevant features and their corresponding complexity while adding some missing functions necessary for transport networks and existing in SDH/SONET, such as implicit operation, administration, and maintenance (OAM) signals exchanged at different levels of connectivity. MPLS-TP is a nonscalable solution for a telecom operator due to its fixed *tunnel* approach that makes it a nonfeasible approach to manage a very large number of connections. Conversely, it offers many advantages for the implementation of operational services, since MPLS-TP provides very similar features to existing SDH, thus simplifying technology migration and delivering new capabilities with similar management

processes and skills than the ones already existing in the power company.

The obsolescence of SDH technology is forcing the migration to MPLS. In the power-utility context, deploying MPLS is not *build from scratch* but part of an evolutionary transformation plan that should define the migration strategy. This plan should consider mission-critical time-sensitive services that require deterministic and symmetric circuits that would have to be emulated across the packet core. Moreover, the utility controls its telecom network from a central network management platform with processes and skills that are adapted to such an operation. In this context, MPLS-TP is a more appropriate technology than IP-MPLS, with or without traffic engineering. Some of the main reasons for this are summarized below:

- *Maintaining full control of the network.* In MPLS-TP, forwarding labels are produced by a central network management system (NMS) allowing end-to-end main and alternate route definitions, as is presently done through SDH. In IP-MPLS on the other hand, the proper operation of the network depends upon control plane communications. Moreover, if a deterministic behavior is necessary for some data streams, then adequate traffic engineering must be introduced to govern routing nodes decision. Adjusting traffic engineering parameters in an IP-MPLS network (MPLS-TE) is complex and requires tuning and adjustments rendering the network subject to nonoptimal settings.
- *Quality of service and deterministic behavior.* Some utilities using dedicated resources, such as separate fibers for protection, may imagine that these constraints are definitively out of their shared network. In reality, other protection-like applications with network-wide coverage will be deployed in the coming years, and dedicated fibers used between adjacent substations can no longer be the solution (e.g., system integrity protection schemes SIPS). Being able to implement time-sensitive applications remains a *must* in an operational network.
- *Size of network and type of traffic.* By its SDH-like behavior, MPLS-TP responds to all existing service requirements, as well as new packet-based services in utility-sized networks. Deploying MPLS-TE on the other hand, is suitable for public networks with highly dynamic data traffic characteristics and too many nodes for centralized control; traffic rules are, hence, given to nodes so that they can build the forwarding labels at any moment (TE).
- *Capability versus complexity.* IP-MPLS provides numerous technical capabilities but with increasing

complexity. Implementing QoS through dynamic resource reservation (RSVP) can be done in IP-MPLS but making it for hundreds of connections is far from being trivial. This level of dynamic complexity for a *static-by-substance* service seems unnecessary. Similarly, performing any meaningful traffic engineering in IP-MPLS (MPLS-TE) requires fairly good knowledge of the traffic shapes and characteristics, which is far from being the case for many new coming and future services over the operational network.

- *Migration from SDH.* Transition to packet for power utility networks with extensive SDH infrastructure, management tools, and skills is almost smooth for MPLS-TP because of its SDH-like behavior and network management. IP-MPLS is a jump into another type of network operation. With a large telecom network, utilities will become entirely dependent on their supplier. IP-MPLS suppliers provide specific tools and features to overcome some of the basic problems but in a nonstandard manner causing further dependence on a single supplier.

As transport functionality is migrating from SDH to MPLS, and Ethernet is the universal service access interface, it is important to consider that Ethernet will have to be transported over MPLS in most of the cases. In fact, we can identify three possible Ethernet transport solutions:

- Ethernet transported over SDH
- Native Ethernet transported over optical links
- Ethernet transported over MPLS.

As was mentioned in the previous paragraph, SDH has been complemented with specific protocols to integrate Ethernet packet traffic to the virtual containers (VC) constituting the SDH payload. Ethernet encapsulation over SDH is defined by the Generic Framing Protocol (GFP), virtual concatenation (VCAT), and the link capacity adjustment scheme (LCAS). However, matching asynchronous data streams such as Ethernet packets to a constant rate container system such as SDH becomes complicated, inefficient, and expensive as the proportion of packet to TDM traffic grows.

Native optical Ethernet transport between substations becomes a candidate solution, as the extent of legacy traffic decreases in quantity and importance as compared to natively Ethernet-interfaced applications. This is, indeed, to be thought of in the present context of IEC 61850 substation communications architecture and gradual migration of substation intelligent electronic devices (IED) into a networked environment. Native

optical Ethernet can use dedicated fibers or dedicated wavelengths (C- or D-WDM).

Native optical Ethernet transport, however, suffers a number of shortcomings:

- Ethernet protocols include mechanisms for restoring connectivity across a meshed network of switches when one or multiple nodes or links become unavailable due to faults (Rapid Spanning Tree Protocol). The time needed for such restoration, depends on several factors, such as network topology, number of nodes, and implementation of the algorithms, so it can range from 20 ms for small and simple networks to hundreds of milliseconds for larger networks.
- *Aggregating services and delay issues.* When multiple communications services are to be transported together, TDM (e.g., SDH) allocates a predetermined communications capacity to each application, therefore guaranteeing a fixed and predetermined transfer time across the network (L1 separation). Native Ethernet, on the other hand, uses the principle of packet queuing. Data packets belonging to different applications are stored in a queue and processed sequentially at each node. Ethernet switches may have the capability to distinguish packets belonging to different applications by associating specific tags to data frames belonging to each connection (L2 separation). Each group of similarly tagged frames constitutes a *virtual local-area network (VLAN)*. Different levels of priority (different queues) may be assigned to different VLANs (IEEE 802.1P and Q). However, priority assignment does not guarantee a fixed delay.
- *Scalability.* As the number of virtual connections to be deployed across the network grows, VLAN allocation proves to be complex and not scalable. Cascaded tagging (stacked tagging) mechanisms have been added to Ethernet to overcome this issue. IEEE 802.1ah, also called mac-in-mac, is a native Ethernet mechanism (L2) that overcomes the scaling limitation of VLANs by re-encapsulating the traffic with an outer Ethernet header carrying input and output addresses of the Ethernet transport network. This way, the provider's Ethernet switches no longer need to learn the large number of end-user MAC addresses. This technique is called provider backbone bridging and separates Ethernet transport from Ethernet LANs of end-users.

The use of MPLS facilities allows deploying virtual private networks (MPLS VPNs) in a unified multiservice network. A VPN is a group of network access nodes

using the same label and is, hence, capable of exchanging data packets in a closed manner across an otherwise public multiservice network. The VPN concept can be applied at layer 2 or layer 3. The first case is a solution for Ethernet transport over MPLS, and the second is the way IP VPN can be implemented across an MPLS backbone.

Implementing separate Ethernet virtual LANs (VLAN) through layer 2 tagging, as described in the previous sections, provides a simple, but not a scalable solution. As the number of VLANs grows, the size of the MAC address table can become extremely large, and the switches constituting the network will have to *learn* MAC addresses per port for the whole network, and VLAN management may become complex.

Transporting Ethernet over MPLS provides the technology for the creation of a core layer overcoming the problem of scalability, while maintaining the end-to-end Ethernet service provision. MPLS can be used to transfer encapsulated data from different technologies over a certain network. An additional label is inserted in the data for the encapsulation purpose, and this label is used for forwarding and classification inside the MPLS network. This additional label can be used to encapsulate layer 2 frames, e.g., Ethernet frames. This solution, called layer 2.5 MPLS or L2 VPN, is very scalable but can be quite complex.

Ethernet service over MPLS can be point-to-point (P2P) or multipoint-to-multipoint (MP2MP):

- The P2P Ethernet service or E-line, also called the pseudowire (PW), is based on a *packet-leased line* concept and can be implemented using the L2 Tunneling Protocol (L2TP).
- The MP2MP Ethernet service (E-LAN) implemented over an MPLS infrastructure is generally referred to as a virtual private LAN service (VPLS).

The Ethernet frame received at the MPLS edge is encapsulated without any modifications. The MPLS label is inserted directly in front of the old destination MAC address, and then a new Ethernet header is added in front of the MPLS label. Two labels are used:

- *Tunnel label.* The tunnel label is used to carry frames across the MPLS network. Core label switch routers (LSR) only look at this label. The tunnel label is removed by the penultimate hop prior to the egress node.
- *Virtual circuit (VC) label.* The virtual circuit label is used by the egress node and determines how to process the frame and where to deliver the frame on the destination network.

### Virtual Private LAN Service (VPLS)

The virtual private LAN service (VPLS) provides a scalable, switched Ethernet LAN over an IP/MPLS network. It uses MPLS layer 2 encapsulation to create an L2VPN. VPLS provides the transport of any type of Ethernet traffic (unicast, broadcast, and multicast) from a source 802.1Q VLAN to a destination 802.1Q VLAN over an MPLS network. VLAN tags are mapped to MPLS label switched paths (LSP). Ethernet over MPLS uses the Label Distribution Protocol (LDP) to dynamically set up and tear down LSPs paths over the MPLS network, which facilitates the implementation of dynamic service provisioning. When MPLS-TP is used, the association between source and destination is established manually and remains fixed during the connection lifetime. VPLS allows us to profit from the implicit service security and availability features of MPLS-TP.

### 14.3.7 Network Architecture

As discussed in the previous sections, substation-to-substation applications require information exchange between fixed peers that are generally adjacent or a small number of links away in terms of telecom network connectivity. They require little or no network routing resilience but tight constraints on time behavior. This pleads in favor of *more physical* – transmission-like – communications architectures providing latency control and implicit security. Service continuity in this case is to be assured through fast and simple preprogrammed switching of end-to-end normal and backup paths.

Network-wide applications, in particular those concerning human operators at undetermined locations and remote processing platforms on the other hand, require flexibility and high-level resilience, as well as a more elaborate security protection, such as access filtering, encryption, authentication, etc. This pleads in favor of *more logical* communications architectures managing topologies and data routing automatically.

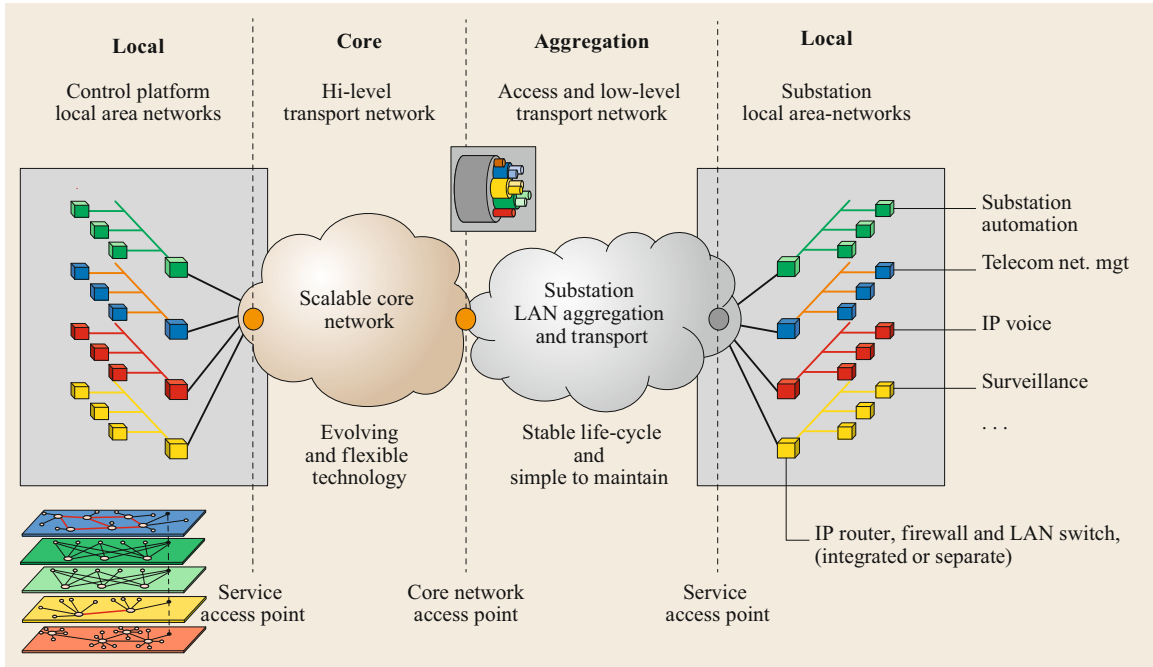

Adopting a hierarchical architecture not only combines these diverging requirements but simplifies network deployment, service migration, trouble-shooting and testing, network extensions and upgrades and future technology migrations.

In comparison to public networks that have three well-differentiated areas, last-mile, access, and core, power utility network architecture has the particularity that final users and network nodes are located at the same sites, substations, power plants, or offices. Consequently, network architecture tends to be simpler. In addition to this, some protection applications require pure transmission services that are almost not related

to the rest of the network. This makes the integration of services over a single technology almost impossible, requiring a multilayered approach that combines several technologies such as fiber optical network, Ethernet, MPLS-TP, etc.

The architecture of the network depends on several factors:

- *Power utility type.* The type of utility is a factor that influences network architecture:
  - Transmission utilities usually have their own fiber infrastructure, so they can implement mission-critical services using their private infrastructure. Furthermore, all their users, out of control centers, are located in substations, so the use of public telecom services are very limited.
  - Generation companies do not have telecom infrastructure and should normally share their operation information with the transmission company and with the system operation authority, so their telecommunications infrastructure is limited to the use of access connections.
  - Distribution companies have a mix of locations, some are in their facilities and some are in the field, or even on the customer's premises. The implementation of operational services requires a mix of technologies and, in most cases, the use of public telecom operators services.
- *Size of the network.* The number of nodes, or sites, is a factor that has a strong influence on the network architecture. Less than 50 nodes does not require a complex architecture, so operational services can be implemented using no more than two different technologies, an optical layer for transmission and transport and a MPLS-TP or plain IP for less time-critical services. For a higher number of nodes, a core network and an access or aggregation network using segmentation techniques must be implemented.
- *Geographical expansion.* The physical distance between nodes is a factor that has an influence in the transmission technology that can be used.
- *Availability of internal communications infrastructure.* The internal communications resources such as fibers, radio links, PLC, etc., will determine the architecture of the network, since their use will be a priority. Sharing these resources with other companies or for IT services is also a factor that must be considered.
- *Internal organization and telecom assets policy.* How IT applications and operational application use telecommunications resources is a key aspect for architecture design, as this will determine the need for virtualization of several services.

**Fig. 14.18** Network architecture with service segregation. (Adapted from [14.1])

Figure 14.18 shows a generic architecture where several services are segregated using different LANs including the core network and the aggregation or access network. Requirements and constraints in the two parts of the network are different, as summarized in Table 14.6.

This approach results in a hierarchical network in which different technologies and different evolution plans can be applied to each part. Moreover, the network may be further partitioned into larger networks, and different technologies may be used in different substation aggregation networks to build a gradual migration plan or to fulfil diverging requirements.

Another concept currently used in power utility telecom network architectures is that of *network overlay*. Network topology is strongly influenced by the power

system layout, but this may not be the optimal topology for telecom service deployment. A transmission layer allows us to change the physical topology by establishing circuits between nonadjacent nodes, so switching nodes may work in an optimal topology. In legacy networks, it is rare to find a single user interface or a single transmission technology, but in modern IEC 61850 systems, the trend is to use Ethernet interface only and fiber optics infrastructure due to the high bandwidth demand of modern operational services.

### 14.3.8 Network Design

Network design may be a complex task, depending on the network size and the number and type of services supported. Complex mathematics is involved in net-

**Table 14.6** Substation aggregation/access and core network requirements

Substation aggregation/access network	Core network
Long life-cycle power applications such as protection requires fixed configurations	Frequent upgrades to keep up with release, bandwidth and technology evolution may be required
Must be easy to deploy and easy to maintain, considering large number of sites and the low level of specialized telecom skills of field staff	Can tolerate more complexity considering the relatively smaller number of sites and usage of more specialized telecom staff
Migration is extremely slow due to number of sites and applications. Must coexist with legacy technologies in many sites with gradual service switch-over	Can be quickly deployed on separate fibers or wavelengths and can be used as a support structure for the more gradual deployment of substation networks
Time-critical applications, such as protection, are often confined to the same substation network	Enterprise networks, if transported over the same network, are confined to core network only

**Fig. 14.19** Multi-level hierarchical transport network. (Adapted from [14.1])

work design and, generally, cannot be achieved without the use of appropriate algorithms. Common sense and experience are also a necessary component to achieve a good network design.

Furthermore, green field network design is a very unusual case, since every power utility already has a communications infrastructure, so the most usual case is usually a migration scenario where some of the existing resources are reused. Telecom technologies and services' life-cycles are issues to be considered when designing a network.

Utility operational applications and substation assets have, in general, a much higher service lifetime than telecommunications services. A newly deployed substation application is expected to operate 10–15 years before being replaced. The adopted communications services for such an application are, moreover, expected to be *stable and field-proven* at the time of deployment. The communications solution, service, or technology must, therefore, be sustainable well beyond the expected lifetime of any new generation, mass-market, consumer-oriented service or technology. If a public operator service is employed, the service may disappear before the end-of-life of the power system application. If a dedicated telecom service is used, the interfacing units or equipment may no longer be supported by the manufacturer. Furthermore, the upgrade of communications system software releases or core components, which is a current operation in most communications networks, may be extremely difficult and may require long-term intervention planning, if critical applications such as power-system protection relaying are to be carried over the network.

Similarly, implementing a new communications infrastructure requires the ability to connect many gener-

ations of power-system applications rendering the issue of legacy interfacing essential. A new communications solution must provide a way to serve existing applications, which may coexist with the systems replacing them for a very long time. In order to assure future upgrade and legacy openness, communications solutions and the corresponding service delivery scheme must not depend upon the use of any proprietary interfaces or technologies and must be technology-independent as far as possible.

Network design is a tradeoff between the four main characteristics:

- Requirements
- Cost
- Performance
- Reliability.

The best design is the one that at the lowest cost can achieve the performance and reliability requirements. The starting point is service requirements. This information is used to define application layer and the underneath layers.

Network design implies the definition of every aspect of the network from its topology to links and node capacity, as well as the choice of the algorithms that support the services. Based on the business policy, the company's financial strength, and its competence in communications, an organization must decide whether to operate the services or network itself, or whether total or partial outsourcing is a more desirable option. An organization must also define its external service plan in order to define the interconnection with other networks or service providers. The plan will regulate the relation between the company and the external commu-

communications customers and/or external service providers. The external plan will also define to which degree its services will provide full interoperability across service borders and across network borders. Based on the business objectives that define the overall communications performance required by the company, the design of any network must start with an investigation of existing and potential users to produce a listing of the required services. These services must be quantified and broken down to produce a quality of service (QoS) specification. This specification should be expressed by means of the corresponding QoS parameters, such as availability, capacity profile, accepted error tolerance and delay parameters. A requirement specification based on these parameters will make up the basic specification for the network design.

This specification will include, amongst others, the following information:

- Number of services to be integrated in the network
- Class of service specification
- QoS objectives for every service including availability level
- Traffic profiles of every service
- Budget
- Any existing constraint such as:
  - Topological constraints
  - Reuse of existing equipment
  - Technological limitations, etc.

The choice of service-network technology depends on the type of service to be offered by the network and on the service-integration architecture chosen. Realtime services, such as SCADA, telecontrol, and teleprotection, are fundamental to power-utility operations.

Public networks are often dimensioned according to the statistical data traffic and some rough empirical guidelines to make the most of the transmission resources. These methods work well for networks based on noncritical services. For mission-critical services, the design of the network should guarantee availability and serviceability and should comply with a number of characteristics typically required to achieve mission-critical performance, such as reliability and security. This cannot be achieved with a design based on statistical approximation but with one based on firm guarantee that consider the worst case and incorporate cybersecurity measures at the design phase.

The implementation of a network supporting different services requires carrying out a complete project baseline. Some generic data, as well as some service-specific data must be gathered into complete project requirements.

The following are required for the implementation of a network supporting mission-critical services:

- Make an overview of all data applications needing communications.
- Define what applications/users require communications. Make an overview of what resources are in use and their traffic profiles.
- Define service requirements, considering availability, resiliency, and cybersecurity.
- Find the load during the busiest hour of the day and in the worst case, like alarm avalanche.
- Build a table to show how the traffic flows between the various nodes.
- Estimate the capacity needed for routing information and other administrative traffic.
- Dimension links and node capacity so that the average load over any one period never exceeds 50% of the total capacity.
- For critical applications or large networks, add resources to give sufficient resilience.
- Identify maximum end-to-end delays.
- Assess the additional capacity required for expected future growth.

To dimension networks with mixed services, the following information is required:

- The number of traffic sources
- Individual capacity requirements – both average and peak
- The delay requirements of each service
- Availability requirements of each service
- Capacity of routers and switches
- Capacity of transport links
- Error performance of these links
- Availability requirement of each network component.

Once the design process starts, it may be possible that the design requirements together with the constraints applied to the selected network technology do not result in a possible implementation, so a renegotiation of the requirements must be carried out. After the monitoring process, which verifies the correctness of the actual network implementation, the network-management information gives an indication to evaluate whether the network covers the business expectations. The analysis of this information, together with any change introduced at the business level, is used to decide whether the whole process must be started again.

It is widely accepted that the best choice for the design of a network that integrates several services is an

overlaid solution. This approach makes the design process even more difficult to accomplish, since the best solution is the one that combines different networking and transport technologies to obtain the cheapest solution that fulfils the design goals. Although IEC 61850 reduces the number of technologies and protocols, we cannot forget that legacy technologies must be integrated in the same infrastructure, so the complexity will remain until legacy technology is discontinued. Although there are design tools that could help in this process, there are no accepted rules for the design, as it is a multidimensional problem without a mathematical solution. That is to say, it cannot be proved that a network is an optimum design but it can only be stated that it is better than another one. For this reason, the objective of the network design process is to achieve the objectives set in the network design specification.

The main points to be considered are:

- *Scalability.* A well-designed network should be scalable with the potential to grow with increasing requirements.
- *Open standards.* The entire design and the components that build the network should be based on open standards.
- *Availability.* The application requirements assuredly demand a level of availability and reliability of the network, including QoS.
- *Modularity.* An important concept to adopt is the modular design approach in building a network.
- *Security.* Considering security risks and taking care of them in the design stage of the IP network is essential for complete certitude in the network.
- *Network management.* Implementing network management should be integrated into the design of the network from the beginning.
- *Performance.* There are two key forms of performance measures, throughput requirement and response time, which should be considered for the network.

The most important steps of the design process are:

- The preparation of the design specification documents, which gathers information from service requirements, company policies, as well as site locations and asset availability.
- The topology design that will lead to the definition of the network architecture, which implies the selection of the technology of every one of the layers that will form the model.
- Service integration and mapping.
- The definition of the management architecture including that of the management centers.

- Cybersecurity architecture.
- Routing design and setup as a function of the naming and addressing and the service mapping.
- Traffic engineering techniques and tools to assure the service level specified as a function of the topology network architecture and routing design.
- Finally, once the final network design has been obtained, a simulation of some services or a part of the network may be advisable as a function of the technology, network size, and architecture selected.
- Once the design has been fully validated, the network can be implemented.
- Using network management tools, a report about service performance can be obtained to check the need for a network redesign.

The above-mentioned issues work together to achieve the three key features of a mission-critical service: dependability, performance, and security. Altogether they provide service *trustworthiness*, which measures the degree of assurance that a service will perform as expected.

In this context, dependability quantifies service reliance, which is a function of the following factors:

- *Reliability.* Measure the continuity of the service when needed.
- *Availability.* Measure the time the service performs according to requirements.
- *Maintainability.* Measure the capability of maintaining the service during maintenance operations.
- *Integrity.* Measure that the service provides information that has not been altered.

Network design processes should be carried out considering these features.

The design of a network that supports operational services using packet technology requires an accurate evaluation of the latency. End-to-end network delay is composed of:

- *Packetization delay (PD).* This is time delay introduced by buffering of data before transmitting them as Ethernet packets. The more data we pack into an Ethernet frame, the higher the PD will be, but the higher the bandwidth efficiency will also be. On the other hand, we can pack very little protection data into each Ethernet frame so that it can be expedited faster, but in this case, the remaining capacity of the Ethernet frame is wasted and, therefore, a lot of Ethernet bandwidth is required for each communications service.
- *Network delay (ND).* This is the time taken for a packet to cross the network. ND is composed of

signal propagation time ( $5 \mu\text{s}/\text{km}$ ) and intermediate node processing, which includes switching and buffering. When the bit rate of the links is much higher than the traffic delivered by a user, it can be assumed that intermediate nodes operate at much faster rates with reduced buffering and processing times. Buffering delay or queuing delay are normally estimated using stochastic methods that consider traffic profile, queue length, and packet size. Realtime mission-critical services cannot use this statistical approach, since the service should guarantee the performance even in the worst case. Network capacity must be dimensioned to guarantee end-to-end delay in the worst case. Queues in the network nodes must be dimensioned to assure that packet loss probability is lower than required.

- *Jitter buffer delay (JBD)*. JBD is the absolute delay generated by dejittering, that is to say, absorbing delay variations of the network through a buffer. The size of the buffer (in packets) depends upon the amplitude of delay variation that must be absorbed. Needless to say, the larger the buffer, the more it introduces absolute delay. This buffer is used only for circuit-emulation services.

For delay-critical services delivered over IP, pre-established static routes are preferred to ensure end-to-end performance.

Migration and integration of legacy technologies in a new network design is a challenge that may introduce a number of difficulties and even some design limitations. The most relevant aspects that may impact the behavior of mission-critical realtime services are given below:

- *TDM to packet network*. The migration from conventional TDM networks towards Ethernet and IP increases the network's bandwidth efficiency considerably due to statistical multiplexing, flexibility, and resilience. However, it can also be a major source of concern for the control of time behavior. Assembling data packets before transmission and store-and-forward of the packet at each intermediate node causes additional buffering delay, which increases with the packet size and with the number of queues. Dynamic data routing gives rise to delay variation and lack of time predictability. These extra delays are not present in TDM networks, so they should be considered to limit the number of hops and allocate the required bandwidth to control the maximum path latency.
- *Multiservice integration*. Bandwidth efficiency in packet networks is achieved through integrating multiple traffic streams into the same packet net-

work. Queuing scheduling mechanisms are often employed to assure a bounded delay for more critical services. It is important to implement reliable service-segmentation mechanisms to isolate traffic flow and prevent service interference. This issue is sometimes masked through overdimensioning of the network an *order of magnitude*, which reduces the interference effect to a negligible level.

- *Network resilience versus fixed routing*. Network resilience ensures the continuity of service in the presence of network faults, but at the same time, renders indeterminate the routing of communications. Time predictability is generally sacrificed for improved resilience. Traffic streams that are sensitive to delay variations must generally be treated separately with fixed routing.
- *L1/L2/L3 partitioning and topological structuring*. In order to provide adequate time performance to critical services while maintaining bandwidth efficiency, flexibility, cost, and resilience, it is necessary to design the network with an adequate level of *information forwarding* at physical, link, and network layers.
  - Direct transmission connections for best time performance but at low bandwidth efficiency (except for services requiring continuous data flows like SV), flexibility, and resilience.
  - Ethernet switching with virtual networking (VLAN) and priority assignment for fast transfer of information packets.
  - IP routing for maximum resilience and multiservicing.

This way, different network topologies can be obtained for different services over the same telecom infrastructure, leading to different numbers of intermediate nodes at each layer.

### 14.3.9 Network Management

Operational information exchange in power utilities is undergoing tremendous growth, which is leading to an ever more complex and extensive communications network, as described in the previous sections. The corresponding operation and maintenance demand specific processes and tools well beyond the ad-hoc management previously employed in most cases. The new operational communications network also employs a new range of technologies, which, moreover, are evolving much faster than before, and hence, require a great diversity of skills; the field worker can no longer be considered as autonomous and increasingly needs to be supported remotely by a wide range of technology experts. These experts can be located in one central facility or increas-

ingly dispersed across the wide footprint of the communications network. They can be in-house or part of an external contractor or vendor organization. Processes and tools need to be adjusted accordingly. The adopted processes, tools, and field communications systems also depend on the organizational aspects of the power company: fusion or separation of operational and corporate enterprise services, of IT and telecom systems, and of local and wide area communications, as well as the adoption of in-house or contracted operation and maintenance services with specific security issues in the latter case.

To provide a better understanding of the operation and maintenance process for telecom networks and services in power utilities, we will analyze the most relevant points:

*Assessment of service provisioning.* Power utilities in the new liberalized market are constantly in quest for cost reduction. Reliability of operational communications services and their cost of achievement are increasing challenged by alternative service-provisioning modes. It is essential to have an O&M process and associated key performance indicators (KPI) to meet operational service imperatives:

- For fair assessment of alternatives (in-house/external)
- For determination of the market's capability to deliver appropriate O&M services
- For consequent partitioning and interfacing of in-house and external service provision.

These processes contribute to network redesign and optimization.

*Increased scope and change of scale.* New power-system applications are bringing a great number of new communications service requirements in substations and across the grid. These applications range from the control and maintenance of the distribution grid, the integration of renewables, and outage prevention, as well as grid stability control and new system protection schemes. This explosion of communications-based intelligent applications is changing the scope and scale of O&M activities. It is also accompanied by the introduction of new communications technologies and the evolution of the telecom networks necessitating multiple skills and tools to maintain the system.

*New rules.* Another major on-going change concerns external regulating authorities and legislation on efficiency of network operation. The power utility is expected to keep its infrastructure in good operating condition and its operational expenditure, including that related to O&M, needs to be precisely determined and justified in order to be able to reflect it in the price of the electrical power delivered. Moreover, the increased

weight of the electrical power utility as a critical national infrastructure, due to the increasing dependence upon power supply, increasingly results in sanctions and penalties for delivery failure. This, in turn, increases the importance of communications reliability and, consequently, the promptness of the O&M.

*New actors and players.* From an incumbent model of vertical power utility, where all components of the power production and delivery were part of a same company (and, therefore, all related communications were internal), the power industry is moving to a partitioned scheme leading to the multiplication of partners requiring exchange of information and consequent multiplicity of technical issues and solutions. The O&M process must now cover such issues as cybersecurity and protocol compatibility for external communications.

*New workforce constraints.* In-house capability of electrical power utilities is shrinking due to an aging workforce, downsizing policies and economic constraints of organization, multiplicity of technologies, and technical issues due to the fact that legacy technologies persist, while new ones are introduced into the network, and the difficulty to attract and maintain appropriate skills. The multiplication of technical issues and solutions, the fast rate of change of technologies, and the fast turnover of technical teams both in-house and outsourced, is leading to a reduced grasp of the network and its potential problems. It is increasingly important to have a formal and specified manner to operate and maintain the network.

*New tools and process automation.* Mainstream telecom and the IT world is proposing a wide range of tools to the utility telecom networks for automating the processes of network and service management. These tools are designed and optimized for public service providers and enterprise networks. Rather than modifying O&M processes according to market tool capabilities, an assessment of O&M practice in the operational context and its required evolution allows the implementation of more suitable and cost-effective tools according to operational requirements.

*O&M cost.* The growing complexity of telecom networks is increasing the cost of the O&M process, and tools are becoming a relevant cost factor in the full life-cycle cost of the system. Proper modeling and implementation of O&M service allows cost optimization.

The above-mentioned issues show the relevance of O&M functionality. In fact, O&M must be considered, planned, and implemented as another service of the telecom network. A network supporting mission-critical services cannot guarantee performance without a well-planned and implemented O&M service. The rest of this section will describe the minimum infrastructure required to implement an O&M service.

### Management Architecture

The management services are organized into a four-layer hierarchical architecture by the ITU-T, as described hereafter. Even if the four-layer – business, service, network, and element – management-layer model (BSNE-ML) has been devised for telecommunications network management services, the conceptual model can be adopted for other information related infrastructure management in the power-utility environment.

*Element management layer (EML).* This layer implements the management of individual equipment. It covers the different tasks related to the maintenance, administration, logging of usage, and statistics of the events recorded from this equipment.

*Network management layer (NML).* This layer implements the management of a group of interconnected equipment performing a particular task. It can be assimilated to system management with end-to-end overall functional and performance requirements. The task of this management layer is, therefore, to interact with each component of the system, whether aggregated together or geographically dispersed, in order to control and coordinate their operation for the proper functioning of the system, to assess the utilization of the system by authorized users and to reconfigure it if necessary in order to fulfil the system's requirements.

*Service management layer (SML).* This layer manages a service delivered to a group of users, e.g., switched voice service or SCADA service, through the monitoring of one or many different systems or networks. It manages the interfacing between the service users and service providers through personalized service availability indications, the measurement of the quality of service, the monitoring of service level agreements taking necessary measures in order to meet the pre-established SLA, and the billing of the services.

*Business management layer (BML).* This layer manages business aspects, which may comprise multiple services, e.g., operational communications, third-party communications, corporate IT infrastructure, or control center facilities, with overall management and/or enterprise responsibility. Business-oriented statistics for system and human resource planning and budgeting, and for the elaboration of executive master plans are typically at this layer.

In a similar manner to the four-layer BSNE management service architecture, the model for management functions to be performed was derived from the world of telecommunications and adapted to the requirements of the power utility's information infrastructure management. The fault, configuration, accounting, performance, and security model (FCAPS) covers the different functions that may have to be implemented for information infrastructure management:

- *Fault management (FM):*
  - Alarm collection and processing
  - Fault-event indication to users
  - Trouble ticketing
  - Maintenance organization and fault escalation
- *Configuration management (CM):*
  - Addition, suppression, and modification of equipment, systems, and channels
  - Provisioning and configuration of new services
- *Accounting management (AM):*
  - Ticketing and billing for the utilization of equipment, systems, network, or services by different categories of internal and external users
- *Performance management (PM):*
  - Monitoring of performance parameters for each service, system, or equipment
  - Statistics and trends for planning purposes and proactive measures
- *Security management (SM):*
  - Access control to facilities, services, devices, etc.

A nonexhaustive list of management functions organized according to the service architecture described is presented in Table 14.7.

Since the implementation of O&M services requires a system view, a management center is required to gather and process network and element information. The network management center (NMC) constitutes the core entity for day-to-day operation, administration, maintenance, and security monitoring of the network, medium-term extension and enhancement planning, as well as an advisory entity for long-term and strategic decision-making through a synthetic and statistical view of the information network, systems, and services.

The technological evolution has widened the scope of the network beyond the limits of telecommunications equipment. The information exchange system includes all communicating entities from the substation IED to the different management platforms of the power utility (power-network management, energy management, enterprise applications, etc.). A more general concept of integrated management information can, therefore, become attractive. In this case, the NMC need not be a single geographical entity but a distributed platform serving the different functional layers of the infrastructure and the different functions in the utility organization.

The following tasks are to be performed through the NMC:

- Control, operate, and manage in a unified manner all elements constituting the telecommunications network including auxiliary systems.

**Table 14.7** Management functions

	<b>Fault</b>	<b>Configuration</b>	<b>Accounting</b>	<b>Performance</b>	<b>Security</b>
Element	Maintenance, supervision, spare management	Parameter setting and recording of equipment, change management	Monitoring of equipment usage	Equipment perf. monitoring, condition monitoring, preventive maintenance	Equipment access monitoring, password management
Network (system)	Network management, end-to-end system analysis,	Group configuration of multiple elements constituting a system/network	Billing of the usage of a system or a network	Network or system performance monitoring, QoS monitoring	System and site-access monitoring
Service	Service availability, QoS monitoring, service impact analysis	Service provisioning, configuration of new services into the network	Billing of voice and data processing, storage and exchange services	Service monitoring	Operational and corporate IT platform security management
Business	Fault statistics, OPEX estimation, SLA monitoring	–	Utility-wide internal IT service billing	Service contract management, SLA monitoring,	Utility-level security engineering

- Supervise, locate, and isolate faults in the system through monitoring of the different elements in a permanent manner (24 h/7 d).
- Supervise IT platforms (servers, workstations, LAN components, etc.) associated with the operation of the system.
- Track all fault management tasks through to conclusion, including restoration of services, replacement of faulty units, return of faulty units to the manufacturer, and restoration of spares to the required level.
- Assign maintenance and problem-solving to appropriate staff, who may be geographically remote and dispersed, or even to an external contractor.
- Supervise network, system, and data security against cyber-attacks, intrusions, and viruses.
- Monitor the performance of the different elements through the measurement of traffic, loss rates, service times, and overall delays in the system. In particular, switching networks and IP infrastructure must be monitored.
- Determine the service impact of infrastructure faults and take appropriate action.
- Produce business-oriented dashboards and management reports with dedicated synthetic information for maintenance management, overall system management, network engineering and planning, cybersecurity management, power-system communications management, and dedicated service-provider business management.
- Perform asset management and inventory activities for the whole system and produce up-to-date network documentation available online to all parties concerned.
- Perform network and system documentation including physical and logical resource management. The documentation must include enough information to identify:
  - Channels multiplexed over a certain higher-level container, through certain equipment or over a certain communications medium.
  - Processes using a particular processing resource.
  - Services carried over a certain network resource.
  - Users affected by the failure of a particular resource.
- Perform directory services, IP address management, priority management, and user inventory functions in general.
- Perform service-oriented and business-oriented management tasks for both internal (the utility) and external customers. In particular, provide customer relationship management (CRM), including service usage monitoring, billing, and service notification for each customer and each category of service, as well as service-level agreement (SLA) monitoring for each customer contract.

### 14.3.10 Business Continuity Management

An extraordinary situation or disaster occurs when the nature of an incident is such that it actually interferes with or poses a significant risk to the operation of the power system and affects critical business objectives. Business continuity management (BCM) provides the availability of processes and resources in order to ensure the continued achievement of the critical objectives.

The telecom infrastructure and service must, therefore, be implemented to:

1. Tolerate the loss of infrastructure in a node, in a link or in a region
2. Tolerate the loss of mains power supply for a relatively long duration
3. Redirect all substation communications (SCADA and voice) to a backup control center when required

(e.g., in the case of destruction or major damage of the control center)

4. Include fast deployment communications systems (e.g., radios, satellites) to implement temporary communications links and networks to replace the damaged or nonoperating facilities or to constitute temporary relays for the EPU's restoration staff
5. Provide specific information exchange facilities for disaster warning, staff coordination, and recovery team communications.

It is important to distinguish between faults and disasters. Operational services should be *fault-tolerant*, which implies that the service is maintained without any degradation of its performance in the event of a fail of a single component, e.g., one link, one node, etc. In the event of a disaster with massive failures, some services may be discontinued and others maintained with a reduced performance, which should be enough to support recovery system operations.

Disaster recovery is not a concept specific to telecommunications but a general plan covering all aspects of the power utility. As such, if telecom assets, infrastructure, and staff are located within the perimeter of utility's premises, then they are integrated into the utility's disaster recovery and business continuity plan (DR/BCP). However, if telecommunications services are provided by a different entity, with staff and assets at other sites, then the coherence of the telecom service provider's DR/BCP with that of the utility must be assured and periodically audited. In the former case, DR/BCP is a very important input for telecommunications network design and must be considered during the entire network life-cycle to verify its feasibility and avoid common mode failures.

Business continuity planning (BCP) is based on:

- Maintaining, resuming, and minimizing the impact of a disaster and recovering the business. It is more than a recovery of the technology.
- It is based on business impact assessment (BI) and risk assessment.
- Regular validation testing.

The disaster recovery plans are generally written to the base of the recovery after a major event: the loss of a plant through fire or flood or the loss of computer or telecommunications systems across the enterprise.

The goal of BCM is to minimize the effects of a disaster with preventive actions. It seeks to establish a culture within organizations to generate greater resilience to ensure continuity of service delivery. The BCM process is defined on different levels within the organization:

- *Strategic level.* Policies, scope, and preconditions are defined here. The process is formalized, and its organization is agreed upon. Responsibility and ownership of BCM is part of this level.
- *Tactical level.* The decisions taken at the strategic level are the framework for the structure of BCM.

Tactical level responsibilities include risk assessments process and the definition of requirements and guidelines. The operational level is responsible for the implementation of predefined tactical actions in order to assure the agreed-upon service levels.

### Evaluating Threats to Critical Activities

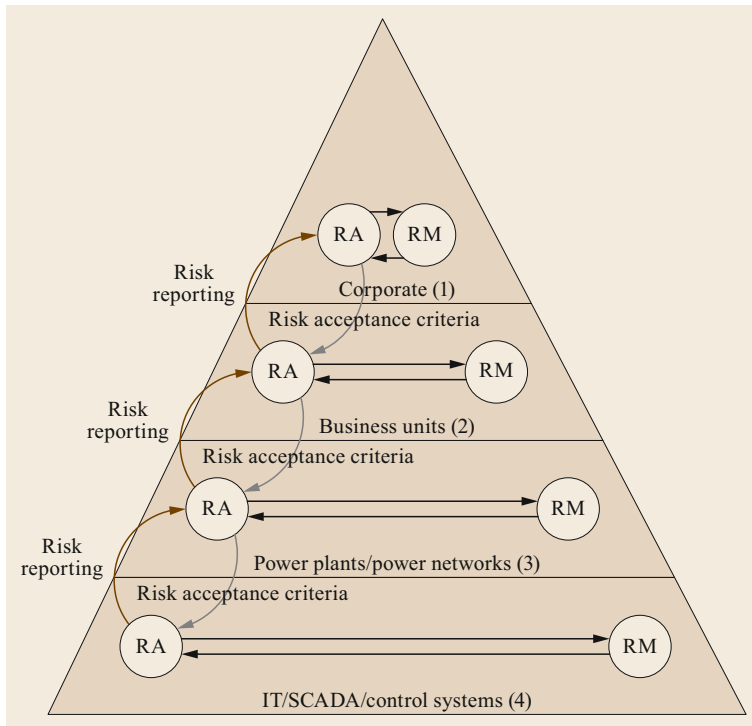

Telecommunications services can be negatively affected by many different threats of different origins, whether natural or intentional acts. Recovery mechanisms must be defined in order to cope with these threats and minimize their impact on the overall service performance. The definition of a recovery procedure requires a risk assessment to be carried out to determine the source of threats and their impact on operational service performance. In fact, this risk assessment study should be part of a company risk assessment process in order to correlate the risk of ICT infrastructure with company operations.

The risk assessment process relies on two inputs, the estimated likelihood of every type of threat and internal vulnerability assessment. The result is a matrix that provides information about the likelihood of a risk and its impact compared with the cost of mitigating it. The company should make a decision about the level of risk that can be accepted, so this will determine the measures to be taken to overcome and minimize the effect of those threats.

Threats faced by a utility can be disasters, failures, or other disruptive events; the most common are included in the following list:

- Natural disasters like floods, earthquakes, rainstorms, typhoon, snowstorm, landslides etc.
- Fire
- Power failure
- Terrorist attacks
- Organized or deliberate disruptions
- Theft
- Major system and/or equipment failures
- Human error
- Cyberattacks or computer viruses
- Legal issues
- Worker strikes.

One important outcome of risk evaluation is the correlation between generic company risks and their effect

**Fig. 14.20** Risk management and risk assessment model. (Adapted from [14.4])

on telecommunications infrastructure. In order to thoroughly analyze every risk and make the right decision in terms of risks accepted and cost of mitigating other risks, a risk management framework has to be used as shown in Fig. 14.20. Layering risk assessment and management process is very important to include every aspect and detail of different functions and technologies included in the company.

The four layers in Fig. 14.20 show the hierarchical levels of the operation's part of a typical power utility. Every level of the organization or layer must carry out its own risk assessment process, inform the upper level, and manage its risks according to the directives set by the upper level. These risk-management objectives are related to the risk-management policy of the company. Each level of the organization has a different set of objectives, as it is exposed to different sets of risks. Nevertheless, it is important to take into account that there are also risk dependencies between levels, so in order to determine global company risk exposure, these dependencies should be considered. On the other hand, these dependencies influence risk assessment and management of a particular layer, since dependencies with other layers must be taken into account. Due to these dependencies, a common framework and language must be used for the identification and management of risks.

The business continuity plans of power utilities should consider the effect of the disruption of critical activities due to external or internal threats. To carry out

this analysis it is important to consider the resources required to support these critical activities and, thus, consider specific threats and their particular vulnerabilities in order to achieve a comprehensive risk assessment. The risk-assessment method chosen depends on the organization, and it is important that the approach is adequate to meet the organization's needs and its own context, also politically, in terms of legislation and geographical location, considering specific risk factors such as flooding, earthquakes, etc. It is important to consider that a BCP must be managed and maintained. The use of new technologies requires a detailed risk analysis and may require the reformulation of the BCP. Some of the more relevant aspects of business continuity management for a power utility are the following:

- Risk and vulnerability analysis. Risk assessment must be updated regularly to identify new vulnerabilities introduced by changes in the implementation of services and system reconfiguration.
- Business impact analysis.
- Response strategies.
- Planning documentation and maintenance.
- Staff training and awareness.

BCP should consider technology failure modes, common failure modes of different systems using the same technology, as well as the risks introduced by cybersecurity attacks, which may have a much higher impact than a natural disaster.

## 14.4 Cybersecurity

Information security is a very important issue affecting the entire information and communications system. It is treated as a full end-to-end process through an appropriate security policy identifying security domains, taking measures to mitigate risks, and devising periodic audit schemes to assess the effectiveness. The scope of information security must cover the system specification phase to the dismantling phase.

### 14.4.1 Basic Principles

This section focuses on the influence of cybersecurity on operational services and its related information. A cybersecurity attack has a direct impact on service reliability or, in a more generic way, on the reliability of the operational system.

The design of a mission-critical operational system is implemented with an architecture and redundancy to be tolerant to a single failure. Up to now, the effect of a cybersecurity attack was not considered in the evaluation of system availability, but this kind of attack may have a much wider influence than device faults. Some types of attacks can affect the reliability of an operation without a total breakdown of the system. Consequently, cybersecurity is becoming a capital aspect of operational system design. Large efforts have been made by the international community to develop standards and recommendations to better protect operational systems.

One aspect that cannot be denied when analyzing the cybersecurity of operational services is its specificities and the big differences that can be identified in comparison with that of information technology systems. Table 14.8 shows the most relevant differences.

In addition to these differences, there are other differences to consider:

- *Architecture.* SAS architecture is rather different from office or data center architecture. In an office, there is a limited number of servers and a large number of hosts working as clients, whereas in a SAS, every IED is a server, and there is only one client, the SAS controller. Furthermore, in an SAS, con-

figuration is static, so there are no DHCP or DNS servers but in an office configuration it is dynamic.

- *Source of attacks.* Office protection from cyberattacks is designed to prevent attacks from outside the LAN. Nevertheless, attacks to a SAS LAN coming from outside the substation are extremely unlikely, as there the connection comes from the control center, which is the most secure domain in a power utility. Attacks to SAS may come from inside the LAN because of uncontrolled or unauthorized work and from remote access. In fact, remote access is the most critical connection from the point of view of cybersecurity. Its protection must be thoroughly analyzed to achieve the required protection level.
- *Types of attacks.* Hosts used in office environment are prone to suffer from virus and malware attacks, whereas IEDs are much less susceptible to these types of attacks. IEDs may suffer other attacks, such as denial-of-service, unauthorized access to gain control of a function or change settings that may produce considerable damage.
- *Configuration principles.* Due to the above-mentioned issues, security configuration must be implemented in a rather specific way in order to protect from internal attacks and from specific attacks that affect the availability and reliability of the SAS. These principles are described by the IEC 62351 family of standards.

Attacks to operational systems or functions are not focused on copying or stealing information but on blocking or gaining control of operational functions, such as control to operated breakers or generators and protection to disconnect loads.

For an attack to be successful, it has to exploit a vulnerability of one or several IEDs. Vulnerabilities may be brought about by several reasons:

- *Poor software quality.* Errors and weakness in operating system and applications.
- *Legacy devices.* Legacy devices have well-known vulnerabilities that cannot be avoided, since these

**Table 14.8** IT versus OT differences

Topic	Information technology	Operational systems
Basic goal	Information	Maximize process availability
Primary risk impact	Access to information	Availability of operation
Security focus	Centralized. Security of servers, Internet access	Decentralized. Security of P&C functions. Minimize Internet access
Availability	95–99%	99.9–99.999%
Patch management	Regular updated. Service disruption	Selective updates. Minimize service disruptions
Mode of operation	Interactive, transactional	Interactive, real time, event driven
Reliability	Depends on staff	Depends on system design and IEDs

devices cannot be updated due to lack of software support from the vendor.

- *Configuration mistakes.* Incomplete configurations may let backdoors be opened or disable protection mechanisms, thus facilitating attacks.
- *Password management.* Changing default passwords, using nonstandard ones, and managing them properly helps to protect from *dictionary* attacks that may gain control of IEDs.
- *Documentation.* Incomplete or errored documentation may lead to operation and maintenance mistakes that are considered as nonmalicious internal attacks.

In the above list, we can notice that technology is not the only factor that determines the degree of protection. In fact, cybersecurity depends on the balance of three major factors:

1. *Technology.* Cybersecurity aspects related to technology involve not only the equipment required to protect operational systems, such as firewalls, but also the proper configuration of every IED. Configuration plays a capital role in achieving a good protection level.
2. *Procedures.* An organization must be aware of cybersecurity risks and, consequently, cybersecurity measures should be included in every operational procedure. Furthermore, specific procedures for cybersecurity management, like passwords, access rights, or certificate management, must be defined.
3. *Human resources.* Company staff need to be trained on cybersecurity. Responsibilities related to cybersecurity must be clearly stated. Security policy and procedures must be known and used by the staff.

To protect an operational system in a cost-effective way it is necessary to carry out a vulnerability assessment analysis. Knowing the vulnerabilities is the starting point of safe system design. Not all the vulnerabilities may be exploited if a corresponding vector attack cannot be used in the operational environment. For instance, if a vulnerability can only be exploited using an email, and this service is not available in our SAS, there is no risk associated with this particular vulnerability.

The following step is to determine the risk introduced by every vulnerability. The risk level is a function of the likelihood of an attack able to exploit this vulnerability. The impact of a successful attack on the availability of the system and on business operation should also be considered. Once risks have been identified and quantified in terms of probability, we produce a risk matrix that will help us to determine how cyber-protection is to be implemented and configured in order to reduce

the probability of a successful attack and assure that its impact on the system will not reduce system availability and reliability below performance objectives.

## 14.4.2 International Standards

There is a large number of standards related to cybersecurity. We will focus on international standards developed for the protection of operational systems. Figure 14.21 shows a hierarchy of cybersecurity standards. The most generic family of standards is the ISO/IEC 27000 series that deals with the implementation and management of cybersecurity in a company. This standard should be applied in any type of organization and has no specific requirements for operational systems.

*IEC 62433* is a series of standards that deals with the cybersecurity aspects of industrial automation and control systems, including power-utility automation systems. It comprises a total of 13 volumes that are grouped into four parts:

- *General part.* This includes generic concepts, conformance metrics and product development requirements.
- *Policies and procedures.* This comprises security management considerations, implementation guide, patch management, and security requirements for service providers.
- *System aspects.* This includes security technologies, risk assessment, and system security requirements.
- *Components.* This includes product development, life-cycle requirements, and security requirements for components.

This standard provides an overview of cybersecurity in the context of operational applications. The role of the three main factors required to build a secure system (procedures, persons, and technology) are presented. Their associated functions along the system life-cycle are developed.

The security domain and the zone design are also relevant contributions of this standard. In this context,

IEC 27000	• Cybersecurity management system
IEC 62443	• Cybersecurity of industrial control systems
IEC 62351	• Cybersecurity of operational systems and control centers
IETF	• Internet standards

Fig. 14.21 International standards

a security domain is a set of devices and applications that share the same security policy. Domains are divided into security zones. A security zone gathers elements that implement one or several functions and are protected by a set of cybersecurity measures that guarantee information confidentiality. In the context of operational systems, security zones are associated with SCADA or SAS functions.

A security zone is defined by:

- Scope: number and location of devices
- Associated risks due to vulnerabilities and threats
- Functions inside the zone
- Access-control methods and rights
- Technologies allowed to implement the zone.

Zones interchange information using *conduits*. A conduit is a communications channel protected by a set of cybersecurity measures. Conduits are treated in a similar way to security zones. Vulnerabilities are associated with telecommunications technologies, and it is usual to forbid some technologies, depending on the type and criticality of the information carried by this conduit. For the technologies allowed, protection measures should be specified, it can range from segmentation using tunnels to encryption.

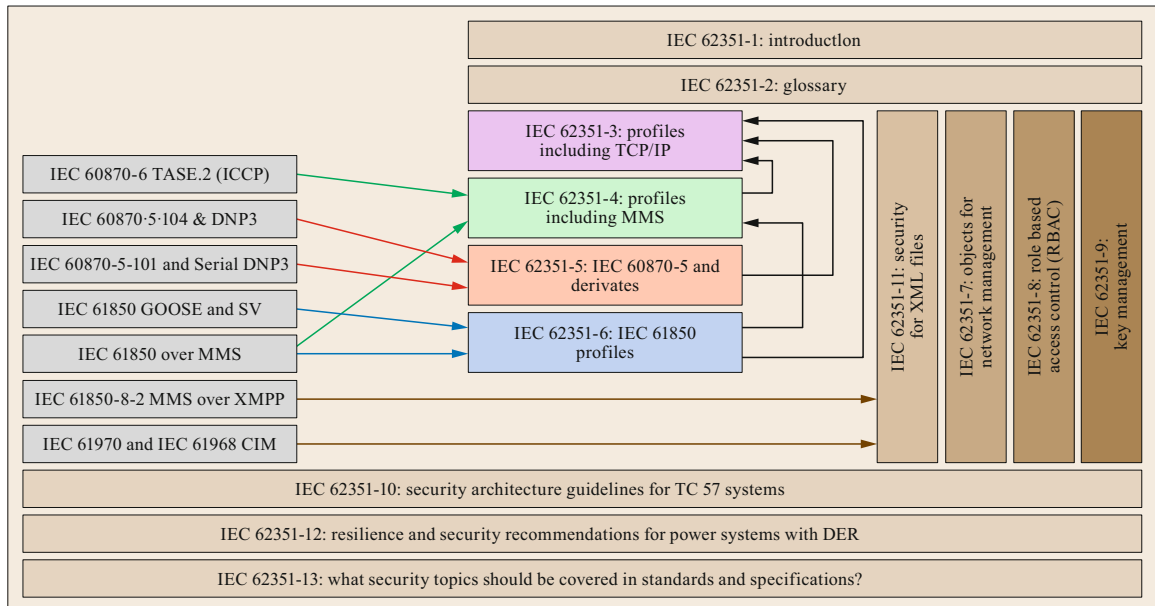

*IEC 62351* is a series of standards focusing on the protection of the SCADA domain. This family of standards provides a clear and simple way of protecting the SCADA infrastructure against almost any type of attack.

The advantage of IEC 62351 is the use of existing resources to implement cybersecurity protection measures. The standard focuses on the key security measures:

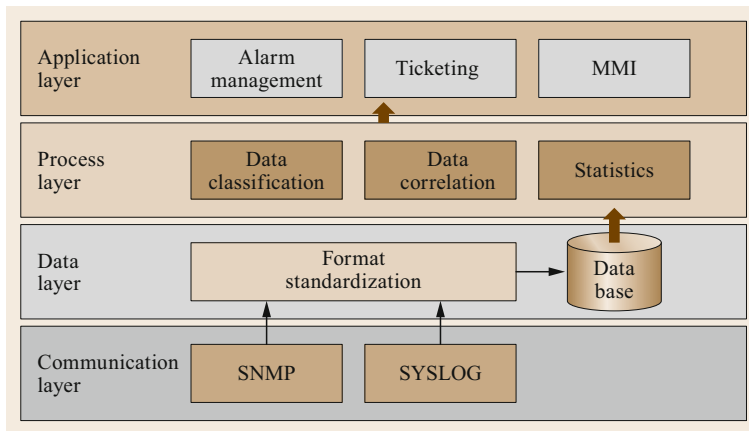

- *Authentication*. This is the most important cybersecurity function. There is no security without authentication. It is required to verify a user's identity and prevent nonauthorized access.
- *Confidentiality*. This has to be used when the communications channel is not reliable to prevent eavesdropping, listening, media playback, etc.
- *Auditing*. It is very important to detect security anomalies and to prevent denial of action or false claim of action.

These functions are implemented using Internet standards or recommendations. Internet standards are prepared by the Internet engineering task force (IETF) that produces a *request for comments* (RFC), which is a document that specifies protocols, formats, and methods to be used to implement services over the Internet; RFCs may become Internet standards, but even in this early stage, they are being used by other standardization bodies.

As mentioned before, access control and use control are the most important cybersecurity functions. IEC 62351 has standardized the role-based access-control (RBAC) method to implement this functionality. IEC 61850 has also adopted this method, which is now

**Fig. 14.22** IEC 62351 architecture. (Adapted from IEC 62351-1)

**Fig. 14.23** Cybersecurity control-center architecture

mandatory for this technology and will become the most common access control method for power-utility operational functions in the near future.

When a person or an entity wants to use a service protected by RBAC, it needs to specify its identity and the role it wants to play in its interaction with the service. This provides a higher level of protection, as the user needs to have a valid identification, and the assigned role limits the possible actions that the user can do within the system. Identity, roles, and properties of RBAC can be expressed using the XACML language that generates XML security configuration files, the format of which is defined with an XML schema.

### 14.4.3 Cybersecurity Control Center

Operational systems can suffer sophisticated attacks that are not addressed to a single IED or function but to a large number of them. These types of attack aim to destroying assets or produce a blackout. These distributed and sophisticated attacks cannot be detected or prevented from a single point of the network. A global view is necessary to detect a collection of anomalies,

which, once correlated, can identify these types of advanced attacks. This dispersed information must be gathered in a cybersecurity control center to be able to process it and produce indications and alarms.

Figure 14.23 shows an example of the functional architecture of such a type of control center.

Information is gathered using standard protocols, such as the Simple Network Management Protocol (SNMP) or syslog. This information is converted to a standard format and stored in a database for later processing. The process layer is where intelligence is implemented to detect sophisticated attacks and produce statistics and reports for auditing purposes. Finally, some applications present the information to the user and generate alarms and working orders.

The cybersecurity control center is a very important component to support active security auditing, which is a key component of a secure system.

Depending on the number of devices connected in the operational network, the size of the cybersecurity control center may range from a single host to an architecture made of several servers that may be physical or virtualized.

## 14.5 Smart Grid

The smart grid is the evolution of the traditional power system based on a hierarchy of bulk generation power transmissions and distributions. This new architecture uses advanced ICT technologies to connect dispersed generators and consumers in an optimal way to obtain economic efficiency.

The most relevant objectives of a smart grid are:

- To support new business models to promote the presence of active users to make the most of electricity.
- To facilitate the use of renewable energies, improving energy efficiency.

- To provide the required level of resilience complying with the established reliability objectives.
- To facilitate the integration of legacy technologies and the migration of existing systems.
- To ensure interoperability to support multivendor solutions.
- To use scalable and modular technologies able to cope with the much higher volume of information and able to adapt to technology evolution.

The smart grid is a very good example of a totally distributed grid, whose working principle is based on ICT.

Consequently, this section is focused on ICT-specific aspects of a smart grid, since this is the key component to implement the *smart* part of the grid.

There are three key factors to implementing a reliable smart grid:

1. *Telecommunications infrastructure.* The deployment of a private telecom infrastructure is not economically feasible, so public telecom services need to be used together with already existing private infrastructure. The fact that public services do not comply with mission-critical services requirements, introduces a drawback that can only be solved by re-designing critical applications and accepting some limitation in the reliability of those critical services.
2. *Applications.* New applications are required to support new operational decentralized principles, for protection, control, and other new functions such as demand response, etc. A large number of new applications is planned and will be gradually deployed to allow the interaction of the power company with dispersed energy consumers, producers, and storage facilities. These applications comprise smart metering at the energy customer's point of delivery, but also the control of electrical loads and distributed power generators, public facilities, such as electrical vehicle chargers and public lighting, as well as industrial and commercial/residential microgrids. This mix of revenue management and operational information exchange is still under research.
3. *Cybersecurity.* Smart grid cybersecurity has to face very important challenges that will require a thorough study starting from the specification phase. The key aspects are:
  - The use of public unreliable communications channels, such as wireless links, channels provided by public telecom operators, and the Internet.
  - The need to protect critical assets located at public sites and, therefore, without physical protection.
  - Extremely large and distributed infrastructure with a large number of different types of IEDs.
  - Public services that imply the interaction of customers with some devices and services using the Internet or directly connected to some IED.

Figure 14.24 shows the smart-grid architecture as defined by [14.5].

Two important aspects must be noted: the model covers all the actors involved in a smart grid distributed into domains and zones. The second and most important aspect is the definition of interoperability at every one of the layers. At the component, the communications and

information layer is achieved by using IEC 61850 standards, and the upper layer is defined by the smart-grid user interface specified by the standard IEC 62939-1.

There are three technologies required to implement a smart grid: the common information model for the implementation of control centers, IEC 61850 for substations, generating plants and field devices, including distributed-energy resources (DER) and the IEC 62351 to provide cybersecurity protection to the whole system. As has already been mentioned, these technologies used Ethernet as the physical access interface and IP as the network protocol.

The design of a smart grid should consider most of the issues already developed in the previous sections. The reader is referred to Sect. 14.3 for topics related to telecommunications network design, IEC 61850 and cybersecurity.

ICT challenges that smart-grid design are faced with are related to the following issues:

- *Scalability.* The expected massive deployment of the smart grid requires scalable solutions and technologies. Nevertheless, this may be a drawback, as high-end technology may be too expensive to justify the initial investment. The use of less-scalable solutions may require frequent retrofitting, which may put the return of the investment at risk.
- *Network management.* Management and operation of a heterogeneous telecom network requires complex management procedures that should be implemented using management centers able to cope with many different technologies as well as the use of externally provided services.
- *IT governance.* The smart grid involves many different applications, some of them devoted to grid operations and others to support customer interaction, and even, in the near future, some IT infrastructure used to provide services to third parties. These issues together with the growing virtualization will require new IT-governance principles.

Although many successful experiences have already been deployed, the complete migration from the *traditional* power system to a new smart-grid architecture will take several years. There are a number of new standards – most of them already approved – that will pave the way to this evolution, thus providing the necessary guarantees of feasibility of this new approach.

The following paragraphs shows the most relevant standards related to smart grids:

- *ISO/IEC 15067-3.* Smart grid application specifications for demand response, distributed-energy resources, and local storage. This standard specifies

**Fig. 14.24** Smart-grid architecture. (Adapted from IEC TR 63097)

a framework to align residential needs to available supplies.

- *ISO/IEC 15045 series*. Gateways to link a home network to the smart grid.
- *ISO/IEC 14543 series*. Residential communications architecture, protocols, network configuration, and network management that carry smart-grid signals.
- *ISO/IEC 29145 series*. Wireless beacon-enabled energy-efficient mesh networks.
- *IEC 61400-25 series*. Communications for monitoring and control of wind power plants. It is considered an expansion of IEC 61850, as it uses the same data modeling, ACSI services, and the same protocol stack.
- *IEC 61588/IEEE 1588*. Precision clock-synchronization protocol for networked measurement and control systems.
- *IEC 61850-90-7*. Object models for power converters in distributed-energy resources, as mentioned in the previous sections.
- *IEC 61850-90-8*. Object models for electric mobility, as mentioned in the previous sections.
- *IEC 61968 series*. System interfaces for distribution management, as mentioned in the previous sections.
- *IEC 61970*. Energy-management system application programming interface, as already mentioned in the previous sections.
- *IEC 62056 series*. Data exchange for meter reading, tariffs, and load control. This standard defines methods, object identity, object modeling and services, communications, and media-access methods to establish instrument interfaces.
- *IEC 62325*. Framework for energy-market communications.
- *IEC 62351 series*. Data and communications security. This series of standards identifies threats to operational systems, including smart grids, and specifies protection methods.
- *IEC 62448*. Power-line communications systems for power-utility applications. Establishes the planning of service and performance parameters for operational requirements.
- *IEC 62746*. System interface between the customer's energy-management system and the power management system. It defines system interfaces, profiles, and communications protocols.
- *IEC 62872*. System interface between industrial facilities and the smart grid.

- *OASIS Energy Interoperation 1.0*. Information model and messages to enable standard communications of energy interoperation, such as demand response events, realtime price, etc.
- *OASIS Energy Market Information Exchange*. Defines an information model and XML vocabulary for the interoperable and standard exchange energy-market-related information.
- *OASIS WS-CALENDAR*. Information model and XML vocabulary for communications schedules generating orders.
- *IEEE P203.5 Smart Energy Profile 2.0*. Standard-based application profile for use in smart-grid home-area networks (HAN) based on IEC CIM (IEC 61968) using the IP Protocol.
- *IEEE 1547.3*. Guide for monitoring, information exchange, and control of distributed resources interconnected with electric power systems. This standard provisions information modeling and case analyses.

## 14.6 Outlook of Future Technologies

The massive deployment of the smart grid, which implies the integration of distributed-energy resources, most of them based on intermittent generating units, will require the use of new technologies that allow new and more advanced services to be supported.

Operational services must maintain or even improve their performance. Although the technologies to come will introduce a number of advantages, they will also present a number of challenges. The most relevant changes that must be considered are:

- *Virtualization*. Telecommunications and virtualization of applications is becoming common practice for the implementation of IT solutions. It brings many advantages and cost reduction. Nevertheless, for mission-critical operational applications, and this is related to telecom services, these solutions bring about many doubts about their reliability and availability, as well as their lack of transparency on how the service is being implemented. Performance assessment is not a guarantee, since service configuration and implementation modes can change without the user being informed. Not to mention cybersecurity concerns, as it is not possible to know the level of protection offered by the service. Internally provided virtual services may be a feasible solution, as power utility can verify which technologies are being used, as well as the proper configuration to prevent a loss of service reliability.
- *Clouds*. Clouds are another way of service virtualization that present similar advantages and drawbacks to those mentioned in the previous paragraph.
- *Big data*. The massive and exponential growth of information gathered by new intelligent devices and new applications will require the use of big-data technology to extract useful information. This information will be used to improve the efficiency and performance of the power system.
- *Wireless communications*. Last-mile communications technologies are evolving towards wireless solutions. Consequently, wired-access interfaces will be used less and less in the future. The transmission capacity of wireless technologies is continuously growing, putting wired solutions aside. These technologies provide great flexibility and mobility and simplify installation procedures, but wireless service reliability is lower than wired solutions, and, in many cases, is not suitable for mission-critical operational applications. The use of wireless solutions has to be thoroughly studied due to their higher latency and lower service reliability.
- *Cybersecurity*. The use of standard and opened technologies enables new attacks. The secure deployment of new technologies requires implementing cybersecurity-protection methods using an engineering approach. That is to say, assessing new vulnerabilities and implementing the right protection measurements. New tools and technology are being implemented to facilitate this new engineering process.

If we focus on telecom technologies, the transmission capacity of fiber optics is far higher than that required for any operational or added-value application. On the other hand, new network technologies will need to be used to cope with the scalability requirements. Among other solutions software-defined networks (SDN) are expected to be the next technology wave.

SDN is a set of techniques used to facilitate the design, delivery, and operation of network services in a deterministic, dynamic, and scalable manner. SDN is a technology currently used in data centers because of its flexibility, scalability, and virtualization.

The SDN architecture is an evolution of traditional connection-oriented networks, that is to say, there is a control plane that set ups connections – or in this case,

data-flow paths – and a forwarding plane that switches packets through pre-established paths.

Forwarding and control planes are decoupled and defined using abstract definition methods. Due to this, applications can specify services and control a network dynamically, accordingly using implementation criteria that better suits the application requirements. The separation between control and forwarding planes is implemented with the goal of reducing complexity and providing flexibility to allow for a faster innovation.

SDN includes four functional layers:

- *Device and resource functional layer.* The resources of the control and management planes of devices are mapped to control and management planes using abstraction techniques. The forwarding plane, which implements the *data path*, is responsible for handling and forwarding packets. It provides switching, routing, packet transformation, and filtering functions. The operational plane controls the operational state of the network device, including the information of the device.
- *Control layer.* The control plane can be distributed among SDN nodes. Its main functionality is the configuration of the forwarding plane by setting the rules to handle network packets. Communications between control-plane entities is implemented using gateway protocols, such as the Border Gateway Protocol (BGP) or other protocols, such as the Path Computation Element (PCE) Communications Pro-

ocol (PCEP). Control-plane functionalities usually include:

- Topology discovery
- Maintenance services
- Packet route setup
- Path failover mechanisms.
- *Management layer.* The management plane is centralized. It implements network-configuration functions as well as fault and monitoring management.
- *Network services layer.* This provides a service-abstractions interface to be used by applications and other services.

When the control plane is centralized, the OpenFlow Protocol is used to communicate the control plane with the forwarding plane.

OpenFlow defines the protocol used by a centralized network controller to control OpenFlow switches. Each OpenFlow-compliant switch maintains one or more flow tables, which are used to perform packet lookups. Tables define packet forwarding actions.

The use of SDN to support operational applications must be assessed. It offers many advantages, but availability, reliability, and implementation architecture must be checked in order to verify the fulfilment of mission-critical operational application requirements.

# Distribution Systems

Nikolaos C. Koutsoukis , Pavlos S. Georgilakis , George N. Korres , Nikos D. Hatziargyriou 

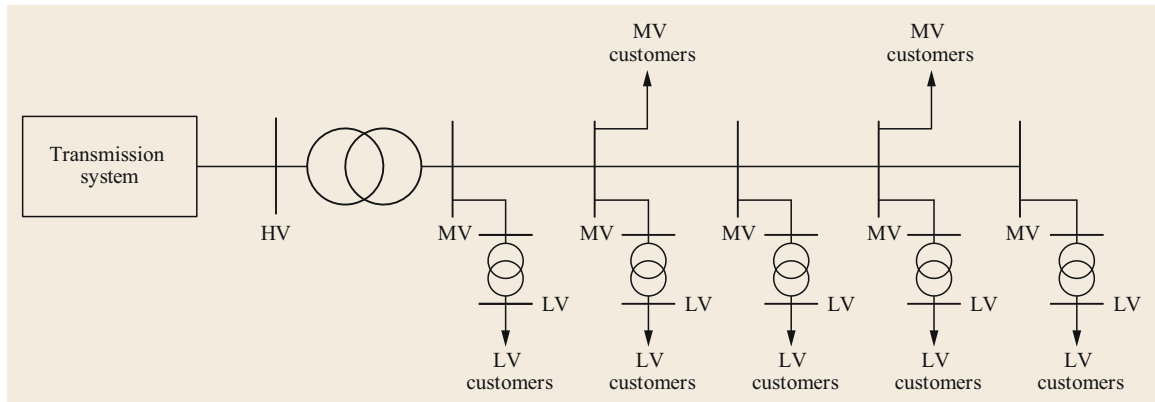

This chapter presents an overview of power distribution networks. The description of the main components of a distribution network are given and various power flow models for the steady state analysis of distribution networks are formulated. The increasing penetration of distributed energy resources into the distribution level has transformed distribution networks into active ones. The basic functions of an advanced distribution management system for the control and monitoring of a distribution network are presented. Furthermore, methods for the operation of the network under normal and emergency operating conditions and for distribution network planning are presented.

## 15.1 Power Distribution Networks

*Power distribution systems* are responsible for delivering electric power from high-voltage transmission or subtransmission systems to the end customers. As shown in Fig. 15.1, the distribution system starts from the primary distribution substation, where a power transformer decreases the high voltage (HV) of the transmission system (35–230 kV) to medium voltage (MV) (1–35 kV) [15.1]. Primary *distribution feeders*, which are MV circuits, connect the primary distribution substation with the secondary distribution substations. The power transformers in the secondary dis-

tribution substations decrease the MV to low voltage (LV) (100–1000 V) [15.1], where residential and commercial end users are connected to the system using secondary distribution lines. Most distribution systems (both primary and secondary) operate in radial configuration, which means that there is only one path from the distribution substation to each end customer. However, operation of meshed MV distribution networks also exists in some countries, feeding major urban areas. The main advantages of the operation of radial distribution networks over meshed ones [15.2, 3] are:

**Fig. 15.1** An example of a distribution network

- Network planning is easier and with lower investment cost.
- Network operation, which includes voltage control and power flow management, is less complex.
- Protection coordination is simpler.
- Short circuit currents are lower.

Distribution networks can be either overhead or underground. Overhead distribution networks have lower investment cost than underground ones, and they are very common in rural areas, where load density is low. Underground distribution networks are usually found in urban areas with high load density, for aesthetic reasons and due to space limitations. Their reliability is higher, since they are not directly affected by weather conditions, e.g., lightning, wind, and freezing. Furthermore, in some areas, distribution networks are designed to be partially overhead and partially underground.

The *infrastructure of distribution systems* is extensive, and its main components are [15.4]:

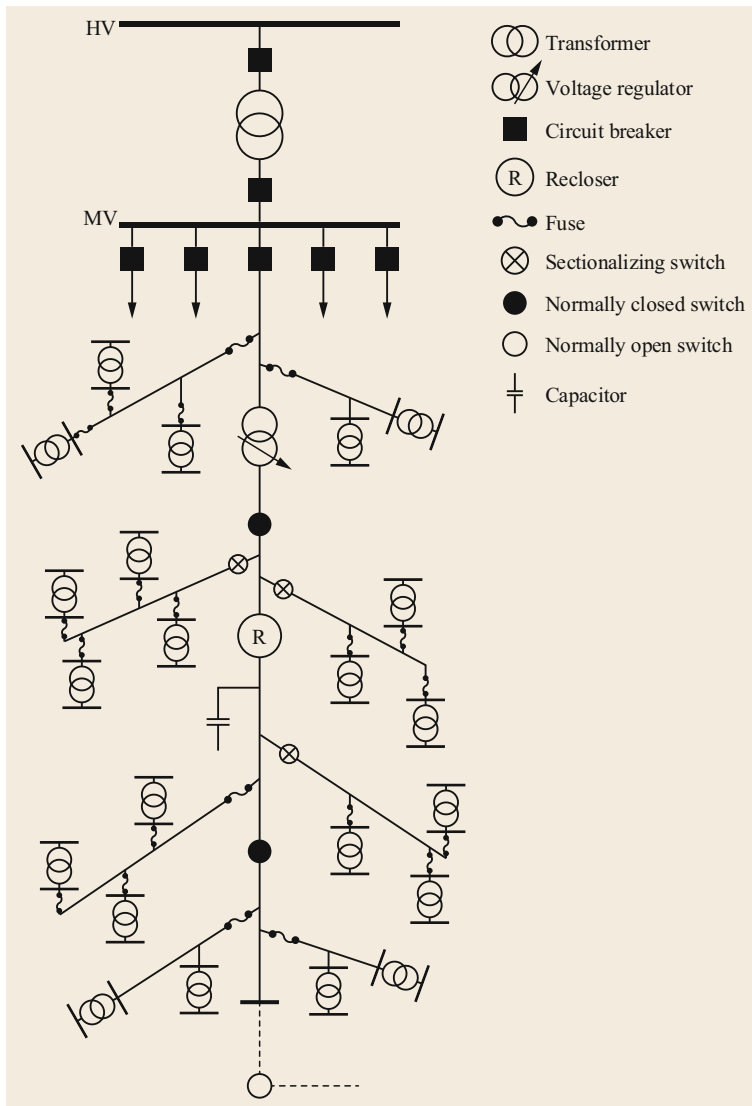

- Distribution substations
- Primary distribution feeders
- Distribution transformers
- Secondary distribution lines
- Voltage regulators
- Shunt capacitors
- Switchgears
- Metering equipment.

The configurations and lengths of distribution networks vary depending on the country, area (urban or rural) and the type of customers they serve. However, most of them share similar characteristics. Figure 15.2 presents the one-line diagram of a *typical* distribution network configuration and its major components. The distribution network comprises one or more feeders (lines) originating from the main substation. The main feeder

is a three-phase circuit, which usually consists of conductors with an ampacity of 400 A and above, and it is considered as the backbone of the distribution network. The distribution lines branching of the main feeder are called laterals, and they connect secondary distribution transformers or other sublaterals. Even though distribution networks are designed to operate as perfectly balanced three-phase power systems, they are inherently unbalanced, mostly due to the uneven connection of single-phase loads or distributed generators along the feeder.

A circuit breaker is placed at the origin of the feeder to protect it from excess current caused by an overload or a short circuit and prevent its damage. A recloser, which is a circuit breaker equipped with relays, is usually placed in the main feeder of overhead lines. Switches and/or disconnectors are also placed along the feeder to sectionalize it for maintenance and restoration purposes. Note that a switch can carry and break current under normal circuit conditions only, and a disconnector can open or close only when the current is negligible. In the case of faults, fuse cutouts or sectionalizing switches, which are disconnectors equipped with a tripping mechanism, are used in the laterals to isolate them from the distribution network. The sectionalizing switches cooperate with the upstream recloser, since they are not rated to interrupt fault currents. Most feeders are connected with at least one other feeder or substation via a line with a normally open switch (tie line). In the case of permanent faults, this switch can be closed to partially restore the load.

Voltage regulators and shunt capacitors are the primary devices for voltage control in distribution networks. Shunt capacitors can be used for reactive power support and power factor correction. Voltage regulators can be placed in the distribution substation and along the feeder to maintain the voltage within its nominal limits.

**Fig. 15.2** A typical distribution network configuration

The main goal of distribution systems is to ensure the continuity of service to load demand at minimum cost. Moreover, they are responsible for integrating distributed energy resources (DER) ensuring certain standards of power quality. DER include distributed generators, mostly based on renewable energy resources (RES), active demand, and storage. Therefore, the role

of distribution systems has become more *active*, creating new challenges. The key to achieving these goals is the optimal operation of the existing network and optimal distribution network planning. Due to the complexity and the large number of components in the distribution network, its optimal operation and planning are complex tasks, which are affected by many factors.

## 15.2 Network Components Modeling

The *steady-state analysis of power distribution networks* requires the effective modeling of various network components. The *equivalent circuit* of each component is necessary to perform technical calculations,

and their combination enables the representation of the actual distribution network. The main components of the power distribution network and their modeling are presented in the following sections.

Fig. 15.3 Single-phase equivalent circuit of a transformer

### 15.2.1 Transformers

Power transformers are static devices that transfer power from one alternating voltage to another through electromagnetic induction. They are the basic components of distribution substations and they are generally used to reduce (i) high voltages (< 230 kV) to primary system voltages (1–35 kV) and (ii) primary system voltages to utilization voltages (120–600 V). The simplified transformer model referred to the primary side is presented in Fig. 15.3. As is shown in Fig. 15.3, transformers can be represented by a series impedance. Distribution transformers with low capacity (rated power) have a larger series resistance than reactance. On the contrary, the resistance of high-capacity transformers can be considered negligible compared to their reactance. For simplification purposes, transformers are sometimes considered ideal, having zero losses and 100% efficiency.

Given the specifications of a transformer, the equivalent transformer impedance referred to the primary winding ( $Z'_{eq}$ ) is calculated as follows

$$Z'_{eq} = R'_{eq} + jX'_{eq}, \quad (15.1)$$

$$R'_{eq} = R_1 + R'_2 = R_1 + a^2 R_2, \quad (15.2)$$

$$X'_{eq} = X_1 + X'_2 = X_1 + a^2 X_2, \quad (15.3)$$

$$a = \frac{N_1}{N_2} = \frac{V_1}{V_2}, \quad (15.4)$$

where,  $R_1$  and  $R_2$  represent the resistance of the primary and secondary winding, respectively;  $X_1$  and  $X_2$  represent the reactance of the primary and secondary winding, respectively; and  $a$  denotes the transformer turns ratio or voltage ratio. Note that complex numbers are marked with bold font. Tables 15.1 and 15.2 present the technical characteristics of single-phase and three-phase distribution transformers [15.5], respectively.

### 15.2.2 Distribution Lines

Distribution lines can be divided into two categories:

- Overhead lines: these have one or multiple conductors (usually three or four), and they are mounted in

Table 15.1 Technical characteristics of single-phase distribution transformers with primary voltage 20 kV and secondary voltage 0.231 kV [15.5]

Rated power (kVA)	R (%)	X (%)	Z (%)
5	2.16	3.37	4.00
10	2.23	3.32	4.00
15	1.87	3.53	4.00
25	1.95	3.49	4.00
50	1.58	3.67	4.00

Table 15.2 Technical characteristics of three-phase distribution transformers with primary voltage 20 kV and secondary voltage 0.4 kV [15.5]

Rated power (kVA)	R (%)	X (%)	Z (%)
250	1.13	3.84	4.00
400	1.00	3.87	4.00
500	0.95	3.89	4.00
630	0.90	3.90	4.00
800	0.97	5.92	6.00
1000	0.94	5.93	6.00
1250	0.96	5.92	6.00
1600	0.96	5.92	6.00

poles made of wood or concrete. Their cost is generally low, since their insulation is provided mostly by air. Conductors are generally made of aluminum (all-aluminum or steel-reinforced) and copper.

- Underground lines: their cost is several times higher than the cost of overhead lines. They are preferred for aesthetic and environmental reasons in urban environments. They are less susceptible to outages due to weather conditions (e.g., lighting, wind, freezing, etc.).

The relatively short length of MV and LV distribution lines, compared to transmission lines, allows simplified modeling. Overhead distribution lines are usually represented by a series impedance circuit ignoring its shunt capacitance. In the modeling of underground distribution lines, the line's shunt capacitance needs to be considered, and the  $\pi$  equivalent line model is used. The typical electrical characteristics of a distribution line are:

- Type (overhead or underground)
- The conductor's material and cross-sectional area
- Series impedance per unit of line length
- Ampacity
- Nominal operating voltage.

Table 15.3 presents the typical electrical characteristics of several overhead lines. In Table 15.3, ACSR stands for aluminum conductor steel reinforced, Cu stands for copper, and Al stands for aluminum.

**Table 15.3** Typical electrical characteristics of various overhead distribution lines

Material and cross-sectional area (mm <sup>2</sup> )	R (Ω/km)	X (Ω/km)	Ampacity (A)	Voltage (kV)
ACSR-16	1.268	0.422	136	20
ACSR-95	0.215	0.334	448	20
Cu-95	0.220	0.358	352	20
Cu-16	1.274	0.334	115	0.4
Cu-35	0.596	0.309	185	0.4

### 15.2.3 Load Models

The term *load* is defined as the aggregation of multiple single devices, such as electrical appliances, lighting, and motors, which consume power and are connected to the system [15.4, 6]. A *load model* is a mathematical representation of the changes in load demand (active and reactive power), usually as a function of the changes in the bus voltage and, in some cases, frequency. Load models can be divided into two categories: dynamic and static [15.7]. Dynamic models represent load demand at any instance of time as a function of voltage, frequency, and time. Dynamic models are typically represented in the form of differential equations and are used in voltage stability studies. Static models represent the power demand of the load (active and reactive) as a function of voltage magnitude and frequency at a particular instant in time (*snapshot*). For power-flow applications, static models that incorporate only the voltage dependence characteristics are used [15.6].

The most common static load models are:

- *Constant impedance load model.* The active and reactive power of constant impedance loads vary proportionally to the square of the voltage magnitude.
- *Constant current load model.* The active and reactive power of constant current loads vary in direct proportion (linearly) to the voltage magnitude.
- *Constant power load model.* Constant power loads draw constant active and reactive power, irrespective of the changes in the bus voltage magnitude.
- *Polynomial load model.* This model represents the active ( $P$ ) and reactive ( $Q$ ) power of the load in relationship to voltage magnitude as follows

$$P = P_0 \left[ c_1 \left( \frac{V}{V_0} \right)^2 + c_2 \frac{V}{V_0} + c_3 \right], \quad (15.5)$$

$$Q = Q_0 \left[ c_4 \left( \frac{V}{V_0} \right)^2 + c_5 \frac{V}{V_0} + c_6 \right], \quad (15.6)$$

where  $c_1$ – $c_6$  are the polynomial model coefficients,  $V$  is the actual voltage magnitude,  $V_0$  is the nominal voltage, and  $P_0$  and  $Q_0$  are the nominal active

and reactive power of the load. This model is often referred to as the *ZIP model*.  $Z$  stands for constant impedance,  $I$  represents constant current and  $P$  refers to constant power.

- *Exponential load model.* This model expresses the relationship between active/reactive power demand and system voltage with an exponential equation, as

$$P = P_0 \left( \frac{V}{V_0} \right)^{np}, \quad (15.7)$$

$$Q = Q_0 \left( \frac{V}{V_0} \right)^{nq}. \quad (15.8)$$

The exponents  $np$  and  $nq$  can be set to any value in order to represent the desired load characteristic. Setting  $np = nq = 2$ , the load is a constant impedance load; setting  $np = nq = 1$ , the load is a constant current load, and setting  $np = nq = 0$ , the load is a constant power load.

- *Frequency-dependent load model.* This is a model that includes frequency dependence on either exponential or polynomial load models. This is achieved by multiplying the relevant exponential or polynomial load model with the frequency factor given by

$$1 + a_f (f - f_0), \quad (15.9)$$

where  $f$  is the actual frequency of the bus considered,  $f_0$  is the nominal frequency, and  $a_f$  is the frequency-sensitivity parameter of the model.

### 15.2.4 Shunt Capacitors

*Shunt capacitors* are used extensively in distribution networks to regulate the voltage and to provide reactive power support. Shunt capacitors are installed at (i) the MV side of the HV/MV substation to provide reactive power support to the transmission system and (ii) along the distribution feeder for voltage support and power factor correction. Based on their installation type, capacitors are categorized as follows:

- *Fixed capacitors:* these are the most common type of capacitor banks, and their connection is permanent. They provide voltage support, but their effect

**Fig. 15.4** Voltage regulator model

on voltage fluctuation along the feeder is limited. Their installation cost is relatively low.

- **Switched capacitors:** these can be switched as a block or in discrete consecutive steps. They are operated manually or by automated control. They reduce the voltage drop and fluctuations along the feeder. However, their investment cost is higher than that of fixed capacitors.

Similarly to the load model, shunt capacitors can be modeled as purely reactive constant impedance or power load.

### 15.2.5 Voltage Regulators

The *voltage regulator* is used to automatically maintain voltages constant along the entire feeder for varying load demand. It consists of an autotransformer with a tap (step) changer in the series winding. Most voltage regulators installed in MV distribution networks enable voltage regulation in a range of  $\pm 10\%$  of the nominal voltage in 32 steps, with voltage change per step equal to 0.625% of the nominal voltage. The voltage regulator is usually modeled as an ideal transformer in series with the distribution line, as shown in Fig. 15.4. The regulated voltage of bus  $j$  ( $V_j$ ) is calculated as a func-

tion of the tap position as

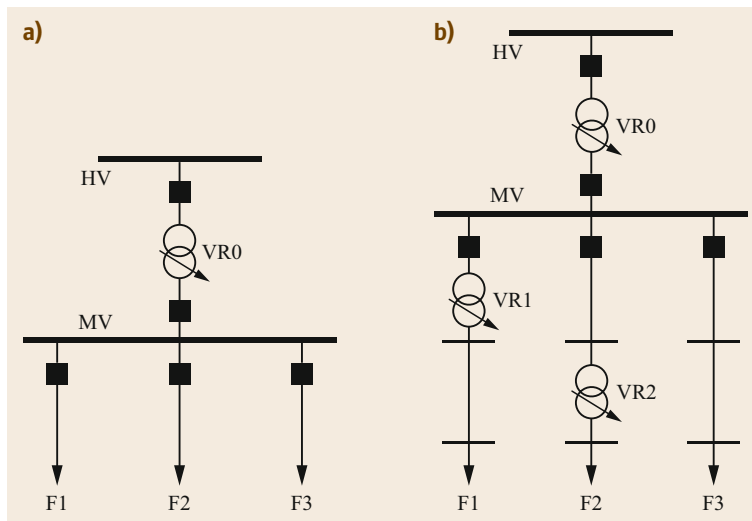

$$V_j = \frac{V_m}{\alpha}, \tag{15.10}$$

$$a_{\text{tap}} = 1 \pm \text{Step tap}_{ij}, \tag{15.11}$$

where  $V_m$  is the voltage of bus  $m$ ,  $a_{\text{tap}}$  is the voltage regulator's ratio, Step is the voltage regulator's step voltage (per unit, p.u.), and  $\text{tap}_{ij}$  is the tap position of the voltage regulator.

The tap position of the voltage regulator is controlled by the line-drop compensator (LDC). The LDC changes the tap position of the voltage regulator in order to maintain the voltage at a regulation point that is located between the voltage regulator and the end of the feeder. The LDC boosts the voltage during heavy load and lowers it during light load. Thus, the range of the voltage fluctuation along the feeder remains relatively small throughout the day.

Most of the HV/MV substations are equipped with a voltage regulator with an on-load tap changer. In this case, voltage regulation is performed simultaneously in all distribution feeders connected to this substation. As is shown in Fig. 15.5a, VR0 regulates the voltage of feeders F1, F2, and F3. The simultaneous voltage regulation is effective when the load variation of all feeders is similar throughout the day, e.g., all feeders serve residential loads. Otherwise, individual voltage regulators are installed along each feeder, which serve customers with different load behaviors. As is shown in Fig. 15.5b, VR0 provides voltage regulation in all feeders; VR1 individually regulates the voltage of feeder F1 in coordination with VR0; VR2 individually regulates the voltage of feeder F2 in coordination with VR0.

**Fig. 15.5a,b** Voltage regulator placement. (a) VR0 regulates the voltage of the three feeders, (b) VR1 and VR2 individually regulates the voltage of feeders F1 and F2, respectively, in coordination with VR0

## 15.3 Power-Flow Analysis of Distribution Networks

*Power-flow analysis* is fundamental for the operation and planning of power distribution systems. The loading of a distribution feeder is inherently unbalanced due to a large number of unequal single-phase loads and the nonsymmetrical conductor spacing of three-phase distribution lines. However, in several cases, it is assumed a perfectly balanced system so that a single-phase equivalent can be used. Sections 15.3.1–15.3.5 present power-flow models for the analysis of balanced distribution networks, while Sect. 15.3.6 presents the analysis of three-phase unbalanced distribution networks. It should be noted that complex numbers are marked in bold font.

### 15.3.1 Branch-Flow Equations

The *AC power-flow problem* is inherently a nonlinear and nonconvex problem. The power flow models presented in Sects. 15.3.1–15.3.5 are based on the branch-flow equations that were first used in [15.8, 9]. The single-phase equivalent circuit of a branch of a distribution system is shown in Fig. 15.6. For the line of Fig. 15.6 that connects bus  $i$  with bus  $j$ ,  $\mathbf{V}_i$  and  $\mathbf{V}_j$  are the complex voltage of bus  $i$  and bus  $j$ , respectively;  $\mathbf{I}_{ij}$  are the complex current on line  $i$ – $j$ ;  $P_{ij}$  and  $Q_{ij}$  are the real and reactive power flows from bus  $i$  to bus  $j$ , respectively;  $\mathbf{z}_{ij} = r_{ij} + jx_{ij}$  is the complex impedance of line  $i$ – $j$ ;  $P_j$ , and  $Q_j$  is the injected active and reactive power at bus  $j$ , respectively, calculated as the load power minus the power generated at bus  $j$ . According to Ohm's law, the voltage drop of branch  $i$ – $j$  can be written as

$$\mathbf{V}_i - \mathbf{V}_j = \mathbf{I}_{ij} \mathbf{z}_{ij}. \quad (15.12)$$

The branch-flow on line  $i$ – $j$  is calculated as

$$\mathbf{S}_{ij} = \mathbf{V}_i \mathbf{I}_{ij}^*. \quad (15.13)$$

To simplify the notation, let  $|\mathbf{V}_i|^2 = U_i$  and  $|\mathbf{I}_{ij}|^2 = I_{ij}^{\text{sqqr}}$ . Then, taking the magnitude squared of (15.12), we have

$$\begin{aligned} |\mathbf{V}_j|^2 &= |\mathbf{V}_i - \mathbf{I}_{ij} \mathbf{z}_{ij}|^2 \\ \Rightarrow U_j &= (\mathbf{V}_i - \mathbf{I}_{ij} \mathbf{z}_{ij}) (\mathbf{V}_i - \mathbf{I}_{ij} \mathbf{z}_{ij})^* \\ \Rightarrow U_j &= |\mathbf{V}_i|^2 - \mathbf{V}_i \mathbf{I}_{ij}^* \mathbf{z}_{ij}^* - (\mathbf{V}_i \mathbf{I}_{ij}^* \mathbf{z}_{ij}^*)^* + |\mathbf{I}_{ij}|^2 |\mathbf{z}_{ij}|^2 \\ \stackrel{(11)}{\Rightarrow} U_j &= U_i - \mathbf{S}_{ij} \mathbf{z}_{ij}^* - (\mathbf{S}_{ij} \mathbf{z}_{ij}^*)^* + I_{ij}^{\text{sqqr}} (r_{ij}^2 + x_{ij}^2) \\ \Rightarrow U_j &= U_i - 2\text{Re}(\mathbf{S}_{ij} \mathbf{z}_{ij}^*) + I_{ij}^{\text{sqqr}} (r_{ij}^2 + x_{ij}^2) \\ \Rightarrow U_j &= U_i - 2(P_{ij} r_{ij} + Q_{ij} x_{ij}) + I_{ij}^{\text{sqqr}} (r_{ij}^2 + x_{ij}^2), \end{aligned} \quad (15.14)$$

where  $\text{Re}(z)$  is the real part, and  $z^*$  is the complex conjugate number  $z$ , respectively.

Using the branch-flow equations, the power-flow balance at each bus can be expressed in terms of voltage square magnitude, current square magnitude, active power branch flow and reactive power branch flow, assuming that all system loads are constant power loads. Assuming radial distribution network operation, let  $W = (N, E)$  be the directed graph that represents the network, in which  $N$  represents the set of buses, and  $E$  represents the set of the distribution lines. Due to its radial configuration, graph  $W$  is a spanning tree, and the root of the tree is the substation bus. Let  $N_{\text{ss}} \subseteq N$  be the set of the substation buses. The direction of the spanning tree  $W$  can be arbitrarily defined with the connection  $(i, j)$  denoting a direction from bus  $i$  to bus  $j$ . For each connection  $(i, j) \in E$ , it is considered that bus  $i$  is the parent of bus  $j$ , or bus  $j$  is the child of bus  $i$ . Let  $N_p(j) \subseteq N$  be the bus set of the parent of bus  $j$  and let  $N_c(j) \subseteq N$  be the bus set of all the children of bus  $j$ . Note that in radial distribution networks, each bus can only have one parent, except for the substation bus, which has no parents. The power-flow analysis variables and parameters are illustrated in Fig. 15.7. Therefore, the power-flow problem can be formulated as

$$\sum_{i \in N_p(j)} (P_{ij} - I_{ij}^{\text{sqqr}} r_{ij}) - \sum_{k \in N_c(j)} P_{jk} = P_j, \quad \forall j \in N \setminus N_{\text{ss}}, \quad (15.15)$$

$$\sum_{i \in N_p(j)} (Q_{ij} - I_{ij}^{\text{sqqr}} x_{ij}) - \sum_{k \in N_c(j)} Q_{jk} = Q_j, \quad \forall j \in N \setminus N_{\text{ss}}, \quad (15.16)$$

$$P_{\text{ss},i} = \sum_{j \in N_c(i)} P_{ij}, \quad \forall i \in N_{\text{ss}}, \quad (15.17)$$

$$Q_{\text{ss},i} = \sum_{j \in N_c(i)} Q_{ij}, \quad \forall i \in N_{\text{ss}}, \quad (15.18)$$

$$U_i I_{ij}^{\text{sqqr}} = P_{ij}^2 + Q_{ij}^2, \quad \forall (i, j) \in E, \quad (15.19)$$

$$\begin{aligned} U_j &= U_i - 2(P_{ij} r_{ij} + Q_{ij} x_{ij}) + (r_{ij}^2 + x_{ij}^2) I_{ij}^{\text{sqqr}}, \\ &\forall (i, j) \in E. \end{aligned} \quad (15.20)$$

**Fig. 15.6** Single-phase equivalent circuit of a branch connecting bus  $i$  with bus  $j$

**Fig. 15.7** Power-flow analysis variables of a radial distribution network

The active and reactive power-node balances are given by (15.15) and (15.16), respectively. The active ( $P_{ss,i}$ ) and reactive ( $Q_{ss,i}$ ) power supplied by the substation at bus  $i$  are calculated by (15.17) and (15.18), respectively. The apparent power flow of line  $i$ – $j$  is given by (15.19). The voltage drop between buses  $i$  and  $j$  is presented in (15.20). The power-flow problem described by (15.15)–(15.20) is a nonlinear programming (NLP) problem due to the nonlinear constraint (15.19). The number of equations is equal to  $2|N| + 2|E|$ , where  $|N|$  and  $|E|$  are the orders of the set of buses and distribution lines, respectively. For radial distribution networks, it is known that  $|E| = |N| - |N_{ss}|$ , where  $|N_{ss}|$  is the order of the set of the substation buses. Hence, the total number of equations is equal to  $4|N| - 2|N_{ss}|$ .

### 15.3.2 Linear Approximation of Branch-Flow Equations

The linearized model of the power-flow equations (15.15)–(15.20) is obtained by eliminating the active and reactive power losses of the lines and considering that all bus voltages are equal to 1.0 p.u. Therefore, the linearized power flow model [15.10] is formulated as

$$\sum_{i \in N_p(j)} P_{ij} - \sum_{k \in N_c(j)} P_{jk} = P_j, \quad \forall j \in N \setminus N_{ss}, \quad (15.21)$$

$$\sum_{i \in N_p(j)} Q_{ij} - \sum_{k \in N_c(j)} Q_{jk} = Q_j, \quad \forall j \in N \setminus N_{ss}, \quad (15.22)$$

$$P_{ss,i} = \sum_{j \in N_c(i)} P_{ij}, \quad \forall i \in N_{ss}, \quad (15.23)$$

$$Q_{ss,i} = \sum_{j \in N_c(i)} Q_{ij}, \quad \forall i \in N_{ss}. \quad (15.24)$$

The power-flow problem described by (15.21)–(15.24) is a linear programming (LP) problem. The number of equations is equal to  $2|N|$ , which is considerably lower compared to the model of Sect. 15.3.1. Using this model, the active and reactive power flow of distribution lines and the active and reactive power supplied by the substation(s) can be calculated approximately.

### 15.3.3 Quadratically Constrained Approximation of Branch-Flow Equations

The NLP power-flow problem described by (15.10)–(15.15) can be simplified to a quadratically constrained programming (QCP) problem. This approximation is achieved by considering that all bus voltages are equal to 1.0 p.u. Thus, the QCP power flow model is formulated as

$$\sum_{i \in N_p(j)} [P_{ij} - (P_{ij}^2 + Q_{ij}^2) r_{ij}] - \sum_{k \in N_c(j)} P_{jk} = P_j, \quad \forall j \in N \setminus N_{ss}, \quad (15.25)$$

$$\sum_{i \in N_p(j)} [Q_{ij} - (P_{ij}^2 + Q_{ij}^2) x_{ij}] - \sum_{k \in N_c(j)} Q_{jk} = Q_j, \quad \forall j \in N \setminus N_{ss}, \quad (15.26)$$

$$P_{ss,i} = \sum_{j \in N_c(i)} P_{ij}, \quad \forall i \in N_{ss}, \quad (15.27)$$

$$Q_{ss,i} = \sum_{j \in N_c(i)} Q_{ij}, \quad \forall i \in N_{ss}. \quad (15.28)$$

The number of equations of the model described by (15.25)–(15.28) is  $2|N|$  as in the model of Sect. 15.3.2. Moreover, the use of the quadratic constraints (15.25) and (15.26) instead of the linear constraints (15.21) and (15.22) increases the accuracy of the model. Similarly to the model of Sect. 15.3.2, the QCP model calculates approximately the active and reactive power flow of distribution lines and the active and reactive power supplied by the substation(s).

### 15.3.4 Conic Approximation of Branch-Flow Equations

The power-flow problem described by the equality constraints (15.20)–(15.25) is, in general, nonlinear due to the nonlinear constraint (15.19). Relaxing the equality constraint (15.19) to inequality, a second-order cone programming (SOCP) approximation of the branch flow can be derived [15.10, 11]. The branch-flow equations are further simplified by dropping the last quadratic term of (15.20), since its value is negligible compared to the values of the remaining terms. Hence, the SOCP approximation of the branch-flow equations is formulated as

$$\sum_{i \in N_p(j)} (P_{ij} - I_{ij}^{\text{sqtr}} r_{ij}) - \sum_{k \in N_c(j)} P_{jk} = P_j, \quad \forall j \in N \setminus N_{ss}, \quad (15.29)$$

$$\sum_{i \in N_p(j)} (Q_{ij} - I_{ij}^{\text{sqtr}} x_{ij}) - \sum_{k \in N_c(j)} Q_{jk} = Q_j, \quad \forall j \in N \setminus N_{ss}, \quad (15.30)$$

$$P_{ss,i} = \sum_{j \in N_c(i)} P_{ij}, \quad \forall i \in N_{ss}, \quad (15.31)$$

$$Q_{ss,i} = \sum_{j \in N_c(i)} Q_{ij}, \quad \forall i \in N_{ss}, \quad (15.32)$$

$$U_i I_{ij}^{\text{sqf}} \geq P_{ij}^2 + Q_{ij}^2, \quad \forall (i,j) \in E, \quad (15.33)$$

$$U_j = U_i - 2(P_{ij}r_{ij} + Q_{ij}x_{ij}), \quad \forall (i,j) \in E. \quad (15.34)$$

SOCP [15.12] problems are convex optimization problems, and they can be solved in polynomial time using primal-dual interior point algorithms. It should be noted that their mixed integer counterparts [15.10] can be efficiently handled by commercial branch and bound solvers, and they can be widely applicable to power engineering problems. The SOCP model approximately calculates the active and reactive power flow of distribution lines; the active and reactive power supplied by the substation(s); and the voltage square magnitude of all buses.

### 15.3.5 Simulation Results

This section evaluates the performance of the aforementioned models of the branch-flow equations using 33-bus, 83-bus, and 135-bus distribution test systems. The bus load data and the technical characteristics of the distribution lines of the 33-bus, 83-bus, and 135-bus distribution test systems can be found in Tables 15.11–15.13 of Appendix 15.A. The following power flow models are analyzed:

- *LP*: this model is described by (15.21)–(15.24).
- *QCP*: this model is described by (15.25)–(15.28).
- *SOCP*: this model is described by (15.29)–(15.34).
- *NLP*: this model is described by (15.15)–(15.20).

The voltage magnitude of the primary substation(s) is equal to 1.0 p.u. in all simulations for each test system. The aforementioned branch-flow models were implemented in the GAMS (general algebraic modeling system) [15.13], and the CONOPT [15.14] solver was used for the solution of LP, QCP, SOCP, and NLP models. All simulations were carried out on a PC with an Intel Core i7 CPU at 3.40 GHz and 4 GB of RAM.

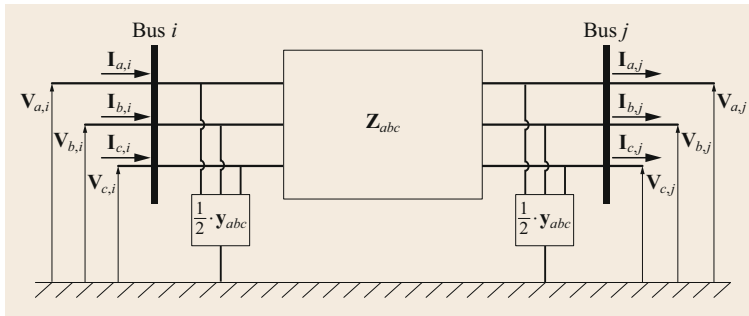

The simulation results of power flow for the aforementioned test systems are presented in Table 15.4. As is shown in Table 15.4, the simulation results of the SOCP model are almost identical to the results of the NLP model, which represents the original branch-flow equations. However, the computation performance of the SOCP model is better than that of the NLP model. Furthermore, the solution of the QCP model derives similar results to the SOCP and NLP models in shorter computation time. As expected, the least accurate power-flow model is the LP model, since it neglects the active and reactive power losses and it considers that the voltage magnitude of all buses is equal to 1.0 p.u. In terms of accuracy and computation performance, the QCP model is more attractive than the LP, SOCP, and NLP models. However, it cannot be used for planning or operation methods that require the calculation of bus voltages or need to consider voltage constraints. In this case, the SOCP model is the most reliable choice.

### 15.3.6 Three-Phase Power-Flow Analysis of Unbalanced Distribution Networks

The model of a three-phase distribution line is presented in Fig. 15.8. The bus voltage and line current are represented by  $3 \times 1$  matrices, while the line's series impedance and shunt admittance matrices are repre-

**Table 15.4** Power-flow analysis results of the 33-bus, 83-bus, and 135-bus distribution systems

33-bus distribution system				
	LP	QCP	SOCP	NLP

**Fig. 15.8** Three-phase distribution line model

sented by  $3 \times 3$  matrices, as follows

$$[\mathbf{V}_{abc}] = \begin{pmatrix} \mathbf{V}_a \\ \mathbf{V}_b \\ \mathbf{V}_c \end{pmatrix}, \quad (15.35)$$

$$[\mathbf{I}_{abc}] = \begin{pmatrix} \mathbf{I}_a \\ \mathbf{I}_b \\ \mathbf{I}_c \end{pmatrix}, \quad (15.36)$$

$$[\mathbf{Z}_{abc}] = \begin{pmatrix} \mathbf{z}_{aa} & \mathbf{z}_{ab} & \mathbf{z}_{ac} \\ \mathbf{z}_{ba} & \mathbf{z}_{bb} & \mathbf{z}_{bc} \\ \mathbf{z}_{ca} & \mathbf{z}_{cb} & \mathbf{z}_{cc} \end{pmatrix}, \quad (15.37)$$

$$[\mathbf{y}_{abc}] = \begin{pmatrix} \mathbf{y}_{aa} & \mathbf{y}_{ab} & \mathbf{y}_{ac} \\ \mathbf{y}_{ba} & \mathbf{y}_{bb} & \mathbf{y}_{bc} \\ \mathbf{y}_{ca} & \mathbf{y}_{cb} & \mathbf{y}_{cc} \end{pmatrix}, \quad (15.38)$$

where,  $\mathbf{V}_a$ ,  $\mathbf{V}_b$  and  $\mathbf{V}_c$  are the complex voltages of phase  $a$ ,  $b$ , and  $c$ , respectively;  $\mathbf{I}_a$ ,  $\mathbf{I}_b$  and  $\mathbf{I}_c$  are the complex currents of phase  $a$ ,  $b$ , and  $c$ , respectively;  $\mathbf{z}_{mm}$  is the series self-impedance of phase  $m$  for  $m = \{a, b, c\}$ ;  $\mathbf{z}_{mn}$  is the series mutual impedance between phases  $m$  and  $n$  for  $\{m, n\} = \{a, b, c\}$  and  $m \neq n$ ;  $\mathbf{y}_{mm}$  is the shunt self-admittance of phase  $m$  for  $m = \{a, b, c\}$ ;  $\mathbf{y}_{mn}$  is the shunt mutual admittance between phases  $m$  and  $n$  for  $\{m, n\} = \{a, b, c\}$  and  $m \neq n$ .

Applying the Kirchhoff's laws, the voltages and currents at bus  $i$  in terms of the voltages and currents

of bus  $j$  are calculated by (15.39)–(15.41) as

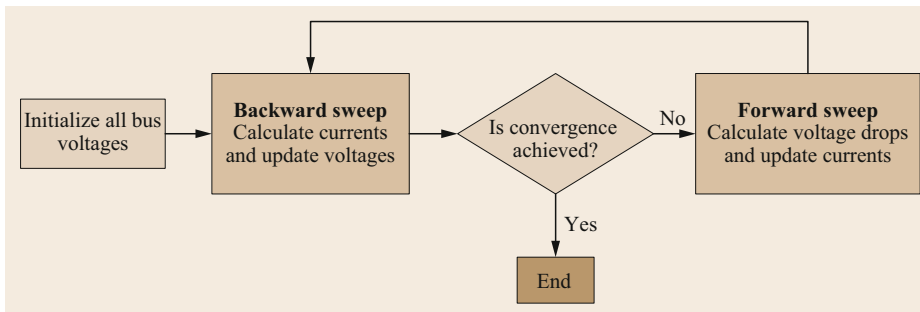

$$[\mathbf{V}_{abc}]_j = [\mathbf{V}_{abc}]_i + \mathbf{Z}_{abc} \left( \frac{1}{2} \mathbf{y}_{abc} [\mathbf{V}_{abc}]_i - [\mathbf{I}_{abc}]_i \right), \quad (15.39)$$

$$[\mathbf{V}_{abc}]_i = [\mathbf{V}_{abc}]_j + \mathbf{Z}_{abc} \left( \frac{1}{2} \mathbf{y}_{abc} [\mathbf{V}_{abc}]_j + [\mathbf{I}_{abc}]_j \right), \quad (15.40)$$

$$[\mathbf{I}_{abc}]_j = \frac{1}{2} \mathbf{y}_{abc} ([\mathbf{V}_{abc}]_i + [\mathbf{V}_{abc}]_j) - [\mathbf{I}_{abc}]_i. \quad (15.41)$$

An efficient method to solve the three-phase power-flow problem is the *backward/forward sweep method* [15.4]. This method consists of three basic steps, and its flowchart is presented in Fig. 15.9. The method comprises an iterative process, which is terminated when a convergence criterion is satisfied. Figure 15.10 shows a simple distribution network example, which helps describe the backward and forward sweep steps. The indexing of the buses is performed using the reverse breadth-first (RBF) and breadth-first (BF) sorting methods [15.15].

The method starts by initializing all the bus voltages. The selected initial values of the bus voltages are

**Fig. 15.9** Flowchart of the backward/forward sweep method

Fig. 15.10 Distribution network example

usually equal to their nominal values. Afterwards, the distribution network is traversed processing the buses and the laterals in the RBF order. For example, in Fig. 15.10, the distribution network will be traversed from the end bus, i.e., bus  $N$ , towards the first bus, i.e., bus zero. In every bus, the currents injected by the load or the shunt capacitor are calculated based on the bus voltage of the current iteration. Then, Kirchhoff's current law is applied in order to determine the incoming injected current ( $I_N$ ). After computing the incoming injected current at bus  $N$ , the voltage of bus  $N-1$  ( $V_{N-1}$ ) is calculated. Hence, all bus voltages and line currents are determined in RBF order and moving the process towards the source bus. Thus, the last examined lateral, which is in fact the main feeder, is processed, and

the bus voltage of the source bus is determined completing the backward sweep step. The voltage of the source bus ( $V_0$ ) is given, and the error between the calculated value of the backward sweep step, and the given value of source bus voltage is computed. If the error is smaller than a given threshold, the power-flow analysis is terminated. Otherwise, the forward sweep step is executed. The selection of the error threshold value is critical because a relative high value may lead to inaccurate results, while a relative small value may lead to multiple iterations.

If the error does not have a value lower than the defined threshold, then the execution of the forward sweep step is necessary. In this step, the currents that were calculated in the backward sweep step are taken as granted, and the bus voltages of the network are calculated considering that the source bus voltage is equal to its given value. The distribution network is, now, traversed processing the buses and the laterals in BF order. For example, in Fig. 15.10, the distribution network will be traversed from the first bus, i.e., bus zero, towards the end bus, i.e., bus  $N$ .

## 15.4 Active Distribution Networks

The increasing penetration of distributed generation (DG) [15.16], the integration of energy storage systems (ESSs) [15.17], and the participation of the consumers in demand-response (DR) mechanisms [15.18] have reshaped the planning and operation of modern distribution networks. The advancements of information and communication technologies (ICT) and the extensive deployment of smart meters and advanced metering infrastructure (AMI) enable the management of DERs transforming the distribution networks from passive to *active distribution networks* (ADNs).

The definition of ADNs, as formulated by CIGRE 2008 WG C6.11 [15.19] is:

ADNs have systems in place to control a combination of DERs, defined as generators, loads and storage. Distribution system operators (DSOs) have the possibility of managing the electricity flows using a flexible network topology. DERs take some degree of responsibility for system support, which will depend on a suitable regulatory environment and connection agreement.

The main goals of the ADN concept can be summarized as follows:

- Increased penetration of DG and storage
- Participation of consumers in DR mechanisms
- Asset management optimization and cost-efficient network operation
- Enhancement of the self-healing capability of the network during an outage
- Power quality improvement
- Ancillary service provision to DSO and transmission system operator (TSO)
- Security improvement from physical and cyber-attacks.

### 15.4.1 Distributed Energy Resources

This section gives a brief overview of the various *distributed energy resources* (DERs) most commonly met in ADNs [15.20]. It should be noted that the section intends to describe small dispersed resources, while larger installations are beyond its scope.

#### Photovoltaic Systems

Photovoltaic (PV) systems directly convert solar energy into electricity [15.21]. They consist of an arrangement of several components, which include solar panels, solar inverters, and mounting and cable equipment.

**Fig. 15.11** A rooftop PV system installed at the Electric Energy Systems Laboratory of the National Technical University of Athens (Courtesy Authors)

A solar panel comprises multiple solar cells, which are made of semiconductor materials and are connected together in various series and parallel configurations. The output direct current of the solar panels is converted into utility frequency alternate current by the solar inverter. Due to the fact that the solar irradiation has a nonlinear effect on the output power of a PV system, a maximum power-point tracking (MPPT) mechanism is employed by the inverter to determine its optimal operating point [15.22].

The main advantage of the PV systems is that their installation and operation do not cause environmental pollution or greenhouse gas emissions. Their main disadvantage is that they are an intermittent source of energy, since they are dependent on a stochastic primary source. Other disadvantages are their relatively low efficiency, e.g., 10–24% and the fact that their output power drops dramatically when even a small portion of the solar panel is shaded. A way to improve their efficiency is the installation of solar trackers, which orientate the solar panels toward the sun. PV systems can be rooftop, pole, or ground mounted. The capacity of the rooftop mounted PV systems ranges from few to several tens of kW. A rooftop-mounted PV system is shown in Fig. 15.11. PV systems with a larger capacity that ranges from few hundreds of kW to few MW are pole or ground mounted.

#### Wind Turbines

Wind turbines convert the kinetic energy of the wind into electricity [15.23, 24]. The output power of a wind turbine depends on wind speed. The wind speed at which the turbine starts to generate power is called cut-in speed, and it is typically equal to 3–4 m/s. The turbine does not generate electric power below the cut-in speed. As the wind speed rises above the cut-in speed, the output power of the wind turbine increases rapidly until it reaches the rated wind speed of the

turbine, which typically ranges from 12–17 m/s. At higher wind speeds, the wind turbine generates its rated output power. The wind turbine is forced to shut down when the wind speed exceeds the cut-out speed, typically around 25 m/s, in order to prevent its damage.

Wind turbines can be classified into (i) horizontal-axis and (ii) vertical-axis wind turbines, with the former being the most common. Horizontal-axis wind turbines have the rotor shaft and generator arranged horizontally at the top of a tower. A small horizontal-axis wind turbine is shown in Fig. 15.12. Vertical-axis wind turbines

**Fig. 15.12** A small horizontal-axis wind turbine installed at the Electric Energy Systems Laboratory of the National Technical University of Athens (Courtesy Authors)

have the rotor shaft and generator arranged vertically to the ground. Similarly to PVs, the main advantage of the wind turbines is that they are a clean source of energy, available worldwide. The main disadvantage is that they are an intermittent power source and, if not properly designed, they can create noise. Larger sized wind turbines are accused of aesthetic problems.

### Small Hydro Turbines

Small hydro stations produce hydroelectric power [15.25]. Hydro turbines convert water pressure into mechanical shaft power, which is used to rotate an electrical generator. Even though there is no global definition of small hydro turbines, their generating capacity usually ranges from 1–25 MW. Installations with a generating capacity from 100 kW to 1 MW are termed mini hydro turbines; installations from 10–100 kW micro hydro turbines, and installations below 10 kW are termed pico hydro turbines. In most cases, small hydro is *run-of-the-river*, which means that there is a small or no water reservoir capacity. Therefore, they have a small environmental impact.

### Microturbines

Microturbines are small combustion turbines, which can be used as small-scale distributed power generation, often in combined heat and power (CHP) applications [15.26]. Their generating capacity ranges from 25–500 kW. The operation of a microturbine is similar to that of conventional gas turbines. They use most commercial fuels, such as natural gas, petrol, propane, and diesel, and their typical efficiency ranges from 20–35%. However, when they are used in CHP applications, their efficiency can exceed 80%. The main advantages of microturbines are that they have a compact size, a small number of moving parts, and low emissions.

### Electrical Energy Storage Technologies

Electrical energy storage systems are recognized to have great potential in meeting challenges for the efficient management of the power systems, created by the intermittency of the generation of renewable power [15.27]. Electrical energy storage systems convert electrical energy to chemical, mechanical, or another storable forms of energy. Then, they can convert this stored energy back to electrical energy, when needed. They can provide various services at the distribution-system level, like load leveling and peak shaving, ancillary services (e.g., voltage and frequency regulation, power quality improvement, and spinning reserves), balancing (firming up) renewable energy power variations, resiliency to ride through blackouts, etc.

There are several energy storage technologies, such as battery energy storage systems (BESS), flywheels, pumped-storage hydroelectricity, compressed air energy storage (CAES), and superconducting magnetic energy storage (SMES) [15.28]. BESS use rechargeable batteries to convert electrical energy to chemical energy. They provide fast response times and, due to their compact size and quiet operation, they can be placed inside or close to buildings, household facilities, or wherever they are needed. The most common technologies use lead-acid, lithium-ion (Li-ion), sodium-sulfur (NaS), and nickel-cadmium (NiCd).

Pumped-storage hydroelectricity facilities pump water from a reservoir at low altitude to another one at a higher altitude during off-peak electricity periods. During periods of high demand, the stored water is released to generate electricity through turbines. Pumped storage enables the use of surplus energy from RES during periods with high load demand.

Flywheels store electricity in kinetic energy by accelerating a rotor. They have a longer lifespan than batteries and they can be used as an uninterrupted power supply, frequency regulation, or for smoothing wind power fluctuations.

CAES systems compress air into a storage vessel, e.g., an underground cavern, during periods of low demand. During periods of high demand, the air is released, heated and used to drive a turbine in order to generate electricity. SMES systems store energy within the magnetic field of a superconducting coil, which has been cryogenically cooled to a temperature below its superconducting critical temperature. They have small power losses and short time delays during charge and discharge.

## 15.4.2 Demand Response

*Demand response* (DR) is defined as:

Changes in electric usage by end-use customers from their normal consumption patterns in response to changes in the price of electricity over time, or to incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardized [15.29].

DR programs provide mutual financial benefits to both utilities and end customers, improve reliability, and can reduce a network's peak load in the long term. Customers who participate in DR can change their energy consumption by partial load curtailment or load shifting from on-peak to off-peak time periods (valley filling). The efficient implementation of DR requires advanced

ICT to enable communication between utility and customers, installation of smart meters, and load control devices. Load control devices are used to remote control specific loads, e.g., motors, compressors, and thermostatic loads, e.g., space/water heating, and refrigeration.

### 15.4.3 From Passive to Active

The configuration of the distribution network has a direct impact on its operation and performance. Traditionally, distribution networks have been planned based on load forecasting, whereas distributed generation is often excluded. The network configurations derived from these planning studies consider maximum load demand and one-directional power flows (from substation to the consumers). Voltage regulation is provided by the on-load tap changers (OLTCs) at the HV/MV substations, in-line voltage regulators, and capacitors. Loss minimization studies involve the reconfiguration of distribution networks on a seasonal or monthly basis. Control actions in these *passive* distribution networks are limited, since all the potential operational issues are solved at the planning stage.

Offline power system analysis is performed to estimate the feasibility of the DG units' connection in order to avoid overvoltages and feeder overloads. These studies consider worst-case load/generation conditions, i.e., maximum load/no generation and minimum load/maximum generation. DG is modeled as a negative load with a constant power factor. This approach, known as the *fit and forget* approach, is acceptable, if DG connections to the network are relatively rare and geographically scattered, and thus do not have a negative impact on network operation and planning. At higher levels of DG penetration, however, the *fit and forget* approach can become a barrier, or it can lead to costly investments of the distribution infrastructure. To deal with these challenges in a reliable and cost-effective way, a more *active* approach is needed.

### 15.4.4 Active Network Management

*Active network management* (ANM) enables the coordinated control of distribution network components, such as OLTCs, voltage regulators, switched capacitors and switches, DG active and reactive output powers, energy storage systems, and flexible loads in an integrated manner. The objective of ANM schemes is to optimize the network operation considering single or multiple criteria. The fundamental difference between passive and active distribution networks is that ANM exploits the capacity and control capabilities of the DERs at distribution level, in order to optimize the network's planning and operational costs.

The large-scale integration of variable RES brings significant challenges to grid operation, which requires new and more complex tools for the distribution management system (DMS), however ANM techniques can exploit the inherent flexibility of the DER to provide cost-effective and efficient solutions for voltage and power-flow management in distribution systems.

The most common ANM schemes can be grouped as follows [15.30, 31]:

- *Coordinated voltage control*: voltage regulation devices are operated in a coordinated way with all available DERs active and reactive power-control capabilities.
- *Adaptive power factor*: the power factor of DG units is adapted in order to absorb or supply reactive power, in coordination with other voltage control devices.
- *Active power curtailment*: DG active power is curtailed due to technical constraint violations. This is usually a last resort scheme, since it has financial implications for the DG operators.
- *Energy storage management*: energy storage used for valley filling and peak power shaving to optimize the operation of the network in a technical and economic way. Energy storage operation can provide several benefits in distribution system operation, but it potentially affects the local energy market.
- *Demand side participation*: modification of the consumers' loads (load reduction, load shifting) either by direct control actions or individual consumer actions through financial incentives, is a great source of flexibility.
- *Distribution network reconfiguration*: the online reconfiguration of distribution networks through remotely controlled switching during normal and emergency conditions.

Table 15.5 summarizes passive and active network solutions to current distribution network problems.

The implementation of ANM requires an advanced communication infrastructure that is more flexible and more demanding than that of traditional distribution networks. The communication infrastructure is a substantial part of ADN, since ANM is highly dependent on real-time information about the network. Simultaneous analysis of power and communication systems is necessary to properly assess the reliability, availability, and security requirements of ADNs [15.32].

In the smart grid era, DMSs could provide real-time monitoring and control in order to improve a network's performance. The management system of an ADN consists of two functional blocks: state estimation and

**Table 15.5** Passive and active network management solutions to the technical challenges of distribution networks

Technical challenges	Passive distribution network	Active distribution network
Feeder overload	<ul style="list-style-type: none"> <li>● Network reinforcement (e.g., reconductoring of feeder segments)</li> <li>● Network reconfiguration</li> </ul>	<ul style="list-style-type: none"> <li>● DG active/reactive power control</li> <li>● ESS integration</li> <li>● DR schemes</li> <li>● Online reconfiguration</li> </ul>

control scheduling. A distribution system state estimator (DSSE) receives real-time measurements from the advanced metering infrastructure installed in the distribution network, and with the proper deployment of pseudomeasurements and the use of network topology, the network status, i.e., nodal voltage magnitude and angle, is estimated. Based on the output values of the DSSE, an operation framework calculates the control values for the devices connected to the network. The set of control values aims at optimizing the power flow in the network and mitigating eventual voltage problems

that may arise in the operation of the grid, resulting from the variability of RES. Furthermore, a short-term load and RES forecasting function is required by the management systems of ADNs that incorporate optimization functions for the grid operation under normal and emergency conditions.

The main goal of ADNs is also to increase renewable DG penetration in existing distribution networks, which have been designed assuming HV/MV substation is the sole power source, while certain technical constraints are kept within their limits.

## 15.5 Distribution Network Monitoring and Control

Electric distribution utilities need to efficiently manage their distribution assets, with the aid of an *advanced distribution management system* (ADMS), in order to ensure higher reliability, improved power quality, data security, and resiliency to natural disasters for the customers [15.33–35]. ADMS is a collection of applications designed to continuously monitor and control, in an optimal manner, the various devices at substations and feeders of the distribution network (circuit breakers, reclosers, line switches, capacitor bank switches, voltage regulators, etc.), acting as a decision support system to the field operating personnel. ADMS includes the network applications, an outage management

system (OMS), and the Supervisory Control and Data Acquisition (SCADA) system.

SCADA gathers the real-time data from various remote locations or plants, presents the data on various HMIs, and records and logs the data on SCADA database management system [15.35, 36]. Figure 15.13 depicts the configuration and components of a SCADA system.

As can be seen from Fig. 15.13, a SCADA system consists of the following main elements:

- *Supervisory computer system*: This is responsible for communicating with the field-level controllers

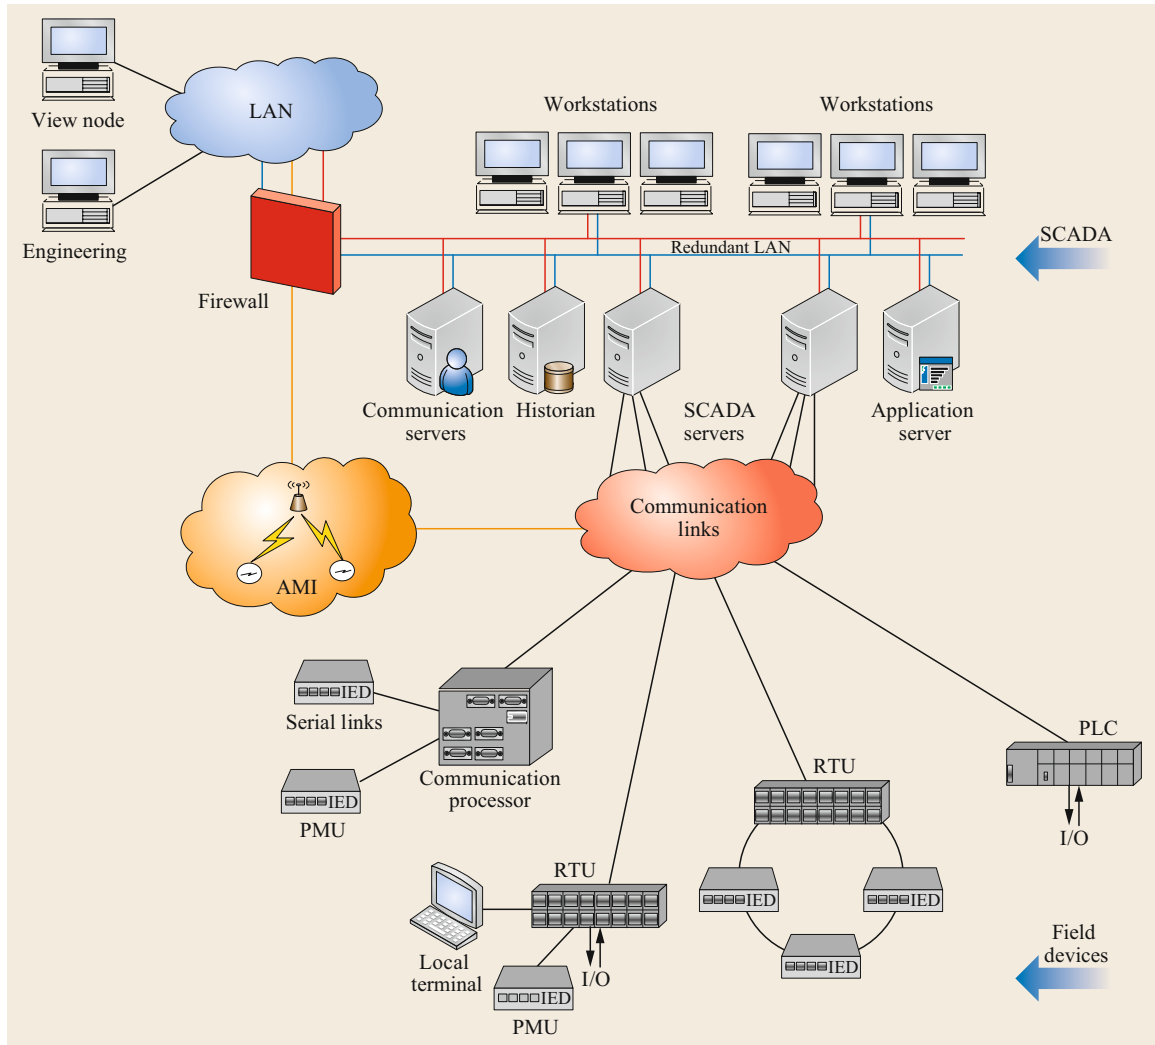

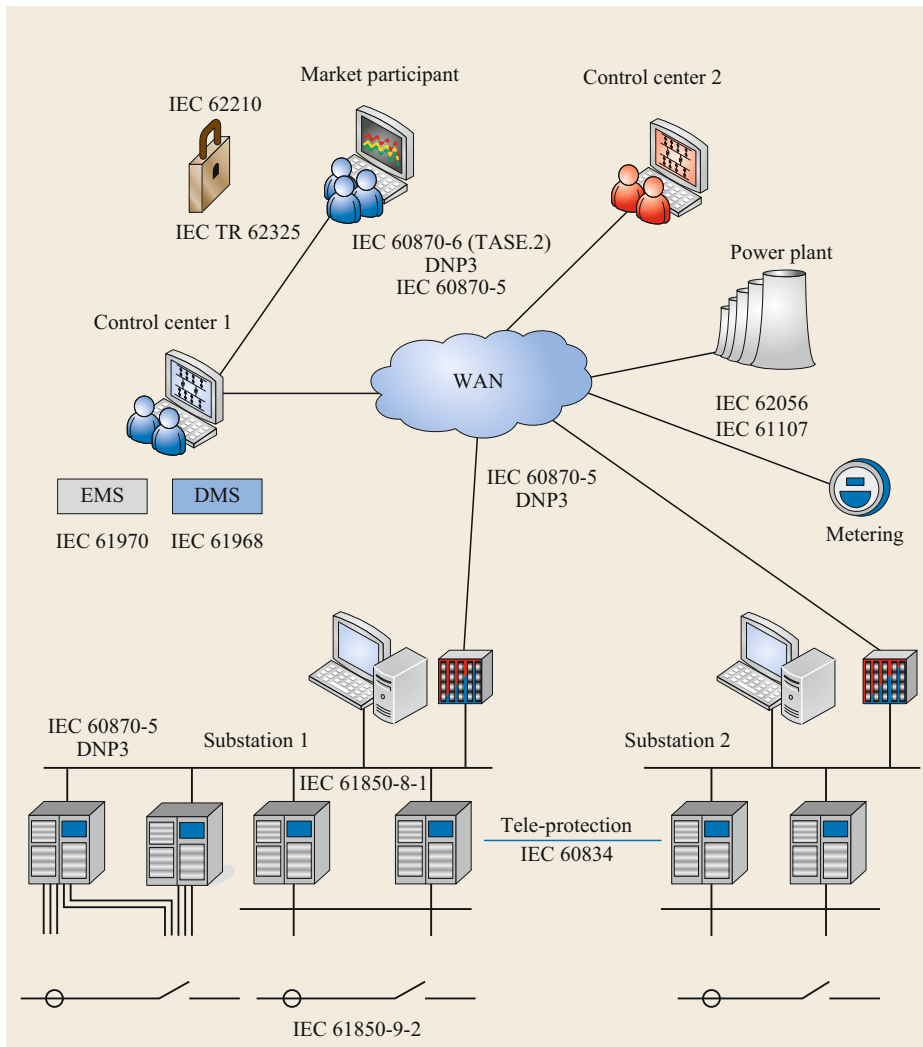

Fig. 15.13 Configuration of a SCADA system

(RTUs and PLCs). The remote terminal units (RTUs) and the programmable logic controllers (PLCs) are connected to sensors and actuators in the process and are networked to the supervisory computers. An RTU is a microprocessor-controlled electronic device that interfaces objects in the physical world to the control system by using messages from the master supervisory system to the control connected objects [15.37, 38]. A PLC is a digital computer used for automation of typically industrial electromechanical processes, such as control of machinery on factory assembly lines, amusement rides, or light fixtures [15.39]. PLCs have more sophisticated embedded control capabilities than RTUs and are programmed in one or more IEC 61131-3 programming languages [15.39]. PLCs are often used

in place of RTUs as field devices because they are more economical, versatile, flexible, and configurable.

- *Communication infrastructure*: This connects the supervisory computer system to the RTUs and PLCs, and may use industry standard or manufacturer proprietary protocols [15.40, 41]. Both RTUs and PLCs operate autonomously on the near-real-time control of the process, using the last command given from the supervisory system. Figure 15.14 depicts the most common communication protocols used in distribution network control.
- *Human-machine interface (HMI)*: This presents information to the system operators graphically in the form of mimic diagrams, which are a schematic representation of the network being controlled, and

**Fig. 15.14** Typical communication protocols used in a power system

alarm and event logging pages. The HMI is linked to the SCADA supervisory computers to provide live data to drive the mimic diagrams, alarm displays, and trending graphs.

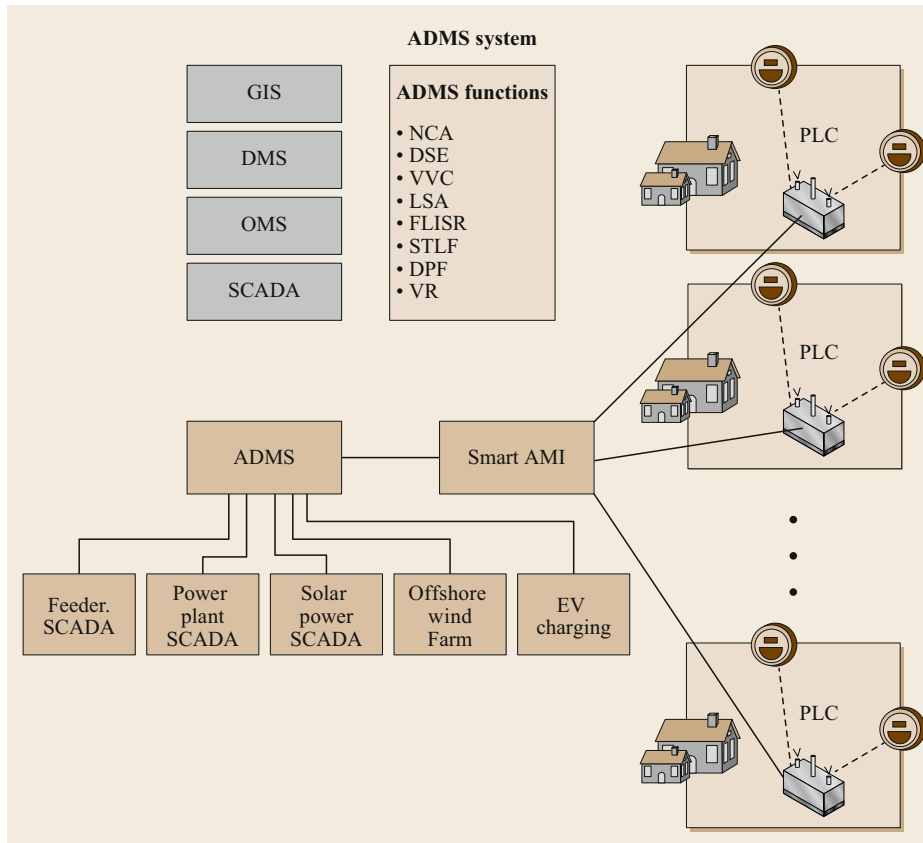

- **Alarm handling:** This checks whether certain alarm conditions are satisfied, to determine when an alarm event has occurred. Once an alarm event has been detected, one or more actions are taken (such as the activation of one or more alarm indicators, and perhaps the generation of email or text messages, so that management or remote SCADA operators are informed).

Figure 15.15 shows the structure of an ADMS system. The OMS includes trouble call, fault detection, fault location, isolation and supply restoration, crew management and outage reporting. The geographic in-

formation system (GIS) integrates hardware, software, and data for capturing, managing, analyzing, and displays all forms of geographically referenced information. GIS manages and maps the location of millions of miles of overhead and underground transmission lines, enabling the distribution utilities to identify vulnerabilities that cause outages, to weigh asset investments, to understand customer satisfaction, and to determine the right location for new facilities and new technology, such as smart grid sensors and smart meters.

The different functions of an ADMS system are briefly analyzed here:

- **Network connectivity analysis (NCA)**  
This helps the operator to identify or locate the feeding point of the various network components. Based on the status of all switching devices, such as circuit

**Fig. 15.15** ADMS functional structure

breakers (CBs), ring main units (RMUs), and isolators, NCA determines the topology and the radial or loop mode of the network.

- **Distribution state estimation (DSE)**  
 DSE is used for estimating the distribution network state and represents the basic DMS function, with all other DMS analytes based on its results. The state estimation (SE) function is based on algorithms especially oriented towards distribution networks, with low availability of real-time data, which must be compensated with historical data. The historical data of the network consist of daily load profiles—current magnitudes and power factors, or active and reactive power for all load classes (industrial, commercial, residential), for all seasons (winter, spring, summer, autumn), for types of days (weekday, Saturday, Sunday, and holidays)—and peak loads for all distribution transformers and/or consumers (peak currents and/or peak powers), and/or monthly electric energy transfers across all distribution transformers.
- **Volt/VAR control (VVC)**  
 This refers to the process of managing the voltage levels and the production, absorption, and flow of re-

active power at all levels in the distribution system. The VVC application helps the operator to mitigate such conditions by suggesting the required tap positions and capacitor switching to ensure the voltage to its limit and, thus, optimize Volt/VAR control.

- **Load shed application (LSA)**  
 The LSA automates and optimizes the process of selecting the best combination of switches to be opened and controlling in order to shed the desired amount of load.
- **Fault location isolation and service restoration (FLISR)**  
 This works in conjunction with SCADA, telecommunications, and distribution automation devices to decrease the number of customers affected by a power outage by automatically opening and closing switches to isolate compromised sections of line and to re-energize healthy sections of the system to restore energy distribution.
- **Short-term load forecasting (STLF)**  
 Short-term load forecasting is an important tool for planning, triggering load management strategies, and for determining unit commitment schedules. It can produce three types of forecasts based on full

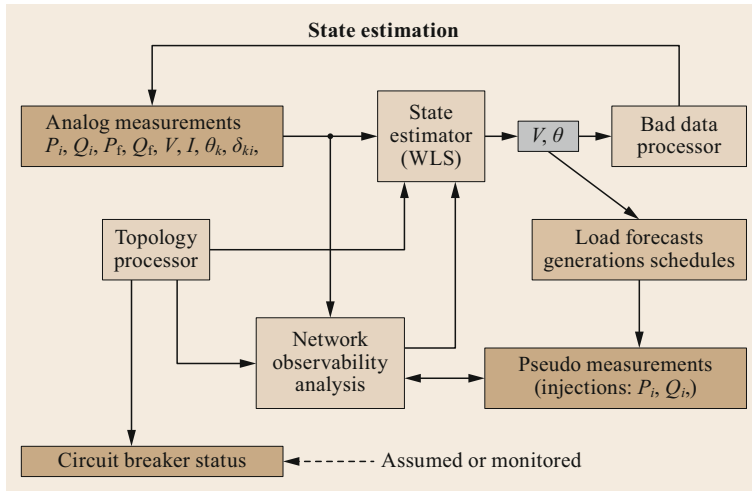

Fig. 15.16 Functionality of DSSE

historical load and weather data: 24-hour forecast, 7-day forecast, and 24-hour forecast, also producing interpolated predictions for 15, 30, 45, and 60 min into the upcoming hour.

- **Distribution power flow (DPF)**  
This provides a power-flow solution that best fits the power system model and the SCADA feeder measurements in the substations, and offers benefits, such as improved detection of system problems, including overloads and voltage violations, and accurate assessment of line losses.
- **Voltage reduction (VR)**  
This helps the operator to reduce, maintain, or restore system voltage in response to event triggers.

The DSSE, which is the key function in the ADMS, will be further described in the following. DSE is carried out based on measurements of electrical variables and calculates the state estimates (all node voltage magnitudes and phase angles) at a specified time. The functionality of state estimation is shown in Fig. 15.16.

In order to derive consistent and qualified state estimates, it is necessary to use all the information available for the distribution network and not only real-time measurements, whose availability is very limited in practice [15.42]. Therefore, the DSSE functionality includes information from different sources, namely: automated meter reading (AMR)/advanced metering infrastructure (AMI), RTUs, and phasor measurement units (PMUs) synchronized by the Global Positioning System (GPS) signal [15.43–55]. Furthermore, smart meters connected to LV nodes can make time-synchronized measurements of active and reactive loads, as well as voltage magnitudes, at predefined time intervals (usually every 15 min), transmitting them to a database server periodically (for instance, daily). This

ensures that the DSE will have, at least, measurements from the previous day of all the loads [15.46, 50]. Based on these measurements a set of pseudomeasurements will be generated and used together with near real-time information, for instance from DGs [15.43, 47], to make the network fully observable and guarantee an adequate degree of redundancy for running the state estimator. This can be accomplished by one of the proposed load estimation models in the literature [15.56–62], which utilize previous-day metered LV consumption data as well as same-day dependent variables, such as temperature, day type (weekday or weekend), humidity, etc. The upstream MV/LV substation load is estimated by aggregating all the downstream LV loads.

Figure 15.17 shows the components of the distribution network control architecture.

The mathematical formulation of the DSSE is based on the following nonlinear measurement model [15.42, 63]

$$z = \mathbf{h}(\mathbf{x}) + \mathbf{e}, \quad (15.42)$$

where  $\mathbf{z}$  is the measurement vector,  $\mathbf{h}(\mathbf{x})$  is the vector of nonlinear functions relating measurements to states,  $\mathbf{x}$  is the true state vector consisting of nodal voltages (magnitudes and phase angles), and  $\mathbf{e}$  is the vector of measurement errors. The class of estimators discussed in this section is based on the maximum likelihood theory and relies on a-priori knowledge of the distribution of the measurement error (normal), with  $E(\mathbf{e}) = 0$  and  $E(\mathbf{e}\mathbf{e}^T) = \mathbf{R} = \text{diag}(\sigma_i^2)$ , where  $\sigma_i^2$  is the variance of the  $i$ -th measurement error. A node is arbitrarily selected as the reference node, and its voltage angle is set to zero.

Measurements can be classified as *critical (nonredundant)* and *noncritical (redundant)*. A critical measurement is one whose elimination from the measurement set makes the network unobservable [15.64]. Crit-

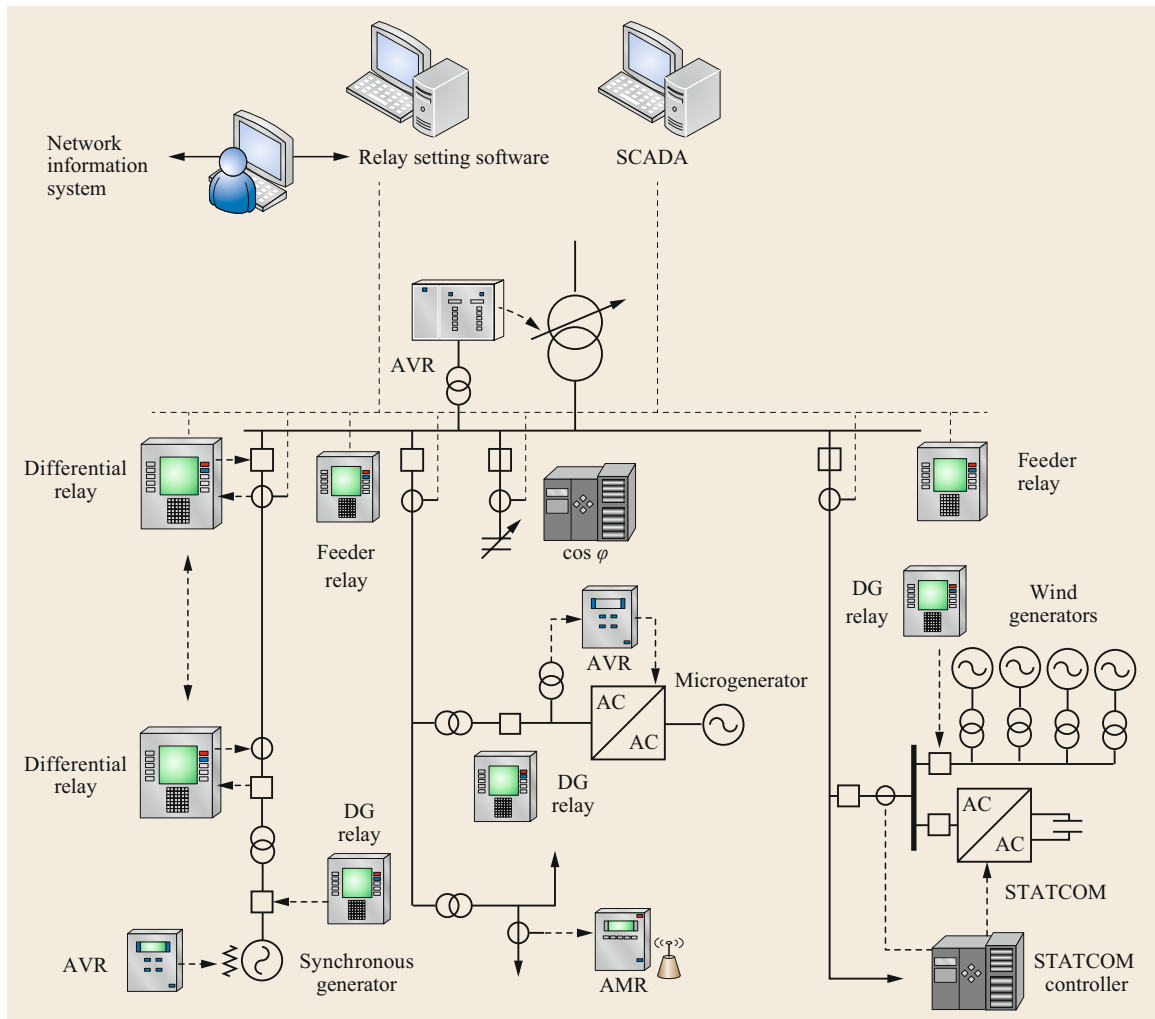

Fig. 15.17 Distribution network control architecture

ical measurements have zero residuals and, therefore, their errors cannot be detected. Noncritical measurements have nonzero residuals, allowing detection and possibly identification of their errors. A minimally dependent set of measurements has the property that elimination of any measurement from this set makes the remaining measurements critical. All the measurements of a minimally dependent set have equal absolute values of their normalized residuals [15.64]. As a consequence, gross error on one or more measurements of a minimally dependent set can be detected but not identified. Since the measurement redundancy is low in distribution networks, a few critical measurements and minimally dependent sets may occur, making the error filtering process rather difficult. This is the reason why forecast load (pseudo) measurements should be as accurate as possible.

The following input information should be available to the state estimator:

- Network electrical parameters
- Network configuration (topology) based on the status of switching devices and the position of transformer taps
- Actual (real-time) measurements subject to errors, due to metering inaccuracies and communication system (voltage magnitudes  $V$ , active and reactive branch power flows  $P_f$  and  $Q_f$ , active and reactive injections  $P_i$  and  $Q_i$  at load and generation nodes, and branch currents  $I$  at primary or distribution substation transformers and often at feeder heads)
- Pseudo measurements subject to errors (forecasted or historical active and reactive load injections  $P_i$

and  $Q_i$  or manually entered measurements of any type)

- Virtual measurements that contain no error (zero injections  $P_i$  and  $Q_i$  at network nodes that have neither load nor generation, zero voltage drops  $V_{ki}$  and  $\delta_{ki}$  at closed switching devices  $ki$ , and zero active and reactive power flows  $P_f$  and  $Q_f$  at open switching devices).

After the execution of the SE algorithm, the voltage magnitudes  $V$  and phase angles  $\Theta$  of the network nodes are estimated. The following output information is provided:

- Voltage magnitudes and phase angles at all nodes
- Active and reactive injected power at each generation and load node
- Active and reactive power flows at both sides of each line, transformer, and switch
- Current flows at both sides of each line, transformer, and switch
- Detection and removal of bad and conflicting data.
- Status of the switching devices with unknown or wrong status.

The problem is finding an estimate  $\hat{x}$  of the state vector that minimizes the following objective function [15.42]

$$J(x) = \sum_{i=1}^m \rho(r_i), \tag{15.43}$$

where  $r_i \approx N(0, 1)$  is the weighted residual of the  $i$ -th measurement

$$r_i = \frac{z_i - h_i(x)}{\sigma_i}. \tag{15.44}$$

Table 15.6 summarizes the approaches adopted for state estimation solution. The different estimators can be characterized based on the choice of the  $\rho$  function.

Performance evaluation of the SE techniques has shown that WLAV and SHGM methodologies cannot be applied to distribution systems [15.44]. The WLS method gives consistent and better quality performance when applied to distribution systems. Hence, WLS is

found to be the suitable solver and is used in this project.

The solution  $\hat{x}$  can be found by the normal equations' (NE) iterative procedure as follows

$$G(x^k) \Delta x^k = H^T(x^k) R^{-1} \Delta z^k, \tag{15.45}$$

where,  $\Delta x^k = x^{k+1} - x^k$ ,  $\Delta z^k = z - h(x^k)$ ,  $H = \partial h / \partial x$ , and  $G = H^T R^{-1} H$  is the Jacobian matrix, respectively, evaluated at  $x = x^k$ , and  $k$  is the iteration index.

Since real-time measurements of node injections (loads) are not available in practical distribution networks, a kind of load modeling is necessary to generate the required load data for the DSSE execution. The load information can be modeled considering one of the following sources [15.53–62]:

- Historical samples obtained for different seasons, days, and times, are stored separately for different load types (residential, industrial, and commercial), based on some monitoring and energy bill data.
- AMI, which transfer customer load information to the utility DMS in a bidirectional way.
- AMR systems, which transmit energy consumption data to the utility for billing, between defined time intervals (minutes to hours), in a unidirectional way.
- Advanced AMR meters, which work as intelligent monitoring devices and utilize the communication infrastructure to provide vital information on low voltage levels.
- Smart GPS synchronized PMU devices, located at strategic nodes of the network, to measure voltage and current phasors.

It is assumed that domestic smart meters connected to a node take synchronized measurements of active ( $P$ ) and reactive ( $Q$ ) consumption of the loads at predefined time intervals. These measurements are transmitted to a database server periodically. In any case, DSE will have the previous day's measurements of all the loads. The proposed SE will reliably estimate the node voltages of a distribution network by using the previous day's measurements (while considering whether the day is a weekday, Saturday, or Sunday).

**Table 15.6** State estimation approaches

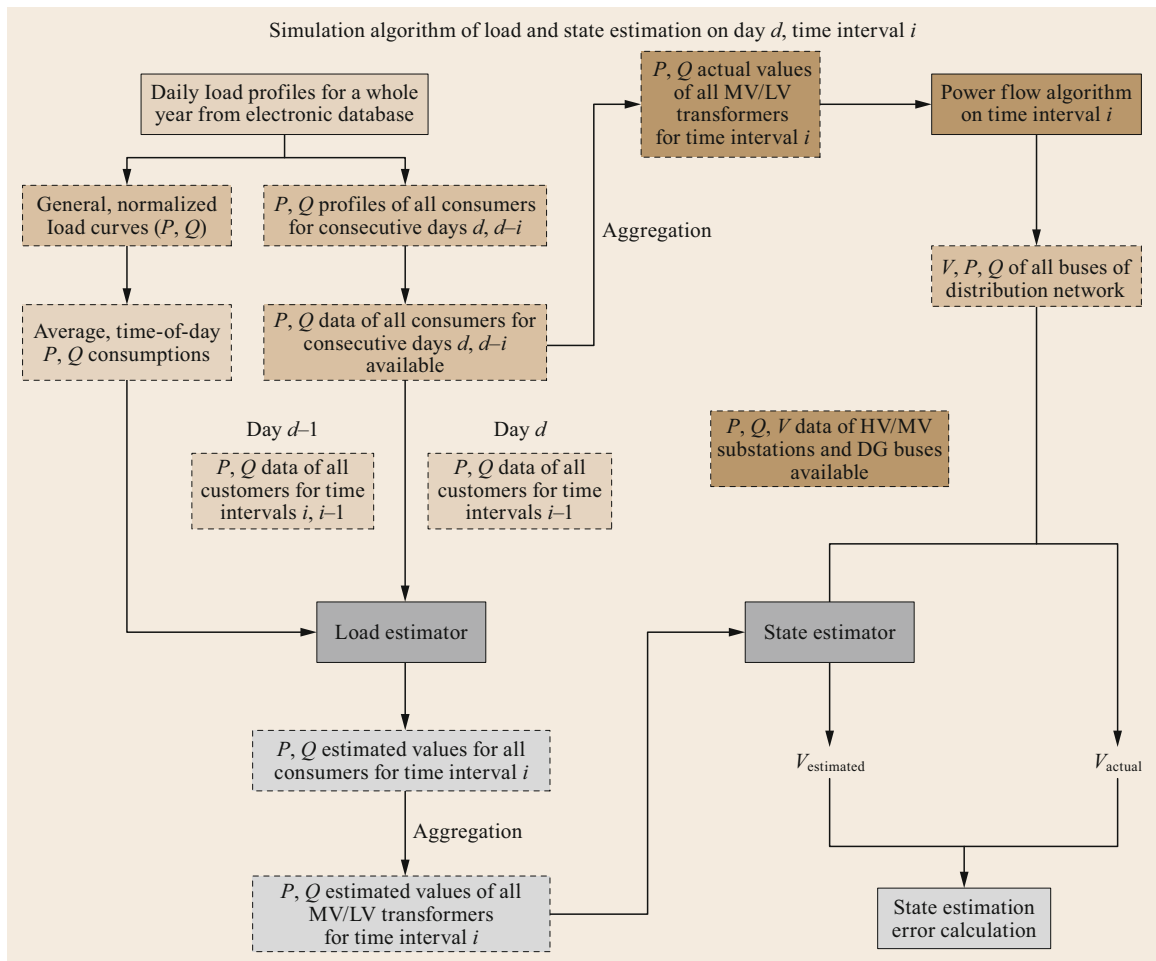

Approach	$\rho(r_i)$	Solution method
Weighted least squares (WLS)	$\frac{1}{2}r_i^2$	Newton iterative
Weighted least absolute value (WLAV)	$ r_i $	Linear programming (LP) or interior point (IP)
Schweppe–Huber generalized-M (SHGM)	$\begin{cases} \frac{1}{2}r_i^2 & \text{if }  r_i  \leq \alpha w_i \\ \alpha w_i  r_i  - \frac{1}{2}\alpha^2 w_i^2 & \text{otherwise,} \end{cases}$ where $w_i$ is the iteratively modified weighting factor and $\alpha$ is a tuning parameter	Iteratively reweighted least squares (IRLS)

HV/MV (primary substation)	<ul style="list-style-type: none"> <li>● <math>P/Q</math> power consumption, <math>V</math> magnitude and/or <math>I</math> magnitude and power factor, in the primary or secondary of the transformer, if available.</li> </ul>

**Table 15.8** Transmission frequency for each data level

Past data of the LV network	It should be available once a day with 24 h of delay (i.e., from $d - 1$ ).
Dynamic data of the LV network	The data of some reference DG and load units (by distribution transformer controllers—DTC) should be available every 15 min with a maximum delay of 1 min.
MV network	It should be available in real time (e.g., on a 1 min time basis).

**Fig. 15.18** Data flow chart of the load and state estimation

The AMR meters installed at distributed generators (DG) will measure the net active power  $P$ , the net reactive power  $Q$ , and the voltage magnitude  $V$  at predefined time intervals and communicate immediately to the server. The SE will also read the  $P/Q$  consumption of the loads connected to each transformer, which will be summed up (as the measurements are time synchronized) to calculate the load of the transformer (and the node). The previous day's loads of the nodes and near real-time power measurements from distributed generators will be used as power injection measurements. Summarizing, the required data for state estimation execution are shown in Table 15.7 [15.42].

The transmission frequency for each data level is shown in Table 15.8 [15.42].

A general framework for the combined simulation of load and state estimation is presented in Fig. 15.18.

The *load estimation algorithm* uses data provided by LV or MV smart meters and deploys a simple time series model [15.62] using basic class-specific load curves associated to each consumer type (e.g., domestic, commercial etc.) to improve the accuracy of individual customer load estimates. Load estimates can be obtained hourly, half-hourly, or at shorter time intervals. Then, all individual load estimates are aggregated, based on topology and connectivity data, to extract load estimates per MV/LV distribution transformers. These values are treated as pseudomeasurements and used as inputs to the state estimation algorithm along with (near) real-time data collected from other points of the power network [15.62]. The time delay in data transmissions from smart meters to data management centers is a parameter that significantly affects the load estimation algorithm performance.

## 15.6 Operation of Active Distribution Networks

Distribution system operation aims at satisfying the load demand in a safe and economical way. The security, quality, and economy of the power supply depend on the control capabilities of the network's equipment. The *operation functions of power distribution networks* can be divided into two categories, each corresponding to different time horizons:

- *Realtime operation*, in which control actions are applied in a short time period; they are calculated based on real-time measurements and state estimation techniques.
- *Day-ahead or schedule operation*, in which control actions of one or more days are calculated based on forecasted values of load demand and renewable generation. Realtime operation management consists of state estimation and control scheduling.

A DSSE receives real-time measurements from the metering infrastructure installed in the distribution network and with the proper deployment of pseudomeasurements and the use of network topology, the network status, i.e., nodal voltage magnitude, and angle, is estimated. Based on the output values of the DSSE, an operation framework calculates the control values for the devices connected to the network. The set of control values aims at optimizing the power flow in the network and mitigating eventual voltage problems that may arise in the grid operation. For the management of ADNs, short-term load and RES forecasting functions that incorporate optimization functions for the grid operation under normal and emergency conditions might be required.

### 15.6.1 Operation of Active Distribution Networks Under Normal Operating Conditions

Under normal operating conditions, control actions aim at the safe and optimum operation of the network, considering variable demand and renewable generation. Control actions in passive distribution networks were limited in the control of network components such as OLTC, switches, and switched capacitors. However, ANM enables the coordinated control of network components and DER to ensure the safe operation of the network. Thus, the network operation becomes more complex with more sophisticated optimization criteria and operational constraints.

The operation of the distribution network depends on the regulatory framework and the level of automation, which differ from one country to another. *The optimal operation of ADNs under normal operating conditions* requires the optimization of several objectives. Some of these can be summarized as follows [15.31, 65]:

- *Minimization of energy losses*: energy loss cost constitutes a substantial part of the network's operational cost, and its minimization improves the network's performance.
- *DG curtailment minimization*: curtailment of DG active power is usually employed to prevent line overload and/or voltage rise along the feeder. DG curtailment has financial consequences for the owners of the DG units, and it can be a barrier for further DG penetration.

- *Minimization of OLTC tap position changes:* frequent operation of OLTCs will shorten their lifetime.
- *Minimization of switch operations:* the reconfiguration of ADNs should be based on a limited number of switch operation. Extensive operation of the switches and switched capacitors will shorten their lifetime.

The aforementioned optimization criteria are not necessarily conflicting and of equal importance. Their priority is determined based on the regulatory framework and the existing infrastructure of the distribution network.

The optimal operation of ADNs is subject to the network's technical constraints. As shown in Sect. 15.3, power-flow balance should be ensured at all system buses. Due to the variability of load demand and renewable generation, voltage constraints need to be considered in order to ensure that bus voltages are kept within their limits for every applied control action. Similarly, line capacity limits should be considered. In the case when reconfiguration is applied, the radiality of the network configuration needs to be maintained. The DG units can absorb or supply reactive power via their inverter interface. The limits of the active and reactive power output of a DG unit are expressed as

$$Q_{DG,i,t} \leq (P_{DG,i,t} - P_{DG,i,t}^{curt}) \tan \varphi_{DG}, \quad (15.46)$$

$$Q_{DG,i,t} \geq -(P_{DG,i,t} - P_{DG,i,t}^{curt}) \tan \varphi_{DG}, \quad (15.47)$$

$$0 \leq P_{DG,i,t}^{curt} \leq P_{DG,max,i}^{curt}, \quad (15.48)$$

$$P_{DG,max,i}^{curt} \leq P_{DG,i,t}, \quad (15.49)$$

$$(P_{DG,i,t} - P_{DG,i,t}^{curt})^2 + Q_{DG,i,t}^2 \leq S_{DG,max,i}^2, \quad (15.50)$$

where  $P_{DG,i,t}$  and  $Q_{DG,i,t}$  are the active and reactive power output of the DG unit at bus  $i$  at period  $t$ ,  $P_{DG,i,t}^{curt}$  is the active power curtailment of the DG unit at bus  $i$  at period  $t$ ,  $\varphi_{DG}$  is the maximum power angle of the DG unit of bus  $i$ ,  $P_{DG,max,i}^{curt}$  is the maximum active power curtailment of the DG unit at bus  $i$  at period  $t$ , and

**Table 15.9** Load data of the 30-bus distribution system

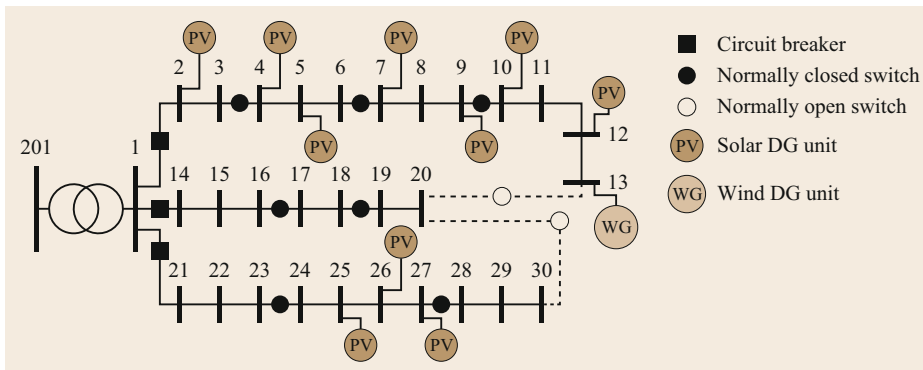

Bus	Load (kVA)
3, 4, 5, 8, 9, 10, 12, 13, 15, 16, 18, 23, 24, 27, 30	50
2, 6, 7, 11, 14, 17, 20, 21, 22, 25, 26	350
19, 28, 29	675

$S_{DG,max,i}$  is the maximum apparent power of the DG unit at bus  $i$ . The maximum and minimum DG reactive power injection limits are given by (15.46) and (15.47), respectively. Note that  $P_{DG,i,t}^{curt}$  is greater than or equal to zero and is limited by (15.48) and (15.49). The apparent DG power output is lower than the apparent power limit of the DG inverter according to (15.50).

**Example 15.1**

Consider the 30-bus distribution of Fig. 15.19, which is a 20kV system with 3 feeders, 29 load buses, 7 normally closed switches, and 2 normally open switches. Each feeder is equipped with a circuit breaker. The length of each feeder segment is 2 km; the length of the tie lines is 3 km and the conductor of the feeders and tie lines is ACSR-95 mm<sup>2</sup> (Table 15.3). The bus load data are presented in Table 15.9; their power factor is 0.95 lagging. The network accommodates 100kW of solar DG at buses 2, 9, 10, 25, 26, and 27; 300kW of solar DG at buses 4 and 12; 500kW of solar DG at bus 7; 600kW of solar DG at bus 5; and 5 MW of wind DG at bus. In this example, the voltage limits are set to ±5% of the nominal voltage.

For the hourly load, and the solar and wind profile of Fig. 15.20, the day-ahead operation of the network is simulated considering two ANM schemes in order to minimize the DG curtailment. The first ANM involves the active power curtailment (APC) of all DG units, while the second ANM scheme involves the APC and the active distribution network reconfiguration (ADNR). As shown in Fig. 15.21, in the first ANM scheme, the DG energy curtailment is equal to 3.812 MWh, while in the second ANM scheme, there is no need for DG curtailment. Note that in the sec-

**Fig. 15.19** The 30-bus distribution system

Fig. 15.21 Curtailed DG active power

and ANM scheme, the normally closed switch in line 16–17 is opened, and the normally open switch in line 13–20 is closed. Furthermore, the necessity of ANM is highlighted in Fig. 15.22. As shown, if passive management is adopted, the voltage limits at bus 13 will be violated. Hence, the distribution network will operate outside its technical limits for a considerable time.

### 15.6.2 Operation of Active Distribution Networks Under Emergency Operating Conditions

Distribution networks are designed with a meshed structure, and they are equipped with normally open

and normally closed switches. However, they operate in radial configuration to simplify protection coordination. Hence, a network component failure will interrupt the power supply to all buses downstream of the faulted area. Network component failures can occur for various reasons, such as extreme weather conditions, component ageing, or an accident. Under these emergency conditions, an OMS aims at resolving the outage and restoration of power supply to customers. As is shown in Fig. 15.23, after the outage alert, the three stages of the *outage management* are [15.66]:

- Fault location
- Fault isolation
- Service restoration.

Fig. 15.22 Bus 13 voltage magnitude (p.u.)

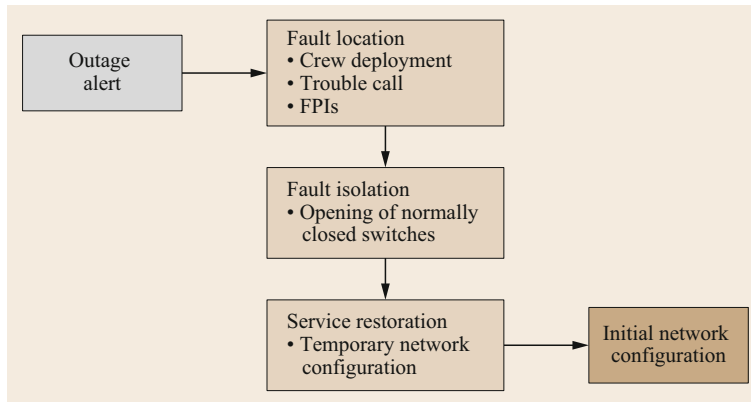

Fig. 15.23 The stages of the FLISR process

The fault location, isolation, and service restoration (FLISR) process needs to be implemented as fast as possible to decrease restoration time and potential lost revenues. Most distribution systems are not fully automated, and some required control actions of the FLISR process need manual operation. Hence, a self-healing distribution system is important, with social and economic benefits. Self-healing can be described as the capability of the distribution system to perform all phases of the FLISR process automatically, without human intervention.

When a fault occurs, the circuit breakers, which are installed at the source of the feeder, or reclosing devices trip, and the power supply to the downstream buses is interrupted. After identifying the faulted feeder, the exact location of the faulted section needs to be determined. Several approaches have been implemented to identify the *fault location*; they are summarized as follows [15.67]:

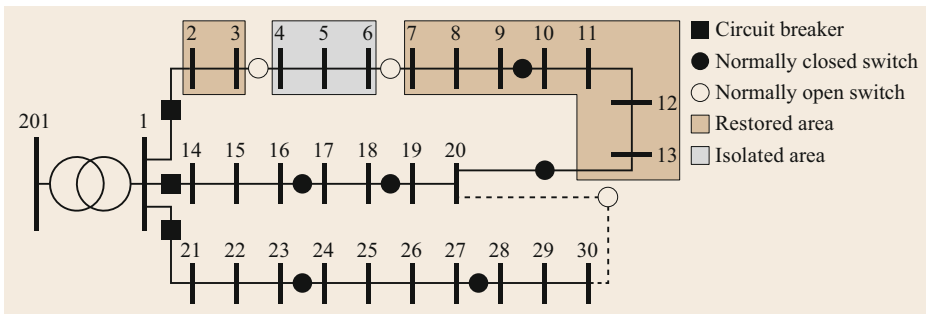

- Crew deployment to visually identify the faulted area and repair it. This approach may prove time consuming, leading to extended interruption periods.
- Direct three-phase circuit analysis-based methods.
- Impedance-based methods.
- Traveling-wave methods.
- Data collected from fault passage indicators (FPIs).

The main drawback of the direct three-phase circuit methods and impedance-based methods is the multiple estimations of fault location. The traveling wave methods may yield inaccurate fault locations due to the presence of laterals and sublaterals.

After fault isolation, *service restoration* aims at determining the appropriate switch operations to restore power supply to the nonfaulted part of the distribution feeder. To achieve this, loads of the nonfaulted part of the distribution feeder are transferred to the neighboring, healthy distribution feeders. Service restoration

**Fig. 15.24** The 30-bus distribution system

**Fig. 15.25** Topology of the 30-bus distribution system after service restoration due to fault in line 5–6

needs to satisfy multiple objectives in a very short time. The objective with the foremost importance is the minimization of the nonsupplied loads. Minimization of the number of switch operations has the second priority. When a service restoration plan is determined, the priority of critical loads, e.g., hospitals, needs to be considered along with the network's technical constraints. There are several methods implemented for the solution of the service restoration problem; they are summarized as follows [15.67]:

- Expert system methods based on knowledge-based if-then-else rules [15.68–70].
- Heuristic methods based on artificial intelligence [15.71–74].
- Mathematical programming methods that formulate the service restoration problem as an optimization problem utilizing global optimization techniques [15.75–77].

Expert-system methods are the most widely used methods for the solution of service restoration. However, they tend to be problem specific, and their rules are normally different among distribution networks. Heuristic

methods require the incorporation of a power-flow model, and they may require multiple iterations to converge to an optimal solution. Mathematical programming methods may require high computation times for large-scale distribution systems.

#### Example 15.2

Consider the 30-bus distribution system of Example 15.1 (Sect. 15.6.2). As is shown in Fig. 15.24, it is assumed that a permanent fault occurs in line 5–6. In this case, the circuit breaker in line 1–2 trips, and the power supply of load buses 2–13 is interrupted. After the fault location has been identified, the normally closed switches in line 3–4 and in line 6–7 are opened to isolate the faulted area. The load buses 4, 5, and 6 will stay out of service until the damaged line is repaired or replaced. Service restoration needs to determine the minimum switch operations to restore power supply to buses 2 and 3, and 7–13. Thus, the circuit breaker in line 1–2 and the normally open switch in line 13–20 are closed, and the power supply of the non-faulted area is restored. The network topology after the implementation of the service restoration plan is shown in Fig. 15.25.

## 15.7 Distribution Network Planning

*Distribution network planning* (DNP) aims at determining the location, capacity, and time period of network investments at minimum cost, in order to serve the load growth and the new loads, while ensuring the safe operation of the distribution network. Depending on the duration of the planning period, the DNP can be classified as short term (1–5 years) or long term (5–20 years). Short-term planning considers network reinforcement or line reconductoring, reconfiguration schemes, and reactive power support options, while long-term planning considers the reinforcement of existing network components, e.g., substation, lines, and the addition of new ones. There are two DNP models [15.78]:

- *Static distribution network planning*, wherein the DNP problem is solved in a single stage considering only the conditions of the final stage of the planning period. In this model, the investment decisions are decoupled from time, and they are implemented at the beginning of the planning period.
- *Multistage distribution network planning*, wherein the DNP problem is solved considering the multiple stages of the planning period. Hence, the investment variables are determined over successive planning stages based on the requirements of each stage.

The multistage DNP formulation is more efficient than the static formulation, since the investment decisions are implemented over the planning period. Thus, the investment decisions required at the first stages of the planning can be implemented immediately, while the ones determined for the later stages of the planning period can be reexamined using updated values of the load forecast. Obviously, the formulation and solution of the multistage DNP model are more complicated than the static ones.

The planning of a distribution network is affected by a large number of miscellaneous factors, such as load growth, the necessity to increase the level of distribution automation, and the increasing DG penetration. The most important of these factors is the forecasted load growth rate of the geographical area that the distribution network serves. Load growth depends on the area development, load density, population growth, customer behavior, and geographical limits. Apart from load growth, modern power distribution systems are facing the challenge to accommodate an increasing amount of DG. Consequently, DNP should also consider future connections of DG units and their increase rate.

The determination of the maximum stress conditions of a planning period is essential for the calculation of the planning requirements. The maximum stress conditions consider load/generation scenarios

with: (i) maximum load/no generation and (ii) minimum load/maximum generation. Furthermore, the determination of representative load/generation scenarios that represent the stochastic behavior of load demand and renewable generation is essential to calculate the cost of energy losses, which is the largest part of the network's operational costs. To derive these representative load/generation scenarios, it is necessary to process historic and statistical data.

The main objective of every DNP formulation is the minimization of the net present value of the investment and operational cost of the network for a planning period. The investment cost is the sum of the costs for the reinforcement and/or addition of network components, and they can be summarized as follows:

- Investment cost for the reinforcement and/or addition of distribution substation (IS)

$$IS = \sum_{i \in \Omega_{SR}} \sum_{a \in \Phi_{SS}} C_{SS,a} y_{i,a,t}^{SR} + \sum_{i \in \Omega_{SA}} \sum_{a \in \Phi_{SS}} C_{SS,a} y_{i,a,t}^{SA}, \quad (15.51)$$

where  $\Omega_{SR}$  and  $\Omega_{SA}$  are the sets of the candidate substations to be reinforced and added, respectively;  $\Phi_{SS}$  is the set of the available types of substations;  $C_{SS,a}$  is the cost of type  $a$  substation; and  $y_{i,a,t}^{SR}$  and  $y_{i,a,t}^{SA}$  are the decision variables for the reinforcement and addition of substation at bus  $i$  using type  $a$  substation at period  $t$ , respectively.

- Investment cost for the reinforcement and/or addition of distribution lines (IL)

$$IL = \sum_{ij \in \Omega_{LR}} \sum_{b \in \Phi_L} C_{L,b} l_{ij} y_{ij,b,t}^{LR} + \sum_{ij \in \Omega_{LA}} \sum_{b \in \Phi_L} C_{L,b} l_{ij} y_{ij,b,t}^{LA}, \quad (15.52)$$

where  $\Omega_{LR}$  and  $\Omega_{LA}$  are the sets of the candidate distribution lines to be reinforced and added, respectively;  $\Phi_L$  is the set of the available types of conductors;  $C_{L,b}$  is the cost per distance of type  $b$  conductor;  $l_{ij}$  is the length of line  $i$ – $j$ ; and  $y_{ij,b,t}^{LR}$  and  $y_{ij,b,t}^{LA}$  are the decision variables for the reinforcement and addition of line  $i$ – $j$  using type  $b$  conductor at period  $t$ , respectively.

- Investment cost for the placement of capacitor banks (IC)

$$IC = \sum_{i \in \Omega_{CB}} \sum_{c \in \Phi_{CB}} C_{CB,c} y_{i,c,t}^{CB}, \quad (15.53)$$

where  $\Omega_{CB}$  is the set of the candidate buses for the placement of capacitors;  $\Phi_{CB}$  is the set of the types

of capacitors available;  $C_{CB,c}$  is the cost of type  $c$  capacitor;  $y_{i,c,t}^{CB}$  is the decision variable for capacitor placement at bus  $i$  using type  $c$  capacitor at period  $t$ .

- Investment cost for the placement of voltage regulators (IVR)

$$IVR = \sum_{ij \in \Omega_{VR}} \sum_{d \in \Phi_{VR}} C_{VR,d} y_{ij,d,t}^{VR}, \quad (15.54)$$

where  $\Omega_{VR}$  is the set of the candidate lines for the placement of voltage regulators;  $\Phi_{VR}$  is the set of the available types of voltage regulators;  $C_{VR,d}$  is the cost of type  $d$  voltage regulator; and  $y_{ij,d,t}^{VR}$  is the decision variable for the voltage regulator placement at line  $i$ – $j$  using type  $d$  voltage regulator at period  $t$ .

For an optimal network reinforcement and expansion plan, it is required to examine as many as possible of the planning alternatives presented in (15.51)–(15.54) in order to achieve the optimal budget allocation. The operational cost consists of several terms, such as the cost for energy losses, reliability costs, and maintenance costs.

The constraints of the DNP can be classified into two categories: (i) the operational constraints and (ii) the constraints associated with the investment decision variables. For a given load forecast and generation, the operational constraints need to ensure that the bus voltages are kept within their limits, the thermal capacity of lines and substations are not violated, and the configuration of the network is radial during the whole planning period. If the investment decision variables of (15.51)–(15.54) are formulated as binary variables, the investment constraints are formulated as

$$\sum_{t \in T} \sum_{a \in \Phi_{SS}} y_{i,a,t}^{SR} \leq 1, \quad (15.55)$$

$$\sum_{t \in T} \sum_{a \in \Phi_{SS}} y_{i,a,t}^{SA} \leq 1, \quad (15.56)$$

$$\sum_{t \in T} \sum_{b \in \Phi_L} y_{ij,b,t}^{LR} \leq 1, \quad (15.57)$$

$$\sum_{t \in T} \sum_{b \in \Phi_L} y_{ij,b,t}^{LA} \leq 1, \quad (15.58)$$

$$\sum_{t \in T} \sum_{c \in \Phi_{CB}} y_{i,c,t}^{CB} \leq 1, \quad (15.59)$$

$$\sum_{t \in T} \sum_{d \in \Phi_{VR}} y_{ij,d,t}^{VR} \leq 1. \quad (15.60)$$

Constraints (15.55) and (15.56) ensure that there will be at most one change in the capacity of the substations that are candidates for reinforcement and addition, respectively. Constraints (15.57) and (15.58) are applied in order to avoid more than one conductor change during the planning period, for the distribution lines

that are candidate to be reinforced or added. According to (15.59) and (15.60), investments in capacitors and voltage regulators can be made at most once in each candidate bus and branch during the planning period.

The advent of ADNs modifies the objectives and the requirements of the planning process [15.79]. Solution methods and concepts that were used extensively for transmission systems are adapted for distribution systems to deliver more cost-effective planning solutions that rely less on traditional network investments and exploit the active management of the DER available [15.80]. Thus, the incorporation of the operational aspects of DER control into the planning process is essential. For example, the control of the active and/or reactive power of the DG units can be considered in the planning process in order to cope with the voltage rise effect caused by DG penetration, alleviate line congestion, and decrease power losses. Energy storage systems can be used to inject energy into the network during periods of low demand; the energy stored in this manner can be returned to the grid at a later time, when load demand is higher. This load shifting effect can eliminate line overloads and/or violation of bus voltage limits, while the cost for network reinforcement can be deferred. Similarly, demand response schemes can be employed, when customers' consumption leads to violation of network's technical characteristics. The way that the most common technical challenges found in distribution networks can be solved considering active management of the distribution network is presented in Table 15.5.

### Example 15.3

Consider the 20 kV distribution network of Fig. 15.26 with two substations, 20 load buses, and a planning period that is divided into three stages; the candidate

Type	$R$ ( $\Omega/\text{km}$ )	$X$ ( $\Omega/\text{km}$ )	Ampacity (A)	Cost (\$/km)
A	1.268	0.422	136	12 000
B	0.576	0.393	261	25 000
C	0.215	0.334	445	56 000

**Fig. 15.27** The reinforcement and expansion plan of the 24-bus distribution system considering passive management

lines for expansion are depicted with dashed lines. The branch and load data can be found in Table 15.11 of Appendix 15.A. The technical and economic characteristics of the conductors available are shown in Table 15.10. The investment cost of a capacitor with a 1.2 Mvar capacity is equal to 8k\$, while the investment cost of a voltage regulator is 42k\$. The capacity of the existing substations is 25 MVA, and the voltage limits are  $\pm 5\%$  of the nominal voltage. The inflation and interest rates are 2% and 8%, respectively. At the first stage, it is planned to install three wind DG units: 5 MW at bus 7; 6 MW at bus 23; and 7 MW at bus 24. Furthermore, it is planned to connect one solar DG unit of 100 kW at each future load bus. Capacitors and voltage regulators can be installed at every corresponding part of the initial network configuration. The optimal reinforcement and expansion plan is determined for two cases: (i) considering the passive management of DG units and (ii) considering the control of the active and reactive power of the DG units.

Figure 15.27 presents the network topology of the 24-bus distribution system at the end of the planning

**Fig. 15.28** The reinforcement and expansion plan of the 24-bus distribution system considering ANM

period considering DG passive management. The total investment cost of the network topology of Fig. 15.20 is 652.09k\$. At the first stage, the distribution line 22–6 is reinforced with a type C conductor to meet renewable DG; lines 3–10, 5–24, and 3–23 are constructed with a type B conductor to connect the new load and the DG points. At the second stage, line 21–1 is reinforced with a type C conductor to meet load demand; line 6–13 is constructed with a type B conductor to connect the load at bus 13; lines 7–11, 2–12, 1–14, 4–15, and 22–17 are constructed with a type A conductor to connect the future load buses. At the third stage, lines 21–2 and 22–8 are reinforced with a type C conductor to meet load demand; lines 3–16, 24–18, 7–19, and 13–20 are constructed with type A conductor. One capacitor is installed at bus 11 at stage two, and another one is installed at bus 7 at the third stage of the planning period to deal with the voltage drop issues.

Figure 15.28 presents the network topology of the 24-bus distribution system at the end of the planning period, incorporating ANM aspects into the planning process. The ANM scheme assumes that the power factor of the DG units can vary from 0.95 lagging to 0.95 leading, and the maximum allowable DG active power curtailment is 5% of the DG rated power. The total investment cost of this topology is 629.58k\$. The difference between the investment cost of Figs. 15.20 and 15.21 is due to the fact that the reinforcement of line 22–6 is deferred to the third stage, and line 7–23 is constructed to connect the wind DG unit of bus 23 instead of line 3–23. Note that the length of line 3–23 is longer than the length of line 7–23.

## 15.8 Summary

This chapter presents the basic principles of power distribution systems and the modeling of their components. Different models for the power-flow analysis of radial distribution networks are given, and results on various distribution test systems demonstrate their accuracy and computational performance. The new challenges faced by modern distribution networks due to the increasing penetration of DER, including renewable DG, are discussed. The principles and functions of an advanced distribution management system for the control and monitoring of the distribution network are presented. The coordinated control

of DERs and network components leads to the transformation of passive distribution networks to active distribution systems. It is shown that the adoption of ANM to the operation of distribution networks under normal and emergency conditions increases the network's efficiency, deals with voltage rise/drop issues, and alleviates line congestion in a cost-effective way. Furthermore, the incorporation of ANM into distribution network planning exploits all network components and DER control capabilities, leading to reinforcement and network expansion planning at lower investment costs.

## 15.A Appendix: Load and Line Data of Distribution Networks

### Nikolaos C. Koutsoukis

School of Electrical and Computer Engineering  
National Technical University of Athens  
Athens, Greece  
[koutsoukis@power.ece.ntua.gr](mailto:koutsoukis@power.ece.ntua.gr)

Nikolaos C. Koutsoukis received the Diploma in Electrical and Computer Engineering from the National Technical University of Athens (NTUA), Greece, in 2012, where he is currently pursuing a PhD in active distribution networks. His research interests include power system planning, distributed generation, and power distribution system control, and automation. He is a member of the Technical Chamber of Greece.

### Pavlos S. Georgilakis

School of Electrical and Computer Engineering  
National Technical University of Athens  
Athens, Greece  
[pgeorg@power.ece.ntua.gr](mailto:pgeorg@power.ece.ntua.gr)

Pavlos S. Georgilakis received his Diploma in Electrical and Computer Engineering and his PhD from the National Technical University of Athens (NTUA), Athens, Greece in 1990 and 2000, respectively. He is currently Assistant Professor at the School of Electrical and Computer Engineering of NTUA. His research interests include power systems optimization, smart grids, and distributed energy resources.

---

### George N. Korres

School of Electrical and Computer Engineering  
National Technical University of Athens  
Athens, Greece  
[gkorres@cs.ntua.gr](mailto:gkorres@cs.ntua.gr)

George N. Korres received his Diploma in Electrical and Computer Engineering and his PhD from the National Technical University of Athens (NTUA), Athens, Greece in 1984 and 1988, respectively. He is currently Professor at the School of Electrical and Computer Engineering of NTUA. His research interests include power system state estimation, power system protection, and industrial automation.

---

### Nikos D. Hatziaargyriou

School of Electrical and Computer Engineering  
National Technical University of Athens  
Athens, Greece  
[nh@power.ece.ntua.gr](mailto:nh@power.ece.ntua.gr)

Nikos D. Hatziaargyriou is Professor at the National Technical University of Athens (NTUA) and Chairman and CEO of the Hellenic Electricity Distribution Network Operator (HEDNO). He is Chair of the EU Technology and Innovation Platform on Smart Networks for Energy Transition. He is author of more than 200 journal publications and 500 conference papers. His research interests include smart grids, distributed energy resources, microgrids, renewable energy sources, and power system security.

# Energy Storage

## 16. Energy Storage

Alfred Rufer

This chapter provides an overview on classical and innovative storage solutions and systems. The historical context and today's motivation for the development and application of energy storage are presented, together with methods and definitions for quantitative and qualitative comparison of different energy storage means. An energy-efficiency-based description method called *The Theory of Ragone Plots* is included.

From the classical pumped storage and its recent evolution as flexible speed-variable pump-turbines to the most recent high-power and high-energy density batteries coupled to smart grid configurations, the chapter will present the main characteristics and properties of each component. In addition, compressed-air technologies, flywheels, as well electrical magnetic and capacitive storage components are introduced. For large-capacity and so-called seasonal storage, the hydrogen storage principle is described.

Finally, system arrangements and applications are described as storage as a grid component, storage for renewable energies, hybrid power plants, or uninterruptible power sources.

Examples of recent realizations of large-scale storage plants complete the chapter.

Additional information and supplementary exercises for this chapter are available online.

Energy storage is an important area of the domain of electric power systems in general. It comprises classical solutions used for a longer time, with the example of large hydropower facilities, and also new technologies issued from the evolution of material sciences, such as the modern lithium-ion-based accumulators. While the principle of centralized power generation is moving slowly into the direction of distributed and renewable sources, energy storage is expected to play a new role in this context, principally due to the variability of the new sources.

Portable or mobile applications are based on batteries and concern lower energy capacity and lower power levels. Essentially, energy density and also power density are in the center of interest of many academic and industry research and development projects and are motivated by increasingly more performance.

Energy storage technologies, components, and systems are described in [16.1], together with the necessary tools and methodologies allowing their proper modeling and design.

## 16.1 The Context of Use of Energy Storage

Large facilities for electrical energy storage have been built in the second half of the twentieth century, in the context of matching the variable power demand (daily cycles) with the installation of nuclear power plants, known for their mostly constant power production. Figure 16.1a shows the typical power profile of weekly consumption, and Fig. 16.1b illustrates one of the newest pump-storage facilities, built in the Swiss Alps, the Nant-de-Drance project. Many facilities have been realized with the motivations of compensating daily variations, such as the examples of the Hongrin–Leman facility in Switzerland, the Raccoon Mountain

Pumped-Storage Plant, west of Chattanooga, TN, US, or the Yagisawa Power Station in Japan.

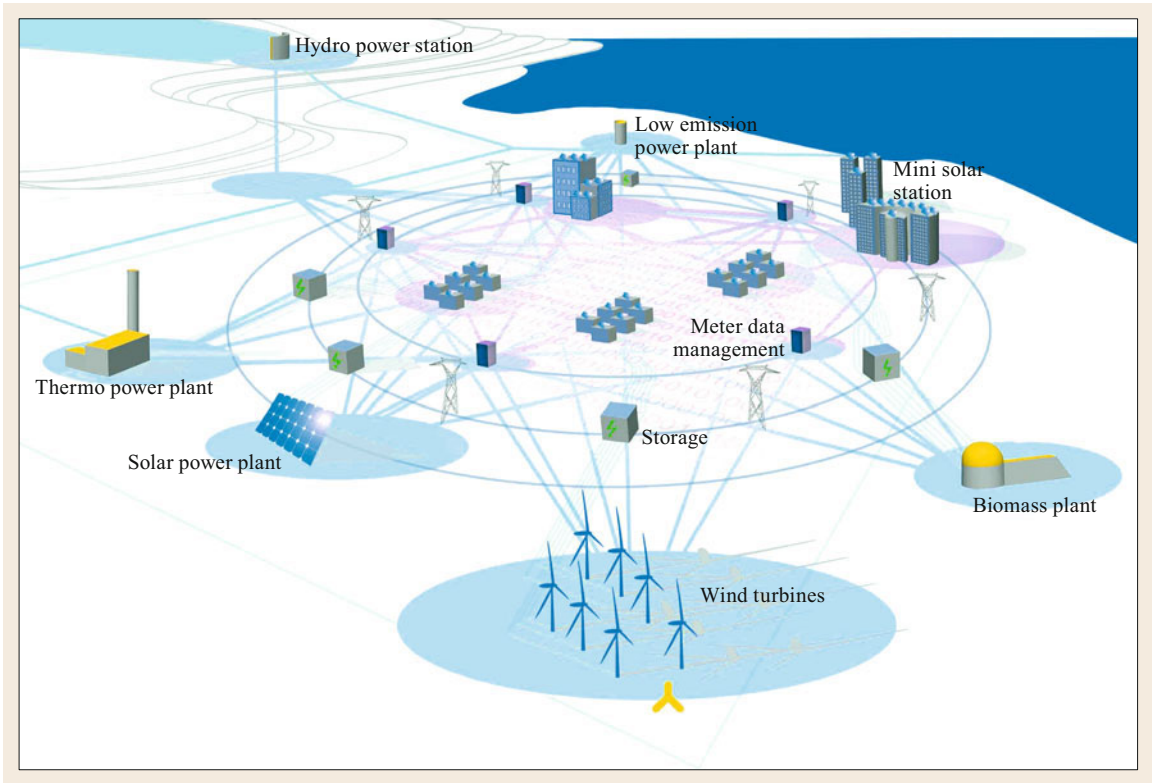

From the end of the twentieth century, another tendency appeared in the context of the development of renewable energy sources. From the classical centralized utility of today, there is a clear movement in the direction of the distributed utility of tomorrow, together with the appearance of so-called smart grids (Fig. 16.2).

Renewable energy sources are known for their variation in time or available power related to meteorology conditions. This is clearly a new motivation for the development and realization of energy storage systems.

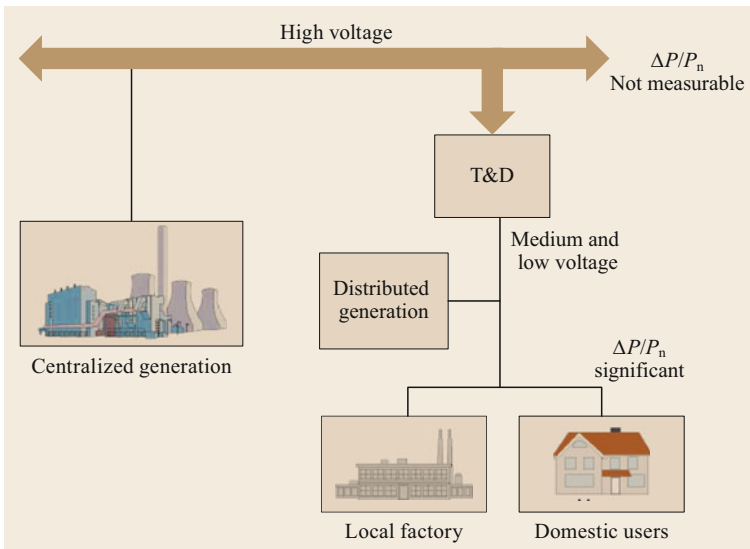

**Fig. 16.1a,b** Daily variations of power demand. **(a)** Profile of demand over a week. **(b)** Pumped-storage plant Nant-de Drance (Switzerland). **(b)** Reprinted with permission from JBcomm, 2019

**Fig. 16.2** From the centralized utility of today to the distributed utility of tomorrow (reprinted with permission from Mario Paolone, 2019)

**Fig. 16.3** Power fluctuations ( $\Delta P/P_n$ ) in centralized and decentralized power generation systems

An additional reason can be found in the principle itself of decentralizing energy production. This concerns power matching between decentralized generators and their loads nearby, which can generate significant and fast variations of the local power demand in local net-

works. Figure 16.3 illustrates the principle of *losing* the averaging effect of the power due to decentralization of production.

A general tendency towards an increasing use of energy storage can be observed.

**Table 16.1** Categorization of energy storage scales and their applications [16.2]

Category	Applications	Storage duration
Power quality and regulation	Fluctuation suppression/smoothing Dynamic power response Low-voltage ride through Line-fault ride through Uninterruptible power supply Voltage control support Reactive power control Oscillation damping Transient stability	< 1 min
Bridging power	Spinning/contingency reserves Ramping Emergency backup Load following Wind power smoothing	1 min–1 h
Energy management	Peak shaving/generation/time shifting Transmission curtailment Energy arbitrage Transmission and distribution deferral Line repair Load cycling Weather smoothing Unit commitment Load leveling Capacity firming Renewable integration and backup Seasonal storage Annual smoothing	5–12 h  Hours to days  > 4 months

Four different aspects are considered:

- First, the use of storage technology in order to solve the problem of availability of renewable energy sources (RES) (day-to-night shift for photovoltaic plants as a first example) or the bridging of a lack of production of fluctuating sources. In many decentralized places where PV (photovoltaic) installations are used, night power is often produced by diesel generators. For ecological reasons, these generators can be replaced by storage techniques and increased PV collectors.
- Second, the potential for enhancing market participation, such as energy or capacity balancing, also ancillaries markets.
- Third, the use of energy storage technology in order to assist some problematic consumers characterized by strong and fast demand, which are not compatible with the local grid-access codes.
- Fourth, a high smart-grid-related potential with diverse innovative functions as final prosumer applications related to sustainable energy concepts.

- A fifth category of use is more related to economic aspects, as in the case of generation using fuel cells. The design of such systems for maximum peak power can lead to unacceptable costs. The design for the *mean value* is more realistic, and the highest power demand can be taken out of a storage device. Also, in the category of economic advantages, storage techniques could allow us to practice the strategy of buy low, sell high.

Table 16.1 gives a further view of the categorization of energy storage scales and their applications in relation to grid applications.

Regarding the applications of voltage support and reactive power control, it must be known that modern power electronic circuits such as VSCs (voltage source converters) used for the interface between storage components and the grid have the inherent property that the active and reactive currents can be controlled separately. As a consequence, such applications can be operated for an unlimited time, if the design of current and thermal capacity is adapted.

## 16.2 General Definitions of Energy Storage

### 16.2.1 Energy and Power

An engineering approach to the topic of energy storage is clearly based on a quantitative characterization. First of all, energy quantities should be clearly defined, as well as all energy transformations. Energy transformations, and this is also valid for a storage process, are characterized by well-defined efficiencies. The quality or efficiency of the process does not only depend on the process type itself, but on the conditions that this process is applied. More explicitly, these conditions can be characterized by what is called power. As a consequence, one has to first properly define what is energy and what is power.

#### Definitions of Energy

The general definition of energy is provided by the conventions of a thermodynamic system in combination with the description of the macroscopic forms of energy of the system. The sum of all energies forms of a system is called the *total energy*.

*Macroscopic energy* of a system is related to its movement and to external effects such as gravity, magnetism, or electricity.

*Microscopic energy* is related to the molecular activity of a system and is often called the *internal energy*.

A simple definition of the total energy is given by the sum of the internal energy  $U$ , the kinetic energy KE, and the potential energy PE, leading to the expression of (16.1) [16.3].

$$E = U + \text{KE} + \text{PE} = U + m\frac{V^2}{2} + mgz, \quad (16.1)$$

where  $m$  is the mass,  $V$  is the velocity of the mass from a given reference point,  $g$  is the gravitational acceleration, and  $z$  is the height of the mass center related to a reference point.

For a system with a rotating mass, the term for the kinetic energy becomes

$$\text{KE}_{\text{rot}} = J\frac{\omega^2}{2}, \quad (16.2)$$

where  $J$  is the moment of inertia, and  $\omega$  is the angular velocity.

When (16.1) is valid for closed systems, it must be completed for so-called open systems by a term corresponding to the energy associated with the flow of material. This energy is characterized through the mass flow rate

$$\dot{m} = \rho \dot{v} = \rho A v_{\text{mean}}, \quad (16.3)$$

$\dot{v}$  being the volumetric flow rate,  $\rho$  the density,  $A$  the section of the flow, and  $v_{\text{mean}}$  the average velocity of the flow.

The energy flow rate associated with the flow of material is given by

$$\dot{E} = \dot{m}e, \quad (16.4)$$

where  $e$  is the specific energy of the material.

Magnetic and electric effects can play a major role in the energy of given systems like inductors or capacitors. These amounts are considered as macroscopic energy and can be calculated as

$$E = E_{\text{mag}} + E_{\text{cl}} = \frac{1}{2}LI^2 + \frac{1}{2}CU^2. \quad (16.5)$$

In (16.1),  $U$  is the internal energy of a system and includes all forms of microscopic energy at the level of the molecular and atomic scale. It corresponds to kinetic and potential energy of molecules and atoms, of nucleons and electrons, and to the energy that binds them together. In the case of energy storage devices, the variation of the internal energy is generally considered and it can be described through (16.6) [16.3]

$$dU = -pdV + TdS + \sum_i \mu_i dn_i. \quad (16.6)$$

The first term on the right-hand side of (16.6) is the work done on the system, where  $p$  is the pressure and  $V$  the volume. The second term corresponds to the heat transferred into the system in terms of temperature  $T$  and entropy  $S$ .

The third term represents the chemical energy and is the form of the internal energy related to the cohesion between the positively charged nucleus of the atoms and their negative electrons. The chemical energy also binds the atoms in the molecule;  $\mu_i$  is the chemical potential of a species  $i$ , and  $n$  corresponds to the number of moles considered.

In the case of an electrochemical battery, the internal energy is expressed through the Gibbs energy  $\Delta G$ . This energy is related to the standard redox potential by the known Nernst law

$$E_{\text{SHE}} = -\frac{\Delta G}{nF} = \left(E_{\text{ox/red}}^0\right)_{\text{SHE}} + \frac{RT}{nF} \ln\left(\frac{\text{ox}}{\text{red}}\right), \quad (16.7)$$

where (ox) and (red) designate the concentrations of the oxidized and reduced forms of the redox couple,  $R = 8.32 \text{ J}/(\text{K mol})$ ,  $T$  is the absolute temperature,  $n$  is the number of electrons implicated in the reaction, and  $F$  is Faraday's constant, as will be explained later in

Sect. 16.8. In (16.7), the index SHE denotes that the potential is referred to the standard hydrogen electrode.

### Power or Energy Flow Rate

The power can be defined as the *energy flow rate* to or from a given system

$$P(t) = \frac{dE}{dt}, \quad (16.8)$$

where:

$P$  (power) is expressed in watt

$E$  (energy) is expressed in joule, or kW h

$t$  (time) in seconds (s), hours (h),

$$1 \text{ J} \hat{=} 1 \text{ W s} \hat{=} 1 \text{ N m}.$$

Example: transformation of electric power into heat

Energy: heating up 100 L of water from 20 to 60 °C needs 4.6 kW h (4.18 J/°C and per gram gives 16.7 MJ or 4.6 kW h).

Power: to do this heating up within 4 h, a 1.15 kW heater is needed; within 1 h, a 4.6 kW heater is needed.

## 16.2.2 System Ratings

In order to design an appropriate storage device and to choose the right solution in relation to a given application, it is important to have a comparative evaluation of the possible capacity and performance. First, the

power range must be defined. Then, with respect to the expected time autonomy, the energy capacity can be defined. Figure 16.4 is a representation of a high number of possible storage solutions over a large power range of 6 decades, starting from the 1 kW level up to the GW level. Different storage technologies are represented, from electrochemical batteries to large-scale pumped hydro storage. CAES (compressed-air energy storage), superconductive magnet energy storage SMES, as well as flywheels are compared. The vertical axis of the figure illustrates the system autonomy, in powers of 10 h. The product of the power multiplied by the time gives the energy capacity. This parameter corresponds to the surface delimited by the horizontal and vertical lines of the values represented in the diagram.

Power bridging means the action to bridge the downtime during a switching transition by carrying the critical load away from a failing power source to a stable alternate source immediately. Energy management should be understood as the task of the planning and operation of larger energy production and energy consumption units connected to the grid. For batteries, the values indicated reflect some of the most important realizations, but in relation to the increase of the possible performance, capacity, and costs, the different fields are expected to evolve continuously.

Regarding time autonomy, a conventional approach considers real systems related to up to several tens of hours. These technologies are represented in the lower half of Fig. 16.4. For longer storage times, such as the so-called seasonal storage, several possibilities exist, which are based on complex transformations. In

Fig. 16.4 Overview on storage systems

Fig. 16.5 Weight and volume energy density

Fig. 16.4, the long-term storage is represented by up to  $10^3$  h. This indicative value could correspond to a transformation from solar power to hydrogen defined over 3 months (100 d) and with a collection of up to 10 h/d. The 1 MW value indicated for this seasonal storage is chosen arbitrarily.

### Energy Density

One important parameter related to a given technology is the energy density. In Fig. 16.5, the energy densities of several techniques are indicated. On the vertical axis, the *weight energy density* is indicated.

The symbol used for the weight energy density is:  $e_m$  (Wh/kg); this parameter is generally indicated in Wh/kg, or in kWh/t. Another parameter for the energy density is the *volume energy density*. The symbol used for the volume energy density is:  $e_v$  [Wh/dm<sup>3</sup>]; this parameter is indicated in kWh/m<sup>3</sup>, or in Wh/dm<sup>3</sup>. These symbols are chosen according recommendations of the IEC [16.4].

The parameters on energy density are important with respect to the choice of technology for a given application. Mobile applications are the most concerned with the weight energy density. In this context, an extreme case of application is the *Solarimpulse* project, which uses modern high-performance batteries in order to fly overnight with energy accumulated during the day by PV cells placed on the airplane wings [16.5].

In opposition to what will be demonstrated in Sect. 16.3.4, the values indicated by the manufacturers of storage components related to energy density generally do not consider any energy efficiency or losses during charging or discharging, nor do they consider any

self-discharging losses. In reality, the internally-stored energy corresponds to a given value that is neither equal to what was supposed to be stored initially, nor to what can be recovered. These values depend on the power level of the energy exchange. A schematic representation of the energy quantities and the related losses is given in Fig. 16.6.

### Power Density and Specific Power

A second possibility to compare storage devices is to quantify their power capability. This is often given by the power density or by the specific power. The power density is the amount of power (the time rate of energy transfer) per unit volume. It is also called the *volume power density*. The symbol used for the power density is  $p_v$  (W/dm<sup>3</sup>). It is expressed in W/dm<sup>3</sup> or in kW/m<sup>3</sup>. It is also possible to give the value of the volume power

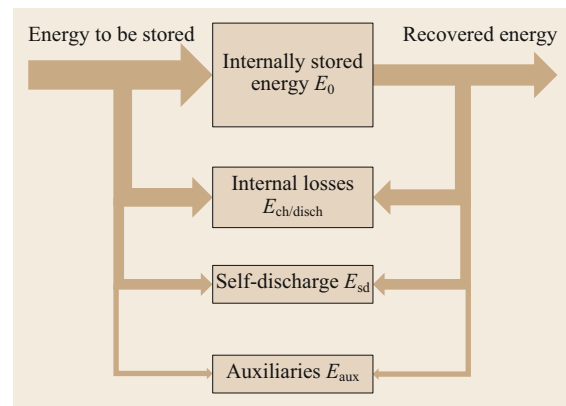

Fig. 16.6 Energy stored and recovered with losses

Fig. 16.7 The Ragone chart

density in  $\text{W}/\text{m}^3$ , as can be seen in some scientific tables [16.5].

The *power-to-weight ratio*, or *specific power*, is the power generated by a source divided by the mass. The symbol used for the *power-to-weight ratio* is  $p_m$  ( $\text{W}/\text{kg}$ ). This parameter is given in  $\text{W}/\text{kg}$  or in  $\text{kW}/\text{t}$ . For powerful devices, such as supercapacitors or thermal generators, the specific power is often given in  $\text{kW}/\text{kg}$ . As was said before for the energy density, these parameters are only an indication given by the manufacturer to define what is possible or admissible for their use. The values indicated cannot be interpreted in the sense of energy efficiency.

## 16.3 Technical Definitions

To define the application of a given storage device correctly and in order to have clear parameters for the design, technical definitions are needed [16.6].

### 16.3.1 General Parameters

#### Capacity

The capacity is the quantity of electricity to be recovered from an accumulator. It is generally expressed in  $\text{A h}$  and corresponds to the time integral of the current

$$C = \int_0^t i(t) dt. \quad (16.9)$$

#### Depth of Discharge

This is the indication of the quantity of electricity already extracted from an accumulator related to its maximum capacity  $C$ ,

$$\text{DoD} = \frac{\int_0^t i_{\text{dis}}(t) dt}{C}. \quad (16.10)$$

### 16.2.3 The Ragone Chart

The Ragone chart is used for the performance comparison of various energy storage devices. The values represented on a Ragone chart are the specific energy or weight energy density  $e_m$  (in  $\text{W h}/\text{kg}$ ) versus the specific power or power-to-weight ratio  $p_m$  (in  $\text{W}/\text{kg}$ ). The axes of a Ragone chart are logarithmic, which allows comparing the performance of very different devices (for example, extremely high and extremely low power). Figure 16.7 gives an example of a Ragone chart used by one manufacturer for the positioning of a given technology in a general context of energy storage devices.

#### State of Charge

This is an indication of the remaining quantity of electricity available from an accumulator, related to its maximum available capacity

$$\text{SoC} = \frac{\text{Amount of remaining charge}}{\text{Practical capacity of an accumulator}},$$

$$\text{SoC} = \frac{C - \int_0^t i_{\text{dis}}(t) dt}{C}. \quad (16.11)$$

The state of charge (SoC) and depth of discharge (DoD),

$$\text{SoC} = 1 - \text{DoD} \quad \text{or} \quad \text{DoD} = 1 - \text{SoC}. \quad (16.12)$$

The SoC and DoD are related to electric charges as current integrals. They are usually applied to electrical and electrochemical accumulators. By analogy, the state of charge can be replaced by the state of energy (SoE), corresponding to the ratio between the remaining amount of energy available ( $E$ ) and the total amount of stored

**Table 16.2** Charging/discharging rates

Battery capacity: $n \text{ A h}$		
C-rate	Time (min)	Current (A)
5 C	12	$5n$
2 C	30	$2n$
1 C	60 (= 1 h)	$n$
0.5 C (or C/2)	120 (= 2 h)	$n/2$
0.1 C (or C/10)	600 (= 10 h)	$n/10$

energy ( $E_{\text{sto}}$ ). SoE is a more universal parameter and can be used for any storage device,

$$\text{SoE} = \frac{E}{E_{\text{sto}}} . \quad (16.13)$$

### Charge and Discharge Rates (C-Rates)

The charge and discharge rates of an accumulator are generally defined through C-rates. With the definition of Sect. 16.3.1, the capacity of an accumulator is usually given at 1 C, which means that a battery rated  $n \text{ A h}$  should deliver  $n \text{ A}$  for 1 h. Choosing different values for the C-rate of the same battery corresponds to a charge or discharge with different times and different currents, as shown in Table 16.2.

The values given in Table 16.2 correspond to an idealized battery without charging/discharging losses. The internal losses can strongly reduce the discharge time or affect the charging time of a given battery.

### 16.3.2 Round-Trip Efficiency Under Normal, Ideal, and Real Conditions

Energy efficiency values are, in a very broad context, highly sensitive parameters. It is, therefore, of great importance to specify the exact conditions of their evaluation in a pragmatic way.

The energy storage cycles considered correspond to a series of charges, discharges, and idle modes. To define the round-trip efficiency properly, it is necessary to first have identical states of energy at the end and at the beginning of the cycle. Even if the storage systems are of huge complexity and of diverse technologies, the energy loss can be divided into two main categories, namely, the loss due to the power transfer  $P_{\text{ch}}$  (charge and discharge) and the loss due to the self-discharge  $P_0$ .

For the round-trip efficiency (index c), one new definition and notation is defined that concerns the ratio between the charging and discharging power. In many references, such as [16.7], the assumption is made that the charge and discharge powers are identical. Such conditions are called *normal*, and this condition will be indicated through the index n. Thus, a first symbolic is proposed: *the normal round-trip efficiency is  $\eta_{\text{cn}}$*  as a general definition.

Further, one should know through the definition of the symbol used for the round-trip efficiency, whether or not it includes the self-discharge loss  $P_0$ . As a consequence, the second proposal is to add the index 0 to the general symbol, if it describes *the ideal normal round-trip efficiency  $\eta_{\text{cn}0}$* .

Finally, if the self-discharge losses are included, the symbol is completed by the letter t, leading to *the real normal round-trip efficiency  $\eta_{\text{cnt}}$* , where the additional index t is an indication that the storage time influences the final value of the energy balance due to self-discharge.

### Charge and Discharge Losses

One can suppose the charge and discharge losses are of the form

$$P_{\text{ch}} \cong \alpha P^2 , \quad (16.14)$$

with  $P$  being the charge or discharge power.

In the case of an electrochemical battery, the parameter  $\alpha$ , which is related to the internal resistor, is dependent on the SoE and also on the direction of the energy transfer. In an electrochemical battery, it can be assumed that the power is proportional to the current (voltage approximatively constant). This is not the case for other storage elements, like capacitors (supercapacitors), where the voltage varies strongly with the state of energy.

### Losses Due to Self-Discharge

Self-discharge losses are generally an increasing function of the state of energy. They are noted as  $P_0(\text{SoE})$ .

### Total Losses

Considering one operating cycle of the storage device that is characterized by one specific power profile  $P(t)$  and by one state of energy  $\text{SoE}(t)$ , the total losses  $P_{\text{loss}}$  are equal to the sum of the charge/discharge losses added to the self-discharge losses

$$P_{\text{loss}} = \alpha P^2(t) + P_0[\text{SoE}(t)] . \quad (16.15)$$

Further, the dissipated energy  $E_{\text{loss}}$  over one complete cycle can be calculated as

$$E_{\text{loss\_cyc}} = \int_0^{t_{\text{cyc}}} \{ \alpha P^2(t) + P_0[\text{SoE}(t)] \} dt . \quad (16.16)$$

By convention, the energy storage device is defined as an *energy sink* and, consequently, the power  $P(t)$  is positive during the charge phase and negative during the

**Fig. 16.8a–c** Successive phases of the round-trip cycle of a storage device. (a) Charging and discharging power  $P(t)$ , (b) energy losses  $E_{loss}(t)$ , (c) state of energy  $SoE(t)$

discharge phase. The profile of the state of energy  $SoE$  is given by

$$SoE(t) = SoE(t_0) + \frac{\int [P(t) - P_{loss}(t)] dt}{E_{sto}}, \quad (16.17)$$

where  $E_{sto}$  is the energetic capacity of the storage device.

As a standard example, Fig. 16.8 shows a specific power profile consisting of three successive phases. First, a charging phase at constant power  $P_M$  during one charging time of  $t_{ch}$ , then an idling phase characterized by a low self-discharge, and finally, a discharging phase at an identical power as during the charging phase, but of a slightly reduced duration  $t_d$  due to the fact that the energy amount recovered during discharging can only be smaller than the amount transferred during the charging phase.

The schematic power profile of Fig. 16.8 illustrates the importance of the specific characteristics of the charge/discharge cycle, the intensity of the charging and discharging power, as the ratio of the different phase durations, especially the duration of the idling mode. The evolution of the energy losses is indicated. Finally, the state of energy  $SoE(t)$  is also represented.

### 16.3.3 The Round-Trip Efficiency

The round-trip efficiency  $\eta_c$  is the ratio of the energy  $E_d$  recovered during the discharge to the energy spent

$E_{ch}$  for the charging process, calculated as a mean value over one charging/discharging cycle. Such a cycle can be chosen arbitrarily, but the  $SoE$  after discharge must be identical to the  $SoE$  before the charging process.

For the ideal example of Fig. 16.8, the ideal normal round-trip efficiency where the self-discharge losses are neglected is calculated according the definitions of Sect. 16.3.2

$$\eta_{cn0} = \frac{E_d}{E_{ch}} = \frac{P_M t_d}{P_M t_{ch}} = \frac{t_d}{t_{ch}}. \quad (16.18)$$

The round-trip efficiency can also be expressed by

$$\begin{aligned} \eta_{cnt} &= \frac{E_{ch} - E_{loss}}{E_{ch}} \\ &= \frac{P_M t_{ch} - \alpha P_M^2 (t_{ch} + t_d) - \int P_0 [SoE(t)] dt}{P_M t_{ch}}. \end{aligned} \quad (16.19)$$

Substituting  $t_d$  by  $t_d = \eta_{cnt} t_{ch}$  leads to

$$\eta_{cnt} = \frac{1 - \alpha P_M}{1 + \alpha P_M} - \frac{\int P_0 [SoE(t)] dt}{P_M t_{ch} (1 + \alpha P_M)}. \quad (16.20)$$

The round-trip efficiency can be expressed in dependency of each phase of the cycle, more precisely through consideration of the *instantaneous power effi-*

ciencies during charging  $\eta_{\text{ch}}$  and discharging  $\eta_{\text{d}}$

$$\eta_{\text{ch}} = \frac{P_{\text{M}} - \alpha P_{\text{M}}^2}{P_{\text{M}}} = 1 - \alpha P_{\text{M}}, \quad (16.21)$$

$$\eta_{\text{d}} = \frac{P_{\text{M}}}{P_{\text{M}} + \alpha P_{\text{M}}^2} = \frac{1}{1 + \alpha P_{\text{M}}}. \quad (16.22)$$

Finally, considering the *self-discharge energy factor*

$$\eta_0 = \frac{\int P_0[\text{SoE}(t)]dt}{P_{\text{M}}t_{\text{ch}}},$$

$$\text{we get } \eta_{\text{cnt}} = (\eta_{\text{ch}} - \eta_0)\eta_{\text{d}}. \quad (16.23)$$

This expression highlights the influence of the individual efficiencies of charging, discharging, and idling (self-discharge) very well. It must be noted that the same expression is obtained for any profile of the charging power ( $P_{\text{ch}}$ ) and the discharging power ( $P_{\text{d}}$ ).

### 16.3.4 The Theory of Ragone Plots

As was described in Sect. 16.3.3, the energy efficiency of a storage device is related to the different losses. Charging and discharging losses, as well as self-discharge losses, directly influence the round-trip efficiency. As a consequence, the amount of energy that can really be recovered from a fully charged storage device must be defined in dependency of the instantaneous power of the energy transfer. This principle of interdependency between the energy density and the power density was described in [16.8].

In [16.8], a general circuit is associated with Ragone plots (Fig. 16.9). The energy storage device (ESD) feeds a load with constant power  $P$ . The ESD contains elements for energy storage. Due to constant power, energy supply occurs only for a finite time  $t_{\text{inf}}(P)$ . The energy amount  $E$  available for the load in dependence of the power  $P$  defines a Ragone plot.

With reference to the general circuit of Fig. 16.9, the ESD may, for example, consist of a voltage source,

**Fig. 16.9** General circuit associated with Ragone plots (adapted from [16.8])

$U(Q)$ , depending on the stored charge  $Q$ , an internal resistor  $R$ , and an internal inductance  $L$ . In reality, this ESD can describe many kinds of electric power sources. The ESD feeds an active load where the power is maintained constant  $P \geq 0$ . Such a load can be realized with an electronically controlled power converter feeding an external user. The current  $I$  and voltage  $U$  at the load are then related nonlinearly by  $U = P/I$ . With reasonable initial conditions

$$Q(0) = Q_0 \quad \text{and} \quad \dot{Q}(0) = \dot{Q}_0,$$

the evolution of the electrical variables is governed by the following differential equation,

$$L\ddot{Q} + R\dot{Q} + U(Q) = -\frac{P}{Q}, \quad (16.24)$$

where

$$\ddot{Q} = \frac{d}{dt}(\dot{Q}) = \frac{d}{dt} \left[ \frac{d}{dt}(Q) \right].$$

Without making reference to a specific physical interpretation of (16.24), the Ragone curve can be defined as follows. At time  $t = 0$ , the device contains the stored energy

$$E_0 = \left( \frac{L\dot{Q}_0^2}{2} \right) + W(Q_0). \quad (16.25)$$

For  $t > 0$ , the load imposes a constant power  $P$  such that  $Q(t)$  satisfies the relation (16.24). For finite  $E_0$  and  $P$ , the ESD is able to supply this power only for a finite time:  $t_{\text{inf}}(P)$ . Starting with the initial stored energy  $E_0$ , the feeding of the load ends when the storage device reaches its state of energy  $\text{SoE} = 0$ . Since the power is time-independent, the amount of energy transferred to the load is

$$E(P) = Pt_{\text{inf}}(P). \quad (16.26)$$

The curve  $E(P)$  versus  $P$  corresponds to the Ragone plot.

#### The Ragone Plot of a Battery

The particular case of an ideal battery is studied based on a simple equivalent circuit as represented in Fig. 16.10. First, and regarding the model leading to (16.24), we assume the condition  $L = 0$ . Then, the ideal battery with a capacity of  $Q_0$  is characterized by a constant cell voltage  $U = U_0$  if  $Q_0 \geq Q > 0$ , and  $U = 0$  if  $Q = 0$ . In a first approach, the leakage resistor  $R_L$  is neglected.

**Fig. 16.10**  
Equivalent scheme of the ideal battery

Equation (16.24) then reads

$$P = UI = (U_0 - RI)I,$$

where  $U$  is the terminal voltage, and  $I = \dot{Q}$  is the current.

The solutions of the quadratic equation are

$$I_{\pm} = \frac{U_0}{2R} \pm \sqrt{\frac{U_0^2}{4R^2} - \frac{P}{R}}. \quad (16.27)$$

At the limit  $P \rightarrow 0$ , two different values of the discharge current are

$$I_+ \rightarrow \frac{U_0}{R} \quad \text{and} \quad I_- \rightarrow 0.$$

For the ideal battery, the constant power sink can also be represented by a constant load resistance  $R_{\text{load}}$ .

The two limits then belong to  $R_{\text{load}} \rightarrow 0$  (short circuit) and  $R_{\text{load}} \rightarrow \infty$  (open circuit), respectively. Considering realistic energy and power conditions, the second solution (open circuit) for the zero power is retained. This corresponds to the solution of (16.27) with the minus sign,  $I \equiv I_-$ .

Now, the battery is empty at time  $t_{\text{inf}} = Q_0/I$ , where the initial charge  $Q_0$  is related to the initial energy  $E_0 = Q_0 U_0$ . The leakage current in the resistor  $R_L$  is taken into account. This current increases the discharge current  $I$  by  $U_0/R_L$ .

The energy being available for the load becomes

$$E_b(P) = Pt_{\infty} = \frac{2RQ_0P}{U_0 - \sqrt{U_0^2 - 4RP + \frac{2U_0R}{R_L}}}. \quad (16.28)$$

Equation (16.28) corresponds to the Ragone curve of the ideal battery. In the presence of leakage,  $E_b(0) = 0$ .

For the extracted energy, there exists a maximum at

$$P = \frac{U_0^2}{\sqrt{2RR_L}}.$$

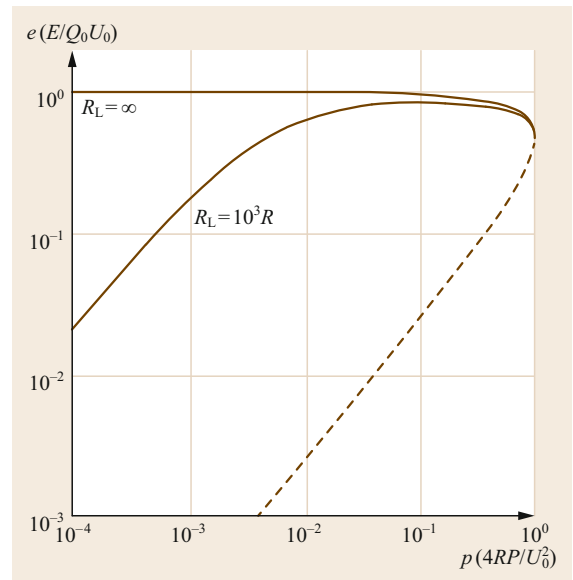

Without leakage  $R/R_L \rightarrow 0$ , the maximum energy is available for vanishing low power  $E_b(P \rightarrow 0) = E_0$ . From (16.28), one concludes that there is a maximum power  $P_{\text{max}} = U_0^2/4R$  associated with an energy  $E_0/2$  (a small correction due to leakage is neglected). This point is the endpoint of the Ragone curve of the ideal battery, where only half of the energy is available, while the other half is lost at the internal resistance.

Finally, the expression of the Ragone plot is given in dimensionless units using

$$e_b = \frac{E_b}{Q_0 U_0} \quad \text{and} \quad p = \frac{4RP}{U_0^2},$$

$$e_b(p) = \frac{1}{2} \frac{p}{\left(1 - \sqrt{1-p} + \frac{2R}{R_L}\right)}. \quad (16.29)$$

The Ragone curves according to (16.29) with and without leakage are shown in Fig. 16.11 for the ideal battery. The branch belonging to  $I_+$  is shown by the dashed curve.

**Fig. 16.11** Ragone curve of the ideal battery (adapted from [16.8])

## 16.4 Electric Power and Energy Storage

Energy systems tend to become *electrically controllable* systems or to somewhere integrate the *electric vector*, because the most convenient and most efficient way to transport, convert, or control the power is in its electric form.

On such a basis, the scheme represented in Fig. 16.12 will be valid for most energy storage systems [16.7]. The input source on the left-hand side is interfaced with a power electronic converter circuit that allows the control of the power flow to the storage means (right-hand side). In the middle, one or more additional conversions can be involved as electromechanical, electro-thermal, or electrochemical conversions.

### 16.4.1 Storage Forms of Energy

In Fig. 16.12, the real storage element shown indicates the *storage form of energy*, representing, in fact, the energy reservoir. This block corresponds to one unit, where the change of the internal state is directly related to the change of the energy content with a high reversibility.

The storage forms of energy can be of different nature, such as:

- The potential energy associated to the earth's gravity when one mass is moved from one altitude to another (for example, water in a pumped storage plant)
- The kinetic energy of a mechanical system in rotation (flywheels)
- The pressure of a compressible fluid (compressed air)
- Covalent bonds of given molecules (electrochemicals)
- Electric or magnetic state variables (electrical field, magnetic field, capacitors, superconducting inductors).

### 16.4.2 The Intermediary Conversion

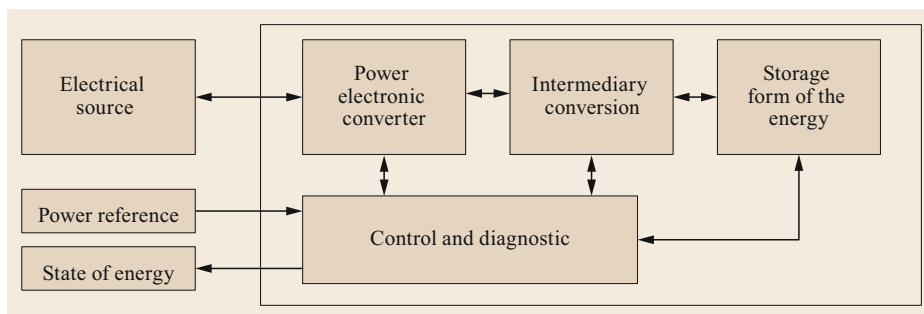

The interface between the storage form unit and the electrical level (output of the power electronic converter) may need the so-called intermediary conversion also shown in Fig. 16.12. The intermediary conversion can be of different nature. For example, it includes the electric motor-generator and the hydraulic pump/turbine in a pump storage plant, or it is simply the electric driving machine of a flywheel. In the case of compressed-air energy storage, the intermediary conversion can involve several successive conversions, such as a water pump in a liquid piston system or a simple motor and compressor.

### 16.4.3 Control and Diagnostics

The control and diagnostic device is essential for the numerous different conversion functions, such as controlling the torque and speed of the driving machine or simply to control the current or voltage. The control quantities are generally related to the power level exchanged during charge and discharge of the storage device.

The value of the instantaneous charge and discharge power level must be related to the typical power density ( $\text{kW}/\text{dm}^3$ ) or specific power ( $\text{kW}/\text{kg}$ ) of the energy storage device itself, according the definitions given above.

The control and diagnostic unit must provide information on SoC, or SoE. The parameter of the depth of discharge (DoD) is also used. In some sensitive cases, the diagnostic unit can give information about the state of health (SoH).

**Fig. 16.12** Electrical energy storage system (ESS)

## 16.5 Energy Storage Systems

In the following chapters, the most well-known storage systems will be presented. They are classified according to a scheme where their main characteristics appear, corresponding to their structure and basic phenomena.

The first category describes storage systems based on physical principles, like gravitational potential forces, air compression, or rotational kinetic energy. The next category encompasses purely electrical systems, like superconductive magnets and capacitors.

Finally, storage systems using electrochemical transformations are presented. Classical battery-energy storage systems and technologies are described, as well as so-called flow batteries. Fuel cells and hydrogen storage are briefly introduced.

For all systems introduced in this chapter, the elementary rules for the quantified storage of energy are given. Another aspect of the descriptions is the presentation of the power electronic circuits and architectures that are needed for a continuously controllable power flow to and from the different storage means.

## 16.6 Storage Systems Based on Physics

Storing energy is usually a repetitive task with a very high number of expected cycles. Contrary to classical electrochemical batteries, where the expected number of cycles is limited due to degradation phenomena, physical systems based on reversible mechanisms of various natures can be used with much higher life cycles. One good example can be found in the hydraulic sector, with classical pumped-hydropower plants. Such systems can, in addition, be realized for very high power levels in the hundreds of MW range.

Another principle is based on gas compression and expansion and is known as CAES (compressed-air energy storage) [16.9–11]. Further mechanical systems are also used based on rotational kinetic energy and are known as flywheels [16.12]. Electrical components like capacitors or inductors are also candidates for energy storage, even if their specific energy capacity is limited. Such systems are generally used for their ability to provide high levels of instantaneous power [16.13–15].

### 16.6.1 Gravitational Hydro-Pumped Storage

#### General Properties

Hydraulic, pumped storage facilities allow storing tremendous amount of energy, allowing supply of the network over several days or months, or, in some cases, compensating seasonal demand.

The ratings of hydropower have been shown comparatively in Sect. 16.2.2. Pumped-storage power plants have used conventional machinery for a longer time, where the electric motor-generator is directly connected to the grid. For such facilities, even when the power level in the generation mode can be controlled through the governor, the variation of the power in the pumping mode is not possible due to the fixed rotational speed of the equipment.

Controlling power in pumping mode is the main reason that modern pumped-storage equipment features variable speeds of the rotating machinery. Furthermore, variable-speed technology has made possible to cope with larger variations of headwater and tailwater reservoir levels to optimize plant performance and to solve specific problems [16.16].

Pumped-storage facilities benefit from good conditions with respect to energetic efficiency and can be operated over several decades as far as the machinery is concerned, even if some periodic revisions are needed. With respect to dams, the lifetime is in the range of centuries.

#### Components of a Hydropower Plant

Figure 16.13 represents a classical pumped-storage facility, where water flows from the lower reservoir (tailwater reservoir) to the upper one (headwater reservoir) in the pumping mode, and in the inverse direction for the generating mode [16.17].

From the headwater reservoir, the water flows through a tunnel and a penstock to the hydraulic machine. This hydraulic machine, which is generally a reversible machine (pump/turbine), is coupled to the electric motor-generator, which is generally a synchronous machine.

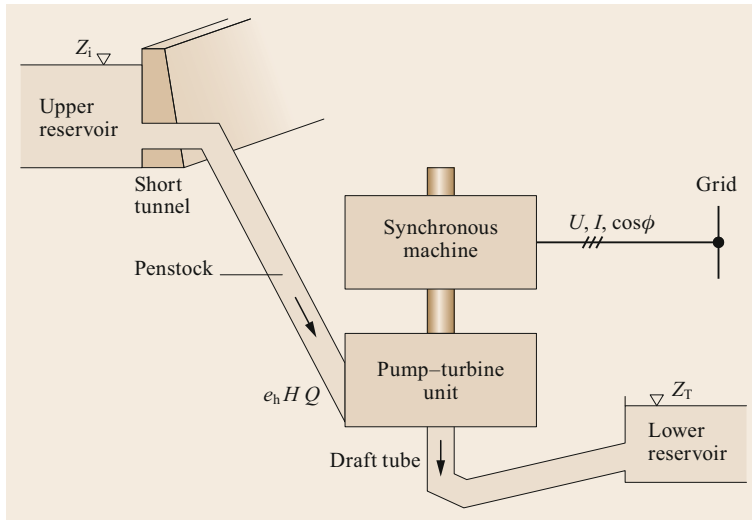

#### Water Power: Definitions

From Fig. 16.13, the following definitions are deduced

$$\text{Head: } H = H_1 - H_2 \quad (\text{m}), \quad (16.30)$$

where head is derived from the headwater and tailwater reservoir levels  $Z_i$  and  $Z_T$ , respectively, as follows

$$\begin{aligned} \text{in generating mode: } H &= H_1 - H_2 \\ &= (Z_i - Z_T) - H_i^{\text{Gen}}. \end{aligned} \quad (16.31)$$

**Fig. 16.13** Schematics of a pumped-storage facility

with  $H_r^{\text{Gen}}$  the head loss in the hydraulic circuit in turbine mode;

$$\begin{aligned} \text{in pumping mode } H &= H_1 - H_2 \\ &= (Z_i - Z_T) + H_r^{\text{Pump}}, \quad (16.32) \end{aligned}$$

with  $H_r^{\text{Pump}}$  the head loss in the hydraulic circuit in pumping mode.

Throughout this document, head losses are considered negligible.

Discharge:  $Q$  ( $\text{m}^3/\text{s}$ )

$$\text{Specific hydraulic energy } e_h = gH = g(H_1 - H_2). \quad (16.33)$$

The dimension of the specific hydraulic energy is  $(\text{m}/\text{s}^2)\text{m} = \text{J}/\text{kg}$ .

Further parameters used are:

- Water density  $\rho$  ( $\text{kg}/\text{m}^3$ )
- Acceleration due to gravity  $g = 9.81$  ( $\text{m}/\text{s}^2$ ).

#### Elementary Relations of Hydropower Generation

**Potential Energy.** The potential energy of a mass of water accumulated through elevation is described ideally by the following relation

$$E = me_h = mgh, \quad (16.34)$$

where  $e_h$  is the specific hydraulic energy, as defined before.

Example: a mass of water of 1000 kg ( $1 \text{ m}^3$ ) at a height of 1000 m has a potential energy of

$$\begin{aligned} E &= 1000 \text{ kg} \cdot 9.81 \text{ m}/\text{s}^2 \cdot 1000 \text{ m} = 9.81 \times 10^6 \text{ Ws} \\ &= 2.73 \text{ kWh}. \quad (16.35) \end{aligned}$$

**Kinetic Energy.** If a mass of water begins to be set in motion (friction free), its accumulated potential energy is converted into kinetic energy according to

$$E = \frac{mv^2}{2}. \quad (16.36)$$

So, the velocity reached by one mass of water through conversion from the potential fall energy into kinetic energy is ideally calculated from

$$mgh = \frac{mv^2}{2}, \quad (16.37)$$

leading to (Fig. 16.14)

$$v = \sqrt{2gh}. \quad (16.38)$$

**Fig. 16.14** Conversion from potential to kinetic energy

**Fig. 16.15** Head versus specific speed for hydraulic turbines and the corresponding shape of the runners. (Reprinted by permission from François Avellan, 2019)

**Pressure.** Considering one reservoir as represented in Fig. 16.14, the pressure at the bottom of the reservoir can be calculated according to

$$p = \rho gh . \tag{16.39}$$

**Power.** A turbine ideally converts the potential energy  $mgh$  of the water into mechanical energy in a given time unit  $t$ . Its power (friction is not considered) is defined as the per-second converted amount of energy

$$P = \frac{m}{t} gh . \tag{16.40}$$

For the same example (16.35), the power becomes

$$\begin{aligned} P &= \frac{1000 \text{ kg}}{1 \text{ s}} \cdot 9.81 \text{ m/s}^2 \cdot 1000 \text{ m} \\ &= 9.81 \times 10^6 \text{ N m/s} = 9.81 \times 10^6 \text{ W} \\ &= 9.81 \text{ MW} . \end{aligned} \tag{16.41}$$

The power can be further calculated by

$$P = \frac{m}{t} gh = \rho Q e_h . \tag{16.42}$$

For a real turbine, the converted power is affected by the turbine efficiency

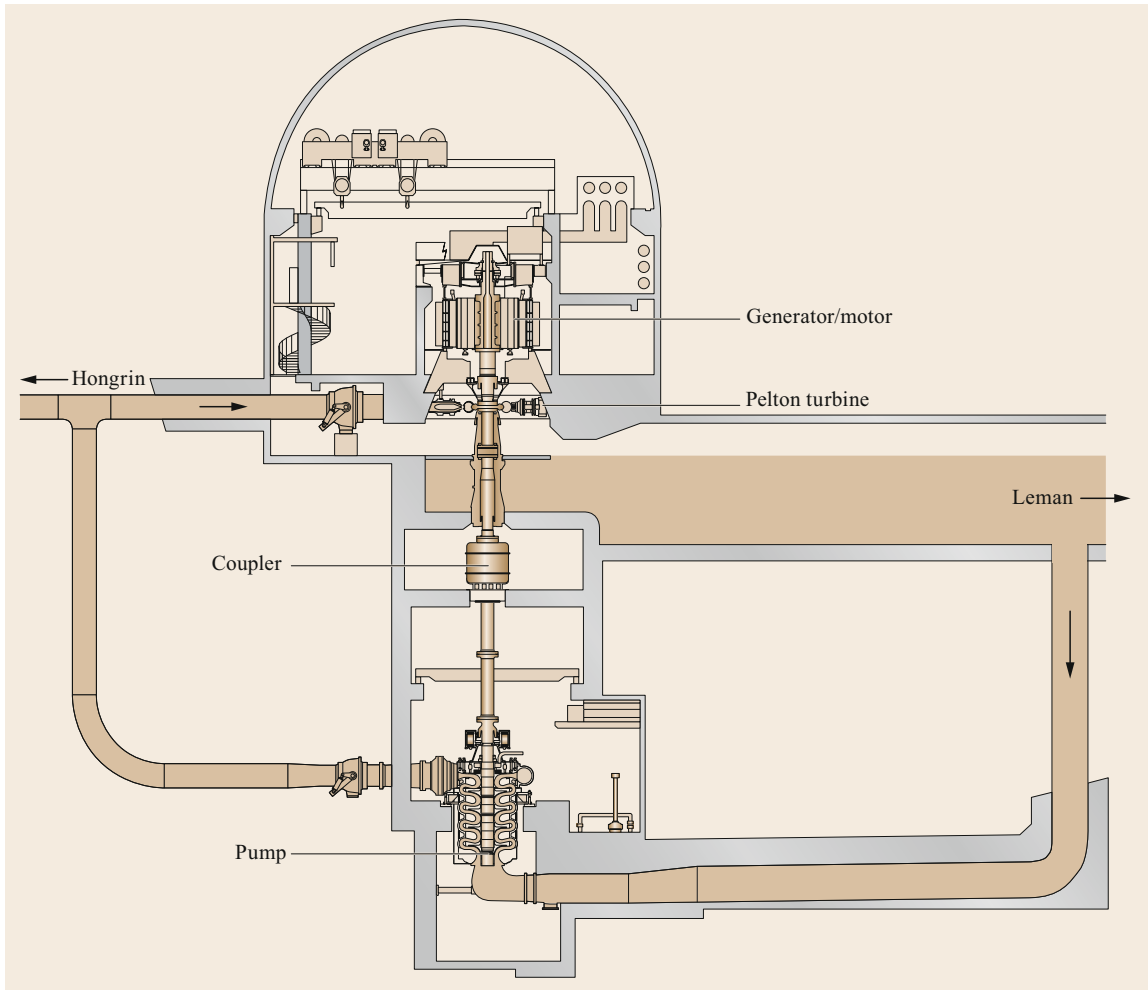

$$P = \eta \rho Q e_h . \tag{16.43}$$

### Classification of Turbines

There are three main types of hydraulic machines:

- The *Pelton* turbine is an impulse turbine with tangential flow and is suited for high-head applications.
- The *Francis* turbine is a reaction machine with radial flow and is suited for medium-head applications.
- The *Kaplan* turbine is another reaction machine but with axial flow. It is suited for low-head applications.

The various types of hydraulic machines are represented in Fig. 16.15. The classification is made using a specific parameter of hydraulic machines, the specific speed. The specific speed is a dimensionless quantity used to characterize hydraulic turbomachines [16.18].

**Fig. 16.16** Example of the 120 MW pump–turbine ternary arrangement of FMHL (Forces Motrices Hongrin Leman, Switzerland)

According to the IEC standard,  $n_{QE}$  is given by

$$n_{QE} = \frac{nQ^{1/2}}{e_h^{3/4}}, \quad (16.44)$$

where  $n_{QE}$  is the specific speed (dimensionless),  $n$  is the runner/impeller rotational speed (Hz),  $Q$  is the flow rate ( $\text{m}^3/\text{s}$ ) at the point of best efficiency, and  $e_h$  is the specific hydraulic energy.

Alternately, hydraulic engineers often use the unit specific speed  $n_Q$  defined as

$$n_Q = N \frac{Q^{1/2}}{H^{3/4}}, \quad (16.45)$$

where  $n_Q$  is the specific speed (not dimensionless),  $N$  is the runner/impeller rotational speed (1/min),  $Q$  is the flow rate ( $\text{m}^3/\text{s}$ ) at the point of best efficiency, and  $H$

is the head (m) per stage at the point of best efficiency. The specific speed value for a turbine is the speed of a geometrically similar turbine that would produce unit power (1 kW) under unit head (1 m).

### Ternary Pump–Turbine Units

A ternary set consists of a motor–generator, a separate turbine, and a pump set. Pump-turbine units based on the use of Pelton machines do not benefit from the reversibility of this type of turbine. As a consequence, the train must be completed by a separated pump. The drawback of this solution is evidently the higher length of the rotating train. However, the train can be started by the turbine without an additional start-up machine. The rotating train has only one direction of rotation, and a changeover from turbine mode to pump mode is possible without changing the direction of rotation.

Figure 16.16 shows an example of a ternary unit as is realized in the FMHL plant in Veytaux Switzerland [16.19]. The FMHL plant uses an upper basin called *Lac de l'Hongrain*, and the lower basin is the lake of Geneva (Lac Léman). One of the characteristics of the plant is the pump submerged under the level of the lake.

### Reversible Pump–Turbine Units

Figure 16.17 illustrates an example of a reversible Francis machine, a 250 MW pump–turbine of a 500 rpm facility.

With reversible pump–turbine sets, the direction of rotation must be inverted for the changeover from turbine mode to pump mode. This can be achieved using a so-called pony motor for the acceleration of the train from standstill to the synchronous rotational speed.

Other solutions exist, where the start-up is realized in the pump mode through a static frequency converter feeding the synchronous machine with variable frequency.

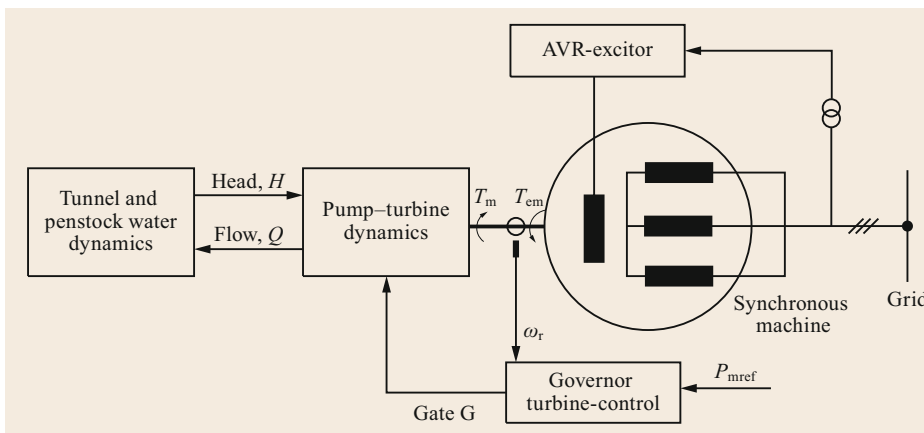

Reversible pump–turbines are traditionally operated with constant speed, but they can also be operated with variable speed. Two solutions are described in [16.1], namely the doubly-fed asynchronous motor generator and the synchronous motor generator with the full-conversion principle, where the static frequency converter is designed for the full power of the motor generator. For both solutions, the reversal of the train is achieved through the main frequency converter.

### Fixed-Speed Pumped Storage

In Fig. 16.18, the structural diagram of a fixed-speed pumped storage plant is shown. The synchronous machine also serves as a motor in the pump mode, as

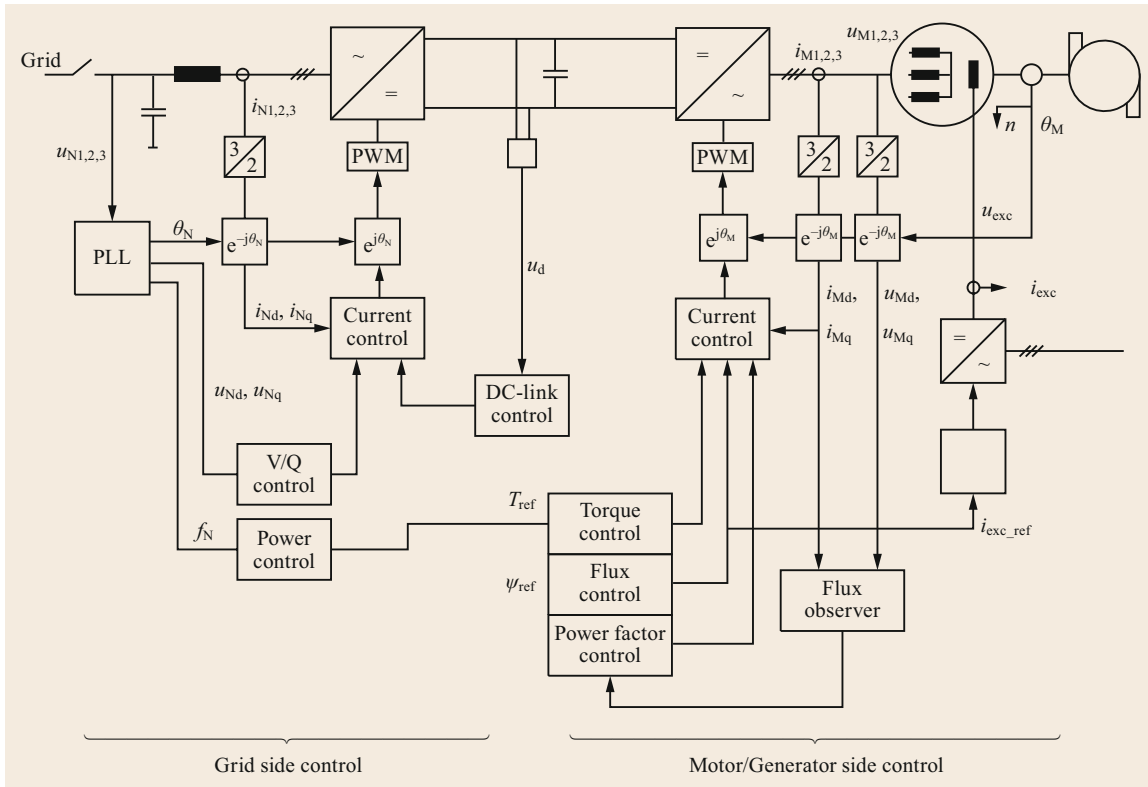

**Fig. 16.17** Reversible pump–turbine unit of 250 MW/500 rpm (courtesy of GE/Alstom)

**Fig. 16.18** Fixed speed pump–turbine system

**Fig. 16.19** Structural diagram of a full-conversion, variable-speed pumped-storage system

a generator for the turbine mode. The synchronous machine is connected to the grid by its armature and is coupled to the reversible hydraulic machine.

The active power is controlled through the governor and turbine control. The imposition of the voltage, as well as the control of the reactive power, is achieved through the machine's excitation system. Because the pump discharge (water flow rate) is linked to the rotation speed of the machines, the level of the power in the pump mode cannot be varied when the motor runs at the synchronism of the grid frequency. This limitation is one of the motivations to realize variable speed pump storage facilities.

### Variable-Speed Pumped Storage

In order to be able to vary the power in the pumping mode, and also to optimize the turbine mode, variable speed-pump-storage plants have been realized [16.20]. For such systems, two different solutions are used for energy conversion from the mechanical shaft to the electric grid.

The simplest method for the adaptation of the variable frequency of the synchronous motor-generator to the grid frequency is to use a static frequency converter. This frequency converter transforms the entire

electric power from the stator side of the machine, where the stator frequency is linked to the rotation speed of the machines, to the electrical grid with its constant frequency. The principal scheme of a variable speed-pumped storage system with full conversion is represented in Fig. 16.19, which shows the complexity of the control needed at the grid and machine sides.

A second possible solution for variable pump storage plants is the so-called doubly-fed induction motor-generator. In such a system, the electric machine is of the asynchronous type, where the wound rotor is interconnected to a frequency converter via slip rings and brushes. The machine's stator is directly connected to the grid. The bidirectional active feeding of the machine's rotor winding makes it possible to cover significant speed excursions in the hyper and hypynchronous domain. A doubly-fed induction motor-generator is shown in Fig. 16.20.

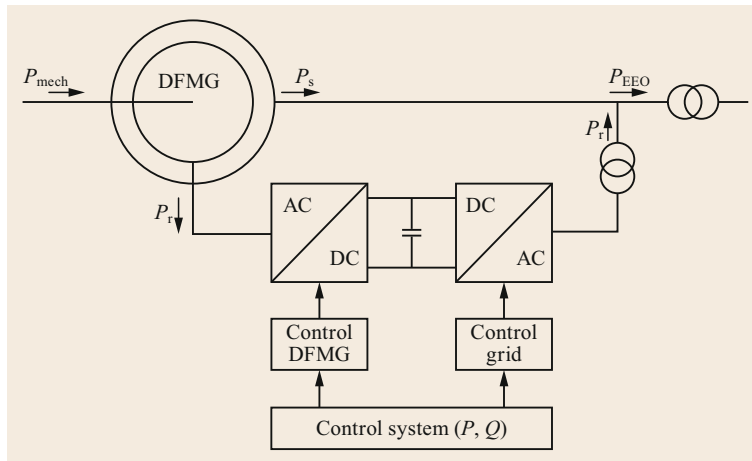

### Example of a Very High Power Variable-Speed-Pumped Storage Plant

An example of a large pumped storage plant is given by the Grimsel 2 facility of the KWO plant (Kraftwerke Oberhasli) in the Bernese Oberland of the Swiss Alps. The variable frequency operation of the 100 MW syn-

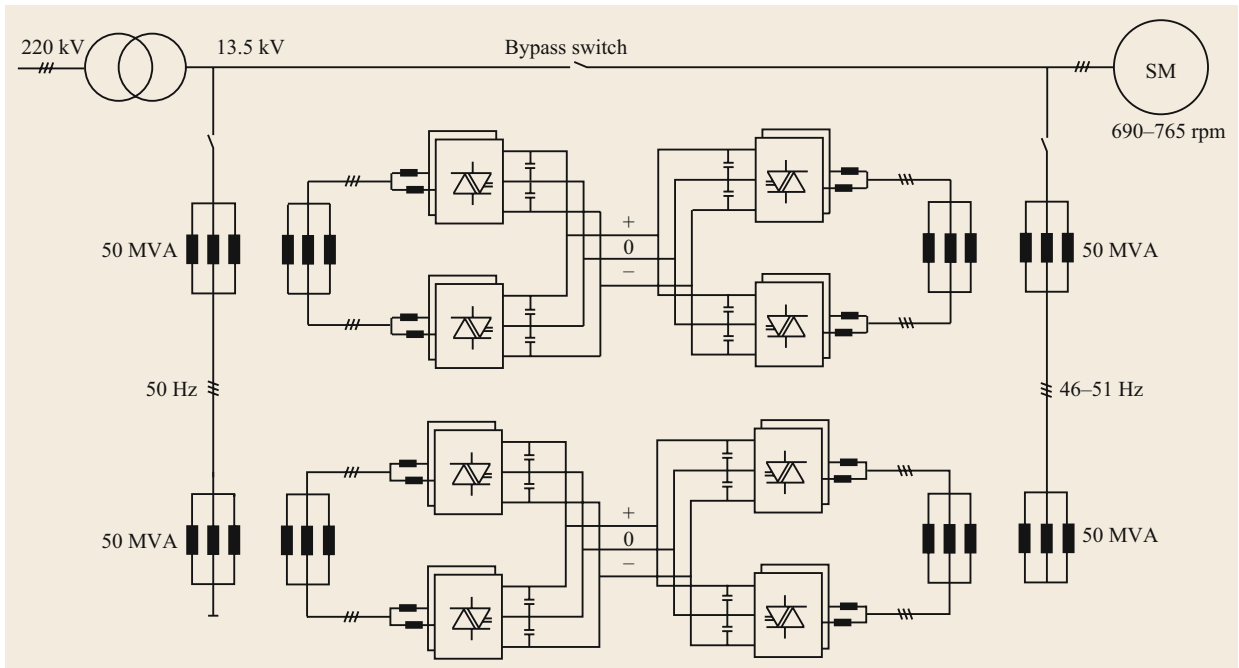

chronous machine is possible through the use of a high-end power electronics converter. The very high power VSC (voltage source converter) used for the synchronous machine is realized through the coupling of submodules with transformers (Fig. 16.21). Two line side transformers feed two line side converters. They are connected to the machine side converters and transformers via two separated DC (direct current) links. The so-called three-level technology is based on a positive and a negative voltage intermediary DC circuit. The

schematic of the complete installation of the Grimsel 2 facility is represented in Fig. 16.21. The full-conversion variable-speed operation range is defined from 690 to 765 rpm, corresponding to stator frequencies between 46 and 51 Hz.

Figure 16.22 shows more details of the KWO 100 MW facility, with Fig. 16.22a showing the variable speed rotating machinery, and Fig. 16.22b the volume occupied in the cavern by the transformers and the frequency converter.

## 16.6.2 Compressed-Air Energy Storage

Compressed-air energy storage CAES is based on the compression and expansion of air. Such systems generally use a compression stage comprising an electric motor driving a compression machine. The compressed air is then stored in a reservoir. For the recovery of the stored energy, an expansion system is provided. This expansion machine is composed of a volumetric expander driving an electric generator. The general scheme of CAES is represented in Fig. 16.23.

The amount of energy stored in a reservoir of volume  $V_1$ , pressurized at a pressure level  $P_1$  and stabilized at the same temperature as the surroundings, can be calculated through the expression (16.46) [16.1, 22]

$$E = P_1 V_1 \left[ \ln \left( \frac{P_1}{P_a} \right) - 1 + \frac{P_a}{P_1} \right]; \quad (16.46)$$

$P_a$  is the pressure of the surrounding (atmosphere). The expression gives the value of the maximum amount of energy that can be recovered from the reservoir that corresponds to a full expansion under isothermal conditions.

CAES systems, dedicated to diverse applications in industry, house-delivered energy, or in transportation have been built over the decades [16.23, 24]. The first utility CAES system was developed in Germany as a 290 MW plant in Huntorf [16.9]. Other systems have been realized, such as the McIntosh facility (Alabama, USA) [16.10].

Figure 16.24 shows the CAES plant in Huntorf Germany. The facility stores energy in an underground cavern, using the compressor stage of a gas turbine (7) and (9) for loading and its turbine in the discharge sequence (3) and (5) (Fig. 16.24). In order to compensate the decrease of the air temperature during the discharge

**Fig. 16.23** General scheme of CAES

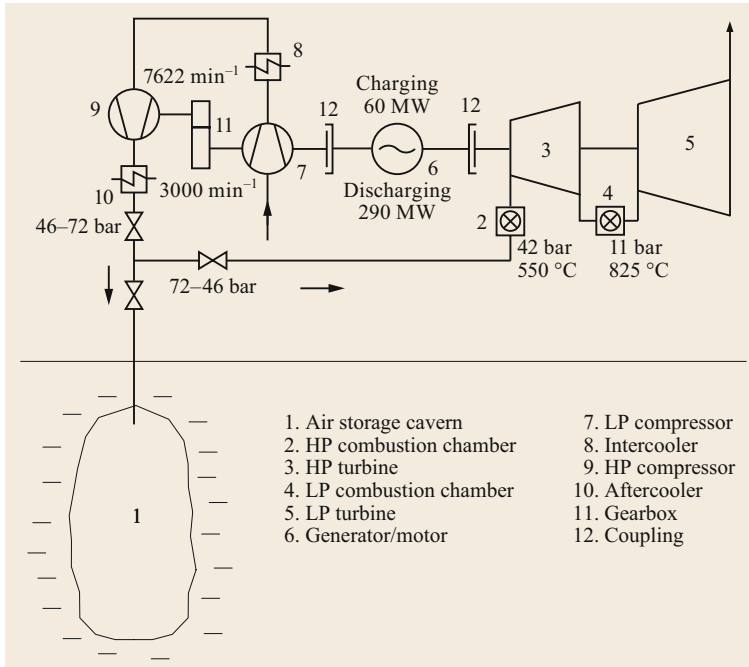

Fig. 16.24 The CAES plant at Huntorf

sequence, the burners of the gas turbine are maintained, (2) and (4) (Fig. 16.24).

### 16.6.3 Rotational Kinetic Energy (Flywheels)

Another possibility to store energy is given through rotational kinetic energy. Such systems also belong to the category of reversible physics phenomena. A flywheel system is generally composed of an electric machine coupled to a rotating mass. With the help of a power electronic converter, the driving torque of the variable-speed machine (positive torque for charging and negative for discharging) can be imposed precisely and makes the control of the exchanged power level possible. Flywheels were for a long time realized based on normal steel and limited speed, but modern equipment benefits from advanced materials like carbon composites and fast-running permanent magnet motors, which

can rotate at several hundred thousands of revolutions per minute (rpm). Partially evacuated encapsulations reduce the aerodynamic losses of the flywheel and motor. A schematic representation of a flywheel system is given in Fig. 16.25.

The amount of energy stored in a rotating mass running at a speed  $\Omega$  is given by

$$E = \frac{1}{2} J \Omega^2, \quad (16.47)$$

where  $J$  is the moment of inertia.

The auxiliaries of a flywheel system provide the partial vacuum needed to reduce aerodynamic losses, and they often include the control of special bearings (magnetic, air). The principle of the flywheel storage, together with detailed models for high performance can be found in [16.12].

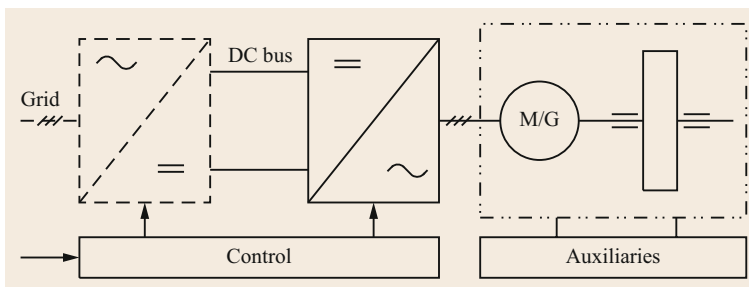

Fig. 16.25 Flywheel system

**Table 16.3** Flywheel shape factors

Flywheel shape	$K$
Constant stress disk	0.931
Flat unpierced disk	0.606
Thin rim	0.5
Rod or circular brush	0.333
Flat pierced disk ( $r_{ext}/r_{int} = 1.1$ )	0.305

### The Specific Energy of a Flywheel

The maximum specific energy of a flywheel rotor is mainly dependent on the rotor's geometry and on the properties of the material used. For an isotropic rotor, the expression of the specific energy  $e_{fw}$  can be expressed by (16.48).

$$e_{fw} = \frac{E}{m} = K \left( \frac{\sigma}{\rho} \right), \quad (16.48)$$

where  $E$  is the kinetic energy of the rotor (J),  $m$  the mass of the rotor (kg),  $K$  the geometric form factor (dimensionless),  $\sigma$  the tensile strength of the material (Pa), and  $\rho$  the density of the material used ( $\text{kg}/\text{m}^3$ ).

The form factor  $K$  depends on the geometry of the flywheel and is also called the flywheel shape factor [16.12]. Essentially, the value of  $K$  comes from the expression of the moment of inertia. Values of  $K$  for different flywheel shapes are given in Table 16.3.

The tensile strength of the material dictates the upper limit of angular velocity

$$\sigma_t = \rho r^2 \omega^2. \quad (16.49)$$

The expression (16.49) can be simplified using the specific tensile strength  $\sigma_t/\rho$  and the tangent velocity  $v_t$ ,

$$\frac{\sigma_t}{\rho} = v_t^2. \quad (16.50)$$

### Aerodynamic Drag of a Flywheel

A flywheel with a high value of specific energy is characterized through the high rotational speed and further through the tangential velocity of the rotor. The friction losses due to the interaction with the surrounding air, even if the rotor runs inside a partial vacuum chamber, should not be underevaluated.

**Fig. 16.26** Example of 600 kW/100 kWh flywheel energy storage system (courtesy of Stornetic [16.25])

The drag force causing the aerodynamic losses can be calculated in a general case through [16.26],

$$F_D = \frac{C_D \rho_g V^2 A}{2}, \quad (16.51)$$

where  $\rho_g$  is the density of the air,  $V$  is the velocity of the undisturbed fluid (m/s), and  $A$  is the projected area of objects as spheres, disks, or plates with axes perpendicular to the flow ( $\text{m}^2$ );  $C_D$  is a constant depending essentially on the Reynolds number.

The problem of the aerodynamic drag force is at the base of a general choice of flywheel manufacturers to operate the rotors under partial vacuum. An example of a recently developed product of a flywheel is given in Fig. 16.26.

## 16.7 Electrical Systems

### 16.7.1 Superconductive Magnetic Energy Storage Systems (SMES)

On the basis of a purely electric/magnetic component like the inductor, energy can also be stored. The energy stored in an inductor can generally be expressed by

$$E = \frac{1}{2}LI^2, \quad (16.52)$$

with  $L$  being the value of the inductance and  $I$  the circulating current. The maximum power  $P_{\max}$  during charging and discharging is given by the values of maximum current in the coil and the maximum voltage delivered by the power electronic converter used for the control of the charging and discharging process. This converter applies a positive voltage while increasing the current (charging) and a negative one while decreasing it (discharging)

$$P_{\max} = U_{\max}I_{\max}. \quad (16.53)$$

SMES systems use superconductivity in order to increase the energy density (higher current in the same support) and in order to reduce the ohmic losses to a minimum value [16.27]. A general scheme of an SMES system is represented in Fig. 16.27.

The power electronic converter provides a positive voltage during the charge process (an increase of the current) and a negative one during discharge.

One must note that during the charged state of an SMES system, the inductor current must always flow. Even if there are no variations of this current (idle mode), and even if the conduction losses in the superconducting coil can be neglected, there are still losses in the interconnections and in the freewheeling paths of the converter. For a long-term idling mode, and also for security reasons, a by-pass switch is generally provided (Fig. 16.27).

### 16.7.2 Capacitive (and Supercapacitive) Systems

The dual element of the inductor is the electric capacitor. It can be used for energy storage according to the

relation giving its energy content

$$E = \frac{1}{2}CU^2, \quad (16.54)$$

with  $C$  being the capacitance and  $U$  the voltage across the capacitor. The charging and discharging of a capacitor is realized by using a power electronic converter. The general scheme of a capacitive energy storage device is represented in Fig. 16.28. Classical high-voltage capacitors can be used for energy storage [16.13] and also more recently-developed supercapacitors characterized by their high capacity value [16.28].

In the case of a capacitive storage system, the power electronic converter must be able to control the capacitor current. A positive current charges the capacitor, while a negative current causes its discharge. A steady-state idling mode is characterized through the flow of a zero current. This is an interesting property with respect to the energy efficiency.

An example of an application of high-power capacitive storage is described in [16.13]. The equipment is dedicated to the smoothing of the power demand of the supply of the magnets of a particle accelerator (CERN). The capacity is around 20 MJ, and the maximum power is at 60 MW (Fig. 16.29).

Since the beginning of the twenty-first century, the capacitive storage has, in general, received higher interest due to the appearance on the market of new components called supercapacitors or double-layer ca-

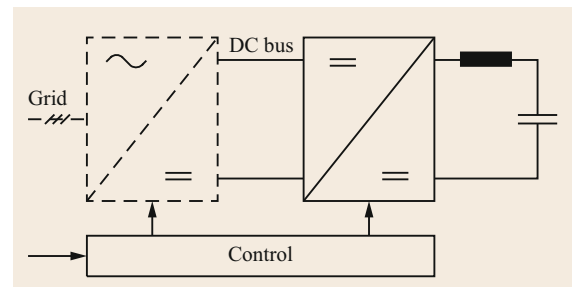

Fig. 16.28 Capacitive energy storage system

**Fig. 16.30** Samples of supercapacitors, single components, and modules

capacitors [16.29]. Examples of such components, which are characterized by capacity values in the thousands of farads, are represented in Fig. 16.30. However, the voltage of supercapacitors is generally  $\approx 2.7$  V, and

powerful storage equipment must use the series connection of a large number of components.

There are applications of supercapacitors in many different sectors where a relative high power demand

during limited time is specified. The applications comprise grid services as voltage support and power buffering, electric vehicle (EV) charging facilities, street lightning, automotive, and bus/tram transportation, or

energy recovery. Industrial applications such as forklifts, cranes, or tractors have been realized as energy-saving and pollution-free alternatives to diesel-powered systems for the lifting and transportation of containers.

## 16.8 Electrochemical Systems

There is a high diversity of electrochemical technologies as potential solutions in the area of energy storage. Many of them are well established, especially in the domain of mobile applications. Larger systems are currently developed for their utilization in connection with public grids [16.30–32].

Nowadays, an increasing number of modern materials are emerging, which often have promising characteristics. This progress is also being made in the direction of higher energy densities and also with respect to power density. Additionally, deeper studies on failure and aging mechanisms aim to reach an increasingly higher number of cycles or longer lifetimes of batteries [16.33].

From the system approach point of view, an electrochemical battery can be seen as a voltage source, the charging and discharging variable being the battery current. Figure 16.31 gives a simplified scheme of a BESS (battery-energy storage system).

The principal scheme of a BESS is very similar to that of a capacitive storage device. Principally, the positive and negative DC current is provided by a DC–DC converter. The interface to the external world can be defined at the DC bus level or through a front-end converter to the AC (alternating current) grid.

A so-called battery management system (BMS) is represented on the right-hand side of Fig. 16.31. This unit has the role of balancing the different elements of the series connection but also has the task of supervising and protecting the overall system.

### 16.8.1 Electrochemical Principles and Properties

Electrochemical storage components, often called electrochemical batteries, are closed systems able to per-

form a reversible conversion from chemical energy to electrical energy. Such transformations can be made with a good efficiency, depending on the operating conditions. Usual values of the energy efficiency are situated around 80–90%.

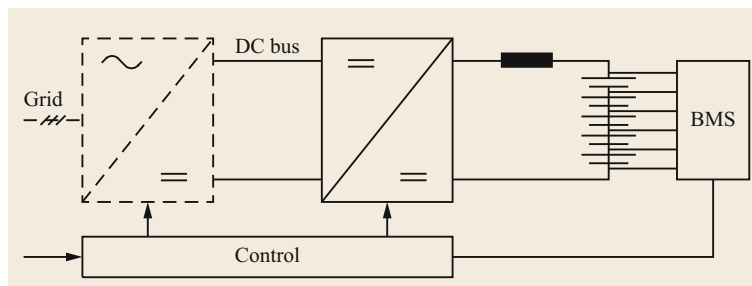

Like other storage components, electrochemical batteries are characterized by their energy density, which is between 30 and 200 Wh/kg. As a comparison, hydrocarbon-based sources present a much higher value of the energy density, of the order of 10 kWh/kg. Contrary to primary cells like the ordinary flashlight batteries, storage batteries are also called secondary batteries and can be recharged. Their electrode reactions can be processed in either direction.

#### The Structure of an Electrochemical Accumulator

Electrochemical accumulators are charged by converting electrical energy into chemical energy and are discharged by an inverse transformation. Each element of a battery is made of a so-called negative active mass able to provide electrons to the external circuit during discharge and a positive active mass able to accept the electrons from the return path of the external circuit.

Figure 16.32 is a schematic representation of an electrochemical cell. The indicated direction of electrons and ion flows corresponds to the battery discharge process.

The transfer of electrons from the active masses to and from the external circuit is possible due to the presence of current collectors assuming the electronic conduction. The positive and negative active masses are of different chemical compositions and have an electric separator in between that prevents the passage of elec-

**Fig. 16.31** Battery-energy storage system (BESS)

Fig. 16.32 Electrochemical cell connected to a load

trons from the positive to the negative side. The internal flow of the electric current is possible due to the displacement of electric charges in the form of ion transfer from one active mass to the other. The separator must be an ionic conductor. Current collectors are generally metallic, and the active masses are porous solids, made from powders, and are soaked by a liquid ion conductor.

### Elementary Principles

The active masses of an electrochemical cell each contain a couple of redox reactants, namely a set of chemical species in reduced form (red) able to provide electrons and to be transformed into another set of chemical species (ox), able to accept electrons. A redox couple is characterized through its potential determined by the Nernst law [16.34]

$$E = E^0 + \frac{RT}{nF} \ln \frac{\text{ox}}{\text{red}}. \quad (16.55)$$

In this relation, (ox) and (red) designate the concentrations of the oxidized and reduced forms of the redox couple,  $R = 8.32 \text{ J}/(\text{K mol})$ ,  $T$  is the absolute temperature, 298 K at 25 °C,  $n$  is the number of electrons implicated in the reaction, and  $F$  is the Faraday constant: 96 500 C/mol.

An electrochemical generator transforms the chemical energy (free enthalpy) into electrical energy provided to the external system in the form of an electrical current.

The negative terminal of an elementary cell is connected to the negative active mass that contains a reducer material (electron source)  $\text{red}_1$ , capable of undergoing an electrochemical oxidation

At zero current, the  $E_1$  potential of the negative terminal is controlled by the Nernst equation related to the  $\text{red}_1/\text{ox}_1$  couple. Symmetrically, the positive terminal is connected to the positive active mass containing an oxidant material (electron acceptor),  $\text{ox}_2$ , capable of undergoing an electrochemical reduction

At zero current, the potential  $E_2$  of the positive terminal is controlled by the Nernst equation related to the  $\text{red}_2/\text{ox}_2$  couple.

The global chemical reaction is then

The voltage of the elementary cell is equal to the difference of the positive and negative potentials.

The transformation of 1 mole of reactant in these conditions releases an electrical energy of  $n$  Faraday, namely a maximum of  $n \times 96\,500 \text{ C} \times (E_2 - E_1) \text{ J}$ . This maximum corresponds to the variation of the standard free enthalpy of the reaction [16.35]. In a general manner, the electrode where the reduction takes place is called the cathode. The electrode where the oxidation takes place is called the anode. In the case of a cell working as a generator (discharge), the cathode will be the positive terminal and the anode the negative terminal. On the contrary (charge), the cathode will be the negative terminal and the anode the positive terminal.

## 16.8.2 Different Types of Accumulators

Several possibilities exist for accumulators like the ones in an aqueous, acid, or alkaline medium, hot accumulators, or accumulators in an organic medium. The aqueous medium presents the advantage of a higher ionic conductivity, but the possible choices for the active masses are limited. Nonaqueous media permit higher cell voltages and a higher number of possible active masses.

### Accumulators with Aqueous Electrolytes

The acid or alkaline aqueous electrolyte is a medium with a relatively good ionic conduction, but the cell voltage is limited by the possible decomposition of water into oxygen and/or hydrogen produced through the oxidant (or reductant) character of the active masses.

**Lead–Acid Accumulators.** Invented by Gaston Planté in 1858, the lead–acid accumulator is today one of the most-used accumulators and must be considered as the cheapest electrochemical storage solution. In the lead–acid battery, both the positive and the negative plates

become lead sulfate ( $\text{PbSO}_4$ ) in the discharged state, and the electrolyte loses much of its dissolved sulfuric acid and becomes primarily water. In the fully charged state, the negative plate consists of lead, and the positive plate consists of lead dioxide. The electrolyte is of concentrated sulfuric acid.

During discharge, the  $\text{H}^+$  ions produced at the negative plate move into the electrolyte solution and are then consumed at the positive plate;  $\text{HSO}_4^-$  is consumed at both plates. The reverse occurs during charge. The discharge process is driven by conduction of electrons from the negative plate back into the cell at the positive plate through the external circuit.

The negative active mass contains a redox couple as

The negative active mass potential is equal to  $E^0 = -0.356\text{ V}$ .

With the positive active mass, another redox couple corresponds to

The potential on the positive side is  $E^0 = 1.685\text{ V}$ .

The global reaction is

The cell voltage corresponds to the difference of potentials and is equal to  $E^0 = 2.05\text{ V}$ .

The sum of the molecular masses of the reactants is  $642\text{ g/mol}$ , so, theoretically a cell can produce  $2\text{ F}$  of charge ( $2 \times 96\,500\text{ C} = 193\,000\text{ C}$  from  $642\text{ g}$  of reactants, or  $83.5\text{ A h/kg}$ ). For a  $2\text{ V}$  cell, this comes to a theoretical value of  $167\text{ Wh/kg}$  of reactants. In reality, a lead–acid cell gives only  $30\text{--}40\text{ Wh/kg}$ , due to the mass of the water and other constituent parts.

During charge and discharge, the potentials of the active masses vary in dependency on the state of chemical conversion. This leads to a variation of the cell voltage in the open-circuit state. In the real case of a lead-sulfuric acid battery, the cell voltage varies from  $2.15\text{ V}$  when fully charged to  $1.6\text{ V}$  when discharged (open circuit).

The acid concentration of the electrolyte brings the maximum of conductivity in the fully charged state of the cells. This brings a high availability of power with up to 10 times the rated current (a  $30\text{ A h}$  battery can deliver  $300\text{ A}$ , delivering  $3.6\text{ kW}$  when the battery voltage is of  $12\text{ V}$ ).

In its discharged state, the lead–acid battery has a relatively weak acid concentration, which limits the available power. By each discharge, lead sulfate is accumulated on the electrodes and is normally dissolved by the next charge. With a too-long discharge or in a too-low state of charge or operation at a too-high temperature, crystals of lead sulfate appear and are no longer dissolved by the charge. The capacity of the battery and its power level are strongly reduced.

In practice, five main categories of lead–acid batteries are available:

- Starter batteries (with grating): these are developed and produced for the automotive industry for the start-up of internal combustion engines. They are designed to be kept permanently charged and to deliver high currents rapidly. They are widely available and at very low costs ( $0.2\text{ EUR}/(\text{Wh})$ ).
- Drive batteries (flat plates): these are similar to starter batteries but present a larger capacity. They are used in small electric vehicles, like autonomous carts or forklifts. They are designed to be charged and discharged on a daily basis and can be operated in low state of charge. Their costs are around  $0.5\text{ EUR}/(\text{Wh})$ .
- Batteries with gel electrolytes (flat plates): these batteries do not need any maintenance and can be operated in any position. They are typically used in small professional equipment (radio communication, shining buoys, etc.). Their capacity is of the order of  $100\text{ A h}$ . Their costs are around  $0.6\text{ EUR}/(\text{Wh})$ .
- Absorbent glass mat (AGM) batteries: in AGM batteries, the sulfuric acid is absorbed by a very fine fiberglass mat, making the battery spill-proof. AGM batteries have a very low internal resistance, are capable of delivering high currents on demand, and offer a relatively long service, even when deep cycled.
- Stationary batteries (tubular plates): these are used in security supply technology. They use a frame structure consisting of a series of vertical spines connected to a common bus bar. The tubular design keeps the active material together and presses it onto the collecting grid. The active lead-oxide mass is held in microporous, nonconductive tubes (gauntlets), which are placed over the individual spines.

**Alkaline Accumulators.** Nonacid electrolyte batteries were initially proposed by Waldemar Junger in 1899 and by Thomas Edison in 1901. These alkaline accumulators were primary batteries and based on a zinc/manganese pair of active materials.

The chemical reactions in the alkaline batteries produce electricity when the manganese dioxide cathode is reduced and the zinc anode becomes oxidized. At the

MnO<sub>2</sub> cathode, water (H<sub>2</sub>O) is consumed, and hydroxyl ions (OH<sup>-</sup>) are produced by the following reaction

At the same time, the anode consumes hydroxyl ions and produces water,

The overall reaction is

The evolution of alkaline batteries has gone through the use of other metals like nickel (Ni), a totally insoluble metal in an alkaline medium. Its oxyhydroxide form NiOOH-layer is used on its positive electrode. The electrochemical reaction at the positive active mass side is

The mode of operation of the positive electrode can be considered as a proton intercalation into the layered crystalline structure of the NiOOH during discharge and disinsertion during charge. The negative active mass is primarily based on zinc metal soaked in a potassium hydroxide solution, like in the original zinc/manganese battery.

**Nickel-Cadmium Accumulators.** Due to the corrosion effects of zinc in the basic solution, the Zn/NiOOH elements were soon replaced by Ni-Cd elements, which rapidly became high-performance rechargeable alkaline batteries. The electrochemical reactions of Ni-Cd batteries are (discharge)

at the negative electrode and

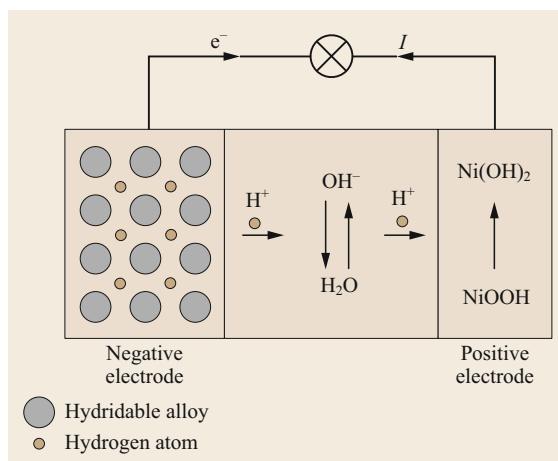

at the positive electrode.

The overall reaction is

Ni-Cd batteries have a specific energy of 40–60 Wh/kg and can easily overcome deep discharge and recharge. They have a nominal voltage of 1.2 V per cell and can be stored in their discharged state. One of the most interesting parameters is the high power capability up to 1 kW/kg. Ni-Cd batteries can be recycled but present

**Fig. 16.33** Discharge of an Ni-MH cell (adapted from [16.34])

the disadvantage of the toxicity of cadmium, which has made this technology obsolete. Another typical behavior of Ni-Cd cells is their memory effect. This effect corresponds to situations where the battery gradually loses its maximum energy capacity if it is repeatedly recharged after being only partially discharged.

**Ni-MH Accumulators.** In Ni-MH accumulators, the problematic cadmium in the cell has been replaced by a metallic alloy capable of storing hydrogen. It works similarly to the Ni-Cd accumulator and has the following characteristics:

- 1.2 V cell voltage
- 40% higher energy density than that of Ni-Cd cells
- A very low memory effect.

The electrochemical reactions in a Ni-MH cell are (discharge)

at the negative electrode and

at the positive electrode. The structure of an Ni-MH element is represented schematically in Fig. 16.33.

The application domain of Ni-MH batteries ranges from portable tools and toys (replacement of Ni-Cd batteries) to the automotive industry (hybrid cars).

#### Accumulators with Nonaqueous Electrolytes

In the beginning of the 1980s, the idea of utilizing lithium (Li), one of the highest electropositive elements

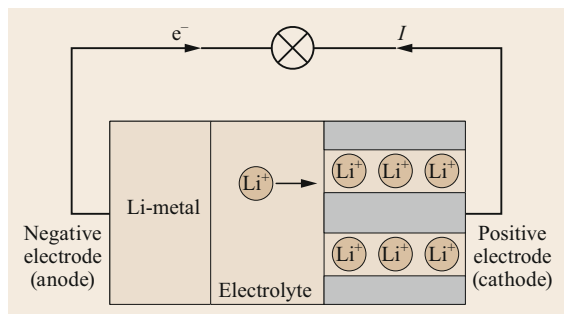

Fig. 16.34 Lithium-metal cell (adapted from [16.37])

( $-3.02\text{ V}$ ), led to the development of chemical compounds able to insert and disinsert Li at the negative electrode. Because of the high reactivity of Li versus  $\text{H}_2\text{O}$ , these developments induced the change from aqueous to nonaqueous electrolytes. Such electrolytes consist of lithium salts dissolved in an organic solvent [16.36]. One should distinguish the lithium metal technology, where the negative electrode is composed of metallic lithium from lithium-ion technology, where lithium remains in ionic state due to the use of insertion/disinsertion compounds at both the negative and the positive electrodes.

**Lithium-Metal Accumulators.** In lithium-metal batteries, the negative electrode (the anode) is made of metallic lithium. During discharge, the lithium ions migrate from this electrode through the electrolyte to the cathode, where they mix with a host material (for example,  $\text{LiMn}_2\text{O}_4$ ). The electrons produced at the anode supply the external circuit and return to the cathode. During charging, the  $\text{Li}^+$  ions migrate in the opposite direction, while electrons are supplied by the external circuit (Fig. 16.34).

**Lithium-Metal Polymer Cells.** Lithium-metal polymer technology uses a lithium-metal electrode at the negative side. The positive electrode is based on vanadium oxide. The electrolyte is a (ion)-conductive polymer membrane based on POE (polyoxide ethylene). A lithium polymer battery costs around  $0.1\text{ EUR}/(\text{Wh})$ , and its energy density is given as  $110\text{ Wh/kg}$  (Batscap). The temperature range for good performance is between  $60$  and  $150^\circ\text{C}$  without security problems.

**Lithium-Ion Accumulators.** A lithium-ion cell is different from a lithium-metal cell at the side of the negative electrode, where pure lithium is replaced by a compound capable of inserting and disinserting lithium ions (Fig. 16.35). The lithium-ion concept uses two materials that allow the reversible exchange of lithium

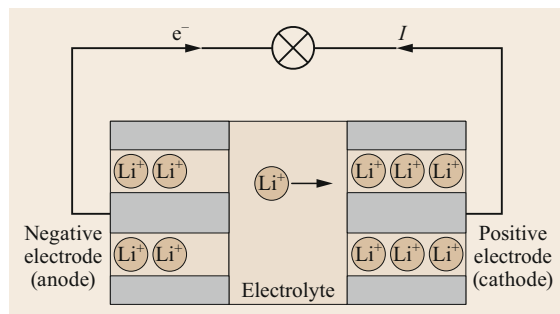

Fig. 16.35 Lithium-ion cell (adapted from [16.37])

ions. The negative electrode (anode) is a thin layer of graphite in which atoms of lithium have been inserted ( $\text{LiC}_6$ ). For the positive electrode (cathode), a lithium-oxide of a transition metal such as  $\text{LiCoO}_2$  can be used. The liquid electrolyte is usually a hexafluorophosphate of lithium ( $\text{LiPF}_6$ ) mixed with a solution (carbonate mixture) [16.36].

Lithium-ion cells present a very high energy density up to  $200\text{ Wh/kg}$ . Their typical potential is  $3.7\text{ V}$ .

**Lithium-Iron Phosphate (LFP) Cells.** Lithium-iron phosphate is a widely spread lithium-ion technology. The positive electrode active material ( $\text{LiFePO}_4$ ) is associated with a negative graphite electrode. These cells are currently the most wide-spread and have replaced classical Li-ion cells based on lithium cobalt dioxide ( $\text{LiCoO}_2$ ). The energy density and the potential of these cells are slightly lower than those of classical Li-ion cells ( $130\text{ Wh/kg}$ ,  $3.3\text{ V}$ ). These batteries need a BMS system (battery management system).

**Lithium-Ion Polymer (Li-Po) Cells.** The mode of operation of these cells is similar to that of other lithium-ion cells. The electrolyte is made of gelled polymer. Their energy density is higher than that of other Li-ion cells, but their supervision and balancing circuits are more complex. The maximum cell voltage ( $> 4\text{ V}$ ) and also the minimum cell voltage ( $\approx 2.7\text{ V}$ ) must be monitored carefully.

**Lithium Titanate Cells (LTO).** LTO batteries are also called SCiB (super-charge ion battery). This technology is characterized by high charging and discharging rates. It is based on the use of a nanocrystalline technology. The specific energy is given as being between  $30$  and  $110\text{ Wh/kg}$ , and the cell voltage is between  $1.9$  and  $2.4\text{ V}$ . The specific power can reach  $5000\text{ W/kg}$ . These batteries can operate between  $-40$  and  $+55^\circ\text{C}$ . The durability cycle is given to be  $6000$  cycles, some manufacturers even indicate  $10\,000$ – $20\,000$  cycles.

**Table 16.4** Common characteristics of different types of batteries

Characteristics	Conventional batteries			Li-ion batteries	
	Lead–acid	Ni–Cd	Ni–MH	Graphite/NMC	LTO
Specific energy (Wh/kg)	40	40–60	30–80	120–200	70–80
Initial costs (EUR/kWh)	150	500	600	120–250	400–800
Life cycle	200–300	1000–1500	300–800	500–4000	15 000–25 000
Cost per life cycle (EUR/kWh)	0.15–0.7	0.3–0.5	0.75–2.0	0.35–0.04	0.024–0.04
Disch. cond. for low ageing	C/3	C/2	C/5	1 C	2 C
Charging rate	C/4–C/8	–	C/10	C/2	2 C
DoD window (%)	50	–	80–100	80	80

**Fig. 16.36** Evolution of lithium-ion battery prices over the past years (adapted from the Bloomberg New Energy Finance survey of more than 50 companies)

### Choosing Between Competitive Battery Technologies

The constant evolution in battery technology and performances addresses the question of the adequate choice to be made by the design of an application. A very general principle produces competition between proved techniques and innovative ones, where even if the performance advantages are evident, the life cycle and ageing phenomena cannot be evaluated due to the lack of hindsight and experience. A common example is given by classical lead–acid batteries, which have been used for decades and can be considered as tried-and-true technology. Especially solar photovoltaic off-grid applications are currently in competition with lighter, smaller lithium-ion batteries, which, in addition, have longer life cycles [16.38].

Several comparison criteria can be used:

- The specific energy
- The initial costs
- The life cycle
- The cost per life cycle
- The state of charge window for low ageing
- The available power for low ageing
- The recommended charging time

All batteries are sensitive to excessive discharging and extreme temperature. Lead–acid batteries lose potential cycles if they are discharged below 50% of their state of charge (SoC) or if discharged faster than C/8. On the other hand, lithium-ion batteries can be discharged to  $\approx 80\%$  SoC and at a rate of C/2 without any long-term

damage. Table 16.4 shows common characteristics of different types of batteries: lead–acid, Ni–Cd, Ni–MH, and two different types of lithium-ion, graphite/NMC (nickel mangan cobalt) and LTO technologies.

The values given in Table 16.4 are indicative values obtained from different sources. They show the available values of specific manufacturers. A more global figure of the evolution of the price of lithium-ion batteries is given in Fig. 16.36.

### High-Temperature Batteries

**Sodium–Sulfur (Na–S) Batteries.** Na–S battery technology is known for its very high energy density, excellent life cycle, low-cost materials, and high efficiency. However, these cells need high temperatures to operate due to the use of molten sodium. Na–S batteries have been developed since the middle of the 1960s (Ford Motor Company USA, Brown Boveri Germany, and NGK in Japan). The packaging of the battery consists of a high-performance thermal insulation enclosure (operating temperature  $\approx 350^\circ\text{C}$ ). Other difficulties of realization are related to the quality of the insulator (brittle ceramics). Safety concerns stem from the need to protect the highly reactive sodium from moisture.

The specific energy is between 150 and 760 Wh/kg (high-temperature version), the volume energy density is  $\approx 150\text{ Wh/L}$ , the specific power is given at 200 W/kg, the nominal cell voltage is 2 V. These batteries have a very good cycle durability (4000–5000 cycles). Very large facilities have been realized (50 MW/300 MW h NGK, [16.39]). The electrolyte of a Na–S cell consists of a beta alumina tube and con-

Fig. 16.37 Sodium–sulfur cell

tains the liquid sodium. The external envelope is made of sulfur (Fig. 16.37). During discharge, sodium ions converted from sodium in the negative electrode pass through the electrolyte and combine with sulfur in the positive electrode to form sodium polysulfide. The electrons flow through the external path. The structure and reactions in a Na–S cell are represented in Fig. 16.38.

The electrochemical reactions in an Na–S cell are (discharge) at the negative electrode

At the positive electrode

The global reaction is

Other chemistries are possible

or

for lower melting temperatures (90–100 °C). An example of a large energy storage plant based on Na–S batteries is shown in Fig. 16.39.

### Flow Batteries

Flow batteries are a new type of electrochemical accumulator composed of two electrodes separated by a proton exchange membrane, as can be found in fuel cells or in electrolyzers. In such flow batteries, the energy storage occurs within the change of concentration of ions at the level of two liquids, an anolyte and a catholyte, circulating from two separated reservoirs [16.40, 41].

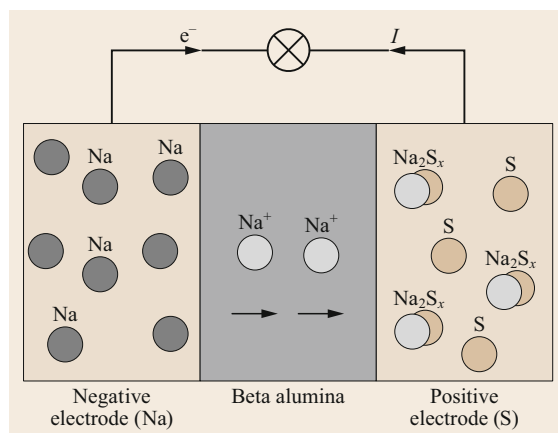

Fig. 16.38 Discharge in an Na–S cell

Fig. 16.39 A 34 MW Na–S storage facility in Japan (courtesy of JWD and NGK)

Flow batteries allow skirting some limitations of classical electrochemical batteries, where the electrochemical reactions create solid composites accumulated on the electrodes where they are generated, and where the mass that can be accumulated is perforce limited. The generation of internal stresses on the electrodes due to variations of the volumetric density of the active materials is another cause of battery ageing phenomena. In flow batteries, the chemical compounds that represent the state of charge are in liquid form and are in solution in the two electrolytes. These electrolytes are pumped from separated reservoirs to the *reactor*, which is composed of the electrodes and the membrane. One main characteristic of flow batteries is that the electrochemical converter (the reactor) is designed for the power level of the accumulator, while the energy capacity is only related to the volume (and mass) of the liquid electrolytes. An example of a flow battery is presented in Fig. 16.40.

Near the main elements of the flow battery, namely the electrolyte reservoirs and the membrane in the reactor, the system comprises electrolyte circulating pumps.

**Fig. 16.40** Redox flow-battery storage system

These auxiliary components need some electric power, which must be included in the calculation of the global efficiency. Dedicated control strategies for circulating

pumps have been proposed [16.42, 43] in order to reach good efficiency, even if the power level of the charge and discharge process is low.

## 16.9 Fuel Cells and Hydrogen Storage

Hydrogen can be used for energy storage as an energy carrier, due to its high energy density of 33 kWh/kg. This high value makes hydrogen a possible candidate for mid and long-term storage, typically such as the so-called seasonal storage in the context of renewable energy sources [16.1].

### 16.9.1 Main Properties of Hydrogen Storage

Compared to other fuels, hydrogen contains three times more energy than diesel fuel, and 2.5 times more than natural gas. Hydrogen can be produced from electricity using electrolyzers, and the reverse transformation from hydrogen to electricity can be realized using a fuel cell. However, hydrogen is difficult to store due to its very low weight density. At atmospheric pressure and ambient temperature, 1 kg of hydrogen needs a storage volume of 11 m<sup>3</sup>. As a consequence, hydrogen is usually compressed at a high pressure level between 350 and 700 bar. This high pressure addresses the question of the volume and weight needed for the reservoir, as well as the energy needed for the compression. Figure 16.41 shows the different energy densities of important energy vectors such as hydrogen, natural gas, propane, diesel fuel, and ethanol.

In the previous sections, the energy densities of different storage means were presented, where typically a powerful Li-ion battery appears with *only* 0.15 kWh/kg. As was mentioned above, hydrogen must be conditioned in order to reach a valid energy density corresponding to a real application, in the sense that the storage volume can be reduced.

Three main techniques can be used for the volume reduction, namely:

- Storage of hydrogen as compressed gas (350–700 bar)
- Storage of hydrogen in its liquid phase (–253 °C)
- Storage of hydrogen in a solid form.

The solid form of hydrogen corresponds to a metallic hydride, where different metals can be used, such as Mg, Al, or other metallic alloys. Table 16.5 indicates the amount of hydrogen mass that can be stored in these three forms.

**Fig. 16.41** Energy densities of important energy vectors

**Table 16.5** Various forms of hydrogen

Technique	Parameters	Amount of hydrogen (kg/m <sup>3</sup> )
Compressed hydrogen	700 bar	42
Liquid hydrogen	-253 °C	70

### 16.9.2 The Power-to-Power Storage System Based on Hydrogen

In Sect. 16.4, an electrical energy storage system (ESS) was defined. In such a system, the input and output of the storage system is interfaced to an electrical source, an electrical distribution system or grid. The storage form of energy, as well as the intermediate conversions are mentioned. An ESS or power-to-power storage system based on hydrogen can be realized using a water electrolyzer and a fuel cell for the intermediate conversions. In addition to these intermediate conversions, hydrogen (and sometimes oxygen) conditioning systems are needed in order to elevate the volumetric energy density. Figure 16.42 shows the elementary structure of an ESS based on hydrogen.

In Fig. 16.42, the basic components of the system are the electrolyzer, the hydrogen storage, and the fuel cell. Between the electrolyzer and the storage reservoir, a hydrogen conditioning device is represented ( $C_{H_2s}$ ), as well as between the storage reservoir and the fuel cell ( $C_{H_2r}$ ). The electrolyzer also produces oxygen that can be stored. In Fig. 16.43, the oxygen path is represented by dotted lines due to the fact that in a large number of modern fuel cells, the oxidation is achieved using ambient air. For this purpose, an air compressor is used (K). For the case of using stored oxygen, conditioning blocks are used ( $C_{O_2s}$ ,  $C_{O_2r}$ ).

The conditioning devices for the storage process ( $C_{H_2s}$ ,  $C_{O_2s}$ ) are generally compressors or liquefiers, while the recovery conditioning devices ( $C_{H_2r}$ ,  $C_{O_2r}$ ) are

simple relieve valves. In the case of solid storage of hydrogen in the form of metal hydrides, the conditioning processes are more complex.

### 16.9.3 Producing Hydrogen Through the Electrolysis of Water

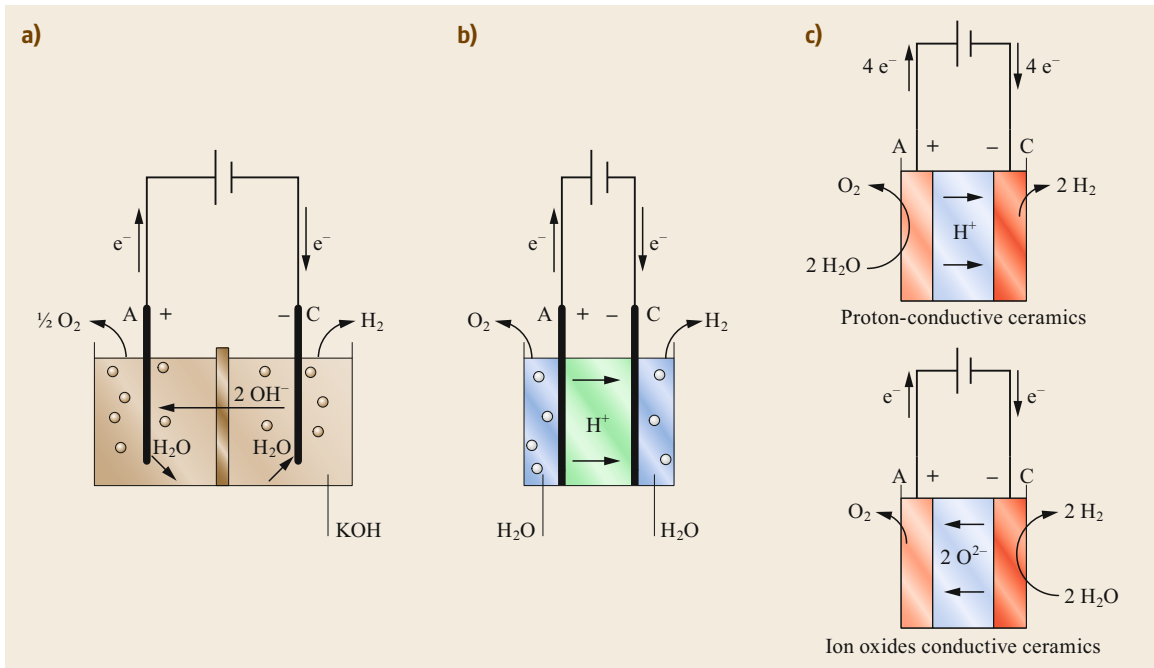

Nowadays, around half of the hydrogen produced around the world is obtained by reforming natural gas, which represents the most economic source. The other half of the hydrogen produced is from coal or oil. Electrolysis of water is a more expensive process and currently represents only a few percent of the total amount of hydrogen produced. However, it allows to convert electrical power into a chemical carrier characterized by a high specific energy. Recently, there has been a growing interest in this conversion, such as the example of recently-built power-to-gas plants [16.44]. Electrolysis of water is a well-known process in the industry for the production of hydrogen and has been developed for the production of hydrogen of high purity.

An electrolyzer is a device for the chemical decomposition of water by circulation of an electric current. It comprises two electrodes, the anode and the cathode, separated by an electrolyte. The electrodes are connected to a DC current source, which allows the circulation of the current, and the electrolyte is the internal ionic conductive means.

Three types of water electrolyzers have been developed or are under research. The most-used system is the alkaline electrolyzer. Then there are solid polymer elec-

**Fig. 16.42** Structure of a storage system based on hydrogen

**Fig. 16.43a–c** Three types of electrolyzers. (a) Alkaline electrolysis, (b) PEM electrolysis, (c) high-temperature steam electrolysis

trolyzers (SPEs), where a proton exchange membrane is used, like in a PEM fuel cell. Finally, a younger technique is based on the electrolysis of water vapor at high temperature, utilizing solid oxide electrolytes (SOEs). Figure 16.43 illustrates the three electrolyzers according to the principles described in the next section.

### 16.9.4 Conversion from Hydrogen to Electricity

In the structural diagram of Fig. 16.42, the output stage of the system that converts the stored hydrogen into electrical power is a fuel cell. A fuel cell allows the direct conversion of hydrogen into current, by chemical reaction between the hydrogen and oxygen. In conventional fuel cells, the oxidant is generally taken from the ambient air.

The schematic diagram shown in Fig. 16.44 shows the main components of a classical PEM (polymer electrolyte membrane) fuel cell with hydrogen and air supply. For such a fuel cell, the energetic balance must be evaluated in detail, taking into account the power necessary for the air compressor when it is operated at partial load [16.45]. Load-current proportional airflow can be a well-adapted control method.

The chemical reactions at anode and cathode side are

**Fig. 16.44** Standard structure of a PEM fuel cell

### 16.9.5 Efficiency Considerations

The overall efficiency of the hydrogen storage defined as the ratio of the electrical output energy to the electrical input energy can be evaluated as the product of the individual part efficiencies, namely the efficiencies of the electrolyzer  $\eta_{\text{elys}}$ , the conditioning or compression stage  $\eta_{\text{con}}$ , and the fuel cell  $\eta_{\text{fc}}$ ,

$$\eta_{\text{global}} = \eta_{\text{elys}} \cdot \eta_{\text{con}} \cdot \eta_{\text{fc}} = 0.55 \cdot 0.9 \cdot 0.5 = 0.247.$$

The use of electrolyzers directly producing hydrogen under pressure or high temperature electrolyzers that

can re-use the thermal dissipation of the fuel cell will lead to a higher energy efficiency of hydrogen storage. Additionally, the storage of hydrogen or simply the use

of fuel cells in the context of CHP (combined heat and power) will increase the benefits of the use of hydrogen in energetic chains based on RES.

## 16.10 System Arrangements and Applications

This section describes system arrangements and applications of energy storage. Different configurations are presented as storage as a grid component, storage in combination with a photovoltaic system, and a more general configuration, such as a hybrid power plant [16.46]. Future applications, such as power buffers dedicated to the fast charging of electric vehicles, are currently the subject of much research and development [16.47, 48].

With most classical applications of battery energy storage, there are so-called uninterruptible power supplies (UPS), with their standard architectures, off-line systems, line-interactive systems, and online double-conversion UPS.

### 16.10.1 Storage as a Grid Component

The application consists of the connection of storage capacity to the private grid. The storage means serves to stabilize the load profiles, to cover power peaks, and to limit the power consumption from the public grid. The system offers grid services as primary and secondary control power. The different components needed for storage as a grid component are represented in the general representation of Fig. 16.45.

As shown in Fig. 16.45, connection to the public grid (1) needs a bidirectional counter (2) where not only the fluctuating power consumption (3) is measured, but also the possible power injection from the battery (4). The

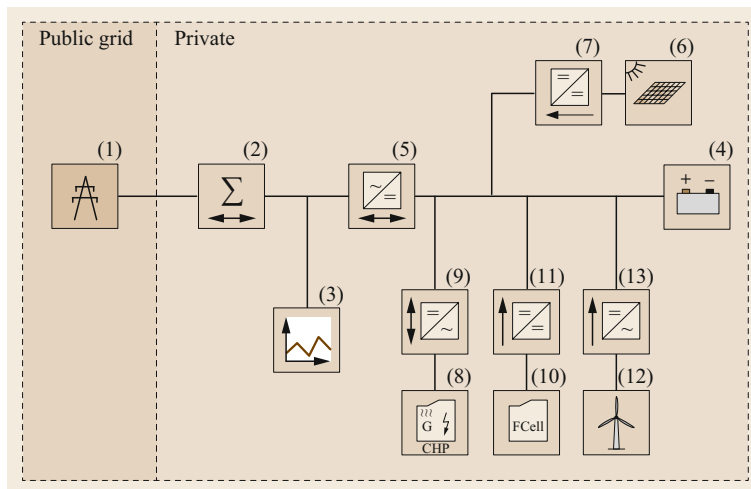

conversion from DC current to AC is achieved through a voltage-source converter (5). Such a device makes it possible to impose positive and negative current injection, as well as capacitive or inductive reactive current.

In Fig. 16.46 the results that can be achieved with storage as a grid component are illustrated. By profiling the power demand it is possible to manage peak demand using power stored during low utilization periods.

The values indicated by blue bars represent the difference of power provided by the storage equipment in addition to the constrained utility value (black dotted line). The light blue values correspond to the additional power taken from the external grid for the compensation of the energy extracted from the battery during peaks.

### 16.10.2 Renewable Energies and the Hybrid Power Plant

The hybrid power plant consists of various producer structures on a shared medium or low-voltage DC bus. Near PV panels they can include generators driven by ICE (internal combustion engine), where low-grade heat is used for house or district heating (CHP) (combined heat and power) ((8) in Fig. 16.45). The producers can also be fuel cells (10) or other sources such as wind generators (12). The different sources are interfaced through dedicated power electronic converters (9), (11), and (13) (as shown in Fig. 16.45). There are many more

**Fig. 16.45** Storage as a grid component and combination with renewable energy sources: the hybrid power plant

Fig. 16.46 Profiled power demand using storage (adapted from [16.46])

examples of hybrid plants with energy storage, where the emissions of diesel generators can be strongly reduced due to the day-to-night shift principle based on electrochemical storage [16.49].

### 16.10.3 UPS Technologies

Various types of uninterruptible power supplies systems have been developed during the past decades, and they currently exist on the market as highly standardized products. In general, there are three different types of arrangements [16.50].

#### Off-Line Topology

When the input mains supply is available, the load is connected to it through a commutation device or switch. The output switch commutates the load to the output of the inverter when the input voltage disappears, and the power is provided by the batteries. The system configuration of an off-line UPS is shown in Fig. 16.47.

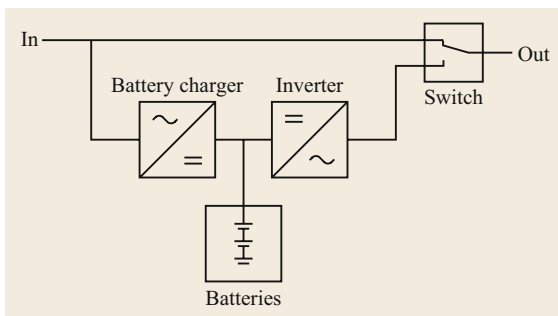

Fig. 16.47 Off-line UPS

#### Line-Interactive Topology

When the input voltage is available, the load is connected to it through an automatic voltage regulator (AVR). This circuit filters and stabilizes the input voltage using passive components and, in many cases, a controlled multi-tap variable-voltage autotransformer. Similarly to the off-line circuit, the load is connected to a battery powered inverter when the input supply fails. The circuit is represented in Fig. 16.48.

#### The On-Line Double Conversion Topology

The input voltage is rectified and reconverted into alternating current. This way, the output voltage waveform is totally independent of the input. All mains disturbances are eliminated, and there is no transient time-switching from the mains to the battery, as the output is always powered by the inverter. In the event of overloads or other possible problems, this type of UPS has an automatic bypass that ensures that the load is powered by the input mains.

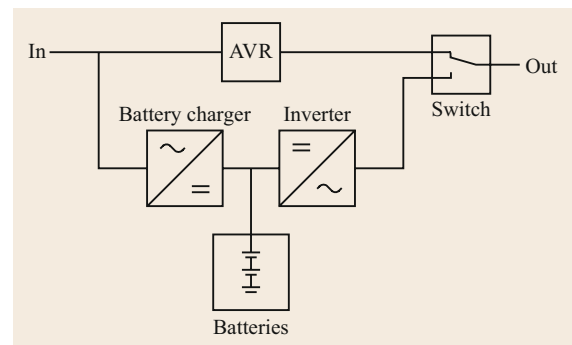

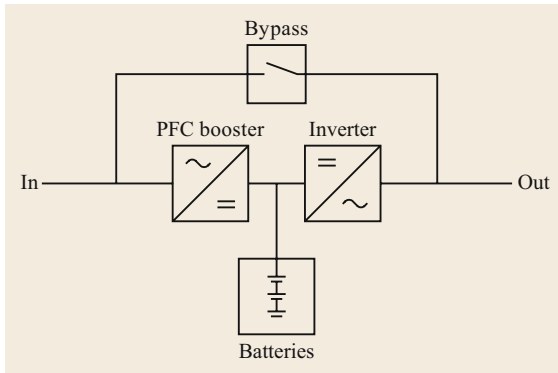

Fig. 16.48 Line-interactive UPS

**Fig. 16.49** On-line double conversion UPS

ered by switching it directly to the input. The on-line double-conversion UPS has the disadvantage that the

power is continuously affected by rectifier and inverter losses, resulting in a lower energy efficiency. The circuit of the on-line double conversion UPS is represented in Fig. 16.49.

For the off-line and line-interactive systems, the battery charger is generally realized with simpler diode rectifiers. The distorted input current of this rectifier circuit is only of a limited impact due to the fact that for normal operating conditions, the input current corresponds to the load current, and the fully charged battery imposes a negligible rectifier current. For the on-line double-conversion UPS, more sophisticated rectifier circuits are used, such as so-called PFC (power factor corrected) rectifiers or active rectifiers with PWM (pulse width modulated) conversion circuits with high power factors or low THD (total harmonic distortion) factors.

## 16.11 Examples of Large-Scale Energy Storage Plants

This section gives some examples of large-scale energy storage facilities in different parts of the world. These examples are a good illustration of the needs for local storage capacities in the context of the change of paradigm in electric power supply generally. Day-to-night shifting functions of photovoltaic generation, also assuming the reliable operation of the local distribution infrastructure, are the main motivations of these new realizations. These new projects further play the role of showcases for the fast-developing battery storage technologies and industry, and also for the evolution of classical techniques like the variable-speed pumped storage with high-capacity power electronics in the range of several hundred megawatt.

### 16.11.1 Nant-de-Drance, Switzerland

A variable-speed pumped storage plant is under construction in the alpine region in western Switzerland. The innovative plant is composed of six doubly-fed induction motor generators, each of 150 MW. The plant has a capacity of 18 400 MW h and a total rated power of 900 MW.

### 16.11.2 Hyundai and the Korea Zinc Energy Storage System

Korea Zinc, a metals melting company, has ordered an industrial energy storage system (ESS) to be installed in Ulsan, Korea in a refinery. The project will be the largest electrochemical battery system in the world and was expected to be commissioned in February 2018.

The technology used is lithium-ion, and the rated power is 150 MW.

### 16.11.3 Hornsdale Power Reserve, South Australia, Jamestown

A lithium-ion-based storage plant (Tesla Powerpack Technology) is under construction in South Australia and will be connected to the South Australian electrical infrastructure. The plant is expected to be charged from renewable energy sources and to support the grid during peak hours, maintaining reliable operation of the electrical infrastructure. The plant will provide up to 100 MW peak power with a capacity of 129 MW h.

### 16.11.4 NGK Sodium–Sulfur (Na–S) Battery

A large sodium–sulfur (Na–S) battery has been installed in the village of Rokkasho, Aomori, Japan and is used for the stabilization of a 51 MW wind power plant. The plant has a rated power of 34 MW and can deliver the rated value during 7 h (238 MW h). The battery is charged at night, when the power demand is low. The battery supplies the national power grid; it has been in operation since 2008.

### 16.11.5 Dalian VFB–UET/Rongke Power

A very large battery-storage plant is expected to be built in the city of Dalian, China. The battery system will be realized on the basis of vanadium redox flow-battery arrays made up of ten (10×) 20 MW/80 MW h

VFB units. The battery system will be connected to the main grid of Liaoning Province, which has experienced stress during extreme weather events. When completed (200 MW/800 MW h), the storage facility will have the capacity to peak-shave  $\approx 8\%$  of Liaoning Province's expected peaking capacity in 2020. Further, the large-scale battery will form an additional load center, which will enhance grid stabilization including securing the power supply and providing black-start capabilities in the event of emergency.

### 16.11.6 Clear Creek Flywheel Wind Farm Project

Ontario's Hydro One Networks Inc. intends to realize a 10-flywheel 5 MW flywheel energy storage (FES) installation. The system will provide local power quality support, by compensating real and reactive power flows from a 20 MW-wind farm technology.

### 16.11.7 Huntorf CAES Plant

The first commercial CAES plant is in operation since 1978 in Huntorf, Germany. The system is fed from thermal and nuclear night-time power to compress and inject the air into two caverns of 310 000 m<sup>3</sup> total volume. The 600 m cavern depth ensures the air's stability through seasonal temperature changes, and guarantees the specified maximum pressure of 100 bar. The compression operation is characterized by a power of 60 MW and lasts 12 h. The turbine operation allows the power generation at 290 MW during 3 h.

#### Additional Information and Exercises

Alfred Rufer received his BS and MS degrees from EPFL (Ecole Polytechnique Fédérale de Lausanne Switzerland) in 1976. In 1993 he became Assistant Professor at EPFL and Full Professor in 1997. He became the Director of the Industrial Electronics Lab at EPFL. Alfred Rufer has published more than 300 conference and journal papers, as well as several patents. He is now Professor emeritus.

# Power Quality

## 17. Power Quality

Oscar Lennerhag , Math Bollen

Power quality concerns the electrical interaction (through voltages and currents) between the electricity grid and equipment connected to it. The field of power quality is subdivided into different types of disturbances, each of which represent one specific deviation from the ideal voltage and/or current. Section 17.1 will introduce the power-quality field, including terminology and a brief history. One of the disturbance types, waveform distortion, or harmonics, is discussed in detail in Sect. 17.2. Other types of disturbances are discussed briefly in Sect. 17.3.

### 17.1 Terminology of Power Quality

This section introduces some of the basic terminology related to power quality and a brief historical introduction. The term *power quality* is commonly used in electric power system studies and it covers a range of phenomena. Some of those phenomena will be discussed in this chapter. For other phenomena and more details on the phenomena described here, the reader is referred to the extended literature on power quality. Some reference books on power quality include [17.1–4].

#### 17.1.1 Origin of the Term Power Quality

A search in IEEE Xplore (19 February 2019) resulted in 21 127 hits for the term *power quality*, 3732 of those were journal papers and 100 were standards. Power quality is a research field with a high amount of standards. This makes power quality a relatively large part

of applied research. A search on Google scholar (on the same date) resulted in about 357 000 hits.

The term *power quality* was first mentioned in an IEEE publication in June 1962 [17.5]: power quality was mentioned as one of the most important parameters for aerospace applications. The early papers on power quality were mainly on aerospace applications. The first use of the term *power quality* in its modern meaning was in a paper by *Alexander Kusko* in 1967 [17.6]. The paper was appropriately named *quality of electric power* and it introduced the *voltage tolerance curve* for voltage dips and voltage swells that would become widely used some 30 years later.

Although the term *power quality* only came into use in the 1960s, the phenomena that are part of the field have been studied for much longer. For example, in a discussion at a meeting of the American Institution

**Fig. 17.1** Number of papers on power quality as a percentage of the number of papers on power engineering in IEEE Xplore

of Electrical Engineers in January 1899, reference was made to the *existence of higher harmonics* [17.7].

The number of publications on power quality has shown a steady growth since about 1995. This is in part due to the general growth in the number of publications. A comparison is therefore made with the total number of publications on *power*. Figure 17.1 shows the percentage of the publications on *power* that are about *power quality* for each year between 1991 and 2017. The figure shows the appearance of power quality as a respected research field between 1995 and 2000. Since the year 2000, about 2.5% of the papers on *power* are about *power quality*. The value in the figure was obtained as the ratio of the number of hits on *power quality* in IEEE Xplore and the number of hits on *power* for each year.

Power quality concerns the (electrical) interaction between the grid and equipment or installations connected to it. Power quality is important for several of the stakeholders in electric power systems. The importance for network customers (consumers, producers and those that are both) is that voltage disturbances can affect electrical equipment connected to the grid. The importance for the network operator is somewhat more complicated. Both current disturbances and voltage disturbances can affect the grid and components in the grid. Information on power quality is also important for the network operator as feedback for investment decisions. Under the regulatory regime in most countries, the network operator is responsible for maintaining sufficient power quality. The network operator in turn can put requirements on the customers to be able to maintain sufficient power quality.

There are different definitions of power quality and the reader is referred to the literature to find out more about them. The authors use the term *power quality* as a combination of *voltage quality* and *current quality*. Voltage quality concerns deviation from the ideal volt-

age; current quality concerns deviations from the ideal current.

In power-quality regulation, the general term *quality of supply* is used to describe how the electricity grid affects the customer. A distinction is thereby made in [17.8] between:

- Continuity of supply: *availability of electricity*; short and long interruptions.
- Voltage quality: *the technical properties of the electricity*, or (using the terminology in this chapter) all other voltage disturbances apart from short and long interruptions.
- Commercial quality: the speed and accuracy with which customer requests are handled.

A term commonly used in standardization is *electromagnetic compatibility* (often abbreviated as EMC). It is defined [17.9] as the

ability of equipment or a system to function satisfactorily in its electromagnetic environment without introducing intolerable electromagnetic disturbances to anything in that environment.

Note that the terms *voltage quality* and *current quality*, that are part of our definition of power quality, are embedded in this definition.

### 17.1.2 Disturbances and Interference

The earlier-mentioned deviations from ideal voltage or current are referred to as *disturbances*: voltage disturbances and current disturbances, respectively. Based on the kind of disturbance, different terms are used like *voltage dips*, *transients* or *even order harmonics*. In reality, there is no such thing as a pure voltage dis-

turbance, or a pure current disturbance. Voltage and current in the power system are strongly linked. For some types of disturbances, like *voltage dips*, it is obvious from the name that it is mainly treated as a voltage disturbance. For other types of disturbances, like *harmonics*, both voltage and current are of interest.

A *power quality disturbance* is, as reasoned above, any deviation from the ideal voltage or current waveform, magnitude or frequency.

Even if the deviation is very small, we refer to it as a disturbance. The term is somewhat confusing because the disturbance does not actually have to disturb anything. The interest in power quality is however in disturbances that do have an adverse impact. This is where we use the term *interference*.

Interference occurs when a power quality disturbance adversely affects equipment. This can be equipment with end-users, but also equipment in the grid. Examples of interference are:

- Equipment trips or mal-functions
- Equipment suffers permanent damage immediately
- Equipment suffers from loss-of-life.

Almost all the studies, measurements, standards and regulation within power quality are related to voltage or current disturbances. However, only the occurrence of interference matters. The ultimate aim of all the work on power quality should be to reduce the probability of interference. In the IEC standards on electromagnetic compatibility, this is formulated as *guaranteeing a high probability of electromagnetic compatibility*.

### 17.1.3 Events and Variations

We saw earlier that power quality disturbances are deviations from the ideal voltage or current. Not all power-quality disturbances are treated equally, and a further classification is needed to understand for example some of the details of standardization and power-quality monitoring. Based on the way they are treated, two groups are distinguishable: *power quality variations* and *power quality events*. This terminology is certainly not unique, but the division in these two types of disturbances is common in many works on power quality.

Variations, are slow and small deviations from the ideal voltage or current. They can be measured at any instant in time or over a pre-defined period. When one is interested in the voltage magnitude (expressed typically as the RMS voltage over a certain period), one has just to go to a wall outlet (or to a voltage transformer in the substation), connect a measurement instrument and obtain the value.

Events, are sudden and large deviations from the ideal voltage or current. To measure events, one has to wait until one occurs. This requires some kind of triggering mechanism.

One of the first documents that listed and described power-quality disturbances is the European standard defining voltage characteristics, EN 50160 [17.10]. The list of disturbances below is largely based on that document. The following types of variations (referred to as *continuous phenomena* in EN 50160) are distinguished:

- Power frequency variations.
- Supply voltage variations.
- Flicker severity.
- Supply voltage unbalance.
- Harmonic voltage.
- Interharmonic voltage.
- Mains signaling voltage.

The following types of events are distinguished:

- Interruptions of the supply voltage.
- Voltage dips.
- Voltage swells.
- Single rapid voltage changes.
- Transient overvoltages.

Differences in terminology are a common feature of power quality and despite several attempts to solve this, the confusion remains. In this book, we will use a certain terminology, but we do not claim that this is the correct or the best terminology. The reader is strongly advised to be careful with terminology, check the meaning of the terms used by others, and explain the used terminology in their own documents. Where possible, commonly used terminology is preferred, but even in this case it is important to explain the meaning of the terms, to avoid confusion.

The definition of variations and events distinguishes between small and large deviations from the ideal. There is no unique distinction between small and large as per the *sorites paradox* [17.11] from the classical Greek period. In power quality monitoring, this paradox is better known as the *triggering problem* and more generally as *what is normal?*

The triggering problem is illustrated in Fig. 17.2. This figure is obtained from a 28 day voltage measurement in a medium-voltage grid. For every 1 min interval, the following two values are plotted (both expressed in percent of the nominal voltage)

$$\max(V_{1\text{cycle}}) - V_{1\text{min}} \quad (17.1)$$

$$\min(V_{1\text{cycle}}) - V_{1\text{min}} \quad (17.2)$$

**Fig. 17.2** Example of voltage variation and possible thresholds. The different colors refer to the three phase-to-neutral voltages

where  $V_{1\min}$  is the RMS voltage over the 1 min window;  $\max(V_{1\text{cycle}})$  and  $\min(V_{1\text{cycle}})$  are the highest and lowest 1-cycle RMS voltages during the same 1 min window.

Consider a hypothetical event that is triggered when one or both values exceed, in absolute value, a certain threshold. As can be seen from the figure, the number of such events detected depends strongly on the threshold setting. For thresholds above 25% of the nominal voltage, not a single event would be detected. For thresholds below 1%, many events would be detected. There is no correct or incorrect threshold setting, although research is ongoing about how to optimize between *fail to detect* and *incorrect detection*. Such studies require detailed insight in the underlying event behind the power-quality event and there is no obvious solution to the triggering problem.

Note that the hypothetical event discussed here is not among the standard list of power-quality events. There are however strong similarities with voltage dips (Sect. 17.3.1) and voltage swells (Sect. 17.3.2).

#### 17.1.4 History of Power Quality

It was already mentioned before that the term *power quality* was first used in aerospace engineering. Through the years, power quality has seen several different drivers. Some of these had to do with certain challenges that occurred. Sometimes, a new solution resulted in renewed interest in power quality.

Some of the drivers for interest in power quality, through the years, are listed here:

- HVDC (high voltage DC) links and large power-electronic converters were a major source of harmonic currents. Much of the work on harmonics

was developed to be able to study the connection of such devices. The harmonic voltage limits in IEEE 519 [17.12], including the fact that they are frequency independent, can be traced back to the connection of large power-electronic converters.

- Arc furnaces and some other large industrial installations are a major source of fast voltage variations. The main impact of this was light flicker, a phenomenon that was common for candle light but that was supposed to have disappeared with the introduction of the incandescent lamp. Once electrical motors were connected to the grid, voltage drops occurred and light flicker reappeared. The *general electric flicker curve* [17.13], developed in the 1930s, allowed for a compromise where a certain level of fast voltage variations were allowed. This curve later resulted in the flickermeter and IEC 61000-4-15 [17.14]. The work on fast voltage fluctuations was driven not just by the need to connect large arc furnaces, but also by the development of the static var compensator (SVC) that allowed for the mitigation of fast voltage variations without the need to increase the fault level. The SVC was based on the same technology as HVDC and large drives, which were the drivers behind much of the work on harmonics.
- The widespread use of televisions in households resulted in a significant source of harmonics at millions of locations in the grid. Cathode ray tubes required a high DC voltage. A diode rectifier directly connected to the 220 or 120 V supply was used. The earliest television used a single diode, with high second harmonic currents as a result. Later designs, with four diodes, resulted in low-order odd harmonics (3, 5, 7, etc.). All televisions

had almost the same current waveform so that they all together resulted in the typical *television peak* in the early evenings for those harmonics.

- Adjustable-speed drives and process control were, upon their introduction in the 1990s, very sensitive to voltage dips [17.15]. This resulted in a shift of emphasis within power quality research from harmonics to voltage dips, with many technical papers and a number of textbooks produced as a result. The same power electronics that has resulted in HVDC and SVC were used to come up with a solution for voltage dips: the *dynamic voltage restorer* (DVR) [17.16]. Many technical papers were written on the DVR and on different control algorithms for the DVR.
- The availability of measurement instruments, data storage and data processing allowed for much more monitoring of the voltage and currents in the grid than with traditional instruments like oscilloscopes and multimeters. With more data becoming available, the need for data analysis appeared almost immediately. Signal processing of power-quality data became a major subject of publications. On the standardization side, the IEC power-quality monitoring standard, IEC 61000-4-30 [17.17], resulted from this.
- Modern equipment contains almost exclusively a power-electronic interface with the grid. Almost all these devices inject harmonics or supraharmonics into the grid. This is one of the reasons for the recent increased interest in waveform distortion.
- Distributed generation has resulted in a significant increase in interest in power quality. Some types of distributed generation are a source of disturbances, e.g., voltage variations, unbalance and waveform distortion. Distributed generation is also susceptible to voltage disturbances at its terminals. The issue that has received most attention in the literature and among transmission system operators is the potential massive tripping of distributed generation. The disturbances most studied in this context are frequency variations and voltage dips. The term *fault-ride-through* is commonly used in the literature.
- The replacement of incandescent lamps with compact fluorescent and LED (light emitting diode) lamps triggered a concern about large increases in harmonic distortion [17.18]. The concern did not (yet) materialize [17.19–21], but certain aspects remain unclear and the research is ongoing. It is for example not clear why the modeling and measurement results differ significantly. The introduction of, especially, LED lamps has also resulted in a renewed interest in light flicker.

### 17.1.5 Power Quality Standards and Regulation

Compared to most other fields within electric power engineering, power quality has a rather large number of standards. Some of those standards are of a mere technical nature, but many of them are of a legal nature. For the latter ones, the contents are still mainly technical, but the document defines obligations for different stakeholders.

Before discussing standards and regulation, it is important to clarify the difference between standardization and regulation. Standardization is a consensus process, where the different stakeholders sit together and discuss different proposals to come to an agreement. It is not always an agreement that everybody is happy with, but all stakeholders at least accept the compromise. Because it is a consensus process, it is also difficult to make changes to standards and an old standard could stay in place because there is no agreement among the stakeholders on a better version. For the same reason, standardization is a slow process. Making even a small change can easily take five years. However, despite that, standards do change and before using a standard, it is good to check the latest version.

Regulation on the other hand is not a consensus process; the regulator gets certain powers under the local law and that allows the regulator to set and/or enforce certain detailed rules. In most countries, the regulator will do this in close collaboration with the different stakeholders. However, in the end the regulator decides, whether the other stakeholders agree or not. Within power quality, the regulation in most countries is strongly related to national or international standards, so that the general discussion on standardization below also holds for regulation.

Where it concerns the detailed standardization for different types of disturbances, standardization has come a long way for long and short interruptions, for slow voltage variations, harmonics, and fast voltage variations that potentially result in light flicker. More work is needed on voltage dips, interharmonics, supraharmonics, fast voltage variations not resulting in light flicker, and on transients.

There are two different types of power-quality standards. The first type is those that define certain types of disturbances, disturbance characteristics or measurement methods. The IEC power-quality measurement standard (IEC 61000-4-30 [17.17]) plays an important role here. The second type are standards that define acceptable limits. These can be limits for the network operator, where EN 50160 [17.10] has become the leading document, but also limits for installations

or individual devices. A large number of IEC product standards set performance requirements for individual devices. Some standards set limits on emissions from equipment, others set limits on the immunity of equipment against voltage disturbances. A big challenge in standardization is to ensure that there is a correct balance between emission and immunity requirements.

We will further discuss the different standards and regulations together with the different types of disturbances in Sects. 17.2 and 17.3.

### 17.1.6 Limits and Interference

The difference between *disturbance* and *interference* was discussed in Sect. 17.1.2. Next to that, a distinction is often made between *acceptable disturbance levels* and *unacceptable disturbance levels*. Whether the level is acceptable or unacceptable is determined not by the presence or absence of interference but by comparing the level with a limit. For example, the voltage distortion is considered unacceptable when the total harmonic distortion (THD) is above a limit set in a standard or by regulation.

The relations between *exceeding the limit* and *occurrence of interference* are shown in Fig. 17.3, where all four combinations occur in reality. The top right relates to cases where the limits are exceeded and where equipment is adversely impacted (where there is interference). This is why there are limits: to avoid interference. The responsibility for the interference is easy to allocate, it is with the one that exceeds the limit. Cases that end up on the bottom left are also easy: this is where the limits are not exceeded and where everything works correctly, i.e., where there is no interference.

The other two blocks in the figure require some further discussion and cases that end up here often result in much discussion. For the block on the upper left, interference occurs while none of the limits are exceeded. Researchers and others that want to promote power quality often use cases like this to show that *the standards do not work* or that *the standards need to*

*be improved*. This is an oversimplification. The aim of standardization is to ensure a small probability of interference, at reasonable costs to society as a whole. As long as cases like this are small in numbers, there is no need for making changes in standardization. When the number of cases increases, or is expected to increase, changes are obviously needed. Even when individual cases do not warrant changes in the standards, it remains worthwhile to study such cases to learn more about the different phenomena and about which specific aspect or characteristic of a disturbance leads to interference. The occurrence of individual cases here may also possibly indicate a larger number of cases in the future.

The cases on the bottom right are the ones where one or more limits are exceeded but there is no interference. These should actually not be of any concern, as there is no interference. When cases like this occur too often, this could be an indication that the limits are too strict. The stakeholder that is responsible for keeping that limit may request for a lessening of the requirements. Two examples of this are:

- The regulator requirements on voltage are not fulfilled, but no equipment is adversely impacted. In that case, the question arises if the network operator (the stakeholder responsible for the voltage under the regulation) should take mitigation measures or not. This differs between countries and there are arguments to be given for both.
- Requirements for the connection of wind power plants often contain very strict conditions on harmonic currents. Especially the ones on higher-order even harmonics are hard to comply with in many cases. However, the choice of those limits is more based on existing levels many years ago than on possible interference.

### 17.1.7 Power Quality Monitoring

There are different types of power-quality monitoring, where the main difference is between short-duration

	Limits not exceeded	Limits exceeded
Equipment impacted	Investigation typically triggered by the owner of the equipment impacted	Measures have to be taken by the network operator or by the source of the emission
Equipment not impacted	Everybody is happy	Measures are actually not needed, but still often required under regulation or contracts

**Fig. 17.3** Relations between interference and exceeding of acceptable limits

manual measurements and long-duration automatic measurements. The latter are ruled by IEC 61000-4-30 [17.17], where so-called *class A instruments* are preferred. Such instruments continuously perform two types of calculations, related to variations and events (Sect. 17.1.3).

For variations, a number of characteristics are calculated and stored over pre-defined periods. Two simple examples are:

- The frequency of the voltage is calculated every 10 s from the number of zero crossings within the preceding 10 s interval.

- The voltage magnitude is calculated every 10 min as the RMS voltage over the preceding 10 min interval.

To detect events, a number of characteristics are calculated continuously and compared with pre-set threshold values. These characteristics are not stored, but once a threshold is exceeded, an event is detected, and the recording and characterization of the event is triggered.

A simple example: a voltage dip is detected when the 1-cycle RMS voltage becomes lower than 90% of the nominal voltage. Once the event is detected, single-event characteristics are calculated from the voltage and/or current waveform.

## 17.2 Harmonics

Harmonic distortion refers to components of the voltage or current at integer multiples of the fundamental frequency. A distinction is typically made between even harmonics, odd harmonics, and DC-components, where DC-components are usually treated differently since their consequences and measurement techniques differ.

A voltage or current waveform containing harmonic distortion (i.e., a periodic but non-sinusoidal waveform) can be decomposed into a sum of harmonic components according to

$$v(t) = V_{DC} + \sum_{h=1}^N \sqrt{2}V_h \sin(h\omega_0 t + \theta_h). \quad (17.3)$$

Harmonic distortion is typically presented in the form of a harmonic spectrum, as is exemplified in Fig. 17.4, for the voltage at the wall-outlet in a low-voltage installation. The bars represent individual harmonics, expressed as percent of the fundamental.

### 17.2.1 Sources of Harmonics

Harmonics are mainly caused by non-linear loads, such as variable speed drives, arc furnaces, computers, LED lamps, etc. Other power system elements that present a non-linear behavior include transformers and power electronic devices in the grid such as FACTS (flexible AC transmission system) and HVDC.

A non-linear device will draw a non-sinusoidal current even when fed by a sinusoidal voltage. Figure 17.5 shows an example of the current drawn by a computer, and its corresponding harmonic spectrum.

Different types of converters (e.g., single- or three-phase, current or voltage source, passive or active) behave differently with regard to the generation of harmonics. Figure 17.6 shows the harmonic current spectrum for a single- and three-phase DC current source (diode rectifier), as well as the corresponding mathematical expression for the generated harmonics,

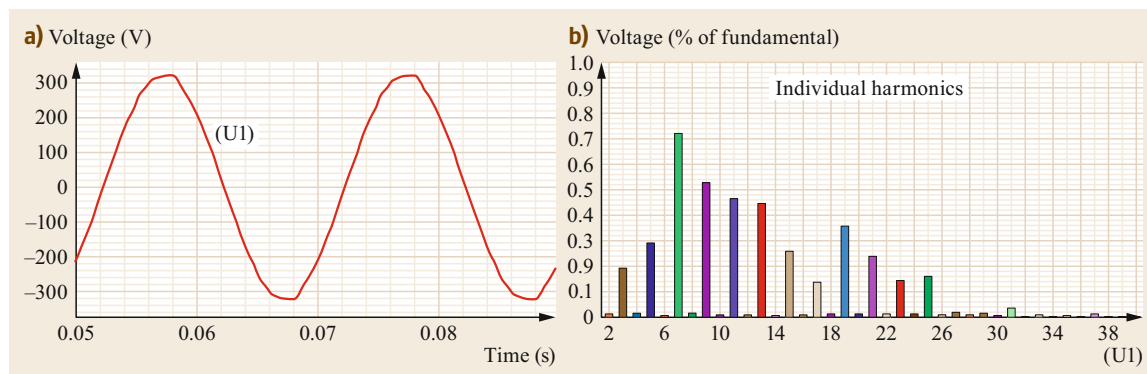

Fig. 17.4a,b Voltage waveform (a) and its corresponding harmonic spectrum (b). Measurement by Metrum PQSmart

Fig. 17.5a,b Current to a computer (a) and the corresponding spectrum (b). Measurement by Dranetz PP1

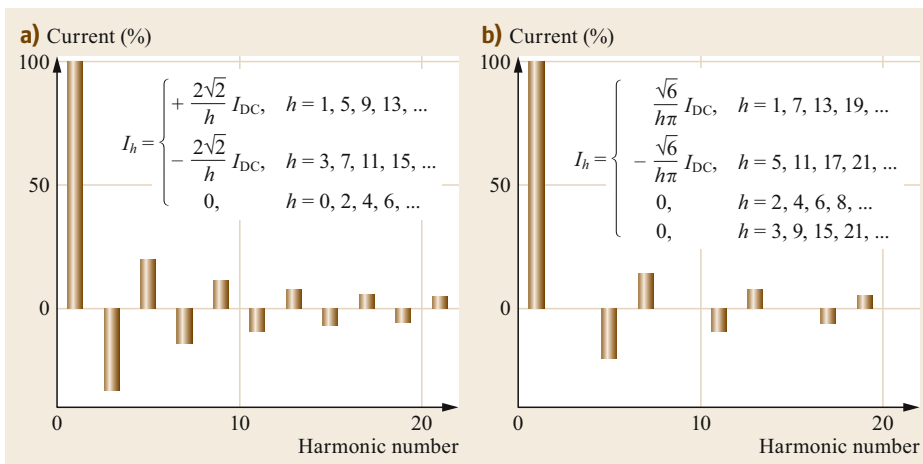

Fig. 17.6a,b Current spectrum of a single-phase DC current source (a) and a three-phase DC current source (b)

Fig. 17.7a,b Current waveform (a) and spectrum (b) of a three-phase DC voltage source

**Fig. 17.8** Emission from three different wind turbines; 95th percentile of the 10 min value of a period of one to three weeks

where  $h$  is the harmonic order,  $I_{DC}$  the DC current and  $I_h$  the resulting harmonic current of order  $h$  [17.4]. A negative value means that the emission is in phase opposition with the fundamental.

Figure 17.7 shows the current waveform and spectrum of a three-phase DC voltage source: a three-phase diode rectifier powering an adjustable-speed drive [17.22].

Modern types of power electronic converters used e.g., in HVDC applications or wind farms utilize an active switching scheme, which results in a less predictable spectrum compared to the spectrum of passive diode rectifiers. While such modern devices perform well regarding low-order harmonics, they instead act as a source of high-frequency harmonics (also known as *supraharmonics*). Figure 17.8 shows an example of harmonic emission from three modern wind tur-

bines [17.23]. When compared to IEEE 519 [17.12], harmonic orders 36 and 40 are exceeded by some of the turbines.

#### Impact of Background Distortion and the Number of Devices

The emission from a non-linear device is affected by the voltage distortion at its terminals. Figure 17.9 shows a comparison of the current to a personal computer when supplied from a clean supply and from a distorted supply [17.24]. When it is fed by the distorted supply, there is a reduction in harmonic currents, especially at higher frequencies.

Similarly, the current emission per device will be reduced as more equipment (computers, televisions, etc.) is added to the same node. Two examples are shown in Fig. 17.10. In Fig. 17.10a, the current spectrum

**Fig. 17.9a,b** Current spectrum of a computer (DC voltage source) when connected to a clean (a) and a dirty supply (b)

**Fig. 17.10a,b**  
Spectrum for 1, 10 and 80 televisions (a), and for an increasing number of computers (b)

for 1, 10 and 80 televisions is compared [17.24], and in Fig. 17.10b, the current spectrum per computer is shown for an increasing number of computers [17.25].

For active converters, the impact of voltage distortion on the emission is more complicated and the emission can increase or decrease with increasing voltage distortion.

### 17.2.2 Impacts of Harmonics

Due to regulation and standardization harmonics are typically not a problem for customers, but occasional problems do occur, typically because of amplification due to resonances. The consequences of high levels of harmonic distortion include increased heating of transformers, capacitors and rotating machines, malfunction of electronic equipment that relies on detecting the voltage zero-crossing, unwanted operation of relays, etc. The following sections describe some of the consequences in more detail [17.4].

#### Transformers

For transformers, the main issue is heating, mainly due to additional losses caused by harmonic currents. The losses are not uniformly spread through the transformer, which can lead to hot spots forming. The heating effect becomes more severe with increasing frequency. Another consequence of harmonics in transformers is audible noise.

#### Cables and Lines

Cables and lines are also impacted in the form of additional heating, but the effect is not as pronounced as for transformers. For cables, there is a risk of hot spots forming in cable joints, especially in the case of higher frequencies.

#### Neutral Conductors

The neutral conductor normally does not carry a significant current in a three-phase system. However, triplen harmonics present in the phase conductors will add in the neutral conductor. In some cases, this can lead to the current in the neutral exceeding the phase current. Consequently, there is a risk of overheating of the neutral conductor, without the overload protection removing the overload.

#### Electronic Equipment

Waveform distortion may cause a shift in the zero crossing or multiple zero-crossings, which will affect equipment that utilizes the voltage zero-crossing to determine the phase-angle.

Indirect effects of waveform distortion on electric equipment include e.g., malfunctions related to the coupling of high-frequency distortion through the power supply circuit.

#### Signaling

Waveform distortion may cause difficulties for signaling, since the distortion may be confused with the control signal. If passive filters are installed to mitigate harmonics this may have the indirect consequence of damping the control signals.

#### Telephone Interference

The inductive coupling of harmonic currents to telephone lines may cause audible telephone interference. A related issue is the appearance of audible noise on hearing loops (*audio induction loops*).

#### Magnetic Fields

A consequence of harmonic currents are magnetic fields at harmonic frequencies. The main magnetic field of

three-phase lines at a certain distance from the line is caused by the zero-sequence current, which is mainly caused by triplen order (3, 9, 15, etc.) harmonic current.

#### Capacitors

High-frequency harmonic currents may cause overheating, fuse blowing and damage to capacitor banks.

#### Rotating Machines

Low-order harmonics may lead to the forming of hot spots in rotating machines. Other effects include torque oscillations and audible noise.

#### Insulation

A high crest factor (caused e.g., by notching or resonances causing amplification of certain harmonics) leads to additional stress on insulation.

#### Protection

High harmonic distortion may cause incorrect operation of relays; this is especially a concern for solid-state relays.

#### Reactance-Earthed Networks

High harmonic distortion may cause detuning of Petersen coils, and may increase the earth-fault current.

#### Lighting and Other Electronics

The main impact on lighting is the destruction of the input capacitor, caused by high harmonic distortion. It has been shown recently that supraharmonics (in the range from 2–150 kHz) can result in light flicker [17.26].

#### Digital Energy Meters

Digital energy meters may give incorrect values because of supraharmonics.

### 17.2.3 Spread of Harmonics

The flow of distorted currents will cause voltage distortion throughout the network. In case of resonances the distortion may be amplified, leading to high distortion levels at nodes some distance away from the harmonic source.

Harmonic studies may involve the calculation of source and transfer impedances, or calculation of harmonic distortion in the network. Several software packages for performing harmonic calculations are available and a comprehensive source on network modeling for harmonic studies can be found in [17.27].

A simple and often used approach to assess the voltage distortion caused by the emission from a certain device is by modeling it as a current source. The system impedance  $Z_h$  is calculated for each harmonic order  $h$

and Ohm's law is used to calculate the voltage distortion  $V_h$

$$V_h = Z_h I_h . \quad (17.4)$$

This model assumes that the current injection is independent of the voltage. In reality, this is not the case, but the model may still be acceptable depending on the type of device that is being considered.

For modern sources of harmonic distortion, including converters used in wind farms, etc., the pure current source model is not suitable. Typically, a Thévenin or Norton equivalent model is used instead, with different values for the source and impedance, depending on the operating point.

#### Harmonic Transfer Impedance

The harmonic transfer impedance relates the voltage at a certain node with the current injected at another node. It can be used to assess the voltage distortion at a remote node following current injection at the local node, and vice versa [17.28, 29]

$$V_r^h = Z_{sr}^h I_s^h . \quad (17.5)$$

Here,  $r$  represents the receiving node, and  $s$  the sending node. In case of several sources, the total harmonic voltage at location  $r$  can be calculated using the superposition principle

$$V_r^h = \sum_{i=1}^N Z_{ri}^h I_i^h . \quad (17.6)$$

#### Study Domain

Harmonic studies are typically performed in the frequency or time domain, depending on the purpose of the study.

*Frequency-domain methods* are robust and allow for a simple definition of harmonic sources, but non-linear devices in the study have to be linearized. Typical applications include frequency scans in order to evaluate resonances, filter design studies and harmonic propagation studies.

*Time-domain methods* allow for modeling of non-linear devices in any level of detail and time-varying properties, including power electronic converters and their control. However, significant effort is often required to incorporate such models correctly, and time-domain simulations can be computationally heavy. Typical applications include studies involving transformer saturation and studies where detailed modeling of power electronic converters is required.

More information on study domains can be found in [17.27].

**Table 17.1** Harmonics and symmetrical components

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Positive sequence	+			+			+			+				+	
Negative sequence		-			-			-			-				-
Zero sequence			0			0			0			0			0

**Harmonics and Symmetrical Components**

In the same way as for the fundamental frequency, harmonics can be transformed into symmetrical components. In a balanced system, each harmonic frequency belongs to one of the sequences, as illustrated in Table 17.1.

Special attention should be given to zero-sequence harmonics due to the way they propagate in the system:

- Zero-sequence harmonics in the three phases will add in the neutral conductor, which may lead to overheating of the neutral.
- Zero-sequence harmonics circulate in the delta windings in transformers, meaning that they will not propagate through the transformer. Thus, any 3<sup>rd</sup> harmonic distortion originates locally.

**Primary and Secondary Emission**

When assessing the contribution of a device to the harmonic distortion, a distinction should be made between primary emission, which refers to any emission originating from the device itself, and secondary emission, which originates from outside of the device. The concept of primary and secondary emission can be explained using Fig. 17.11 [17.28].

In this case, the primary emission is driven by the current injected by  $J_1$ , and the secondary emission is driven by  $E_2$ . It is not straightforward (or even possible, depending on the assumptions made) to distinguish between primary and secondary emission through field measurements alone.

**Resonances**

Resonances are often the cause of high harmonic distortion and interference.

**Fig. 17.11** Primary and secondary emission.  $I$ : emission,  $J_1$ : internal emission,  $Z_1$ : device impedance,  $Z_2$ : grid impedance,  $E_2$ : background voltage

A *parallel resonance* is characterized by a large impedance at the resonance frequency. If a parallel resonance is excited by a harmonic current, there is a risk of significant voltage distortion, even for moderate levels of current distortion. Consider a simple system with source impedance  $L$  and shunt capacitance  $C$ . The impedance seen from the harmonic source will be

$$Z(\omega) = \frac{j\omega L}{1 - \omega^2 LC} \tag{17.7}$$

At the resonance frequency, the impedance becomes infinite. The resonance frequency is determined by

$$f_{res} = \frac{1}{2\pi\sqrt{LC}} \tag{17.8}$$

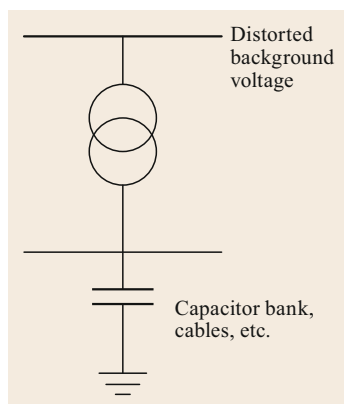

Figure 17.12 shows a typical parallel resonance circuit, where a transformer is energized in the presence of a cable. The cable capacitance and source inductance form a parallel resonance circuit, and the transformer acts as a source of harmonic currents.

A *series resonance* is characterized by a small impedance at the resonance frequency. Figure 17.13 shows an example of a series resonance circuit, which consists of a transformer with a capacitance connected to its secondary side. In case of high background distortion on the primary side of the transformer, this may lead to high harmonic distortion on the secondary. The relation between the voltage at the secondary side,  $V_{sec}$ , and the primary side  $V_{prim}$ , is

$$\frac{V_{sec}(\omega)}{V_{prim}(\omega)} = \frac{1}{1 - \omega^2 LC} \tag{17.9}$$

**Fig. 17.12** Parallel resonance circuit

**Fig. 17.13** Series resonance circuit

The impedance at the resonance frequency will depend on the damping (series and shunt resistances in the grid). However, the damping is typically not known, especially at higher frequencies. Resonances are generally not a problem if the damping is high or if there is no emission around the resonance frequency.

#### 17.2.4 Mitigation of Harmonics

Harmonics can be mitigated by limiting the emission from equipment, by the use of harmonic filters or by strengthening the network. The latest developments focus on the use of power electronics and active filtering to mitigate harmonics. A comprehensive source on harmonic mitigation can be found in [17.30].

##### Passive Filters

Passive filters are cheaper and more commonly used than active filters. A passive filter consists of a combination of inductances, capacitances and resistances arranged in specific ways to suppress certain harmonics. There are several types of passive filters, with the single-tuned *notch* type filter being the most common. At the resonance frequency, the filter acts as a current sink, meaning that all harmonic current passes through the filter. The sharpness of the filter is determined by its  $Q$ -value, where a high  $Q$  means it is sharply tuned to a certain frequency and a low  $Q$  means it has a low impedance over a wide range of frequencies. A filter bank consists of a combination of filters, such as 5th and 7th, 11th and 13th, and high-pass filters.

##### Active Filters

Active filters are power electronics-based devices that aim to reduce the harmonic distortion through dedicated control algorithms. The reduction can be achieved either by compensating the harmonic currents or through impedance shaping. Active filters are more flexible than

passive filters, but also more complicated and more expensive.

#### 17.2.5 Harmonic Measurements

Harmonic measurements deal with the monitoring of voltages and currents in the power system. Captured voltages and currents are transformed into the frequency domain and processed in order to obtain suitable indices for quantifying the harmonic distortion.

IEC 61000-4-7 [17.31] and IEC 61000-4-30 [17.17] provide guidelines for harmonic and interharmonic measurements and instrumentation.

##### Measurement Transformers

In cases where a direct connection is not possible, measurement transformers are used to provide a signal level that is compatible with the measurement equipment. Although the behavior of measurement transducers at the fundamental frequency is well-defined, their suitability for measurements of higher frequencies may be limited.

**Voltage Transformers.** For low-voltage measurements, it is possible to connect the measurement equipment directly to the terminals. For measurements at higher voltage levels, a voltage transformer is required. There are several types of voltage transformers available, the most common being inductive voltage transformers (IVTs) and capacitive voltage transformers (CVTs).

IVTs are designed to have a mostly linear behavior around the fundamental frequency. Due to their construction, resonances between the winding inductances and stray capacitances may introduce large phase and magnitude errors at frequencies above the fundamental. Based on performed tests, IVTs applied in medium voltage networks have been deemed suitable up to 1 kHz (60% of the tested units manage to cover the entire harmonic spectrum up to 2 kHz). However, this is without consideration of requirements on the accuracy of the measured phase angle. As the system voltage increases, resonances may appear at lower frequencies, and IVTs used for high voltage are deemed suitable only up to a few 100 Hz [17.32].

CVTs consist of a capacitive voltage divider (CVD) and an electromagnetic unit (EMU). The CVD and the EMU are tuned so that they are in resonance at the fundamental frequency. This means that a small shift in frequency will cause large errors in magnitude and phase, with resonance frequencies as low as 200 Hz reported. Thus, CVTs are generally considered unsuitable for measuring harmonics [17.32, 33]. There are ways to improve the performance of CVTs for harmonic

**Fig. 17.14** Overview of frequency range of different voltage transformer technologies

**Fig. 17.15** Overview of the frequency range of different current transformer technologies

measurements, e.g., by utilizing current measurements immediately after the LV capacitance and at the earth connection.

Other types of voltage transformers include CVDs, resistive voltage dividers (RVDs) and resistive-capacitive voltage dividers (RCVDs). RVDs are impacted regarding magnitude and phase above 800 Hz. CVDs and RCVDs are able to accurately monitor transients up to 1 MHz or higher, meaning they are suitable for harmonic measurements even in the supraharmic range. A summary of the suitability of different voltage transformers is given in Fig. 17.14 [17.32].

**Current Transformers.** Inductive current transformers with a toroidal and ferromagnetic core are most commonly used in the power system today. Their frequency

response is determined by the transformer inductances and capacitances. While the capacitances may have a significant effect on the measurements at high frequencies, the impact is deemed negligible for the traditional harmonic range [17.32, 33]. In cases where a DC-component may be present, air-gap current transformers should be used to avoid offsets in the core flux. Aside from inductive current transformers, there are several other options, such as Rogowski coils or optical current transformers. A summary of the suitability of different current transformers is given in Fig. 17.15 [17.32].

#### Signal Processing

After the signal has been sampled, a discrete Fourier transform (DFT) is used to obtain the harmonic spec-

**Fig. 17.16** Example of quantization (conversion to digital representation)

**Fig. 17.17** Fourier transform of rectangular window

trum of the sampled waveform. However, this process results in different unavoidable artefacts.

**Aliasing.** When sampling an analogue signal with a sampling frequency  $f_s$ , the highest frequency component in the digital signal will be equal to half of the sampling frequency. This frequency is referred to as the Nyquist frequency. Frequencies above the Nyquist

frequency in the sampled signal will appear in the spectrum at lower frequencies. This is referred to as aliasing.

Aliasing is mitigated by use of an anti-aliasing filter (analogue low-pass filter) before the analogue-to-digital converter (ADC).

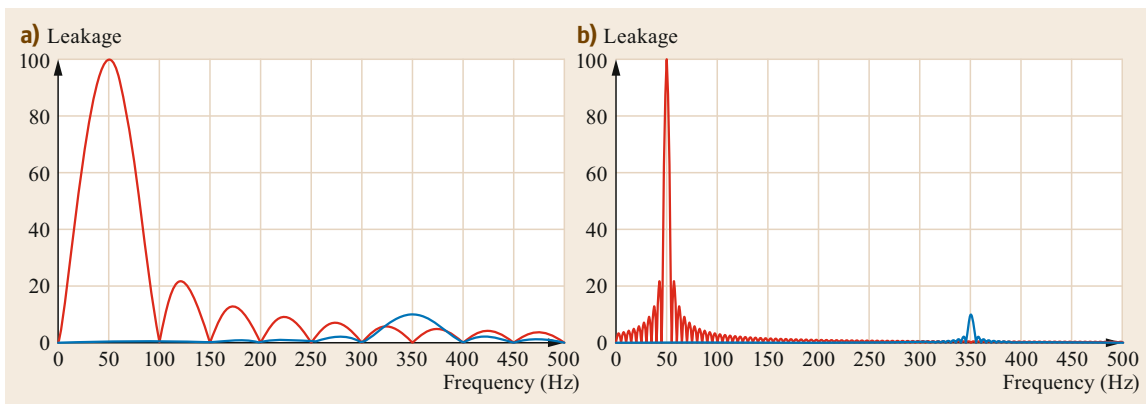

**Quantization Noise.** When a continuous signal is converted to its digital representation through an ADC, a range of discrete values are used to represent the signal, as shown in Fig. 17.16. The difference between the signal and its digital representation is called the quantization error. This error will appear in the frequency domain as a form of broadband noise.

Quantization noise can be reduced by utilizing a higher bitrate in the A/D conversion or by using a higher sampling frequency.

**Spectral Leakage.** When analyzing a continuous signal, only a small portion of the signal is observed. This is done through a process referred to as windowing. When a DFT is applied to a windowed signal, this will result in *leakage* to frequencies other than the actual frequency content of the signal. Consequently, it may be difficult to distinguish actual and leaked frequency components from each other. Spectral leakage can be demonstrated by examining the Fourier transform of a rectangular window, shown in Fig. 17.17.

The window length determines the width of the main lobe. As an example, Fig. 17.18 shows the same signal for window lengths of 20 and 200 ms, respectively. The signal consists of a 50 Hz component and a 350 Hz component.

The impact of spectral leakage can be reduced by choosing an appropriate window function. IEC prescribes a rectangular window, but when analyzing interharmonics, e.g., Hanning or Hamming windows may be more appropriate.

**Fig. 17.18a,b** Fourier transform of 50 Hz (red) and 350 Hz (blue) signal with a window length of 20 ms (a) and 200 ms (b)

**Fig. 17.19** Harmonic groups and subgroups as defined in IEC 61000-4-7

### Quantifying Harmonic Distortion

IEC 61000-4-30 [17.17] prescribes the use of a 10 cycle (200 ms) window in a 50 Hz system. After applying the DFT, this results in a frequency spectrum with a resolution of about 5 Hz (one tenth of the power-system frequency). The results can be presented e.g., as the absolute value of the harmonic components, or by aggregating the harmonic components into groups.

**Groups and Subgroups.** For assessment of harmonics, IEC 61000-4-30 [17.17] prescribes the use of harmonic groups and subgroups, as defined in IEC 61000-4-7 [17.31]. An overview of the concept of harmonic groups and subgroups is shown in Fig. 17.19 for a 50 Hz system, where  $n$  represents the harmonic order [17.4].

**Total Harmonic Distortion (THD).** THD is commonly used to quantify waveform distortion. It is defined as the relative signal energy at frequencies other than the fundamental

$$\text{THD} = \frac{\sqrt{\sum_{h=2}^H V_h^2}}{V_1} \quad (17.10)$$

Since THD is given in relation to the fundamental, care should be used when evaluating current THD. As an

alternative, total demand distortion (TDD) can be used, which instead relates the distortion to the maximum or rated current

$$\text{TDD} = \frac{\sqrt{\sum_{h=2}^H I_h^2}}{I_{1, \max}} \quad (17.11)$$

### 17.2.6 Standards and Regulation

A distinction should be made between power-quality standards that define types of disturbances, disturbance characteristics or measurement methods, and those that define acceptable limits.

IEC 61000-4-7 [17.31] defines measurement instrumentation for testing equipment against applicable emission limits as well as for measurement of harmonic voltages and currents in the power system.

IEC 61000-4-30 [17.17] defines measurement methods and methods to interpret results for various power quality parameters, including harmonics, flicker, dips, etc.

IEEE 519 [17.12] provide recommendations for voltage limits (applicable to the network operator) and current limits (applicable to network users) referred to the point of common coupling (PCC). As an example, Table 17.2 presents the current distortion limits

**Table 17.2** IEEE 519: Current distortion limits for systems rated 120 V through 69 kV

Maximum harmonic current distortion in percent of $I_L$						
Individual harmonic order (odd harmonics) <sup>a,b</sup>						
$I_{sc}/I_L$	$3 \leq h < 11$	$11 \leq h < 17$	$17 \leq h < 23$	$23 \leq h < 35$	$35 \leq h \leq 50$	TDD
< 20 <sup>c</sup>	4.0	2.0	1.5	0.6	0.3	5.0
20 < 50	7.0	3.5	2.5	1.0	0.5	8.0
50 < 100	10.0	4.5	4.0	1.5	0.7	12.0
100 < 1000	12.0	5.5	5.0	2.0	1.0	15.0
> 1000	15.0	7.0	6.0	2.5	1.4	20.0

<sup>a</sup> Even harmonics are limited to 25% of the odd harmonic limits

<sup>b</sup> Current distortions that result in a DC offset are not allowed

<sup>c</sup> All power generation equipment is limited to these values of current distortion

**Fig. 17.20** Reference levels of harmonic current emission for low-voltage equipment according to IEC 61000-3-2

given in IEEE 519 for systems rated 120 V through 69 kV.

$I_{SC}$  refers to the maximum short-circuit current at the PCC and  $I_L$  the maximum demand load current at the PCC under normal operating conditions.

IEC 61000-3-2 [17.34] specifies current emission limits for equipment rated  $\leq 16$  A per phase. An example is given in Fig. 17.20.

**Fig. 17.21** Voltage distortion limits given in EN 50160 up to 1 kV

EN 50160 [17.10] defines voltage distortion limits that the network operator should comply with. Figure 17.21 presents the permissible harmonic levels (given as percent of the fundamental) for voltages up to 1 kV.

IEC 61000-2-4 [17.35] defines compatibility levels for conducted disturbances in industrial installations in the frequency range 0–9 kHz.

## 17.3 Other Power-Quality Disturbances

### 17.3.1 Voltage Dips

Voltage dips are short duration reductions in voltage magnitude. Different documents give different values for the range of durations and residual voltage of a voltage dip. Generally, a drop below 90% of the nominal voltage for up to about a minute is considered a voltage dip.

#### Description and Characterization

Voltage dips are, in standards, described by two single-event characteristics: residual voltage (*dip magnitude*) and dip duration. These two characteristics are defined in IEC 61000-4-30 [17.17] and in IEEE 1564 [17.36]:

- The dip duration is defined as the length of time during which the 1-cycle RMS voltage is less than the voltage-dip threshold in at least one of the measurement channels.
- The residual voltage is defined as the lowest 1-cycle RMS voltage in any of the measurement channels.

Next to the standard characteristics, a number of additional single event characteristics have been discussed in the scientific literature. Most emphasis has been on

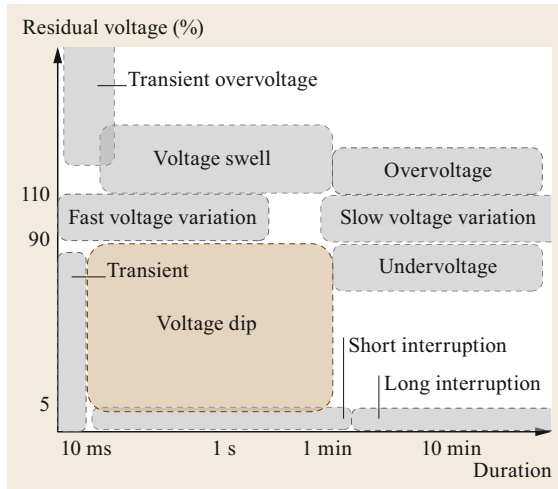

three-phase unbalance, where an early classification in dip types [17.37] still receives a lot of attention. Phase-angle jump [17.38, 39] and point-on-wave [17.40] have been discussed in the literature by different authors as well.

It was mentioned before that different documents give different values for the range of duration and residual voltage of voltage dips. When one of these single-event characteristics is beyond the indicated range, the disturbance should strictly speaking not be referred to as a voltage dip. There is, however, no reason for a hard limit and the same disturbance may be referred to in different ways. The different types of disturbances, in relation to voltage dips, are summarized in Fig. 17.22 as a function of residual voltage and duration.

#### Origins and Impacts

Voltage dips are due to short-duration increases in current magnitude, typically at another location than where the dip is measured. The main causes of voltage dips are:

- High currents during short-circuits and earth faults.
- High currents during transformer energizing.
- High currents during motor start or start of other equipment with a high starting current.

**Fig. 17.22** Different types of voltage disturbances separated by voltage and duration

The drops in voltage due to high currents with capacitor energizing could also be treated as voltage dips, but these events are generally considered as voltage transients and not as dips.

A number of different aspects of voltage dips have a direct impact on the performance of equipment connected to the grid:

- The actual drop in voltage results in a reduced energy flow between the grid and the device. For consumption equipment, this results in a shortage of energy, leading, for example, to a drop in speed for an electrical motor. For production equipment, it results in a surplus of energy with the device connected to the grid. This same disruption of the energy flow results in angular instability after a fault. This impact of the voltage dip is most severe for balanced dips (due to three-phase faults) and is dependent on both residual voltage and duration.
- The change in magnitude and phase angle of the voltage at the start of the dip affects the operation of equipment. For example, high currents on the rotor-side of the converter with a double-fed induction generator. Not only the residual voltage (the drop in voltage) is of importance here, but also the phase-angle jump and the point-on-wave of dip starting.
- The unbalance or distortion during the dip affects the operation of equipment. High current unbalance and overcurrent through diode rectifiers could result in tripping of the rectifier. High harmonic voltage distortion (for a dip due to transformer energizing) could affect the control system of large converters.

To quantify this kind of impact, additional characteristics are needed, like type of unbalanced dip or the spectrum of the voltage during the dip.

- The change in magnitude and phase angle of the voltage at the end of the dip affects the operation of equipment. Many grid-connected devices contain a capacitor, on the AC side, or the DC side, or both. The sudden rise in voltage at the end of the dip gives a high inrush current that could result in tripping of fuses or overcurrent protection.

Additional characteristics like point-on-wave of dip ending, phase-angle jump, and the details of the voltage recovery are also important in quantifying this impact [17.41].

All of these impacts can result in tripping of the device or otherwise malfunctioning. In industrial installations, this can easily result in an interruption of a complicated production process. Such a process can take a long time to restart; a voltage dip as short as 100 ms can result in several hours of lost production.

Repetitive dips can result in long-term equipment damage. The overcurrent for each individual dip may not lead to the device tripping, but many of them over a longer period cause damage to the device.

#### Standards and Regulation

There is no consistent set of standards or regulation for voltage dips, but some individual standards do exist.

Methods for immunity testing are defined in IEC 61000-4-11 [17.42], IEC 61000-4-34 [17.43] and IEEE 1668 [17.44]. The IEC standards only define tests for unbalance dips; the IEEE standard also includes tests for balanced dips. The definition of residual voltage and duration in IEC 61000-4-30 [17.17] and IEEE 1564 [17.36] is however only relevant for balanced dips.

Immunity requirements are part of some IEC product standards, like IEC 61800-3 [17.45] for adjustable-speed drives. For equipment without immunity requirements in a specific product standard setting, the generic immunity standards IEC 61000-6-1 [17.46] and IEC 61000-6-2 [17.47] hold. The immunity requirements aim at avoiding damage to equipment, not to ensure that equipment remains connected to the grid during a voltage dip.

Some industry standards contain immunity requirements for equipment as well. The ones published by ITIC and SEMI are the ones most commonly used and cited. A general discussion on immunity of equipment and installations against voltage dips has been published by an international group of experts [17.48].

Voltage-dip regulation is based on the definition of a *responsibility-sharing curve* in the voltage-duration

**Fig. 17.23** Voltage-tolerance curve (indicative compatibility curve) recommended by the Council of European Energy Regulators

plane. An example is shown in Fig. 17.23. The customer or owner of the installation is responsible for dips above the curve; the network operator is responsible for dips below the curve. The responsibility does in this case not imply that the network operator is responsible for all costs and consequences of dips below the curve. Instead, a regulatory agency can put limits on the number of dips below the curve. Hence the use of the term *indicative compatibility curve* as a synonym. The curve shown in Fig. 17.23 is the one recommended by the European energy regulators [17.49]. Voltage-dip regulation is in place in a few countries only, where different countries use different responsibility-sharing curves, and with significant differences in the regulations.

#### Trends and Unsolved Issues

An important reason for continued interest in voltage dips is the susceptibility of production units to voltage dips. A serious concern for transmission-system operators is the potential mass tripping of production units due to a voltage dip. A serious fault at transmission level could result in the tripping of production units over a large geographical area. The resulting shortage of production could cause frequency, voltage and/or angular instability of the transmission system. Instead of *voltage dip immunity*, the term *fault-ride-through requirements* is often used. The basic phenomenon remains the voltage dip at the terminals of the production unit. The main interest in literature has been on the fault-ride-through of wind turbines [17.50, 51], but more recently also photovoltaic (PV) installations have received attention [17.52].

Voltage dips remain an important issue for industrial installations. In the scientific literature, there is only limited interest in the impact of voltage dips on industrial equipment and installations. After a large number

of publications on this subject up to about 2005, interest in the subject diminished. Modern industrial equipment is often of another type than that of 20 years ago (with *active front end* instead of *diode rectifier*) and it may react differently to voltage dips.

The definition of additional characteristics for voltage dips remains of interest for research and for standardization. The next step in standardization, after residual voltage and dip duration, is likely to be unbalance (often referred to as *dip type*), and phase-angle-jump. Standard methods for defining point-on-wave require a serious amount of further development [17.53].

The treatment of large amounts of voltage-dip data is another emerging subject. Some work was also done here up to 2005, but recently, research has been taken up again [17.54]. Both the availability of increasing amounts of data (*big data*) and a new generation of algorithms (*deep learning*) have contributed to this.

### 17.3.2 Voltage Swells

Voltage swells are short-duration increases in voltage magnitude. Swell durations are up to about 1 min. A voltage exceeding 110% of nominal is generally considered a voltage swell.

#### Description and Characterization

Voltage swells are characterized by two single-event characteristics, both defined in IEC 61000-4-30 [17.17]: *maximum swell voltage* and *swell duration*. The definition of these characteristics is very similar to the definition of dip characteristics.

The definitions of swell and dip in IEC 61000-4-30 are such that the same event can be classed as a dip and as a swell. That occurs with a three-phase measurement when one of the phase-to-neutral voltages is above the swell threshold and another one below the dip threshold. Such events can occur due to single-phase faults.

#### Origins and Impacts

Voltage swells are often presented as the opposite phenomenon to voltage dips. That is an oversimplification as there are differences in both the origin and impact of the two phenomena. A number of causes for voltage swells can be distinguished:

- A single-phase fault can result in a voltage rise in the non-faulted phases. The severity of the voltage rise depends on the location of the fault and on the ratio between zero and positive-sequence source impedance. There is also a significant difference here, depending on the system grounding at the voltage level where the fault occurs.

- The starting of a large single-phase load can result in a voltage rise in the other two phases. Like with swells due to single-phase faults, the voltage rise increases for an increasing ratio between zero and the positive-sequence impedance. These swells are of lower magnitude (less voltage rise) than the first kind, but they are of longer duration.
- The sudden loss of a large load will result in a voltage rise. When the loss of load occurs in the low or medium-voltage network, the voltage rise will be long term. In that case the phenomenon is more typically referred to as a (long-duration or sustained) overvoltage. When the loss of load occurs at a higher voltage level, the on-load tap-changer will bring the voltage back to within its normal range. As a result, the customers will see a voltage rise of a few minutes' duration.
- A broken neutral conductor can, under some conditions, result in an overvoltage over the terminals of single-phase connected low-voltage equipment. These overvoltages can be high, up to the line voltage (170% of the normal voltage) resulting in permanent damage to the equipment. The broken conductor can result in overvoltage or in undervoltage depending on the load balancing between the three phases [17.55].
- Making an incorrect connection in the low-voltage network could expose end-user equipment to the line voltage. This will almost immediately result in permanent damage to end-user equipment.

As was mentioned before, the system grounding plays an important role in the occurrence of voltage swells during single-phase faults. Two types of grounding should be distinguished here: solid grounding versus all methods where there is some kind of impedance between the neutral and ground. The latter aims at limiting the fault current, but a consequence is the occurrence of voltages up to about 180% in the non-faulted phases. Those voltages occur only between phase and ground, not between the phases. Equipment connected to such a system will either be connected phase-to-phase or through a delta-wye-connected transformer. In both cases, the equipment will experience at most a minor dip or swell during the fault.

High voltage in the non-faulted phases also occurs in solidly grounded systems. For locations further away from the transformer, the zero-sequence source impedance becomes significantly bigger than the positive-sequence one. The result is that the voltage in the non-faulted phases rise during a single-phase-to-ground fault. Equipment, which is typically connected phase-to-neutral in such a system, will be exposed to this voltage rise. In other words, the equipment experiences a swell.

### Standards and Regulation

There are limited standards on the immunity of equipment against voltage swells. The ITIC curve includes a part on voltage swells, but no IEC standards set any requirements.

The power-quality regulation in Sweden defines two responsibility-sharing curves for voltage swells in low-voltage networks.

### Trends and Unsolved Issues

There is very limited research work going on about voltage swells. The general rise of the voltage magnitude with an increased connection of small-scale photovoltaics could result in an increased number of voltage swells. Insufficient data is available to know if this would be a serious concern.

There is also some interest in voltage swells, because of the overvoltage ride-through requirements for production units in some countries.

### 17.3.3 Long Interruptions

Long interruptions are characterized by the complete absence of voltage for more than a few minutes.

#### Description and Characterization

Long interruptions are a concern for all customers connected to the grid. The statistical properties of long interruptions are discussed within the field *power system reliability* and details of this can be found in some of the textbooks on reliability [17.56–58].

Long interruptions are not commonly treated as a power quality issue. In fact, the terminology used by the European energy regulators distinguishes between continuity of supply (long and short interruptions) and voltage quality (all other voltage disturbances).

Long interruptions are characterized through their duration. This duration is defined in the IEC power quality measurements standard, IEC 61000-4-30, [17.17] as the time that the one-cycle RMS voltage is below the interruption threshold (for example 10% of the nominal voltage). For reliability statistics, and in regulation, the duration of an interruption is defined more commonly as the time elapsed between the opening and closing of an interrupting device.

Statistics on long interruptions are gathered by most network operators, either for internal use or on request of the regulator. What is reported and published are typically only a small number of system indices. These are defined in IEEE 1366 [17.59]; the ones most commonly used are SAIFI (system average interruption frequency index) (also known as *interruption frequency*), SAIDI (system average interruption duration index) (*unavailability*) and CAIDI (customer average

interruption duration index) (*average interruption duration*). Such average values are a suitable performance index for the network as a whole but have limited value for individual customers. Few network operators publish data on the number of interruptions experienced by individual customers.

### Standards and Regulations

Many countries have limits on the number and duration of long interruptions. An up-to-date overview on this is produced every few years by the *Council of European Energy Regulators (CEER)* [17.8]. For details, the reader is referred to those reports. Different types of standards and regulations are used in different countries:

- Limits on system indices (SAIFI, SAIDI). These are typically used as a quality adjustment to the tariffs that the network operator is allowed to charge to its customers. A minor adjustment in tariff can result in a large change in the financial result of the company. Such quality adjustments are thus an important regulatory instrument.
- Limits on the number or duration of interruptions for individual customers. The enforcement could be in the form of compensation that the network operators have to pay to the impacted customers.

### Trends and Unsolved Issues

Regulation and gathering of statistics on long interruptions considers them as events with a sudden start and a sudden end. Details of the start or end of an interruption are not considered in the statistics or in the regulations. Measurements show large differences between interruptions in the way the voltage disappears and the way in which the voltage recovers when the supply is reconnected. The start of the interruption could be due to a fault followed by protection clearing. The customer will experience a dip followed by a complete disappearance of the voltage. A large part of the different dip characteristics discussed in the literature (Sect. 17.3.1) will also apply here.

When an interruption is due to an incorrect tripping of the protection, or due to manual switching, the voltage will disappear immediately. Several measurements show transient overvoltages during the start of such an interruption. The impact of this on equipment has never been systematically studied. The increased presence of small-scale production units (specifically solar power) has put this subject on the agenda again. The emphasis in the research is very much on methods to avoid uncontrolled island operation, not on the potential impact on equipment connected to the uncontrolled island.

When the voltage recovers, this can occur suddenly, it can occur slowly, or there can be oscillations after the interruptions for a while. A specifically complicated and potentially disruptive case is the saturation of transformers due to the voltage recovery. This results in high levels of harmonic voltage distortion. Especially for unloaded transformers the distortion can continue for several seconds. Harmonic resonances could further amplify the voltage distortion resulting in temporary overvoltages.

### 17.3.4 Short Interruptions

Short interruptions (*momentary interruptions* in many publications and in IEEE documents) are events during which the voltage has completely disappeared for a few minutes.

#### Description and Characterization

The term *short interruption* or *momentary interruption* refers to interruptions with a duration of a few minutes. There is no difference in the start (or cause) of short and long interruptions. The difference is in the speed with which the supply is restored. With short interruptions, the restoration is typically automatic, whereas it is manual with long interruptions.

In some countries, the term *transient interruption* is used for durations of a few seconds or less. The terminology used within IEEE is rather confusing, with different standards using different terms. In an important power-quality standard, IEEE 1159 [17.60], the following terms are used:

- Momentary interruption: up to 3 s
- Temporary interruption: between 3 s and 1 min
- Sustained interruption: longer than 1 min.

The standard that defines reliability indices, IEEE 1366 [17.59], defines a momentary interruption as an interruption with a duration up to 5 min. Interruptions lasting longer than 5 min are sustained interruptions. In most European countries, any interruption with a duration longer than 3 min is a long interruption; a duration lasting up to 3 min is a short interruption.

Following the IEC power-quality monitoring standard, IEC 61000-4-30 [17.17], an event should only be called an interruption when all three voltages are below the interruption threshold. An event with only one or two voltages below that threshold would be classed as either a voltage dip or an undervoltage. In regulation, an event might be considered as an interruption already when one of the voltages is below the threshold.

**Fig. 17.24** Correlation between number of long interruptions and number of short interruptions for about 100 000 low-voltage customers connected to a Swedish network operator

### Origins and Impacts

Short interruptions are a concern for industrial customers and for some domestic customers. The impact is in between the impact of a voltage dip and the impact of a long interruption.

The impact of a short interruption is in almost all cases less than the impact of a long interruption. Automatic (fast) restoration is thus generally an improvement compared to manual (or slow) restoration. Automatic reclosing is however combined typically with so-called *fuse-saving*. This combination results in a reduction of the number of long interruptions and an increase in the number of short interruptions. The total number of (short and long) interruptions increases, however. When the impact (economic consequences) of a short interruption is much less than for a long interruption, such a scheme is an improvement. When the impact is about similar, it is a deterioration. The latter is the case for many industrial installations. The appropriateness of such schemes has therefore been under discussion for many years.

### Standards and Regulation

There are limited requirements in standards and regulation on the number and duration of short interruptions. Some countries require network operators to report the number of short interruptions. Like with long interruptions, statistics can be averages over all customers or data at the individual customer level. In Sweden, network operators have to provide data on the number of short and long interruptions for each individual customer. This data has been used in [17.61] to obtain the required density of monitoring to estimate high-order statistics.

Some further statistics are shown in Figs. 17.24 and 17.25. Both figures are based on the number of interruptions for about 100 000 individual customers with a network operator in the middle of Sweden. The former figure shows that there is very little correlation between the number of short interruptions and the number of long interruptions for individual customers. Regulation of long interruptions does thus not automatically result in a reduction of the number of short interruptions as well. Figure 17.25 shows that the number of short interruptions varies a lot between individual customers, even when they are in a limited geographical area (in this case, connected to the same network operator). The average number of short interruptions over all customers was 5.1 for that year. However, almost all customers experienced a different number, with some experiencing only one or two and some experiencing 10 or more short interruptions. The average number of short interruptions does not provide any information for the number of short interruptions experienced by an individual customer.

### Trends and Unresolved Issues

There is limited interest for short interruptions in regulation and in research. Short interruptions are mainly an issue for remote rural customers. The average number of short interruptions that customers experience is small, but some customers can experience several tens of them per year, which would be a serious issue for those customers. See [17.61] for a discussion of some statistics about short interruptions.

An unresolved issue is the impact of multiple short interruptions on equipment. There have been consistent

**Fig. 17.25** Density function of the number of interruptions for customers connected to a Swedish network operator

(mainly oral) reports of equipment damage due to the occurrence of two short interruptions briefly after each other, for example as part of a non-successful auto-reclosing sequence. There has never been a systematic study to find out if there is an increased probability of equipment damage because of a second short interruption.

A related issue is the impact of transient interruptions (with a duration of less than a few seconds) on equipment. Regulation on the number and duration of short interruptions could result in an increase in the number of transient interruptions. This could actually result in an increased impact on end-user equipment, especially in an increased number of cases where equipment is damaged.

### 17.3.5 Transients

#### Description and Characterization

Transients are large and sudden deviations from the ideal voltage lasting less than one cycle of the power-system frequency. The term *transients* covers a range of phenomena and several different classification schemes for transients have been introduced. None of these schemes has reached broad acceptance.

A list of possible characteristics for transients is given in an informative annex with IEC 61000-4-30 [17.17]. The standard does not give any definition or guidance on how to calculate the values of these indices. Although many power-quality monitors detect, record, and characterize transients, there is no commonly accepted standard method for this. A consequence of this is for example that there is limited data available on voltage transients. Another consequence is that the subject is not part of any regulatory document. This results

in no pressure or incentives to develop standard characterization methods.

#### Origins and Impacts

Three major types of transients can be distinguished, based on their origin:

- Normal switching transients, where capacitor energizing gives the most severe transient. Peak voltages during normal switching transients are up to about 180% of the nominal peak voltage (square root of two times the nominal RMS voltage). Higher peak voltages can occur when other capacitor banks are located nearby.
- Abnormal switching transients are associated with phenomena like pre-strike, restrike and current chopping. Oscillations of high amplitude and high frequency occur close to the element being switched. This is especially a concern for the switching elements and the subject of several books on switching transients [17.62–65]
- Lightning transients cause the highest voltage magnitudes, up to megavolts where the lightning strikes.

The impact of transients depends strongly on the kind of transient, in terms of duration, frequency, and magnitude. Switching transients are some concern for industrial customers. Transient overvoltages are a serious concern for low-voltage customers, especially those supplied from overhead distribution lines.

#### Standards and Regulation

A range of standards exists that define the testing of equipment against switching and lightning overvoltages, e.g., IEC 60060-1 [17.66].

### Trends and Unsolved Issues

The replacement of overhead transmission lines by underground cables will result in lower resonance frequencies of the transmission grid. Operational states with high amounts of renewable electricity production (and hence less conventional production connected to the transmission grid) will also result in lower resonance frequencies than traditionally occur.

The main unresolved issue is the lack of standards or commonly-accepted methods for characterizing transients.

### 17.3.6 Interharmonics

#### Description and Characterization

The term *interharmonics* refers to frequency components that are not an integer multiple of the power-system frequency, e.g., 170 Hz in a 50 Hz system.

#### Origins and Impacts

Sources of interharmonics include cyclo-converters and other frequency converters, arc furnaces, power electronic converters used for solar or wind power, etc. Mechanisms for the origin of interharmonics are often complicated, but the case of frequency conversion is well understood. When two systems with different operating frequencies are connected to each other, interharmonics can occur on both sides of the frequency converter.

In the case of wind power, conversion from the turbine-side frequency  $f_{in}$  to the power-system frequency  $f_{out}$  results in the generation of additional frequency components. The generated harmonics by a wind turbine with a 6-pulse rectifier on the turbine side together with a voltage source converter (VSC) on the grid side can be described by [17.67]

$$f = 6kf_{in} \pm (6n \pm 1)f_{out} \quad (17.12)$$

Table 17.3 shows the resulting frequency components for a selection of values of  $k$  and  $n$ .

As can be seen, the generated interharmonics will appear in pairs, which is exemplified in Fig. 17.26 and which was verified through measurements at the terminals of a wind-turbine transformer in [17.67]. The turbine-side frequency was varied, and the power-system frequency was kept constant at 50 Hz.

Several of the impacts of interharmonics are similar to those of harmonics, including e.g., additional heating of components. Other consequences include light flicker and interference with power-line communications.

#### Standards and Regulation

IEC 61000-4-7 [17.31] and IEC 61000-4-30 [17.17] define measurement instrumentation and methods for

**Table 17.3** Example of generated frequency components for  $k = 1, 2, 3$  and  $n = 0, 1$

	$n = 0$	$n = 1$	
$k = 1$	$6f_{in} \pm f_{out}$	$6f_{in} \pm 5f_{out}$	$6f_{in} \pm 7f_{out}$
$k = 2$	$12f_{in} \pm f_{out}$	$12f_{in} \pm 5f_{out}$	$12f_{in} \pm 7f_{out}$
$k = 3$	$18f_{in} \pm f_{out}$	$18f_{in} \pm 5f_{out}$	$18f_{in} \pm 7f_{out}$

**Fig. 17.26** Correlation between interharmonic frequencies

measuring interharmonics. A similar aggregation into groups and subgroups is defined for interharmonics as for harmonics.

With regards to standardization, there is no consensus on interharmonic limits. Some standards such as IEEE 519 [17.12] suggests interharmonic limits with the goal of preventing light flicker, but only in the range 0–120 Hz.

#### Trends and Unsolved Issues

While the traditional interharmonic sources are well understood, there is a lack of understanding of modern sources of interharmonics. Little is also known about existing levels of interharmonics, and it is unclear what levels would be acceptable.

There is ongoing research on light flicker in modern types of lighting, one potential cause being interharmonics above 100 or 120 Hz [17.68].

### 17.3.7 Supraharmonics

Supraharmonics refer to waveform distortion in the frequency range of 2–150 kHz.

#### Description and Characterization

Fig. 17.27 shows the current waveform of a modern television and Fig. 17.28 shows the corresponding current spectrum [17.69]. Emission can be seen up to around 70 kHz.

Fig. 17.27 Current waveform of a modern television

Fig. 17.28a–c Current spectrum of a modern television, showing harmonics (a), and supraharmonics (b,c)

### Origins and Impacts

The main sources of supraharmonics are power-electronic converters (active or passive) and transmitters used for power-line communication. Several studies have been done on emission from new types of equipment, including LED lamps, PV inverters and wind turbines [17.69–71]. It was found that while there is a reduction of low-order harmonics, there is instead emission at higher frequencies. It was further shown that a substantial amount of devices emit supraharmonics.

Similarly for harmonics, resonances play an important part in the propagation of supraharmonics. A well-known example concerns the Eagle-Pass HVDC light installation where 13–40% of the fundamental voltage could be seen at 12.4 kHz (approx. 10 times the switching frequency) due to resonance conditions [17.72]. The

propagation of supraharmonics has been studied e.g., in [17.73] and [17.74], where it was found that the current is mainly flowing between devices, rather than towards the grid.

Several cases of interference due to supraharmonics can be found in the literature, including e.g., [17.75]:

- Interference with power-line communication
- Interference with electrical equipment, such as light dimmers or medical equipment
- Audible noise

Many more cases have been reported informally that never appear in the technical literature.

### Standards and Regulation

While some standards exist already, EN 50065-1 [17.76] and IEC 61000-3-8 [17.77] for power-line communication, IEC 61000-2-2 [17.78] for compatibility levels, IEC 61000-4-19 [17.79] for certain immunity requirements, there is no accepted framework covering the entire supraharmonic range. Work is ongoing within the IEC, IEEE and CENELEC to develop standards, including limits, compatibility levels and test methods.

### Trends and Unsolved Issues

There are several gaps in the understanding of the origin and spread of supraharmonics, but due to needs for standardization and an increase in emission, the supraharmonic range has gained significant attention by researchers. One of the driving factors is that the supraharmonic range coincides with the frequencies used for power-line communication.

The impact of supraharmonics on equipment need to be studied further, and there is a need for models that are suitable for the supraharmonic range.

Measurements in the supraharmonic range are not trivial; they require measurement transducers and measurement equipment with a high accuracy for both amplitude and phase angle over a wide frequency range.

### 17.3.8 Slow Voltage Variations

Slow voltage variations are variations of the voltage magnitude on a time scale of minutes or longer. The term *supply voltage variations* is used in EN 50160 [17.10].

#### Description and Characterization

The most-common way of characterizing slow voltage variations is through the 10 min value as defined in IEC 61000-4-30 [17.17]. That standard however also allows for calculation over other period lengths (like 1 min) as well as the so-called *very-short value* over 150 or 180 cycles of the power-system frequency (about 3 s).

There is no standardized method to characterize slow voltage variations in a three-phase system, apart from characterizing them as three individual values. The most obvious approach would be to quantify the slow voltage variations by means of the positive-sequence voltage. Negative-sequence and zero-sequence voltage can be treated as part of the voltage unbalance (Sect. 17.3.10).

### Origin and Impact

Limiting slow voltage variations is an important part of the design of distribution networks, especially for rural distribution networks. In such networks, the voltage drop determines the maximum feeder length. Traditionally, the voltage drop during high load has been the main limitation.

The main impact of slow voltage variations is on equipment with low-voltage customers. The actual variations in voltage are normally not of concern. Instead, the concerns are high or low values of the supply voltage, referred to as *overvoltage* and *undervoltage*, respectively.

Both too low and too high voltages could result in equipment damage. Overvoltage could lead to reduced lifetime of equipment. Complaints about premature failure of incandescent lamps used to be a warning flag for the network operator that the voltage was too high. With most equipment it is not the high supply voltage (a high 10 min value) that makes the equipment fail. The high average value will make fast voltage variations and transients start from a higher voltage. These short duration overvoltages and transients result in a reduction in equipment lifetime.

High operating voltage at higher voltage levels (medium voltage or higher) will result in increased magnetizing current for transformers. This current has a high harmonic content, causing increased harmonic voltage distortion. This relation between high operating voltage and harmonic voltage distortion is one of the many relations between types of power-quality disturbances. The historical compartmentalization of power quality into different types of disturbances has limited the attention these relations attract [17.80].

Low supply voltage can result in mal-functioning of electronic equipment. It will also make equipment more susceptible to voltage dips. Some equipment, like many electrical motors, take a higher current when the voltage is lower. A sustained low voltage will thus result in a sustained high current, causing increased heating and reduced lifetime.

### Standards and Regulation

Limits on slow voltage variations are in place in many countries. The voltage characteristics in EN 50160

[17.10] are the base for power-quality regulation in most European countries and in several countries outside of Europe. According to EN 50160, the 10 min RMS value of the voltage shall be between 90 and 110% of the nominal voltage for at least 95% of the week. Beyond that, the voltage shall be between 90 and 115% of nominal all of the time. This holds for customers connected to the low-voltage network; other requirements hold for other voltage levels. The regulatory requirements in most European countries are stricter than this. Either the limits shall be kept for more than 95% of the time, or lesser deviations are allowed. Some examples for European countries are listed here:

- In Spain, the 10 min RMS voltage shall be between 93 and 107% of the nominal voltage for 95% of the week.
- In Hungary, the 10 min RMS voltage shall be between 92.5 and 107.5% of the nominal voltage for 95% of the week.
- In Norway, the 1 min RMS voltage shall be between 90 and 110% of the nominal voltage, all of the time.
- In Sweden, the 10 min RMS voltage shall be between 90 and 110% of the nominal voltage, all of the time.

There are no immunity standards setting requirements on equipment for long-term overvoltage or undervoltage. IEC 61000-4-14 [17.81] defines a set of tests for fast variations in voltage. Those variations come in three groups:

- Stepwise increase and decrease by 8 or 12% of nominal starting from the nominal voltage.
- Stepwise decrease by 8 or 12% starting from 110% of nominal
- Stepwise increase by 8 or 12% starting from 90% of nominal

The 12% steps are for equipment to be used in industrial environments (so-called class 3 environments). The voltage is constant for about 2 s, the increase or decrease takes about 100 ms, and a number of stepwise increases and decreases should be considered.

### Trends and Unsolved Issues

The hosting capacity [17.82, 83] is the amount of new production or consumption that can be connected to the grid without unacceptably deteriorating the reliability or power quality [17.84]. The voltage rise is commonly setting the limit for small-scale solar power. This has put slow voltage variations back on the agenda again.

The (expected) appearance of electric vehicle charging and electric heating makes slow voltage variations

of further importance. The classical solution against excessive slow voltage variations (i.e., overvoltage or undervoltage) has been to add more transformers and in that way reduce the feeder length. Many research teams study alternative methods, where curtailment of production and consumption appears the most effective one. Reactive-power control is also often mentioned as a solution, but in low-voltage networks, it is more likely to make the situation worse. For remote customers, the ones where voltage drop or rise becomes an issue first, the source impedance is mainly resistive. Injecting reactive power will not have much impact in the voltage drop or rise over the low-voltage cable or line, but instead will mainly impact the voltage on LV side of the distribution transformer. By mitigation, for example, for an overvoltage with one customer, an undervoltage is created for other customers.

For larger installations, connected to the medium-voltage network or for installations connected directly to the distribution transformer, reactive-power control may be a possible solution.

### 17.3.9 Fast Voltage Variations

Fast voltage variations are changes in voltage magnitude at time scales up to a few minutes.

#### Description and Characterization

The term *fast voltage variations* refers to variations in the RMS voltage that occur faster than slow voltage variations. Most of the attention is given to time scales up to a few seconds, the voltage variations that traditionally resulted in light flicker with incandescent lamps. This is also referred to as *voltage flicker* or (rather confusingly) simply *flicker*. The European standard EN 50160 [17.10] uses the term *rapid voltage changes*, which is not fully free of confusion either. Two types of rapid voltage changes are distinguished in the standard: *continuous rapid voltage changes* and *individual rapid voltage changes*. The latter ones are actually commonly referred to as simply *rapid voltage changes*.

#### Origins and Impacts

Fast variations in RMS voltage are mostly due to fast variations in current taken by installations. The kind of voltage variations that result in light flicker are mainly due to large industrial installations, like arc furnaces. Individual rapid voltage changes are due to tap-changer operations or switching of capacitor banks. In weak parts of the grid (like remote rural networks), load switching can also result in rapid voltage changes.

The main consequence of fast voltage variations is light flicker. Modern lamps are typically less sensitive to voltage variations than the classical incandescent

lamps, but some compact fluorescent or LED lamps are more sensitive than incandescent lamps [17.68].

#### Standards and Regulation

The standards and regulation on fast voltage variations are all based on the incandescent lamp. An eye-brain-lamp model has been developed that formed the base for the flickermeter in IEC 61000-4-15 [17.85]. The level of fast voltage variations is characterized using short-term and long-term flicker severity (Pst and Plt, respectively). Contrary to its name, this characteristic quantifies voltage variations, it does not quantify light flicker. However, for the voltage at the terminals of an incandescent lamp it is an indicator of light flicker as well. The definition of Pst and Plt is such that 1.0 is a natural limit in regulation and standards.

#### Trends and Unsolved Issues

The transition from incandescent lamps to LED lamps has resulted in an increased interest for light flicker and hence for fast voltage variations. One of the conclusions from the early work on that subject is that light flicker with LED lamps is much more complicated than with incandescent lamps. Not only fast voltage variations, but also other voltage disturbances, can result in light flicker.

Medium-timescale voltage variations (less than a few minutes, but more than a few seconds) are becoming important because variations in solar-power production occur on this timescale. There is however very little information on the existing levels of these variations [17.86, 87].

### 17.3.10 Voltage Unbalance

The term *voltage unbalance* refers to the situation in which the three voltages do not form a balanced three-phase system.

#### Description and Characterization

There are two fundamentally different ways to quantify voltage unbalance: through the negative-sequence voltage; or through the difference between the three RMS voltages.

The characterization method prescribed by IEC defines the voltage unbalance as the ratio between the negative-sequence and positive-sequence voltage. Like for slow voltage variations and harmonics, the basic measurement window is 10 or 12 cycles of the power-system frequency (in a 50 or 60 Hz system, respectively). These values are next aggregated into 10 min values.

Although not defined in any standard, the zero-sequence unbalance can be defined in an equivalent way.

In fact, this definition is used by some manufacturers of power-quality monitors.

The IEEE, next to the IEC definition, defines the unbalance as the relative difference between the highest and the lowest RMS voltage. See [17.88] for a comparison between the IEC and IEEE characterization methods.

### Origins and Impacts

Voltage unbalance is due to either unbalance in the grid or unbalance in equipment connected to the grid [17.89]. The latter is the one that gets most attention in the literature and in connection studies. Large single-phase loads (railway power supplies, certain furnaces in the steel industry) can cause a voltage unbalance over a wide geographical area. Smaller single-phase loads connected to weak parts of the grid, like in agricultural installations, can result in high unbalance locally.

The unbalance of the grid, non-transposed transmission lines, and transformers, do actually make a large contribution to the voltage unbalance as well. At transmission level, this contribution could be the dominating one.

In distribution networks with single-phase laterals, voltage unbalance can occur on the main feeder when the load is unevenly distributed over the laterals.

The negative-sequence voltage impacts three-phase equipment connected to the grid. The main studied impact is on directly connected rotating machines, both synchronous and induction machines. The negative-sequence voltage results in a high negative-sequence current through the machine. When the machine is lightly loaded, it can easily cope with the additional heat generated by the negative-sequence currents. However, the machine cannot operate at its rated power because it would get too hot. The motor or generator will have to be derated. This could be expensive for large industrial motors; the motor may have to be replaced by a motor of higher rating. For large synchronous machines, the solution is to reduce the produced power.

With three-phase converters, voltage unbalance also results in large current unbalance. This holds both for converters with active front-end and for diode rectifiers. The currents during voltage unbalance can become much higher than during balanced operation. This can result in damage to the diodes or in protection operations tripping the rectifier.

### Standards and Regulation

Limits on voltage unbalance are given in several national and international documents. Standardization and regulation for voltage unbalance is very similar to the standardization and regulation for harmonic voltages.

### Trends and Unsolved Issues

There is an increased interest in voltage unbalance because of the expected high penetration of single-phase PV installations [17.90] and electric vehicle charging.

An unsolved issue is the impact of high levels of voltage unbalance on the currents with three-phase converters. The impact on voltage-source converters is probably easy to formulate. The impact on three-phase diode rectifiers may turn out to be more complicated.

### 17.3.11 Frequency Variations

The ideal frequency in the power system is normally 50 or 60 Hz, the so-called nominal frequency. The frequency is however not constant and small variations occur due to unbalances between production and consumption of electrical energy. Frequency variations are very much a transmission system issue and frequency deviations are rarely so much that they have any effect on equipment connected to the grid.

#### Description and Characterization

An example of frequency variations is shown in Fig. 17.29. The figure shows the variations in 10 s frequency values measured by a portable monitor during a period of slightly more than one week. During the first part of the measurement, the monitor was located to a wall-outlet in Turin, Italy, part of the central European interconnected grid. The second part of the measurement was done in Gothenburg, Sweden, part of the Northern European interconnected grid. Because the central European grid is much bigger, the frequency variations are smaller. This rule does not hold generally, as for example the frequency on the Swedish island of Gotland is more constant than on the Scandinavian mainland.

#### Standards and Regulation

The frequency, at most locations in the world, rarely comes out of the range 49.5–50.5 Hz (or, 59.5–60.5 Hz in a 60 Hz system). The impact of frequency on equipment in that range can be neglected. During major events on the transmission system (like system splitting or island operation), the frequency may deviate more. Under-frequency load shedding or tripping on under/over frequency could result in installations being affected. One may argue on whether this is a power-quality or a system-operational issue, but the impact on end users is the same, nevertheless.

#### Trends and Unsolved Issues

With the predicted growth in island operation of microgrids, frequency variations may become a power-quality issue in the future. Recent studies in a single-house microgrid [17.91] have shown that the frequency

**Fig. 17.29** Frequency variations in the Central European interconnected grid (*left*) and in the Northern European Interconnected Grid (*right*). The measurements were performed using Metrum PQsmart

**Fig. 17.30** Fast frequency shifts measured in the central European interconnected system

in that microgrid regularly gets out of the band from 49 to 51 Hz. Further studies are needed on frequency variations in microgrids.

Deviations from the ideal frequency are normally described as a variation, but certain phenomena could better be described as events. Examples are the sudden

drop in frequency due to the disconnection of a large production unit (a well-known phenomenon) and the fast shifts in frequency that happen around the start of the hour due to the operation of the electricity markets (a generally unknown phenomenon). An example of the latter is shown in Fig. 17.30.

## 17.4 Power Quality in Microgrids

In recent years there has been a rising interest in microgrids, e.g., as alternatives to grid expansion in rural areas. Microgrids may be operated as grid-connected or as islands. When operated as grid-connected they behave, from a power-quality viewpoint, in the same way as other grid-connected installations. It is during island operation that large differences occur.

Microgrids typically contain a large share of power electronics, e.g., battery storage systems and PV, and generally have a larger system impedance compared to the centralized grid. This has led to concerns e.g., regarding voltage variations and distortion levels when in islanded operation. However, there is a lack of experience regarding power quality in existing microgrids

and while there are some recent publications on the subject [17.91–93], more research is needed. There is especially a lack of measurements of power quality in real-world microgrids during island operation.

Microgrids are also presented by several authors as a way of improving power quality, as any distur-

bances originating elsewhere in the grid are avoided during island operation. By properly switching between grid-connected and island operation, the optimal power quality can be selected [17.94, 95]. Even here, there is a lack of experience from real-world microgrids.

## 17.5 Conclusions

Power quality concerns the interaction between the electricity network and the customer (network user) or between the network and equipment connected to it. Power quality is a broad subject covering a wide range of phenomena, so called *power-quality disturbances*. Different types of phenomena affect different customers and often the network operator. Different types of disturbances require different analysis tools and different mitigation methods. An important distinction is the one between variations and events.

A large part of the power-quality field has become classical knowledge, where little new research is being done. Some of the new developments in electric power engineering, like solar power and LED lamps, have resulted in renewed interest in some power-quality disturbances. The other types of disturbances and the impact on more classical equipment require further research and knowledge gathering.

### Oscar Lennerhag

Independent Insulation Group  
Ludvika, Sweden  
[oscar@i2group.se](mailto:oscar@i2group.se)

Oscar Lennerhag received his M.Sc. from Chalmers University of Technology in 2013. He is working for the Independent Insulation Group, Ludvika, Sweden, and as a PhD student at the Luleå University of Technology, Skellefteå, Sweden. He has published several papers on power quality and is involved in several CIGRE working groups within the topics of harmonic analysis and transient overvoltages.

### Math Bollen

Luleå University of Technology  
Skellefteå, Sweden  
[math.bollen@ltu.se](mailto:math.bollen@ltu.se)

Math Bollen is a professor of electric power engineering at Luleå University of Technology, Skellefteå, Sweden. He is a leading researcher on power quality, with extensive experience on a range of subjects, both in academia and industry. Math Bollen has worked for the Swedish energy regulator as a consultant, and at universities in Sweden, the United Kingdom and the Netherlands.

# 18. Electricity Markets and Regulation

Philip Southwell, Gregory H. Thorpe, Alex Cruickshank, Colin Ray

The reliability and cost of electricity is critical to the success of modern economies. Infrastructure needed to provide the desired services requires large amounts of capital expenditure and governments are keen to ensure prices are kept to a minimum while maintaining the required reliability. To this end, electricity markets have been introduced to allow electricity generating and retailing companies to compete. At the same time regulations have been put in place to minimize anticompetitive activities and ensure that any monopoly services are charged at fair and reasonable rates.

This chapter explores the design and operation of electricity markets and regulation in relation to power systems. It briefly considers the evolution of the electricity industry and provides a general description of the range of market models used and the associated regulation applied to assist their efficient operation. Practical examples from various countries around the world are also provided.

The design and application of the various market models continues to evolve and it is recommended that the reader access current information to stay aware of the

latest developments. A useful source is work by Study Committee C5, which can be found at the e-cigre web site (<https://e-cigre.org>). Other sites include those that

have a regulatory or government sponsored oversight of the operations of the parties. Examples include Ofgem in the UK (<https://www.ofgem.gov.uk/about-us/who-we-are/gas-and-electricity-markets-authority>), ENTSOE in Europe (<https://www.entsoe.eu>), AEMC in Australia (<https://www.aemc.gov.au>) and FERC in the US (<https://www.ferc.gov/market-oversight/market-oversight.asp>).

One area that is in its infancy at the time of writing relates to developments such as micro-grids with distributed generation, battery storage and smart load control. These are now becoming viable and are likely to operate both as local micro-markets and as participants in the larger markets.

This chapter addresses the design and operation of markets and regulation in relation to power systems. The discussion will cover the topic at a reasonably high level and provide references where appropriate to a more detailed examination.

There are many texts that can provide a detailed description of markets, their structure and their benefits and failings. It is however useful to give a brief overview in order to set the context for a discussion of electricity markets.

Any mechanism that brings buyers and sellers together to trade by establishing prices for a quantity of product or service is a market. The concept of trading has been around since very early civilization. Trading can occur by direct negotiation between a seller and a buyer or an organized market where buyers and sellers compete to achieve a trade that produces the best commercial return.

Markets are beneficial when the competitive pressures on the players lead to higher efficiency than the alternative (e.g., a central utility) but only if the costs of running the market are less than the benefits gained. Markets need to be *workably competitive* to deliver value. When there is a risk of inefficient outcomes because of insufficient competition leading to the exercise of market power, regulators or governments often apply rules or place limits on commercial behaviors. It is always a difficult trade-off between rules to limit market behaviors and the reduced efficiency that can result. However, potentially distorted outcomes are better than allowing excessive market power. One way to achieve this balance is to limit the periods or conditions where one or more players can dominate but allow sufficient time to signal an opportunity for new investment. An often forgotten aspect of market power is that it can either raise or lower prices. For example, a strong player can force prices down until its competitors are forced out of the market. This enhances the market power of the strong player who is then free to raise prices.

Throughout history there have been examples of market failure. In recent times, the sub prime mortgage disaster that led to the global financial crisis and the collapse of Lehmann Brothers in the US are good examples [18.1]. An example related to electricity is the California market in the US where, amongst other things, market failure led to widespread interruptions to supply, bankruptcy of Enron and near bankruptcy of other utilities. This is discussed in more detail in the section on North America.

In some cases, a product or service can be a natural monopoly. For example, electricity network infrastructure can be viewed as a monopoly as it is normally difficult to duplicate. This is because of economic and environmental barriers for construction of a second transmission line in competition with an existing one. In these situations, prices, behaviors and service levels are often regulated, or otherwise managed. An industry regulator is often charged with overseeing the activities of monopolies but other solutions are also used such as by the auctioning of a license to build and operate the network infrastructure, as is done in Brazil.

Regulation often appears in conjunction with competitive arrangements in order to ensure some level of protection for the participants in the market. Electricity has been subjected to some form of regulation for many years, particularly in relation to transmission and distribution. This has included regulation of customer tariffs, monitoring and approval of expenditure and, various aspects of technical and safety performance.

In order to minimize conflicts of interest, transmission and distribution systems are often separated from generation and retailing. However, many arrangements have also evolved where distribution and retailing are combined, or remain combined when a previously vertically integrated utility is disaggregated. In these systems regulators often require the commercial arrangements to be ring-fenced from each other.

Third party access to transmission and distribution is central to competitive electricity markets. Access involves a set of rights and obligations that allow new entrants to connect to the network in order to compete. Over the last 30 years, access and market or competition-oriented reforms have been introduced to the electricity sector in many countries.

This chapter examines the foundations of the electricity industry and how competitive markets can enhance its economic efficiency and therefore assist in minimizing costs to end users. The chapter introduces a number of the different forms of electricity trading that have emerged as the industry has matured technically and economically. The description starts by very briefly tracing the evolution of the industry from a small

disaggregated service through to a large central commodity and most recently back towards a more disaggregated, market-oriented industry driven by dramatic changes in technology and cost. Current electricity markets have evolved around larger power systems and the discussion that follows will mainly focus on these. Developments such as microgrids with distributed generation, battery storage and smart load control are now becoming viable and it is likely that these systems will

participate in the larger markets and internal *micro-markets* will develop within the microgrids. A number of examples of markets that have been implemented across the world are briefly described, together with some particular challenges that have been faced as they have evolved. The second half of the chapter focuses on key aspects of regulation of electricity businesses, together with a high level description of the regulation implemented in a number of countries.

## 18.1 Electricity Industry Structure

Electricity has two challenging characteristics. Firstly there must be equilibrium between the quantity dispatched and that consumed by loads and storage mediums at any instant (net of losses incurred in transport across networks). Until recently the only loads that were material were those of end use customers, including relatively inflexible hydro pumped storage, and this required flexible generation facilities to track variations in customer load. More recently, large flexible chemical storage technology has emerged. As the following sections will explain, the development of flexible storage is reducing the need for flexible generation and also counteracting the introduction of intermittent generation technology. Secondly the laws of physics govern the physical operation of the power system and these determine the path electricity will flow, rather than any commercial or regulated mechanism.

Power systems are the interconnection of a number of generators and end users located over a wide area. The earliest power systems from the late 1800s and into the first half of the twentieth century were township systems with local generation. Over time the systems of separate townships were linked together to share costs with generation distributed across the townships and eventually connecting very large areas. In the second half of the twentieth century as the size of the consumer demand grew, larger and larger generators were built. Eventually most of the township generation was retired leading to the era of central generation. This development led to industry structures based on specific functions for generation, transmission, distribution and the interface with end consumers (retailing).

From the late twentieth century the cost of small and distributed generation fell dramatically reducing the benefits of scale and leading to a shift in the mix of generation back towards a combination of central and distributed generation. Much of the distributed generation of today utilizes wind and solar-photovoltaic (PV) technologies, which also bring benefits of low

emissions of carbon dioxide. This shift is blurring the distinction between generation, transmission, distribution and retailing. For example, individual consumers may now host solar-PV on their household rooftop and export to their neighbors via the distribution network. Retailers may facilitate this transfer or simply be bypassed.

The newer technologies have different technical characteristics. Wind, solar-PV, wave and tidal generation technologies are generally non-synchronous in that they are usually connected via power electronics in contrast with spinning AC machines that are directly connected. They exhibit low (or no) inertia, which is important as this affects the rate at which power system frequency can deviate from the level needed for the power system to remain stable. Where the percentage of this form of generation is significant, it can change the dynamic performance of power systems. In some power systems, this shift is already requiring a major change in their operation. For example, where previously high fault currents due to short circuits may have restricted operation, the newer technologies create fault currents that may be too low to be detected by existing protection equipment.

Sitting between pure supply and pure consumption, large scale battery storage technology is reshaping the operation of power systems. Hydro pumped storage along with limited numbers of flywheels and compressed air energy storage have been in use for many years but limited by cost or suitable location. Recent technological developments and lower costs of chemical battery storage are allowing deployment of storage devices across the entire supply chain. Batteries are being installed in conjunction with intermittent technologies connected to major transmission facilities and *behind the meter* in households to better match the requirements of end customer demand. Storage devices such as batteries or flywheels can also counteract the effects of low inertia from other new technologies. While the cost and performance of batteries are constantly im-

proving, they are currently more suitable for short term back up which allows time for longer-term support such as gas turbines or hydro storage to be brought into service.

Rooftop solar-PV, micro-generators and some small wind farms are typical examples of small generators, embedded in the distribution system. As the development of these technologies grows quite rapidly around the world, their effect is becoming more pronounced. For example, large-scale application of rooftop solar-PV may reduce the power flows from higher voltage levels of the system at a particular substation to zero. It could even result in power flows from lower to higher voltage levels of the system at the substation. Power flows can also swing dramatically as intermittent clouds appear and screen the PV cells. While, in parts of the world the majority of current rooftop solar-PVs are not yet metered, recent technological innovations in measurement, communications and trading, including through the application of block-chain concepts, are resulting in these widely distributed resources being more closely monitored and controlled. This also makes possible *peer to peer* trading arrangements with potentially strong effects on the physical and commercial operation of the broader system and any market operating on it.

## 18.2 Industry Organization

While the physics of the electricity supply process is the same everywhere, there are many ways the industry can be organized commercially and functionally.

Historically, the dominant organizational model was a utility that owned all elements of the supply chain

An extreme example of the variability of solar can be seen from the impact of the solar eclipse that occurred in Europe in March 2015.

At the time of the eclipse the installed solar-PV capacity in the Continental European synchronous system was approximately 89 GW, and the potential solar-PV reduction was expected to be as high as 34 GW. The effect in Germany is shown in Fig. 18.1. The gradient of the steep ramp that shows the sudden loss of solar-PV generation was estimated to be 2–4 times higher than normal daily ramping, while the short morning peak caused a significant increase in demand for flexible power plants. While the actual reduction in solar-PV output was lower on the day (19.2 GW), due to more than expected cloud cover, there was still a substantial change. The event was anticipated, however, and adequate reserves were scheduled, ensuring there was no risk to power system security. The key points are that there needs to be adequate back up to cover the significant loss of generation that can occur and the solar event may cause a much more rapid ramp rate than would normally occur.

Utilities in the US also undertook contingency planning and scheduled additional generation for the solar eclipse in the US in August 2017. However, it had a fairly minimal impact, partly due to the lower than expected temperatures and some cloud cover [18.2].

Large-scale wind and solar-PV farms have also been constructed to take advantage of economies of scale and the benefits of being close to strong wind and solar resources. While it is possible to predict the timing and size of the outputs of these intermittent sources over the short term with reasonable accuracy, wind strength does not always align with the demand of customers. In addition, local cloud cover can affect the output of large-scale solar facilities (which is less of an issue with distributed small-scale solar-PV). Fast acting and flexible generation, storage systems and transmission interconnectors can be used to counter the effect of variations (and any inaccuracies). Renewable energy technologies with substantial inherent storage, in particular solar-thermal, have a dispatchability advantage over technologies without storage. Solar-thermal also brings significant inertia, accentuating its advantage, although at significantly higher cost for now.

or contracted specific activities such as individual generators. The internal operations of these utilities were based on a management hierarchy. The entities typically had a franchise to supply end-consumers in defined geographic areas and government-appointed bodies regu-

lated prices charged to end consumers. A variation of this model was where local supply boards took bulk supply from central generators.

In the early years, there was massive growth of the power systems driven by strong social objectives. Governments took a lead role; either directly through government owned entities or regulated private companies. As the systems grew, the efficient size of generating units also increased and the number of generating companies within a particular power system remained relatively small. In addition, the IT and communications systems were not yet suitable to host real time competition. These circumstances tended to make monopoly ownership and control of generation the natural path.

As the power systems evolved, major utilities interconnected their networks forming large power systems across different government boundaries and between countries, continuing the earlier pattern of interconnection between townships. Interconnected utilities established agreements and sometimes, common control facilities to coordinate the operation of their power systems.

Since the early 1990s, many utility-based arrangements have been amended to introduce third party

access to the networks and competitive market mechanisms with the aim of reducing the cost to the end customer by:

- Providing end consumers with a choice of supplier
- Introducing short term competition into day-to-day operation of power systems and, in particular
- Devolving many decisions including investment decisions to individual generators, retailers and customers, i.e., away from a command and control based central management by system controllers.

The short-term competitive day-to-day operations of power systems have been enabled by advances in communication, supervisory control and data acquisition technologies that have allowed the vast amount of data needed to manage a power system this way. The devolution of decisions required a dramatic move away from the centralized hierarchy model of managing a power system. In particular, the power system operators became managers of system security and service providers to competing generation and retailing businesses, which all depend on the neutrality of the network businesses to reach their customers.

## 18.3 Electricity Markets

Specific technical characteristics of electricity are that it is invisible and, when supplied via a shared alternating current network, it is also indivisible. In addition, supply and demand must be balanced on a second-by-second basis. Together, these factors restrict the form a market can take for trading of the physical product. Forward sales for electricity, however, can be transacted much like any other commodity. For example, this could be in a financial exchange or by direct negotiation in *over the counter* sales. The need to balance real time supply and demand will generally mean delivery does not perfectly match forward sale volumes and some form of real time balancing or spot market is needed in parallel with the forward market.

In order for disaggregated entities to collectively make economically efficient decisions that also maintain security and reliability, they require timely information about supply, demand and cost. A number of market models have evolved to provide a platform for a central market and system operators have been allocated the task of receiving and publishing this information. The various models employ a different mix of central control and disaggregated decision-making, where the separate generators and retailers are responsible for their own commercial wellbeing.

### 18.3.1 Supply and Demand

To run a power system effectively there needs to be adequate capacity to meet total demand and an ability to match variations in demand across each day. The total customer demand varies across the day and across the year in most systems. The variation is generally more pronounced in countries located away from the equator and varies with the season and use of heating and cooling. Figure 18.2 presents a typical winter demand curve for a day in a cool climate and shows overnight load is low and there is a peak that occurs for a short period in the early evening, generally driven by domestic cooking, lighting and in some cases, heating.

Traditionally, generation plant has been characterized by the role it plays. Generation plant that runs most hours of the day is termed base load. Plant that is used only occasionally, or for limited hours per day to follow variations in demand, is termed peaking plant, with intermediate load plant running for part of the time. The most cost effective mix of technologies will depend on the capital and operating cost of available technologies and fuels and can only be assessed over the long term. Decisions about which technology is best to run within a day depend on the controllable cost of operation, the

**Fig. 18.2** A cool climate winter daily demand curve

variable operating cost of plant that has been built (i.e., excluding sunk capital cost) and the shape of the daily demand curve. The demand in Fig. 18.2 would be met using the lowest cost plant across the entire day (making this plant base load) and higher cost plant for less time during the peaks.

Historically, in large power systems, coal, nuclear, hydro or combined cycle gas fired generation generally operated near to 24 h a day (base load). These generators typically have high capital costs and low operating costs and, with the possible exception of hydro, are not designed to be turned on and off on a regular basis. On the other hand, peaking plant such as open cycle gas turbines have a much lower capital cost but higher operating costs and are much easier to turn on and off. In a market system where generators offer a price to the system operator for dispatch you would expect the lowest cost generators to offer low prices at low load times to ensure that they run all the time.

More recently there has been a substantial increase in wind and solar generation in many countries. The operating costs of these technologies are low as there is no fuel cost. So, they will want to run as often as the wind blows or the sun shines. In bid based market arrangements they will also tend to bid lower prices to ensure they run when they can. This will be in direct competition with traditional base load plants and will put pressure on their revenue streams. While this may drive efficiency, it can also impact on the overall financial viability of the generator.

As the penetration of wind and solar generation continues to increase, markets have to increase flexibility to balance surpluses and deficits both within a particular power system and across the interconnections between the systems. In many cases this will be across international borders and this is driving the need to standardize

market structures and systems where these interconnections can and do occur.

Variable operating and maintenance costs of offshore wind farms can be more substantial, and potentially be above the prevailing market price. Operators should therefore aim to run the wind farms as much as possible whenever the market price is above their variable operating and maintenance costs, while scheduling outages at times that have the lowest impact on revenue.

As discussed above, the growth of distributed generation, mostly in the form of rooftop solar-PVs and, more recently, associated storage, is opening up opportunities for customers to participate in the market, both in terms of sale of surplus generation and demand management.

### 18.3.2 The Role of Markets

A market is only useful if it ensures generation capacity is introduced and withdrawn in a timely manner. Markets may signal the right time through prices rising or falling as demand grows. For example, higher prices will encourage higher cost generators to run more often or, if a new lower cost source of power is available, it may undercut operation of an incumbent technology. On the other hand, reducing customer demand may cause prices to fall. Entry and exit of capacity may also be centrally managed in terms of price or volume and market arrangements will focus on efficient use of incumbent capacity. Given the significance of electricity in most countries, if new entry does not occur in a timely manner, reliability of supply will fall suggesting market failure and this will usually lead to government intervention.

A centrally managed process to determine the level of capacity may be used where markets pay for capacity or availability, separately to dispatched energy. In this case, generators are paid to guarantee that their plant will be available at times of system stress even if they otherwise do not run often or at all.

In order to design or understand a market for electricity, it is important to be clear about the definition of the product or products that are being traded, be it capacity, energy, availability, frequency keeping services or network support. Electricity systems are highly integrated and market arrangements for one or more products generally affect others. As noted, transmission and distribution networks are often regulated, even if there is a market in operation for other parts of the industry such as generators and retailers. Network costs can be optimized, and therefore the combined costs of generation and networks charged through to users reduced, by lowering infrastructure investment to optimum levels and by leveling demand to reduce the size

of peaks and troughs. Subsidies have been provided to some market participants as part of a (legitimate) social policy agenda of governments. A technology specific subsidy can also impact the operation of markets and ironically, market design activities usually need to consider how these non-market subsidies are applied.

There may also be constraints in the transmission and distribution systems, which may limit the amount of electricity that an individual generator can sell. These constraints can impact on the returns to the affected generators as well as the reliability of supply for some end customers. Examples of these constraints are thermal capacity limitations or operational restrictions in relation to system security or stability. In a market situation these constraints need to be clearly identified to

minimize the likelihood of contractual disputes at a later date.

In summary, the overall goal of a market is to achieve market efficiency in both the short term and the long term. In the short term, output should be produced in the right quantities by the lowest cost generators and consumed by those that are prepared to pay the most. In order to achieve this, generators are dispatched to achieve the best economic outcome starting with the lowest short run marginal cost. In the long term the market must provide signals to trigger the timely investment in appropriate quantities of new generation. It must also generate confidence that investors will receive a reasonable return on their investment considering the risks involved.

## 18.4 Market Models

This section introduces a number of the market models that have evolved around the world. Specifically, the following models are described:

- A vertically integrated utility
- A vertically and horizontally disaggregated utility with only utility plant connected
- A competitive market only at the time of investment
- Separate capacity management combined with central dispatch of energy
- A general overview of energy-only markets and specific descriptions of:
  - A pool system with a marginal system price
  - A pool system with pay as bid.

The section then continues to discuss the operation of retail competition and a brief overview of using a market for transmission expansion.

One way to understand the differences in the models is to consider where each sits on a spectrum of central disaggregated control and the allocation of risk. This is illustrated in Table 18.1. Generally, the more centralized the control the more the risk is retained by central entities and ultimately passed through to the end consumers in the form of fees and tariffs. Conversely, the more devolved the decision-making; the more the individual generators and retailers carry the commercial risks (and rewards) of decisions in the industry.

Prior to the introduction of markets, the traditional function of a system operator was to manage system security, physical dispatch, system reserves and network loading. To manage the commercial interactions with buyers and sellers a new function emerged – market operator or power exchange. Around the world the activities involved in managing security, dispatch, network

loading, network switching, metering, market registration and settlement are combined in a number of ways. A range of labels has emerged for the different activities and combinations, for example system operator, market operator or transmission system operator. The label independent is generally applied when independence of the system operator or transmission operator is required. For the market operator or power exchange, this level of independence is always assumed regardless of the label. The role varies from market to market but can be seen as the entity that runs the trading activities that are not handled by the traditional system operator.

### 18.4.1 Vertically Integrated Utility

The traditional utility, operated under a centralized hierarchy model, sits in column 1 at the left hand end of the spectrum in Table 18.1. In this model, individual generators are generally owned by or contracted to the utility and carry little risks other than for their own performance. Any errors in forecasting, in the choice of which units to dispatch, in the fuel to purchase or the trades with adjacent networks, stay with the central utility and are ultimately paid for by its owners – be they end consumers or private investors.

### 18.4.2 Vertically and Horizontally Disaggregated Utility with only Utility Plant Connected

The next step along the spectrum is in column 2 of Table 18.1. Here, vertical and horizontal disaggregation has been used to allow financial separation of the generators and network components of the electricity supply. However, there is no commercial market and the

Table 18.1 Spectrum of market options

1. Vertically integrated utility		2. Vertically and horizontally disaggregated utility. Only utility plant connected		3. Competitive market at time of investment/tendering only. Only successful tenderers can connect.		4. Competitive market third party access		
Direct management control	Direct management control	Transfer pricing	Utility tenders for PPA (power purchase agreement)	Independent single buyer tenders for PPA	Separate capacity management combined with central dispatch of energy	Investment to centrally administered capacity. Balancing or spot price market used for dispatch	Investment based on price. Balancing or spot price market used for dispatch	Energy only (combined investment and operating price incentive)
				Investment based on physical standard. Operations under utility control				Back up intervention (e.g. strategic reserve)
								No intervention

Low market influence

Strong market influence

Level of administrative control

Level of competition

generators are still under direct management control or a form of transfer pricing is introduced.

### 18.4.3 Competitive Market at Time of Investment Only

This is illustrated in column 3 of Table 18.1 and can be described as a single-buyer/power purchase agreement (PPA) model. Traditionally, many utilities operated with a combination of owned generation and other contracted generators. In a single buyer model, competition occurs only at the time of contracting. In this case, the buyer would normally tender for a generator supply and enter into a long-term contract or PPA with the successful bidder. At the simplest level, the buyer may be the utility but there may be concerns that it has some level of vested interest in the outcome. A more sophisticated model is where the entity assigned the role of single buyer is commercially independent. It has no allegiance to any particular generation business. The single buyer will liaise with or be integrated with a market operator.

The model does not readily allow any choice of supplier to end consumers. In principle it does allow for multiple retailers to buy from the single buyer and compete on retail margin and service offering but the benefits of this form of competition are small. A single buyer is often seen as a transitional step to greater levels of competition.

A variation on the single buyer is a PPA market where individual blocks of demand enter into contracts with generators under long term PPAs. This arrangement differs from a single buyer in that it is demand or customer focused as it is the demand side or customers who decide to purchase, typically in the form of large industrial loads or retailers. A similar mechanism to a single buyer market is often used as a means to coordinate the operation of the contracted generators.

Single-buyer/PPA arrangements need a mechanism to commercially account for times when generators produce more or less than their contracted amounts and this is often termed out of balance. Out of balance can be calculated and priced in a number of ways. For example, all contracted generators may be required to inform the market operator of their intended outputs in advance. Uncontracted or partially contracted sellers may be required to bid to the market operator their willingness to raise or lower output at various quantities and prices. Depending on the needs of the balancing market and the competitiveness of their bids, these uncontracted or partially contracted sellers may or may not physically run.

As the arrangements become more sophisticated, they begin to look more and more like the shared or

pooled price arrangements that sit further along the spectrum of industry structures.

#### 18.4.4 Separate Capacity Management Combined with Central Dispatch of Energy

A widely used structure for competitive participation provides for a payment for capacity separate from payment for dispatched energy. This arrangement is often described as a capacity market but is more correctly a capacity plus energy structure. It falls within column 4 of the spectrum in Table 18.1. The arrangement reflects the typical structure of earlier PPA contracts that cover availability plus dispatch payments and provide for close management of the level of capacity present in the market [18.3].

In these market arrangements, one (but rarely both) of the amount of capacity or the price of capacity is set administratively. For example:

- The amount of capacity considered to be needed to meet a reliability standard is calculated and a competitive process run to acquire that amount, with the price being determined by the market responses; or alternatively
- The price that will be paid for capacity is announced and calls for parties to provide capacity at that price are made.

The acquisition process can be a tender, subscription or auction.

These markets typically arrange dispatch on the basis of prices submitted by generators rather than costs of production that are used in PPA and single buyer arrangements. Prices provide much greater flexibility and competitive tension in the market than a cost based regime. However, the typical objective is that sufficient competition will drive prices down to costs and, in the process, create incentives for an economically efficient mix of generation and continual pressure for improvement. Later sections discuss the common situation where this assumption about adequate competition is not valid and measures to control market power are overlaid on the operation of the market.

Typically a central or pool price is derived from the prices of the generators that are dispatched. This real time market price is most commonly set by the marginal value of generation to the system (often approximated by the price of the highest priced generation dispatched). All generation dispatched is paid at this market price.

Different implementations of this design include day-ahead, intra-day and longer-term markets, which set a price for agreed volumes of electricity in advance of dispatch. These markets can be for physical quanti-

ties or they can be financial contracts that settle against the real time price. The real time price is then applied only for the volumes not covered by advance markets.

The real time price can thus be seen to be equivalent to the out of balance price of PPA arrangements and the day-ahead markets or the price paid for *unders and overs* of actual compared to contracted volumes.

In these designs it is usual that a central government or other regulated body determines the amount of capacity or the price that is to be paid for capacity that is passed through to customers. Customers therefore bear the risk to the extent that the central body over or under-estimates demand, the flexibility or price elasticity of demand, or the availabilities of installed generation equipment.

#### 18.4.5 Energy-Only Markets

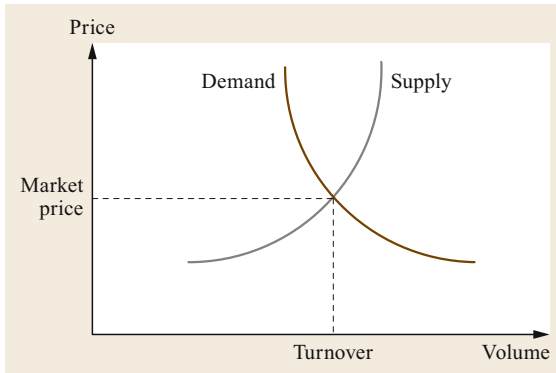

At the right hand end of the spectrum in column 4 of Table 18.1, a market arrangement that pays only for energy dispatched on the basis of a price offered for dispatch transfers the commercial risk to the industry players. Critically, this relies on competition between these players to contain prices, as without sufficient competition there is a risk of uncompetitive prices. These markets have an energy market that operates along similar price based lines to that of a capacity market, but with quite different price outcomes. Generators earn revenue from the market only when dispatched. This type of market relies on price incentives to ensure sufficient capacity is available. As a result price must rise above the short run cost of generation for long enough for the efficient amount of generators to recover all costs. In principle the price will reflect the cost of generation and the risk of scarcity of supply to customers. When generation reserves are very low the price will approach or reach the value of customer scarcity. This price can be politically unacceptable prompting the use of low price caps but creating a risk of 'missing money', whereby potential investors do not have confidence that they will achieve an acceptable return on investment, aside from other risks such as plant performance and the level of demand.

Typically, day-ahead, intra-day and longer-term markets also operate in conjunction with the real time market.

In these designs, far more of the investment risk of the industry initially sits with generators. Generators and retailers may, however, enter into hedging or other longer term contracts to reallocate that risk in return for price certainty.

There are many variants of each of the basic forms. Within energy only markets, two specific examples are *pool system with marginal system price* and *pool system with pay as bid*.

**Fig. 18.3** Supply–demand curve

#### Pool System with Marginal System Price

For this system, the sellers bid (confusingly analogous to offers to sell in most financial markets) to the market operator their willingness to sell various quantities at nominated prices. All the energy that they wish to sell is bid into the market and for this reason the market is sometimes described as a gross pool. One form of this design sees the bid quantities accumulated to form an aggregate supply curve. Buyers bid to the market operator their willingness to buy at various quantities and prices. These are accumulated to form an aggregate demand curve. This demand curve has traditionally been relatively inelastic as most customers are currently unable to respond to price signals. The quantity traded is at the intersection of these curves. The price is also at the intersection of these curves. The clearing price is the rate for all bidders for all quantities. This is illustrated in Fig. 18.3.

The system marginal price is the price set by the most expensive unit needed to meet the demand quantity. Only sellers that bid below this price will physically run.

A more sophisticated version is based on a mathematical optimization. Generators and any demand blocks that choose to participate in the wholesale market, offer their prices. The market operator then determines the economically efficient combination of generation and demand needed to meet customer needs, accounting for network losses and security constraints. The market price is one of the outputs of the mathematical optimization.

#### Pool System with Pay as Bid

Pay as bid arrangements differ from pay at marginal price described in the previous section in the way the market price is determined, but are otherwise very similar.

For this system, sellers bid to the market operator their willingness to sell at various quantities and prices. These are accumulated to form an aggregate supply curve. Buyers bid to the market operator their willingness to buy at various quantities and prices. These are accumulated to form an aggregate demand curve. The quantity traded is at the intersection of these curves. Only sellers that bid below this intersection physically run.

Each generator that is dispatched is paid at the price it offered and each block of load pays at the price they offered to buy at. Experience shows, and many commentators note, that in practice the price in pay as bid arrangements often trends towards the marginal price, as participants learn that their dispatch is unchanged until they bid above the marginal price.

#### 18.4.6 Retail Competition

While an objective of wholesale market reform is to facilitate competition amongst suppliers, choice of supplier (retailer) for end customers is very often a key objective. The competition that then results between retailers can put downward pressure on profit margins and encourage the improvement of service standards. Retail margins are generally quite low and there is a need to spread the costs over several products with similar metering and billing requirements. Large companies can achieve economies of scale that tend to encourage the amalgamation of smaller retailers. However, too few retailers may hamper competition and lead to monopolistic behavior. Customers are given freedom of choice over their preferred retailer.

#### 18.4.7 Market for Transmission Expansion

There have been attempts to use a market mechanism to drive down the costs of transmission infrastructure rather than to rely on regulatory oversight. An example of this is in Brazil. In this case, a planning process is used to assess future transmission requirements. The federal regulatory agency then holds auctions for bidders who will build, own and operate the facilities. The winner of this auction is the one who requires the lowest annual revenue over thirty years. While initially successful, recent auctions have failed to attract significant competitive bidders. To some extent this is due to regulatory uncertainty caused by rule changes and the forcing of companies who are renegotiating expiring contracts to substantially reduce prices by placing a ceiling on allowed revenues.

## 18.5 Market Structures Around the World

This section provides some practical examples of electricity markets around the world. It draws on a recent CIGRE technical brochure number 626 [18.4], which has surveyed the current status of electricity markets in selected countries. In some cases other sources from the various countries have also been used. These markets are evolving and some may look quite different in the future. They do, however, provide concrete examples that relate to the theory discussed earlier. One significant change that is occurring relates to the growing penetration of wind and solar generation coupled with growing opportunities for demand response, demand flexibility and energy storage. These present particular challenges to the current market arrangements due to the variable nature of wind and solar energy. Government policies and a range of direct and indirect subsidies are also driving the growth in these forms of generation.

### 18.5.1 Europe

While a form of trading of electricity commenced in Norway in 1971, for the rest of Europe, market liberalization began in England and Wales and the remaining Nordic countries in the early 1990s. These early markets, while still visible, are now incorporated into a pan-European market that covers energy and the implicit trading of network capacity.

European directives have been enacted since 1996 to establish a common internal electricity market in Europe, which is still evolving. These directives have established common rules for the generation, transmission and distribution of electricity both for the organization and functioning of the sector and for the operation of the market. Key outcomes have been:

- Unbundling of monopoly activities – i.e., separation of generation from transmission
- Third party access to all electricity networks
- Entry of new suppliers or load serving entities into markets
- Customer rights to choose their supplier
- Establishment of a National Regulatory Authority for each member state and
- Establishment of network codes or rules, derived from a common European root, which address issues such as connection to the network, operation of the market and operation of the power system.

In many cases, trading in electricity is by bilateral contracts, but in some cases, a market operator or power exchange has been created. These power exchanges take various forms across Europe, some of which are

private entities. For example, the European Energy Exchange (EEX) in Leipzig, operates spot and derivatives markets and EPEX SPOT operates a spot market. German EEX AG and French Powernext SE own this latter market. There is a forward market for deliveries up to six years in advance and a spot market for day-ahead and intra-day trades. Buyers and suppliers submit their bids by midday on the day before as part of electricity auctions in the day-ahead market. After the day-ahead auction closes further bids can be made in the intra-day market. This trading closes 45 min before delivery. Finally, TSOs procure balancing capacity to cover unforeseeable imbalances through a competitive bidding process in a balancing market.

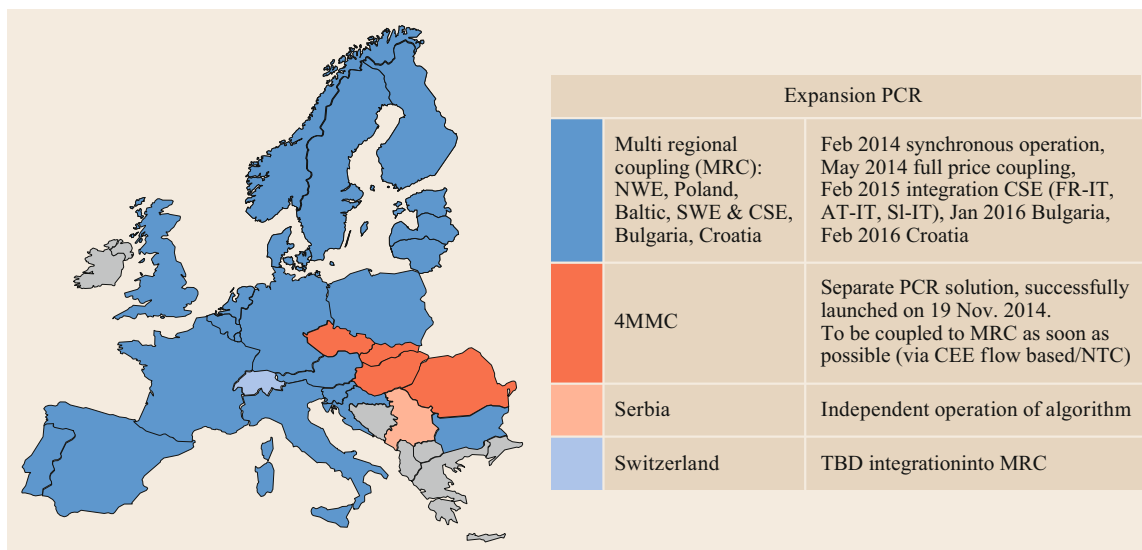

As these markets have evolved moves have been initiated to couple the various markets. In some cases this has been enhanced by the installation of new physical interconnections, for example across the Baltic and North Seas. The stronger these interconnections are, the less the physical constraints will impede the competitive pressures and the more opportunities there will be to dispatch the lowest cost generation. In the move to an integrated European market, work has been undertaken to develop a common approach to calculating cross-border transmission capacity, defining bidding areas and creating efficient trading mechanisms.

In May 2014, two regions, the north west region and the south west region were price coupled with common synchronized operation as shown in Fig. 18.4. The price coupling of regions (PCR) now includes Belgium, Denmark, Estonia, Finland, France, Germany, Austria, Great Britain, Latvia, Lithuania, Luxembourg, the Netherlands, Norway, Poland, Sweden, Italy, Bulgaria, Croatia, Portugal and Spain. The coupling of the day-ahead markets has enabled more efficient allocation of interconnection capacities of the involved countries. Market prices are calculated simultaneously, operational procedures are harmonized and offers are made to the market in a coordinated way. In addition, other countries are being brought into the PCR as soon as possible.

#### Nordic Market Overview

A market for electricity trading in Norway commenced in 1971. This took the form of a power pool, which allowed generators to trade surpluses and deficits of power through a central grid. Virtually all power generation in Norway is by hydroelectricity whereas the other Scandinavian countries have a mix of hydro, nuclear, coal and other fuels.

Electricity market liberalization in the Nordic countries commenced in 1991 and now includes Norway, Sweden, Finland, Estonia, Latvia, Lithuania and Den-

**Fig. 18.4** Developments for price coupling of regions. (Source: ENTSOE, PCR Status report, Q3, 2017 [18.5])

mark. As part of the process, a regulator and a transmission system operator were established in each country. All networks were separated from competitive activities and are now open to third party access by all customers.

Trading of electricity is by direct physical contracts between generators, retailers and customers, with all having the option to access the power pool to trade at the margin. For the pool, buyers nominate the energy needed and the price they are prepared to pay each hour and sellers nominate how much they can deliver each hour and for how much. The hourly price is set for where the sell and buy prices meet. There is no capacity payment unless there is a transmission constraint. Within NordPool there is a spot market (ELSPOT) that settles quantities and price nine hours before delivery, taking into account interconnection limitations. There is also another spot market (ELBAS) that operates in Sweden and Finland and settles two hours before delivery. Both require physical delivery. Each transmission system operator operates a balancing market to enable physical balance in real time. There is an organised futures market for financial hedging up to three years in advance.

There is no capacity market although this may be considered in the future if there is concern that the market does not trigger timely investment in new generation. Stagnating load growth, a rapid increase in renewable generation and high penetration of hydro are mitigating the risk of insufficient generation investment. Most of the recent renewable generation has been intermittent wind generation, however, and the capability to manage dispatch is being compromised. While not a capacity market, Sweden maintains

a strategic reserve. This is a capacity remuneration mechanism as discussed in more detail in the CIGRE technical brochure 647 [18.3], which describes the capacity mechanisms used in the various countries.

#### UK Market Overview

The United Kingdom (UK) comprises Great Britain (GB) and Northern Ireland. GB encompasses England, Wales and Scotland. The system in Northern Ireland became part of the single electricity market in 2007. Liberalization in GB was first instituted in 1990 with, initially; different market arrangements in Scotland separate from those in England and Wales.

Historically, fuel for power generation in GB has been dominated by coal, gas, and nuclear. Recent years have seen a growing percentage of renewable generation mostly in the form of wind turbines but also, increasingly, from solar PV. At the time of writing there are interconnections with France, the Netherlands and Ireland with further interconnections under development to Belgium and Norway and still others under consideration. In 2016, the GB system was run for some hours without any coal generation for the first time ever and coal fired power stations are predicted to close completely by 2025.

The first England and Wales market required all electricity to be bought and sold through a common pool. For each trading period there was a single input and a single output price. The pool input price was set by the last bid accepted to fill the quota of capacity for each half hour. Bidding into the market was optional. There was also a capacity payment made to encourage generators to offer capacity. This payment was based

on estimates of the value of lost load (VOLL) and loss of load probability (LOLP). Concerns with this mechanism included that it rewarded shortages rather than new investment and that generators could manipulate the pool price by withdrawing generation plant at critical times.

Scotland did not enter into this market. It retained two vertically integrated utilities with contracts in place between them to allow the mix of power plants to be optimum for both companies. Due to the lack of competitive pressure, the businesses were heavily regulated with prices linked to the England and Wales pool price. A similar process was adopted in Northern Ireland. The wholesale market in Scotland was merged with that in England and Wales in 2005 to form a single GB market with a single GB system operator adopting the structure that was put in place in England and Wales in 2001.

Amongst other things, concerns over excessive pool prices, potential gaming of the complex pool rules and the lack of demand side participation led the government to change the market. In March 2001, new electricity trading arrangements (NETA) were introduced. Under these new rules, encouragement was given to the decentralized trading of energy via bilateral contracts between generators and suppliers acting on behalf of end customers. To cover any remaining imbalances, there was also access to an optional power exchange to cover contractual imbalances and a balancing mechanism (BM). For the BM, participation is compulsory for larger generating units and suppliers and optional for others. The resulting market is similar to that operating in the Nordic power pool. The BM accepts bids and offers up to *gate closure* at 1 h ahead of delivery. The BM is managed by the system operator part of National Grid, which in 2018 is being separated from the transmission company that owns the transmission network in England and Wales. (There are two further transmission owners covering the north and south of Scotland).

The general view by Ofgem, the GB regulator, was that the NETA reforms had performed well alongside other factors such as falling fuel prices, a generous capacity margin and increased competition in generation with significant reductions in wholesale prices [18.6].

In 2013, the government introduced further reform with the objective of providing incentives to invest in secure, low carbon electricity; improving the security of Great Britain's electricity supply; and improving affordability for customers. A key aspect of this reform was the introduction of a capacity market to ensure sufficient reliable capacity during periods of higher risk such as when high demand coincides with low wind power generation. The market operates as two auctions, one for year-ahead capacity and the other for capacity four years ahead. The successful bidders enter into

capacity agreements that allocate payments for guaranteed capacity availability.

A further support to renewable generation providers is in the form of long term contracts for difference that provide stable and predictable revenue streams for investors. If the wholesale market price is higher than the contract price, the generator makes a payment and if the price is lower, it receives a payment.

The reform also introduced an offtaker of last resort scheme, which facilitates a contract between a renewable generator and a licensed supplier through a competitive auction where the contract must be at a discount below the market reference price. This process is used where the renewable generator cannot secure a contract via usual commercial means.

### German Market Overview

The electricity market in Germany is Europe's largest with an installed generation capacity of 184 GW. Full deregulation of the domestic electricity market occurred in 1998. There are four transmission companies that own and operate their respective transmission systems Amprion, ENBW Transportnetze, TenneT and 50 Hz transmission. Transmission is legally unbundled with defined rules for non-discriminatory third party access. Power generation and distribution is provided by a few large companies and a large number of small distribution companies. The larger companies are RWE, E.ON, innogy SE, Uniper, EnBW and Vattenfall.

As mentioned earlier, the German market is coupled with 15 neighboring countries and the exchange price for the day-ahead market is calculated jointly for the coupled markets. The coupled market determines the lowest price from any market zone until the cross-border interconnections are fully utilized and then it reverts to the lowest price in the particular market zone where the load is being served.

In June 2016, the German Federal Parliament approved a number of reforms to the power market and agreements about transferring existing lignite power stations into an emergency reserve. Ultimately these generators will be phased out permanently.

The main driver of the reforms is to ensure efficient power station operation and overall security of supply as the amount of renewable generation continues to grow. The main reforms include [18.7]:

- Strengthen the price signal to investors – in times of supply scarcity, peak prices will not be capped and may increase substantially which should signal investment opportunities to power station investors. They may choose to invest in peaking plant such as open cycle gas turbines, load management or storage.

- Penalties for insufficient power delivery – traders must ensure they buy sufficient power to supply their customers and not rely on grid operators to make up the difference.
- Increased competition for flexible power options or peaking plant – providers of flexible options, including electric vehicles in the future, will have access to the balancing market.
- Reduce network costs – firm access to all renewable generation will no longer be required and network charges across the country will be harmonized.
- Provide a capacity reserve – similar to the strategic reserve in Sweden, this will ensure adequate capacity is retained in constrained network regions and support power system security for extreme events. This plant will not be part of the power market to ensure there is no distortion of the competitive elements of the market.
- Mothballing of inefficient lignite power plants – these will be put on temporary standby for a period of four years before being permanently closed.
- Smart meters will be rolled out – this will commence with the largest customers and be governed by a cost benefit ceiling and strict data security.

### 18.5.2 Australia

The National Electricity Market (NEM) encompasses eastern and southern Australia (Fig. 18.5 [18.8]). It is geographically one of the largest interconnected AC systems in the world covering 5 200 km from tropical Queensland to western South Australia. The maximum demand of the NEM is now (2017) approximately 37 GW.

Economic reform of the electricity sector began in the early 1990s. Victoria was the first to establish a market within the state, followed by NSW and later still a form of market arrangement in South Australia. The states collaborated and designed the National Electricity Market (NEM), which commenced December 1998. The NEM covers all of the east coast of Australia but not Western Australia or the Northern Territory, which are not interconnected with the east coast system.

At the time of writing the NEM consists of five major and two minor transmission companies, seventeen distribution companies, twenty-five major and twenty-five smaller retailers and individual market customers as well as eighty-one generators.

The market design is similar in some ways to early versions of the UK model. The participants in the NEM are a mixture of private and government owned utilities. A key industry change was the disaggregation of generation, transmission, distribution and retail during the early 1990s in the lead up to the start of the NEM.

Western Australia followed later with disaggregation into generation, retail and a combined transmission distribution business occurring in 2006. More recently the disaggregated generator has been re-combined with the retailer and this larger business is intended to compete with other smaller combined generator retailers. The size of the market and the lack of diversity limit the extent of the competition that can occur.

The current market model in the NEM is consistent with the above description of a pool system with a marginal system price [18.9]. It is a gross pool, trading in energy only and it is broken down into regions, which follow state boundaries and each has its own spot price. There are no capacity payments. The intention is that as the spot prices increase, or rather forecasts of future spot prices increase, this signals to investors that the addition of new generation will be a profitable venture. While the visible trading in the market is seen as a spot price, behind the scenes there is extensive bilateral contracting to reduce the risk from short-term price variations. Today, many of the separate generation and retailing businesses have merged into a few very large gen-tailers. There is a reliability and emergency reserve trader, which is a function available to the market operator to contract for electricity reserves ahead of a period where there is a predicted shortage of generation. This is a form of strategic reserve as described for Sweden and Germany and discussed in more detail in [18.3].

In the NEM, the Australian energy market operator (AEMO) is both the market and system operator and is required to be independent of market participants. The market is intended to operate commercially at all times. AEMO has powers of direction to maintain reserve margins and ensure secure operation of the transmission network. There is also a spot market for frequency control services.

A snap shot of the data dashboard for Queensland in the Australian national electricity market is shown in Fig. 18.6 [18.10]. The chart shows 30 min data including current and historical spot prices, forecast spot prices, current and historical scheduled demand and forecast scheduled demand for a twenty-four hour period. Figure 18.6 is regularly updated. To obtain the latest figure, go to: <https://www.aemo.com.au/energy-systems/electricity/national-electricity-market-nem/data-nem/data-dashboard-nem>. Then select price and demand and QLD.

The spot market is used to instantaneously match wholesale electricity supply and demand in real time. AEMO centrally coordinates the dispatch process and determines which generators will meet the demand based on 5 min bids from the generators for quantity and price. AEMO then arranges the dispatch of the generation accordingly.

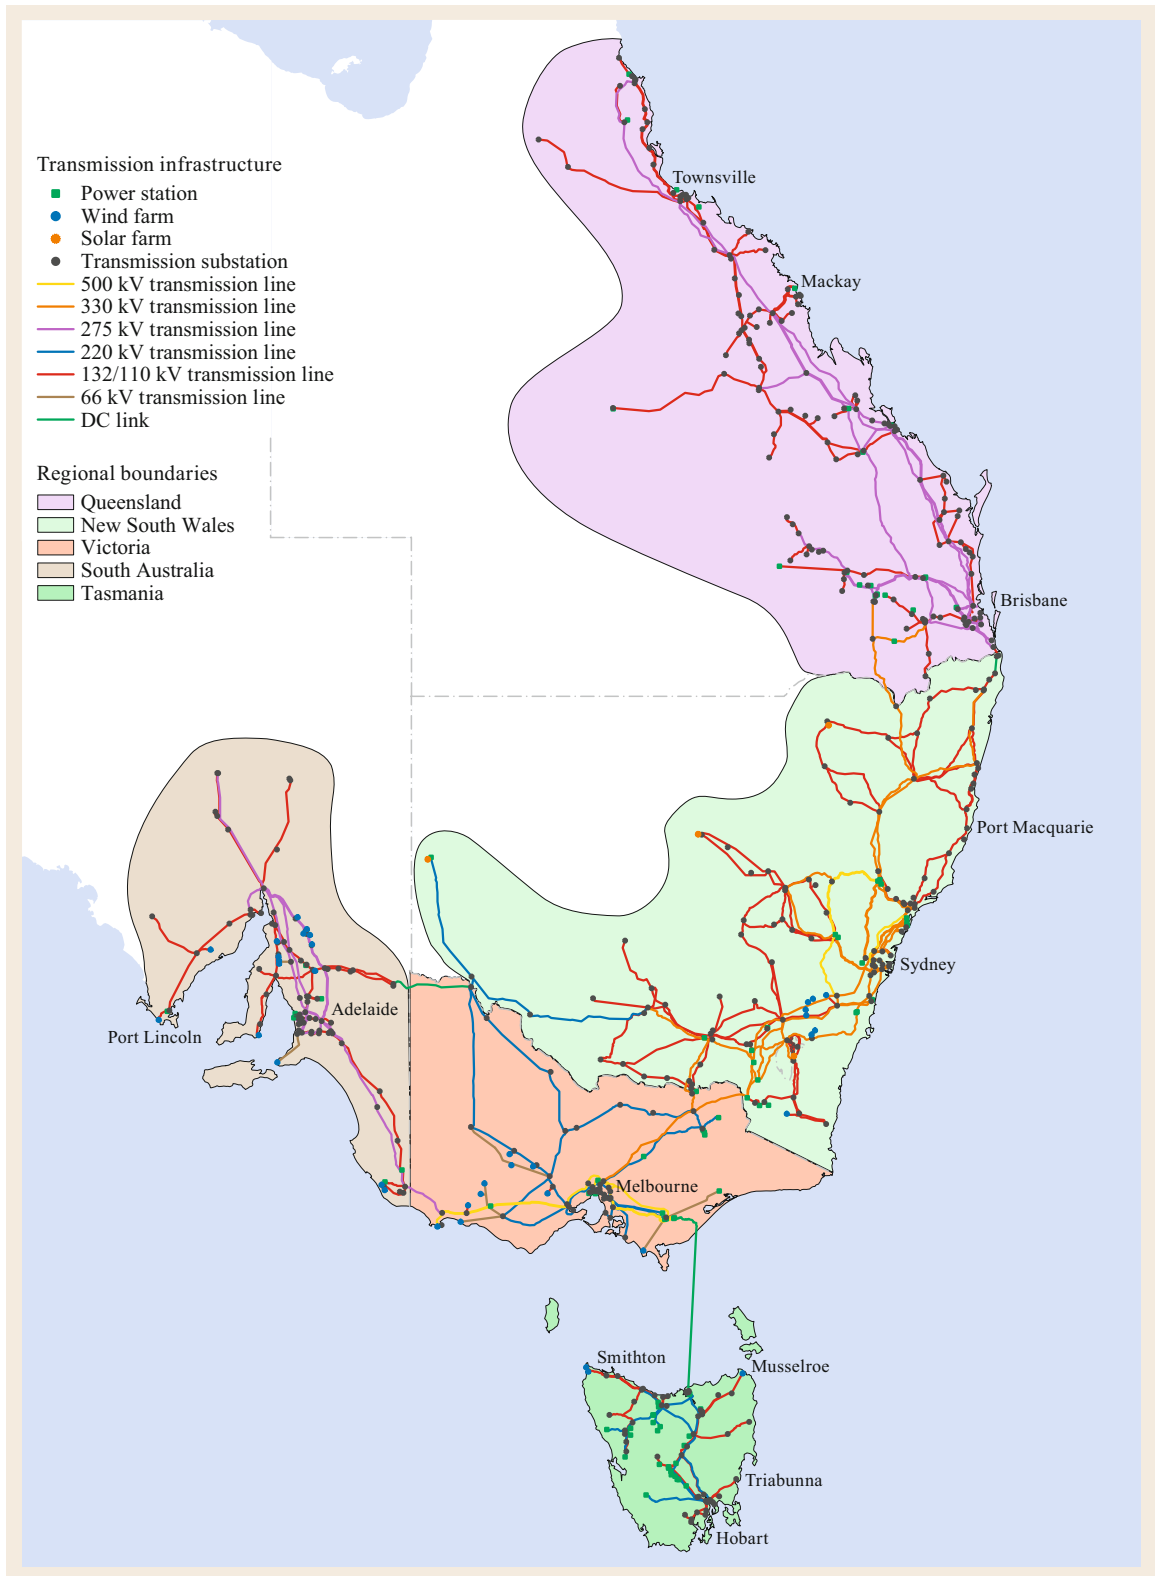

Fig. 18.5 The Australian national market (reprinted by permission from [18.8], ©AEMO 2016)

**Fig. 18.6** 30 min data for Queensland in the Australian national market: Electricity price and demand, Queensland, 01.06.2018 (reprinted by permission from [18.10], ©AEMO 2018)

Currently, every 5 min, participant bids are used to determine a dispatch price and the average of six consecutive bids is used to determine the spot price for each half hour of trade. Prices are submitted the day ahead for each trading interval but can be varied with around 10 min notice. The dispatch system assesses the demand and constraints at the start of each 5 min interval and then calculates the dispatch solution and price. The spot prices are used for financial settlement of all energy traded. From 2021 the spot price for settlement of trades will be moved to the 5 min price.

During times of generator shortage, where there may be inadequate reserves of generation to meet the customer demand, the bid prices may go very high. In order to protect the customers, the spot price is capped to nearly 15 000 \$ (AUD)/MWh (2019–20) [18.11]. This cap is periodically reviewed and is set to create incentives for sufficient capacity to meet the market reliability standard. A temporary lower cap is set if the spot price is consistently high over a rolling seven day period.

The NEM has now been in operation for nearly twenty years. It was introduced at a time of excess generation capacity in most regions followed by a period of stagnating demand coupled with a significant surge of investment in renewable generation in the form of wind and solar-PV.

As in most parts of the world, electricity is considered to be an essential commodity and loss of supply due to a major system blackout or a sudden surge in electricity prices are guaranteed to receive intense political focus. Both of these events coincided recently in Australia, mainly focused in South Australia, which experienced a statewide blackout at a time when electricity prices have been rising excessively. To some this

is an indication that the electricity market is not working very well.

On Wednesday September 28, 2016 a major storm in South Australia, including two tornadoes, brought down transmission towers and caused a number of transmission lines to trip, including the primary interconnector to the adjoining state of Victoria. During this period, a large number of voltage dips caused a number of wind farms to power down. The sudden loss of this generation, coupled with the loss of transmission lines and the input from interconnection, caused frequency drops in excess of those allowed for in the under frequency load shedding schemes. This led to a state wide blackout. At the time of the event, wind power was supplying almost half of the state's power needs.

Analysis of the event by AEMO [18.12] determined that settings on the wind farms coupled with a large number of network outages due to the storm exceeded the systems ability to deal with the resultant rapid fall in frequency. To some extent this can be remedied by modifying the wind farm settings. However, there is a longer-term issue developing due to the changes to the nature of the grid where less synchronous generation is leading to more periods with low inertia and low fault levels. This has been exacerbated by the unexpected size of withdrawal of older coal and gas fired generation. AEMO is recommending that frequency response services traditionally provided by synchronous generators should be procured from non-synchronous generators where feasible or from services such as demand response or synchronous compensators.

As a result of this blackout and the rapidly rising prices across the NEM, the government initiated a review into the future security of the NEM. This has led to the recent publication of the review report by the chief scientist in Australia, Dr. Alan Finkel. Of direct relevance to this chapter is a recommendation that all new generators must meet technical requirements to contribute to fast frequency response and system strength and that there must be a minimum level of inertia maintained within each region. In the future it recommends a move to a market based mechanism for procuring fast frequency response if there is a demonstrated benefit. It also recommends an orderly transition to a clean energy target via an emissions reduction trajectory. All large generators should provide at least three years notice of closure. The need for a strategic reserve to act as a safety net in exceptional circumstances should be considered. In addition, an integrated grid plan should be developed to promote the development of renewable energy zones. There should also be greater transparency and clarity associated with the setting of retail prices, together with stronger governance over the NEM. For consumers, issues associated

with demand management, distributed energy resources and improved energy efficiency should be examined. If adopted the review panel believes its recommendations will lead to lower costs, greater security and reliability coupled with lower emissions. We can expect there to be a number of changes to the NEM over the next few years as the industry grapples with these recommendations.

Another recommendation of that report was to establish an energy security board (ESB) comprising the three peak regulatory bodies (the Australian Energy Market Commission – the rule maker, AEMO – the System and Market Operator and the Australian Energy Regulator – the economic regulator and market surveillance entity). The ESB proposed the development of a National Energy Guarantee (NEG) which would combine a requirement to contract capacity that is able to be dispatched with a requirement to contract low emissions plant. This simultaneous requirement on retailers was in response to reliability problems that were then plaguing the market. The problems had developed as a result of uncertainty and extended policy inertia that placed future investment at risk. The lack of investment hampered responses to the operating challenges of the NEM due to the change in technology mix in the market and the withdrawal of coal fired plant. In the event,

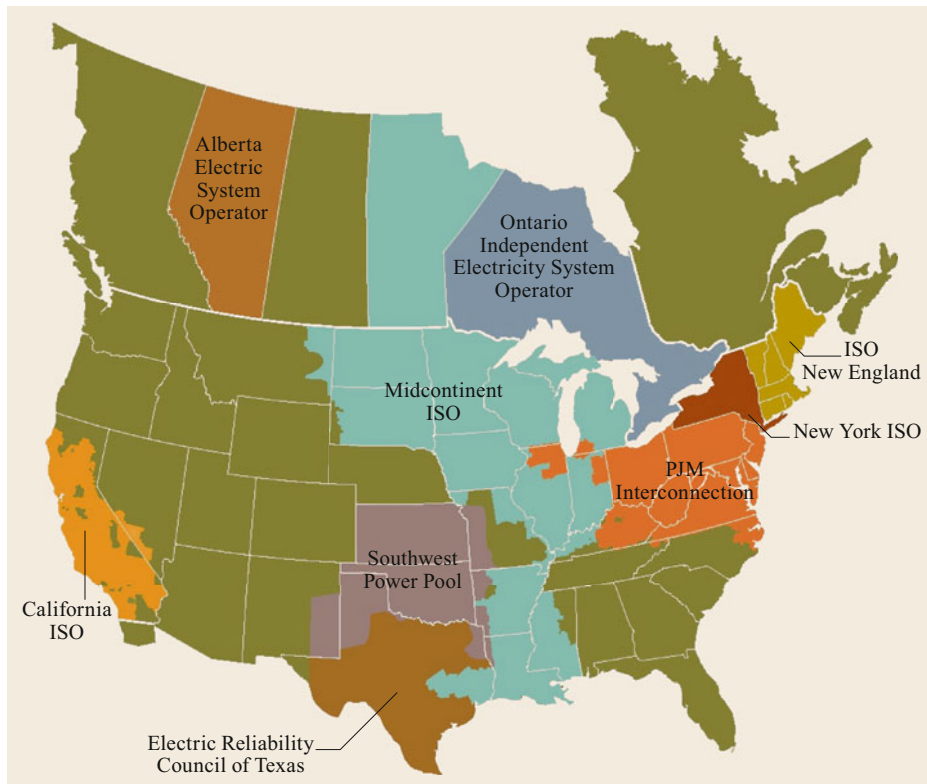

only the obligation on retailers to contract plant that could be dispatched to meet their loads, the Retailer Reliability Obligation, was implemented (in July 2019). Mechanisms to limit emissions are still being debated by governments.

### 18.5.3 North America

Market liberalization in North America began when the US federal energy regulatory commission (FERC) mandated transmission open access across the US in the late 1990s. At this time, wholesale trading was permitted between all utilities with some basic rules governing use of the transmission system; there were no rules for an electricity market.

More formal markets began to evolve by the early 2000s with rules in place to govern how the trading should occur. In parallel with this, parts of Canada also established markets to allow trading with their US neighbors.

There are now nine markets as illustrated in Fig. 18.7. Each has an independent system operator (ISO) or regional transmission operator (RTO), which manage both the market trading and the system operation. These organizations are independent of the generator or network functions.

**Fig. 18.7** Markets in North America (reprinted by permission from IRC)

### Pennsylvania, New Jersey, Maryland (PJM)

The PJM interconnected power pool was formed in 1927 and is one of the oldest and largest centrally coordinated power systems in the world. It now operates as an independent regional transmission organization operating the wholesale electricity market and managing the high voltage transmission grid. In 1997, PJM began to expand from the long standing group of eight investor owned utilities and now has members operating in all or parts of Delaware, Illinois, Indiana, Kentucky, Maryland, Michigan, New Jersey, North Carolina, Ohio, Pennsylvania, Tennessee, Virginia, West Virginia, and the district of Columbia and supplying more than 65 million people.

In 2018, PJM had an installed generation capacity of 180.086 GW with approximately 10 GW of demand side management also available [18.13, 14]. PJM operates a day ahead spot market with energy only prices and a real time (5 min) market, also with energy only prices. The major portion of electricity is traded via bilateral contracts between generators and customers or is self generated and consumed within vertically integrated utilities. There is also an ancillary services market.

FERC oversees the PJM market and loads or retailers are required to have or contract for capacity plus a reserve margin or pay a penalty. There are a number of points of congestion across PJM and a system of financial transmission rights (FTR) is applied within a number of zones that allows market participants to cover potential losses related to delivering energy to the grid. The FTR holder collects revenue based on the day ahead hourly congestion price difference across an energy path. These FTRs are traded along with the energy produced.

### California

It is informative to examine the market evolution in California, as there were some significant challenges with the initial set up. California started deregulation in March 1998 and intended to complete the transition by 2002. Before deregulation, eighty percent of electricity was supplied by three vertically integrated utilities. These were Pacific Gas and Electric (PG&E), Southern California Edison (SCE) and San Diego Gas and Electric (SDG&E). The remainder of power was supplied by a number of municipalities and public power utilities. At this time, peak demand was about 45 GW and installed generation was about 44 GW with the remainder being imported, mostly from the Pacific North West region. The generating resources are a mixture of gas, nuclear, hydroelectric, coal and renewables.

The California market was initially modeled on the one established in the UK and was established roughly

at the same time as the one in Australia. As part of the market development, vertically integrated utilities had to divest most of their generation. There was a short-term day-ahead market, which closed sixteen hours before delivery and a day of market that closed eight hours before delivery. In addition there was a real time market for imbalances 45 min before delivery and an extensive ancillary services market.

About eighty-five percent of the energy was traded through the market. In the original design, most of the energy was bilaterally traded and settled via the power exchanges. Like PJM, there were two stages; the development of the dispatch schedules a day ahead and then the on the day balancing. Initially, only one power exchange was developed, CALPX, and so there was only one day-ahead schedule.

The day-ahead schedule was driven by the planned dispatch and usage of participants, which were lodged with CALPX – based on bilateral agreements and adjustments bid into the day-ahead process. A feasible solution was developed, with a day-ahead price, which was given to the operator. On the day the market ran, the programmed schedule was varied to match changes in load and generation.

There was a cap on the price for the day-ahead market, which was to be the main price. While there was no formal limitation on financial products for the balancing pool, the existence of the power exchanges meant that risk management was not required for the (expected) low amounts of energy to be settled in the pool.

A further complication was that there was a separation of the physical and market functions. An independent system operator (ISO) was established to deal with the actual technical management of the power system and generation dispatch and to financially deal with occasional imbalances in the real time market. The market functions were incorporated into a power exchange, which dealt with the actual financial energy transactions. The market only traded in energy and not capacity and there was a cap on the market price.

Concerns about pollution in California had increased the reliance on power imports from other states but the transmission infrastructure had not kept pace with this leading to transmission congestion with other states and within the state. Customers were allowed full retail choice from day one, however, some of the investments in generation were considered uneconomic in a competitive environment and the retail rates were frozen until the stranded assets were paid off. The general expectation was that lower prices would eventuate over time, particularly due to the entry of new high efficiency gas turbines. The pool was designed to be compulsory, where generators lodged hourly bids to meet demand at prices of their choosing and a common

pool price was set by the last generator to be loaded in that hour.

There were a number of issues worth noting which would later prove to be of concern. None of the markets were physically binding. Ultimately, real time dispatch compliance was purely voluntary which resulted in difficulty maintaining system stability and reliability. There was a lack of a single unambiguous price for electricity to be used for hedging and investment decisions. There was some concern about the use of the fixed cap in that it may have sent adverse signals to participants for investment decisions and could also act as a target for bidders when prices are on the rise. There were long lead times on approvals for new transmission lines and generators.

California is a summer peaking area and in the 1998 and 1999 summers, temperatures were typically average. There was above average runoff into the hydroelectric dams of the Pacific North West and California was allowed to import low cost hydropower from these areas. The three major utilities PG&E, SCE and SDG&E were starting to divest their generators but still owned most of them. Natural gas prices were low to moderate, averaging around 2 \$US/GJ. Wholesale electricity prices generally remained in the 20–30 \$US/MWh range. Electricity pool prices were well below the levels of wholesale prices previously embedded into the tariffs that had been frozen for the major utilities. These utilities were therefore quite profitable at this time and were able to pay off the stranded asset charges more quickly than expected.

All this changed in the summer of 2000. Average temperatures were higher than normal with several heat waves. Water inflows in the Pacific North West returned to their long-term averages and reduced the amount of hydropower available. Natural gas prices increased to 10 \$US/GJ, a five fold increase and gas transport capacity reached its limits. In California, all gas fired generators needed to purchase nitrous oxide emission credits when operating and the price of those credits increased. The marginal cost of operation of an open cycle gas turbine exceeded 150 \$US/MWh. As a result of all these coincident events, price spikes began to occur in May and by June prices had reached record levels.

In reaction to these events, the California ISO lowered its wholesale price cap from 750 to 500 \$US/MWh and then a month later to 250 \$US/MWh. However, there was no noticeable effect on the pool prices. At this time, SDG&E had moved out of the rate freeze. The average monthly residential bill in San Diego went from 40 to 68 and then to 130 \$US from June to July 2000—more than trebling over the summer months. General price levels throughout the western states, caused ma-

nor energy intensive industries, including most of the aluminum smelters in the Pacific North West, to curtail output or cease production.

Not surprisingly, there was considerable anger amongst customers who forced the state government to cap residential prices around pre existing levels. Price caps were also implemented at the wholesale level leading to almost 12 billion \$US of costs that retailers were unable to recover from customers. These retailers were forced into bankruptcy (or would have been without government support) while owners of generators reported record profits.

A number of factors in the design of the market can be identified as contributing to the surge in prices. There was limited demand side response. The rate freeze prior to the sudden increase in prices had given no signal to conserve energy or in fact develop strategies to manage varying prices. There was a sudden increase in power production costs coincident with an unexpected increase in demand due to unusually high temperatures. The fact that the three major utilities had to buy and sell all their energy needs through the California Power Exchange, coupled with restrictions on their ability to forward contract, removed their ability to mitigate price volatility. There was also withdrawal of large capacity from the market close to days of high prices indicating a possible abuse of market power. This last issue was a practice extensively used by Enron, an aggressive market trader at the time.

Traders looked for ways to maximize profits within a market structure that was new, complex and had little oversight or governance. Enron found a way to play the California power exchange off against the California ISO. The ISO was only meant to deal with occasional imbalances in a real time market. Daily schedules of load and generation were expected to be more or less equal. However, Enron and others would deliberately overstate expected customer loads, leading the ISO to pay a premium for delivering more power and a premium for removing load from the grid.

Ultimately Enron filed for bankruptcy in December 2001 becoming the largest bankruptcy in US history at that time. This was driven by illegal corporate practices and most of their top executives were tried for fraud after it was revealed that Enron's earnings had been overstated by hundreds of millions of dollars. The risks inherent in the market design had ultimately captured one of its most aggressive players who tried to hide their financial position with the hope that they could trade their way out of trouble.

A number of changes were put in place to address the problems. There was a move from compulsory spot market trading to bilateral trading as used in the other electricity markets in the US. FERC was given the au-

thority to investigate abuse of market power where any bids over 150 \$US/MWh need to be justified and may be investigated. New generation was fast tracked. The oversight of the California ISO was changed from one representing stakeholder interests to an expert panel appointed by the governor. Finally, the California power exchange was dissolved and the market and operational roles were combined into the ISO.

#### 18.5.4 Brazil Market Overview

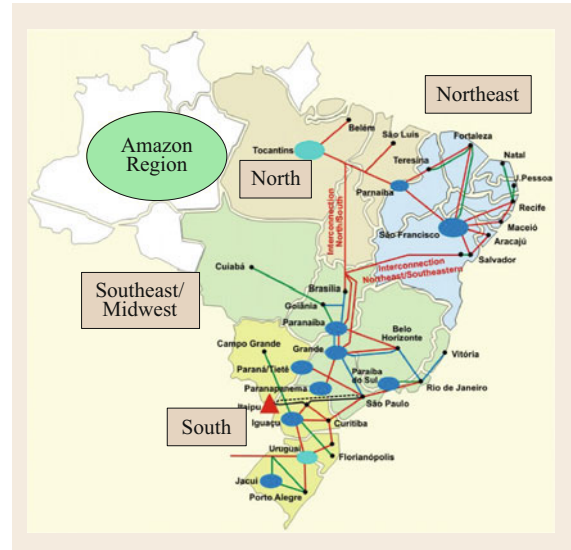

Brazil has the largest electricity market in South America with a generation capacity of more than 137 GW, dominated by hydro power with most of the remainder supplied by fossil fuels, biomass and small amounts of wind and solar. There is limited interconnection with neighboring countries. Unbundling of generation, transmission, distribution and retailing occurred in the 1990s, although generators and retailers may be integrated. Third party access to the transmission is available to all parties on commercial terms.

There are two market environments. The first requires bilateral energy contracts to be established between generators and retailers that are considered to have captive customers. These are conducted by auctions in a regulated environment. The second allows unregulated contracts to be established between generators, uncontracted customers (generally if the load is greater than 3 MW), retailers and traders.

Generators, through long and medium term contracts, must supply 100% of the total demand of each retailer. A spot market allows for short term contracts to cover the difference between longer term contracts and real demand.

Auctions for new and existing generation capacity are carried out annually with new generation offered long term contracts. The regulator sets a ceiling price for these auctions.

There is a separate market operator and system operator. The market operator manages the long term and spot markets, with the marginal cost for the spot market

**Fig. 18.8** The Brazilian subsystems and regions (reprinted by permission from [18.4], ©CIGRE 2015)

provided by the system operator used as a reference for the spot market. The system operator is responsible for generation dispatch, power balance management and the coordination of ancillary services. The regulator oversees both operators.

There are four large subsystems as shown in Fig. 18.8 and there is a procedure to deal with transmission congestion within and between these regions where this impacts on lowest cost dispatch and contractual arrangements.

There are some specific market challenges that are currently being reviewed. These include the timely development of adequate transmission for sufficient generator competition and cross border flows. This is coupled with the growing interconnection of renewable energy sources, particularly when these occur as distributed generation that is not under the control and monitoring of the system operator.

## 18.6 Regulation

This section will examine the role of regulation in the operation of power systems.

### 18.6.1 Electricity as an Essential Service

Electricity is unique in that it must be available the instant it is required and must be consumed or stored the instant it is produced. Failure to meet these require-

ments results in a disruption to the power system where loads or generators may be tripped and, in the extreme, major power blackouts may occur. There have been examples of these blackouts in virtually all developed countries. They often lead to front-page news and government led inquiries.

There is no doubt that electricity is now considered an essential service in all developed economies. Fre-

quent loss of power or loss of power to customers for extended periods can lead to significant economic loss and have major political implications. Customers rely on electricity in almost every aspect of daily life from lighting and air conditioning through to the operation of most appliances as well as most aspects of manufacturing. It is becoming more and more important for transport and electric vehicles are predicted to overtake petrol and diesel fuelled vehicles as the preferred form of transport within the next twenty years. A number of countries have announced plans to phase out petrol and diesel vehicles including France, Germany, UK, China, India and Norway. While the timing for some countries is still being finalized, some have already declared a target year. For example, France has recently announced that it will outlaw the sale of petrol or diesel vehicles by 2040 [18.15]. China is currently studying the timing of a move to phase out fossil fuel vehicles and has commenced using incentives and subsidies to guide this outcome. It is currently the world's largest manufacturer of electric vehicles [18.16]. This has been driven partly by the growing smog problem in the major cities, partly by industrial policy and by commitments to acting on climate change.

Electric vehicles and a growing number of appliances rely on battery power as their energy source. While this is generally not the case at the moment, there is the opportunity to control the timing of charging of these devices so that the power demand is aligned to the capacity of the power system. There is also the possibility to use the electric vehicles as a source of ancillary services to the electricity system in the future. Accommodation of large scale charging of electric vehicles will require changes to industry operation practices and installed infrastructure capacity. A recent study by Vector in New Zealand estimates that power demand per dwelling could increase between 100% for slow trickle charging and 2000% for rapid charging [18.17]. Minimization of peak power increases and optimization of infrastructure usage will require a range of market design changes coupled with effective regulatory controls on both the utilities and the electric vehicle industry.

### 18.6.2 Vertical Integration and Disaggregation

As previously discussed, power system industry structures have evolved to take advantage of economies of scale, with large interconnected transmission systems allowing the shared use of generation reserves and larger, more efficient generators. In many cases this has resulted in vertically integrated business structures where the utility generates, transmits, distributes and sells the electricity. As discussed below, the introduc-

tion of competition between interconnected generators and also between retailers has placed more attention on the interconnecting networks. In some cases this has led to rules that financially ring fence the networks from the rest of the business. In others it has led to complete separation of the businesses.

### 18.6.3 Transmission and Distribution as Natural Monopolies

The transmission and distribution or network components of the utilities are considered natural monopolies as it is not economic to duplicate these components, and even if it were, it would be unlikely to be publicly or environmentally acceptable. As a result, the networks are in a privileged position and able to charge monopoly rents for the use of their services. It could be argued that too high a charge for service would result in the end customer going elsewhere for their power. However, this would almost certainly be at a much higher incremental cost and result in inefficient use of assets. Governments are well aware of this problem and in most countries have installed a regulator to oversee the investment in new assets and the allowed return on any investment in those assets. In other countries such as Brazil and Chile, competitive auctions are used to try to ensure the lowest cost provision, operation and maintenance of transmission infrastructure.

### 18.6.4 Economic Regulation of Monopolies

It is difficult for an external party to fully understand the internal costs of a utility or the link between investment and the quality of service provision. Attempts to build this understanding could lead to extensive duplication of resources, add significant costs to the process of oversight and therefore limit the benefits of regulation. The overall aim of regulation is to drive the business to deliver the desired quality of service at the lowest cost that is sustainable over the long term. Regulators therefore tend to focus on the outputs in terms of cost of service and delivery against prescribed service standards. At the simplest level, this may be a monitoring of the prices charged for the service, any annual increases relative to inflation and the performance against agreed service level targets. In addition, benchmarking with other similar organizations may be used to assess their relative efficiency.

While this may result in a lower cost of regulation, there may be a concern that the initial prices at the start of the regulation process may be too high. While benchmarking can help here, it is difficult to ensure a level playing field when comparing organizations. The historical timing of large investments and past decisions

on technical issues are linked to the perspective on future conditions at the time the investment decisions were made. For example, an expectation of a high load growth may lead to a choice of a higher standard voltage level and the use of larger standard transformers. Accurate load forecasting is notoriously difficult and this may lead to the investment appearing inappropriate in hindsight. In addition, utilities vary in size and small utilities have fewer opportunities to enjoy the benefits of economies of scale.

Services are normally classified as regulated or non-regulated services. Regulated services are those not subject to adequate competition to drive lower prices and are normally classed as monopoly services. Conversely non-regulated services are those that are subject to competition (say by means of an auction) or can be provided by a number of entities. Classification of these services can be complicated further when the utility is vertically integrated. In this case it is possible for the utility to load additional costs into the network part of the business, which has the added benefit of allowing the utility to charge lower prices or make larger profits in the unregulated generation or network parts of the business. To some extent this can be overcome by requiring financial ring fencing of the regulated network components of the business but this still carries the risk associated with the regulator having less information on the internal workings of the business. In a number of cases, this has led to a requirement for the vertically integrated business to sell its network assets.

### 18.6.5 Rate of Return Regulation

For this form of regulation, the regulator scrutinizes the utility investment to ensure that the investment is required and efficient. It then allows sufficient revenue to ensure the utility fully recovers its costs. This form of investment is popular with investors as it allows a consistent return despite fluctuations in the economy. However, it does not provide strong incentives for the utility to operate efficiently.

### 18.6.6 Price Control

To reflect the information asymmetry between the regulator and the utility, regulators often choose to use incentives to drive the business to improve its efficiency. In this case, if the utility spends less than forecast for the regulatory period, it will be allowed to keep a portion of the difference between actual and forecast revenue as a reward. Conversely, if the utility spends more than forecast, a portion of the difference between actual and forecast revenue will be applied as a penalty. In both cases, this will then be taken into account when setting

desired revenue and consequent price settings for the next regulatory period.

### 18.6.7 Revenue Determination

A more intrusive regulatory model is to require the network business to propose and justify its required revenue for a regulatory period that could typically be five years. This revenue would be determined based on the total anticipated efficient capital, operating and maintenance costs over the regulatory period together with asset depreciation, tax liabilities and a commercial return on the capital investment. To determine the capital costs, an asset valuation of all existing and proposed new primary and secondary assets would be required. Then a rate of return on this capital would need to be proposed based on identified risks and known costs of capital. This would typically be based on allowing a reasonable return on equity to reflect efficient equity finance costs and a return on debt that reflects the costs of regularly sourcing debt within the regulatory period. As part of the revenue determination model, revenue cap or price caps are usually applied for the regulatory period to apply incentives to the utilities and provide price certainty.

### 18.6.8 Revenue Cap

Revenue cap regulation fixes the revenue that the utility can receive regardless of actual output or demand. Prices are set based on the allowed revenue and forecast electricity consumption but if actual consumption differs from forecast consumption, the allowed revenue is corrected in the following year. There is therefore no incentive to incorrectly forecast the expected consumption. In this model, prices may be more volatile if demand is less predictable. It is also possible to apply an incentive in the form of  $CPI - X$ , where  $CPI$  is the general inflation rate in the economy and  $X$  is an estimation of the utility's expected efficiency gains. This provides a very strong incentive to find efficiency gains.

### 18.6.9 Price Cap

For price cap regulation, prices are regulated rather than the revenue. The initial starting price is set and then it is adjusted each year by  $CPI - X$  as described for revenue cap regulation. If electricity consumption rises in the regulatory period, revenue will increase and if it falls, revenue will reduce. This should encourage the utility to adjust the timing of investments to suit changing load expectations and to drive efficiencies harder when consumption falls. On the other hand the  $X$  is known in

advance of the regulatory period, which allows the utility to plan and deliver efficiencies over the period.

In reality there may be limited opportunities to take action on investment timing, as is the case for transmission, which usually has long lead-time projects. It is therefore more common to use price cap regulation for distribution investments, as these are usually more short term.

### 18.6.10 Pricing Methods

The subject of electricity pricing is complex and varies from country to country. This section will provide a high level overview of this topic. More detailed information can be found in the reference documents referred to in Sect. 18.7.

Ideally pricing should be efficient in that it recovers all the required revenue of the utilities while providing signals to customers that support the efficient use of electricity. Unfortunately, many practical issues may interfere to tarnish this objective. Governments are well aware that any large increase in electricity prices can cause headaches for them and therefore often place controls on the actual prices that can be applied. In some cases the government will subsidize the end price in order to deliver on social issues. In addition, ambitious renewable energy targets have been set by governments to combat climate change. To help increase the rate of installation of the renewable generators, subsidies have been applied either as payments for the surplus energy generated or by direct government payments that effectively reduce the capital cost of the renewable generator installation. As the efficiency of both the technologies involved and the production processes have improved and significant economies of scale have been achieved, the level of subsidy has been reduced.

The cost components of the pricing are driven by the wholesale prices from the generators, the network prices from the transmission and distribution companies and by a charge from the retailers. All of the participants will need to recover fixed and variable costs. However, accurately modeling the end charges on each of the total fixed and total variable costs will not necessarily produce the ideal result. For example, one could argue that the majority of costs incurred by a network business will be fixed costs as they are either incurred as a result of capital investment in the infrastructure or maintenance costs incurred to support the infrastructure. Once the investment decisions are made, neither of these costs varies over time. Network costs generally make up a proportion of between 30 and 50% of total costs.

Fossil-fuelled generators will have a higher proportion of variable costs. While they still need to recover

the capital costs of the generator, the dominant cost will be the fuel. In the case of renewable generators such as wind and solar, the majority of the costs are fixed as the fuel is free leaving only maintenance as a variable cost. However, maintenance costs can be substantial for offshore wind turbines. Hydro is also dominated by fixed costs and nuclear is mostly a fixed cost, as it must continue to operate regardless of the demand from the end customer. If these costs were all passed through directly to the end consumer, the main component would be a fixed charge. There would then only be a small price signal to the end customer to vary their consumption at various times of the day.

variable prices can be used to encourage customers to apply demand management to reduce the peaks and troughs of daily load consumption. This should reduce the need for investment in new generation and network capacity as well as improve the utilization of existing infrastructure. Despite the difficulties in accurately providing cost reflective pricing, variability in pricing is a useful tool to encourage customer behavior that will lower overall costs.

Generators would prefer to operate at their maximum output whenever they are available, particularly in the case of base load generators such as coal, nuclear and combined cycle gas turbines. Open cycle gas turbines and large storage hydro generators are generally more flexible but are still keen to maximize their revenue, whereas solar and wind want to operate at their maximum possible output whenever the sun shines or the wind blows. In a market context, these parties are likely to price their output to ensure optimum output. This price will also be influenced by any longer term bilateral or hedging contracts that are in place.

End customers, on the other hand would like the electricity to be available at all times of the day and night at 100% reliability. They are however open to price signaling and, in many cases, would be prepared to vary their consumption to reduce their overall costs. This is becoming more and more possible with the advent of new technologies such as smart metering and remote appliance switching. Many household appliances are now available with batteries and some industries may be prepared to reduce demand occasionally for a fee.

Tariffs are determined by considering each class of customer. For example, domestic and other low use customers require more infrastructure and their peak loads are concentrated at times of the day that match system peak loads. On the other hand, industrial loads are generally fed by less network infrastructure and consume a more uniform load throughout the day. They can therefore be charged a lower tariff. Usually the tariff will have demand (\$/kW) and energy (c/kWh) compo-

nents with the demand charge higher for more peaky loads. Where meters have suitable capability, time of use tariffs are used to try to influence demand and reduce the overall system peak or to shift demand to times when renewable energy is abundant. Overall the setting of tariffs is partly political and social and is not an exact science. However, as technology improves, there are increasing opportunities to provide customers with more choice about the reliability and cost of their electricity and suppliers with a greater understanding of the impact of price signals.

Electricity pricing is set to try to achieve a balance between adequate signaling of the generator's desired mode of operation and meeting the end customer's needs for electricity availability at the best possible price. This applies regardless of whether the generators signal their requirements through a market structure or as regulated entities. Governments often intervene in the price setting to meet social objectives, particularly at the domestic customer level. For example, they may apply a uniform tariff across the entire customer supply area so that customers in the central business district pay the same price as those in remote country areas despite the fact that it costs much more to supply the remote customers. If the remote customers were to be charged based on the real costs to supply them they may choose an alternative such as a stand-alone supply.

The approach to pricing across the world varies depending on a range of factors, particularly related to the level of power industry restructuring. CIGRE Working Group C5.16 [18.18] has surveyed a number of countries to determine the types of costs that impact on end user billing and the methods and trends for practically allocating costs in both regulated and competitive market environments. The survey concluded that the main electricity cost drivers are a mix of fixed costs, capacity costs and variable energy costs. The retail billing components therefore include a balanced mix of fixed charges for common shared customer costs, demand charges for capacity, energy charges for fuel and other operating costs and policy charges for taxes and other externally imposed costs. The survey revealed that the extent of using demand charges varied widely, driven to some extent by the desire for rate simplicity, metering limitations and historical perspectives on electric service.

Large scale embedded generation has a significant impact on the use of the network. When combined with storage and smart meter enabled load control, the use of the network can be reduced to zero for extended periods. This has significant implications for transmission and distribution pricing. Most domestic electricity consumption is measured in kilowatt-hours and virtually all network costs are fixed, based on a return

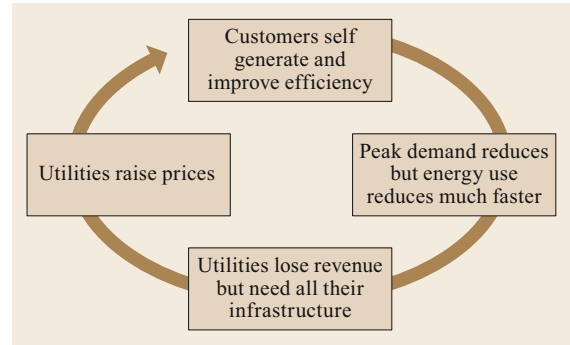

Fig. 18.9 The death spiral

on the large capital investment and operating costs to operate and maintain the infrastructure regardless of the energy that flows through the system. To maintain the required revenue to service the network costs when energy consumption is falling requires the price on a unit of energy to be increased. This may lead to more customers investing in distributed generation with consequent higher energy delivery prices. This leads to what has been termed a *death spiral*, where the rising costs increase exponentially as the energy reduces (Fig. 18.9). Ultimately this could lead to prices for connection to the network being so high that no one can afford to connect.

Rapidly increasing prices is one possibility and will depend on the responses of the network utilities and the development of new technologies. While significant installations of roof top solar are likely to continue, helping to exacerbate the above problem, large-scale renewable generators are still more economic than small-scale generators and these will require transmission lines to bring this energy from remote locations to load centers. This may encourage greater use of the network resulting in lower per kWh customer charges. In addition, individual houses that have surplus generation may want to trade this with others in the neighborhood. This will again require greater use of the network and will exert downward pressure on network prices. Electric vehicles and electrification of heating are also likely to increase demand on the networks. Ideally incentives will be placed on this increasing load to minimize the impact on peak loads. A key factor will relate to how the pricing structures adapt and how the customers respond to these changing opportunities.

### 18.6.11 Performance Reporting

While keeping the end price of electricity as low as sustainably possible is a key focus of regulators, it is also important to ensure technical performance is maintained or, in some cases, improved. One of the ways that

regulators can keep tabs on the relative performance of monopoly network businesses is to require performance reporting. As discussed earlier there may be some difficulties comparing different organizations, particularly if they have different histories and current environments. However, comparisons will provide some useful information and the tracking of performance of a particular utility from one year to the next is certainly an effective model.

Utilities will generally use a number of both financial and technical performance indicators to help drive performance improvement in the organization. A number of these are likely to end up in the utility annual report as direct feedback to staff, stakeholders and shareholders. The regulator may use the annual report or even ask the utility to nominate certain indicators. They may also have additional requirements, especially where there is required ring fencing of monopoly components within the organization.

Regulators may also use a financial reward and penalty scheme to provide an incentive for the utility to improve performance. For this to work well, it is important to ensure that performance targets are reasonable and the rewards are sufficient without being excessive. Incentives may also be provided to drive innovation. Network utilities are necessarily conservative in their operations as large scale extended black outs can be catastrophic for both the utility and the country. With this rider, it is important that the regulatory controls do not stifle innovation, which can improve performance or reduce costs. In some cases, a value of loss of load may be used to justify network investments. This is often based on survey results to determine the value of the electricity to the customer at a particular time of day. This perceived value would tend to vary depending on how recently the respondents have experienced a black-out. Regulators therefore tend to prefer a lower value for this, although it is still usually significantly greater than the normal energy charge and will vary depending on, amongst other things, whether the supplied area is the central business district, a commercial area or a suburban domestic load area. Smart meters and dynamic pricing may also provide useful data for the customer electricity valuation adopted by the regulator.

### 18.6.12 Regulated Versus Non-Regulated Services

Within the transmission or distribution business there may be services that the utility provides that are not obligatory and can be provided on a contestable basis from a range of suppliers. These are not regulated but need to be ring fenced from the regulated business to ensure no cross subsidies. In some cases, transmission

and distribution connections are not part of the regulated income and the connection can be either built by the user in accordance with prescribed standards or be subject to a separate competitive tender.

Similarly a utility may choose to build a transmission interconnector as an unregulated asset or merchant line. In this case, it would not have a regulated income but derive its revenue from users that wish to utilize the asset on a pay for service basis. These kind of interconnectors are not common but have generally been used to link power systems where the price in one system is different to the price in the adjacent system. The transmission business then leverages this difference to fund the cost of the interconnector. These types of interconnector are less popular due to the much higher risks involved as the price differentials between the adjacent systems can vary over time and investors tend to prefer the long term certainty of a regulated return on the asset.

### 18.6.13 Treatment of Losses

Electricity is produced and used at many different locations and there are product losses as it is transported to the loads. Generation must make up these losses at all times, which, on a typical system, tend to be on average in the order of four to five percent. The value of these losses will vary from one location to another, depending on the distance and transmission or distribution voltage. These losses have an economic and environmental cost. Network businesses may have an incentive within their revenue or price control to reduce the losses. However, these are not always under their control. As dispatch of the generators in different locations changes so too will the current flows in the network and the losses will increase or decrease with the square of the current. This may occur in relation to large generators connected at transmission level or for distributed generators such as rooftop solar. In some countries the penetration of rooftop solar is so significant that at some times of the day the current flow reverses away from the load back into the transmission system. A useful discussion on the management of network losses can be found in a recently published CIGRE reference paper [18.19].

There are some losses that can be controlled by the network businesses but for this to be meaningful there needs to be accurate metering at the points of connection of loads or generators. While the end customer load will have tariff quality metering, the generators may not. Certainly, many rooftop solar systems will not currently have metering and their input will simply be seen by the customer tariff metering as a reduction in load.

Where the metering issue can be resolved, there may still be issues such as electricity theft and the re-

duced accuracy of meters as they age to deal with, although this latter aspect is less of an issue for digital meters. It may therefore be more practical to provide a reward for the utility that reduces losses when it provides specific evidence of the cost benefit for the particular location where the action has been taken. For example a transmission line voltage could be increased or a high loss transformer could be replaced with a low loss transformer.

#### 18.6.14 Metering/Smart Meters

As mentioned in the above section on losses, tariff meters provide a very important role in the management of the power system. They ensure that customers are paying the correct amount for their service and that the utilities receive the required recompense for the service they provide.

In recent times, smart meters have been introduced into an increasing number of countries. A smart meter may vary in complexity but fundamentally it consists of a tariff meter that records electricity consumption in intervals of one hour or less and is able to communicate with a central control system. In some cases the meters have been introduced to combat theft and in other cases for a range of technical solutions that enable customers to manage their load and reduce their cost based on price signals provided by the utility.

For example there may be a shortage of generation resulting in a very high wholesale price. The smart meter could be sent a signal from the retailer, the supplier or the load aggregator asking for load to be reduced. This would normally be based on the contractual relationship between the company and the customer. One input to the company's decision-making could be scarcity price signals from a power exchange or congestion price signals from a system operator. The smart meter could then send a signal to various appliances either switching them off or reducing their load. One of these could be a non essential load such as a pool pump or an air conditioner that could be switched to run with a fan only for say 15 min in the hour. The customer would receive a reduced tariff to compensate for the inconvenience of the power reduction. Various appliances can also be set in advance to operate at times of low demand. Ultimately, with the use of batteries at the load point, it would be possible to match the load to the ideal generation profile. In the case of wind and solar, this would be when the sun shines or the wind blows. While some countries have taken major steps to roll out smart meters to all or most customers, the technology is still considered expensive by some, especially if it requires the replacement of perfectly good meters that are already installed at the load points. Evaluating the full

costs and benefits is complex and the subsequent large capital investment may prove difficult to justify without some overriding government policy directive.

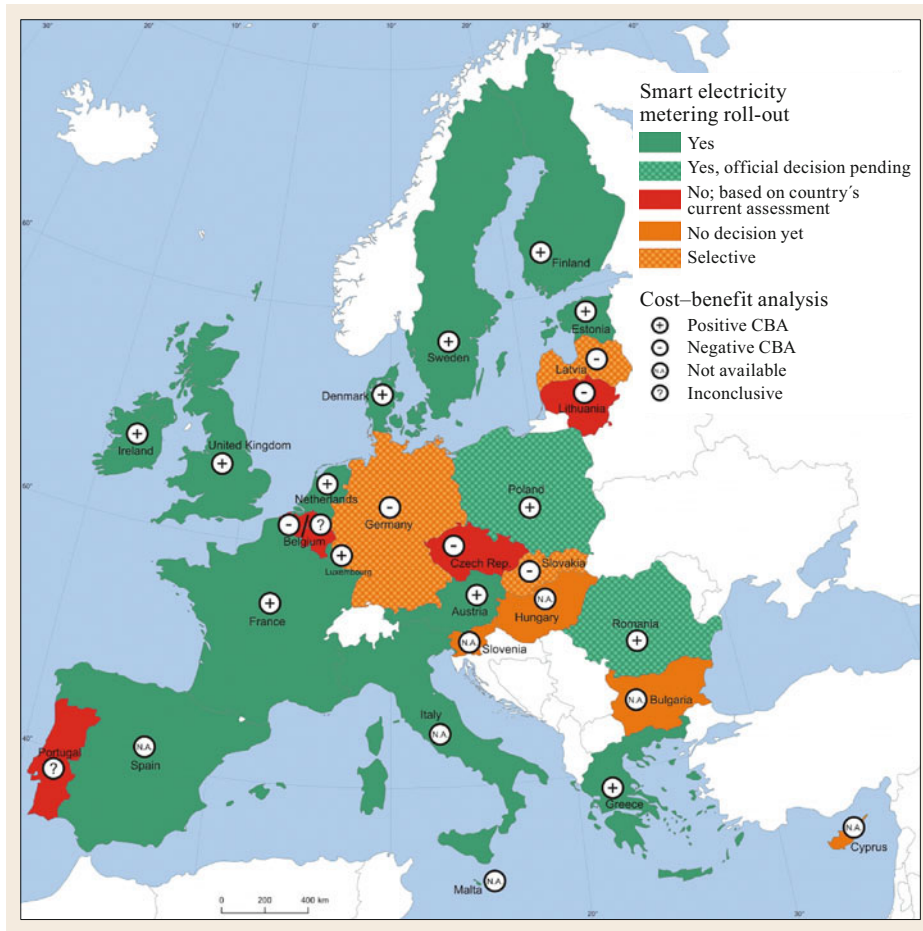

The European Commission has directed that 80% of customers should have smart meters by 2020, providing an incentive for member states. Some countries (e.g., Italy and Spain) had already rolled out smart meters and other countries are well on the way (e.g., France and the Netherlands) but others are well behind (e.g., UK and Germany) [18.20]. Figure 18.10 shows the current (2017) responses from member countries, as reported by the EC Joint Research Center Website.

Other parts of the world have also made progress with the installation of smart meters. For example, in Australia, Victoria has achieved a 96% rollout and there has also been a significant rollout in South Australia and New South Wales. A national electricity market rule now requires smart meters for new and replacement meters. In China more than 400 million meters had been rolled out by 2017 whereas in other parts of the world such as Eastern Europe, Latin America, the Middle East and Africa, the rollout has been quite limited [18.22].

#### 18.6.15 Technical Regulation

In parallel with economic regulation it is also desirable to monitor the technical aspects to ensure the power system delivers the required reliability and quality. Instantaneous matching of supply and demand is required if the power system is to meet the required standards. It must also withstand sudden disturbances such as system faults and deliver electricity within prescribed bands of voltage and frequency. In addition, interference such as harmonic distortion must be managed to ensure customer equipment does not mal-operate or become damaged. In order to manage these impacts, power systems are designed with a level of redundancy, installed equipment must meet prescribed standards and steps are taken to reduce power quality issues such as harmonic distortion to within prescribed limits. The level of reliability and quality is usually chosen to meet customer needs and will usually vary from major city central business districts where high levels of redundancy and power quality are required to remote rural loads, which would normally have lower standards. The chosen standards are also limited by economic limitations.

It is also important that customers that connect to the network meet required standards as they may impact on other customers that are connected. These standards are designed to assist the system and network operators to meet system standards. For example, the sudden switching of a large load onto a network that is not rated to take it may result in large unacceptable voltage swings for nearby customers and in the extreme, may cause the

**Fig. 18.10** Smart metering rollout (EC Joint Research Centre, 2017) [18.21]

supply circuit to trip causing loss of supply to other customers on the same feeder. There are also safety standards that must be met to ensure public safety.

While the power systems are designed and built to meet the prescribed standards, they must also be operated within defined rules to ensure the required power system performance is delivered. Prior to the deregulation of the electricity industry and the introduction of electricity markets, many of the technical issues were managed internally by the various electricity businesses. Open competition amongst generators and amongst retailers has meant that the technical rules and standards are required to be public. This ensures clear accountability and avoids accusations of bias, particularly if vertically integrated utilities are involved.

### 18.6.16 Technical Rules

Published technical rules or grid codes now governs many utilities. These documents may have been produced by utilities but they will normally have been

subject to review and public consultation by regulators prior to publication. It is beyond the scope of this chapter to go into detail on the technical rules; however, the section on regulation models around the world will highlight some of the differences between countries and provide references to the various documents that are applicable in those countries.

A recent CIGRE publication on the review of drivers for transmission investment decisions [18.23] has established that the main reason for expansion or new build projects is security of supply followed by new connections, generation integration and economically motivated projects. The report also noted that compliance with technical planning criteria is the primary determinant of reinforcement and that most transmission investments are made on a long-term basis. In a number of cases, changes to planning criteria are being made to reflect the changing industry, particularly in relation to integration of high levels of renewable energy sources. In addition, changes are also being made to accommodate new technology or industry wide prac-

tices. In many cases, economic principles such as the cost of unserved energy and societal impacts are considered as part of the review of the planning criteria.

### 18.6.17 Service Standards

The earlier section on performance reporting referred to the technical performance indicators that regulators monitor to ensure that cost cutting does not result in poor service outcomes for customers. This requires the relevant utility to publish its performance against the various service standards. These service standards may relate to the frequency of interruptions to supply or the duration of the outages.

### 18.6.18 Environmental Regulation

In addition to all the technical requirements necessary to deliver a sustainably reliable power supply at a reasonable cost, many countries have imposed additional environmental requirements on the electricity utilities and their customers. These may be at a local level, say for an individual town, a region or state level, an individual country or for an entire continent. While the various political leaders may agree these at a high level, the detailed interpretation and implementation of the requirements is left to individual areas. In most cases, satisfying these additional requirements will add costs to the delivery and consumption of power. While some attempts have been made to quantify the costs of inaction on these issues, they are not yet universally accepted.

### 18.6.19 Climate Change

Climate change is an issue that has maintained considerable global attention for a number of years. In December 2015, 195 countries agreed to a global climate deal that is legally binding [18.24]. This agreement aims to limit the increase in CO<sub>2</sub> emissions from those countries to a level that scenarios indicate would restrain the increase in average global temperatures to significantly less than 2 °C above pre industrial levels and ideally as low as 1.5 °C above. While the global commitment has remained resolute for most signatories, at the time of writing the US appears to be reducing some of the previously committed actions where it believes they will have a negative impact on its economy [18.25] and, it is reported that many countries are expected to fail to meet their commitments.

The actions taken by countries in relation to these climate change commitments will directly impact on the electricity sector, particularly where they are reliant on fossil fuels. Common actions to be taken relate to

use of less fossil fuels, an increase in renewable energy, control of CO<sub>2</sub> production and a drive to improve energy efficiency. Each of these actions can have a direct impact on costs of electricity and interfere in the pure economic drivers in a commercial market. Regulatory oversight is required to ensure actions and related cost impacts are clear, open and accountable.

### 18.6.20 Energy Efficiency

Energy efficiency refers to the ability to produce more for the consumption of less energy. The World Energy Council has produced a useful report on the current status of energy policies around the world [18.26]. It considers the policies and trends that are occurring in relation to this topic. Energy efficiency is one of the simplest ways to reduce the impact of fossil fuels on the environment as well as ensuring a more sustainable approach to the use of the world's scarce resources. Often it can pay for itself in a relatively short period. Some countries have set aspirational targets and others have legislated to eliminate some of the less efficient plant, equipment and appliances. Others use labels to advise consumers of the appliance efficiency at the time of purchase.

A key problem in relation to energy efficiency relates to the disaggregated nature of the supply chain. If the maximum end customer benefits are to be achieved, the reward must be spread appropriately across all parties that contribute to the efficiency. This will require clear price signals and profit incentives that encourage an integrated approach to the problem.

Within the electric power system, efficiencies can be gained by modifying the design, construction and operation of the system components, reduction of network losses (while avoiding suboptimal generator dispatch) and the use of energy storage. The use of smart meters and intelligent devices allows the ability to control and influence consumption rates and timing, which can improve efficiency of the whole system. Choosing the optimum mix of these factors will determine the ultimate system efficiency.

The various aspects can be described as shown in Fig. 18.11 as presented at the CIGRE symposium in Bologna [18.27].

Various approaches can be used to encourage energy efficiency. The electricity market can send signals and reward efficient operators; although to work well, this would require access to storage and demand side management together with clear price signals. Regulatory targets can be set, although this can be distortionary as it may lead governments to back politically attractive technologies. International standards can improve interoperability as long as they don't stifle innovation and competition.

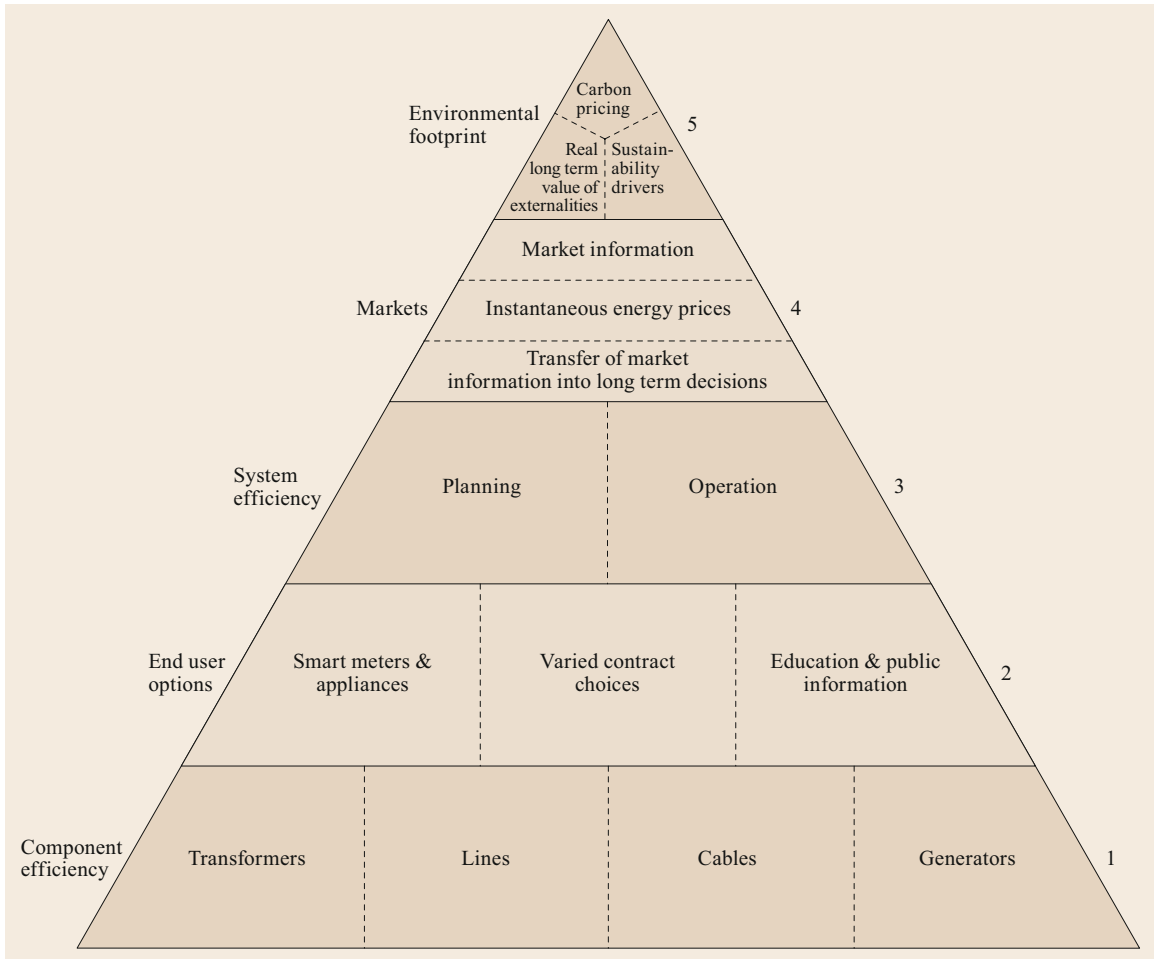

Fig. 18.11 Energy efficiency pyramid (reprinted by permission from [18.27])

### 18.6.21 Visual Impact

As power consumption around the world has increased so have the number, size and density of transmission lines and substations. In addition the growing number of large-scale renewable energy projects that are adding to and sometimes displacing existing fossil fuel generators are driving further construction of new transmission lines. In some cases transmission interconnectors are being built to connect the diverse generation and load portfolios of adjacent countries in order to lower the overall cost to customers. Line routes to supply the cen-

tral business districts of large cities are also becoming more difficult and expensive to procure. In many of these cases there is considerable public opposition to the construction of these assets due to the visual impact. As a result, more lines are being placed underground or, at the very least, suboptimal line routes are being used to avoid contentious areas. These changes will generally lead to increased construction costs, which will need special consideration by the regulator. Evidence needs to show that the chosen route was the lowest practical cost for the service provided and that the utility has not simply taken the easy way out.

## 18.7 Regulation Models Around the World

This section considers a few examples of the regulation models applied across the world. There are similarities between them as well as an overall consistency

with the descriptions above. Some detail has been provided to demonstrate the differences between the countries that often reflect the history of evolution of

electricity markets and deregulation within the different regions.

### 18.7.1 United States

In general the US follows the methodologies discussed above although this varies between states, unless it falls under the jurisdiction of the federal regulatory body. The following discussion highlights a few general points in relation to the US. One source of a more detailed examination can be obtained from [18.28].

The majority of utilities are privately owned with the remainder mostly owned by government entities or local communities. Electricity generation is generally fuelled by coal, gas and nuclear with some hydro and a growing proportion of solar and wind.

In recent times there has been a huge surge in gas generation, which has coincided with the rapid expansion of the use of shale gas. This has resulted in the replacement of a large number of aging coal fired generators. The US is now considered to be the world's leading natural gas producer. When operated in parallel with intermittent generation from wind and solar, open cycle and to a lesser extent combined cycle gas turbines are more able to follow rapid changes in generator output than coal and nuclear and gas has the added advantage of emitting lower greenhouse gases than coal.

Some states have unbundled their transmission and distribution monopoly components from the contestable generation components.

Regulation generally occurs at a state level unless it relates to interstate transmission. This will include any part of the state system that has an impact on the interstate transmission as well as the transmission interconnector itself. The federal regulatory body is known as the Federal Energy Regulatory Commission (FERC). Third party access is allowed to the transmission system by law and the tariff for access is approved by FERC. The North American Electric Reliability Council (NERC) oversees reliability and the adopted standards are legally binding.

Generally in the US, rate of return regulation is used and this provides a steady stream of revenue to cover the costs to the utility of producing, transmitting and distributing electricity. Electricity regulation is used to protect public interest and allow access to all at an approved price.

The scope of regulation in the US generally follows the principles described earlier in Sect. 18.6. This includes revenue determination and the setting of prescribed service standards and prices to customers. Many states are being influenced by legislated environmental requirements, particularly in relation to the use of renewable energy. The costs of implementation of these

requirements fall under the jurisdiction of the regulators assuming the utilities wish to recover these costs as regulated revenue. There is also some oversight of the boundary between regulated and unregulated revenue to ensure no cross subsidies. This may require the use of subsidiary companies.

In general there is no prescription on the timing of when a utility should seek regulatory approval of a major review of prices and service standards. However, this normally occurs every two to five years.

The review process generally involves a hearing where the utility presents evidence to justify the requested changes. A process of interrogation then follows where the utility may present expert witnesses and, in some cases, other affected parties may provide evidence. There is also usually an opportunity for the general public to provide comment or evidence. Negotiations then commence with the goal of achieving an agreed settlement on the final outcome. Ultimately this leads to a final order by the regulator.

Annual costs are determined based on analysis of actual expenditure and revenue in a past year, taking into account the effects of weather and any other significant disruptions and expenditure forecast for a future year. The process requires the utility to submit these costs as evidence to support any required rate increase.

Utilities are allowed to earn a reasonable rate of return on their regulated asset base considering the level of risk they are facing. Traditionally this would have been a relatively low risk, although there may be some argument that this risk is changing with the rapid growth of renewable and gas generation leading to a lower demand for existing coal generation. This new generation may be installed at different locations to the existing facilities leading to some level of stranding of transmission assets. The rate of return is normally calculated as a weighted average cost of capital taking account of the varying rates for equity and debt.

While traditional costs are relatively consistent each year, significant events such as major storms or the closing of a nuclear power station are usually considered separately.

Tariffs are determined by considering each class of customer as described in Sect. 18.6. Charges for connection to the electricity network are subject to regulation and may include cross subsidies if this is considered an economically efficient way of recovering costs. The charges are required to have reasonable terms and conditions set at a fair price.

### 18.7.2 Great Britain

In Great Britain, generation assets were split from network assets as part of major reforms to the electricity

sector in 1990. Transmission was divided into three parts each of which is now privately owned. One sector was a combination of England and Wales, another was northern Scotland and the third was a combination of southern and central Scotland. There is one system operator for the whole of Great Britain, National Grid Electricity Transmission plc (NGET), which is also the owner of the England and Wales transmission system. There are 14 licensed distribution companies, which are owned by six different groups. There are also a number of smaller distribution network operators.

All of these transmission and distribution companies are considered natural monopolies and are regulated by Ofgem that also has a role to oversee the operation of the markets.

The transmission and distribution networks are regulated by an RIIO framework where revenue = incentives + innovation + outputs. This model is intended to drive improvements in performance in relation to both safety and reliability and lower costs for customers by providing incentives for the network businesses. It is also intended to encourage addressing wider environmental objectives such as those associated with climate change. To this end it encourages innovation, recognizing that this may have a higher risk than traditional investment. The framework is used to set price controls for a period of eight years.

While Ofgem requires each network business to submit proposals on how it will deliver within the RIIO framework, it also provides a number of documents on how the submissions should be structured and the information that should be provided. Amongst other things, these include comment on expected content in relation to the environment, stakeholder consultation, losses and innovation. Network businesses are required to propose for approval, performance targets with financial penalties and rewards, an allowed revenue requirement and mechanisms that would be used to cover unforeseen developments that may require changes to the allowed revenue.

The success of the latest scheme may not be fully understood until the next regulatory period is reviewed in 2021; however, Ofgem is already proposing that a more onerous scheme will apply in the next review. It is claiming that there have been significant improvements in reliability, costs to customers and customer satisfaction under Ofgem's current and past regulation [18.29].

The framework also gives an incentive for the network businesses to reduce losses, which are the main opportunity to improve energy efficiency, provided the solutions do not lead to suboptimal generator dispatch. Losses include theft as well as those on the network. Network businesses are required to publish their strategies

to reduce their losses as part of their compliance with the RIIO framework. A useful reference has been published by Ofgem titled *Energy efficiency directive: An assessment of the energy efficiency potential of Great Britain's gas and electricity infrastructure* [18.30].

As regulation has developed in the UK, so has its complexity with regulatory submissions running into hundreds of pages that provide considerable detail on how they propose to deliver on their expenditure and performance targets.

One of the changes made under the new regime is to consider the total proposed expenditure rather than separately considering operating and capital expenditure. This reflects a view that there has been cost shifting between the two categories in the past.

A further change is the eight-year period rather than the previous five-year duration. Longer time frames are possible as the industry and Ofgem are now more mature and both sides have considerable experience. It also reflects the fact that transmission and distribution investments are generally long term. There is still some risk that technological change will accelerate the transformation to alternative forms of energy provision and produce an unforeseen risk on the network companies. However, this can be dealt with to some extent by the change mechanisms that are built into the regulatory process.

### 18.7.3 Australia

The Australian Energy Regulator (AER) [18.31] carries out regulation of the electricity sector in Australia other than in Western Australia. This includes monitoring the operation of the electricity market and the allowed revenue of the network businesses. In Western Australia the Economic Regulation Authority (ERA) [18.32] carries out a similar but independent role. Consideration was recently given to moving the role to the AER, but it remains with the ERA at the time of writing. Network businesses are considered natural monopolies and have to submit proposals to the AER on their required revenue in accordance with a prescribed framework and timeline. This framework is set out in national electricity law and rules. The approach is similar to the RPI – X incentive regime that was used in the UK prior to the implementation of the new RIIO regime. In this case, the X is an efficiency factor and the regulator expects the business to find a range of efficiencies that exceed those driven by this framework. As the revenue is approved for a five-year period, there is an incentive for the network business to reduce expenditure by more than the regulated X factor over the period and therefore increase its profits. The regulator can also look at these found efficiencies and factor them into the next review.

During the review process, factors considered include the projected electricity demand, the age of the infrastructure, operating and financial costs and network reliability and safety. Decisions usually apply for five years. Under the prescribed framework, the AER determines the allowed revenue for the business that covers its efficient costs by using a building block model. These building blocks include capital expenditure, operating and maintenance costs, asset depreciation and taxation liabilities. The AER also determines an allowed rate of return on capital taking into account debt, equity and risk issues amongst other things. The incentive to defer cost savings towards the end of the regulatory period that may occur in a traditional CPI – X regime is counteracted by an efficiency carryover mechanism in the building block approach.

The AER also reports on the performance of the market and electricity businesses including customer issues relating to affordability and disconnection of customers for non-payment of bills. It also administers a retailer of last resort scheme as a protection for customers in case an electricity retailer fails.

As for the UK model, the Australian regime is evolving. The current rules are quite prescriptive and revenue submissions run into many hundreds of pages. The prescriptive nature of the regime makes it quite difficult to make changes that may produce more favorable outcomes for the customer. Under the original process, the network business could appeal if it perceived the regulator's decision to be unreasonable. On the surface, this appears acceptable as the regulator is attempting to strike the correct balance between the long-term interests of the customer and those of the network business and various decisions may therefore be subject to challenge. Also, an appropriate return is necessary to ensure that the network business owner will continue to invest its capital. However, there were a number of concerns raised that, amongst others, the process produced unjustifiably higher prices for cus-

tomers, the long process led to significant regulatory and price uncertainty and that the appeals may be related to procedural correctness rather than the merits of the outcome. As a result, the appeal process has been removed, except for decisions related to the disclosure of confidential or protected information. The lawfulness of the regulator's decision can, however, still be subject to a judicial review in the Federal Court. This limits the review to breaches of the rules of natural justice or errors of law rather than the merits of the regulator's decision.

#### 18.7.4 Nordic Countries

Deregulation in the Nordic countries started in Norway in 1991 followed by Finland in 1995 and Denmark and Sweden in 1996. There is one transmission system operator in each country and a large number of distribution companies (varying from 84 in Denmark to 380 in Sweden). Consistent with previously discussed models, revenue cap electricity regulation is now used in all the Nordic countries.

Differences in approaches in each of the Nordic countries are in the detail. For example different models are used for deciding the allowed rate of return. In addition, the assessment of the regulatory asset base varies leading to large differences in the applied revenue caps. Similarly, benchmarking and efficiency targets may be applied differently. The regulatory period is one year in Denmark, four years in Finland, five years in Norway and four years in Sweden.

Incentives are provided to ensure reliability is maintained despite incentives to lower costs. These vary between countries, but in all cases attempts are made to relate the rewards and penalties to the customer value of the reliability.

NordREG, the Nordic energy regulator, has produced a detailed overview of the economic regulation of electricity grids in Nordic countries [18.33].

## 18.8 Conclusion

This chapter has provided an overview of the current state of electricity markets and associated regulation. This has included the development of the electricity industry structure and its organization. A more detailed explanation of electricity markets and the various models that have been adopted to facilitate competition then follow, as well as some examples from around the world. A similar approach has been used to explain the use of regulatory oversight.

The chapter is necessarily at a reasonably high level and the reader is encouraged to further explore at a more detailed level to view the latest developments and in depth explanations regarding the design and operation of market and regulatory schemes that are used across the world. Widespread adoption of electricity markets is relatively recent, occurring over the last twenty-five to thirty years and the models used continue to be developed and refined.

The drive to reduce the carbon footprint of electricity supply while ensuring the end price to customers remains affordable is ongoing. To some extent this is dependent on the evolution of existing and the development of new technologies. This includes storage mechanisms such as batteries, new distributed generations and a range of new smart load control processes. Some of these will increase the number of competitive generators and loads in the market as well as change the nature of their operation. In some cases this may put pressure on the traditional monopoly

status of the network businesses. Electricity markets will need to evolve to facilitate the new forms of trading and customer expectations. In addition, regulatory oversight will need to change to ensure it supports market developments that benefit the end customers.

**Acknowledgments.** The Authors would like to thank Keith Bell, Scottish Power Professor of Smart Grids at the University of Strathclyde, for his valuable feedback on the market in the United Kingdom.

### Philip Southwell

Southwell Power System Consulting  
Shenton Park, WA, Australia  
[phil.southwell.cigre.ci@gmail.com](mailto:phil.southwell.cigre.ci@gmail.com)

With degrees in Electrical Engineering and Management, Phil has over 40 years experience in power system planning, design and regulation, including several years as a senior executive of Western Power in Australia. He was Chair of CIGRE Study Committee C1 on System Development and Economics, is a Fellow of Engineers Australia and a Fellow and Honorary Member of CIGRE.

### Gregory H. Thorpe

Executive  
Oakley Greenwood Pty Ltd  
Margate Beach, QLD, Australia  
[gthorpe@oakleygreenwood.com.au](mailto:gthorpe@oakleygreenwood.com.au)

Greg holds qualifications in Electrical Engineering, Business and Alternative Dispute Resolution. He advises on industry and competitive market design and operation across Asia-Pacific. He has held positions with regulators, market operators and utilities. He sits on industry dispute panels in Australia and Singapore and has provided testimony in Court and arbitrations for commercial and market rule matters.

### Alex Cruickshank

Energy Consulting  
Oakley Greenwood Pty Ltd  
Margate Beach, QLD, Australia  
[acruickshank@oakleygreenwood.com.au](mailto:acruickshank@oakleygreenwood.com.au)

Alex Cruickshank received his BSc in 1974 and an MBA in 1990. He has worked for energy utilities, regulators and government advising on markets and rules in relation to the energy industry and the Australian National Electricity Market. He is on international study and working groups as part of CIGRE and chairs Study Committee C5 on Electricity Markets and Regulation.

### Colin Ray

Colin Ray Consulting  
Stratford on Avon, Warwickshire, UK  
[colin@colinray.org.uk](mailto:colin@colinray.org.uk)

Colin has more than 40 years experience in the electricity industry including privatization within England and Wales. He was chairman of the CIGRE committee on System Development and Economics and a member of a World Energy Council Task Force on transmission interconnectivity. He was awarded the CIGRE Gold Medal honor in 2012 for services to CIGRE and the industry.
